Exposure Meters. When gelatin dry plates came into general use, and were made of many different degrees of sensitiveness, the want of a guide to the proper exposure for the various makes of plates under different conditions of lighting began to be felt, and several means were devised for meeting it. Some of them depend solely upon data derived from observations of the action of the principal factors affecting the result, namely: (1) the speed of the plate; (2) the angular power of the sun's light for the time of day; (3) the latitude and its position at the particular time of day; (4) the effective diaphragm aperture of the lens; (5) the nature of the subject and its illumination as affected by local and atmospheric conditions. With the work of W. B. Coventry (1869) and of Hurter and Driffield (1898) supplemented by practical observations, the action of the light upon sensitive paper exposed near the camera or the subject at the time. Both methods are in some cases of undoubted use, but the information given by instruments of this kind can only be considered as approximate, and much is left to the judgment of the operator, whose surest guide is the interlaced blind of different plates to which he is familiar. There is, however, a standard practice of using a particular type of plate, may not be so for others. This was improved upon by the adoption, in 1878, of Leon Warnerke's \"Sensitometer,\" which was in use as a standard for some years. It consisted of a transparent scale of 25 squares of different intensities, marked with opaque numbers and arranged so that each number indicated a doubled rapidity. This was placed in a frame in front of the sensitive plate, and exposed for thirty seconds to the constant light emitted by a phosphorescent tablet, illuminated with the instrument, which was previously excited by burning one inch of magnesium ribbon in front of it. The exposed plate was then developed and fixed, the numbers and the corresponding numbers recorded. In 1890 F. Hurter and V. C. Driffield introduced an entirely new system of calculating the sensitiveness of plates of different rapidities. They make a series of exposures in seconds on different plates in a position or position of the plate at a standard interval of one metre distance. After development for a certain fixed period with a standard developer, fixing, washing and drying, the \"densities\" or logarithms of the opacities of the different parts are measured. The result is a special graph of the plate, producing a curve, one portion of which will practically be a straight line. The position of this line with reference to a scale of exposures given on the diagram decides the rapidity of the plate, while its length indicates the degree of the plate for the truth rendering of tone. The elaborate investigations by which these results were obtained are of great interest, and were published in the \"Journal of the Society for Chemical Industry\" (1890, 1891), and subsequently in the \"Photo-Miniature Series.\" The sensitivity shown on the H. & D. scale is directly proportional to the speed number given. The method has been adopted by several dry-plate makers in
denoting the sensitiveness of their different brands, and is more or less the basis on which the plate-speeds for the modern English daguerreotypes and exposure meters are calculated. Several systems of photometry and measurement of the speed of the plates have been discussed at the meetings of the Congrès International de Photographie, in 1889, 1891, 1900, and 1905, but no definitive standard has been finally adopted. In Germany the work of J. Scheiner's sensimeter has been adopted, and appears to be extending. It is based on a system of photographing the graduated tints given by rotating sectors. A full account of the instrument, and of a system of sensitometrie based on its use, is given by J. M. Eder in the Photographische Correspondenz (1898) p. 459, and (1900) p. 244. In 1901 Chapman Jones brought out a convenient plate-tester on the same principle as the Warnerke sensimeter, but calibrated by the addition of an actinometer, and which is useful for the comparison of orthochromatic dry plates, colour screens, light filters, &c. It consists of a screen plate, 43\frac{1}{4} in., containing a series of twenty-five tints of graduated sensitiveness; a series of coloured squares, blue, green, yellow and red, and a strip of neutral grey, all five being of approximately equal luminosity; a series of four squares of special pure colours, each representing a definite portion of the spectrum in space of line design, over which is superposed a half-tone negative. To use the instrument, a quarter-plate of the brand to be tested is exposed behind the screen for a few seconds to the light of a standard candle power, and the readings are taken at fixed angles.

An examination of the plate will show the sensitiveness, range of gradation, possible range of exposure, sensitiveness to colour, size of grain, amount of halation, and the most suitable light for development. A further development of the actinometer is that any brand of plates may be readily tested by the user and compared with any standard he may find convenient. In making these and similar plates, light should be allowed to act for a fixed period and at a uniform temperature (Ph. Journ., 1901, 28, p. 246).

The next important factor is the actinic power of the light. It depends markedly on the height of the sun for the latitude of the places and the time when the photograph is taken, and exposures in bright sunlight are found to vary approximately as the cosecant of the sun's altitude above the horizon. The light of the sun itself is practically constant (1901), p. 179, and the increase given year after year, but is liable to more or less local and temporary diminution by the amount of cloud, haze, dust, &c., present in the atmosphere at the time. It is also affected by the time of day, increasing from sunrise to noon and decreasing from noon to sunset. The remaining factor is the effective diaphragm aperture of the lens in relation to its focal length. In most cases of ordinary outdoor exposures this can be taken at its normal value, but becomes smaller and increases exposure if the focal length is much increased for photographing near objects. Besides these principal factors, the nature and colour of the objects, their distance, and the amount of light received and reflected by them under various atmospheric conditions, have a marked influence. The amount of light measured by the instrument as shown (op. cit. p. 75) how the "light coefficient L." for full sunlight, can be found, and has given a table of values of L. for the latitude of London, throughout the year, for a period of ten days in each month, and throughout the year, also the relative coefficients for "diffused light," "cloudy," "dull" and "very dull." Tables of exposures for different subjects under varying conditions of light have been prepared by W. K. Burton, A. S. Platt, F. W. Mills, Sir D. Salomons, and others, and in preparing them Dr J. A. Scott's tables, showing monthly and daily variations of light for countries about N. lat. 53°, are generally used. The more modern tables, such as are published in the "standard exposure handbooks," also take into account the plate speeds, but unfortunately there is no uniform standard of plate speeds, owing to the difficulty of fixing a definite standard of light. The subject is fully treated in the British Journal of Photographie (1902), p. 375. The circumstances of H. Hurst's "Calcul du temps de pose en photographie," and similar works by A. de la Baume Pluvellé, G. C. D. Espinasoux and others.

Based on the same principle as these exposure tables, various photograms and exposure meters are in use. One of the most important is the apparatus of the "infallible" exposure meter. It consists in magnifying the image of the diaphragm and plate through a lens and representing the coefficients for plate-speed, light and diaphragm are arranged as in a slide rule, so that, when properly set, the normal exposure required can be found by inspection, and increased at the diminished accuracy, to the circumstances. Hurst and Driffield's "Actinograph" the light coefficient is given by a printed card showing the curves for every day in the year and for every hour of the day, the unit being the 1st part of the scale corresponding to the sun's zenith at 9°. The first part shows the diurnal range, the second and third parts 1° and 2°, the fourth part, 1°, the fifth part, 0°. An actinograph degree of light will produce a perfect negative of an ordinary landscape. An additional scale is given for five different degrees of illumination—"very bright," "bright," "mean," "full," "very dull." A table of factors for "views," "portraiture," "interiors," "copying," is also given, and these regulate the factor to be taken for the exposure. The scales are engraved on boxwood, and there are two sliding pieces (fig. 68).

It is specially adapted for use with plates of speed numbers agreeing with the H. & D. scale, but can be used with any plate of which the relative speed number is known. Convenient exposure meters have been made since 1890 by A. Watkins, of Hereford, in different forms based upon an actinometrical test of the light at the time of exposure. In the complete "Standard Meter" (1896) scales corresponding to "speed of plate," "diaphragm f numbers," "light," "subject" and "enlarging," marked P. D. A. S. and E., are arranged on rings adjusted in round apertures. The plate-speeds are taken from a table and the "light coefficient," or "actinometer number," is ascertained at the time by exposing a piece of sensitive paper in the actinometer at the end of the instrument for the number of seconds required to match a fixed tint as shown by an attached pendulum. Many improvements have been made in the latest pattern (1908) is made in metal and gives (fig. 69). "Dial meter (1901) is a simpler form in a circular metal case with four apertures marked plate," stop," ace" and "exp." above the corresponding scales, and an actinometer for testing the light. The numbers showing the speed of the plate in use, the f value of the diaphragm, and the actinometer exposure in seconds are brought into the respective apertures and the exposure required is read off in the "explosure" aperture. An "indoor meter," is also made, and a "hand camera calculator" for use with the plate, "Actinometer," plates, "Queen Bee" and "Bee" meters (1903), are later, smaller and more convenient patterns which have superseded the "Dial" meter and have the plate numbers and exposures marked round the case, and the scales of "f numbers" and "speed of plate." This is revolved till the f number on the right is opposite the speed number of the plate; opposite the actinometer number on the left, found as above, will be found the exposure in seconds (fig. 70). The "Queen Bee" meter is similar to the "Bee" meter, but of better construction and fitted with a pendulum.

G. F. Wynne's "Infallible" exposure meter (1893) is also in dial form, but the sensitive paper is exposed directly, no pendulum is used, and the scales are open on the dial. In use, the glass carrying the movable scale is turned until the actinometer time in seconds upon the exposure scale is opposite the diaphragm number of the plate, as given in the list of plate speeds; the correct exposure will then be found against the speed number of the scale. There are practically only two scales: the scale of diaphragms representing the diaphragm apertures in numbers, the speed of plate and the variation of exposure due to subject; and the time scale, representing the actinometer time and the exposure (fig. 71). The actinometer is protected by a yellow glass screen when not in use. In a smaller form the scales are on the
Self-developing dry plates were introduced in 1906, in which the developing agent is mixed in the film itself, as in the Ilford process. The plate, after exposure and washing soda for development, or, as in the Wellington "Watala" plates, applied on the back of the plate, plain water only being required for development, this application also preventing halation. The plates are usually prepared with an emulsion of silver chloride with or without free silver nitrate and other haloids.

The rendering of photographic plates isochromatic or sensitive to a given wavelength of light is a matter of much interest, and one which has been greatly improved by the use of new dyes, especially those of the isocyanin group, prepared by Dr E. König of the Hoechst works, and also by photochromes, or "pinachromes," which confer on a silver bromide plate a high degree of sensitiveness for red as erythrosin does for yellow; also F. Bayer's "Amauto" plates, and Dr A. Hauron's "Bayer" series of preparing panchromatic plates (see E. Jb., 1905, pp. 183, 335). Panchromatic plates are now largely manufactured and used for all photographic work in which a true rendering of the relative colour luminosities is essential, and more particularly in scientific work. Existing methods of rendering in which plates are required to be sensitive to red, green and blue-violet. They are made in different degrees of general and colour sensitiveness, according to the purpose for which they are required, using, for this purpose, "actinometer," or "papier noir" filters, by which the effect of the required subject can be simulated and the paper density noted, and the paper scale changes in density after a time. A better form is "E. Degen's Normal Photometer" (1905), consisting of two sliding violet glass prisms, one adjusted for the actinometer plate, the other for the ordinary plate or the one whose sensitiveness is to be determined. They are mounted with their outer faces parallel. In use, the upper slide with prism is drawn out so that the pointer coincides with the division indicating the diaphragm aperture, and then with the diaphragm set to be used; the object is then moved directly through openings at one end of the instrument, and the lower slide is drawn out and pushed back slowly till the object is viewed almost obscured. The attached pointer will then indicate the exposure required, or, reversing the order, the diaphragm aperture for a given exposure can be found. Auxiliary scales are attached for very short or long exposures. The principle of construction is that of the photometer of Bunsen and Kirchhoff to the visible spectrum, and its photographic use is described by G. Heyde's "Actino-Photometer" (1906) is on a somewhat similar principle, and consists of a circular metal box with dark violet glass viewing screens in the centre of both sides. Light enters via an obscuring iris inside the case worked by revolving the back of the box. On the front of the instrument exposure tables are given for plates of every rapidity, and for diaphragm apertures from f/3 to f/45. Exposure meters of this type are specially applicable for open-air work where there is sufficient light for ready measurement. Other simple actinometers are in use for carbon and process printing, consisting generally of transparent prisms, placed in different positions to the light, with gelatin, &c., or of a photographed scale graduated by increasing exposures. The "Burton actinometer," for pigment printing, made on this principle, contains several small negatives of different densities, and is of the ordinary size of a transparency. It is made on a line scale, and can be used with the ordinary positive also, and with the help of a comparator, or comparison screen, to determine the exact exposure. A separate field is given for each of the three primary colours, by which the exposure can be intercompared. The exposure required for any kind of paper or process is then indicated by the position of the line on the scale corresponding to the desired result. A plate which is exposed too long will not give a proper colour reproduction, and this is known as an "iris" or "halation." 

Sensitivity Plates, Films and Papers

Sensitive Dry Plates.—A special feature of modern photography is the use of trustworthy ready-prepared sensitive dry plates and films in different grades of sensitiveness, so that there is, necessity for the photographer to prepare his own plates, nor, indeed, could he do so with any advantage. The practice of outdoor and studio photography has thus been greatly simplified; and although with wet collodion there was the advantage of seeing the results at once and re-taking a picture if necessary, the uncertainties connected with the use of the silver bath and collodion, and the amount of cumbersome apparatus necessary for preparing and developing the plates, are all avoided by this process. It is, in fact, a great economy of time, in using dry plates as compared with wet, by deferring development. In tropical climates, also, dry plates can be used when work with wet plates would be impossible. On the other hand, for work requiring more or less instantaneous results, prepared plates must not be overlooked. Besides their use in taking negatives, gelatin dry plates are also largely used for printing transparencies, lantern slides, enlargements, &c. For negative work, they are applied to glass, with an emulsion of silver haloid alone or with the addition of silver iodide or chloride, and are to be obtained in five or six degrees of rapidity: "slow," for photography; "normal" for general purposes when quick exposures are not required; "rapid," for work requiring great care in use to avoid fog. In order to prevent halation, or irregular action by reflection from the back surface of the glass, dry plates are coated with a non-actinic "backing," which can easily be removed before development.

Another class of exposure meters comprises those in which the intensity of the light is estimated visually by extinction in a medium-transmitting diaphragm. Among these, the instrument described by J. Découdron's (1888), in which the exposure is judged by the disappearance of a series of small clear openings on a graduated scale of densities when laid on the most important part of the image as it appears enlarged. Its principal advantage is that no readings or calculations are necessary, and the paper scale changes in density after a time. A better form is "E. Degen's Normal Photometer" (1905), consisting of two sliding violet glass prisms, one adjusted for the actinometer plate, the other for the ordinary plate or the one whose sensitiveness is to be determined. They are mounted with their outer faces parallel. In use, the upper slide with prism is drawn out so that the pointer coincides with the division indicating the diaphragm aperture, and then with the diaphragm set to be used; the object is then moved directly through openings at one end of the instrument, and the lower slide is drawn out and pushed back slowly till the object is viewed almost obscured. The attached pointer will then indicate the exposure required, or, reversing the order, the diaphragm aperture for a given exposure can be found. Auxiliary scales are attached for very short or long exposures. The principle of construction is that of the photometer of Bunsen and Kirchhoff to the visible spectrum, and its photographic use is described by G. Heyde's "Actino-Photometer" (1906) is on a somewhat similar principle, and consists of a circular metal box with dark violet glass viewing screens in the centre of both sides. Light enters via an obscuring iris inside the case worked by revolving the back of the box. On the front of the instrument exposure tables are given for plates of every rapidity, and for diaphragm apertures from f/3 to f/45. Exposure meters of this type are specially applicable for open-air work where there is sufficient light for ready measurement. A plate which is exposed too long will not give a proper colour reproduction, and this is known as an "iris" or "halation."
are remarkably good and practically solve the problem of direct colour photography in a simple and fairly inexpensive manner (see Agenda Lanc. 1019). In 1882, E. Fenske's "Thames" colour plate (1908) the tricolour screen is formed by rows of circular dots coloured alternately orange-red and green and the intermediate spaces blue. It is used also when the roll is placed in contact with a panchromatic plate, the unclosed side towards the screen. It carries nearer marks for adjusting it to the finished picture after development and reversal of the image. These screens, being more transparent than the pictures, require a long band of black for a good rendering, and it is not so perfect. In the Jougla "Omnicolore" plate (1909) the tricolour screen and sensitive surface are combined on one plate as in the "Autochrome," but the screen is made up of a series of equal white and green discs, each being on the same film but with great saving of bulk and weight and no loss of efficiency, though such films are sometimes liable to deterioration by long keeping before or after exposure. They are made in two thicknesses, stiff or flexible, the stiff being used exactly as plates, but in a cartridge, the other being backed with a card or glass plate, while the flexible are made in separate sheets with cardboard backing, as in the "Kodak" films, or in convenient packages of twelve or more in film packs of various sizes. Films of this kind have been used for many years past also been prepared in long strips of different widths suitable for use in hand cameras of the Kodak types and in roll-holders. In the earlier models the films were used alone, and being unprotected had to be changed in the dark room, but, as already stated, they are now supplied on spools in cartridges which can be changed in daylight. C. Silvy seems to have been the first to use such a film; in his case, however, the film is attached to a much longer strip of black paper, and rolled up, so that several turns of the paper have to be unrolled before the film is ready for exposure, this point being marked on the paper. During the exposure the paper cover is removed, and the negative is visible through a red screen at the back of the holder. When all have been exposed, the black paper is rolled on for several turns, and then taken out of the holder the loose end is fastened up till the black paper is adhering to the film. In the original the film is a 14". landscape work, it is now usual to make them isochromatic, and they may be used with or without a yellow screen. They are also made "non-curving" by being coated with gelatin on both sides. Negatives taken on these thin films have the advantages that they can be printed from every side without perceptible loss of definition, which is useful in printing by the single transfer carbon process, and in some of the photo-mechanical printing methods. Flexible transparent gelatin film and rolls have also been prepared on hardened gelatin, but it is difficult to retain the original dimensions of the film owing to expansion of the gelatin. Paper coated with sensitive emulsion has also been used for making photographs on this principle, but they are, however, still used in meteorological and other self-recording instruments. Stripping films of thin celluloid upon a paper support were introduced by Messrs Wellington and Ward, and had advantages both on ordinary, and now made.

Photographic Printing Papers.—Pari passu with the supply of ready-prepared plates, all kinds of photographic printing papers can now be obtained readу for use, so that the photographer has not the trouble of preparing out or preparing his own paper. The old albumedised papers have been generally superseded by ready-prepared sensitive papers coated by machinery with emulsions of silver haloids in gelatin, with or without citrate or other organic salts, the chloride being used for most of the "P.O.P." or "printing out papers," which contain more or less free silver nitrate, and in the "self-toning" papers some salt of gold. Some of these printing out papers are also made with emulsions of silver chloride in collodion, and known as "C.C." or "collodiochloride." The basis of most of the developable bromide papers used for enlargements and direct copying, containing no free silver nitrate, and with which an invisible image is brought out by development, much in the same way as with dry plates, is silver bromide. These papers are made in great variety of tints and surfaces, "smooth" and "rough," "glossy" and "mat," for producing different effects. They are largely used for direct printing by artificial light or daylight, for enlargements, and for printing photographic post-cards, &c., in large numbers by machinery, the prints being made on a long band with an almost instantaneous exposure, and developed and fixed by being passed through the proper solutions on large rollers or other. Papers for the platinotype processes, sensitized with salts of platinum and iron, are also manufactured for printing by direct printing by artificial light, and are useful for photos of similar kinds. Reprints of books on the subject are still in use. For producing special effects similar to those obtained by toning with gold, the colour of the print being determined by the exposure, short exposures giving purple and long exposures brown or reddish tones. The process is a rapid one, the operations of printing, developing, fixing, and washing being completed within about ten minutes or even less.

For the various methods of printing in permanent pigments ("Autotype," &c.) tissues are prepared coated with pigmented gelatins, and various combinations of plates, sensitized with silver salts, have been used. The plates and tissues have been obtained by printing from suitable negatives in three colours with specially prepared yellow, blue and pink tissues. Similar papers, prepared with pigments and gums of gelatin, are used in the "Omnicolore" process, and "single transfer" papers, coated with plain gelatin, are used in the pigment printing processes to receive the developed print, and are also useful for photo-lithography, the new "oil-printing" methods, and in trichromatic printing on paper by the Sanger-Shepherd method and Dr König's "Pinotype." For Manly's "Ozotype" and "Ozobrome" processes special gelatinized and pigmented papers are made. These papers are prepared for the use of architects, engineers, &c., in rolls of considerable width, for the direct reproduction of tracings and drawings as blue or black prints by these and similar methods.

For the "Factorial" and "Dark-room Clock." The fact that the two principal factors in the development of modern photographic dry plates with a suitable developer are time and temperature, and also that a prolonged immersion in dilute solutions is in many cases a more convenient and equally efficient method of development, has led to the construction of apparatus for enabling the operation to be carried out almost automatically and for timing its duration.

In 1894 A. Watkins brought out his factorial system of development based on the principle "that with a correct exposure on a given plate with a given developing agent, the time of development determined for a given printing opacity has a fixed arithmetical ratio to the time of appearance of the high lights of the image, provided the developing power of the solution remains constant during development; and this rule holds good for all variations of exposure amount within the limits of the photographic definition of those limits which have been found safe in practice" (Photo. News, 1894, 38, pp. 115, 729; and further, Ph. Journ., 1900, 24, p. 221). By a series of observations he ascertained the multiplying factors of most of the developers in ordinary use, and in 1905 brought out his "factorial calculator" and a "dark-room clock" for facilitating the working of the method. The former is made of aluminium, and consists of two circular disks, the upper smaller one indicating the number of units which are equivalent to the "Factorial" or its "Factorial" calculator, and the lower one indicating the number of units which are equivalent to the "Factorial" or its "Factorial" calculator. The second disk shows the "time of appearance" in seconds or minutes. In use the pointer is set to the factor for the development in use, and against the "time of appearance" side of the inner scale will be found the total number of minutes required for complete development (fig. 72).
PHOTOGRAPHY

The "calculator" can be used with any ordinary clock or watch, but the "dark-room clock" (fig. 73) has been specially constructed for the factorial system for use in "development." It is a dial, 10 in. long, with 100 seconds divisions, very plain for dark rooms, centre seconds hand, stop action and outside indicator to mark the second hand. The second hand completes its cycle in 100 seconds, while the minute hand does so in 10 minutes, or sufficient for the longest ordinary development, though it runs on, if necessary, very much longer, both hands starting together always at 0.

In 1908 Watkins brought out another system of "thermo-development" by time dependent on the use of a standard "time developer," the duration of development was modified according to the make and speed of the particular plate in use. The temperature variations were indicated by a movable scale, or "thermo-calculator," on the bottle of developer, the Variations in the development is given approximately on the " Watkins' Plate Speed List," which thus shows the "speed of plate" and "speed of development with the standard developer at 60°." This method is well adapted for plates, films and stand development in tanks or machines, no observation of the plate being required, and the times are most conveniently observed with the "dark-room clock."

Full details of these two distinct methods of development will be found in the 4th edition of the Watkins Manual of Exposure and Development.

C. W. Piper's "photographer's stop clock" (1906) is a more elaborate clock, much simpler to use than the "development filler." It is fitted with an arrangement for all photographic operations in which accurate control in regard to time is of importance. It is fitted with a gong and arranged to work by "time" or "bulb." Once started, by pressure on a lever or bulb, it will continue to work until the stopped striking the gong at the completion of every minute, when the seconds hand reaches the zero point. A second pressure on the bulb stops the clock, so long as the pressure is continued, whilst pressure on a lever stops it permanently. It is thus useful for timing any intermittent operations, whilst the clock adds up the separate times and prevents the occurrence of errors difficult to avoid when timing with an ordinary watch. By an additional attachment, a prolonged time exposure with the camera may be terminated, or an "instantaneous" or short "time" exposure given at any prearranged time.

Messrs. Houghton's "Ensign" clock for time development has a dial with 60 divisions, a single hand, and is fitted with a gong. It can be set to ring an alarm bell at the expiration of any period from one minute to one hour, can be started or stopped immediately and is easily read in the dark-room. It requires no winding up, the action of setting providing the tension for the recording movements. It can be stopped and started at will and the bell arranged to give a short or prolonged ring. S. Stanley's is another convenient form, with a 6 in. dial, divided into 60 seconds and 60 minutes, the thick hand recording the seconds and the thin hand the minutes.

Several forms of developing tanks and machines have been constructed for developing a number of plates or rolls at one time. The Kodak "Automatic Developing Tank" (1905) is a useful arrangement by which a number of exposed rolls of film can be developed in a dark-room (fig. 74). The exposed film is wound from the spool into a reel celluloid apron contained in a box A, then placed in the tank B, where it is left in a dilute developer for about twenty minutes, and requires no attention. It gives very good results. For the "Brownie" films a special daylight developing box is made. With ordinary film "Brownie" tanks, exposed plates can be removed from the dark-room, from the plate holders and placed, in pairs back to back, in a special framework holding six pairs, which is lowered into a metal tank containing the developer, and is left with the cyanotype paper in the tank, thus can be inverted during development. A clock face, with pointer, by which the period of development may be noted is fitted outside the tank. Another apparatus of the kind is made for developing celluloid films exposed in the "Premo Film Packs" (fig. 75).

Other forms are made, and in some the fixing and washing can also be effected. They suitably provide for a large number of exposed plates or films, and have been found to work with efficiency and regularity. Eastman Kodak Co. brought out in 1901 a machine for developing paper prints on bromide or galatashes.

PHOTOGRAPHIC PRINTING APPARATUS

For ordinary printing purposes pressure frames, with or without glass fronts, are used for holding the negative and sensitive paper in close contact during exposure to light. They are fitted with hinged backs enabling the progress of the printing to be seen. The pressure is usually given by bell springs or with screws and wedges acting on the back. They are made in different kinds shown in the dealer's catalogues. For copying large tracings and engineers' drawings by the cyanotype and similar processes large glazed frames are used, mounted on a stand with axle, so that they may be easily turned over for re-filing or fixed at a suitable angle to the light. The pressure is given by an elastic cushion or vacuum arrangement, by which the sensitive plate is pulled through a rubber sheet covering the back of the frame, thus securing a perfectly uniform pressure of about 14 lb to the square inch without strain on the front glass. Such frames are also useful for various photo-mechanical printing processes with large negatives or metal plates.

For rapid printing of post-card and other negatives up to 8½ X 6½ in. a handy and simple apparatus the "Rapid" has been brought out, consisting of a frame fixed for oil, gas or electric light, with a sloping flap, in which a special printing frame is fixed and arranged so that the prints can be rapidly exposed one after another (B. J. A. 1909), p. 691. In another form arrangements are made for exposing a large number of printing frames on a suitable stand, in one or two tiers round a central arc lamp, which may be provided, as in the "Westminster" revolving printing frame, with a shade to protect the eyes of the operator when exposing the prints.

For printing tracings, &c., in long rolls, cylinder and rotatory machines of various types are used, so that the tracing and sensitive paper may be drawn together at a regulated speed in close contact across a glass or semi-circular surface within which electric arc or mercury vapour lamps supply the source of light. Several machines of this kind are described in Eder's Jahrbuch for 1908, also in the patent records and photographs.

III.—PICTORIAL PHOTOGRAPHY

PICTORIAL PHOTOGRAPHY

Picorial photography differs from other branches of photog-
graphic practice in the motive by which it is prompted. Employ-
ing the same methods and tools, it seeks to use photographic processes as a means of personal artistic expression. Thus in the early days of Fox Talbot's calotype, about 1846, David Octavius Hill, a successful Scottish painter, took up this method of portraits, and, guided by an artist's knowledge and taste, and unfettered by photographic convention, which indeed had the bias of novelty to their favour, worked with a freedom which for genuine pictorial quality have perhaps never been surpassed, especially if some allowance be made for the necessary imperfections of the "Talbotype" (see plate). Whether they were in their day typical examples of Talbotype with all the latest improvements, Hill probably never cared. When, again, a few years later, Sir William J. Newton, the eminent miniature painter, read a paper before the newly formed Photographic Society of Great Britain (now the Royal Photographic Society), his recommendation to depart from the custom of defining everything with excessive sharpness caused his address to be almost epoch-making. "I do not conceive it to be necessary or advisable," he said, "for the artist to repre-
sent, or at least to try to represent, at the attainment of every minute detail, which to endeavour at producing a broad and general effect. . . . I do not consider that the whole of the subject should be what is called 'in focus'; on the contrary, I have found in many in-
stances that the object is better obtained by the whole subject being a little out of focus." The doctrine has been consistently repeated ever since, but only within the last decade of the 19th century was the suppression or diffusion of focus received by photographers generally with anything more than ridicule or contempt, because it was unorthodox. O. G. Rejlander, Mrs Julia Margaret Cameron, H. P. Robinson, and others, by precept or practice, strove against such photographic conventions as had arisen out of those technical exigencies to which pictorial qualities were so often sacrificed. As late as 1868, in the Manual of Photographic Manipulation, by Lake Price, the old advice to arrange a group of persons in crescent form, so as to adapt the subject to the curve of the field of the lens, was repeated with the additional recommendation of plotting out on the ground beforehand the "curve of the focus" as a guide. As a defiance of this dictum, Rejlander, in 1869, produced a group of the members of the Solar Club in which some of the chief figures were set wide out of the "curve of the focus." The mere technical difficulties of this performance with wet collodion plates, and in an ordinary upper room, need not be touched upon here, but it is to be noted as one of those triumphant departures from convention which have marked the progressive stages of pictorial photography. At about the same period, Mrs Cameron, carrying the recommendation of "a little out of focus" rather further, regardless of how her lens was intended to be used by its maker, secured the rendering dictated by her own taste and judgment, with the result that many of her portraits, such as those of Tennison, Carlyle, &c., are still in their way unsur-
passed. Contemporaneously, Adam Salomon, a talented sculp-
tor, "sunned" down the too garish lights of his photographic prints, and strengthened the high lights by working on the back of the negative. During the concluding quarter of the 19th century, probably the most powerful influence in pictorial photography was that of H. P. Robinson, who died in February 1901, and, but for a brief period about the year 1875, was one of the most prolific "picture makers." Inspired by Rejlander, of whom he was a contemporary, Robinson will perhaps be best remembered by his earlier advocacy of combination printing. As early as 1853 Berwick and Annan exhibited a photograph which was the result of printing from more than one negative, a figure from one plate being cunningly introduced into a landscape print from another. Then came from Rejlander "The Two Ways of Life," in which, with wonderful ingenuity, thirty different negatives were combined. Robinson followed, and between 1858 and 1859 he exhibited numerous examples of combination-printing, one of the most popular and fairly typical examples being "Carolling" (see plate), which received a medal in the exhibition of the Royal Photographic Society in 1887.

Though in this combination-printing one may perhaps perceive the germ of incentive towards the production of special effects not seen in the original, yet the practice was not destined to become very popular, for even in the most capable hands there remains the difficulty, if not impossibility, of fitting a portion of one negative into a print from another and still preserving true relative quality, and even true proportion. Skilfully produced, eminently popular in character through "Carolling" may be, such errors are not absent. Of this combination-printing Dr P. H. Emerson has said: "Cloud printing is the simplest form of combination-printing, and the only one admissible when we are considering artistic work. Rejlander, however, in the early days of photography, tried to make pictures by combination-
printing. This process is really what many of us practised in the nursery, that is, cutting out figures and pasting them into white spaces left for that purpose in the picture-book. With all the care in the world the very best artist living could not do this satisfactorily. Nature is so subtle that it is impossible to do this sort of patchwork and represent her. Even if the greater truths be registered, the lesser truths, still important, cannot be obtained, and the softness of outline is easily lost. The rela-
tion of the figure to the landscape can never be truly represented in this manner, for all subtle modelling of the contour of the figure is lost."

Pictorial photography received a large accession of votaries in consequence of the greater facilities offered by the introduction of the gelatino-bromide, or dry-plate, process, which, although dating from 1880, did not notably affect photographic communities until some years afterwards; and although improvement in appliances and instruments had little to do with the advance of the pictorial side of photography, yet, indirectly at least, the dry-plate and the platinotype printing process have had an undoubted effect. The former gave enormously increased facility, and dispensed with tedious manipulations and chemical knowledge, while its increased light-sensitiveness decreased the limitations as to subjects and effects. The platinotype process was discovered in 1874-1880 by W. Willis, who employed his chemical skill and knowledge to give the world a printing process more likely than the hitherto prevalent silver papers to satisfy artistic requirements.

Up to 1882 but few outdoor photographers had ventured to run counter to the general dictum that photographs should only be taken during sunshine or good bright light, and unquestioning
PHOTOGRAPHY

Aroused into greater activity by these events, the Royal Photographic Society began to pay more attention to what had now become the more popular phase. At subsequent exhibitions the technical and scientific work was hung separately from the "Art Section," and a separate set of judges was elected for each section. It became the custom to allot by far the greater amount of space to the "artistic"; and later, artists were elected as judges, by way of encouraging those who were devoted to the pictorial side to send in for exhibition. In the autumn of 1900 the New Gallery was secured, and a comprehensive exhibition of all phases of photography was held.

It is interesting to note that a distinct movement pictorial photography is essentially British in origin, and this is shown by the manner in which organized photographic bodies in Vienna, Brussels, Paris, St Petersburg, Florence and other European cities, as well as in Philadelphia, Chicago, &c., following the example of London, held exhibitions on exactly similar lines to those of the London Photographic Salon, and invited known British exhibitors to contribute. The international character of the "Linked Ring" encouraged an interchange of works between British and foreign exhibitors, with the result that the productions of certain French, Austrian and American photographers are perfectly familiar in Great Britain. This, in the year 1882, led to a remarkable cult calling itself "The New American School," which had a powerful influence on contemporaries in Great Britain.

It may be well to glance at such improvements of process or apparatus as have not been direct and essential means to pictorial advance, but rather modifications and improvements made in response to the requirements of the artistic aspirant. Such improvements are of two sorts—those which are designed with the aim of securing greater accuracy of delineation, the correction of distortion and of apparent exaggeration of perspective, and the more truthful rendering of relative values and tones; and those which give the operator or general public the power of giving the finished result. While great advances have been made in photographic optics, it cannot be said that pictorial work has been more improved or perfected than it was 20 years ago. Some of the most successful exponents preferring to use the simplest form of uncorrected objective, or even to dispense with the lens altogether, choosing rather to employ a minute aperture, technically a "pinhole." This is but one example of many which might be quoted to bear out the statement that in photography the advance of anything in the nature of artistic qualities has not been correlated with mechanical improvements. The hand camera can be said to have had an influence in the progress of photography never dreamed of by those who have witnessed the birth and growth of photography, and by removing the encumbrance of heavy tools has widened its sphere of operations; but it is perhaps in connexion with the plates and printing processes that more direct advantages have been made in recent years. The fact that the emulsion is no longer proportional to their luminosity was long regretted as an obstacle to correct representation; but by the introduction of orthochromatic and antichromatic plates in 1886 (when B. J. Edwards bought the Tailford and Clayden processes) and orthochromat plates this original disability was removed; while with increased rapidity in the orthochromatic plate colour values may still further be corrected by the use of coloured screens or light filters, without interfering with the practicability of making sufficiently rapid exposures for most subjects. Again, by a better knowledge of what is required in artistic representation, certain methods have found a place in the formulated treatment of ordinary, unequal, and local intensification and reduction, but utility of these is restricted. By the artistic worker it is claimed that the lens and camera are the tools, and the negative the preliminary sketch or study, the finished print standard of success or failure, and the work of the photographer is that of a painter. At the production of the print various means of personally controlling the formation of the image have been resorted to. The employment of development of phototype by means of glycine has its champions, but to a painter little used, its resuscitation being chiefly due to two or three prominent workers in New York. Here should also be mentioned the revival in 1898 of roughsurfaced printing papers, chiefly those sensitized with silver, the roughest texture drawing papers being employed to break up the excessive sharpness of the photographic image, and by the superficial inequalities introducing the effect.
PHOTOGRAPHY, CELESTIAL

of luminousness to over-dark shadows and variety to blank whites. The almost forgotten process of Pouncey, and of Poitevin, now known as the gum bichromate process, was rehabilitated in 1894 by M. Rouillé Ladjovsky expressly to meet the needs of the pictorial worker. Perhaps the best results that have been achieved by it are those of M. Robert Demachy of Paris, though many English workers have also used it with remarkable success. In R paper of any kind may be selected, the number of times that the emulsion is to modify the printed image to almost any extent, even to introducing and eliminating lights and shadows, and in other ways to depict objects of the same image given by the negative, depends upon the fact that the coating of gum and pigment (which, being bichromatized, becomes insoluble in proportion as it is acted upon by light) holds the pigment but imperfectly, and yields it up upon a vigorous action of the solvent. According to its nature, the operator can lighten or deepen in tone any portion. Numberless variations of other methods, such as brush development and local toning or stopping, have been suggested with the same object. Other workers have shown that by deliberately shutting off and admitting the light to various parts of the negative while printing, the disposition of the lights and shades in the print can be modified to so great an extent as to alter the general contour of the scene. Examples of an original unaltered print, and one which has been thus modified, are shown in the accompanying plate. Portions are shaded in by allowing the light to have access to them, while the negative in which case the image with all its details, prints more deeply on the paper. By moving the original when the action of the light is to flatten and suppress both detail and contrast. Latterly some few have resorted to extensive working by employing the light on the negative only, and on the paper by hand is practised on the film to render too prominent features less obtrusive, and objects in the background are merged by an intricacy of lines and cross-hatching. Many of the results are very pleasing, although to some extent the original artistic points of the negative are lost. On the other hand, to exclude for purity of method and the exclusion of extraneous aids is very like setting up an arbitrary standard no less unreasonable than those conventions against which pictorial photography has so long striven.

PHOTOGRAPHY, CELESTIAL. The requisites for celestial photography are best explained by a comparison with ordinary photography in several essential points.

a. Illumination.—In taking a portrait artificial light is used, being thrown on to the face of the sitter either directly or by reflection. If the day is dull a longer exposure is required, and artificial light may be used when the daylight fails. In photographing the stars there is no question of illuminating them by artificial light; for the strongest searchlight which we could throw in the direction of the heavenly bodies would have no sensible effect. The light used is their own, and its feebleness renders it all the more impossible to keep up a steady light on the ground, as we attempt to get images of fainter objects. The invention of the dry plate, by making it possible to give very long exposures, caused a revolution in celestial photography. With the wet plate, exposures were limited to the few minutes during which the film would remain wet; but the dry plate can remain in the telescope for days, weeks or even years if necessary. On the approach of daylight, the cap is put on the camera, or the plate removed into the dark room; but when night returns the plate is put back in the telescope, which is accurately pointed to the same stars, the cap is removed, and the exposure is resumed without any loss from the interruption.

b. Magnification.—In taking a portrait we can obtain a large or small size by placing the camera near the sitter or far away. But this method is not available for the heavenly bodies, since we cannot sensibly approach them. To magnify an image we must lengthen the focus of the camera, either directly or indirectly. The direct method is to construct a lens or mirror of long focus; the camera becomes similar in length to a telescope; and indeed resembles a telescope in other respects, except that we take away the eye-piece and put in a photographic plate instead. If, however, we already have a lens of short focus which we wish to use, we may lengthen the focus indirectly by using a secondary magnifier, that is by putting in another lens near the focus of the first. In either case the profitable magnification is limited, not only by the imperfections of the optical apparatus but by disturbances in the atmosphere. Air currents, either outside or inside the telescope, act as irregular lenses of varying shape, and produce such defects in the image that we gain nothing by enlarging it beyond a certain point. Such air disturbances do not trouble the ordinary photographer at all, or scarcely at all: he is only concerned with a few feet of air, whereas the celestial photographer cannot escape from the necessity of looking through many miles of it.

c. Steadiness.—In taking a portrait the photographer is only concerned to fix his camera firmly and to induce his sitter to remain still. The heavenly bodies are in constant motion, though their real and apparent movements are fortunately smooth, except for air disturbances above mentioned. If, therefore, it was possible to devise perfectly smooth clockwork, we could keep the camera or telescope continually pointed to the required star or stars. But human workmanship has not yet made clockwork of sufficient strength and accuracy to keep a large telescope satisfactorily pointed. The clockwork which had been found good enough for use with visual telescopes was soon found to be quite inadequate for photography. The first method adopted was to bind two telescopes, one visual and the other photographic, firmly together; and by looking through the visual telescope, and using the slow motion screws; the other telescope was kept properly pointed for taking a photograph. As it was sometimes found that extremely fine movements were required, electrical arrangements were devised, whereby the observer, on simply pressing a button, could accelerate or retard the rate of the clockwork by a minute amount, instead of actually turning the screws by hand. And about the same time the idea arose of making these corrections automatically. This automatic correction is based on the principle that a freely swinging pendulum, which has no work to do, will naturally keep much better time than a clockwork which has to drive a heavy telescope; and if such a pendulum is therefore arranged to send a current every second through certain electro-magnets, apparatus can be devised to detect whether the clockwork is going properly; and to correct it in the right direction, if it is not. One or more of these three methods, which may be called hand-guiding, electrical control, and automatic electric control, are used in taking all celestial photographs.

The Photographic Image.—The image of a star on the plate should be, theoretically, merely a point; but in practice it is a small patch on the plate which grows in size as the exposure is lengthened, while at the same time it becomes darker in the middle. The reason of this is that light is many-coloured, and when we attempt to focus it by clockwork which has to drive a heavy telescope; and if such a pendulum is therefore arranged to send a current every second through certain electro-magnets, apparatus can be devised to detect whether the clockwork is going properly; and to correct it in the right direction, if it is not. One or more of these three methods, which may be called hand-guiding, electrical control, and automatic electric control, are used in taking all celestial photographs.

PHOTOGRAPHY, CELESTIAL

produced is magnified, it is seen to have a shape like that of a kite. As the exposure is prolonged the small kite-shaped figure gradually increases in size from the point towards the head, and this defect is the more pronounced the farther we depart from the centre of the plate. The result is, speaking generally, that the images near the centre of a plate may be fairly small and circular, but at a certain distance from the centre they become distorted and large. It is a practical problem of great importance to have this distance as great as possible, so that the field of good definition may be large. Estimating in terms of angular distance from the centre of the field, the reflecting telescope has a good field of not more than 4°, a lens of the ordinary refractor a field of about 1°, while if two compound lenses are used (as is the case in portrait photography) the field may be very greatly extended, 10° or 15° having been successfully covered. This is naturally a very great advantage of the "doublet" over other forms of telescope, an advantage which has only recently been fully realized. But there is a compensating drawback; to get a large field we must either use a large plate, which is liable to bend or to have a permanent curvature; or if we use a small plate the picture will be on a small scale, so that we lose accuracy in another way.

Star Charts may be made only by photography with any degree of precision of these advantages. The Cape Photographische Durchmusterung is a photographic survey of the southern hemisphere by means of 250 plates each covering 5° × 5° taken at the Royal Observatory, Cape of Good Hope; the plates being afterwards measured at Groningen in Holland by Professor J. C. Kapteyn who recorded the places to O°.1 and O°.1. A much higher degree of accuracy is aimed at in the international scheme for a map of the whole sky undertaken jointly by eighteen observatories in 1887. The plates are only 2° × 2°, and each of the eighteen observatories must take about 600 to cover its zone of the sky once, 1200 to cover it twice. Exposures of 6 min. 30 Min., and 1 h. are given, the telescope being pointed in a slightly different direction for each exposure; so that each star to about the 9th magnitude shows 3 images, and stars to the 11th or 12th magnitude show 2; which has the incidental advantage of distinguishing stars from dust-specks. A réseau of lines accurately ruled at distances of 5 mm. apart in two directions at right angles is impressed on the plate by artificial light and developed along with the star images; and by use of these reference lines the places of all stars shown with 3 min. exposure are measured with a probable error which, by a resolution of the executive committee, is not to exceed 2 sec. of arc. An additional scheme for a series of plates covering the whole sky has also been adopted, with much longer exposure has proved too costly, and only a few observatories have attempted it. Meanwhile Professor E. C. Pickering of Harvard, by using doublet lenses which cover a much larger field at once, has photographed the whole sky many times over. The plates have not been measured, and would not in any case yield results of quite the same accuracy as those of the international scheme; but being systematically stored at the Harvard Observatory they form an invaluable reference library, from which the history of remarkable objects can be read backwards when once attention is drawn to them. Thus the history of the asteroid Eros, discovered in 1898, was traced back to 1894 from these plates; new stars have been found on old plates, and the tracing of their blazing up recovered within narrow limits; and the history of many variable stars greatly extended. The value of this collection of photographs will steadily increase with time and growth.

Spectroscopic Star Charts.—By placing a glass prism in front of the object glass of a telescope the light from each star can be extended into a spectrum: and a chart can thus be obtained showing not only the relative positions, but the character of the light of the stars. This method has been used with great effect at Harvard; and from inspection of the plates many discoveries have been made, notably those of several novae.

The Geometry of the Star Chart.—Let OS in the figure be the object glass with which the photograph is taken, and let its optical centre be C. Let PL be the plate, and draw CN perpendicular to the surface of the plate. The point N is of fundamental importance in the geometry of the star chart and it is natural to call it the plate centre; but it must of course be regarded as established from two other points which should theoretically, but may not in practice, coincide with it. The first is the centre of the plate where it is assumed to be placed in position. In the figure NL is purposely drawn longer than PN, and this point probably would correspond to the right of N. The second point is that where the optical axis of the object glass (CG in the figure) cuts the plate. The object glass, it will be noticed, is put with an exaggerated tilt so that CG falls to the right of CN. To secure adjustment, the object glass should be "tangled on" to the tube by a familiar operation, so that the tube is parallel to CG; and then the plate should be set normal to the tube and therefore to CG. This is done by observing reflected images, combined with rotation of the plate in its plane.

The form of the curve will in general be curved: so that the points of best focus for different stars lie on a surface such as AGB (purposely exaggerated). The best practical results for focus will thus be obtained by compromise, placing the plate so that the stars, as seen from it, be nearer the object glass: exact focus only being possible for a particular ring on the plate. The star A will thus be represented by a small patch of light, on the plate, which will grow in size as aberration increases. When we measure the position of its image we select the centre as best we can; and in practice it is important that the point selected should be that where the line Ca drawn from the star to the optical centre cuts the plate. If this can be done, the circle of the chart represents the spherical projection of the heavens from the point C on to the plane PL. The stars are usually conceived as lying on the celestial sphere, with an arbitrary radius and centre at the observer, which is in this case the object glass; describing such a sphere with C as centre and CN as radius, the lines BC and CA project the spherical surface on to a tangent plane at the point N, which we call the plate centre. If we point the telescope to a different part of the sky, we select a different tangent plane on which to project. It is a fundamental property of projections that a straight line projects into a straight line; and in the present instance we may add that every straight line corresponds to a great circle on the celestial sphere. Hence if we measure any rectilinear co-ordinates (x, y) of a series of stars on one plate, and co-ordinates (X, Y) of the same stars on another plate, and (x, y) are connected by a linear relation, so must (X, Y) be. This property leads at once to the equation

where the numerators are any linear functions of (x, y) but the denominators being the same linear function.

A particular case the co-ordinates

represent the rectangular co-ordinates of a star of RA and declination \( \theta \), projected on the tangent plane at the north pole. If the same star be projected on the tangent plane at the point (A, D), then its rectangular co-ordinates \((\epsilon, \eta)\) will be

and

the axis of being directed towards the pole. It can readily be verified that \((\epsilon, \eta)\) can be obtained from \((x, y)\) by relations of the form (1). The co-ordinates \((\epsilon, \eta)\) have been named "standard co-ordinates" and represent star positions on an ideal plate free from the effects of distortion and refraction. On such plates with not too large a field, differential refraction and aberration are so small that their product by squares of the co-ordinates may be neglected, and the actual star positions \((x, y)\) are connected with \((\epsilon, \eta)\) by linear relations. The main object of these equations is obviously not disturbed by the choice of origin of axes and of orientation; in which the effects of precession and nutation for any epoch may be included. Hence to obtain the standard co-ordinates \((\epsilon, \eta)\) of any object on a plate it is necessary to know the position of the plate centre (the point N in fig. 1) and the six constants in the relations

where \((x, y)\) are rectilinear co-ordinates referred to any axes. The constants can theoretically be determined when there are three stars on the plate for which \(x, y\) are known; but in practice it is better to take as many \(x, y\) known stars as possible. These equations
are well adapted to solution by least squares or any equivalent device.

Photography of Nebulae and Clusters.—Some of the earliest and most striking successes in celestial photography were the pictures of nebulae. Dr. A. A. Common (1841–1903), F.R.S., of Edinburgh, by the way, in 1884 with a successful picture of the great nebula in Orion, taken with a 3 ft. concave mirror by Calver. Dr Isaac Roberts (1829–1904) was the first to show the real structure of the great nebula in Andromeda, by a photograph also taken with a reflector. In the clear atmosphere of the Lick Observatory in California, small nebulae were photographed in great numbers by Professor J. E. Keeler (1857–1906); and it was shown what a large percentage were spiral in form. Prof. G. W. Ritchey, at the Yerkes Observatory, has followed up these successes with a 2½ ft. reflector, and is constructing a 5-ft., to be erected on Mt Wilson (Cal.); but he has also shown that pictures of clusters are best taken with a telescope of long focus, such as the great Yerkes reflector; and incidentally that this telescope, although intended for visual work, can be adapted to photography by using a “colour screen” just in front of the plate, which sifts out the rays not brought to focus.

Photography of the Moon.—G. W. Ritchey has used the same device of a colour screen for the moon, and obtained even better pictures than those obtained at Paris, which were previously the best. The positions of a large number of craters and other points have been measured by Dr J. H. G. Franz and S. A. Saunder on photographs, and a new epoch in lunular topography is thus far by been created.

Photography of the Planets.—Some striking successes have been obtained at the Lowell Observatory, Flagstaff, Arizona: by cutting down the aperture of the object-glass some of the delicate markings, called canals, on the planet Mars have been photographed; but even these do not approach what can be seen by the eye.

Photography of Comets.—Some wonderful pictures have been obtained of comets by Professor E. E. Barnard and others. Here, as in the case of nebulae, the photograph is superior to the eye in detecting faint luminosity, and delicate details of the tail structure have been photographed which could never be seen. In several pictures the tails have an appearance of violent shattering, and if successive pictures can be obtained at such times we may learn something of the nature of such disturbances.

Solar Photography.—The light of the sun is so intense that the chief difficulty is to obtain a short enough exposure. When successfully taken, photographs of the surface show the well-known spots and the motting of the surface. The image sensibly falls off in intensity towards the limb, owing to the absorption of light by the solar atmosphere; and the bright faculae (which are thus inferred to lie above the main absorbing layer) are seen near the limb. But an immense advance in solar photography was made about a dozen years ago by the invention of the spectroheliograph, which is an instrument for photographing in the light of one very definite colour—say a single hydrogen line. The faculous appearances can be photographed with this instrument all over the sun’s disk, instead of merely near the limb. The appearance presented varies enormously with the line selected, or (in the case of the wide “lines” in the spectrum, such as the H and K lines) with the particular part of the same line selected. But for a full account of such matters reference must be made to the articles SUN and SPECTROHELIOGRAPH.

PHOTOMETRY (from Gr. φως, φωτός, light, φωτιαν, a measure), the art and science of comparing the intensities or illuminating powers of two or more sources of light. As in all scientific measurements, its methods are attempts to give quantitative accuracy to the crude comparisons made by the eye itself. The necessity for this accuracy in practical affairs of life has arisen because of the great development of artificial lighting in recent times. The eye soon learns to associate with any particular source of light a quality of brightness or power of illumination which diminishes with increase of distance of the source from the eye or from the surface illuminated. This quality depends upon an intrinsic property of the source of light itself, generally known as its “candle power.” The aim of photometry is to measure this candle power; and whatever be the experimental means adopted the eye must in all cases be the final judge.

In the photometric comparison of artificial lights, which frequently vary both in size and colour, direct observation of the sources themselves does not yield satisfactory results. It is found to be much better to compare the illuminations produced on dead white surfaces from which no regular reflection takes place, or through colourless translucent material uniformly illuminated by the light placed on the further side. By such processes there is always loss of light, and we must be certain that the various coloured constituents of the light are reduced in the same proportion. This necessary condition is practically satisfied by the use of white diffusing screens.

Two principles of radiation underlie many photometric applications, namely, the inverse square distance law, and J. H. Lambert’s “cosine law.” Both can be established on theoretical grounds, certain conditions being fulfilled. But as these conditions are never absolutely satisfied, the application of the two laws must in the end be tested by experiment. Since we find that within the errors of observation four candles, placed together at a distance of 2 ft. from a diffusing screen, produce the same illumination as one candle at a distance of 1 ft., we may regard the inverse square distance law as satisfied. Thus if two lights of intensities A and B produce equal illuminations on a screen when their distances from the screen are respectively a and b, we at once write down the relation between the two intensities in the form A : B = a² : b². The theoretical basis of the law follows at once from the universally accepted view that light is energy radiating outwards in all directions from the source. If we assume that there is no loss of energy in the transmitting medium, then the whole amount of radiant energy passing in one second across any closed surface completely surrounding the source of light must be the same whatever the size or form of the surface. Imagine for simplicity a point source of light, or its equivalent, a uniformly radiating spherical surface with the point at its centre, and draw round this point a spherical surface of unit radius. Across this surface there will pass a definite amount of radiant energy, in other words a definite total luminous flux, E, which will be the same for all concentric spherical surfaces. Since the area of a spherical surface of radius r is 4πr², the flux which crosses unit area is E/4πr². This quantity is the “illumination.” It is measured in terms of the unit called the lumen, which is defined as the illumination produced by a light of unit intensity on a perfectly white surface at a distance of 1 ft. In the great majority of photometers the illuminations are compared, and the intensities are deduced by applying the law of the squared distances.

Lambert’s cosine law has to do with the way in which a luminous surface sends off its radiations in various directions. It is a matter of common observation that the disk of the sun appears equally bright all over the surface. Careful measurements show that this is not strictly true; but it is sufficiently near the truth to suggest that under certain definable conditions the law would hold accurately. Again, when a glowing surface is viewed through a small hole in an opaque plate, the brightness is very approximately independent of the angular position of the incandescent surface. This is the same phenomenon as the first mentioned, and shows that the more oblique, and therefore larger, element of surface sends the same amount of radiation through the hole. Hence the amount per unit surface sent off
PHOTOMETRY

at a given angle with the normal must be less than that sent off in the direction of the normal in the inverse ratio of the areas of the corresponding normal and oblique elements; that is, as the cosine of the given angle to unity. For most practical purposes, and so long as the obliquity is not great, Lambert’s law may be assumed to hold.

In almost all accurate methods of photometry the aim is to bring the illuminating powers of the two sources to equality. This may be effected by altering the distance of either light from the illuminated surface. Or we may use polarized light and diminish the intensity of the stronger beam by suitable rotation of a Nicol prism, a method particularly useful in spectro-photometers. The same result may also be effected by interposing absorbing disks, the precise absorbing powers of which must, however, be known with great accuracy. Another useful method is that first described by H. Fox Talbot in 1834, and used with effect by Professor William Swan (1849), and more recently by Sir W. de W. Abney.

Talbot’s Law.

Talbot’s law is thus enunciated by H. von Helmholz: “When any part of the retina is excited by regularly periodic intermissions of light, and when the period is sufficiently short, the resulting impression will be continuous, and will be the same as that which would be produced if the whole light were distributed uniformly throughout the whole period.” Talbot deduced the principle from the well-known experiment in which a continuous luminous line is produced by rapid rotation of a luminous point. If the principle be granted, it is obvious that any mechanism by which a ray of light is obstructed in a regularly rhythmical manner during definite intervals $t'$, separated by intervals $t$, during which the light is allowed to pass, will have the effect of reducing the apparent brightness of the ray in the ratio $\frac{t}{t' + t}$. This is frequently accomplished by placing in the ray a rotating disk perforated by radial sectors, the so-called Talbot disk.

If photometric results are to be of general value it is essential to have a unit in which to express all other intensities. For example, electric lights are classified according to their “candle-power.” The candle, in terms of whose brightness the brightness of other sources of light is to be expressed, must, of course, fulfill the conditions demanded of all standards. It must give under definite and easily defined conditions a definite and constant luminous effect, and it must be easily reproducible. The earlier attempts to get a candle of constant brightness were not very satisfactory. The British standard is a sperm candle which weighs $\frac{1}{4}$ lb, and loses in burning 120 grains per hour. It is found that these conditions are not sufficient to determine the luminous power of the candle, since the length and shape of the wick, the height of the flame, and the composition, temperature and humidity of the atmosphere all have an effect upon its brightness. The same is true of other similar sources of light—for example, the German standard candle, which is made of paraffin, has a diameter of 2 cm., and has its wick cut until the flame is 5 cm. high, but which with all precautions suffers continual alterations in brightness. For ordinary practical purposes, however, these candles are steady enough. Other kinds of flame have also been used as a standard source of light. The oldest of these is the French Carcel lamp, which is provided with a cylindrical Argand burner, and gives the standard brightness when 42 grammes of colza oil are consumed per hour. The supply and draught are regulated by clockwork. The supply and draught are regulated by clockwork. A. G. Vernon-Harcourt’s pentane standard, in which a mixture of gaseous pentane and air is burnt so as to maintain a flame 2 5/8 in. high at ordinary barometric pressure, gives good results and is available to suit the several conditions. Several forms of this standard have been constructed, one of the most important being the 10-candle-power pentane lamp, in which air saturated with pentane vapour is burnt in a specially-designed burner resembling an Argand lamp. For photometric purposes a definite length of the lower part of the flame is used, the upper part being hidden within an opaque tube. The amyl-acetate lamp designed by H. von Hefner-Altenek has been elaborately studied by the German authorities, and at present is probably more used than any other flame for photometry. It is of simple construction, and gives the standard brightness when it burns with a flame 4 cms. in height in still air of humidity 85% and free from carbon dioxide. The presence of carbon dioxide and increase in the humidity have a marked effect in diminishing the brilliancy of the flame. If the vapour pressure is $\alpha$ and the barometric pressure $p$, the strength of the flame, when all other conditions are fulfilled, is given by the formula

$$I = \frac{0.049 - 1.5e}{(p - \alpha)}$$

One disadvantage for photometric purposes is the reddish colour of the flame as compared with the whiter artificial lights in general use.

For an interesting account of the various experimental investigations into the properties of the Hefner flame see E. L. Nichols, "Standards of Light." Transactions of the International Electrical Congress, vol. II (St. Louis, 1904). Angstrom’s determination of the radiation of the flame in absolute energy units is also of special interest.

Attempts have been made, but hitherto with limited success, to construct a convenient standard with acetylene flame. Could a satisfactory burner be devised, so that a steady brilliancy could be easily maintained, acetylene would, because of its intense white light, soon replace all other flames as standards.

J. Violle has proposed to use as standard the light emitted by a square centimetre of surface of platinum at its melting point, but there are obvious practical difficulties in the way of realizing this suggested standard. J. E. Petavel and Hefner, who carefully examined the necessary conditions for producing it (Proc. Roy. Soc. 1899), finds that the platinum must be chemically pure, that the crucible must be made of pure lime, that the fusion must be by means of the oxy-hydrogen blow-pipe, that the gases must be thoroughly mixed in the proportion of 4 volumes of hydrogen to 3 of oxygen, and that the hydrogen must contain no hydro-carbons. Under these conditions the variation in the light emitted by the molten platinum would probably not exceed 1%. O. Lummer and F. Kurlbaum have proposed as a standard a strip of platinum foil 25 mm. wide and 0.015 mm. thick brought to incandescence by an electric current of about 80 amperes. The temperature of the strip is fairly constant, and the radiation is transmitted through a water trough 2 cm. in width. This ratio is determined by means of a bolometer, and so long as it is adjusted to $\frac{1}{4}$th the light is practically constant.

For comparative photometric work the incandescent electric light is very convenient, having the one great advantage over candles and flames that it is not affected by atmospheric changes. But it does not satisfy the requirements of a primary standard. It ages with use, and when run at constant voltage gradually loses in brilliancy, partly because of changes in the filament itself, partly because of the deposit of carbon on the interior of the bulb. Professor J. A. Fleming has shown that very good results can be obtained if carbon filaments carefully selected and run in ordinary bulbs for a definite time at a little above their normal voltage are remounted in large clear glass bulbs 6 or 8 in. in diameter. If used sparingly, and never above their marked voltage, these large incandescent bulbs have been found to remain constant for years, and therefore to be eminently suitable as secondary standards. In his Handbuch for the Electrical Laboratory and Testing Room (vol. II) Fleming concludes that the best primary standards are the Violle incandescent platinum and the Vernon-Harcourt pentane one-candle flame; and that the most convenient practical standards are the Hefner lamp, the ten-candle carbon dioxide, and the Fleming lamp, both incandescent electric lamps. Comparisons of the intensities of these various standards do not give quite concordant results. Thus three different authorities have estimated the 10-candle pentane lamp as being equal to 10-75, 11-0, 11.4 Hefner lamps.

A specially constructed instrument or piece of apparatus for comparing light intensities or illuminations is called a
PHOTOMETRY

527

photometer. The earlier forms of photometers were very simple and not capable of giving very precise results. The principles of construction are, however, the same in all the recognized forms down to the most elaborate of recent inventions. Two of the earliest forms were described by P. Bouguer and W. Ritchie. The Ritchie wedge constitutes the basis of many varieties of type. Two of the lights to be compared illuminate the sides of the triangles so placed between them that the eye set in front of the wedge sees the two sides illuminated each by one of the lights. The edge should be as sharp as possible so that the two illuminated surfaces are in close contact. The illuminations are made equal either by shifting the wedge along the line joining the lights or by moving one of the lights nearer to or farther from the wedge as may be required. The lights given out by the sources are then as the squares of the distances from the matched parts of the surfaces. Count Rumford’s photometer suggested the comparison of the intensity of the shadows of the same object thrown side by side on a screen by two lights to be compared. In this case the shadow due to one source is lit up by the other alone; and here again the amounts of light given out by the sources are as the squares of their distances from the screen when the shadows are equally intense. The shadow-casting object should be near the screen, so as to avoid penumbra as much as possible; yet not too near, so that the shadows may not overlap.

R. Bunsen suggested the very simple expedient of making a grease-spot on white paper for photometric purposes. When the paper is equally illuminated from both sides the grease-spot cannot be seen except under very close inspection. In using this photometer, the sources are placed in one line with the grease-spot, which lies between them and can be moved towards one or other. To make the most accurate determinations with this arrangement the adjustment should first be made from the side on which one source lies, then the screen turned round and the adjustment made from the side of the other source—in both cases, therefore, from the same side of the paper screen. Take the mean of these positions (which are usually very close together), and the amounts of light as are the squares of the distances of the sources from this point. The efficiency of the two inclined mirrors so that the view shows both sides of the paper simultaneously.

Sir Charles Wheatstone suggested a hollow glass bead delivered internally, and made to describe a rapid closed path, for use as a photometer. When it is placed between two sources we see two parallel curves of reflected light, one due to each source. Make these, by trial, equally bright; and the amounts of light from the sources are, again, as the squares of the distances.

William Swan’s prism photometer, invented in 1869, is a beautiful application of the principle embodied in Bunsen’s grease-spot photometer (see Trans. Roy. Soc. Ed. vol. xxv.). The part of the instrument is fundamentally the same as that described by O. Lummer and E. Brodhun in 1889.

It consists of two equal right-angled isosceles glass prisms placed with their diagonal faces together so as to form a cube (Fig. 1), and cemented together by a small patch of Canada balsam, which prevents the light from passing out into a circle when the prisms are pressed together. In the figure, which represents a central section of the prism, the Canada balsam is represented by the letter N. The light from two illuminated surfaces, PQ, RS, is allowed to fall on the face AB, which is cemented to the face AD. In each case that part of the light falling internally on the portion of the diagonal face which is not backed by the Canada balsam is totally reflected. On the other hand, the light which falls on the portion backed by the Canada balsam is almost wholly transmitted. Thus an eye placed in the position q receives light from both sources, the surface RS supplying nearly all the light that seems to come from the patch N, while the surface PQ supplies all the light which comes from the region immediately surrounding N. The patch N will in general be visible; but it will quite disappear when the luminosity of the ray QT, which traverses the Canada balsam, is equal to that of the ray PQ, which has traversed, after total reflection from the surface PQ. This condition of invisibility of N is arrived at by adjusting the positions of the two lights with the aid of the R. Brodhun’s photometer. The brightnesses of the two sources will then be as the squares of their distances from their respective screens.

The essential part of Lummer and Brodhun’s photometer is a combination of prisms very similar to Swan’s. Its most improved form the bi-prism or “optical cube” has one Lummer and Brodhun’s component prisms cut in a peculiar manner, the Bi-prism. The diagonal face is partly cut away, so that the central portion of this face is made to coincide with the diagonal face of the other prism. The Canada balsam is dispensed with, the surfaces being pressed closely together so that the axes of the two prisms are placed in the same plane. The instrument convenient for use with an optical bench, Lummer and Brodhun make the illuminated surfaces which are to be compared the opposite sides of an opaque screen set in the continuation of the diagonal (CA) of a square, the barycentre of the cut-out parts being totally reflected. The general result is the production of two similar luminous patches l and r, each of which is surrounded by a field of the same intensity as the other patch. When the photometric match is made the whole region will be uniformly bright. But, by insertion of strips of glass so as to weaken equally the intensity in the surrounding fields, the match will be obtained when these fields are made of equal intensity and the two patches are the same size. The same thing is done from them. Under these conditions the eye is able to judge more certainly as to the equality of intensity of the two patches, and an untrained observer is able to effect a comparison with an accuracy which is impossible with most forms of photometer.

J. Joly’s diffusion photometer consists of two equal rectangular parallelepipeds of a translucent substance like paraffin separated by a thin opaque plate l. It is set between the source, by reflection from symmetrically situated mirrors so as to enter the sides AB and AD perpendicularly. An important modification, due also to Lummer and Brodhun, is the following: By means of a second portion of the photometer, which is a new prism, the half of the diagonal face of the one prism, and from the other half of the same prism there is removed in like manner all but a part l corresponding to the part r. The portions which have not been removed are pressed against the diagonal face of the other prism, and become the parts through which light is freely transmitted. On the other hand, the light which enters the second prism and falls on the portions of surface backed by the layers of air filling the cut-out parts is totally reflected. The general result is the production of two similar luminous patches l and r, each of which is surrounded by a field of the same intensity as the other patch. The method is made applicable perpendicularly on the face of an elastic vibrator so as to render it capable of a slight to-and-fro oscillation about a mean position.

A form of photometer which is very adapted for measuring the illuminating power of a radiant surface is set up on a revolving axis, which is turned so as to bring a horizontal tube across one end of which is fitted another tube at right angles. This second tube can be rotated into any position perpendicular to the horizontal tube. The eye looks along the cross tube, at the farther end of which is placed another piece of ground glass illuminated from the outside. The illuminations of the two pieces of ground glass are viewed simultaneously, being brought to equality, either by shift of the ground glass to or from the standard light, or by means of two Nicol prisms placed in the cross tube. One advantage of the instrument is its portability.

The photometry of incandescent electric lamps has led to several special modifications and devices. The candle power varies distinctly in different horizontal directions and on measurement by any particular direction is not therefore very useful. Sometimes the lamp is rotated about three times a second about a vertical axis and an average value thus obtained. But there is always a risk of the filament breaking; and in all cases the effect of centrifugal force must alter the form of the filament and therefore the distances of the different parts from the screen. Accurate demands either the measurement of the radiation intensity in a number of directions all round the lamp, or one combined...
PHOTOMETRY

measurement of as many rays as can be conveniently combined. One of the best methods of effecting this is by means of Matthews's C. P. Matthews's integrating photometer. By the integrating use of twelve mirrors arranged in a semicircle whose Photometer diameter coincides with the axis of the lamp, twelve rays are caught and reflected outward to a second set of twelve mirrors which throw the rays on to the surface of a photometric screen. This combined effect is balanced by the illumination produced by a standard lamp on the other side of the screen (see Trans. Amer. Inst. Elect. Eng., 1902, vol. xix.).

So long as the lights to be compared are of the same or nearly the same tint, the photometric match obtained by different observers is practically the same. If, however, they are of distinctly different colours, not only do different observers obtain different results but those obtained by the same observer at different times are not always in agreement. Helmholtz was of opinion that photometric comparison of the intensities of different coloured lights possessed no real intrinsic value. There can be little doubt that in a rigorous sense this is true. Nevertheless it is possible under certain conditions to effect a comparison which has some practical value. For example, when the intensities of two differently coloured lights differ considerably there is no difficulty in judging which is the stronger. By making the one light pass through a fairly large range of brightness we may easily assign limits outside which the intensities are undoubtedly different. After some experience these limits get close; and many experimenters find it possible, by taking proper precautions, not only to effect a match, but to effect practically the same match time after time. According to Abney, whose memoirs on colour photometry (Phil. Trans., 1886, 1892) form a most important contribution to the subject, the observer in making his judgment as to the equality of luminosity of two patches of colour placed side by side must not begin to think about it, but must let the eye act as unconsciously as possible. His method was to compare the coloured patch with white light given by a particular standard and cut down to the proper intensity by use of a Talbot's rotating sector, which could be adjusted by means of a suitable mechanism while it was rotating.

At the same time, although the eye may be able to effect a difference in the intensity of two patches of colour of a particular luminosity, it has been long known that a change in the luminosity will destroy the apparent equality. This depends upon a physiological property of the retina discovered by J. E. Purkinje in 1825 (see below, Celestial Photometry). In virtue of this property the blue and violet end of the spectrum is more stimulating to the eye than the red end when the general luminosity is low, whereas at high luminosities the red gains relatively in brightness until it becomes more stimulating than the blue. Unless therefore account is taken in some definite measurable manner of the absolute brightness, there must always be some uncertainty in the photometric comparison of the intensities of differently coloured sources of light.

Instead, instead, of trying to effect a photometric match in any of the ways which have been found sufficient when the sources are of the same or nearly the same tint, we may effect important practical comparisons in what is called heterochromatic photometry by an appeal to other physiological properties of the eye. For example, the power of clearly discriminating patterns in differently coloured lights of various intensities is obviously of great practical importance; and this power of detailed discrimination may be made the basis of a method of photometry. According to this method two lights, one of which is to illuminate two exactly similar Observed patterns of lines drawn, for example, on the sides of a Ritchie wedge, and their distances are adjusted until the patterns are seen equally distinct on the two sides. Application of the usual distance law will then give the relation between the two lights. A discrimination photometer constructed on this principle has been designed by J. A. Fleming. Its results do not agree with the indications of an ordinary luminosity photometer; for it is found that the eye can discriminate detail better with yellow than with blue light of the same apparent luminous intensity.

Another and very promising method of photometry depends upon the duration of luminous impressions on the retina. J. A. Plateau observed that the blending of a homogeneous impression of a pattern of alternate Photometry, sectors of black and some other colour marked on a disk when that disk was rotated occurred for rates of rotation which depended on the colour used. A form of experiment suggested in Professor O. N. Rood's Modern Chromatics seems to have been first carried out by E. L. Nichols (Amer. Journ. of Science, 1881). A black disk with four narrow open sectors was rotated in front of the slit of a spectroscope. When the rotation was not too quick the yellow part of the spectrum appeared as a succession of flashes of light separated by intervals of darkness of appreciable length when viewed through both the red and violet ends no apparent interruption in the steady luminosity could be observed. As the rate of rotation increased the part of the spectrum in which flicker appeared contracted to a smaller length extending on each side of the yellow, and finally with sufficiently rapid alternation the yellow itself became steady. This seems to show that the retinal image persists for a shorter time with yellow light than with light of any other colour; for with it the intervals of darkness must be shorter before a continuous impression can be obtained. Now yellow is the most luminous part of the spectrum as it affects the normal human eye; and E. S. Ferry (Amer. Journ. of Science, 1892) has shown that the duration of illumination impression, if not entirely, is determined by the luminosity of the ray. Hence the determination of the minimum rate of intermittence at which a particular colow of light becomes continuous may be regarded as a measure of the luminosity, the slower rate corresponding to the lower luminosity. Although in the experiment just described the red part of the ordinary solar spectrum becomes continuous for a slower rate of intermittence than the yellow part, yet we have simply to make a red ray as luminous as the yellow ray to find that they become continuous for the same rate of intermittence. It is, however, highly improbable that the duration of impression depends only on the luminosity of the light and not to some extent upon the wave-length. There are indeed phenomena which require for their explanation the assumption that the duration of luminous impression does depend on the colour as well as on the brightness.

Nevertheless the luminosity is by far the more important factor, as shown by Ogden N. Rood's experiments. He found (Amer. Journ. of Science, 1893) that, when a disk whose halves differ in tint but not in luminosity is rotated rather slowly, the eye of the observer sees no flickering such as is at once apparent when the halves differ slightly in luminosity. Rood himself suggested various forms of photometer based on this principle. In his latest form (Amer. Journ. of Science, Sept. 1890) the differently coloured beams of light which are to be compared photometrically are made to illuminate the two surfaces of a Ritchie wedge set facing the eye. Between the wedge and the eye is placed a cylindrical concave lens, which can be set in oscillation by means of a motor in such a way that first the one illuminated surface of the wedge and then the other is presented to the eye in sufficiently rapid alternation. The one source of light is kept fixed, while the other is moved about until the sensation of flicker disappears. From work with this form of instrument Rood concluded that "the accuracy attainable with the flicker photometer, as at present constructed, and using light of different colours almost spectral in hue, is about the same as with ordinary photometers using white light, and that a light of exactly the same color..."

Various modifications of Rood's forms have been constructed from time to time by different experimenters. The Simmance and Abadsky flicker photometer is an ingenious and yet mechanically simple method by which (as it were) the wedge itself is made to oscillate so as to throw on the eye in rapid succession first one side and then the other. The rim of a wheel of white material is bevelled
PHOTOMETRY

in a peculiar manner. The sharp edge, which passes slightly obliquely across the rim from one side of the wheel to the other and back again, is the meeting of two exactly similar and symmetrically opposed different ways and having their axes parallel to, but on opposite sides of, the axis of rotation of the wheel. As the wheel rotates with its rim facing the eye, the interference of the rays crosses and recrosses and the line of vision during each revolution. Hence first the one illuminated side and then the other are presented to the eye in rapid alternation. The inventors of this instrument claimed that their instrument can be used to detect differences of the relative intensities of two lights, whether of the same or of different colour (Phil. Mag., 1904). There is no doubt that results obtained by different observers with a flicker photometer are in better agreement than with any other form of the instrument. The comparative ease with which the balance is obtained even when the tints are markedly different shows that its action depends upon a visual distinction which the eye can readily appreciate, and this distinction is mainly one of brightness.

The spectrophotometer is an instrument which enables us to make photometric comparisons between the similarly coloured portions of the spectra of two different sources of light, or of two parts of the same original source after they have passed through different absorbing media. When it is desired to compare the intensities of the spectra from two different sources a convenient form is the one described by E. L. Nichols. A direct vision spectroscope mounted upon a carriage travels along a track between the two sources. In front of the slit two right-angled triangular prisms are set so that the light from each source enters the one side of one prism perpendicularly and is totally reflected into the spectroscope. The two spectra are then seen side by side. Attention being fixed on some chosen narrow portion, say, in the green, the instrument is moved along the track between the sources until the two portions appear of the same intensity. The process is then repeated until the whole spectrum has been explored.

In Lummmer and Breeden's form of spectrophotometer the rays to be compared pass in perpendicular lines through the modified Swan double prism, and then together side by side through the spectroscope. By the ingenious arrangement in the form of the two prisms, Professor D. B. Brace (Phil. Mag., 1899) made the combined prism serve to produce the spectra as well as to effect the desired comparison. In this arrangement the compound prism ABC (fig. 2) is made up of two equal right-angled prisms ADB and ADC placed with their longer sides in contact, so that the whole forms an equilateral prism with three parallel faces, Part of the interface AD is silvered, the silvering forming a narrow central strip running parallel to DS. Along the rest of the interface the two prisms are cemented together with Canada balsam or other material having as nearly as possible the same refractive index as the glass. When two rays RS enter symmetrically from opposite sides of the base of the compound prism as shown in the diagram, the ray R will pass through the prism except where the silver strip intercepts it, and will form a part of a spectrum visible to the eye placed at R', while the same portion of the spectrum will be transmitted past the point S where the two rays are again separated from the silvered surface. Thus two systems of incident parallel rays of white light will form on emergence two spectra with corresponding rays exactely parallel. With these and other forms of the instrument the action of the instrument is to make the two systems of equal intensity by a method which enables him to compare the original intensities of the sources. In most cases the relative intensities of the portions of the spectra being compared cannot conveniently be altered by varying the positions of the sources of light. Recourse is therefore generally had to one of the other methods already mentioned, such as the use of polarizing prisms or of rotating sectors. Under certain conditions K. Vierordt's method of obtaining the appearance of uniform width is of great value, but too great confident cannot be placed upon it.

In other types of spectrophotometer, such as those associated with the names of H. Tränain, A. Crova, H. Wild, G. Hünfer, J. König, and W. Wollast, a part of the spectrum is cut off by a diaphragm and placed on the focal plane of a spectroscope. As the diaphragm is moved, the points of intersection of the spectra are made use of, the others being cut out. These two methods make use of the differences in the intensity of the parts of the spectrum illuminated and the eye a Nicol prism is introduced the intensities of any two narrow corresponding portions of the two spectra can be readily equalized. In terms of the intensity of one spectrum the intensity of the other of the original rays can be calculated. An important application of the spectrophotometer is to measure the absorptive powers and extinction coefficients of transparent substances for the visible spectrum. By comparing the intensities of the portions of the two contiguous spectra are made equal—in other words, a match is established. Into the path of the rays of one of the spectra the absorbing substance is then placed in the path of the second. A measure of the loss of luminosity due to the interposition of the absorbing substance is thus obtained.

To facilitate experiments of this nature Dr J. R. Milne has devised a spectrophotometer which presents some novelties of construction (see Proceedings of the Optical Convention, 1905, vol. i). The light from a bright flame is suitably projected by a lens so as to illuminate a small hole at the end of the collimator. The rays from this point-source are made parallel by the collimator, and then pass, partly through the absorbing medium, partly through the space above it. These two streams of the original rays are then admitted through three prismatic glasses and then fall upon a screen with two similar rectangular openings, the upper one allowing the unabsorbed part of the beam to pass, the lower part which has been transmitted through the absorbing medium is reflected back and the difference in the two images converges the rays suitably upon a Wollaston prism, so that two spectra are seen side by side, having their light polarized in perpendicular planes. A Nicol prism is placed between the Wollaston prism and the eyepiece of the telescope, and by its rotation in the manner already described the intensities of any two corresponding portions of the two spectra can be brought to equality. The two methods of adjustment are of great value, one method satisfies the requirements of a good spectrophotometer for (1) the rays through the absorbing medium can be made strictly parallel; (2) the two spectra can be brought with ease accurately to line up; (3) the rays from each spectrum can be made conjugate to the retina of the observer's eye; (4) not only does the two spectra touch accurately along their common edge, but the two fans of rays which proceed from every point of the common edge lie in one and the same plane; (5) the eye is called upon to judge the relative intensities of not two narrow slits but of two broad uniformly illuminated areas. Milne also points out that this instrument can be used as a spectropolarimeter.

In D. B. Brace's method of spectrophotometers the position which depend for their action upon the properties of polarized light are necessarily open to serious objections, such as: selective absorption in the calcaspar, altering the relative intensities of the constituents in the original rays; selective losses by reflection of polarized rays at the various optical surfaces; and the necessarily imperfect performance of all forms of polarizing media. To eliminate these defects as far as possible great care in construction and arrangement is needed, otherwise corrections must be applied. A. Crova, one of the earliest workers in this subject, effects the photometric comparison of differently coloured lights by matching those monochromatic rays from the two spectra which have the same intensity, by using the whole collection of rays that make up the lights. Careful experiment alone can determine this particular ray, but were it once ascertained for the various sources of light in use the method would have the merits of rapidity and accuracy sufficient for
PHOTOMETRY

practical needs. Spectrophotometric observations are necessary to
determine the position in the spectrum of the particular mono-
chromatic ray, but when it has been determined a coloured
glass may be made to allow of the neighbourhood of this
ray to pass, and the photometric comparison may then be
affected by looking through this glass.

This article has been confined strictly to the methods of visual
photometry, with very little reference to the results. Comparison
of intensities of radiation by photographic means or by methods
depending on the effects of heat introduces considerations quite
distinct from those which lie at the basis of photometry in its usual
signification.

(C. G. K.)

CELESTIAL, OR STELLAR, PHOTOMETRY

The earliest records that have come down to us regarding
the relative positions of the stars in the heavens have always
been accompanied with estimations of their relative
brightness. With this brightness was naturally associated
the thought of the relative magnitudes of the luminous bodies
from whence the light was assumed to proceed. Hence in the
grand catalogue of stars published by Ptolemy (c. 150 A.D.),
but which had probably been formed three hundred years
before his day by Hipparchus, the 1200 stars readily visible
at the naked eye in Alexandria were divided into six
classes according to their lustre, though instead of that term
he uses the word μεδόν or “magnitude”; the brightest he
designates as being of the first magnitude, and so downwards
till he comes to the minimum visible, to which he assigns the
sixth. These magnitudes he still further divides each into three.

To those stars which, though not ranging in any particular order
of brightness, nevertheless exceed the average of that order in
lustre he attaches the letter μ, the initial letter ἡμψίων (greater),
and to those in the same order which exhibit a lustre inferior to
that of the average he affixes the letter ε, the initial letter of ἐξάσων.

With this sort of subdivision he passes through all the
six orders of magnitude. He does not, indeed, tell us the
precise process by which these divisions were estimated, but the
principle involved is obvious. It is one of the many remarkable
instances of the acuteness and precision of the Greek mind that
for upwards of 1300 years no real improvement was made in
these estimations of lustre. J. Flamsteed extended the estima-
tion of magnitude of stars visible only by the telescope, and he
improved Ptolemy’s notation by writing 4.3 instead of δ, μ—
indicating thereby an order of magnitude brighter than the
average of a fourth, but inferior to that of a third—and 3.4 for
δ, ε, and so on; but it was not till the year 1796 that any real
advance was made in stellar photometry. Sir W. Herschel,
instead of assigning a particular magnitude to stars, arranged
them in small groups of three or four or five, indicating the order
in which they differed from each other in lustre at the time of
observation. This method was admirably adapted to the
discovery of any variations in brightness which might occur in
the lapse of time among the members of the group. Sir William
observed in this way some 1400 stars, published in four cata-
louges in the Philosophical Transactions from 1796 to 1799; and
two additional catalogues were discovered among his papers
in 1883 by Professor E. C. Pickering of Harvard (see Harvard
Annals, xiv. 345), and have recently been published by Colonel
J. Herschel (Phil. Trans., 1906). These researches of the
elder Herschel were in due time followed by those of his son,
Sir John, about the year 1836 at the Cape of Good Hope. He
both extended and improved the methods adopted by his father
at Slough, and by a method of estimated sequences of magnitude
he was enabled to arrange all the stars visible to the naked eye at
the Cape, thereby introducing the order of their relative lustre,
and then to reduce his results into the equivalent magnitudes
adopted by the universal consent of astronomers. Sir John,
however, like his father, left this important labour incomplete.
Not only is the work one of great and continuous effort, but the
effects of ever-varying meteorological conditions greatly impede
it. Moreover, there is an unsatisfactory indefiniteness attending
all estimations made by the unaided eye; numerical or quantita-
tive comparisons are out of the question, and hence we find

Sir John, in the very midst of establishing his “sequences,”
adopting also an instrumental method which might lead him
to more definite results.

It is to Sir John Herschel that we are indebted for the first
successful attempt at stellar photometry by what may be
termed “artificial” means. He deflected the light of the moon
(by means of the internal reflection of a rectangular prism)
through a small lens 0.12 in. in diameter and of very short
focus (0.23 in.) so as to form a sort of artificial star in its
focus. With strings and a wooden pole he could move this
artificial star of comparison so as to be in the same line of sight
with any actual star whose light he proposed to measure. Other
strings enabled him to remove it to such a distance from the eye
that its light was adjudged to be sensibly the same as that of
the star compared; and the distance was measured by a gradu-
ated tape. While he was thus busy at the Cape of Good Hope,
K. A. Steinheil at Munich had completed for Dr P. L. Seidel
an instrument nearly the same in principle but more manageable
in form. He divided the small object-glass of a telescope into
two halves, one of which was movable in the direction of its
axis. The images of two stars whose light he desired to compare
were formed by prismatic reflection, nearly in the same line of
sight, and one of the lenses was then moved until the light of
the two images seemed equal. The distance through which it
was necessary to bring the movable lens furnished the data for
comparing the relative lustre of the two stars in question.

More recently other photometers have been devised, and de-
dscriptions of three of them, with which considerable researches
have been conducted, will now be given. With the first mentioned
below Professor Pickering of Harvard has made more than a
million measures with his own eyes. The results of his observa-
tions, and of those of his assistants, will be found in the Harvard
Annals especially in vol. xiv. published in 1901, which con-
tains a general catalogue of about 24,000 stars brighter than
magnitude 7.5, north of declination −40°. With the Zöller
photometer Drs Gustav Müller and P. Kempf of Potsdam have
recently completed a similar piece of work, their catalogue of
stars north of the equator brighter than 7.5 containing 14,199
stars (Potsdam Publications, 1907, vol. viii.). The catalogue
of Professor C. Pritchard was smaller, containing 2784 stars
brighter than magnitude 6.5; north of declination −10°; but it was published in 1886, when very little had yet been
done towards the systematic measurement of the brightness of
the stars (Uranometria nova oxonianis, vol. ii. of the Oxford
University Observatory publications).

vols. xiv. and xxi.) consists of two telescopes placed side by side pointing
due east, the light from the stars on the meridian being reflected into them by two mirrors inclined at an angle of 45° to this direction.

If there were a star exactly at the Pole, one of these mirrors
Pickering's Meridian Photometer. Minors, which was used for fainter stars. The second telescope also is provided with a small motion in the perpendicular direction, so as to command a degree or two on each side of the meridian. Near the common eyepiece of the telescopes there is a double image prism which indicates the position of the star selected, and the other remaining pencils are used in a similar way. The two pencils are observed by the observer, who by rotating the prism round its axis can equalize them at a definite reading depending on their relative intensities. This reading gives in fact the difference of magnitude between the two stars selected. It may be remarked that the position of the double image prism is important. It should be just within, not at, the common focus: this position prevents any noticeable colour in the images, and gives the ordinary and extraordinary pencils a sufficient separation so that the eye-stop may permit the entire exclusion of one without the loss of any part of the other. If the prism were exactly at the focus, and the instrument was perfectly limited, the secondary images would coincide with the others and thus lead to errors in observing. But in the actual construction of the instrument the secondary images would appear, if at all, only as adjectives of the star's position, and are not likely to produce any inconvenience. It is worthy of note that Professor Pickering has extended his survey into the southern hemisphere, so that the Harvard photometry is the most complete of all. Each observation consists of four comparisons; after the first observation the observer reverses the position of the star images in the field, and also reverses the double-image prism. The former precaution is necessary in order to eliminate a curious error depending on the relative position of the images, which were considered to give a certain magnitude: Errors of this kind affect all estimations of the relative brightness of two stars in the same field, as has been repeatedly shown by Aston. (Ann. Roy. Obs. South Africa Mon. Not. R.A.S. April 1897), who found that his eye-estimations of the brightness of variable stars required a correction depending on the position-angle of the comparison stars. An advantage over the previous methods is a wider range of comparison.

In Zöllner's instrument an artificial star is taken as the standard of comparison. There is only one telescope, and inside the tube near the eye-end a plate of glass placed at an angle of 45° intercepts rays from a star placed 50 feet from a Nicol plate placed at the other end of the telescope, which is a quarter-wave plate. The Nicol plate, when placed in the light of the star, will produce a double image of the star. If the position of the Nicol plate is reversed, the images will be interchanged. The plate, therefore, is placed in line with the object glass, giving the limiting intensity at which each pure colour vanishes. If we start with lights C D E F G of the colours usually denoted by these letters in the spectrum, and each so bright that it appears to the eye as bright as an amyl-acetate lamp at 1 ft., and if then the intensity of each be gradually diminished, the C light will disappear when the original intensity has been reduced to 22,000 ten-millionths of the original value. The other colours will disappear at the following intensities, all expressed in ten-millionths of the original: D at 350, E at 35, F at 17, and G at 15. If then we had a mixture of two lights, one of C colour as bright as before, and the other of G colour two-thirds fainter (a mixture of the same stars forming a double image which the eye is not able to distinguish the G light at all), and if we continually reduced the combined intensity, the luminosity of the C light would diminish so much more rapidly than that of the G that the latter would begin to assert itself, and when the combined intensities were reduced to 22,000 ten-millionths of the original value, the C light would have all disappeared, while the G light would not. Hence the colour of the light would appear pure violet, though it was originally deep red. This extreme case shows that the "last ray to disappear" when a light is gradually extinguished may be very different in colour from that of the original light, and when more usual light-mixtures are considered, such as those of sunlight and starlight, which are nearly independent of the eye, the "last ray to disappear" is found to be in the green, very near E in the spectrum. This result has two important bearings on the use of the wedge photometer. In the first place,
either the wedge itself should be of a greenish hue, or green light should be used in finding the scale-value (the constant B in the formula \( m = A + Bw \)). In the second, star magnitudes obtained by extinction with the wedge will agree better with those obtained by photography than those obtained with other visual photometers, since photographic action is chiefly produced by rays from E to G in the spectrum, and the E light of ultimate importance (the wedge light) will appear in the spectrum approximately the same as the D light with which other photometers are chiefly concerned. It would also appear that results obtained with the wedge photometer are independent of the aperture of telescope employed, which is not the case with other photometers.

Passing now to the consideration of photographic methods, it is found that when a plate is exposed to the stars, the images of the brighter stars are larger and blacker than those of the fainter ones, and as the exposure is prolonged the increase in size and blackness continues. Much of the light is brought to an accurate focus, but, owing to the imperfection of perfect achromatism in the case of refractors, and to imperfect correction and diffraction, there are rays which do not come to accurate focus, grouped in rings of intensity gradually diminishing outward from the focus. As the brightness of the star increases, or as the time of exposure is prolonged, outer and fainter rings make their impression on the plate, while the impression on the inner rings becomes deeper. Hence the increase in both diameter and blackness of the star disks. As these increase concurrently, we can estimate the magnitude of the star by noting whether the increase in diameter or in blackness, or both. There is consequently a variety in the methods proposed for determining star magnitudes by photography. But before considering these different methods, there is one point affecting these methods which is of fundamental importance. In photography a new variable comes in which does not affect eye-observations, viz., the time of exposure, and it is necessary to consider how to make due allowance for it. There is a simple law which is true in the case of bright lights and rapid plates, that by doubling the exposure the same photographic effect is produced as by increasing the intensity of a source of light twofold, and so far as this law holds it gives us a simple method of comparing magnitudes. Unfortunately this law breaks down for faint lights, and Mr. W. Abney, who has been a vigorous advocate for the complete accuracy of this law up till 1893, in that year read a paper to the Royal Society on the failure of the law, finding that it fails when exposures to an amyl-acetate lamp at 1 ft. are reduced to 0.001, and "signally fails" for feeble intensities of light; indeed, it seems possible that there is a limiting intensity beyond which no length of exposure would produce any sensible effect. This was bad news for astronomers who have to deal with faint lights, for a simple law of this kind would have been of great value in the complex department of photometry. But it seems possible that a certain modification or equivalent of the law may be used in practice. Professor H. H. Turner found that for plates taken at Greenwich, when the time of exposure is prolonged in the ratio of five star magnitudes the photographic gain is four magnitudes (Mon. Not. R. A.S. lv. 775), and a closely similar result has been obtained by Dr. Schwartzschild using the method presently to be mentioned.

Stars of different magnitudes impress on the plate images differing both in size and blackness. To determine the magnitude, Turner ascribed to the character of the image, the easiest Test of a Magnitude. A very small quantity to measure is the diameter of the image, which, however, is determined with a micrometer, it is a simple matter to record the diameter as well, in spite of the indefiniteness of the border. Accordingly we find that various laws have been proposed for representing the magnitude of a star by the diameter of its image, though these have usually been expressed, as a preliminary, as relations between the diameter and time of exposure. Thus G. P. Bond found the diameter to increase as the square of the exposure, Turner as the cube, Pritchard as the fourth power, while W. H. M. Christie has found the law that the diameter varies as the square of the logarithm of the exposure within certain limits. There is clearly no universal law—it varies with the instrument and the plate—but for a given instrument and plate an empirical law is found. The law at first seems to indicate that, all in all, a series of images may be produced of stars of known brightness and known exposures, and, using this as a scale of reference, the magnitudes of other images may be inferred by interpolation. A most important piece of systematic work has been carried out by the measurement of diameters in the Cape Photographic Durchmusterung (Ann. Cape Obsr. vols. iii., iv. and v.) of stars to the tenth magnitude in the southern hemisphere. The measurements were made by Professor J. C. Kapteyn of Groningen, on photographs taken at the Cape of Good Hope Observatory; he adopts as his purely empirical formula

\[
m = B (\text{diameter} + C),
\]

where B and C are obtained independently for every plate, from comparison with visual magnitudes. C varies from 10 to 28, and B from 90 to 260. The part of the sky photographed was found to have an important bearing on the value of these constants, and it was in the course of this work that Kapteyn found a systematic difference between stars near the Milky Way and those far from it, which may be briefly expressed in the law, the stars of the Milky Way are in general bluer than the stars in other regions of the sky. It is intended, however, in the present article to discuss methods rather than results, and we cannot here further notice this most interesting discovery.

Of methods which choose the blackness of the image rather than the diameter for measurement, the most interesting is that initiated independently by Pickering at Harvard and C. Schwartzschild at Vienna, which consists in taking star images considerably out of focus. The result is that these images no longer vary appreciably in size, but only in blackness or density; and that this gradation of density is recognizable through a wide range of magnitudes. On a plate taken in good focus in the ordinary way there is a gradation of the same kind for the faintest stars; the smallest images are all of approximately the same size, but vary in tone from grey to black. But once the image becomes black it remains so, and the change in density is not easy to follow. The images out-of-focus method seems to possess the advantage by the published results of Dr. Schwartzschild, who used a prepared comparison scale of densities, and interpolated for any given star from it. The most satisfactory photographic method would certainly be to take account of both size and blackness, i.e. to measure the total deposit in the film; as, for instance, by interposing the whole image in a given beam of light, and measuring the diminution of the beam caused by the obstruction. But no considerable piece of work has as yet been attempted on these lines.

Even in a rapid sketch of so extensive a subject some notice must be taken of the application of photometry to the determination of the relative amount of light received on the earth from the sun, the moon and the planets. Some methods by which these ratios have been obtained are as simple as they are ingenious; and for them we are mainly indebted to the labours of W. Bouguer and W. C. Bond (1789-1839). The former compared the light received from the sun with that from the moon in the following fashion in 1725. A hole one-twelfth of a Paris inch was made in the shutter of a darkened room; close to it was placed a concave lens, and in this way an image of the sun 9 in. in diameter was received on a screen. Bouger found that this light was equal to that of a candle viewed at 16 in. from his eye. A similar experiment was repeated with the light of the full moon. The image now formed was only two-thirds of an inch in diameter, and he found that the light of this image was comparable with that of the same candle viewed at a distance of 50 ft. From these data and a very simple calculation it followed that the light of the sun was about 256,289 times that
of the moon. Other experiments followed, and the average of all the results was that the light of the sun was about 300,000 times the average light of a full moon, both being viewed in the heavens at the same altitudes. The details will be found in Bouguer's "Traité d'optique". W. H. Wollaston in 1839 tried a series of experiments by which the number 8,072 was obtained; but the omission of certain necessary precautions vitiates the result (Phil. Trans. 1839). Bond (Mem. Amer. Acad. 1861, p. 295) adopted a different process. He formed the image of the sun on a silvered globe of some 10 in. diameter; the light of this image was reflected on to a small mercurial thermometer bulb; and then this second image was compared with a Bengal light so moved that the lights appeared to be equal. The same process was adopted with the full moon instead of with the sun. The result was that the sun's light was 470,980 times that of the moon. Seidel long before this date had compared the light of the mean full moon with that of Jupiter in mean opposition; his result is 4630. So also this light of Jupiter was found to be 4864 times that of Venus at her brightest; and Jupiter was found to give 8-2 times the light of a Lyrae. If, then, these numbers could be accepted with confidence, we should have the means of comparing the light received from the sun with that received from any of the stars. Adopting these precarious numbers on the authorities of Bond and Seidel we have the following results:

- Sun's light = 470,980 that of the full moon.
- " " = 622,000,000, Venus at her brightest.
- " " = 302,815,000, Jupiter at mean opposition.
- " " = 5,970,500,000, Sirius.

Lastly, Bouguer, by comparing the light of the full moon viewed at different altitudes with an artificial light, found that the atmosphere absorbs 1877 of the light incident on it at the zenith of any place. Professor Pritchard, from photometric measures taken at Cairo, found this number to be 157. At Oxford it was 209. Thus Bouguer's determination indicates an absorptive capacity in the atmosphere of Brittany just midway between those of Oxford and Cairo. Seidel at Munich expresses "surprise" at finding his own results so nearly accordant with Bouguer's. Although rather outside the domain of photometry in the strict sense, a word or two may be said here about recent attempts to measure the heat received from the stars, the first being made with the "radio-micrometer" of C. V. Boys. (Proc. Roy. Soc. 1890). This is an extremely delicate instrument for measuring radiant heat, and consists of a very light thermo-electric circuit (two tiny bars of antimony and bismuth soldered together at one edge, the outer edges being connected by a hoop of copper wire) suspended by a quartz fibre (a torsion fibre of the very greatest sensitiveness) in a strong magnetic field. A minute quantity of radiant heat falling on one of the junctions of the circuit sets up a current in the circuit, which thus rotates in the magnetic field until brought to rest by the torsion of the fibre. For use on the heavenly bodies the radiant heat is collected to focus by a reflecting telescope (an object-glass would absorb it), and when the telescope is pointed to the moon the varying radiation from different parts of the disk is beautifully shown. No heat comes from the unlit portion, and of the illuminated portion the maximum is obtained from near the limb. But when pointed to the brightest stars no indications were obtained, although the instrument is sensitive enough to detect the heat from a candle more than a mile off. It seems certain that indications of heat from the stars obtained by previous observers must be spurious. It is also manifest that to obtain satisfactory results even more sensitive apparatus must be devised, and by using a radiaimeter and the powerful resources of the York Observatory E. F. Nichols succeeded in 1868 and 1869 in obtaining indications of heat from Arcturus and Vega, as well as from Jupiter and Saturn (Astrophysical Journ. xiii. 101), the heat received being comparable with that from a candle 6 m. away. We may place alongside this result that obtained by W. J. Dibdin (Proc. Roy. Soc. April 1892), who compared candlelight with twenty-one stars ranging to the sixth magnitude, and found the light of a second magnitude star equal to that of a candle at 1260 ft. (H. H. T.)

PHRAATES (Phraiates; Pers. Franky, modern Forhât), the name of five Parthian kings.

1. PHRAATES I., son of Priapatius, reigned c. 175-170 B.C. He subdued the Mardi, a mountaneous tribe in the Elburz (just north of the Caspian). He died young, and was the successor not only of his sons, but his brother Mithradates I. (Justin xii. 5).

2. PHRAATES II., son of Mithradates I., the conqueror of Babylonia, reigned 138-127. He was attacked in 130 by Antiochus VII. Sidetes, who, however, in 129 was defeated and killed in a great battle in Media, which ended the Seleucid east of the Euphrates (see SELUCID DYNASTY). Meanwhile the kingdom was invaded by the Scythians (the Tochari of Bactria), who had helped Antiochus. Phraates marched against them, but was defeated and killed (Justin xiii. 11; Johannes Antioch. fr. 60).

3. PHRAATES III., "the God" (Phlegon, fr. 12 ap. Photius cod. 97 and on some of his coins), succeeded his father, Sanatrauces, in 70 B.C., at the time when Lucilius was preparing to attack Tigranes of Armenia, who was supreme in western Asia and had wrested Mesopotamia and several vassal states from the Parthian kingdom. Naturally, Phraates declined to assist Mithradates of Pontus and Tigranes against the Romans (see Tigranes). He supported his son-in-law, the younger Tigranes, when he rebelled against his father, and invaded Armenia (65 B.C.) in alliance with Pompey, who abandoned Mesopotamia to the Parthians (Dio. Cass. xxvii. 45, 51; Appian, Mithr. 104; Liv. Epit. 100). But Pompey soon overrode the treaty; he acknowledged the elder Tigranes, took his son prisoner, occupied the vassal states Gordyene and Osroene for the Romans, and denied the title of "king of kings," which Phraates had adopted again, to the Parthian king (Plut. Pompe. 33, 38; Dio. Cass. xxvii. 5 seq.). About 57 Phraates was murdered by his two sons, Orodès I. and Mithradates III.

4. PHRAATES IV., son of Orodès I., by whom he was appointed successor in 37 B.C., after the death of Pacorus. He soon murdered his father and all his thirty brothers (Justin xiii. 5; Plut. Cross. 33; Dio Cass. xli. 23). He was attacked in 36 by Antonius (Mark Antony), who marched through Armenia into Media Atropatene, and was defeated and lost the greater part of his army. Believing himself betrayed by Artavasdes, king of Armenia, he invaded his kingdom in 34, took him prisoner, and concluded a treaty with another Artavasdes, king of Atropatene. But when the war with Octavianus Augustus broke out, he could not maintain his conquests; Phraates recovered Atropatene and drove Artaxues, the son of Artavasdes, back into Armenia (Dio. Cass. xlix. 24 sqq., 39 sqq., 44 sqq.; cf. li. 16; Plut. Antonius, 37 sqq.). But by his many cruelties Phraates had roused the indignation of his subjects, who raised Tiridates II. to the throne in 32. Phraates was restored by the Scythians, and Tiridates fled into Syria. The Romans hoped that Augustus would avenge the defeat of Crassus on the Parthians, but he contented himself with a treaty, by which Phraates gave back the prisoners and the conquered eagles (20 B.C., Mon. Anc. 5, 40 sqq.; Justin xiii. 5); the kingdom of Armenia also was recognized as a Roman dependency. Soon afterwards Phraates, whose greatest enemies were his own family, sent five of his sons as hostages to Augustus, thus acknowledging his dependence on Rome. This plan he adopted on the advice of an Italian concubine whom he made his legitimate wife under the name of "the goddess Musa"; her son Phraates, commonly called Phraatases (a diminutive form), he appointed successor. About 4 B.C. he was murdered by Musa and her son (Joseph. Ant. xviii. 3, 4).

5. PHRAATES V., or PHRAATASES, the younger son of Phraates IV. and the "goddess Musa," with whom he is associated on his coins. Under him a war threatened to break out with Rome about the supremacy in Armenia and Media. But when Augustus sent his adopted son Gaius Caesar into the east in order to invade Parthia, the Parthians preferred to conclude a
PHRANTZA—PHRENOLOGY

treaty (A.D. 1), by which once again Armenia was recognized as in the Roman sphere (Dio. Cass. iv. 19; Velleius ii. 101). Soon after Phraataces and his mother were slain by the Parthians, about A.D. 5 (Joseph. Ant. xvii. 2, 4). (Ed. M.)

PHRANTZA, GEORGE [GEORGIOSS PHRANTZES] (1421-c. 1477), the last Byzantine historian, was born in Constantinople. At an early age he became secretary to Manuel II. Palaeologus (1425-1448), prefect of Sparta, and subsequently great logothete (chancellor). At the capture of Constantinople by the Turks (1453) he fell into their hands, but managed to escape to Peloponnesus, where he obtained protection at the court of Thomas Palaeologus, despot of Achaea. After the downfall of the Peloponnesian princes (1460) Phrantza retired to the monastery of Tarchaniotes in Corfu. Here he wrote his Chronicle, containing the history of the house of the Palaeologi from 1258-1476. It is a most valuable authority for the events of his own times.

Editions by I. Bekker (1838) in the Corpus scriptorum hist. Byz., and in J. P. Migne, Patrologia Graeca, civit; see also C. Krumbacher, Geschichte der byzantinischen Literatur (1897).

PHRAORITES, the Greek form of Fravarishk, king of Media. According to Herodotus (i. 102) he was the son of Deoetes, and began the Median conquests. He first subdued the Persians, and then a great many other peoples of Asia, till at last he attacked the Assyrians, but was defeated and killed in a battle, after a reign of twenty-two years (about 646-625 B.C.; but perhaps, as G. Rawlinson supposes, the fifty-three years of Deoetes ought in reality to be transferred to him). From other sources we obtain no information whatever about Phraorites, but the data of the Assyrian inscriptions prove that Assur-bani-pal (see Babylonia and Assyria), at least during the greater part of his reign, maintained the Assyrian supremacy in Western Asia, and that in 645 he conquered Susa. The Medes too were subject to him as far as the Elburz and the central Iranian desert.

When after the assassination of Smerdis all the Iranian tribes, the Babylonians and the Armenians rebelled against Darius and the Persian rule, "a man of the name of Fravartish (i.e. Phraorites), a Mede, rebelled in Media and spoke to the people thus: I am Khshathrita, of the family of Uvakhshata (Cyzaxares)." He reigned for a short time, but was defeated by Hygrodes, and afterwards by Darius himself, taken prisoner in Rhagae (Rai), and executed in Ebcbatana (339 B.C.; see inscription of Darius at Behistun). (Ed. M.)

PHRENOLOGY, from Gr. ψυχις, mind, and χατρος, discourse, the name given by Thomas Ignatius Forster to the empirical system of psychology formulated by F. J. Gall, and developed by his followers, especially by J. K. Spurzheim and G. Combe, by whom it was named "craniology," "craniology," "physiognomy" or "zoonomy," The principles upon which it is based are five: (1) the brain is the organ of the mind; (2) the mental powers of man can be analysed into a definite number of independent faculties; (3) these faculties are innate, and each has its seat in a definite region of the surface of the brain; (4) the size of each such region is the measure of the degree to which the faculty seated in it forms a constituent element in the character of the individual; (5) the correspondence between the outer surface of the skull and the contour of the brain-surface beneath is sufficiently close to enable the observer to recognize the relative sizes of these several organs by the examination of the outer surface of the head. It professes primarily to be a system of psychology, but its second and more popular claim is that it affords a method whereby the disposition and character of the subject may be ascertained.

In his view, as in that of most of the earlier writers of other nations of antiquity, the heart is the seat of life; to it, not to the brain, the Hebrew writers refer thoughts and affections, while they considered judgment as seated sometimes in the head, sometimes in the kidneys. This was likewise the teaching of the Egyptian philosophers; and hence, while many rites were practised and prayers offered for the preservation of the heart of the deceased, there were none for the conservation of the brain. We learn from Diogenes Laertius that Pythagoras held more accurate physiological views, as he taught that the mind and the intellect have their seat in the brain. The theory of Hippocrates was Pythagorean rather than Aristotelian, for, although in one passage in his work De conde he expresses himself doubtfully, yet elsewhere he clearly states that he considers the brain to be the index and messenger of the intellect. The cerebral seat of sense-perception is also taught by Plato, who puts into the mouth of Socrates the theory that the brain is the organ affected by the senses, whereby memory and opinion arise, and from whence knowledge springs. The classic poets also notice this dependence of mind on brain; for example, in the Clouds (v. 1726) Strepilades accuses Amyneas of not being in his right mind, and, on being asked why, responds, "You seem to me as if you had had a concussion of the brain."

The two founders of anatomical science, Erasistratus and Herophilus, who lived in the days of Ptolemy Soter, taught not only that the brain was the seat of sensation and of intellect, but also that there was therein a certain degree of localization of function. Erasistratus believed that the sensory nerves arose from certain brain-membranes. Herophilus maintained that the vital forces resided in and circulated from the ventricles of the brain, at least so we gather from Celsius and the other authors who have preserved his views. By the influence of the writings of Galen, which directly teach that the brain is the seat of soul and intellect the Pythagorean doctrine prevailed among the later philosophers. According to the Galenic theory the animal spirits have their origin in the ventricles of the brain, and pass into the heart from which they are conveyed by the arteries through the body. Galen in one place (viii. 139) refers their origin to the brain-substance, but the ventricular theory was that adopted by his followers, some of whom supposed that there was some relation between the shape of the head and the character and disposition of the mind. The Arabian physicians Averroes and Rhazes adopted the Galenic doctrine and developed the hypothesis of a fourfold ventricular localization of faculties, which the Greeks had originated. Avicenna added to these a fifth region. Such of the early Christian authors as referred in

1 In the Chaldean portion of Daniel (ii. 28, 4v. 5, vii. 1 visions and thoughts are referred to the head. For other particulars as to early views see Nasse on the psychical relations of the heart in Zeitschr. J. psychische Archite (1818), vol. i. A few of the later medical writers express similar views; see Santa Cruz, Opusculum medica (Madrid, 1624).

their writings to the relation of soul to body naturally adopted the teaching of Galen which they accommodated to their theology, thereby conferring on it an importance which rendered correction difficult. Tertullian in a sense expresses his belief in a theory of localization as also at a later period does Thomas Aquinas.

Early in the 13th century Albertus Magnus gave a detailed description of the distribution of mental and psychical faculties in the head. The anterior region he assigned to judgment, the middle to imagination, and the posterior to memory. A somewhat similar allocation was made by Gregory, doctor of medicine in Montpellier (1290), who assigned common sensation and the reception of impressions to the anterior cornua of the lateral ventricles, _phantasia_ to the posterior, this power being two-fold (_imaginativa_ and _cogitativa_), judgment or _aestimativa_ to the third ventricle, and memory to the fourth. Figures of a similar division were given by Petrus Montagnana and Lodo- vico Dolez still later by Ghirardello and by Theodoric Gall of Antwerp. That the "vital spirits" resided in the ventricles was doubted by many, and denied by a few of the anatomists of the 17th century. G. Bahn in 1621 attacked the old view, and Hoffmann of Altorf showed that, as the ventricles were closed cavities, they could not transmit any material fluid. That these spirits existed at all was doubted by Alexander Benedictus, Plantner, and a few others; but they were believed in by the great majority of 17th and even of 18th century medical writers, many of whom conceived that the ventricles were _semper pleni spiritibus animalibus fummulis simulibus, quorum beneficia intelligimus, sentimus, et moveremus_, and the cerebral was to the ventricles as the _callosum_ region to the _ventriculi_.

Columbus ridiculed the idea that the convoluted surface of the brain might have anything to do with intellect, as the ass, a proverbially stupid animal, has a convoluted cerebrum. According to his view, the convolutions are for the purpose of lightening the brain and facilitating its movements. The grey matter of the surface of the cerebral was recognized as the true dynamic element by M. Malephl and T. Willis.

The latter regarded the convoluted surface of the cerebral as the seat of the memory and the will, the convolutions being intended to retain the animal spirits for the various acts of imagination and memory. Imagination he described as seated in the corpus callosum, sense-perception in the corpus striatum, and _impetus et perturbatio_ in the basal parts of the cerebral above the _corpus callosum_. The thalamus was regarded as the centres of sight and the cerebellum of voluntary acts. Succeeding anatomists simply varied these localizations according to their respective fancies. G. M. Lancisi placed sense-perception in the corpus callosum, R. Viesseurs in the centrum ovale majus. R. Descartes supposed the soul to be seated in the pineal gland, others in the brain-commissures especially the pons Varolii. Meyer considered abstract ideas to arise in the cerebellum, and memory to have its seat at the roots of the nerves.

Of later writers three deserve special notice, as having largely prepared the way for the more modern school of phrenology. J. A. Unzer, of Halle, in his work on physiology extended the pre-existing theories of localization. Metzier, twenty years before the publication of Prochaska's work, had proposed to make a series of observations on the anatomical characters of the brains of persons of marked intellectual peculiarity; but apparently he did not carry this into effect. In a more special manner Prochaska of Vienna may be looked upon as the father of phrenology, as in his work on the nervous system, published in Vienna in 1784, are to be found the germs of the later views which were propounded in that city twelve years later.

The system formulated by Gall (q.v.) is thus a modern expansion of an old empirical philosophy, and its immediate parentage is apparent, although, according to Gall's account, it was with him the result of independent observations. These, he tells us, he began to make at an early age, by learning to correlate the outward appearances and mental qualities of his school-fellows. Gall's first published paper was a letter in the _Deutscher Merkur_ of December 1798, but his principal expositions were oral, and attracted much popular attention, which increased when, in 1802, he was commanded by the Austrian government, at the instance of the ecclesiastical authorities, to discontinue his public lectures. In 1804 he obtained the co-operation of Spurzheim (1776-1832), a native of Longwich, near Treves, who became his pupil in 1800, and proved a powerful ally in propagating the system. The system and pupil at first taught in harmony, but they found it advisable to separate in 1813; and we find Spurzheim, several years after their parting, declaring that Gall had not introduced any improvements into his system since their separation (notes to Chevèneix, p. 99). "My philosophical views," he also says, "widely differ from those of Gall." In Paris, where he settled in 1807, Gall made many influential converts to his system. F. J. V. Broussais, H. M. D. de Blainville, H. Cloquet, G. Andral, E. Geoffroy St-Hilaire, Vimont and others adopted it and countenanced its progress. Gall visited Great Britain, but the diffusion of phrenology here was chiefly due to Spurzheim, who lectured throughout the country and through America, and with the aid of his pupil, George Combe, attracted a large popular following. His most influential disciples were J. Elliotson, Andrew Combe, Sir G. S. Mackenzie, R. Macnish, T. Laycock and Archbishop R. Whately, and in America Caldwell and J. Godman. On the opposite side many influential men took up a strongly antagonistic position, prominent among whom were J. Barclay the anatomist, P. M. Roget, Sir Charles Bell, Sir W. Hamilton, F. Jeffrey, H. P. Brougham, T. Brown and Sir B. Brodie. The nature of the system rendered it eminently fitted to catch public attention, and it rapidly attained to so great a

2 Summa theologicae, ed. Migne, i. 1094, 1106-7. Prochaska and his translator, Laycock (Mind and Brain, ii. 163), charge Duns Scotus with holding this view; probably he did, but he does not express it, as he simply specifies the cerebrum and its root, the spinal cord, as the source of the nerves along which sensory impulses travel. Comment. de anima, i. 515 (Leiden, 1637).
3 Opera, iii. 124, vi. 201 (Amsterdam, 1621).
4 Lütium medicinae, 101 (Venice, 1494).
5 Avicenna's fifth region is interposed between _imaginativa_ and _aestimativa_ (De naturalit. vi. 2). Thomas Aquinas combines the brain, which he tells us were convoluted, with the spinal cord; on the other hand, he says of ratio particularis, "medici assignant determinatum organum, scilicet medium partem capitis" (i. 1106).

18 Some of the medieval views were very fanciful, thus Shabbethai b. Abraham, the earliest Jewish writer on medicine (d. A.D. 959), thought that the spirit of life has its seat in the brain, and that through the sinuses of the skull, the Shekinah in the heavens arched over the earth and waters. See Der Mensch als Gottes Ehenkind, ed. Jellinek (Leipzig, 1854), and Castelli, Commento (Florence, 1850).
19 Vermischte medicinsche Schriften (1764), i. 58.
degree of popularity that in 1832 there were twenty-nine phrenological societies in Great Britain, and several journals devoted to phrenology in Britain and America; of these the Phrenological Journal, a quarterly, edited chiefly by George Combe with aid from others of the Edinburgh confraternity, notably Sir George Mackenzie and Macnich, "the modern Pythagorean," lived from 1823 to 1847, through twenty volumes. The controversy in many places was heated and often personal, and this largely increased the popular interest. In the Edinburgh Review the theory was severely criticized by Thomas Brown, and afterwards in a still more trenchant manner by Jeffrey. In Blackwood it, was ridiculed by Professor John Wilson. Being a subject which lent itself easily to burlesque, it was parodied cleverly in a long rhyme by two authors, "The Craniad," 87 pages long, published in 1817, while, on the other hand, verse was pressed into its service in the rhyme "Phrenology in Edinburgh" in 1824. The best defence of the system was that by Chenevix in the third number of the Foreign Quarterly, afterwards reprinted with notes by Spurzheim.

The Faculties and their Localities.—The system of Gall was constructed by a method of pure empiricism, and his so-called organs were for the most part identified on slender grounds. Having selected the place of a faculty, he examined the heads of his friends and casts of persons with that peculiarity in common, and in them he sought for the distinctive feature of their characteristic trait. Some of his earlier studies were made among low associates, in gaols and in lunatic asylums, and some of the qualities located by him were such as tend to become perverted to crime. These he named after their excessive manifestations, mapping out organs of murder, theft, &c.; but as this cast some discredit on the system the names were changed by Spurzheim, who claimed as his the moral and religious considerations associated with it. Gall marked out on his model of the head the places of twenty-six organs as round enclosures with vacant interspaces. Spurzheim and Combe divided the whole scalp into oblong and conterminous patches (see the accompanying figures). Other methods of division and other names have been suggested by succeeding authors, especially by Cox, Sidney Smith (not Sydney), Toulmin Smith, K. G. Carus of Dresden, Don Mariano Cubí i Solar, W. B. Powell of Kentucky, J. R. Buchanan of Cincinnati, Hittel of New York. Some, like the brothers Fowler, raise the number of organs to forty-three; but the system of Spurzheim and Combe is that which has always been most popular in Britain. Spurzheim separated the component faculties of the human mind into two great groups and subdivided these as follows:—

I. Feelings, divided into—
1. Propensities, internal impulses inviting only to certain actions.
2. Sentiments, impulses which prompt to emotion as well as to action.
A. Lower—those common to man and the lower animals.
B. Higher—those proper to man.
II. Intellectual faculties.
1. Perceptive faculties.
2. Reflective faculties.

In the following list the locality and the circumstances of the first recognition of the organ are appended to the names, which are mostly the inventions of Spurzheim. Gall's names are placed in brackets.¹

Propensities.
1. Amativeness (Instinct de la génération), median, below the inion; first determined by Gall from its heat in an hysterical widow, supposed to be confirmed by many observations, and referred to the cerebellum.²

² Other burlesque and satirical writings were published at this time, notably The Phrenologists, a farce by Wade (1830); The Head-phoners, or Phrenology opposed to Divine Revelation, by James the Less; and A Helmet for the Headpiece, or Phrenology incompatible with Reason, by Daniel the Seer.

³ For topographical purposes Broca's names are adopted as the most convenient for localities on the head.

¹ Apollonius Rhodius speaking of the love of Medea for Jason (Argonautica, iii. 760-765) says, διαρηγία τ' ἀγάπης ἀδελφῶν βίου· ἐν τούτῳ δ' ἀκριβῶς ὁμοίως γνώμη ἐκείνῳ διὰ χρόνον, ὡμοφώνει τόσον καὶ κεφάλης, ὡς ἐκείνων ἵππος ἤρας. . . .

² Philoprogenitiveness (Amour de la proéminure), median, on the squama occipitalis, and selected as the organ for the love of children because this part of the skull is usually more prominent in apes and in women, in whom the love of children is supposed to be stronger than in men.

³ Concentrativeness, below the obelion and over the lambda. This is a region of uncertain function, unnoticed by Gall, but described as Inhabitiveness by Spurzheim, because he found it large in cats and in a clergyman fond of his home. It has since been considered by Combe to be the seat of the power of concentration, whereof he believed Inhabitiveness to be a special case.

4. Adhesiveness (Amidité), over the lateral area of the lambdoidal suture. This region was prominent in a lady introduced to Gall as a model of friendship, and is said by him to be the region where persons who are closely attached put their heads together.

5. Combativeness (Instinct de la défense), above the asterion; it was found by Gall by examining the heads of the most quarrelsome of his low companions whom he had beforehand stimulated by alcohol. It was verified by comparing this region with the same part of the head of a quarrelsome young lady.

6. Destructiveness (Instinct carnassier), above the ear mentus. This is the widest part of the skulls of carnivorous animals, and was found large in the head of a student so fond of torturing animals that he became a surgeon, also large in the head of an apothecary who became an executioner.

7. Allimentiveness, over the temporal muscle and above the ear. Hoppé describes it as being large in a gourmand acquaintance, and he therefore supposes it to be the origin of selecting food.

8. Secretiveness (Ruse, Finesse), the posterior part of the squamous suture.

9. Acquisitiveness (Sentiment de la propriété), on the upper edge of the front half of the squamous suture. This part of the head Gall noticed to be prominent in the pickpockets of his acquaintance.

10. Love of Approval (Vénére), outside the obelion; the region in which Gall saw a preference on the head of a lunatic who fancied herself queen of France.

11. Cautionness (Circumspection), on the parietal eminence; placed here because an ecclesiastical hesitating disposition and a vacillating councillor of state had both large parietal eminences.
PHRENOLOGY

3. Comparison (Canale, 2010) of the frontal, upper temporal region of the forehead, where a Newton friend of Cail's, of the 1st, and 2nd, or 3rd, two prominent eyes. Old authors had noted the contrast between prominent convexity of forehead and prominent convexity of the whole forehead, a point of view which is explained by the fact that the forehead is not a large table, but a part of the skull. In front of the forehead, there are a large and prominent region, where the prominent eye of Cail's, of the 1st, or 2nd, and 3rd, two prominent eyes.

4. The frontal area is divided into two parts: the forehead and the temporal region. The forehead is divided into two parts: the frontal and the parietal region. The parietal region is divided into two parts: the parietal and the occipital region. The occipital region is divided into two parts: the occipital and the temporal region. The temporal region is divided into two parts: the temporal and the parietal region.

5. The forehead is divided into two parts: the frontal and the parietal region. The parietal region is divided into two parts: the parietal and the occipital region. The occipital region is divided into two parts: the occipital and the temporal region. The temporal region is divided into two parts: the temporal and the parietal region.

6. The forehead is divided into two parts: the frontal and the parietal region. The parietal region is divided into two parts: the parietal and the occipital region. The occipital region is divided into two parts: the occipital and the temporal region. The temporal region is divided into two parts: the temporal and the parietal region.

7. The forehead is divided into two parts: the frontal and the parietal region. The parietal region is divided into two parts: the parietal and the occipital region. The occipital region is divided into two parts: the occipital and the temporal region. The temporal region is divided into two parts: the temporal and the parietal region.

8. The forehead is divided into two parts: the frontal and the parietal region. The parietal region is divided into two parts: the parietal and the occipital region. The occipital region is divided into two parts: the occipital and the temporal region. The temporal region is divided into two parts: the temporal and the parietal region.

9. The forehead is divided into two parts: the frontal and the parietal region. The parietal region is divided into two parts: the parietal and the occipital region. The occipital region is divided into two parts: the occipital and the temporal region. The temporal region is divided into two parts: the temporal and the parietal region.
identical convolutions in different brains consist of nerve-cells with precisely the same connections. The general arrangement results from the fact of the brain surface under constant, hence as the different tracts of surface undergo proportional overgrowth they may fold along different lines. The occurrence of small differences in the rate of growth, which is conditioned by the density of the tissue pattern, can hardly fail to cause considerable alteration in the place of definite territories of grey cells. Some method for the determination of the limits of these shifting of place is required before comparisons are possible.

4. The comparison of the rate of growth of brain with the development of mental faculties is important not only to the phrenologist but to the psychologist. No observations have yet been made by the phrenologist who can refer to the first and rather crude observations of the earlier anatomists. We have, however, recently learned from the researches of T. L. W. von Bischoff, Tucecz, Cunningham, and S. Exner that the size of the frontal lobes increase more rapidly by the occipital and parietal lobes increasing more than the frontal or temporo-sphenoidal. During these and the four succeeding years the brain of the fetus is about 1.5 times the adult brain, the rate of growth in the frontal lobes is much less than in the latter part of the period. At birth the brain weights one-tenth of the weight of the body, and averages about 1.1 oz. For the first year brain-growth and consequently expansion of the skull is, with great rapidity, the growth during a large part of this period averaging one cubic centimetre daily. This enormous increase is chiefly due to the rapid development of medullated nerve-fibres, which are deficient in the foetal brain. During the second and third years growth takes place more slowly, the occipital and parietal lobes increasing more than the frontal or temporo-sphenoidal. Other local variations in structure have been described by Elliot Smith and other histologists.

5. The teaching of anatomy with regard to phrenology may be summarized thus: (1) the rate of growth of brain is concurrent with the rate of development of mental faculty; (2) there is some degree of structural differentiation as there are varying rates of development of different parts of the cerebral surface; (3) there is no accordance between the regions of Gall and Spurzheim and definite areas of cerebral surface.

**Physiological Aspect.**—The theory of some of the older meta-
physicians, that the mind, in feeling and reflection, makes use of no material instrument is not now accepted by psychologists. It was advanced by Brougham and Jeffrey as against the theory of phrenology; but the doctrine that the brain is the organ of the mind is now universally received. While it is probable that certain molecular changes in the grey matter are antecedents or concomitants of mental phenomena, the precise nature of these processes, to what extent they take place, or how they vary among themselves, have as yet been determined experi-
mentally. It is only, that the occurrence of the change can only be demonstrated by some such course method as the altered pulsation of the carotid arteries, the increase of the temperature of the head, the abstraction, during brain-action, of blood from other organs as shown by the plethysmograph, or the formation of lecithin and other products of metabolism in brain-substance. As yet no light has been shed on the connexion between the molecular changes in the nerve-cell and the phenomena of thought and feeling.

While our knowledge of the anatomy of the brain, especially of the grey nuclei and of the white hands uniting them, has in recent years become much more accurate (see articles BRAIN AND MUSCLE AND NERVE), our knowledge of the physiology and of the functional centres is still more fragmentary, even when the utmost allowance is made for the data in the hand of C. S. Sherrington, A.S.F. Grünhäf, F. Gottz and others; and the hypotheses relating to the division of labour in the nerve-centres is chiefly based on anatomical structure. Certain masses of grey nerve-matter situated in the spinal cord and medulla oblongata are so linked by nerve-cords to organs outside the nervous system which are set apart for the discharge of separate functions that they obviously form parts of the mechanism for the fulfilment of such functions. In cases where these can be subjected to experiment we learn that they are nervous centres presiding over the discharge of such functions; and it has been determined by experiment, or else deduced from physiological and anatomical considerations, that in most cases these centres are more directly connected with the segmental elements of the body than a certain localization of function; hence the centres of pelvic actions, of respiration, cardiac action, and inhibition of vasomotor influence, deglutition, secretions, &c., can be mapped out in ascending series. As certain of these centres are united by bands of fibres to the larger fatten and eat them, an abuse of the organ of phlogenitiveness; see also GarciIaco de la Vega, Hist. des Insects, i. 12. Mem. de l'acad. de médecine (1840), viii. 149.

12. Martius tells us that the Caribs castrate their own children, and the artificial topography of the Caribs has bulged the squama occipitis, they decided that these huge bulges mere lovers of women, &c.
and higher-lying grey portions of the nervous centres there is an *a priori* presumption in favour of the extension of this principle of localization. This has been premised on metaphysical as well as on anatomical grounds. A. B. Bonnet long ago believed each portion of the brain to have a specifically separate function, and Herbert Spencer has said that the physiologicalist is led to the conviction that different parts of the cerebrum subserve different kinds of mental action. Localization of function is the law of all organization; separateness of duty is universally accompanied with separateness of structure, and it would be marvellous were an exception to exist in the cerebral hemispheres. Let it be granted that the cerebral hemispheres are the seats of the higher psychological activities; let it be granted that among these higher psychological activities there are distinctions of kind which, though not definite, are yet practically recognizable, and it cannot be denied, without going in direct opposition to established physiological principles, that these more or less distinct kinds of psychological activity must be carried on in more or less distinct parts of the cerebral hemisphere.

For a masterly review of the old and the new association and localization theories, see W. Wundt’s *Grundzüge der physiologischen Psychologie*, l. 289 sqq.; also the same author’s *Essays*, Leipzig (1888), pp. 109 sqq.

There is a large weight of evidence in favour of the existence of some form of localization of function. So little is known of the physical changes which underlie psychological phenomena, or of the succession of the psychological processes themselves, that we cannot as yet judge as to the nature of the mechanism of these centres. So much of the psychic work of the individual life consists in the interpretation of sensations and the translation of these into motions that there are strong *a priori* grounds for expecting to find that much of the material of the nervous centres is occupied with this kind of work, but in the present conflict of experimental evidence it is safer to suspend judgment. That these local areas are not centres in the sense of being indispensable parts of their respective motor apparatuses is clear, as the function abolished by ablation of a part returns, though tardily, so that whatever superintendence the removed region exercised apparently becomes assumed by another part of the brain. Experimental physiology and pathology, by suggesting other functions for parts of the brain-surface, are thus directly subservient of many details of the phrenology of Gall and Spurzheim.

**Psychological Aspect.**—The fundamental hypothesis which underlies phrenology as a system of mental science is that mental phenomena are resolvable into the manifestations of a group of separate faculties. A faculty is defined as “a convenient expression for the particular states into which the mind enters when influenced by particular organs; it is applied to the feelings as well as to the intellect, thus the faculty of benevolence means every mode of benevolence induced by the organ of benevolence.” (Combe). In another work the same author says it is “used to denote a particular power of feeling, thinking, perceiving, connected with a particular part of the brain.” The assumption is contained in the definition that the exercise of a faculty is the physical outcome of the activity of the organ, and in several of the standard works this is illustrated by misleading analogies between these and other organs; thus the organs of benevolence and of firmness are said to be as distinct as the liver and pancreas. The mind, according to another author, consists of the sum of all the faculties. In this view the unity of consciousness is somewhat difficult to explain, and consequently there is assumed by others a single unifying substratum, and on this the organs are supposed to act; thus thoughts are defined as “relations of the simple substance, mind, to certain portions of the encephalon.” (Welsh, *Phren. Journ.* 1. 206.) Gall himself believed that there was but a single primary physiological saw, felt, tasted, heard, or the brain to have the thought and killed (*Fonctions du cerveau*, i. 243); and the American exponent of phrenology, Caldwell, says “the mind is as single in its power as it is in its substance; it is a quickening and operating principle, essential to all the mental faculties, but does not, by any means, possess them itself” (Element, p. 16). It is not easy to understand the supposed relation of this hypothetical substratum to the separate faculties acting on it. It must be both immaterial and unconnected with the brain, as it is said to have the power to alter the state of the organs supposed to exist in the cerebral hemispheres are all parcell out among the faculties, and none are left for the unifying *nous*.

Each organ is considered as engaged, either independently in bringing forth its own product, or collectively with others in elaborating compound mental states, and according to their several degrees of development and activity they are considered capable of perceiving, conceiving, recollecting, judging or imagining each its own subject. This mechanical conception of the division of labour in the production of the phenomena of mind has the charm of simplicity, but is attended with the difficulty that arises in discriminating the operations of the different organs one from the other. Phrenologists are apt to be vague respecting the limits of the several faculties, as about the boundaries of the separate organs. It was pointed out by Jeffrey that the lines of demarcation between benevolence, adhesiveness and philoprogenitiveness were indeterminate, although the organs are not very close, and the same applies to other organs.

It is unfortunate for the clearness of the definition that, although historically the faculties were the first phenomena noted, independent of and previous to their localization, yet in the definition the faculties are defined in terms of their localities.

The following arguments are adduced in favour of the fundamental separateness of the faculties: (1) analogy—elsewhere in the animal economy division of labour is the rule; (2) the variety of mental endowment observed among children before they are influenced by education, and the inequalities in the mental endowments of individuals; (3) the phenomena of insanity, especially of monomania; (4) the varying periods at which individual faculties attain their maximum development; (5) the phenomena of dreams, and the awakening of a limited number of faculties during them; (6) pain being felt in an organ when it is overtaxed.

Such faculties are supposed to be primary—(1) as exist in some men and not in others, (2) as vary in their development in the sexes, (3) as are developed in varying proportions with regard to other faculties, (4) as may act separately from other faculties, (5) as are not necessarily simultaneous with other faculties in action, (6) as are hereditary, and (7) as may be singly diseased.

According to the development of their powers mankind may be divided into six classes: (1) those in whom the highest qualities are largely developed and the animal qualities feeble; (2) those with the reversed conditions developed, with large animal and feeble intellectual and moral faculties; (3) those in whom good and evil are in constant war, with active animal and strong intellectual faculties and sentiments; (4) those partial geniuses in whom a few qualities are unusually developed, while the rest are at or below the mediocré standard; (5) those men of moderate endowment in whom some faculties are nearly or quite deficient; (6) those with an unvarying standard of undistinguished mediocrity in all their faculties.

It is perhaps unfortunate that the word “faculty” has been used in this sense of original power by phrenologists. It would have been better to employ, as Mr Lewes suggests, the term

1 It is interesting in this connexion to note that in a case published by Professor Hamilton in *Brain* (April 1884), where a tumour existed in the temporal lobe, the pain was persistently referred to the forehead. Many similar cases are to be noticed among the records of localized brain-lesions. Bearing on this point also it is worth noting, once for all, that in nothing is the purely hypothetical nature of phrenological description better realized than in the accounts of what these authors call the “natural language of the faculties.”—that poets are supposed to touch ideal city when composing, musicians to press on tone and time, and painters on form and colour, when in the exercise of their arts! Yet we are gravely taught this in the standard works on the subject.
PHRENOLOGY

"function" for the native activity of an organ, and to leave "faculty" for the expression of an acquired activity. "Faculty is properly limited to active power, and therefore is abusively applied to the mere passive affections of the mind" (Hamilton, Lectures, I. 177).

An attempt has been recently made by Dr Bernard Holländer to correlate the doctrines of phrenology with the modern physiological and pathological observations which bear upon the localization of the brain. In his work, The Mental Functions of the Brain, under the sub-title "The Revival of Phrenology" (1901), and in Scientific Phrenology (1902), the author endeavours to bring Gall's clinical and pathological instances into line with more modern observations. He deprecates the craniology of Gall, as far as it deals with mere "bumps," and honours him, with justice, as the recorder of many facts worth saving out of the wreck of his system; and he endeavours, though with doubtful success, to establish an unbroken connexion between phrenology, in the Greek sense, and our present knowledge of cerebral localization.

The substance of Holländer's first work is of two kinds. The one kind is a tabulated statement of many hundred cases of different forms of mania, with injury or disease limited to one portion of the brain; the other kind is a tabulated statement of cases of mania, or disease, due to injury or disease or loss of some definite instinct or faculty of consciousness.

He divides the tabulated cases of mania into three groups: (i) Mania melancholia; (ii) Mania furiosa; (iii) Mania suprakanatische." The division is based on the following four points: (i) Mania melancholia is especially associated with injury or disease of the parietal lobe of the brain, more particularly or exclusively with the convolutions of the supramarginal type; (ii) Mania furiosa is especially associated with injury or disease of the central portion of the temporal lobe; (iii) Mania suprakanatische is especially associated with injury or disease of the posterior portion of the temporal lobe.

The second kind of cases, where injury or disease of the brain, sufficient to be localized to one part or another of its grey matter, was followed by perversion, exaltation or loss of some one instinct, habit or faculty, includes cases of kleptomania, cases of voracious hunger and thirst, cases of sexual deformities, and cases of certain special memories, as of words, tunes, numbers and the like. These two collections of recorded cases, taken from a vast mass of clinical and pathological literature accumulated during the past century, have been arranged by Dr Holländer with great industry; so as to extend the limits of the study of cerebral localization, and to advance it from the observation of the motor areas and the special senses to the observation of the higher acts and states of consciousness. Scientific phrenology, in another subjective point of view, is engaged over finer and finer issues of microscopic and experimental work; and, from its subjective point of view, is becoming more and more psychological, seeking a higher level of interpretation, and a stricter guide to cerebral localization in terms of a more increasingly complex. The motor centres, governing the voluntary movements of the body, are considered to be not simply motor, but also those centres which are concerned with the voluntary localization of the brain, of the physical changes accompanying consciousness, and of consciousness.

Of the two kinds of cases that Dr Holländer has tabulated, it cannot be said that the cases of mania are convincing. Some of them are altogether beside the mark; e.g. he quotes two cases of melancholia, after an injury over the left parietal bone, which were cured by an operation limited to the scalp (evisceration of a painful scar, removal of a small nerve-tumour of the scalp); in neither case was there any suggestion of the management of a homonymous hemianopsia, but the persons were cured of their melancholy. Again, the acceptance of these cases as the localization of these insane thoughts involves the localization of sane thoughts in the same areas of the brain, and the method of diagnosis is rendered futile by the patient's being in a state of total amnesia. If 1000 cases of mania, selected on the above principles, were tabulated, it might possibly be found that the brain damage included the mental state which he attributes to those convolutions, yet this argument is insecure, partly because Sherrington's work, the arch of the arcuate systeme, has rendered it necessary to reconsider the present localization of the motor area in man, and partly because the interpretation of facial and muscular movements as representing this or that state of the emotions, is always precarious.

The second kind of cases, where injury or disease limited to one portion of the brain is followed by perversion, or loss of some faculty, involves the more important consideration of the cases of voracious hunger and thirst, those of true kleptomania, and those of the loss of certain special memories. It is not so easy to believe that the cerebellum is in any primary way associated with sexual desire; its position, its structure and its proved association with the co-ordination of muscular movements seem clearly to indicate that its work is wholly subordinate and complementary to the work of the cerebral hemispheres; and the false inference derived in its favour from the temptation theory is sufficiently variable to make conclusions from it uncertain. The spongy layer or diploe which separates the two compact tables may vary considerably in amount in different parts of the same skull, as in the cases described by Professor Humphry (Journ. of Anat. vii. 137). The frontal sinus, that approprium phrenologicum, is a reality, not unfrequently of large size, and may wholly occupy the regions of five organs. The centres of ossification of the frontal and parietal bones, the muscular crests of these and of the occipital bones also, differ in their prominence in different skulls. Premature synostoses of sutures mould the brain without doing much injury to its function. Such cases as those of Andreas, with enormous skulls, in other directions modifying sometimes to an extreme degree the relation of brain-surface to skull-surface. The writer has found such displacements in extremely scaphocephalic skulls; the same is true of accidental deformations due to pressure on the infantile skull before it consolidates. Artificial malformations alter the apparent skull shape considerably while they affect the relative development of the parts of the brain cortex but little. All these and other cogent reasons of a like kind, whose force can be estimated by those accustomed to deal with the component parts of the head, should lead phrenologists to be careful in predicating relative brain-development from skull-shape. Psychology, physiology, and medicine have no such practical working of the system and to show how worthless the so-called diagnoses of character really are. Its application by those who are its votaries is seldom worse than amusing, but it is capable of doing positive social harm, as in its proposed application to the discrimination or selection of servants and other subordinate officials. It has even been proposed to use it for the purposes of the guarantee society and for the selection of parliamentary representatives. The sarcastic suggestion which originated with Christopher North of moulding children's heads so as to suppress the evil and foster the good was actually repeated in good faith by a writer on phrenology, but experience of the effects of malformation leads one to be sceptical as to the feasibility of this mode of producing a socius Utopia.

It is impossible to fix a date for the beginning of the Phrygian kingdom. It appears to have arisen on the ruins of an older civilization, whose existence is revealed to us only by a few monuments which it has left. These monuments, which are found in Lydia, Phrygia, Cappadocia and Lycaonia, as well as in north and central Syria, point to the existence of a homogeneous civilization over those countries; they show a singularly marked style of art, and are frequently inscribed with a peculiar kind of hieroglyphics, engraved *boustrophedon*; and they originated probably from a great Hittite kingdom, whose kings ruled the countries from Lydia to the borders of Egypt. There can be no doubt that the Phrygian was an ancient road-system, to which the "royal road" from Sardis to the Persian capital, Susa (Herod. v. 55). The royal road followed a route so difficult and circuitous that it is quite unintelligible as the direct path from any centre in Persia, Assyria or Syria to the west of Asia Minor. It can be understood only by reference to an imperial centre far in the north. The old trade-route from Cappadocia to Sinope, which had passed out of use centuries before the time of Strabo (pp. 540, 546), fixes this centre with precision. It must be far enough west to explain why trade tended to the distant Sinope,4 hardly accessible behind lofty and rugged mountains, and not to Amias by the short and easy route which was used in the Graeco-Roman period. This road-system, then, points distinctly to a centre in northern Cappadocia near the Halyos. Here must have stood the capital of some great empire connected with its extremities, Sardis or Ephesus on the west, Sinope on the north, the Ephrates on the east, the Cilician Gates on the south, by roads so well made as to continue in use for a long time after the centre of power had changed to Assyria, and the old road-system had become circuitous and unsuitable.5 The precise spot on which the city stood is marked by the great ruins of Boghaz Keui, probably the ancient Pteria, of which the wide circuit, powerful walls and wonderful rock-cut tombs make the site itself naturally the most remarkable in Asia Minor. On this site Winckler found in 1907 the records of the Hittite kings who fought against Egypt and Assyria.

The ancient road from Pteria to Sardis crossed the upper Sangarius valley, and its course may be traced by the monuments of this early period. Close to its track, on a lofty plateau which overhangs the Phrygian monument inscribed with the name of "Midas the King," is a great city, inferior indeed to Pteria in extent, but surrounded by rock-sculptures quite as remarkable as those of the Cappadocian city. The plateau is 2 m. in circumference, and presents on all sides a perpendicular face of rock 50 to 200 ft. in height. This natural defence was crowned by a wall partly Cyclopean, partly built of large squared stones.6 This city was evidently the centre of the old Phrygian kingdom

1 *Fya*nna on the Midas tomb. It is expressly recorded that *pyarrios* is a Lydian word. *Boustrophedon* resists all attempts to explain it as a purely Greek formation, and the termination assimilates it to certain Phrygian words.

2 Sinope was made a Greek colony in 751 B.C., but it is said to have existed long before that time.

3 When the Persians conquered Lydia they retained, at least for a time, this route, which they found in existence.

4 The stones have all fallen, but the line where they were fitted on the rocks can be traced by any careful explorer. The small fortress Pishimish Kalesi is a miniature of the great city beside it. (See Perrot, *Explo. Arch.ROL* p. 169 and pl. viii.)
PHRYGIA

of the Sangarius valley, but at least one of the monuments in it seems to belong to the older period of Cappadocian supremacy, and to prove that the city already existed in that earlier time. The Phrygian kingdom and art therefore took place of an older civilization. It is probable that the tradition of battles between the Phrygians and the Amazons on the banks of the Sangarius preserves the memory of a struggle between the two races and the victory of the Phrygians.

Of the monuments that exist around this city two classes may be confidently referred to the period of Phrygian greatness. That which is inscribed with the name of "Midas the King" is the most remarkable example of one class, in which a large perpendicular surface of rock is covered with a geometrical pattern of squares, triangles, and circles, and surmounted by a pediment inscribed in the centre by a pilaster in low relief. In some cases a floral pattern occupies part of the surface, and in one case the two sides of the pediment are filled by two sphinxes of archaic type. In some of these monuments a doorway is carved in the lower part; but in one case, viz., the sphinx monument just alluded to, the valves of the door are thrown wide open and give access to a little chamber, on the back of which is sculptured in relief a rude image of the Mother-goddess Cybele, having on each side of her a lion which rests its forepaws on her shoulder and places its head against her knees. It has been found hidden behind the wooded front; in other cases no grave can be detected, but it is probable that they are all sepulchral. The imitation of woodwork is obvious on several monuments of this kind. The second class is marked by the heroidal type of two animals, usually lions rampant, facing one another, but divided by a pillar or some other device. This type is occasionally found conjoined with the preceding; and various details common to both classes show that there was no great difference in time between them. The heroidal type is used on the monuments which appear to be the older, and the geometrical pattern is often employed on the inscribed monuments, which are obviously later than the earliest uninscribed. Monuments of this class are carved on the front of a sepulchral chamber, the entrance to which is a small doorway placed high and inaccessible in the rocks. There are also many rock monuments of the Roman time.

Early Phrygian art stands in close relationship with the art of Cappadocia. The monuments of the type of the Mida tomb are obviously imitated from patterns which were employed in cloth and carpets and probably also in the tilework on the inside of chambers varying slightly according to the material. Such patterns were used in Cappadocia, and the priest in the rock-structure at Ibris wears an embroidered robe strikingly similar in style to the pattern of the Mida tomb; but the idea of using the pattern as the Phrygians did seems peculiar to themselves. The heroidal type of the second class is found also in the art of Assyria, and was undoubtedly adopted by the Phrygians from earlier art; but it is used so frequently in Phrygia as to be specially characteristic of that country. While Phrygian art is distinctly non-Oriental in spirit, its resemblance to archaic Greek art is a fact of the greatest importance. It is not merely that certain types are employed both in Phrygia and in Greece, but several favourite types in early Greek art can be traced in Phrygia, employed in similar spirit and for similar purposes. The heroidal type of the two lions is the device over the principal gateway of Mycenae, and stamps this, the oldest great monument on Greek soil, with a distinctly Phrygian character. Mycenae was the city of the Pelopidae, whom Greek tradition unhesitatingly declares to be Phrygian immigrants. A study of the topography of the Argive plain suggests the conclusion that Mycenae, published in Journ. Hell. Stud. (1884).

1 The monuments of Phrygia fall into two groups, which probably mark the sites of two cities about 60 miles distant from each other: i.e., Metropoli and Conus. One group lies round the villages of Yazil-Kaya, Kumbet, Yapuluk and Bakshish; the other beside Ilyen, Bel Keui, Dauli and Topye; but the idea of using the pattern as the Phrygians did seems peculiar to themselves. The heroidal type continues on gravestones down to the latest period of paganism. Carpets with geometrical patterns of the Mida-tomb style are occasionally found at the present time in the houses of the peasantry of the district.

2 Midea and Tiryns form a group of cities founded by an immigrant people in opposition to Argos, the natural capital of the plain and the stronghold of the native race. Midea appears to be the city of Midas, and the name is one more link in the chain that binds Mycenae to Phrygia. This connexion, whatever may have been its character, belongs to the remote period when the Phrygians inhabited the Aegean coasts. In the 8th and probably in the 9th century B.C. communication with Phrygia seems to have been maintained especially by the Greeks of Cyme, Phocaea and Smyrna. About the end of the 8th century Mida, king of Phrygia, married Damedice, daughter of Agamennon, carried him also the works of Oriental and Phrygian artisans. The Greek alphabet was carried to Phrygia and Pteria, either from Sinope or more probably direct east from Cyme, in the latter part of the 8th century. The immense importance of Sinope in early times is abundantly attested; and we need not doubt that very intimate relations existed at this port between the Ionic colonists and the natives. The effects of this commerce on the development of Greece were very great. It affected Ionia in the first place, and the mainland of Greece indirectly; the art of Ionia at this period is almost unknown, but it was probably closely allied to that of Phrygia. A striking fact in this connexion is the use of a very simple kind of Ionic capital at the base of the Mermnad monument, suggesting that the "proto-Ionic" column came to Greece over Phrygia. It is obvious that the revolution which took place in the relations between Phrygians and Greeks must be due to some great movement of races which disturbed the old paths of communication. Abel is probably correct in placing the inroads of the barbarous European tribes, Bithynians, Thyni, Mariandyni, etc., into Asia Minor about the beginning of the 9th century B.C. The Phrygian element on the coast was weakened and in many places annihilated; that in the interior was strengthened; and we may suppose that the kingdom of the Sangarius valley now sprang into greatness. The kingdom of Lydia appears to have been the importunity of the Phrygian art and to have completely barred the path between Phrygia and Cyme or Smyrna. Ionia maritime enterprise opened a new way over Sinope. The downfall of the Phrygian monarchy can be dated with comparative accuracy. Between 670 and 650 the Cimmerians in their destructive progress over Asia Minor overran Phrygia; the king Midae in despair put an end to his own life; and from thenceforth the history of Phrygia is a story of slavery, degradation and decay, which contrasts strangely with the earlier legends. The catastrophe seems to have deeply impressed the Greek mind, and the memory of it was preserved. The date of the Cimmerian invasion is fixed by the concurrent testimony of the contemporary poets Archilochus and Callinus, of the late chroniclers Eusebius, etc., and of the inscriptions of the Assyro king Esar-haddon. The Cimmerians were finally expelled from Asia Minor by Alyattes before his war with the Medes under Cyaxares (590–585 B.C.). The Cimmerians, therefore, were ravaging Asia Minor, and presumably held possession of Phrygia, the only country where they achieved4 recent discoveries of old Phrygian art are to be found in the most recent Greek bronze work in Olympia, Italy and the northern lands.

5 Hippoman, fr. 36 (49), proves that a trade-route from Phrygia down the Maeander to Miletus was used in the 6th century.
complete success, till some time between 610 and 590 Phrygia then fell under the Lydian power, and by the treaty of 585 the Halys was definitely fixed as the boundary between Lydia and Media (see Lydia and Persia). The period from 675 to 585 must therefore be considered as one of great disturbance and probably of complete paralysis in Phrygia. After 585 the country was ruled again by its own princes under subjection to Lydian supremacy. To judge from the monuments, it appears to have recovered some of its old prosperity; but the art of this later period has to a great extent lost the strongly marked individuality of its earlier bloom. The later sepulchral monuments belong to a class which is widely spread over Asia Minor from Lycia to Pontus. The graves are made inside a chamber excavated in the rock, and the front of the chamber imitates a house or temple. No attempt is made to conceal the entrance or to render it inaccessible. The architectural details are in some cases unmistakably copied, without intentional modification, from the architecture of Greek temples; others point perhaps to Persian influence, while several—which are perhaps among the early works of this period—show the old freedom and power of employing in new and original ways details partly learned from abroad. This style continued in use under the Persians, under whose rule the Phrygians passed when Cyrus defeated Croesus in 546, and lasted till the Roman period. One monument appears to presuppose a development of Greek plastic art later than the time of Alexander and is almost certainly of the Roman time. It would, however, be wrong to suppose that the influence of truly Hellenic art on Phrygia began with the conquest of Alexander. Under the later Mermnad kings the Lydian empire was penetrated with Greek influence, and Xanthus, the early Lydian historian, wrote his history in Greek. Under the Persian rule perhaps it was more difficult for Greek manners to spread far east; but we need not think that European influence was absolutely unfelt even in Phrygia. The probability is that Alexander found in all the large cities a Greek majority and trade. Very little is to be learned from the ancient writers with regard to the state of Phrygia from 585 to 300. The slave-trade flourished: Phrygian slaves were common in the Greek market, and the Phrygian names Midas and Manes were stock-names for slaves.

Herodotus (i. 14) records that a king Midas of Phrygia dedicated his own chair at Delphi; the chair stood in the treasury of Cypselus, and cannot have been deposited there before 680 to 660 B.C. It is not improbable that the event belongs to the time of Alyattes or Croesus, when Greek influence was favoured throughout the Lydian empire; and it is easy to understand how the offering of a king Midas should be considered, in the time of Herodotus, as the earliestmade by a foreigner to a Greek city. The Phrygian troops in the army of Xerxes were armed like the Armenians and led by the same commander.

It is to be presumed that the cities of the Sangarius valley gradually lost importance in the Persian period. The final catastrophe was the invasion of the Gauls about 270 to 250; and, though the circumstances of this invasion are almost unknown, yet we may safely reckon among them the complete devastation of northern Phrygia. At last Attalus I. settled the Gauls permanently in eastern Phrygia, and a large part of the country was henceforth known as Galatia. Strabo mentions that the great cities of ancient Phrygia were in his time either deserted or marked by mere villages. The great city over the tomb of Midas has remained uninhabited down to the present day. About 5 m. west of it, near the modern Kumbet, stood Metropolis, a bishopric in the Byzantine time, but never mentioned under the Roman empire.

Alexander the Great placed Phrygia under the command of Antigonus, who retained it when the empire was broken up. When Antigonus was defeated and slain, at the decisive battle of Ipsus, Phrygia came under the sway of Seleucus. As the Pergamene kings grew powerful, and at last confined the Gauls in eastern Phrygia, the western half of the country was incorporated in the kingdom of Pergamum. Under the Roman empire Phrygia had no political existence under a separate government, but formed part of the vast province of Asia. In autumn 85 B.C. the pacification of the province was completed by Sulla, and throughout the imperial time it was common for the Phrygians to date from this era. The imperial rule was highly favourable to the spread of Hellenistic civilization, which under the Greek kings had affected only a few of the great cities, leaving the mass of the country purely Phrygian. A good deal of local self-government was permitted; the cities struck their own bronze coins, inscribed on them the names of their own magistrates, and probably administered their own affairs at times purely locally. The western part of the country was pervaded by Graeco-Roman civilization, and is perhaps more Greek than the central, and in the country districts the Phrygian language continued in common use at least as late as the third century after Christ.

When the Roman empire was reorganized by Diocletian at the end of the 3rd century Phrygia was divided into two provinces, distinguished at first as Prima and Secunda, or Great and Little, for which the names Pacatiana and Salutaris soon came into general use. Pacatiana comprised the western half, which had long been completely pervaded by Graeco-Roman manners, and Salutaris the eastern, in which the native manners and language were still not extinct. Each province was governed by a pretor and a phrygianus about A.D. 412, but shortly after this date an officer of consular rank was sent to each province (Hierocles, Synecd.). About 535 Justinian made some changes in the provincial administration: the governor of Pacatiana was henceforth a comes, while Salutaris was still ruled by a consularis. When the provinces of the Eastern empire were reorganized and divided into themata the two Phrygias were broken up between the Anatolic, Opsician and Thracesian themes, and the name Phrygia finally disappeared. Almost the whole of Byzantine Phrygia is now included in the vilayet of Brusa, with the exception of a small part of Paroikia and the district of Thesimonials (Karayuk Bazar and Ceretapa (Kayadibi), which belong to the vilayet of Konia, and the district of Laodicea and Hierapolis, which belongs to Aïdin. The principal modern cities are Kutahia (Cotyaeum), Eski Shehir (Dorylaeum), Afiom Kara Hisar (near Pynmessus), and Ushak (Tranapopolis).

It is impossible to say anything definite about the boundaries of Phrygia before the 5th century. Under the Persians Great Phrygia extended on the east to the Halys and the Salt Desert; Xenophon (Anab. i. 2, 19) includes Iconium on the southeast within the province, whereas Strabo makes Tyriaeum the boundary in this direction. The southern frontier of Asia was divided about Themisionum (Karayuk Bazar) and Ceretapa (Kayadibi), which belong to the vilayet of Konia, and the district of Laodicea and Hierapolis, which belongs to Aïdin. The principal modern cities are Kutahia (Cotyaeum), Eski Shehir (Dorylaeum), Afiom Kara Hisar (near Pynmessus), and Ushak (Tranapopolis). included in the Byzantine Phrygia, but in earlier times assigned
to Lydia and Mysia. Great part of southern and western Phrygia
is drained by the Maeander with its tributaries, Sandykly Tchai
(Glaucus), Banaz Tchai, Kopli Su (Hippurius), and Tchuruk Su
(Lycus); moreover, some upland plains on the south, especially the
Dombai Ova (Aulocra), communicate by underground channels
with the Maeander. Finally, the Karayuk Ova in the extreme southwest drains through the Kazanes, a tributary of the Indus, to the
Lycian Sea. Phrygia Parorius and all the river-valleys are exceedingly fertile, and agriculture was the chief occupation of the ancient
inhabitants; according to the myth, Gordius was called from the
plough to the throne. The high-lying plains and parts of the vast
Axylon furnish good pasturage, which formerly nourished countless
flocks of sheep. The Romans also obtained fine horses from Phrygia.

were Cybele, the Mother, the reproductive and nourishing power of
Earth, and Sabazius, the Son, the life of nature, dying and reviving

every year (see GREAT MOTHER OF THE GODS). The annual vicissitudes of the life of Sabazius, the Greek Dionysus, were accompanied
by the mimic rites of his worshippers, who mourned with his sufferings and rejoiced with his joy. They enacted the story of his birth
and life and death the Earth, the Mother, is fertilized only by an act
of violence by her own child the representative of the god was probably slain each year by a cruel death, just as the god himself died.
The rites were characterized by a frenzy of devotion, unrestrained
enthusiasm, wild orgiastic dances and wanderings in the forests,
and were accompanied by the music of the flute, cymbal, and tambourine. 4 At an early time this worship was affected by Oriental
influence, coming over Syria from Babylonia. Sabazius was identified with Adonis or Attis (Atys), Cybele with the Syrian goddess;
and many of the coarsest rites of the Phrygian worship, the mutilation of the priests, the prostitution at the shrine, 6 came from the
countries of the south-east. But one point of Semitic religion never
penetrated west of the Halys: the pig was always unclean and
abhorred among the Semites, whereas it was the animal regularly
used in purification by the Phrygians, Lydians, Lycians and Greeks.
The Phrygian religion exercised a very strong influence on Greece.
In the archaic period the Dionysiac rites and orgies spread from
Thrace into Greece, in spite of opposition which has left many traces
in tradition, and the worship of Demeter at Eleusis was modified
by Cretan influence ultimately traceable to Asia Minor. Pindar
erected a shrine of the Mother of the gods beside his house, and the
Athenians were directed by the Delphic oracle to atone for the
execution of a priest of Cybele during the Peloponnesian War by

barbarian
ritual of Phrygia.
The rites spread first
unmodified
among the common people and those engaged in foreign trade.
The comic poets satirized them, and Plato and Demosthenes inveighed against them; but they continued to spread, with all their
fervid enthusiasm, their superstition and their obscene practices,
wide among the people, whose religious cravings were not satisfied
with the purely external religions of Hellenism.
The orgies or'
mysteries were open to all, freemen or slaves, who had duly performed
the preliminary purifications, and secured to the participants
salvation and remission of sins.
Under MYSTERIES (q.v.) a distinction of character has been pointed out between the true Hellenic
mysteries, such as the Eleusinian and the Phrygian; but there
In

itself, however, was very early converted to Christianity.
inscriptions in the country begin in the 2nd and are abundant in the
3rd century. There is every appearance that the great mass of the
people were Christians before 300, and Eusebius (H.E. y. 16) is
probably correct in his statement that in the time of Diocletian
there was a Phrygian city in which every living soul was Christian.
The great Phrygian saint of the 2nd century was named Avircius
Marcellus (Abercius) the mass of legends and miracles in the late
biography of him long brought his very existence into dispute, but a
fragment of his gravestone, discovered in 1883, and now preserved
in the Lateran Museum in Rome, has proved that he was a real person, and makes it probable that the wide-reaching conversion of the
The strange
people attributed to him did actually take place.
enthusiastic character of the old Phrygian religion was not wholly
lost when the country became Christian, but is clearly traced in the
various heresies that arose in central Anatolia. Especially the wild
ecstatic character and the prophecies of the Montanists recall the
old type of religion. Montanus (see MONTANISM) was born on the
borders of Phrygia and Mysia (probably south-east from Philadelphia), and was vehemently opposed by Abercius.
Of the old Phrygian language very little is known; a few words
are preserved in Hesychius and other writers. Plato mentions that
"
"
the Phrygian words for
"fire," &c., were the same as the
dog,
and to these we may add from inscriptions the words for

According to others, Attic yields a lexicon of Sicily. Zinc forty-seven best Lobeck Her laugh, led to the thought of the Trojan Lobeck. Her laugh, led to the thought of the Trojan.

Some She had been destroyed by Alexander the Great (336), on condition that the words "Destroyed by Alexander, restored by Phryne the courtesan," were inscribed upon them. On the occasion of a festival of Poseidon at Eleusis she laid aside her garments, let down her hair, and stepped into the sea in the sight of the people, thus suggesting to the painter Apelles his great picture of Aphrodite Anadyomene, for which Phryne sat as model. She was also (according to some) the model for the statue of the Cnidian Aphrodite by Praxiteles. When accused of profaning the Eleusinian mysteries, she was defended by the orator Hypereides, one of her lovers. When it seemed as if the verdict would be unfavourable, he rent her robe and displayed her lovely bosom, which so moved her judges that they acquitted her. According to others, she herself thus displayed her charms. She is said to have made an attempt on the virtue of the philosopher Xenocrates. A statue of Phryne, the work of Praxiteles, was placed in a temple at Sparta by the side of a statue of Aphrodite by the same artist.

See Athenaeus, pp. 536, 567, 583, 585, 590, 591; Aelian, *Var. Hist.* ii. 11; *Hellenica* xxxv. 11; *Mitra* xxi. 71.

**PHRYNICHUS**—1. Son of Polyphrion and pupil of Thespis, one of the earliest of the Greek tragedians. Some of the ancients, indeed, regarded him as the real founder of tragedy. He gained his first poetical victory in 521 B.C. His famous play, the *Capture of Miletus*, was probably composed shortly after the conquest of that city by the Persians. The audience was moved to tears, the poet was fined for reminding the Athenians of their misfortunes, and it was decreed that no play on the subject should be produced again. In 476 Phrynichus was successful with the *Phoinissae*, so called from the Phoenician women who formed the chorus, which celebrated the defeat of Xerxes at Salamis (480). Thermistocles acted as choragus, and one of the objects of the play was to remind the Athenians of his great deeds. The *Persians of Aegyptus* (472) was an imitation of the *Phoinissae*. Phrynichus is said to have died in Sicily. Some of the titles of his plays, *Donatides, Actaeon, Alcestis, Tantalus*, show that he treated mythological as well as contemporary subjects. He introduced a separate actor as distinct from the leader of the chorus, and thus laid the foundation of dialogue. But in his plays, as in the early tragedies generally, the dramatic element was subordinate to the lyric element as represented by the chorus and the dance. According to Suidas, Phrynichus first introduced female characters on the stage (played by men in masks), and made special use of the trochaic tetrameter.

Fragments in A. Nauck, *Trogusiae graecorum fragments* (1887).

2. A poet of the Attic comedy and a contemporary of Aristophanes. His first comedy was exhibited in 426 B.C. He composed ten plays, of which the *Solidary (Mephoros)* was exhibited in 414 along with the *Birds* of Aristophanes and gained the third prize. The *Muses* carried off the second prize in 405, Aristophanes being first with the *Frogs*, in which he accuses Phrynichus of employing vulgar tricks to raise a laugh, of plagiarism and bad versification.

3. **PHRYNICHUS ARABUS**, a grammarian of Bithynia, lived in the 2nd century A.D. According to Suidas he was the author of (1) an *Atticis*, or *On Attic Words*, in two books; (2) *Tithemns* ὑπαγεία, a collection of subjects for discussion; (3) *Σωκρατικὴ παρασκευή*, or Sophistic Equipment, in forty-seven (or seventy-four) books. As models of Attic style Phrynichus assigned the highest place to Plato, Demosthenes and Aeschines the Socratic. The work was learned, but prosy and garrulous. A fragment contained in a *Pedia MS* was published by B. de Montfaucon, and by I. Bekker in his *Anecdota graeca* (1812). Another work of Phrynichus, not mentioned by Photius, but perhaps identical with the *Atticis* mentioned by Suidas, the *Selection (Ἐξελήφα) of Attic Words and Phrases*, is extant. It is dedicated to Cornelius, a man of literary tastes, and one of the imperial secretaries, who had invited the author to undertake the work. It is a collection of current words and forms which deviated from the Old Attic standard, the true Attic equivalents being given side by side. The work is thus a lexicon anti-barbarum, and is interesting as illustrating the changes through which the Greek language had passed between the 4th century B.C. and the 2nd century A.D.

Editions of the *Ἐξελήφα*, with valuable notes, have been published by C. A. Lobec (1820) and W. G. Rutherford (1881); Lobec devotes his attention chiefly to the later, Rutherford to the earlier usages noticed by Phrynichus. See also J. Brennus, *De Phrynico Atticismo* (1885).

4. An Athenian general in the Peloponnesian War. He took a leading part in establishing the oligarchy of the Four Hundred at Athens in 411 B.C., and was assassinated in the same year (Thucydides viii.).

**PHTHALAZINES** (benzo-orthiodiazines or benzopyridazines), in organic chemistry a group of heterocyclic compounds containing the ring complex shown in formula I. They are isomeric with the cinolines (p. 99). The parent substance of the group, phthalazine, C₉H₈N₂, is best obtained from the condensation of hydroxybenzamide with hydrazine (D. Gabriel, *Ber.*, 1903, p. 2370), or by the reduction of chlorophthalazine with phosphorus and hydriodic acid (Ber., 1897, p. 3024). It possesses basic properties and forms addition products with alkyl iodides. On oxidation with alkaline potassium permanganate it yields pyridazine dicarboxylic acid. Zinc and hydrochloric acid decompose it with formation of orthoxylylene diamine.

The keto-hydro derivative *phthalasone*, C₉H₈O₂N₂, (formula II.), is obtained by condensing phthalic anhydride with hydrazine (D. Gabriel, *Ber.*, 1893, p. 185), and leads to chlorophthalazine which with zinc and hydrochloric acid gives isonidine, C₉H₇N, and with tin and hydrochloric acid phthalimidine, C₉H₈O₂N₃, the second nitrogen atom being eliminated as ammonia.

CH₃

**PHTHALIC ACIDS**, or benzene dicarboxylic acids, C₉H₈(COOH)₂. There are three isomers: (1) ortho, or phthalic acid; (2) meta, or isophthalic acid; (3) para, or terephthalic acid.

Phthalic acid was obtained by Laurent in 1836 by oxidizing naphthalene tetrachloride, and, believing it to be a naphthalene derivative, he named it naphthalenic acid; Marignac determined its formula and showed Laurent's supposition to be incorrect, upon which Laurent gave it its present name. It is manufactured by oxidizing naphthalene tetrachloride (prepared from naphthalene, potassium, chloride and hydrochloric acid) with nitric acid, or, better, by oxidizing the hydrocarbon with fuming sulphuric acid, using mercury or mercuric sulphate as a catalyst (German pat. 91, 202). It also results on the oxidation of ortho-
dederivatives of benzene. It forms white crystals, melting at 215° with decomposition into water and phthalic anhydride; the latter forms long white needles, melting at 126° and boiling at 256°. Heated with an excess of lime it gives benzene; calcium benzolate results when calcium phthalate is heated with one molecule of lime to 330°-350°. The acid (and anhydride) are largely used in the colour industry (see Fluorescens; Phenolphthalein).

Phthalyl chloride, CH₄(COCl)₂ or CH₄(CCl₄)(CO)Cl, formed by heating the anhydride with phosphorus chloride, is an oil which solidifies at 0° and boils at 275°. In some reactions it behaves as having the first formula, in others as having the second. Phthalyl chloride with phosphorus pentachloride gives two phthalylene tetrachlorides, one melting at 88° and the other at 47°. They cannot be changed into one another, and have been given the formulars CH₄(CCl₅)(COCl) and CH₄(CCl₅)Cl. Phthalimide, CH₄(CO)₂-NH, is formed by heating phthalic anhydride or chloride in ammonia gas or by molecular rearrangement of ortho-cyanbenzoic acid. It forms N-metallic and alkyl salts. Bromine and potash give antranilic acid, CH₄(NH₂)(CO)₂H. (See Indigo.)

Isophthalic acid is obtained by oxidising meta-xylene with chromic acid, or by fusing potassium meta-sulphobenzene, or meta-bromobenzene with potassium formate (terephthalic acid is also formed in the last case). It melts above 300°, and dissolves in 780 parts of cold water and in 460 of boiling. The barium salt (1-6H₂O) is very soluble (a distinction between phthalic and terephthalic acids). Uvic acid, 5-methyl isophthalic acid, is obtained by oxidising mesitylene or by condensing pyracemic acid with barium oxide. Terephthalic acid, formed by oxidising para-dederivatives of benzene, or best by oxidising caraway oil, a mixture of cymene and cuminal, with chromic acid, as almost insoluble in water, alcohol and ether; it sublimes without melting when heated.

For the reduced phthalic acids see Polyethylene.

**PHYSIS** (Gr. φύσις “waving”), a term formerly applied (like “Consumption”) to the disease of the lung now known as Tuberculosis (q.v.).

**Phylactery (φυλλατήριον), a Greek word meaning “guard” (i.e. against misfortune), i.e. an amulet. It is applied in the New Testament to the tefillin or “prayer-thong” worn by orthodox Jews daily at morning-prayer (whether at home or in the synagogue). The title employed in Hebrew, tefiloth, seems really to be derived from an Aramaic term meaning “attachments,” “ornaments”; it corresponds to the Biblical Hebrew word rendered “frontlets” (leotfith). The tefillin or phylacteries are worn, one on the left arm (the “hand-teffila”), and the other on the head (the “head-teffila”). In each case the leather thongs support a small satchel which is fastened to the arm and the forehead respectively, and contains certain passages of the Law written (in Hebrew) on parchment, viz. Exod. xiii. 1-10 and xi. 11-16; Deut. vi. 4-9 and xi. 13-21. The custom of wearing phylacteries seems to have been derived in the first instance from the Pharisees. By the Sadducees and the generality of the people in the time of Christ it seems not to have been practiced. Later it became—not without protest— one of the badges of orthodox Judaism. It is significant that the custom is entirely unknown to the Samaritan community.

The phylacteries, together with the “fringe” (leotfith) and door-post symbol (mesnæa)—which latter consists of a piece of parchment, containing the Hebrew text of Deut. vi. 4-9 and xi. 13-21 enclosed in a glass or metal tube, and fixed upon the right hand post of the door of each dwelling-room in a house—form the three visible signs of identity by which the Israelites is constantly reminded of his duty to God (cf. Num. xv. 39-46; Deut. vi. 9; xi. 26). The “fringe” (or tassels) was originally attached to the common outer garment—a large square wrap—the loose end of which hung over the left shoulder. This garment with tassels is mentioned in the New Testament (Matt. xxiii. 5; xvi. 36; xxiii. 5 and parallels). Among modern Jews it has succeeded in two forms: (1) the fringed praying shawl called talith worn by every male orthodox Jew at the synagogue morning service; and (2) an under-garment, shaped like a chest-protector, one part covering the chest, the other the back, which is worn continuously by male orthodox Jews. It is called Arba Kanfoth (i.e. “Four Corners,” Deut. xxii. 12) or “little Talith,” and is, of course, “fringed.” Both phylactery and mezuzah were supposed to keep off hurtful demons (Targ. on Cant. viii. 3).

See Surenhusius, Mischna, i. 9 seq.; and Bodendeschatz, Kirch. Verf. d. heutigen Juden, iv. 9 seq. (W. R. S.; G. H. Bo.)

**Phylarchus,** a Greek historian, who flourished during the time of Aratus, the strategus of the Illyrian League, in the 3rd century, and often served as a king himself. His birthplace is variously given as Athens, Nau克拉西, or Sicyon. He was probably a native of Nau克拉西, and subsequently migrated to Athens. He was the author of a history in 28 books, covering the period from the expedition of Pyrrhus king of Epirus to Peloponnesus (272) to the death of the Spartan king Cleomenes (220) after his defeat by Antigonus Doson. Polybius (ii. 56-63) charges him with undue partiality for Cleomenes and unfavourable towards Aratus; Plutarch (Aratus, 38), who is of the same opinion, did not hesitate to use him freely in his own biographies of Agis and Cleomenes.

**Phyllite,** a mountain formation, on a pass leading from Athens to Bocotia and Thebes, and commanding a fine view of the Attic plain. It is situated on the south-west end of Mt. Parnes. It is chiefly famous for its occupation by Thrasybulus at the head of the Athenian exiles during the rule of the Tyrant T tyranny (404 B.C. After defending himself from attack, with the help of a snowstorm, he succeeded by a venturesome night march in seizing Munychia. Close to Phyle is the cliff called Harmas, over which the Pythian lightnings were watched for from Harmas.

**Phyllite** (Gr. φύλλον, a leaf, probably because they yield leaf-like plates, owing to their fissility), in petrology, a group of rocks which are in practically all cases metamorphosed argillaceous sediments, consisting essentially of quartz, chlorite and muscovite, and possessing a well-marked parallel arrangement or schistosity. They form an intermediate term in the series of altered clays or shaly deposits between clay-slates and biotite-mica-slates. They have their origin in the crystalline constitution to the phyllites, but are finer grained and are distinguished also by a very much better cleavage. In the phyllites also white mica (muscovite or sericite) is more abundant as a rule than in slate, and its crystalline plates are larger; the abundance of mica gives these rocks a glossy sheen on the smooth planes of fissility. Many of the best Welsh slates are rich in small scales of white mica, which polarize brightly between crossed nicols. The Cornish slates are still more micaceous and rather coarser grained, so that they might be called mica-slates or even phylmites.

A microscopic section of a typical phyllite shows green chlorite and colourless mica both in irregular plates disposed in parallel order, with a greater or smaller amount of quartz which forms small lenticular grains elongated parallel to the foliation. Grains of iron oxide (magnetite and haematite) and black graphic dust are very scarce, if present. For many years the phyllites were believed to be formed from silt or clay-slates by various degrees of chloritization. For many years the phyllites were believed to be formed from silt or clay-slates by various degrees of chloritization. Very tiny blue needles of tourmaline are by no means rare in phyllites, though rarely overlooked. Garnet occurs sometimes, a good example of garnetiferous phyllite being furnished by the rock from the Lower Greensand near Fockell in the Eastern Counties, which is black in colour and contains many small, sharply defined crystals of magmatic garnet. Hornblende, often in branching feathery crystals, is a less frequent accessory. In some phyllites a mineral of the chloritoid group makes its appearance; it is a dark bluish-green, rather coarse-grained variety of sericite, and occurs in large sub-hexagonal plates showing complex twinning, and lying across the foliation planes of the rock, so that they seem to have developed after the movements and pressures which gave rise to the foliation had ceased.
PHYLOXERA

The structural variations presented by the phylloxeras are comparatively few. The most finely crystalline specimens have generally the most perfect and regular arrangement of their constituents. The foliation is generally flat or linear, but in some rocks is undulate or crumpled. From the imperfection of their cleavage phylloxeras are rarely suitable for roofing materials; their softness renders them valueless as road stones, but they are not uncommonly employed as inferior building materials. They are extensively used in the two parts of the world where metamorphic rocks occur; as in the Scottish Highlands, Cornwall, Anglesey, north-west Ireland, the Alps, Norway, the Great Lakes in America, &c. (J. S. F.)

PHYLOXERA (Gr. φυλλόξερα, leaf, and ἔφιδως, dry), a genus of insects belonging to the family of Aphidaceae, or Plant-lice, in the Homopterous section of the order Hemiptera. It is chiefly known from the causal relation of one of its species to the most serious of vine-diseases. The name was first given in 1834 to a plant-lice which was observed to 'dry up the leaves' of oak. In the lapse of six, eight or twelve years, according to the temperature, the larvae hatch out of the eggs. These are at first yellowish in colour and flabby; but as they grow older they are rosette or assimile, brown or black, and the root-dwellers, the presence of which can be detected by their softness and the wrinkle which they cause to the surface of the soil. The terminals of the species are characterized by the large sized and numerous egg-shaped yellowish-brown colour, which is observed in the vine-wine of Radicola. This seems to be the case in the American species, and it is observed that the American species, and its is the only species which attacks the vine, the Phylloxera vastatrix, or grape-louse, is reprinted from the article Vine in the 9th edition of this encyclopedia.

If, however, the insect were constant with this method of reproduction, the disease could be isolated by surrounding the infected patches with a deep ditch full of some such substance as coal-tar, which would prevent the insects spreading to the root of healthy vines. The fertility of the parthenogenetically produced insects is also diminished after a certain number of generations has been produced. As the summer wears on a second form of insect appears amongst the root-dwellers, though hatched from the same eggs as the first generation above. These are the nymphs, destined to acquire wings; their body is more slender in outline, and at first they bear well-marked tubercles. After several molts the rudiments of two pairs of wings appear, and then the insects creep up to the surface of the earth, and on to the vine. Here it undergoes its fifth and sixth molt, and appears as a winged female, capable of reproducing parthenogenetically. The winged form has a slender body with distinct head (fig. 2). The eyes are well developed, with numerous facets; the antennae are not solid as of root-dwellers, the wings are transparent, with few nervures, and are well adapted for flight. The anterior pair reach far beyond the end of the abdomen; the posterior are narrower and not so long. These winged forms are about 1 mm. long. They fly about from July till October, living upon the sap of the vine, which is sucked up by the rostrum from the leaves or buds. They lay their parthenogenetically produced eggs in the angles of the veins of the leaves, in the buds, or, if the season is already far advanced, in the bark. In very damp or cold weather the insect remains in the ground near the surface, and deposits its eggs there. The eggs are very few in number and of two sizes, small and large (fig. 3, b and c). From the larger a female (fig. 4) is hatched in eight or ten days, and simultaneously, for the first time in the life-history of the Phylloxera, a male (fig. 3) appears from the smaller egg. Neither male nor female has wings; the rostrum is replaced by a functionless tube, and there is no alimentary canal. They are larger in some rocks than in others, and differ from it and the other forms in the last joint of the antennae. The life of these sexual forms lasts but a few days, and is entirely taken up with reproduction. The female is fertilized by the male and three or four days later lays a single egg—the winter-egg—and then dies. This egg is laid in the clefts of the bark of the vine, and as it is protectively coloured it is almost impossible to find it. Here the winter eggs remain undevolved during the cold months; but in the following spring, as a rule in the month of April, they give rise to a female insect without wings, which resembles the root-dwelling forms, but has pointed antennae. These forms are termed the stock-mothers; they creep into the buds of the vine, and, as these develop into the young leaves, insert their proboscis into the upper side. By this means a gall is produced on the under side of the leaf.

of the leaf is protected by similar structures. Within this gall the stock-mother lives and surrounds herself with numerous paraphenom- genetically produced eggs—sometimes as many as two hundred in a single gall; these eggs give rise to a few or eight or even a hundred progeny (Philacola), some of which form new galls and multiply in the leaves, whilst others descend to the roots and become the root-dwelling forms already described. The galls and the gall-producing form are much commoner in America than in the Old World.

The particular species of phylloxera which attacks the vine is a native of the United States, probably originating among the wild vines of the Colorado district. It was first observed in 1856 by Asa Fitch (1809-1878), who did not suspect its mischief, and called it Pemphigus vitifoliae. In 1863 it was independently discovered by Westwood in an English vineyard at Hammersmith; he was ignorant of Fitch’s observation, and called it Peritymbia vitisana. From 1858 to 1863 there were many importations of American vines for grafting purposes to Bordeaux, Roquesmaure and other parts of France, England, Ireland, Germany, Portugal, &c. It is practically certain that the deadly phylloxera was imported on these plants. A year or two later certain vine-growers in the South of France began to complain of the new vine-disease. M. Delorme, of Arles, in 1865, appears to have been the first who recognized its novelty and had a presentiment of disaster. The disease steadily spread outwards in concentric circles from its first place of lodgment near Roquesmaure. Within two or three years whole departments were infested. In 1866 a second centre of infection made its appearance near Bordeaux. The vine-growers were at their wits’ ends. There was no possibility for this new plague, which threatened to be even more costly than the oidium. The completeness of the ruin which threatened them may be illustrated by the statistics for a single commune, that of Graveson, whose average annual production of wine in the years 1865-1867 was about 220,000 gallons. In 1868 this fell to 121,000 gallons, in 1869 to 48,400 gallons, in 1870 to 8800 gallons, and by 1873 to 1100 gallons.

In 1868 Planchon proved that the disease was due to a new species of phylloxera, which was invariably found on the roots of the affected vines, and to which he accordingly gave the prophetic name of Phylloxera vastatrix. During the next ten years a series of students, of whom only Riley and Balbiani need be mentioned here, worked out the natural history of Phylloxera vastatrix, and proved its identity with the American grape-louse. Its devastations rapidly assumed gigantic proportions. In France, where the disease was by far the most prevalent—owing in great part to the obstinacy with which the vine-growers at first refused to take any reasonable precautions against its spread—M. Lalande, president of the chamber of commerce at Bordeaux, in 1888 calculated the direct loss to the country by the phylloxera at 10 milliards (£400,000,000), or double the indemnity which had been paid to Germany in 1871.

The phylloxera has made its appearance in almost every vine-growing country in the world. Thus it appeared in Austria-Hungary in 1869; in Italy, in spite of the frantic efforts made—as in other countries—to keep it out by strict legislation against the import of vines, in 1879; in Russia in 1880; in Germany, on the Rhine and Moselle, and in Switzerland in 1872; in Iberia, Spain and Portugal, about 1880; in Australia, at Geelong, about 1880; it has since twice broken out in Victoria, and has ravaged the vineyards of South Australia and New South Wales in 1880. It is, in spite of a long and arduous struggle to check the import of the phylloxera, it appeared about 1884. In 1885 it crossed the Mediterranean to Algeria. There was only one country where its ravages were long unimportant; that was its home in the United States. When the native vines became, by the operation of natural selection, immune to its attacks. Yet no imported vine has ever lived there more than five years, and in 1890 the phylloxera crossed the Rocky Mountains, and seriously damaged the vineyards of California, where it had previously been unknown.

Three different methods of fighting the pest have been successfully adopted. One is to kill the phylloxera itself; another, to destroy it along with the infected vines, and plant fresh and healthy plants; the third, to adapt the secular therapeutics of nature, and to introduce American vines which a long acquaintance with the phylloxera has made immune to its ravages. Insecticides, of which the bisulphide of carbon (CS) and the sulpho-carbonate of potassium (KSCS) remain in use, were injected into the earth to kill the phylloxera on the roots of the vine. These methods were chiefly advocated in vineyards of the first class, where it was worth while to spend a good deal of money and labour to preserve the old and famous vines: the Château Leoville Poyferré and Clos Vougeot are instances. Some good judges attribute the peculiar and not unpleasant flavour of certain clarets of 1858 to the phylloxera. The second plan was largely adopted in Switzerland and on the Rhine, where measures resembling those taken with cattle suspected of anthrax were applied to all diseased vineyards. The third plan, which consists in replanting the affected vineyard with American vines—such as the Vitis labrusca, V. riparia, V. rupestris or V. monticola—has proved the most generally successful.

A very good bibliography will be found in Les Insectes de la vigne, by Professor Majet of Montpellier (1890), which is the best book on the subject. Reference may also be made to the classic memoirs of Planchon, culminating in Les Moeurs de la phylloxera de la vigne (1877); Dreyfus, Unter Phylloxerinen (1886); Lichtenstein, Histoire du phylloxera; les Rapports annuels à la commission internationale du phylloxera, and the excellent Report on Phylloxera drawn up by the Hon. J. W. Taverner (Victoria, 1890, No. 68).

PHYSHARMONICA, a keyboard instrument fitted with free-reeds, a kind of harmonium much used in Germany. The phyrsharmonica resembles a small harmonium, but is differentiated from it by having no stops; being without percussion action, it does not speak readily or cleanly, and in its harmonics the bellows are worked by the feet by an alternate movement, which also affords a means of varying the dynamic force of the tone according as more or less energetic pedalling increases or decreases the pressure of the wind supply. The phyrsharmonica was invented in 1818 by Anton Häckel, of Vienna; in the original instrument the bellows were placed right and left immediately under the shallow wind-chest, and were worked by means of pedals connected by stout wire. A specimen, having a compass of four octaves and a very sweet tone, is preserved in the collection of Paul de Wit, formerly in Leipzig, now transferred to Cologne.

(K. S.)

PHYSICAL PHENOMENA, in the terminology of spiritualism and psychical research, molar or molecular phenomena in the physical world not traceable to ordinary causes and referred to the action of spirits or of mediums in abnormal psychical states. Among the phenomena or alleged phenomena are: materialization, levitation or elongation of the medium; passage of matter through matter, alteration of weight in a balance, tying of knots in an endless cord, apports (objects brought from a distance) and movements of objects (telekinesis); the production of writing, imprints of plaster or other objects; raps, voices and other sounds, including music; spirit photographs; lights and perfumes. To these may be added immunity against the effects of fire and the untying of ropes.

Analogous phenomena are found in many parts of the world (see PATERGUEST; FIREWALKING); spectral lights are associated with the tombs of Mahomedan saints, with Buddhist shrines, with religious revivals, with Red Indian and other magicians, &c., and as sporadic phenomena in the Highlands and Norway. Levitation is asserted of Australian wizards, the rope-trick of Eskimo angeloks; glyphs and direct visions are found in Mexican and Tibetan cults.

See F. Podmore, Modern Spiritualism; F. W. H. Myers, Human Personality, ii. 506; Journal S. P. R., vii. 309 sq.

PHYSIOCRACTIC SCHOOL, the name given to a group of French economists and philosophers. The heads of the school were François Quesnay (1694-1774) and Jean-Jacques Rousseau (1712-1778). The principles of the school had been put forward in 1755 by R. Cantillon, a French merchant of Irish extraction (Essai sur la nature du commerce en général), whose biography W. S. Jevons has elucidated, and whom he regards as the true founder of political economy; but it was in the hands of Quesnay and Gournay that they acquired a systematic form, and became the creed of a united group of thinkers.
and practical men, bent on carrying them into action. The members of the group called themselves les économistes, but it is more convenient, because unambiguous, to designate them by the name physiocrates (Gr. φύση, nature, and σκηνή, to rule), invented by P. S. Dupont de Nemours (1739-1817), who was one of their number. In this name, intended to express the fundamental idea of the school, much more is implied than the subjection of the phenomena of the social, and in particular the economic, world to fixed relations of coexistence and succession. This is the positive doctrine which lies at the bottom of all true scientific inquiry. But the law of nature referred to in the title of the sect was something quite different. The theological dogma which represented all the movements of the universe as directed by divine wisdom and benevolence to the production of the greatest possible sum of happiness had been transformed in the hands of the metaphysicians into the conception of a jus naturae, a harmonious and beneficial code established by the favourite entity of these thinkers, nature, antecedent to human institutions, and furnishing the model to which they should be made to conform.

The general political doctrine is as follows: Society is composed of a number of individuals, all having the same natural rights. If all do not possess (as some members of the negative school maintained) equal capacities, each can at least best understand his own interest, and is led by nature to follow it. The social union is really a contract between these individuals, the object of which is the limitation of the natural freedom of each so far as it is inconsistent with the rights of the others. Government, though necessary, is a necessary evil; and the governing power appointed by consent should be limited to the amount of interference absolutely required to secure the fulfilment of the contract. In the economic sphere this implies the right of the individual to such natural enjoyments as he can acquire by his labour. That labour, therefore, should be undisturbed and unfettered, and its fruits be guaranteed to the possessor; in other words, property should be sacred. Each citizen must be allowed to make the most of his labour; and therefore freedom of exchange should be ensured, and competition in the market should be unrestricted, no monopolies or privileges being permitted to exist.

The physiocrats then proceed with the economic analysis as follows: Only those labours are truly "productive" which add to the quantity of raw materials available for the purposes of man; and the real annual addition to the wealth of the community consists of the excess of the mass of agricultural products (inland and abroad) over their cost of production. On the amount of this produit net depends the well-being of the community and the possibility of its advance in civilization. The manufacturer merely gives a new form to the materials extracted from the earth; the higher value of the object, after it has passed through his hands, only represents the quantity of provisions and other materials used and consumed in its elaboration. Commerce does nothing more than transfer the wealth already existing from one hand to another; what the trading classes gain thereby is acquired at the cost of the nation, and it is desirable that its amount should be as small as possible. The occupations of the manufacturer and merchant, as well as the liberal professions and every kind of personal skill, are considered as "useful" indeed, but they are "sterile," drawing their income, not from any fund which they themselves create, but from the superfluous earnings of the agriculturist. The revenue of the state, which must be derived altogether from this net product, ought to be raised in the most direct and simplest way—namely, by a single impost of the nature of a land tax.

The special doctrine relating to the exclusive productiveness of agriculture arose out of a confusion between "value" on the one hand and "matter and energy" on the other. A. Smith and others have shown that the attempt to fix the character of "sterility" on manufactures and commerce was founded in error. And the proposal of a single impôt territorial falls to the ground with the doctrine on which it was based. But such influence as the school exercised depended little, if at all, on these peculiar tenets, which indeed some of its members did not hold. The effective result of its teaching was mainly destructive. It continued in a more systematic form the efforts in favour of the freedom of industry already begun in England and France. It was to be expected that the reformers should, in the spirit of the negative philosophy, exaggerate the vices of established systems; and there can be no doubt that they condemned too absolutely the economic action of the state, both in principle and in its historic manifestations, and pushed the laissez- faire doctrine beyond its just limits. But this was a necessary incident of their connexion with the revolutionary movement, of which they really formed one wing. In the course of that movement, the primitive social contract, the sovereignty of the people and other dogmas now seen to be untenable, were habitually invoked in the region of politics proper, and had a transitory utility as ready and effective instruments of warfare. And so also in the economic sphere the doctrines of natural rights of buying and selling, of the sufficiency of enlightened selfishness as a guide in mutual dealings, of the certainty that each member of the society will understand and follow his true interests, and of the coincidence of those interests with the public welfare, though never demonstrated to their satisfaction, by dispassionate examination, were temporarily useful as convenient and serviceable weapons for the overthrow of the established order.

These conclusions as to the revolutionary tendencies of the school are not at all affected by the fact that the form of government preferred by Quesnay and some of his chief followers was what they called a legal despotism, which should embrace within itself both the legislative and the executive function. The reason for this preference was that an enlightened central power could more promptly and efficaciously introduce the policy they advocated than an assembly representing divergent opinions and fettered by constitutional checks and limitations. Turgot used the absolute power of the Crown to carry into effect some of his measures for the liberation of industry, though he ultimately failed because unsustained by the requisite force of character in Louis XVI. But what the physiocratic idea with respect to the normal method of government was appears from Quesnay's advice to the dauphin, that when he became king he should "do nothing, but let the laws rule," the laws having been, of course, first brought into conformity with the jus naturae. The partiality of the school for agriculture was in harmony with the sentiment in favour of "nature" and primitive simplicity which then showed itself in so many forms in France, especially in combination with the revolutionary spirit, and with their mistaken idea of the natural state of man; the members of the physiocratic group were undoubtedly men of thorough uprightness, and inspired with a sincere desire for the public good, especially for the material and moral elevation of the working classes. Quesnay was physician to Louis XV., and resided in the palace at Versailles; but in the midst of that corrupt court he maintained his integrity, and spoke with manly frankness what he believed to be the truth. And never did any statesman devote himself with greater singleness of purpose or more earnest endeavour to the service of his country than Turgot, who was the principal practical representative of the school.

The physiocratic school never obtained much direct popular influence, even in its native country, though it strongly attracted many of the more gifted and earnest minds. Its members, writing on dry subjects in an austere and often heavy style, did not find acceptance with a public which demanded before all things charm of manner in those who addressed it. The physiocratic tenets, which were in fact partly erroneous, were regarded by many as chimerical, and were ridiculed in the contemporary literature; as, for example, the impôt unique by Voltaire in his L'Homme aux quarante écus, which was directed in particular against P. P. Mercier-Larivière (1720-1794). It was justly objected to the group that they were too absolute in their view of things; they supposed, as Smith remarks in speaking of Quesnay, that the body politic could thrive only under one precise régime—that, namely, which they recommended—and
thought their doctrines universally and immediately applicable in practice. They did not, as theorists, sufficiently take into account national diversities or different stages in social development. They also did not, as politicians, adequately estimate the impediments which ignorance, prejudice and interested opposition present to enlightened statesmanship.

The physiocratic system, after guiding in some degree the policy of the Constituent Assembly, and awakening a few echoes here and there in foreign countries, soon ceased to exist as a living power; but the good elements it comprised were not lost to mankind, being incorporated into the more complete construction of Adam Smith.

Physiognomy, the English form of the middle Greek φυσιογνωμία, a contraction of the classical Φύσις, nature, and γνωμή, an interpreter, (1) a term which denotes a supposed science of the discovery of the dispositions of the body by the lineaments of the body "(Racon); (2) is also used colloquially as a synonym for the face or outward appearance, being variously spelled by the old writers: *φυσιογνωμία* by Lydgate, *φησιογνωμία* in Udall's *translation of Erasmus on Mark iv., physiomyic in Bale's English Voyetaries* (i. 2. p. 44), and *ψηνομία* in All's *well that ends well*, iv. 5 (first folio).

Physiognomy was regarded by those who cultivated it as a twofold science: (1) a mode of discriminating character by the outward appearance, and (2) a method of divination from form and feature. On account of the abuses of the latter aspect of the subject its practice was forbidden by the English law. By the act of parliament of 17 George II. c. 5 (1743) all persons tending to have skill in physiognomy were deemed rogues and vagabonds, and were liable to be publicly whipped, or sent to the house of correction until next sessions. The pursuit thus stigmatized as unlawful is one of great antiquity, and one which in ancient and medieval times had an extensive though now almost forgotten literature. It was very early noticed that the good and evil passions by their continual exercise stamp their impress on the face, and that each particular passion has its own expression. Thus far physiognomy is a branch of physiology. But in its second aspect it touched divination and astrology, of which Galen 3 says that the physiognomical part is the greater, and this aspect of the subject bulked largely in the fanciful literature of the middle ages. There is evidence in the earliest classical literature that physiognomy formed part of the most ancient practical philosophy. Homer was a close observer of expression and of appearance as correlated with character, as is shown by his description of Thersites and elsewhere. Hippocrates, writing about 450 B.c., expresses his belief in the influence of environment in determining disposition, and in the reaction of these upon feature, 4 a view in which he is supported later by Trogus. Galen, in his work *Περί τῶν ὑπ’ ὑπώρηκον φυσικά*, having discussed the nature and immortality of the soul, proceeds in ch. vii. to a brief study of physiognomy (ed. Kühn iv. 795). In this work Galen makes several crude physiognomical speculations, saying that he might criticize them but feared to waste time and become tedious over them. In chapter viii. he quotes with approbation the Hippocratic doctrine referred to above; 2 and

2 The Act 39 Elizabeth c. 4 (1597-1598) declared "all persons fayning to have knowledge of Physionomie or like fantastical Ymaginacie" liable to be stripped naked from the middle upward and openly whipped till the body be bloomed by physiognomical speculation, which was revised by 13 Anne c. 26 (1715), still further by 17 George II. c. 5, which was re-enacted by the Vagrancy Act 1824. This last act only specifies palmistry.

*Περὶ ακταλαῖῶν προφητικαί* (ed. Kühn xix. 530).

7 *Περὶ ακταλαῖῶν προφητικαί* (ed. Kühn xix. 530).

8 See also Blackwell's *Inquiry*, (2nd ed 1756), p. 330.

The practice of physiognomy is alluded to in many of the Greek classics. Apion speaks of the meteorscopists, who judge by the appearance of the face, and CLEANthes the Stoic says it is
possible to tell habits from the aspect (cf. Ecclus. xix. 29, 30). Poleman (c. A.D. 150) compiled a treatise (published 1524, in Latin) on the subject, similar in character but inferior to Aristotle, yet he excels in graphic descriptions of different dispositions, and differs only from Aristotle in some of his animal comparisons. A more important work was written by a converted Jew, Adamantius, about A.D. 415. This is in two books, the first on the expression of the eye, the second on physiognomy in general, mostly Aristotelian in character.

Among the Latin classical authors Juvenal, Suetonius and Pliny in well-known passages refer to the practice of physiognomy, and numerous allusions occur in the works of the Christian Fathers, especially Clement of Alexandria and Origen (for example, the familiar passage in his work against Celsus, i. 35).

While the earlier classical physiognomy was chiefly descriptive, the later medieval authors particularly developed the predictive and astrological side, their treatises often digressing into chiro- mancy, onychomancy, clidomancy, podoscopy, spasmatomancy, and other branches of prophet-like lore and magic.

Along with the medical science of the period the Arabs contributed to the literature of physiognomy; 'Ali b. Ragel wrote a book on naevi; Rhazes (1040) devoted several chapters to it; and Averroes (1153) made many references to it in his De sanitate, p. 82 (Lelden, 1537). Avicenna also makes some acute physiognomical remarks in his De animis et animalibus, which was translated by Michael Scot about 1270. Among medieval writers Albertus Magnus (born 1205) devotes much of the second section of his De animalibus to physiognomy; but this chiefly consists of extracts from Aristotle, Poleman and Loxus. He does not enter into the animal comparisons of his predecessors, but occupies himself chiefly with simple descriptive physiognomy as indicative of character; and the same is true of the scattered references in the writings of Duns Scotus and Thomas Aquinas. The famous sage of Bologna, Michael Scot, while court astrologer to the emperor Frederick II., wrote his treatise De hominis phisiosignia, much of which is physiological and of curious interest. It was probably composed about 1272, but not printed until 1477. This was the first printed work on the subject. Physiognomy also forms the third part of his work De secretis naturae. In 1535 Pietro d'Abano delivered in Paris a course of lectures on this subject (afterwards edited by Blondus, 1544), a few years before he was burned for heresy.

The 16th century was rich in publications on physiognomy. The works of the classical authors before mentioned were printed, and other treatises were published by John de Indagine, Cocles, Andreas Corpus, Michael Blondus, Janus Cornaro, Anselm Duociel, Pomponius Ronscucus, Gratardus, Lucas Gauricus, Tricassus, Cardanus, Taisniers, Magnus Hund, Rothman, Johannes Padovanus, and, greatest of all, Giambattista della Porta. The earliest English works were anonymous: On the Art of Foretelling Future Events by Inspection of the Hand (1504), and A Pleasant Introduction to the Art of Chirocranie and Physiognomy (1588). Dr Thomas Hill's work, The Contemplation of Man byke, containing a singular Discourse after the Art of Physiognomy, published in 1571, is a quaintly written adaptation from the Italian authors of the day. The undated book on moles and naevi by "Merlin Britannicus," after the model of 'Ali ibn Ragel, is of about the same date.

The development of a more accurate anatomy in the 17th century has caused the manner in which interest in physiognomy, by substituting fact for fiction; and consequently the literature, though as great in quantity, became less valuable in quality. The principal writers of this age were T. Campanella, R. Cocolanus, Clement, Timpler, J. E. Gallmard, Moldanaria, Septalibus, Saunders, C. Lahr (a precursor of Charles Bell), Elsholz, de la Bellière, J. Evelyn (in the appendix to Numismatic), Baldus, Bulwer (in his Pathyromotomia), Fuchs, Spontoni, Ghiradelli,

1 For Scriptural allusions to physiognomy see Vecchius, Observationes in dtt. script. (Naples, 1641). Other classical references are contained in the Prooemium to the 1593 edition of the works of Baptista Portae.

Chiaramonti, A. Ingegneri, Finella, De la Chambre, Zanardus, R. Fludd, and others of less importance.

The 18th century shows a still greater decline of interest in physiognomy. Historians of philosophy, like J. Meursius and Franz, re-edited some of the classical works, and G. G. Fülleborn reviewed the relation of physiognomy to philosophy. Indeed, the only name worthy of note is that of J. K. Lavater (q.v.). The other authors of this century were Peuschen, Spon, Schutz, Wegelin, J. Pernetti, Girtanner, Grohmann, and several anonymous writers, and from the anatomical side G. M. Lancisi, J. Parsons and Peter Camper. The popular style, good illustrations and pious spirit pervading the writings of Lavater have given to them a popularity they little deserved, as there is no system in his work, which chiefly consists of rhetorical comments upon the several portraits. Having a happy knack of estimating character, especially when acquainted with the histories of the persons in question, the good pastor contrived to write a graphic and readable book, but one much inferior to Porta's or Aristotle's as a systematic treatise. The treatises of Nicolai and of Lichtenberg were written to refute his theory. With Lavater the descriptive school of physiognomists may be said to have ended, as the astrological physiognomy expired with de la Bellière. The few works which have since appeared, before the rise of the physiological school of Sir Charles Bell and Charles Darwin, are undeserving of notice, the development of phrenology and having shown itself to be far from satisfactory by taking into itself whatever was likely to be alive of the older school. The writers of the 19th century are Hörstig, Mann, Rainer, Thoné, A. Stöhr, Scheler, Dr Rubel's, Polli, Cardona, Mastráini, Diez, Carus, Pifferit, Burgess and P. Gratialet.

The physiological school of physiognomy was foreshadowed by Parsons and founded by Sir Charles Bell, whose Essay on the Anatomy of the Expression, published in 1806, was the first scientific study of the physical manifestation of emotions in the terms of the muscles which produce these manifestations. In the later editions of this essay the thesis is elaborated with greater detail. Moreau's edition of Lavater, in 1807, was somewhat the same as the old lines. In 1809 Dr Conolly of Glasgow wrote his defence of a scientific physiognomy based on general physiological principles. The experiments of G. B. A. Duchenne (Mécanisme de la physiognomie humaine, Paris, 1862) showed that by the use of electricity the action of the separate muscles could be studied and by the aid of photography accurately represented. These observations confirmed by experimental demonstration the hypothetical conclusions of Bell. The machinery of expression having thus been indicated, the connexion of the physical actions and the psychical state was made the subject of speculation by Herbert Spencer (Psychology, 1855). These speculations were reduced to a system by Darwin (Expression of Emotions, 1872), who formulated and illustrated the following as fundamental physiological principles:

1 Certain complex acts are of direct or indirect service, under certain conditions of the mind, in order to relieve or gratify certain sensations or desires; and whenever the same states of mind are induced the same sets of actions tend to be performed, even when they have ceased to be useful. (2) When a directly opposite state of the mind is induced to a direct act with which it is connected, there is a strong and involuntary tendency to perform a reverse action. (3) When the sensorium is strongly excited nerve-force is produced in excess, and is transmitted in different directions, depending on the connexions of nerve-cells and on habit.

The last of these propositions is adversely criticized by P. Mantegazza as a truism, but it may be allowed to stand with the qualification that we are ignorant concerning the nature of the influence called "nerve-force." It follows from these propositions that the expression of emotion is, for the most part, not under control of the will, and that those striped muscles are the most expressive which are the least voluntary. To the foregoing may be added the following three additional propositions, so as to form a more complete expression of a physiological philosophy:

(4) Certain muscles concerned in producing these skin-folds become strengthened by habitual action, and when the skin diminishes
PHYSIOLOGUS

in elasticity and fluidness with advancing age, the wrinkles at right angles to the course of the muscular fibres become permanent. (5) To some extent habitual muscular action of this kind may, by affecting local nutrition, alter the contour of such bones and cartilages as are related to the muscles of expression. (6) If the mental dispositions and peculiar actions are inherited by children from their parents, it may be that the facility in, and disposition towards, certain forms of expression are like in manner matters of heredity.

Illustrations of these theoretic propositions are to be found in the works of Bell, Duchenne and Darwin, and in the later publications of Theodor Piderit, Mimike and Physiognomik (1886) and Mantegazza, Physiognomy and Expression (1890), to which the student may be referred for further information.

Information on artistic anatomy as applied to physiognomy see the catalogue of sixty-two authors by Ludwig Chouiant, Geschicht und Bibliographie der anatomischen Abhandlungen, etc. (Leipzig, 1852), and the works of the authors enumerated above, especially those of Aristotle, Franz, Porta, Cardan, Corvis and Bulwer. For physiognomy of disease, besides the usual medical handbooks, see Cabuchet, Essai sur l’expression de la face dans les maladies (Paris, 1801); Mantegazza, Physiognomy and Pain (1893); and Polli, Saggio di fattanomonia e poligonomia (1837). For ethnological physiognomy, see amongst others Gratirical, and amongst moderns the writers cited in the various texts on anthropology, especially Schade, Physiognomy and Race (Paris, Harms, Anthrop, Inst.) (1836-1839). The study of the physical characteristics of criminals is discussed at great length by Lombroso, L’Uomo deforme (1897); Ferri, L’Omicidio (1895); and Baer, Der Verbrecher in seinen Haussituationen (1890), and Harrison, The Criminal (1901). (A. MA.)

PHYSIOLOGUS, the title usually given to a collection of some fifty Christian allegories much read in the middle ages, and still existing in several forms and in about a dozen Eastern and Western languages. As nearly all its imagery is taken from the animal world, it is also known as the Bestiary. There can be hardly a doubt about the time and general circumstances of its origin. Christian teachers, especially those who had a leaning towards Gnostic speculations, took an interest in natural history, partly because the passages of Scripture that they wanted to explain, and partly on account of the divine revelation in the book of nature, of which also it was man’s sacred duty to take proper advantage. Both lines of study were readily combined by applying to the interpretation of descriptions of natural objects the allegorical method adopted for the interpretation of Biblical texts. Now the early Christian centuries were anything but a period of scientific research. Rhetorical accomplishments were considered to be the chief object of a liberal education, and to this end every kind of learning was made subservient. Instead of reading Aristotle and other naturalists, people went for information to common books of Oriental and Arabian folklore, folk-tellers’ tales and fragments of missapplied science were set forth in an elegant style. Thus theological writers were not the least prepared to test the worth of the marvellous descriptions of creatures that were current in the schools on the faith of authorities vaguely known as “the history of animals,” “the naturalists,” and “the naturalist” in the singular number (φυσιολόγος).1 So they took their notions of strange beasts and other marvels of the visible world on trust and did their best to make them available for religious instruction. In some measure we find this practice adopted by more than one of the Fathers, but it was the Alexandrian school, with its pronounced taste for symbolism, that made the most of it. Clement himself had declared that natural lore, as taught in the course of higher Christian education according to the canon of truth, ought to proceed from “cosmogony” to “the theological idea,” and even in the little that is left of the works of Origen we have two instances of the proceeding in question. And yet the fact that these reappear in the Physiologus would not suffice to stamp the work as a series of extracts from Alexandrian writings, as parallels of the same kind can be adduced from Epiphanius (loc. cit.) and Eusebius Syrus (Off. Syr. ii. 17, 136). Father Cahier would even trace the book to Tatian, and it is true that that heresiarch mentions a writing of his own upon animals. Still, the context in which the quotation occurs makes it evident that the subject-matter was not the nature of particular species nor the spiritual lessons to be drawn therefrom, but rather the place occupied by animal beings in the system of creation. On the other hand, the opinion of Cardinal Pitra, who referred the Physiologus to the more orthodox though somewhat peculiar teaching of the Alexandrians, is fully borne out by a close examination of the irregularities of doctrine pointed out in the Physiologus by Cahier, all of which are to be ascribed with in Origen. The technical words by which the process of allegorizing is designated in the Physiologus, like ἄνθρωπος, θεωρία, ἀναγωγή, ἀλληγορία, are familiar to the students of Alexandrian exegesis. It has, moreover, been remarked that almost all the animals mentioned were at home in the Egypt of those days, or at least, like the elephant, were to be seen there occasionally, whereas the structure of the hedgehog, for instance, is explained by a reference to the sea-porcupine, better known to fish-buyers on the Mediterranean. The fables of the phoenix and of the conduct of the wild ass and the ape at the time of the equinox owe their origin to astronomical symbols belonging to the Nile country.2 In both chapters an Egyptian meaning is named, and elsewhere the antelope bears its Coptic name of “anthelope.”

That the substance of the Physiologus was borrowed from commentaries on Scripture is confirmed by many of the sections opening with a text, followed up by some such formula as “but the Physiologus says.” When zoological records failed, Egyptian-Hellenic ingenuity was never at a loss for a fanciful invention distilled from the text itself, but which to succeeding copyists appeared as part of the teaching of the original Physiologus. As a typical instance we may take the chapter on the ant-lion—not the insect, but an imaginary creature suggested by Job, iv. 11. The exceptional Hebrew for a lion (בָּשָׂם) appeared to the Septuagint translators to call for a special rendering, and as there was said to exist on the Arabian coast a lion-like animal called “myrmex” (see Strabo xvi. 774; Aelian, N.A., vii. 47) they ventured to give the compound noun “myrmekoleon.” After so many years the commentators had lost the key to this unusual term, and only knew that in common Greek “myrmex” meant an ant. So the text “the myrmekoleon hath perished for that he had no nourishment” set them pondering, and others reproduced their meditations, with the following result: “The Physiologus relates about the ant-lion—that his father hath the shape of a lion, his mother that of an ant; the father liveth upon flesh, and the mother upon ant-lion, a compound of both, and in part like to either, for his fore part is that of a lion, and his hind part like that of an ant. Being thus composed, he is neither able to eat flesh like his father, nor herbs like his mother; therefore he perished from inanition”; the moral follows.

At a later period, when the Church had learnt to look with suspicion upon devotional books likely to provoke the scoffing of some and lead others into heresy, a work of this kind could hardly meet with her approval. A synod of Pope Gelasius, held in 496, passed censure, among others, on the “Liber Physiologus, qui ab haeresicis conscriptus est et B. Ambrosii nomine signatus, apocryphus,” and evidence has even been offered that a similar sentence was pronounced a century before. Still, in spite of such measures, the Physiologus, like the Church History of Eusebius or the Pastor of Hermas, continued to be read with general interest, and even Gregory the Great did not disdain to allude to it on occasion. Yet the Oriental versions, which had certainly nothing to do with the Church of Rome, show that there was no systematic revision made according to the Catholic

3 Including the Apocrypha. See the Icelandic account of the elephant, also a decidedly Alexandrian fragment upon the μύργας, found upon 4 Mac. i. 5, which has gone into the scholia upon the Odyssey xviii. 2 (Sti. 533, ed. Dindorf, Oxford, 1855).
PHYSIOLOGUS 553

standard of doctrine. The book remained essentially the same, albeit great liberties were taken with its details and outward form. There must have been many imperfect copies in circulation, from which people transcribed such sections as they found or chose, and afterwards completed their MS, as occasion served. Some even rearranged the contents according to the alphabet or to zoological affinity. So little was the collective consciousness as a literary work with a definite text that every one assumed a right to abridge or enlarge, to insert ideas of his own, or fresh scriptural quotations; nor were the scribes and translators by any means scrupulous about the names of natural objects, and even the passages from Holy Writ. Physiologus had been abandoned by scholars, and left to take its chance among the tales and traditions of the uneducated mass. Nevertheless, or rather for this very reason, its symbols found their way into the rising literature of the vulgar tongues, and helped to quicken the fancy of the artists employed upon church buildings and furniture.

The history of the Physiologus has become entwined from the beginning with that of the commentaries on the account of creation in Genesis. The principal production of this kind in our possession is the Hexaemeron of Basil, which contains several passages very like those of the Physiologus. For instance, in the seventh homily the fable of the nuptials of the viper and the conger-eel, known already to Acian and Oppian, and proceeding from a curious misreading of Aristotle (Hist. An. v. 4, § 40 b, Bekk.), serves to point more than one moral. Notwithstanding the difference in theology, passages of this kind could not but be welcome to the admirers of the Alexandrian allegories. In fact a medley from both Basil and the Physiologus exists under the title of the Hexaemeron of Eustathius; some copies of the first bear as a title Περὶ φυσιολογίας, and in a Milan MS. the "morals" of the Physiologus are ascribed to Basil. The Leyden Syriac is supplemented with literal extracts from the latter, and the whole is presented as his work. Other copies give the names of Gregory Theologus, Epiphanius, Chrysostom and Isidore.

As far as can be judged, the emblems of the original Physiologus were the following: (1) the lion (footprints rubbed out with tail; sleeps with eyes open; cubs receive life only three days after birth by their father's breath); (2) the sun-lizard (restores its sight by looking at the sun); (3) the charadrius (Deut. xiv. 16; presses recovery or death of parents); (4) the ass (calls it into life by its own blood); (5) the owl (or nyktis kores, loves darkness and solitude); (6) the eagle (renews its youth by sunlight and bathing in a fountain); (7) the phoenix (revives from fire); (8) the hoopoe (redeems its parents from the isles of old age); (9) the wild ass (suffers no male besides itself); (10) the viper (born at the cost of both its parents' death); (11) the serpent (sheds its skin; puts aside its venom before drinking; is afraid of man in a state of nudity; hides its head and abandons the rest of its body); (12) the ant (orderly and laborious; prevents stored grain from germinating; distinguishes wheat from barley on the stalk); (13) the sirens and onocentara (Isa. xlvi. 21, 22; compound creatures); (14) the hedgehog (pricks grapes upon its quill); (15) the cock (or watchful, stimulating death); (16) the panther (spotted skin; enmity to the dragon; sleeps for three days after meals; allures its prey by sweet odour); (17) the sea-tortoise (or aspidochelone; mistaken by sailors for an island); (18) the partridge (hatches eggs of other birds); (19) the vulture (assisted in birth by a stone with loose kernel); (20) the ant-lion (able neither to take the one food nor digest the other); (21) the weasel (conceals by the mouth and brings forth by the ear); (22) the unicorn (caught only by a virgin); (23) the beaver (gives up its tests when pursued); (24) the hyaena (a herald of death); (25) the otter (hydris; enters the crocodile's mouth to kill it); (26) the ichno (covers itself with mud to kill the dragon; another version of No. 25); (27) the crow (takes but one zoological name, its life); (28) the turtle-dove; same nature as No. 27; (29) the frog (either living on land and brought by rain, or in the water without ever seeing the sun); (30) the stag (destroys its enemy the serpent); (31) the salmonander (quenches fire); (32) the diamond (powerful against all danger); (33) the swallow (brings forth both but once; misleading of Aristotle, Hist. An. v. 13); (34) the tree called periconex (protects pigeons from the serpent by its shadow); (35) the pigeons (of several colours; led by one of them, which is of a purple or golden colour); (36) the antelope (or hydriopus; caught by its horns in the thicket); (37) the fire-fly (of two sexes, one green, the other red); (38) the mandrake (adheres to iron); (39) the saw-fish (sails in company with ships); (40) the ibis (flies only along the shore); (41) the ibex (descres a hunter from afar); (42) the diamond again (read "carbuncle"); found only by night; (43) the elephant (conceives after partaking of mandrake; brings forth in the water; the young protected from the serpant by the father; when fallen is lifted up only by a certain small individual of its own kind); (44) the agate (employed in pearl-fishing); (45) the wild ass and ape (mark the equinoxx); (46) the Indian stone (relieves patients of the dropsy); (47) the heron (fouches no dead body, and keeps to one dwelling-place); (48) the sycamore (or wild frg; grubs living inside the fruit and coming out); (49) the ostrich (devours all sorts of things; forgetful of its own eggs). Besides these, or part of them, certain copies contain sections of unknown origin about the bee, the stork, the tiger, the woodpecker, the spider and the wild boar.

The Greek text of the Physiologus exists only in late MSS., and has to be corrected from the translations. In Spanish there are full copies of 15th-century MSS., published in J. P. N. Land's Aeneodata syriaca: thirty-two chapters with the "morals" left out in a very late Vatican copy, published by Tychsen; and about the same number later in a large Latin MS. in British collections. In Armenian Pitta gave some thirty-two chapters from a Paris MS. (13th century). The Aethiopic exists both in London and Paris, and was printed at Leipzig by Dr Hommel in 1877. In Arabic we have fragments at Paris, or portions of which remained for the Spicilegium solemens, and another version of thirty-seven chapters at Leiden, probably the work of a monk at Jerusalem, which Land translated and printed with the Syriac. The Latin MSS. of which are, after all, only a fragment of the work for the Speculum naturale; and several copies in theological works are to be found in Grein's Bibliothek, vol. i. The Provençal (c. 1520), published in Bartsch's Christomathia provencal, omits the "morals," but is remarkable for its peculiarity of form. But the most curious is a text preserved by Philippe de Thau (1121), by Guillaume, "clerc de Normandie," also, about the same period, by Pierre, a clergyman of Picardy. All the Old-French materials have not yet been thoroughly examined, and it is likely that some of those versions of the book either remain to be detected or are now lost past recovery. A full account of the history of the Physiologus should also embrace the subjects taken from it in the productions of Christian art, the parodies suggested by the original work, e.g. the Bestiaire d'amour by Richard de Fournival, and finally the traces left by it upon the encyclopaedic and literary work of the later middle ages.

PHYSIOLOGY

from Gr. φύσις, nature, and ἀγγείος, discourse, the science or theory of the properties, processes and functions of living organisms. Physiology is distinguished from anatomy as being primarily with the functions of an organism, rather than its structure. The two main branches of the science are animal and plant (vegetable) physiology, and in animal physiology that of man stands out as primarily associated with the word.

Ever since men began to take a scientific interest in the problems of life two distinct rival explanatory principles of vital phenomena have claimed attention: a natural and a mystical principle. The first outcome of the scientific attempt to explain vital phenomena adopted the natural method and by a unitary principle was the doctrine of the Pneuma, held by the followers of Hippocrates, which found its clearest expression in Galen's system. According to this doctrine, the origin of all vital phenomena was a very fine substance, the Pneuma, which was supposed to exist in atmospheric air, to be inhaled into the lungs of man, and thus through the blood to reach all the parts of the body, where it produced vital phenomena. This doctrine—an attempt to explain the phenomena of life which was not altogether natural, but even materialistic—was accepted by the middle ages together with Galen's system. With its translation into the Latin spiritus, however, the conception of the Pneuma lost its original force. The spiritus animales of the middle ages developed into mystical powers, the result being the explanation of vital phenomena by a supernatural theory. Not until the scientific renaissance of the 16th and 17th centuries did views again undergo a change. After the establishment of a scientific method in physiology by William Harvey, and the development of Descartes' mechanical system of regarding living bodies, the natural explanation of vital phenomena once more universally found favour. Two schools arose, which endeavoured by dissimilar methods to find a mechanical explanation of vital phenomena: the tautophysical, originating with the gifted and versatile Borelli, and the sartulichemical, founded by the Dutchman, F. de la Boë (Sylvius). But when both chemical and physical methods of explanation failed at such problems as, for instance, irritability and evolution, another change in opinion took place. By degrees there emerged once more the tendency to explain vital phenomena by mystical means, finding expression in the Animism of Stahl, to quote an example; and in the second half of the 18th century Vitalism, originating in France, began its victorious march throughout the whole scientific world. Again the opinion came to be entertained that the cause of vital phenomena was a mystical power (force hypermécanique)—that "vital force" which, neither physical nor chemical in its nature, was held to be active in living organisms only. Vitalism continued to be the ruling idea in physiology until about the middle of the 19th century, and its supremacy was only gradually overthrown by the great discoveries in natural science of that century. The chemical discoveries resulting from Wöhler's synthesis of urea first showed that typical products of the animal body, the production of which had hitherto been supposed to be solely the result of the operation of vital force, could be obtained artificially by purely chemical methods. Then above all came the discovery of the law of the Conservation of Energy by Robert Mayer (1814-1878) and Hermann von Helmholtz (1821-1894), and its application to the living organism by Mayer, Helmholtz, Pierre Louis Dulong (1785-1838), Edward Frankland, Max Rubner and others, to prove that the manifestations of energy by the organism are simply the result of the quantity of potential energy received into the body by means of food. Finally, the stupendous results arrived at by Darwin and the establishment of the fundamental law of "biogenesis" by Ernst Haeckel, prepared the way for a natural explanation of the enigma of evolution and structure of organisms. Thus by the second half of the 19th century the doctrine of vital force was definitely and finally overthrown to make way for the triumph of the natural method of explaining vital phenomena, which down to this time had continued to spread and flourish with an unparalleled fertility. It would, it is true, appear as if in our day, after the lapse of half a century, mystical tendencies were again disposed to crop up in the investigation of life. Here and there is heard once more the watchword of Vitalism. But all the so-called neo-vitalistic efforts—such as those of Alexander von Bunge (1803-1890), Georg Evon Kindleisch (b. 1835), Johannes Reinke (b. 1849) and others—have nothing to do with the old Vitalism. They originate solely in a widespread confusion with regard to the boundaries of natural science, their principal tendency being to amalgamate psychological and speculative questions with problems of purely natural science. In the face of all these efforts, which by their unfortunate designation of Vitalism and Neo-vitalism give rise to entirely false conceptions, and which by their intermingling of psychological questions and questions of natural science have led to mere confusion in research, it is essential that natural philosophy should be called upon to realize its own limits, and above all clearly to understand that the sole concern of physical science is the investigation of the phenomena of the material world. Physiology, as the doctrine of life, must therefore confine itself to the material vital phenomena of organisms. It is self-evident, however, that only such laws as govern the material world will be found governing material vital phenomena—the laws, that is, which have hitherto been brought to their most exact and most logical development by physics and chemistry, or, more generally speaking, by mechanics. The explanatory principles of vital phenomena must therefore be identical with those of inorganic nature—that is, with the principles of mechanics.

The investigation of vital phenomena in this sense requires, in the first place, an exact knowledge of the substratum in which these phenomena are manifested, just as in chemistry' Ultimate and physics a thorough knowledge of the composition Elements of of the material world is a necessary premise to the investigation of the phenomena of inorganic nature. The knowledge of the composition and structure of organisms has in the course of the scientific development of anatomy attained an ever-increasing minuteness of detail, without having as yet reached a definite limit. The last important step in this direction was the discovery by Matthias Jakob Schleiden (1804-1881) and Theodor Schwann (1810-1882) that all organisms are built up of elementary living structural components, namely of cells (see CYTOLOGY). The details of the anatomical construction of organisms are described under various appropriate headings, and a general guide to these will be found under ANATOMY and ZOOLOGY. We would here merely point out that a cell is the simplest particle of living substance which appears to be permanently capable of life. Different elements are essential, however, to the existence of the cell—two, at least, so far as has hitherto been discovered—the protoplasm and the nucleus. It must at present be regarded as at least very doubtful whether the centrosome, which in recent times it has been possible to demonstrate as existing in very many cells, and which appears sometimes in the protoplasm, sometimes in the nucleus, is a general and third independent cell-constituent. On the other hand, the number of special constituent parts which appear in various cell-forms is very large. A question which has long been discussed, and which has received special and animated attention, is that with regard to the finer structure of the cells—with regard, that is, to the protoplasm and the nucleus lying in it. Views on this subject have diverged very widely, and several totally diverse theories have been opposed to one another. One theory maintains that the living cell-substance has a reticular structure; another, that it is fibrillous. According to a third theory, the essence of the construction of the cell-substance lies in the granules which it contains; and according to a fourth, it lies in the ground-substance in which these granules are embedded. One view holds this ground substance to be homogeneous, another regards it as possessing a fine foam-structure. It may at present be regarded as
incontrovertible that living substance is more or less fluid, and
that there does not exist any general structure for all cell-forms. But
in some special cases all the theories which have been quoted are to
a certain extent correct. In different cells there are reticular, fibrillar
and granular differentiations respectively, and differentiations in
fossil-structure; in many cells, however, the protoplasm appears to be
beyond doubt homogeneous and without a distinct structure, and only under certain
conditions to assume changing structures. But the fact which is of most
importance for the right understanding of vital phenomena is that the cell-substance is always more or less fluid, for only
in a fluid substratum can such intense chemical processes be
enacted as are to be found in every living cell.

Where the analytical powers of the microscope in anatomy can go no farther, chemical analysis of the composition of the cell steps in. By its means the discovery is made that there is
no elementary difference between organic and inorganic nature, for
only such chemical elements as are known to exist in the
inorganic world are found in the organic. On the other hand,
however, the living cell-substance possesses chemical compounds
which find analogues nowhere in inorganic nature. The character-
istic organic substances which are present in every cell are
proteids and protid-comounds. Besides these there occur,
widely disseminated, carbohydrates, fats and other organic
substances, which partly originate in the decomposition of
proteids and their compounds, and are partly used for their
construction. Lastly, there are in addition great quantities of
water and some inorganic salts.

Such are the structure and composition of the substratum in
which vital phenomena play their part. When we consider
vital phenomena themselves in the various living organisms—prosta, plants, animals—there
appears an incalculable diversity of phenomena.

Here, however, as in the case of the structure of organisms, we
have to analyse and to penetrate ever farther and deeper
till we reach the fundamental phenomena. We then find that
the great variety of vital manifestations can be traced
back to a few fundamental general groups, which are precisely
the same groups of phenomena as those to be observed in
inorganic nature. All the processes that take place in the organic
world may be regarded from the three different standpoints of
their changes in substance, in energy and in form; for substance,
energy and form are all necessary to our conception of matter.

Accordingly, the general elementary vital phenomena likewise
fall into three groups—metabolism, the mechanism of energy,
and the assumption of form. Every cell, so long as it is living,
takes in certain substances from its environment, submits them
to chemical transformation in its interior, and gives out other
substances. This metabolism is manifested in several special
functions—in nutrition and digestion, respiration and circula-
tion, secretion and excretion. The essence of the whole
process is the fact that while out of these ingested stuffs
living substance is always again being formed by the living
substance which already exists, it is itself continually under-
going decomposition, and the products of this decomposition
are what the cell gives off again to the outside. With
metabolism, however, there is inseparably associated a
transformation of energy. These substances taken in by
the cell contain a large quantity of potential energy, which is
transformed into kinetic energy. This has for its result the
manifold activities of the organism, more especially motion, heat,
electricity and light. Finally, the chemical transformations in
living substance may also manifest themselves outwardly in
change of form; in the case generally in the matter of growth,
reproduction and development. The three general elementary
groups of vital phenomena are therefore in reality merely the
expression of the various aspects of one and the same process
—of the actual vital process itself. The ultimate object
of all physiology is to discover what this vital process is—that
is to say, what is the exact cause of these manifold vital
phenomena—a goal from which it is at the present day still very
remote.

As every physical and chemical phenomenon of inorganic
nature occurs only under distinct conditions, so vital phenomena
are also dependent upon certain conditions of life.

Every living body, every living cell, requires food, water,
oxygen, and, further, a certain temperature and a certain pressure in its environment. These are the general
conditions of life. But the special conditions on which depends
the continued existence of the individual forms of organisms are as
numerous as the forms of organisms themselves. Now, just as
the physicist or chemist varies those conditions under which a
phenomenon occurs in order to get at its causes, so does the
physiologist try to experiment with vital phenomena, altering
the vital conditions: and testing the changes which are thereby
produced. The great importance of this method consists in the
power it gives the experimenter of analysing vital phenomena
systematically from definite points of view. Every change in
its normal vital conditions which produces any effect whatever
upon an organism is termed a stimulus. This is the only general
definition we have for a conception which is of such vast
importance to physiology. According to it, experimental physiology is
tirely a physiology of stimuli. It further follows from
this conception of stimulation that there must be an enormous
multiplicity of stimuli, since each particular vital condition
may be subjected to some change capable of acting upon it as a
stimulus. But, besides this, other factors may be brought to bear
upon organisms which have absolutely no place among their
vital conditions; for instance, many chemical reagents and
currents. These influences come under the general
definition of stimulus, because they likewise imply a change
in the conditions under which the organism lives. From their
qualitative nature stimuli are distinguished as chemical, thermal,
photic, mechanical and electrical. Each of these several
varieties may, however, be applied quantitatively in various
degrees of intensity, and may in consequence produce quite
different results. This opens up to experimental physiology a
vast field of research. But the physiology of stimulation is
not only of the greatest value as a means of research: its
importance is much increased by the fact that in nature itself
stimuli are everywhere and constantly acting upon the
organism and its parts. Hence the investigation of their
action comes to be not merely a means, but a direct end of
research.

Although it is not at present possible to define all the laws that
govern stimulation, on the one hand because the number of
stimulating effects known to us in the whole organic
world is as yet too limited, and on the other because
those already known have not yet been thoroughly
analysed, yet it is within our power to classify stimula-
ting effects according to their various characteristics, and
to ascertain a few facts concerning their general and funda-
mental conformity to law. The first fact, apparent at a glance at a great many of the various forms of stimulation,
is that all their effects are manifested in either a
quantitative or a qualitative alteration of the characteristic vital
phenomena of each living object. The quantitative is the
usual mode of action of stimuli. It is generally found that a
stimulus either increases or diminishes the intensity of vital
phenomena. In the first case the effect is one of excitation; in
the second of depression. It is the more important to bear in
mind this twofold operation of stimuli, owing to the fact that
in former times physiologists were very apt to conceive of
excitation and stimulation as identical. It is now, however, an
undisputed fact that depression may also occur as a typical effect
of stimulation. This is most apparent in cases where the same
stimulus that produces excitation may on being applied for a
longer period and with greater intensity, produce depression.
Thus narcotics (alcohol, ether, chloroform, morphia, &c.) on
certain forms of living substance produce the phenomena of
excitation when their action is weak, whereas when it is stronger
they produce complete depression. Thus, likewise, temperature
stimuli act differently upon vital phenomena according to the
degree of temperature: very low temperatures depressing,
medium temperatures exciting with increasing intensity, and higher temperatures from a certain height upwards again depressing. The effects of stimulation are not, however, always manifested in merely quantitative changes of the normal vital phenomena. Sometimes, especially in the case of long uninterrupted and chronic stimuli, stimulation is found gradually to produce phenomena which are apparently quite foreign to the normal vital phenomena of the cell in question. Such qualitative alterations of normal vital phenomena are perceptible chiefly in chronic maladies in the cells of different organs (the heart, liver, kidneys, spleen, etc.), in which the vital conditions become gradually more and more modified by the cause of the malady. To this category pertain all the so-called chronic processes of degeneration which in pathology are known as fatty degeneration, mucous degeneration, amyloid degeneration, and so forth. The characteristic element in all these processes is that the normal metabolic processes are divested into a strong current due to the altered vital conditions of the cells of the organ affected, so that substances are formed and accumulated in the cell which are entirely foreign to its normal life. But this class of stimulation is still very obscure as regards causes and inner processes, and it is within the range of possibility that the ultimate cause of the qualitative changes in the normal metabolism is to be found simply in the processes of excitation and depression which chronic stimulation produces in separate parts of the metabolism. Thus, at least with regard to fatty-metamorphosis (fatty degeneration), it is highly probable that fat is deposited in the protoplasm simply because, owing to an inadequate supply of oxygen, it cannot when it originates, be oxidized in the same proportion as it is formed, whereas in the normal cell all fat which originates in metabolism is consumed as soon as it is produced. According to this conception, therefore, fatty degeneration is attributable primarily to a depression of the processes of oxidation in the cell. If we may accept this view as correct with regard to the other metamorphic processes also, the qualitative changes in vital phenomena under the influence of stimuli would after all depend simply upon the excitation or depression of the constituent parts of the vital process, and, according to such a view, all stimuli would act primarily only as exciting or as depressing agents upon the normal process of life.

In accordance with the three groups into which general vital phenomena are divided, it follows as a matter of course that the excitation or depression produced by a stimulus can manifest itself in the cell's metabolism, assumption of form, and manifestation of energy. The effects of excitation upon the production of energy are the most striking, and were therefore in former times frequently thought to have a claim par excellence to rank as stimulating effects. These reactions attract most attention in cases where the production of energy is proportionately very great—as with muscle, for instance, which is made to twitch and paddle when it is exposed to a strong process of discharge (Ausschlüssegange), however, lie at the bottom of cases like these. Potential chemical energy, which is stored up in a considerable quantity in living substance, is converted by the impulse of the stimulus into kinetic energy. Therefore the amount of the effect of stimulation—that is to say, the quantity of work performed—bears no proportion whatever to the amount of energy acting as a stimulus upon the muscle. The amount of energy thus acting may be very small as contrasted with an enormous production of energy on the part of the living substance. It will not do to make generalizations, however, with regard to this proportion as was frequently done in former times. All processes of stimulation are not processes of discharge. The influence of many stimuli, as has been observed, acts more in the way of depression than in excitation, so that in certain circumstances a stimulus actually diminishes the normal liberation of energy. There is therefore no general law as to the proportion which the amount of energy acting as a stimulus upon living substance bears to the amount of energy liberated.

Among special varieties of stimulation there is one class of stimuli which has attracted particular attention—namely, those which act unilaterally upon free-moving organisms. It is principally with the lowest forms of life that we have here to do—unicellular protista and free-living cells in the bodies of higher organisms (sperm-cells, leucocytes, etc.). When from one and the same stimulus—be it chemical, thermal, photic, electrical, or of any other kind—upon these organisms in their medium, they are impelled to move in a course bearing a definite relation to the source of the stimulus—either directly towards that source or directly away from it, more rarely in a course transverse to it. This directive action of stimulation is under such a fixed conformity to law, that it vividly recalls such purely physical processes as, for instance, the attraction and repulsion of iron particles by the poles of a magnet. For example, if light falls from one side upon a vessel full of water containing unicellular green algae, according to the intensity of the light these organisms swim either towards the illuminated side, where they form a compact mass on the edge of the vessel, or away from it, to cluster on the opposite edge. In the same way infusoria in water are observed to hasten towards or to flee from certain chemical substances, and leucocytes in our bodies act in the same manner towards the metabolic products of pus-forming bacteria which have penetrated into an open wound. The suppuration of wounds is always accompanied by an amazing conglomeration of leucocytes at the seat of the lesion. Perhaps the most striking effects are those of the constant electric current upon unicellular organisms, since in this case the motion follows the cause with absolutely automatic regularity, certainty and rapidity. Thus, for example, after the establishment of the current many infusoria (Paramecium) accumulate at the negative pole with great celerity and without deviation, and then return again with equal celerity as soon as the direction of the current is altered. As such cases of directive stimulation may occur among all varieties of stimuli whenever stimuli act unilaterally, they have been designated, according to the direction in which they occur in relation to the source of the stimulus, as positive or negative chemotaxis, phototaxis, thermotaxis, galvanotaxis, and so forth. The strange and perplexing element in these phenomena becomes clear to us as soon as we know the characteristic method of locomotion for each form of organism, and whether the stimulus in question in the given intensity exercises an effect of excitation or of depression upon the special form. The direction of motion is the essential mechanical result of unilateral stimulation of the organs of locomotion. Seeing that these reactions are exceedingly widely distributed throughout the whole organic world, and possess a deep biological significance for the existence and continuance of life, the interest they have awakened is thoroughly justified.

One of the most important physiological discoveries of the 19th century was that of the "Specific Energy of Sense-substances." Johannes Müller was the first to establish the fact that very different varieties of stimuli applied to one and the same organ of sense always produce one and the same variety of sensation, and that, conversely, the same stimulus applied to the different organs of sense produces a different sensation in each organ—the one, in fact, which is its specific attribute. Thus, for example, mechanical, electrical and photic stimuli applied to the optic nerve produce no other sensation than that of light; and, conversely, any one variety of stimulus—take the electrical, for example—produces sensations of light, hearing, taste or smell, according as it affects the optic, auditory, gustatory or olfactory nerves. This law of the "Specific Energy of Sense-substances," as Johannes Müller (1809-1875) called it, has come to have a highly important bearing upon scientific criticism, since it proves experimentally the things of the outer world are in themselves in no way discerned by us, but that we determine the same outward object—the electric current, or a mechanical pressure, for instance—we receive altogether different sensations and form altogether different conceptions according to the sense-organ affected. But this law does not possess significance for psychology alone; as regards physiology also it has a much more general and more comprehensive force than Müller ever anticipated. It holds good, as demonstrated by Ewald Hering (1834) and others,
not of sense-substances only, but of living substance generally. Each cell has its specific energy in Johannes Müller's sense, and in its extended form there is no more general law for all the operations of stimuli than this law of specific energy. To take examples, whether a muscle be stimulated by a chemical, mechanical, thermal or electrical stimulus the result is in each case the same—namely, a twitching of the muscle. Let a salivary gland be stimulated chemically, mechanically, electrically or in any other way, there always follows the same specific action—a secretion of saliva; no matter what be the kind of stimulus acting upon it, the liver-cell always reacts by producing bile, and so on. On the other hand, be it the same stimulus—the electric current, for example—gives in each form of living substance a specific result: twitching in the muscle, secretion of saliva in the salivary gland, production of bile in the liver-cell, &c. That is, of course, with the proviso that the effect of the stimulus be exciting and not depressing. The following general formulation, however, of the law of specific energy brings the depressing stimuli also within its scope: "Different stimuli produce in each form of living substance an increase or a diminution of its specific activity." As already observed, it will probably be found that those weak chronic forms of stimulation which produce qualitative changes may also be comprised under this general law.

The knowledge thus far acquired from analysis of vital phenomena and their changes under the influence of stimuli affords but a very indefinite temporary basis for the theory of the actual vital process itself, of which vital phenomena are the outward manifestation. The conceptions to which physiological research has hitherto attained in this matter are of a more or less doubtful nature. The facts contained in them still require to be linked together by hypotheses if we are to obtain even a vague outline of what lies hidden behind the great riddle of life. Such hypotheses, serving as they do to link facts consistently together, are absolutely essential, however, to the further progress of research, and without their aid any systematic investigation would be impracticable. But at the same time it must never be forgotten that these hypotheses are merely provisional, and that whenever they are found to be no longer in harmony with the widening range of new experiences and ideas they must either be proved to be facts or be subjected to modification. This is the point of view from which we must deal with modern ideas concerning the nature of the actual vital process—the mechanism of life.

The fundamental fact of life is the metabolism of living substance which is continually and spontaneously undergoing decomposition and reconstruction. It is this process which is called "life" and the help of the food-substances it takes in. These processes of decomposition and of reconstruction may be briefly designated as dissimilation (catabolism) and assimilation (anabolism) respectively. Now the question arises: How are we to understand this process of dissimilation and assimilation from a mechanical standpoint? It is quite evident that we have to do with some chemical occurrence; but how are the chemical transformations brought about? There are obviously two possibilities. It is conceivable that the decomposition of food-stuffs and the formation of excretion-products in the cell-body are caused by the repeated casual encounter of a great series of chemical combinations and by their repeatedly reacting upon one another in the same manner, bringing about transformations and forming waste products which are excreted, while at the same time certain chemical affinities are always taking in from without new chemical combinations (food-stuffs) and uniting them. This theory was in fact occasionally advanced in former times, particularly in its chemical aspect, and the belief was especially entertained that the enzymes in living substance might play an important part in these transformations. This assumption, however, leads to no clear and lucid image of what takes place, and, moreover, draws too largely upon auxiliary hypotheses. It has therefore met with but little acceptance. The other possible explanation of metabolism is that its whole process is confined to one single class of chemical combinations whose tendency it is to be constantly undergoing spontaneous decomposition and regeneration. This latter theory was founded by Ludimar Hermann (b. 1838), Eduard Friedrich Pfüger (b. 1829) and others, and has met with universal recognition because of its naturalness, simplicity and clearness.

Starting with this hypothesis, the path of further research lies clear and well defined before us. In the first place, we are obviously met by the question: What conception are we to form of these combinations on which hinges the whole vital process? Among the organic matters which compose living substance, proteids perform the most important part. These proteid-combonds form the only organic matter which is never absent from any cell. They form also the greater part of all the organic compounds of the cell, unless reserve-stuffs are accumulated to a considerable extent, and they are by far the most complicated of the compounds of living substance. While animal life is impossible without proteid food, there are, on the other hand, animals which can continue to subsist on proteid alone. This series of facts proves very conclusively that proteids and their compounds play by far the most important part of all organic matter in the processes of life. The idea thus naturally presents itself that the required hypothetical combination forming a new proteid molecule can be found to bear a very close relation to proteids. But another point must be here considered. The proteids and their compounds known to us are, comparatively speaking, stable compounds, which never undergo spontaneous decomposition so long as they are protected from outward injury, whereas the hypothetical combination which lies at the centre of organic metabolism is extraordinarily liable and continually undergoing spontaneous decomposition. Therefore we have to think of ordinary proteids in this case, but of still more complicated combinations, the atoms in the molecule of which have a strong tendency to group themselves in new arrangements. Owing to these and analogous matters, these substances are termed "biogens." When we come to inquire how such labile biogen molecules are built up out of the proteids of food, we find our knowledge very much restricted. Doubtless the intramolecular addition of inspired oxygen has much to do with it; for living substance when deprived of oxygen loses its irritability—that is to say, its tendency to decomposition. The fact that the decomposition of living substance is always associated with the formation of carbonic acid—a circumstance obviously necessitating the aid of oxygen—also points to the absolute indispensableness of oxygen in the matter. Pfüger has further suggested that the proteids and living substance owes its lability to the mechanism of metabolism.
complex by the circumstance that the living cell exhibits various morphological differentiations—above all, the differentiation in protoplasm and nucleum. Again, a transformation of energy is inseparably connected with metabolism. Along with food and oxygen potential chemical energy is continually being introduced into the cell, to be accumulated in the biogen molecules, and at their decomposition transformed into kinetic energy, which finds an outlet in the various manifestations of energy in the cell—motion, heat, and so forth. In the light of this hypothesis the operations of stimuli also become comprehensible. Seeing that there is an initial tendency to the occurrence of certain definite chemical processes, which are associated with the reconstruction and decomposition of biogen molecules, various stimuli will either further or hinder the course of these processes. Thus, the cell forth is more or less outward disturbance, and which always continues in the unvarying medium provided by an exact sufficiency of food, will be in “metabolic equilibrium”—that is to say, its assimilation and its dissimilation will be equal (A = D). When, however, the influence of external stimuli is brought to bear upon them—that is to say, any change in their environing vital conditions—A and D will either be altered in similar proportion, or their mutual equilibrium will be disturbed. In the former case the vital processes will merely be intensified in their course; in the latter and usual case the result will be determined according to the part of metabolism affected by the disturbance. When the effect of a stimulus is to excite D continuously in a high degree without correspondingly increasing A, the result is a dying off—an atrophy. In the contrary case, when A remains continuously greater than D, the result is growth, increase and reproduction of the cell. Experience proves, however, that A and D stand in a certain relation of mutual dependence to each other, with the result that when D has been increased by a stimulus, for example, A correspondingly increases during the stimulation, and continues to do so after its cessation, till the loss in living substance proceeding from the stimulation of D is eventually made good, and metabolic equilibrium is restored. The muscle may be taken as an example of this self-regulation of metabolism common to all living substance (Hering’s Selbststeuerung des Stoffwechsels). When a muscle has been fatigued by some stimulation causing an enormous increase of D, there is a corresponding spontaneous increase in A. After some time the muscle is observed to have recovered. It has once more become capable of working; its metabolism is again in equilibrium.

The vital phenomena of the cell may be derived mechanistically from metabolism and the changes it undergoes under the influence of stimuli. Our ability to do this will increase more rapidly as we become better acquainted with the details of this metabolic series that metabolism of the cell itself. The foregoing outline must be regarded, of course, as embodying only a fragmentary hypothesis, which can serve as a guide for further research only so long as it does not clash with facts, and which must be amplified, specialized and developed with the widening of specific knowledge regarding the cell’s metabolism. The relations already known are so exceedingly complex that only by slow degrees can we pursue the investigation of separate fragments of the entire metabolic series. The differentiation of nucleus and protoplasm in the living substance of the cell alone gives rise to an extraordinary complication in the metabolic process, for these two parts of the cell stand in the most complicated correlation with one another as well as with the environing medium—a fact of which the experiments made by vivisection in various free-living cell-forms have furnished abundant evidence. The farther such knowledge advances, the more rounded, clear and free from hypotheses will become our conception of the cell’s metabolism. But the cell is the elementary component part of all organisms, and from the life of individual cells is constructed the life of the separate tissues and various organs, and thus of the entire organism. Hence the cell is the only vital element which the organism possesses, and therefore the investigation of the vital processes in its separate cells leads ultimately to a knowledge regarding the mechanism of life in the whole.

Vegetable physiology is dealt with in the article PLANTS: PHYSIOLOGY. For details of different parts of the animal body, see ANIMAL HEAT; RESPIRATORY SYSTEM; VASCULAR SYSTEM; TOUCH; SMELL; SIGHT; EMISSION; HEARING; VOICE; MUSCLE AND NERVE SENSES; HYPONOTISM; BRAIN; SPINAL CORD; SYMPATHETIC SYSTEM; BLOOD; LYMPH; PHAGOCYTOSIS; DIGESTIVE ORGANS; NUTRITION, &c.

The principal modern English textbooks of animal physiology are those of Sir Michael Foster (1861), Professor Korsch (1898), Halliburton (1909), and Starling (1909). See, however, the bibliographical notes to the separate articles.

PIACENZA (Lat. Placentia), a town and episcopal see of Emilia, Italy, the capital of the province of Piacenza, 42½ m. S.E. of Milan and 91 m. N.W. of Bologna by rail. Pop. (1906), 107,786. It lies on the next-higher level, near the right bank of the Po, which here is crossed by road and railway bridges, just below the confluence of the Trebia. It is still surrounded by walls with bastions and fosse in a circuit of 4 m. The cathedral was erected between 1122 and 1233, in the Lombard Romanesque style, under the direction of Santo da Sambuceto, on the site of a church of the 9th century which had been destroyed by earthquake. The west front has three doors with curious pillared porches. The campanile is a massive square brick tower 223 ft. high; the iron cage attached to one of its windows was put up in 1495 by Ludovico il Moro for the confine of the Piacenza. The St. Augustine’s Church is a large church supported by one hundred pillars; the entire edifice has been restored since 1858, and the frescoes by Guercino and Caracci, which decorate parts of its roof, though good in themselves, are inappropriate to its severe style. Sant’ Antonino, which was the cathedral church till 877, is supposed to have been founded by St Victor, the first bishop of Piacenza, in the 4th century, and restored in 903; it was rebuilt in 1104, and altered in 1557. It was within its walls that the deputies of the Lombard League swore to the conditions of peace ratified in 1183 at Constance. The Gothic brick vestibule (II Paradiso) on the north side is one of the older parts of the building. San Francesco, a spacious Gothic edifice begun by the Franciscans in 1278, was erected on the site of the palace of Ubertino Landi, a leader of the Gibelline party. S. Savino, a fine Romanesque building of A.D. 903 (well restored in 1903), contains a mosaic pavement of this period with curious representations, including one of a game of chess. S. Sisto, which dates from 1400, and takes the place of the church founded in 874 by Angilberga (consort of the emperor Louis II), lost its chief attraction when Raphael’s Sistine Madonna (now in Dresden) was sold by the monks in 1754 to Frederick Augustus III. Its place, however, is occupied by a copy by Avanzini, and there are also several good intarsias by Gaetano Busseto. S. Sepolcro and S. Maria della Campagna are both good examples of Lombard Romanesque; the latter is rich in frescoes by Pordenone. S. Anna, dating from 1334, was the church of the barefooted Carmelites. Of the secular buildings the most interesting is the Palazzo Comunale, begun in 1281, one of the finest buildings of its kind in Italy. The square in front is known as the Piazza dei Cavalli, from the two bronze equestrian statues of Ranuccio (1620) and his father Alexander, prince of Parma, governor of the Netherlands (1623). Both were designed by Francesco Mochi. The Palazzo dei Tribunali and the Palazzo degli Sceti are fine early Renaissance brick buildings with terra-cotta decorations. The huge Farnese palace was begun by Vignola’s designs by Margaret of Austria in 1558, but it was never completed, and since 1800 it has been used as barracks. Other buildings or institutions of note are the old and the new bishop’s palace, the fine theatre designed by Lotario Tomba in 1803, the great hospital dating from 1471, the library presented to the commune in 1846 by the marquis Ferdinando Landi, and the Passerini library founded in 1685. The Museo Civico, formed in 1903, contains collections of antiquities (though many of the Roman antiquities of Piacenza have passed to the museum of Parma), some good Flemish tapestries and a few pictures. The castle erected by Antonio da Sangallo the younger has been demolished. Piacenza is the junction of the Milan and Bologna line with that from Voghera and Turin. From Codogno, 7 m.
PIANOFORTE

559
to the north, a branch line runs to Cremona. By road Piacenza is 88 m. north-east of Genoa. The town has an arsenal, a technical and arts school, and various industries—iron and brass works, foundries, silk-throwing, printing works and flour-mills.

Piacenza was a Roman colony in 218 B.C. While its walls were yet unfinished it had to repulse an attack by the Gauls, and in the latter part of 218 it afforded protection to the remains of the Roman army under Scipio which had been defeated in the great battle on the Trebia. In 205 it withstood a protracted siege by Hasdrubal. Five years later the Gauls burned the city; and in 190 it had to be recruited with three thousand families. In 187 it was connected with Ariminum and the south by the construction of the Via Aemilia. Later on it became a very important road centre; the continuation northwards of the Via Aemilia towards Milan, with a branch to Ticinum, crossed the Po there, and the Via Postumia from Cremona to Dertona and Genoa passed through it. Later still Augustus reconstructed the road from Dertona to Vade, and into Galilia Narbonensis, and gave it the name of Julia Augusta from Piacenza onwards. The rectangular arrangement of the streets in the centre of the town, through which pass the two Via Aemilia, is no doubt a survival from Roman times. Piacenza is mentioned in connexion with its capture by Cinna and a defeat of the forces of Carbo in the neighbourhood (82 B.C.), a mutiny of Julius Caesar’s garrison (50 B.C.), another mutiny under Augustus (40 B.C.), the defence of the city by Spurinna, Otho’s general, against Caesar, Vitellius’s general (A.D. 69), and the defeat of Aurelian by the Marcomanni outside the walls (A.D. 271). In 546 Totila reduced Piacenza by famine. Between 997 and 1035 the city was governed by its bishops, who had received the title of count from Otho III. At Roncaglia, 5 m. to the east, the emperor Conrad II. held the diet which passed the Salic law. In the latter part of the 12th century it was one of the leading members of the Lombard League. For the most part it remained Guelph, though at times, as when it called in Galeazzo Visconti, it was glad to appeal to a powerful Ghibelline for aid against its domestic tyrants. In 1447 the city was captured and sacked by Francesco Sforza. Having been occupied by the papal forces in 1521, it was in 1545 united with Parma (q.e.) to form an hereditary duchy for Pierluigi Farnese, son of Paul III. In 1746 a battle between the Franco-Spanish forces and the Austrians was fought under the city walls, and in 1796 it was occupied by the French. In 1848 Piacenza was the first of the towns of Lombardy to join Piedmont; but it was reoccupied by the Austrians till 1859.

PIANOFORTE (Ital. piano, soft, and forte, loud). The group of keyed stringed musical instruments, among which the pianoforte is latest in order of time, has been invented and step by step developed with the modern art of music, which is based upon the simultaneous employment of different musical sounds. In the 16th century the “organum” arose, an elementary system of accompaniment to the voice, consisting of fourths and octaves below the melody and moving with it; and the organ (q.v.), the earliest keyed instrument, was, in the first instance, the rude embodiment of this idea and convenient means for its expression. There was as yet no keyboard of balanced key-levers; all the keys were drawn out like modern drawer-locks to admit the compressed air necessary to make the pipes sound. About the same time arose a large stringed instrument, the organistrum,1 the parent of the now obsolete hurdy-gurdy; as the organ needed a blower as well as an organist, so the player of the organistrum required a handle-turner, by whose aid the three strings of the instrument were made to sound simultaneously upon a wheel, and, according to the well-known sculptured relief of St George de Boscherville, one string was manipulated by means of a row of stoppers or tangents pressed inwards to produce the notes. The other strings were drones, analogous to the drones of the bagpipes, but originally the three strings followed the changing organum.

In the 11th century, the epoch of Guido d’Arezzo, to whom the beginning of musical notation is attributed, the Pythagorean monochord, with its shifting bridge, was used in the singing schools to teach the intervals of the plain-song of the church. The practical necessity, not merely of demonstrating the proportionate relations of the intervals, but also of initiating pupils into the different graduations of the church tones, had soon after Guido’s time brought into use quadruple-fashioned monochords, which were constructed with scales, analogous to the modern practice with thermometers which are made to show both Réaumur and Centigrade, so that four lines are indicated as many authentic and as many plagal tones. This arrangement found great acceptance, for Aribio,2 writing about fifty years after Guido, says that few monochords were to be found without it. Had the clavicord then been known, this make-shift contrivance would not have been used. Aribio, strangely enough, decried it because it would improve the organ, and “by the grace of God” invented a monochord measure which, on account of the rapidity of the leaps he could make with it, he named a wild-goat (capra). Jean de Muris (Musica speculativa, 1325) teaches how true relations may be found by a single-string monochord, but recommends a four-stringed one, properly a tetrachord, to gain a knowledge of unfamiliar intervals. He describes the musical instruments known in his time, but does not mention the clavichord or monochord with keys, which could not have been then invented. Perhaps one of the earliest forms of such an instrument, in which stoppers or tangents had been adopted from the organistrum, is shown in fig. 1, from a wood carving of a vicar choral or organist, preserved in St Mary’s church, Shrewsbury. The instrument to which it is supposed that this interesting figure may be attributed is 1460, but the conventional representation shows that the instrument was then already of a past fashion, although perhaps still retained in use and familiar to the carver.

In the Weimar Wunderbuch, a MS. dated 1440, with pen and ink miniatures, is given a “clavicordium” having 8 short and apparently 16 long keys, the artist has drawn 12 strings in a rectangular case, but no tangents are visible. A keyboard of balanced keys existed in the little portable organ known as the regal, so often represented in old carvings, paintings and stained glasses. Vitruvius, De architecture, lib. x. cap. xi, translated by Newton, describes a balanced keyboard; but the key apparatus is more particularly shown in The Pneumatics of Hero of Alexandria, translated by Bennet Woodcroft (London, 1851). In confirmation of this has been the remarkable recovery at Carthage3 of a terra-cotta model of a Hydraulikon or water organ, dating from the 2nd century A.D., in which a balanced keyboard of 18 or 19 keys is shown. It seems likely the balanced keyboard was lost, and afterwards reinvented. The name of

1 See “Musica arboris scholaestici,” printed by Martin Gerbert in Scriptores ecclesiastici de musica sacra (1784), ii. 197; and in J. P. Migne, Patrologiae cursus completus, vol. 150, col. 1307.

---

1 An organistrum is shown in the lower right hand corner of the full page miniature of a fine 14th century psalter of English workmanship, forming part of the Hunterian collection in University Court Library, Glasgow. No. 31 in Catalogue of the Exhibition of Illuminated MSS. at the Burlington Fine Arts Club (1908).
regal was derived from the rule (regula) or graduated scale of keys, and its use was to give the singers in religious processions the note or pitch. The only instrument of this kind known to exist in the United Kingdom is at Blair Atholl, and it bears the very late date of 1630. The Brussels regal may be as modern. These are instances of how long a some-time admired musical instrument may remain in use after its first intention is forgotten. We attribute the adaptation of the narrow regal keyboard to what was still called the monochord, but was now a complex of monochords over one resonance board, to the latter half of the 14th century. It was accomplished by the substitution of tangents fixed in the future ends of the balanced keys for the movable bridges of the monochord or such stoppers as are shown in the Shrewsbury carving. Thus the monochordium or "payre of monochordis" became the clavicordium or "payre of clavicordis"—pair being applied, in the old sense of a "pair of steps," to a series of degrees. This use of the word to imply gradation was common in England to all keyed instruments; thus we read, in the Tudor period and later, of a pair of regals, organs, or virginals. Ed. van der Straeten reproduces a so-called clavicord of the 15th century from a MS. in the public library at Ghent. The treatise is anonymous, but other treatises in the same MS. bear dates 1503 and 1504. Van der Straeten is of opinion that the drawing may be assigned to the middle of the 15th century. The scribe calls the instrument a clavicimbalum, and this is undoubtedly correct; the 8 strings in the drawing are stretched from back to front over a long soundboard, the longest strings to the left; 8 keys, a long and a short with levers to which are attached the jacks, are seen in a horizontal line behind the keyboard, and behind them again are given the names of the notes a, b, c, d, e, f, g, h. In the Weimar Wunderbuch is a pen-and-ink sketch of the "clavicimbalum" placed upon a table, in which we recognize the familiar outline of the harpsichord, but on a smaller scale. The keyboard shows white and black notes—the latter short keys, one between each group of two white keys, precisely as in the instrument reproduced by Van der Straeten—but no mechanism is visible under the strings.

The earliest known record of the clavicord occurs in some rules of the minnesingers, dated 1404, preserved at Vienna. The monochord is named with it, showing a differentiation of these instruments, and of them from the clavicymbalum, the keyed cymbal, cembalo (Italian), or psaltery. From this we learn that a keyboard had been, or was early adapted to, the several fixed stringed instruments, the "cembalo" of Boccaccio, the "sautrie" of Chaucer. There were two forms of the psaltery: (1) the trapeze, one of the oldest representations of which is to be found in Orcagna's famous Trionfo della Morte in the Campo Santo at Pisa, and another by the same painter in the National Gallery, London; and (2) the contemporary "testa di porco," the pig's head, which was of triangular shape as the name suggests. The trapeze psaltery was strung horizontally, the "istromento di porco" either horizontally or vertically—the notes, as in the common dulcimer, being in groups of three or four unisons. In these differences of form and stringing we see the cause of the ultimate differentiation of the spinet and harpsichord. The compass of the psalteries was nearly that of Guido's scale; but according to Mersenne, the lowest interval was a fourth, G to C, which is worthy of notice as anticipating the later "short measure" of the spinet and organ.

The simplicity of the clavicord inclines us to place it in order of time, before the clavicymbalum or clavichordale; but we know not how the sounds of the latter were at first excited. There is an indication as to its early form to be seen in the incidents of the church of the Certosa near Pavia, which compares in probable date with the Shrewsbury example. We quote the reference to it from Dr Ambros. He says a carver represents King David as holding an "istromento di porco," which has eight strings and as many keys lying parallel to them; inside the body of the instrument, which is open at the side nearest the right hand of King David, he touches the keys with the right hand and damps the strings with the left. The attribution of archaism applies with equal force to this carving as to the Shrewsbury one, for when the monastery of Certosa near Pavia was built by Ambrogio Fossana in 1472, chromatic keyboards, which imply a considerable advance, were already in use. There is an authentic representation of a chromatic keyboard, painted not later than 1426, in the St Cecilia panel (now at Berlin) of the famous Adoration of the Lamb by the Van Eycks. The instrument depicted is a positive organ, and it is interesting to notice in this realistic painting that the keys are evidently boxwood, as in the Italian spinets of later date, and that the angel plays a common chord—\(\text{A}\) with the right hand, \(\text{F}\) and \(\text{C}\) with the left. But diatonic organs with eight steps or keys in the octave, which included the \(\text{B}\) flat and the \(\text{B}\) natural, as in Guido's scale, were long preserved, for Praetorius speaks of them as still existing nearly two hundred years later. This diatonic keyboard, we learn from Sebastian Virdung (\textit{Musica getutscht und ausgesogen}, Basel, 1511), was the keyboard of the early clavichord. We reproduce his diagram as the only authority we have for the disposition of the one short key.

The extent of this scale is exactly Guido's. Virdung's diagram of the chromatic is the same as our own familiar keyboard, and comprises three octaves and a note, from \(\text{F}\) below the bass stave to \(\text{G}\) above the treble. But Virdung tells us that even then clavichords were made longer than four octaves by repetition of the same order of keys. The introduction of the chromatic order he attributes to the study of Boetius, and the consequent endeavour to restore the three musical genera of the Greeks—the diatonic, chromatic and enharmonic. But the last-named had not been attained. Virdung gives woodcuts of the clavicordium, the virginal, the clavicymbalum and the clavicytherium. We reproduce three of them (figs. 3, 6 and 12), omitting the virginal as obviously incorrect. Writers on musical instruments have continually repeated these drawings without discerning that in the printing they are reversed, which puts the keyboards entirely wrong, and that in Luscinius's Latin translation of Virdung (\textit{Musurgia, sive praxis musicæ}, Strasburg, 1530), which has been hitherto chiefly followed, two of the engraving, the clavicymbalum and the clavicytherium, are transposed, another cause of error. Martin Agricola (\textit{Musica instrumentalis}, Wittenberg, 1520) has copied Virdung's illustrations with some differences of perspective, and the addition, here and there, of errors of his own.

Still vulgarly known as monochord, Virdung’s clavichord was really a box of monochords, all the strings being of the same length. He derives the clavichord from Galilei’s monochord as he does the virginal from the psaltery, but, at the same time, confesses he does not know when, or by whom, either instrument was invented. We observe in this drawing the short sound-board, which always remained a peculiarity of the clavichord, and the straight sound-board bridge—necessarily so when all the strings were of one length. To gain an angle of incidence for the tangents against the strings the keys were made crooked, an expedient further rendered necessary by the “fretting”—three tangents, according to Virdung, being directed to stop as many notes from each single group of three strings tuned in unison; each tangent thus made a different vibrating length of string. In the drawing the strings are merely indicated. The German for fret is Band, and such a clavichord, in that language, is known as a “gebundenenes Clavichord” both fret (to rub) and Band (from binden, to bind) having been taken over from the lute or viol. The French and Italians employ "touche" and "tasto," touch. Praetorius who wrote a hundred years later than Virdung, says two, three and four tangents were thus employed in stopping. There are extant small clavicords having three keys and tangents to one pair of strings and others have no more than two tangents to a note formed by a pair of strings, instead of three. Thus seven pairs of strings suffice for an octave of twelve keys, the open notes being F, G, A, B flat, C, D, E flat, and by an unexplained peculiarity, perhaps derived from some special estimation of the notes which was connected with the church modes, A and D are left throughout free from a second tangent. A corresponding value of these notes is shown by their independence of chromatic alteration in tuning the double Irish harp, as explained by Vincentio Galleli in his treatise on music (Dialogo della musica, Florence, 1581). Adlung, who died in 1762, speaks of another fretting, but it must have been an adaptation to the modern major scale, the "free" notes being E and B. Clavicords were made with double fretting up to about the year 1700—that is to say, to the epoch of J. S. Bach, who, taking advantage of its abolition and the consequent use of independent pairs of strings for each note, was enabled to tune in all keys equally, which had been impossible so long as the fretting was maintained. The modern scales having become established, Bach was now able to produce, in 1722, Das wohltemperierte Clavier, the first collection of preludes and fugues in all the twenty-four major and minor scales for a clavichord which was tuned, as to concordance and dissonance, fairly equal.

The oldest clavichord, here called manicordo (as French manicorde, from monochord), known to exist is that shown in Fig. 4. It will be observed that the lowest octave is here already bridge, indispensable for the vibration, besides acting as the sound exciters (fig. 5). The common damper to all the strings is a list of cloth, interwoven behind the tangents. As the tangents quitted the strings the cloth immediately stopped all vibration. Too much cloth would diminish the tone of this already feeble instrument, which gained the name of “dumb spinet” from its use. In the clavichord in Rubens’s St Cecilia (Dresden Gallery)—interesting as perhaps representing that painter’s own instrument—the damping cloth is accurately painted. The number of keys there shown is three octaves and a third, F to A—the same extent as in Handel’s clavichord now in the museum at Maidstone (an Italian instrument dated 1726, and not fretted), but with the peculiarity of a combined chromatic and short octave in the lowest notes, to which we shall have to refer when we arrive at the spinet; we pass it by as the only instance we have come across in the clavichord.

The clavichord must have gone out of favour in Great Britain and the Netherlands early in the 16th century, before its expressive power, which is of the most tender and intimate quality, could have been, from the nature of the music played, observed, —the more brilliant and elegant spinet being preferred to it. Like the other keyboard instruments it had no German name, and can hardly have been of German origin. Holbein, in his drawing of the family of Sir Thomas More, 1528, now at Basel, indicates the place for “Clavikordi un ander Seytinspill.” But it remained longest in use in Germany—until even the beginning of the 19th century. It was the favourite “Klavier” of the Bachs. Besides that of Handel already noticed there is in existence clavicords the former possession of which is attributed to Mozart and Beethoven. The clavichord was obedient to a peculiarity of touch possible on no other keyboard instrument. This is described by C. P. Emmanuel Bach in his famous essay on playing and accompaniment, entitled Versuch über die wahre Art das Klavier zu spielen (“An Essay on the True Way to play Keyboard Instruments.”) It is the Bebung (trembling), a vibration in a melody note of the same nature as the tremolo frequently employed by violin players to heighten the expressive effect; it was gained by a repeated movement of the fleshy end of the finger while the key was still held down. The Bebung was indicated in the notation by dots over the note to be affected by showing how many times the note should be repeated. According to the practice of the Bachs, as handed down to us in the above mentioned essay, great smoothness of touch was required to play the clavichord in tune. As with the monochord, the means taken to produce the sound disturbed the accuracy of the string measurement by increasing tension, so that a key touched too firmly in the clavichord, by unduly raising the string, sharpened the pitch, an error in playing deprecated by C. P. Emmanuel Bach. This answers the assertion which has been made that J. S. Bach could not have been nice about tuning when he played from preference on an instrument of uncertain intonation.

The next instrument described by Virdung is the virginal (virginalis, proper for a girl), a parallelogram in shape, having the same projecting keyboard and compass of keys the same as the clavichordium. Here we can trace derivation from the psaltery in the sound-board covering the entire inner surface of the instrument and in the triangular disposition of the strings. The virginal in Virdung’s drawing has an impossible position with reference to the keyboard, which renders its reproduction as an illustration useless. But in the next drawing, the clavicimbalum, this is rectified, and the drawing, reversed on account of the keyboard, can be accepted as roughly representing the instrument so called (fig. 6). There would be
no difference between it and the virginal were it not for a peculiar
unmistakable to the Italian "spinetta," a name unnoticed by Virdung or by his
from the same year 1511, pub-
ished his Spiegel der Orgelmacher (Organ-builders' Mirror), and named the clavicordium and clavicimbalum as familiar
instruments. In the first place, the keyboard, beginning ap-
parently with B natural, instead of F, makes the clavicimbalum
smaller than the virginal, the strings in this arrangement being
shorter; in the next place it is almost certain that the Italian
spinet compass, beginning apparently upon a semitone, is
identical with a "short measure" or short octave organ
compass, a very old keyboard arrangement, by which the lower
note, representing B, really sounded G and C sharp in like
manner A. The origin of this may be deduced from the psaltery
and many representations of the regal, and its object appears
to have been to obtain dominant basses for cadences, harmonious
closings having early been sought for as giving pleasure to the ear.
Authority for this practice is to be found in Mersenne, who, in
1636, expressly describes it as occurring in his own spinet (spinetta).
He says the keyboards of the spinet and organ are the same.
Now, in his Latin edition of the same work he renders
earliest used we have no evidence. The little crown-quill points
project from centred tongues in uprights of wood known as
"jacks" (fig. 7), which also carry the dampers, and rising by
the depression of the keys in front, the quills set the strings
vibrating as they pluck them in passing, springs at first of steel,
later of bristle, giving energy to the twang and governing their
return J. C. Scaliger in Poetices libri septem (1561, p. 51 c. 1.)
states that the Clavicimbalum and Harpichordum of his
boyhood are now called Spinets on account of those quill
points (ab illis mucronibus), and attributes the introduction of the
name "spinetta" to them (from spina, a thorn). We will
leave harpichordum for the present, but the early identity of
clavicimbalum and spinetta is certainly proved.
Scaliger's etymology remains unquestioned until
Signor Ponscichs di Florence discovered another derivation.
He found in a rare book entitled Conclusio nel duomo dell' or-
organo, di D. Adriano Banchieri (Bologna, 1608), the following
passage, which translated reads: "Spinetta was thus named
from the inventor of that oblong form, who was one Maestro
Giovanni Spinetti, a Venetian; and I have seen one of
those instruments, in the possession of Francesco Storici,
organist of the magnificent community of Montagnana,
within which this inscription—Joannes Spinetti Venetus feci,
A.D. 1503." Scaliger's and Banchieri's statements may be
combined, as there is no discrepancy of dates, or we may
rely upon whichever seems to us to have the greater authority,
always bearing in mind that neither invalidates the other.
The introduction of crow-quill points, and adaptation to an oblong
shape is in the instrument previously in a trapèze form, are syn-
chronous; but we must accept 1503 as a late date for one of Spinetti's
instruments, seeing that the altered form had already become
common, as shown by Virdung, in another country as early as
1511. After this date there are frequent references to spinets in
public records and other documents, and we have fortunately
the instruments themselves to put in evidence, preserved in
public museums and in private collections. A spinet dated 1490
was shown at Bologna in 1888; another old spinet in the Conserva-
toire, Paris, is a pentagonal instrument made by Francesco di
Portalupi at Verona, 1523. The Milanese Rossi were famous
spinet-makers, and have been accredited (La Nobiltà di Milano,
1595) with an improvement in the form which we believe was
the recessing of the keyboard, a feature which had previously
to be entirely projected; by the recessing a greater width was
obtained for the sound-board. The spinets by Annibale Rosso at South
Kensington, dated respectively 1555 (fig. 8) and 1577, show this
alteration, and may be compared with the older and purer form of
one, dated 1568, by Marco Jadra (also known as Marco "dalle
spinet"") or "dai cembali"). Besides the pentagonal spinet,
there was an heptagonal variety; they had neither covers nor
stands, and were often withdrawn from decorated cases when
required for performance. In other instances, as in the 1577
Rosso spinet, the case of the instrument itself was richly adorned.
The apparent compass of the keyboard in Italy generally
exceeded four octaves by a semitone, E to F; but we may regard
the lowest natural key as usually C, and the lowest sharp key as
usually D, in these instruments, according to "short measure."
The rectangular spinet, Virdung's "virginal," early assumed
in Italy the fashion of the large "cassoni" or wedding chests.
The oldest we know of in this style, and dated, is
the specimen belonging to M. Terme which
figures in L'Art decoratif (fig. 9). Virginal is not an Italian name;

1 A. J. Ellis (History of Musical Pitch, p. 318) sees the B in
Mersenne's outline diagram.

FIG. 8.—Milanese Spinetta, by Annibale Rosso, 1555: South
Kensington Museum.
the rectangular instrument in Italy is “spinetta tavola.” In England, from Henry VII. to Charles II., all quilled instruments (stromenti di pennino), without distinction as to form, were known as virginals. It was a common name, equivalent to the contemporary Italian clavicordo and Flemish clavissegel. From the latter, by apocope, we arrive at the French clavie - r (clavis, a key), a keyboard, being in its turn adopted by the Germans to denote any keyboard stringed instrument.

FIG. 9.—Spinetta Tavola (Virginal), 1568; Vict. and Albert Museum.

Mersenne (op. cit., liv. iii., p. 158) gives three sizes for spinets—one 2½ ft. wide, tuned to the octave of the “ton de chapelle” (in his day a half tone above the present English medium pitch), one of 3½ ft. tuned to the fourth below, and one of 5 ft. tuned to the octave below the first, the last being therefore tuned in unison to the chapel pitch. He says his own spinet was one of the smallest it was customary to make, but from the lettering of the keys in his drawing it would have been of the second size, or the spinet tuned to the fourth. The octave spinet, of trapeze form, was known in Italy as “ottavina” or “spinetta di serenata.” It had a less compass of keys than the larger instrument, being apparently three and two-third octaves, E to C—which by the “short measure” would be four octaves, C to C. We learn from Praetorius that these little spinets were placed upon the larger ones in performance; their use was to heighten the brilliant effect. In the double rectangular clavissegel of the Netherlands, in which there was a movable octave instrument, we recognize a similar intention. There is a fine spinet of this kind at Nuremberg. Praetorius illustrates the Italian spinet by a form known as the “spinetta traversa,” an approach towards the long clavicumbo or harpsichord, the tuning pins being immediately over the keyboard. This transposed spinet, more powerful than the old trapeze one, became fashionable in England after the Restoration, Haward, Keene, Slade, Player, Baudin, the Hitcheocks, Mahoon, Haxby, the Harrir family, and others having made such “spinets” during a period for which we have dates from 1664 to 1784. Pepsy bought his “Espinette” from Charles Haward for £5, July 13, 1664.

The spinets of Keene and Player, made about 1700, have from two to three divided bays of the back and end of the keyboard, as in the description by Mersenne, quoted above, of a spinet with short measure. Such divided sharps have been assumed to be quarter tones, but enharmonic intervals in the extreme bass can have no justification. From the tuning of Handel’s Italian clavicord already mentioned, which has this peculiarity, and from Praetorius we find the further halves of the two divided sharps were the chromatic semitones, and the nearer halves the major thirds below i.e. the dominant fourths to the next natural keys. Thomas Hitchcock (for whom there are dates 1664 and 1703 written on keys and jacks of spinets bearing Edward Blunt’s name and having divided bass sharps) made a great advance in constructing spinets, giving them the wide compass of few octaves, from G to G, with very fine keyboards in which the sharps were inlaid with a slab of the ivory or ebony, as the case might be, of the naturals. Their instruments, always numbered, and not dated as has been sometimes supposed, became models for contemporary and subsequent English makers.

We have now to ask what was the difference between Seiliger’s harpsichordum and his clavicymbal. Galilei, the father of the astronomer of that name (Dialogo della musica antica e moderna, Florence, 1581), says that the harpsichord was so named from having resembled an “arpa giacente,” a prostrate or “couched” harp, proving that the clavicymbal was at first the trapeze-armed spinet; and we should therefore differentiate harpsichord and clavicymbal as, in form, suggested by or derived from the harp and psaltery, or from a “testa di porco” and an ordinary trapeze psaltery. We are inclined to prefer the latter. The Latin name “clavicymbalum,” has early been replaced by spinet and virginal, was in Italy and France bestowed upon the long harpsichord, and was continued as clavicembalo (gravecembalo, or familiarly cembalo only) and clavecin. Much later, after the restoration of the Stuarts, the first name was accepted and naturalized in England as harpsichord, which we will define as the long instrument with quills, shaped like a modern grand piano, and resembling a wing, from which it has gained the German appellation “Flügel.” We can point out no long instrument of this kind so old as the Roman cembalo at South Kensington (fig. 11). It was made by Geronimo of Bologna in 1522, two years before the Paris Porta-lupis spinet. The outer case is of finely tooled leather. It has a spinet keyboard with a compass of nearly four octaves, E to D. The natural keys are of boxwood, gracefully arcaded in front. The keyboard of the Italian cembalo was afterwards carried out to the normal four octaves. There is an existing example, dated 1626, with the bass keys carried out without sharps in long measure (unfortunately altered by a restorer). It is surprising to see with what steady persistence the Italians adhered to their original model in making the instrument. As late as the epoch of Cristofori, and in his 1722 cembalo at Florence, we still find the independent outer case, the single keyboard, the two unisons, without power to reduce to one by using stops. The Italians have been as conservative with their forms of spinet, and are to this day with their organs. The startling “piano e forte” of 1598, brought to light from the records of the house of D’Este by Count Valdigheri of Modena, after much consideration and a desire to find in it an anticipation of Cristo- fori’s subsequent invention of the pianoforte, we are disposed to regard as an ordinary cembalo with power to shift, by a stop.

1 In the harpsichord Cristofori made for Prince Ferdinando de’ Medici in 1722, recently acquired by Mr. Stearns, of Detroit, and presented by him to the University of Michigan, U.S.A., there are three keyboards, thus arranged: 1st, highest keyboard, octave string only; 2nd, octave and first unison; 3rd, lowest, 12th unison. A harpsichord similarly designed with three keyboards, inscribed “Vincentius Sodi Florentinus Fecit, Anno Domini 1779,” was presented by Mrs. J. Crosby Brown to the Metropolitan Museum, New York.

2 In the Kraus Museum Catalogue (1901), No. 559.

3 See Van der Straeten, vi. 122.
from two unisons (forte) to one string (piano), at that time a Flemish practice, and most likely brought to Italy by one of the Flemish musicians who founded the Italian school of composition. About the year 1600, when accompaniment was invented for monody, large cembalos were made for the orchestras to bring out the base part, the performer standing to play. Such an instrument was called "archicembalo," a name also applied to a large cembalo, made by Vito Trasuntino, a Venetian, in 1606, intended by thirty-one keys in each of its four octaves—one hundred and twenty-five in all—to restore the three genera of the ancient Greeks. How many attempts have been made before and since Trasuntino to purify intonation in keyboard instruments by multiplying keys in the octave? Simultaneously with Father Smith's well-known experiment in the Temple organ, London, there were divided keys in an Italian harpsichord to gain a separate G sharp and A flat, and a separate D sharp and E flat.

Double keyboards and stops in the long cembalo or harpsichord came into use in the Netherlands early in the 16th century. We find them imported into England. The following citations, quoted by Rimbaud in his History of the Pianoforte, but imperfectly understood by him, are from the privy purse expenses of King Henry VIII., as extracted by Sir Harris Nicolas in 1827.

"1530 (April). Item the vj daye paied to William Lewes for ii payer of virginals in one coffer with iii lippes stopped to Grenewich iii li. And for ii payer of virginals in one coffer brought to the More other iii li."

Now the second instrument may be explained, virginals meaning any quilled instrument, as a double spinet, like that at Nuremberg by Martin van der Beest, the octave division being movable. But the first cannot be so explained; the four stops can only belong to a harpsichord, and the two pair instrument to a double-keyed one, one keyboard being over, and not by the side of the other. Again from the inventory after the king's death (see Brit. Mus. Harl. MS. 1410) fol. 247—

"Two fair pair of new long Virginals made harp-fashion of Cipres, with keys of ivory, having the King's Arms crowned and supported by his Grace's beasts within a garter gilt, standing over the keys."

We are disposed to believe that we have here another double keyboard harpsichord. Rimbaud saw in this an upright instrument, such as Virdung's clavicinium (fig. 12). Having since seen the one in the Kraus Museum, Florence, it seems that Virdung's drawing should not have been reversed; but he has mistaken the wires acting upon the jacks for strings, and omitted the latter stretched horizontally across the soundboard (see Clavicinium). We read in an inventory of the furniture of Warwick Castle, 1584, "a faire paire of double virginals," and in the Hengrave inventory, 1603, "one great pays de double virginals." Hans Ruckers, the great clavising maker of Antwerp, lived too late to have invented the double keyboard and stops, evident adaptions from the organ, and the octave string (the invention of which was so long attributed to him), which incorporated the octave string with the large instrument, to be henceforth playable without the co-operation of another performer, was already in use when he began his work. Until the last harpsichord was made by Joseph Kirkman, in 1758, scarcely an instrument of the kind was constructed, except in Italy, without the octaves. The harpsichord as known throughout the 18th century, with piano upper and forte lower keyboard, was the invention of Hans Ruckers's grandson, Jean Ruckers's nephew, Jan Couchet, about 1640. Before that time the double keyboards in Flemish harpsichords were merely a transposing expedient, to change the pitch a fourth, from plagal to authentic and vice versa, while using the same groups of keys. Fortunately there is a harpsichord existing with double keyboards unaltered, date 1638, belonging to Sir Bernard Samuelson, formerly in the possession of Mr. Spence, of Florence, made by Jean Ruckers, the keyboards being in their original position. It was not so much invention as beauty of tone which made the Ruckers's harpsichords famous. The Ruckers harpsichords in the 18th century were fetching such prices as Bologna lutes did in the 17th or Cremona violins do now. There are still many specimens existing in Belgium, France and England. Handel had a Ruckers harpsichord, now in Buckingham Palace; it completes the number of sixty-three existing Ruckers instruments catalogued in Grove's Dictionary of Music and Musicians.

After the Antwerp make declined, London became pre-eminent for harpsichords—the representative makers being Jacob Kirckmann and Burckhard Tschudi, pupils of a Flemish master, one Tabel, who had settled in London, and whose business Kirckmann continued through marriage with Tabel's widow. Tschudi was of a noble Swiss family belonging to the canton of Glarus. According to the custom with foreign names obtaining at that time, by which Handel became Handel, and Schmidt Smith, Kirckmann dropped his final n and Tschudi became Shudi, but he resumed the full spelling in the facies of the splendid harpsichords he made in 1766 for Frederick the Great, which are still preserved in the New Palace, Potsdam. By these great makers the harpsichord became a larger, heavier-strung and more powerful instrument, and fancy stops were added to vary the tone effects. To the three shifting registers of jacks of the octave and first and second unisons were added the "lute," the charm of which was due to the favouring of high harmonies by plucking the strings close to the bridge, and the "harp," a surging or muting effect produced by impeding the vibration of the strings by contact of small pieces of buff leather. Two pedals were also used, the left-hand one a combination of a unison and lute. This pedal, with the "machine" stop, reduced the upper keyboard to the lute register, the plieca of which acted upon the strings near the wrest-plank bridge.
only; the lower keyboard to the second unison. Releasing the machine stop and quieting the pedal restores the first unison on both keyboards and the octave on the lower. The right-hand pedal was to raise a hinged portion of the top or cover and thus gain some power of "swell" or crescendo, an invention of Roger Plenius,¹ to whom also the harp stop may be rightly attributed. This ingenious harpsichord maker had been stimulated to gain these effects by the nascent pianoforte which, as we shall find, he was the first to make in England. The first idea of pedals for the harpsichord to act as stops appears to have been John Hayward's ("Haward") as early as 1676, as we learn from Mace's Musicke's Monument, p. 235. The French makers preferred a kind of knee-pedal arrangement, known as the "genouillière," and sometimes a more complete muting by one long strip of buff leather, the "sourdine." As an improvement upon Plenius's clumsy swell, Shudi in 1766 patented the Venetian swell, a framing of louvres, like a Venetian blind, which opened by the movement of the pedal, and becoming in England a favourite addition to harpsichords, was early transferred to the organ, in which it replaced the rude "nag's-head" swell. A French harpsichord maker, Marius, whose name is remembered from a futile attempt to design a pianoforte action, invented a folding harpsichord, the "clavecín brisé," by which the instrument could be disposed of in a smaller space. One, which is preserved at Berlin, probably formed part of the camp baggage of Frederick the Great.

It was formerly a custom with kings, princes and nobles to keep large collections of musical instruments for actual playing purposes, in the domestic and festive music of their courts. There are records of their inventories, and it was a custom to keep such a collection in playing order that Prince Ferdinand dei Medici engaged a Paduan harpsichord maker, Bartolommeo Cristofori, the man of genius who invented and produced the pianoforte.² We fortunately possess the record of this invention in a literary form from a well-known writer, the Marchese Scipione Maffei; his description appeared in the Giornale dei letterati d'Italia, a publication conducted by Apostolo Zeno. The date of Maffei's paper was 1711. Rimbault reproduced it, with a technically imperfect translation, in his History of the Pianoforte. We learn from it that in 1709 Cristofori had completed four gravecembali col piano e forte—keyed psalteries with soft and loud—three of them being of the long or keyless harpsichord form. A synonymy in Italian for the original cembalo (or psaltery) is "salterio," and if it were struck with hammers it became a "salterio tedesco" (the German hackbrett, or chopping board), the latter being the common dulcimer. Now the first notion of a pianoforte is a dulcimer with keys, and we may perhaps not be wrong in supposing that there had been many attempts and failures to put a keyboard to a dulcimer or hammers to a harpsichord before Cristofori successfully solved the problem. The sketch of his action in Maffei's essay shows an incomplete stage in the invention, although the kernel of it—the principle of escapement or the controlled rebound of the hammer—is already there. He claims it to be a "moderato" lever (anguetta mobile) or hopper, working, when the key is depressed by the touch, in a small projection from the centre of the hammer-butt. The return, governed by a spring, must have been uncertain and incapable of further regulating than could be obtained by modifying the strength of the spring.

¹ Mace describes a primitive swell contrivance for an organ 65 years before Plenius took out his patent (1741).

² The invention of the piano by Cristofori, and him alone, is now past discussion. What is still required to satisfy curiosity would be the discovery of a Forte Bianco or Frederici square piano, said to antedate by a year or two Zumpe's invention of the instrument in London. The name Forte Bianco was derived, consciously or unconsciously, from the Saxon German peculiarity of interchanging B and P. Among Mozart's effects at the time of his death was a Forte-Biano mit Pedal (see Vierzehnter jährlicher Bericht des Museums, "Salzburg", Dec. 19, 1791). Also wanted is the "old movement" for the long or grand pianos, sometimes quoted in the Broadwood day-books of the last quarter of the 18th century with reference to the displacement by the Backers English action.

Moreover, the hammer had each time to be raised the entire distance of its fall. There are, however, two pianofortes by Cristofori, dated respectively 1720 and 1726, which show a much improved, we may even say a perfected, construction, for the whole of an essential piano movement is there. The earlier instrument (now in the Metropolitan Museum, New York) has undergone considerable restoration, the original hollow hammer-head having been replaced by a modern one, and the hammer-butt, instead of being centred by means of the holes provided by Cristofori himself for the purpose, having been lengthened by a leather hinge screwed to the block;² but the 1726 one, which is in the Kraus Museum at Florence, retains the original leather hammer-heads. Both instruments possess a contrivance for determining the radius of the hopper, and both have been unexpectedly found to have the "check" (Ital. paramatello), which regulates the fall of the hammer according to the strength of the blow which has impelled it to the strings. After this discovery of the actual instruments of Cristofori there can be no longer doubt as to the attribution of the invention to him in its initiation and its practical completion with escapement and check. To Cristofori we are indebted, not only for the power of playing piano and forte, but for the infinite variations of tone, or nuances, which render the instrument so delightful.

But his problem was not solved by the devising of a working action; there was much more to be done to install the pianoforte as a new musical instrument. The resonance, that most subtle

and yet all-embracing factor, had been experimentally developed to a certain perfection by many generations of spinet and harpsichord makers, but the resistance structure had to be thought out again. Thicker stringing, rendered indispensable to withstand even Cristofori's light hammers, demanded in its turn a stronger framing than the harpsichord had needed. To make his structure firm he considerably increased the strength of the block which holds the tuning-pins, and as he could not do so without materially adding to its thickness, he adopted the bold expedient of inverting it; driving his wrest-pins, harp-fashion, through it, so that tuning was effected at their upper, while the wires were attached to their lower ends. Then, to guarantee the security of the case, he ran an independent string-block round it of stouter wood than had been used in harpsichords, in which block the hitch-pins were driven to hold the farther ends of the strings, which were spaced at

³ Communicated by Baron Alexander Kraus (May 1908).
equal distances (unlike the harpsichord), the dampers lying between the pairs of unisons.

Cristofori died in 1731. He had pupils, but did not found a school of Italian pianoforte-making, perhaps from the peculiar Italian conservatism in musical instruments we have already remarked upon. The essay of Scipione Maffei was translated into German, in 1725, by König, the court poet at Dresden, and friend of Gottfried Silbermann, the renowned organ builder and harpsichord and clavicord maker. Incited by this publication, and perhaps by having seen in Dresden one of Silbermann's pianofortes, Silbermann appears to have taken up the new instrument, and in 1726 to have manufactured two, which J. S. Bach, according to his pupil Agricola, pronounced failures. The trebles were too weak; the touch was too heavy. There has long been another version to this story, viz. that Silbermann borrowed the idea of his action from a very simple model contrived by a young musician named Schroeter, who had left it at the electoral court in 1721, and, quitting Saxony to travel, had not afterwards claimed it. It may be so; but Schroeter's letter, printed in Mitzler's Bibliothek, dated 1738, is not supported by any other evidence than the recent discovery of an altered German harpsichord, the hammer action of which, in its simplicity, may have been taken from Schroeter's diagram, and would sufficiently account for the condemnation of Silbermann's earliest pianofortes if he had made use of it. In either case it is easy to distinguish between the lines of Schroeter's interesting communications (to Mitzler, and later to Marpurg) the bitter disappointment he felt in being left out of the practical development of so important an instrument.

But, whatever Silbermann's first experiments were based upon, it was ascertained, by the investigations of A. J. Hipkins, that he, when successful, adopted Cristofori's pianoforte without further alteration than the compass and colour of the keys and the style of joinery of the case. In the Silbermann grand pianofortes, in the three palaces at Potsdam, known to have been Frederick the Great's, and to have been acquired by that monarch prior to J. S. Bach's visit to him in 1747, we find the Cristofori framing, stringing, inverted wrest-plank and action complete. Fig. 15 represents the instrument on which J. S. Bach played in the Town Palace, Potsdam.

It has been repeatedly stated in Germany that Frederici, of Gera in Saxony, an organ builder and musical instrument maker, invented the square or table-shaped piano, the "fort bien," as he is said to have called it, about 1758-1760. No square piano by this maker is forthcoming, though an "upright grand" piano, made by Domenico del Mela in 1739, with an action adapted from Cristofori's has been discovered by Signor Ponsich of Florence. Victor Frederici, of Dresden, and friend of Gottfried Silbermann, the renowned organ builder and harpsichord and clavicord maker, invented a grand piano, dated 1745 (fig. 16). In Frederici's upright grand action we have not to do with the ideas of either Cristofori or Schroeter; the movement is practically identical with the hammer action of a German clock, and has its counterpart in a piano at Nuremberg; a fact which needs further elucidation. We note here the earliest example of the leather hinge, afterwards so common in piano actions and only now going out of use. Where we are to look for Schroeter's copyist if not found in Silbermann, Frederici, or, as we shall presently see, perhaps J. G. Wagner? It might be in the harpsichord we have mentioned, which, made in 1712 by one Brock for the elector of Hanover (afterwards George I. of England), was by him presented to the Protestant pastor of Schuelsen, near Hanover, and has since been rudely altered into a pianoforte (fig. 17). There is no altered harpsichord in the museum at Basel which appears to have been no more successful. But an attempted combination of harpsichord and pianoforte appears as a very early intention. The English poet Mason, the friend of Gray, bought such an instrument at Hamburg in 1755, with "the cleverest mechanism imaginable." It was only under date of 1763 that Schroeter published for the first time a diagram of his proposed invention, designed more than forty years before. It appeared in Marpurg's Kritische Briefe (Berlin, 1764). Now, immediately after, Johann Zumpe, a German in London, who had been one of Shudi's workmen, invented or introduced (for there is some tradition that Mason had to do with the invention of it) a square piano, which was to become the most popular domestic instrument. It would seem that Zumpe was in fact not the inventor of the square piano, which appears to have been well known in Germany before his date, a discovery made by Mr George Rose. In Paul de Wit's Musical Instrument Museum—formerly in Leipzig, now transferred to Cologne—there is a small square piano, 27 in. long, 10 in. wide and 4½ in. high, having a contracted keyboard of 3 octaves and 2 notes. The action of this small instrument is practically identical in every detail with that of the square pianofortes made much later by Zumpe (Paul de Wit, Katalog des musikhistorischen Museums, Leipzig, 1903. No. 55, illustration, p. 38). Inside is inscribed: "Friedrich Hildebrandt, Instrumentenmacher in Leipzig, Quergasse," with four figures.

For arguments in favour of Schroeter's claim to the invention of the pianoforte see Dr Oscar Paul's Geschichte des Claviers (Leipzig, 1868).

1 See Cesare Ponsich, II Pianoforte, sua origine e sviluppo (Florence, 1876), p. 37.

2 This translation, published at Hamburg and reproduced in extenso, may be read in Dr Oscar Paul's Geschichte des Claviers (Leipzig, 1868).
almost illegible. Paul de Wit refers the instrument to the middle of the 18th century. It has all the appearance of being a reduced copy of a well-established type, differing very little from the later models, except that it has no dampers. It seems probable that this small instrument is a converted clavichord, and that the action may have been suggested by Schroeter's model, left in 1721 at the Elector Court of Saxony. Burney tells us all about Zumpe; and his instruments still existing would fix the date of the first at about 1765. Fetis narrates, however, that he began the study of the piano on a square piano made by Zumpe in 1762. In his simple "old man's head" action we have the nearest approach to a realization of Schroeter's simple idea. It will be observed that Schroeter's damper would stop all vibration at once. This defect is overcome by Zumpe's "nipplestick" damper.

Another piano action had, however, come into use about that time or even earlier in Germany. The discovery of it in the simplest form is to be attributed to V. C. Mahillon, who found it in a square piano belonging to Henri Gosselin, painter, of Brussels. The principle of this action is that which was later perfected by the addition of a good escapement by Stein of Augsburg, and was again later experimented upon by Sebastian Erard. Its origin is perhaps due to the contrivance of a piano action that should suit the shallow clavichord and permit of its transformation into a square piano; a transformation, Schroeter tells us, had been going on when he wrote his complaint. It will be observed that the hammer is, as compared with other actions, reversed, and the axis rises with the key, necessitating a fixed means for raising the hammer, in this action effected by a rail against which the hammer is jerked up. It was Stein's merit to graft the hopper principle upon this simple action; and Mozart's approbation of the invention, when he met with it at Augsburg in 1777, is expressed in a well-known letter addressed to his mother. No more "blocking" of the hammer, destroying all vibration, was hitherto to vex his mind. He had found the instrument that for the rest of his short life replaced the harpsichord. V. C. Mahillon secured for his museum the only Johann Andreas Stein piano which is known to remain. It is from Augsburg, dated 1780, and has Stein's escapement action, two unisons, and the knee pedal, then and later common in Germany.

Mozart's own grand piano, preserved at Salzburg, and the two grand pianos (the latest dated 1790) by Huhn of Berlin, preserved at Berlin and Charlottenburg, because they had

FIG. 21.—Stein's Action (the earliest so-called Viennese), 1780. belonged to Queen Luise of Prussia, follow Stein in all particulars. These instruments have three unisons upwards, and the muting movement known as *celeste*, which no doubt Stein had also. The wrest-plank is not inverted; nor is there any imitation of Cristofori. We may regard Stein, coming after the Seven Years' War which had devastated Saxony, as the German reinventor of the grand piano. Stein's instrument was accepted as a model, as we have seen, in Berlin as well as Vienna, to which city his business was transferred in 1794 by his daughter Nanette, known as an accomplished pianist and friend of Beethoven, who at that time used Stein's pianos. She had her brother in the business with her, and had already, in 1793, married J. A. Streicher, a pianist from Stuttgart, and distinguished as a personal friend of Schiller. In 1802, the brother and sister dissolving partnership, Streicher began himself to take his full share of the work, and on Stein's lines improved the Viennese instrument, so popular for many years and famous for its lightness of touch, which contributed to the special character of the Viennese school of pianoforte playing. Since 1862, when Steinway's example caused a complete revolution in German and Austrian piano-making, the old wooden cheap grand piano has died out. We will quit the early German piano with an illustration (fig. 22) of an early square piano action in an instrument made by Johann Gottlob Wagner of Dresden in 1753. This interesting discovery of Mahillon's introduces us to a rude imitation (in the principle) of Cristofori, and it appears to have no relation whatever to the clock-hammer motion seen in Frederic's.

Burney, who lived through the period of the displacement of the harpsichord by the pianoforte, is the only authority to whom we can refer as to the introduction of the latter instrument into England. He tells us, in his gossiping way, that the first hammer harpsichord that came to England was made by an English monk at Rome, a Father Wood, for an English gentleman, Samuel Crisp of Chepstow; the tone of this instrument was superior to that produced by quills, with the added power of the shades of *piano* and *forte*, so that, although the touch and mechanism were so imperfect that nothing quick could be executed upon it, yet in a slow movement like the "Dead March" in Saul it excited wonder and delight. Fulke Greville afterwards bought this instrument for 100 guineas, and it remained unique in England for several years, until Plenius, the inventor of the lyrichord, made a pianoforte in imitation of it. In this instrument the touch was better, but the tone was inferior. We have no date for Father Wood. Plenius produced his lyrichord, a *sostenente*

---

1 Reece's *New Cyclopaedia*, art. "Harpsichord."
Pianoforte, 1755. Fulke Greville’s could have been no longer unique. The Italian origin of Father Wood's pianoforte points to a copy of Cristofori, but the description of its capabilities in no way confirms this supposition, unless we adopt the very possible theory that the instrument had arrived out of order and there was on one in London who could put it right, or would perhaps divine that it was wrong. Burney further tells us that the arrival in London of J. C. Bach in 1759 was the motive for several of the second-rate harpsichord makers trying to make pianofortes, but with no particular success. Of these Americus Backers (d. 1776), said to be a Dutchman, appears to have gained the first place. He was afterwards the inventor of the so-called English action, and as this action is based upon Cristofori’s we may suppose he at first followed Silbermann in copying the original inventor. There is an old play-bill of Covent Garden in Messrs Broadwood's possession dated the 16th of May 1797, which has the following announcement:

"End of Act 1. Miss Brickler will sing a favourite song from Judith, accompanied by Mr Dibdin on a new instrument call'd Piano Forte."

The mind at once reverts to Backers as the probable maker of this novelty. Backers's "Original Forte Piano" was played at the Thatched House in St James's Street, London, in 1773. Ponsicchi has found a Backers grand piano at Pistoria, dated that year. It was Backers who produced the action continued in the direct principle by the firm of Broadwood, or with the reversed lever and hammer-butt introduced by the firm of Collard in 1835.

The escapement lever is suggested by Cristofori's first action, to which Backers has added a contrivance for regulating it by means of a button and screw. The check is from Broadwood; Cristofori's second action. No more durable action has been constructed, and it has always been found equal, whether made in England or abroad, to the demands of the most advanced virtuosi. John Broadwood and Robert Stodart were friends, Stodart having been Broadwood's pupil; and they were the assistants of Backers in the installation of his invention. On his deathbed he committed it to Broadwood's care, but Stodart appears to have been the first to advance it—Broadwood being probably held back by his partnership with his brother-in-law, the son of Shudi, in the harpsichord business. (The elder Shudi had died in 1773.) Stodart soon made a considerable reputation with his "grand" pianofortes, a designation he was the first to give them. In Stodart's grand piano we first find an adapation from the lyric chord of Plenus, of steel arches between the wrest-plank and belly-rail, bridging the gap up which the hammers rise, in itself an important cause of weakness. These are not found in any contemporary German instruments, but may have been part of Backers's. Imitation of the harpsichord by "octaving" was at this time an object with piano makers. Zumpe's small square piano had met with great success; he was soon enabled to retire, and his imitators, who were legion, continued his model with its hand stops for the dampers and soundboard, with little change but that which straightened the keys from the divergences inherited from the clavichord. John Broadwood took this domestic instrument first in hand to improve it, and in the year 1780 succeeded in entirely reconstructing it. He transferred the wrest-plank and pins from the right-hand side, as in the clavichord, to the back of the case, an improvement universally adopted after his patent, No. 1379 of 1783, expired. In this patent we first find the damper and piano pedals, since universally accepted, but at first in the grand pianofortes only. Zumpe's action remaining with an altered damper, another inventor, John Geib, patented (No. 1571 of 1786) the hopper with two separate escapements, one of which soon became adopted in the grasshopper of the square piano, it is believed by Geib himself; and Petzold, a Paris maker, appears to have taken later to the escapement effected upon the key. We may mention here that the square piano was developed and continued in England until about the year 1860, when it went out of fashion.

To return to John Broadwood—having launched his reconstructed square piano, he next turned his attention to the grand piano to continue the improvement of it from the point where Backers had left it. The grand piano was in framing and resonance entirely on the harpsichord principle, the sound-board bridge being still continued in one undivided length. The strings, which were of brass wire in the bass, descended in notes of three unisons to the lowest note of the scale. Tension was left to chance, and a reasonable striking line or place for the hammers was not thought of. Theory requires that the notes of octaves should be multiples in the ratio of 1 to 2, by which, taking the treble clef C at one foot, the lowest F of the five-octave scale would require a vibrating length between the bridges of 12 ft. As only half this length could be conveniently afforded, we see at once a reason for the above-mentioned deficiencies. Only the three octaves of the treble, which had lengths practically ideal, could be tolerably adjusted. Then the striking-line, which should be at an eighth or not less than a ninth or tenth of the vibrating length, and had never been cared for in the harpsichord, was in the lowest two octaves out of all proportion, with corresponding disadvantage to the tone. John Broadwood did not venture alone upon the path.
towards rectifying these faults. He called in the aid of proficient men of science—Tiberius Cavallo, who in 1788 published his calculations of the tension, and Dr Gray, of the British Museum. The problem was solved by dividing the sound-board bridge, the lower half of which was advanced to carry the bass strings, which were still of brass. The first attempts to equalize the tension and improve the striking-place were here set forth, to the great advantage of the instrument, which in its wooden construction might now be considered complete. The greatest pianists of that epoch, except Mozart and Beethoven, were assembled in London—Clementi, who first gave the pianoforte its own character, raising it from being a mere variety of the harpsichord, his pupils Cramer and for a time Hummel, later on John Field, and also the brilliant virtuosi Dussek and Steibelt. To please Dussek, Broadwood in 1797 carried his five-octave, F to F, keyboard, by adding keys upwards, to five and a half octaves, F to C. In 1794 the additional bass half octave to C, which Shudi had first introduced in his double harpsichords, was given to the piano. Steibelt, while in England, instituted the familiar signs for the employment of the pedals, which owes its charm to excitement of the imagination instigated by power over an acoustical phenomenon, the sympathetic vibration of the strings. In 1799 Clementi founded a pianoforte manufactory, to be subsequently developed and carried on by Messrs Collard.

The first square piano made in France is said to have been constructed in 1776 by Sebastian Erard, a young Alsatian. In 1786 he came to England and founded the London manufactory of harpsichords and pianofortes bearing his name. That eminent mechanician and inventor is said to have at first adopted for his pianos the English models. was introduced by William Stodart in 1822. A pressure-bar bearing of later introduction is claimed for the French maker, Bord. The first to see the importance of iron sharing with wood (ultimately almost supplanting it) in pianoforte framing was a native of England and a civil engineer by profession, John Isaac Hawkins, known as the inventor of the ever-pointed pencil. He was living at Philadelphia, U.S.A., when he invented and first produced the familiar

**Figure 27.** Steinway’s Grand Piano Action, 1884. The double escapement as in Erard’s, but with shortened balance and usual check.

**Figure 28.** Hawkins’s Portable Grand Piano, 1800. An upright instrument, the original of the modern cottage piano or pianino. In Messrs Broadwood’s museum and unrestored.

**Hawkins.**

However, in 1794 and 1801, as is shown by his patents, he was certainly engaged upon the elementary action described as appertaining to Gosselin’s piano, of probably German origin. In his long-continued labour of inventing and constructing a double escapement action, Erard appears to have sought to combine the English power of gradation of tone with the German lightness of touch. He took out his first patent for a “repetition” action in 1808, claiming for it “the power of giving repeated strokes without missing or failure, by very small angular motions of the key itself.” He did not, however, succeed in producing his famous repetition or double escapement action until 1821; it was then patented by his nephew Pierre Erard, who, when the patent expired in England in 1835, proved a loss from the difficulties of carrying out the invention, which induced the House of Lords to grant an extension of the patent.

Erard invented in 1868 an upward bearing to the wrest-plank bridge, by means of agraffes or studs of metal through holes in which the strings are made to pass, bearing against the upper side. The wood bridge with down-bearing strings is clearly not in relation with upward-striking hammers, the tendency of which must be to raise the strings from the bridge, to the detriment of the tone. A long brass bridge on this principle discovery that has since been introduced as novel. His instrument (fig. 28) is in a complete iron frame, independent of the case; and in this frame, strengthened by a system of iron resistance rods combined with an iron upper bridge, his sound-board is entirely suspended. An apparatus for tuning by mechanical screws regulates the tension of the strings, which are of equal length throughout. The action, in metal supports, anticipates Wornum’s in the checking, and still later ideas in a contrivance for repetition. This remarkable bundle of inventions was brought to London and exhibited by Hawkins himself:
but the instrument being poor in the tone failed to bring him pecuniary reward or the credit he deserved. Southwell appears to have been one of the first to profit by Hawkins's ideas by bringing out the high cabinet pianoforte, with hinged sticker action, in 1807. All that he could, however, patent in it was the simple damper action, turning on a pivot to relieve the dampers from the strings, which is still frequently used with such actions. The next steps for producing the lower or cottage upright piano were taken by Robert Wornum, who in 1811 produced a diagonally, and in 1813 a vertically, strung one. Wornum's perfected crank action (fig. 29) was not complete until 1826, when it was patented for a cabinet piano; but it was not really introduced until three years later, when Wornum applied it to his little "piccolo." The principle of this centred lever check action was introduced into Paris by Pleyel1 and Pape, and thence into Germany and America. It was not, however, from Hawkins's invention that iron became introduced as essential to the structure of a pianoforte. This was due to William Allen, a young Scotsman in the employ of the Stodarts. He devised a metal system of framing intended primarily for compensation, but soon to become, in other hands, a framing for resistance. His idea was to meet the divergence in tuning caused in brass and iron strings by atmospheric changes by compensating tubes and plates of the same metals, guaranteeing their stability by a cross batoning of stout wooden bars and a metal bar across the wrest-plank. Allen, being simply a tuner, had not the full practical knowledge for carrying out the idea. He had to ally himself with Stodart's foreman, Thom; and Allen and Thom patented the invention in January 1820. The firm of Stodart at once acquired the patent.

We have now arrived at an important epoch in pianoforte construction—the abolition, at least in England and France, of the wooden construction in favour of a combined construction of iron and wood, the former material gradually asserting pre-eminence. Allen's design is shown in fig. 30. The long bars shown in the diagram are really tubes fixed at one end only; those of iron lie over the iron or steel wire, while those of brass lie over the brass wire, the metal plates to which they are attached being in the same correspondence. At once a great advance was made in the possibility of using heavier strings than could be stretched before, without danger to the durability of the case and frame. The next step was in 1821, to a fixed iron string-plate, the invention of one of Broadwood's workmen, Samuel Hervé, which was in the first instance applied to one of the square pianos of that firm. The great advantage in the fixed plate was a more even solid counterpoise to the drawing or tension of the strings and the abolition of their undue length behind the bridge, a reduction which Isaac Carter2 had tried some years before, but unsuccessfully, to accomplish with a plate of wood. So generally was attention now given to improved methods of resistance that it has not been found possible to determine who first practically introduced those long iron or steel resistance bars which are so familiar a feature in modern grand pianos. They were experimented on as substitutes for the wooden bracing by Joseph Smith in 1708; but to James Broadwood belongs the credit of trying them first above the sound-board in the treble part of the scale as long ago as 1808, and again in 1818; he did not succeed, however, in fixing them properly. The introduction of fixed resistance bars is really due to observation of Allen's compensating tubes, which were, at the same time, resisting. Sébastien and Pierre Erard seem to have been first in the field in 1823 with a complete system of roller and silk attachments from treble to bass, with a simple mode of fastening them through the sound-board to the wooden beams beneath, but, although these bars appear in their patent of 1824, which chiefly concerned their repetition action, the Erards did not either in France or England claim them as of original invention, nor is there any string-plate combined with them in their patent. James Broadwood, by his patent of 1827, claimed the combination of string-plate and resistance bars, which was clearly the completion of the wood and metal instrument, differing from Allen's in the nature of the resistance being fixed. Broadwood, however, left the brass bars out, but added a fourth bar in the middle to the three in the treble he had previously used. It must be borne in mind that it was the trebles that gave way in the old wooden construction before the tenor and bass of the instrument. But the weight of the stringing was always increasing, and a heavy close overspining of the bass strings had become general. The resistance bars were increased to five, six, seven, eight and, as we have seen, even nine, according to the ideas of the different English and French makers who used them in their pursuit of stability.

The next important addition to the grand piano in order of time was the harmonic bar of Pierre Erard, introduced in 1838. This was a gun-metal bar of alternate pressing and drawing power by means of screws which were tapped into the wrest-plank immediately above the treble bearings, making that part of the instrument nearly immovable; this favoured the production of higher harmonics to the treble notes, recognized in what we commonly call "ring." A similar bar, subsequently extended by Broadwood across the entire wrest-plank, was to prevent any tendency in the wrest-plank to rise, from the combined upward drawing of the strings. A method of fastening the strings on the string-plate depending upon friction, and thus dispensing with "eyes," was a contribution of the Collards, who had retained James Stewart, a man of considerable inventive power, who had been in America with Chickering. This invention was introduced in 1837. Between 1847 and 1849 2Sometime foreman to the pianoforte maker Mott, who attracted much attention by a piano with sosteäsente effect, produced by a silk attachments in 1817. But a sosteäsente piano, however perfect, is no longer a true piano such as Beethoven and Chopin wrote for.

---

1 Pleyel exhibited a small upright piano in Paris in 1827. Pierre Erard did not turn his attention to upright pianos until 1831.
Mr Henry Fowler Broadwood, son of James, and grandson of John Broadwood, and also great-grandson of Shudi (Tschoudi), invented a grand pianoforte to depend practically upon iron, in which, to avoid the conspicuous inequalities caused by the breaking of the scale with resistance bars, there should be no bar parallel to the strings except a bass bar, while another flanged resistance bar, as an entirely novel feature, crossed over the strings from the bass corner of the wrest-plank to a point upon the string-plate where the greatest accumulation of tension strain was found. Broadwood did not continue, without some compromise, this extreme renunciation of ordinary resistance means. After the Great Exhibition of 1851 he employed an ordinary straight bar in the middle of his concert grand scale, his smaller grands having frequently two such as well as the long bass bar. After 1862 he covered his wrest-plank with a thick plate of iron into which the tuning pins screw as well as into the wood beneath, thus avoiding the crushing of the wood by the constant pressure of the pin across the pull of the string, an ultimate source of danger to durability.

The introduction of iron into pianoforte structure was differently and independently effected in America, the fundamental idea there being to use a single casting for the metal plate and bars, instead of forging or casting them in separate pieces. Alpheaus Babcock was the pioneer to this kind of metal construction. He also was bitten with the compensation notion, and had cast an iron ring for a square piano in 1835, which, although not a success, gave the clue to a single casting resistance framing, successfully accomplished by Conrad Meyer, in Philadelphia, in 1833, in a square piano which still exists, and was shown in the Paris Exhibition of 1878. Meyer's idea was improved upon by Jonas Chickering (1797-1853) of Boston, who applied it to the grand piano as well as to the square, and brought the principle up to a high degree of perfection —establishing by it the independent construction of the American pianoforte.

We have now to do with over- or cross-stringing, by which the bass division of the strings is made to cross over the tenor part of the scale in a single, double or treble disposition at diverging angles—the object being in the first instance to get longer bass strings than are attainable in a parallel scale, and in the next to open out the scale and extend the area of bridge pressure on the sound-board. In the 18th century clavicorders were sometimes overstrung in the lowest octave to get a clearer tone in that very indistinct part of the instrument (strings tuned an octave higher being employed). The first suggestion for the overstringing in the piano was made by the celebrated flute-player and inventor Theobald Boehm, who carried it beyond theory in London, in 1831, by employing a small firm located in Cheapside, Gerock & Wolf, to make some overstrung pianos for him. Boehm expected to gain in tone; Pape, an ingenious mechanician in Paris, tried a like experiment to gain economy in dimensions, his notion being to supply the best piano possible with the least outlay of means. Tomkinson in London continued Pape's model, but neither Boehm's nor Pape's took permanent root. The Great Exhibition of 1851 contained a grand piano, made by Lichtenhal of St Petersburg, overstrung in order to gain symmetry by two angle sides to the case. It was regarded as a curiosity only. Later, in 1855, Henry Engelhard Steinway (originally Steinweg; 1707-1871), who had emigrated from Brunswick to New York in 1849, and had established the firm of Steinway & Sons in 1853 in that city, effected the combination of an overstrung scale with the American iron frame, which exhibited in grand and square instruments shown in London in the International Exhibition of 1862, excited the attention of European pianoforte makers, leading ultimately to important results. The Chickering firm claim to have anticipated the Steinways in this invention. They assert that Jonas Chickering had begun a square piano on this combined system in 1853, but, he died before it was completed, and it was brought out later. It is often difficult to adjudicate upon the claims of inventors, so rarely is an invention the product of one man's mind alone. However, the principle was taken up and generally adopted in America and Germany, and found followers elsewhere, not only in grand but in upright pianos, to the manufacture of which it gave, and particularly in Germany, a powerful impetus.

Since 1885 the American system of a metal plate in one casting, and cross- or over-stringing by which the spun bass strings cross the longer steel diagonally, has become general in Europe with the exception of France, where the musical taste has remained constant to the older wooden structure and parallel stringing throughout. The greater tenacity of the modern cast-steel wire favours a very much higher tension, and consequent easier production of the higher partials of the notes, permitting a sostenuto unknown to Beethoven, Schumann or Chopin. While in 1862 the highest tension of a concert grand piano worked out at sixteen tons, since 1885 thirty tons has been record. Generally speaking, the rise in tension may be expressed musically by the interval of a minor third, to the great advantage of the standing in tune. First shown by Henry Steinway in the London Exhibition of 1862, this altered construction attracted extraordinary attention at Paris in 1867, and determined the German direction of manufacture and a few years later the English. What is now particularly noticeable wherever pianos are made is the higher average of excellence attained in making, as well as in pianoplaying. Naturally the artistic quality, the personal note, characterizes all first-class instruments, and permits that liberty of choice which appertains to a true conception of art.

Much attention has been given of late years to the touch of pianos, to make it less tiring for the modern performer, especially since, in 1885 & 1886, Anton Rubenstein went through the herculean feat of seven consecutive historical recitals, repeated in the capital cities and principal musical centres of Europe. For even this stupendous player a light touch was indispensable. In
to form a continuous flange, which enables the frame to bear
the increased modern tension while providing additional elas-
ticity and equality of vibration power throughout the scaling.
The absence of barring and bracing tends to subdue the metallic
quality of tone so often observable in pianofortes constructed
with heavy iron frames, and the barless steel frame being so
much more elastic than the latter, no loss in resonance is per-
ceptible. The tone of the barless grand is of singular beauty
and sonority and is even throughout the compass.

The problem of resonance—with stringed keyboard instru-
ments, the reinforcement or amplification of sound—has, from
the days of the lute- and spinet-makers, been
empirical. With lute, guitar, and viol or violin
the sound-box comes in, combining in the instrument,
the distinct properties of string and enclosed air or
wind. With the spinet, harpsichord and piano we have to do
chiefly with the plate of elastic wood, to amplify the initial
sound of the strings; and the old
plan of a thin plate of spruce, put
in slightly convex and with an
under-harring of wood for tension,
has absorbed the attention of
piano-makers. The violin belly,
with its bass har and sound post,
has relation to it; but the recent invention of the Stroh violin has
shown that the initial string
vibrations may be passed through
a bridge, be concentrated,
and adequately transferred to an
aluminium disk not much larger
than half a crown. The piano,
with its numerous strings, cannot
be so reduced, but the reinforce-
ment problem is open to another
solution, tentative it is true, but
a possible rival. The “Gladi-
ator” soundboard is the invention
of Albert Schulz, late director
of the piano manufactory of
Ritmüller and Söhne of Göttingen.
Dr Moser’s name has been
associated with the inventor’s in
the English patent. In the
“Gladiator” two slabs of wood,
with grain of opposed direction
to give the necessary tension, are
 glued together, and the whole
system of belly bars is done away
with. There is a thinning round
the edge, to facilitate promptness
of speech. As we are still feeling
our way towards an accurate
and comprehensive statement of
resonance, this invention is one
claiming scientific interest, as well
as being of possible practical im-
portance.

To return to the touch. The
desirability of what is called
repetition—that the
jack or sticker, which
from the depression of the key
delivers the blow that raises
the hammer to the strings, should
never be far away from the
notch or nose which receives the
impulse—is as much an object
of consideration with piano-
makers now as it has been since
Sebastian Erard began those
experiments in 1808 which ended
always be heavier in that department, and lighter in the treble
from the lesser weight. In balancing the keys, allowance has
to be made for the shorter leverage of the black keys. When
the player touches the keys farther back the leverage is propor-
tionately shortened and the weight increased, and there is also
an ascending scale in the weight of the player’s blow or pressure
from pianissimo to fortissimo. The sum of the aggregate force
expended by a pianist in a recital of an hour and a half’s duration,
if calculated, would be astonishing.

The most important structural change in pianos in recent
years has been the rejection of support given by metal bars
or struts between the metal plate to which the strings are hiched
and the wrest-plank wherein the tuning-pins are inserted.
These bars formed part of William Allen’s invention, brought
forward by Stodart in 1820, and were first employed for rigidity
in place of compensation by the Paris Erards two years later.
Broadwood in London introducing about that time the fixed
metal plate. The patent No. 1231, for the barless or open-scale
piano, taken out in London in 1888 by H. J. Tschudi Broadwood,
is remarkable for simplification of design as well as other qualities.
Ten years elapsed after the taking out of the patent before
the first barless grand was heard in public (January 1898 at St
James’s Hall). The metal frame, bolted in the usual manner
to the bottom framing, is of fine cast steel entirely free from any
transverse bars or struts, being instead turned up round the edges

Fig. 35.—Cary’s Repeating Action. 1, the butt in which the
hammer is glued. E, a
spring attached to the butt by
a link of silk cord passed
through a wire guide. The
object is that though the
key may be still pressed down,
the hammer returns but a
short distance to ensure a
quick response to the blow if
repeated.
in his famous "double escapement" action. The principle of this great action, like that of Worren patent piano in 1826, has become general. But Joseph Henry Cary in 1833 (patent No. 2283) invented a simple contrivance for repetition in all pianos, neglected at the time, and subsequently patented and disputed over by others, which has only been preserved in records of the patent office, while the inventor has left no other mark. But the utility of the invention has come to light. It is increasingly used in actions of upright pianos, and, in combination with the old English grand action, is successfully competing with the Erard action proper and the simplified Herz-Erard, of late years so very generally employed.

There has been a great change in the freer technique of piano-playing, partly favoured by the development of piano-making, but reacting and obliging the piano-makers to keep their attention incessantly alive to the aim and requirements of the players. It is true that the genius of Beethoven dominates a technique that has become obsolete, and so completely that the adequate performance of his piano works still gives to the sense as well as to the intellect the highest pleasure, but his annotations to Cramer's Studies, as preserved by Schindler, betray the close touch of the clavichord-player and the student of C. F. E. Bach's Essay on Clavichord-Playing, as well as the weakness as a musical instrument of the early piano. The inventor of a technique so original, and at the time (c. 1839) so extraordinary, as Chopin's, sat at the piano with his elbows immovable, using, for flexibility, neither wrist nor arm. With Chopin, to play loudly was anathema. The modern free style of playing comes from Czerny—whom Beethoven despised as having no legato (Bindung)—through Liszt to the Rubinstein's and to the splendidly equipped performers of our time, to whom the pedal has become indispensable for cantabile and effect.

The most expert performers are now rivalled technically by the recent extraordinary invasion of the American automatic pianos—The Angela, Pianola, Pianola Velocell, and other varieties of the same idea. The use of the perforated roll acts by means of the ingenious and indeed faultless application of pneumatic leverage to the ordinary piano, doing duty for the pianist's fingers; and it is made possible to play louder or softer, faster or slower, by mechanical arrangement. Such an instrument lacks the player's touch, which is as personal and indispensable for sympathy as the singer's voice or violinist's bow. Still, to a violinist, it is a benefit to have a correct coadjudor in a Beethoven or Brahms sonata with one of these handy companions, just as it is to a singer. But let us commend the accomplishments to his or her repertory. The Apollo has the addition of a useful transmitting apparatus—an aid, however, that, though often tried, has never yet been adopted; it is possibly too disturbing to the musician's ear. The mechanical tuning-pin is an analogous experiment which comes regularly under notice as the years go by, to be as persistently rejected. The most practical of these tuning inventions was the Alibert, shown in the Inventions Exhibition, 1835. Here, pressure upon the strings above the wrest-plank bridge modified their tension after a first rough adjustment to pitch had been effected.

The perforated music-sheet, a mechanism common to pianoplayers in the 18th century as well as self-playing pianos, first appears in a French patent, 1842. A United States patent for a keyboard piano-player was issued to E. D. Bootman (Dec. 18, 1866), and the first pneumatic keyboard piano-player was patented in France in 1863 by M. Fournnears. Between 1879 and 1902 a total of 55 patents had been issued in the States. The first complete automatic piano-player ready for performance was the Angelus (No. 24799, 1897). The specification is from a communication to the British patent office by Edward Hollingworth White, of Meriden, New Haven county, Conn., U.S.A. There is a pneumatic chest, fasteners, key levers, bellows and pedals. The whole apparatus is contained in a portable cabinet mounted upon carriages. The bellows and operating pedals may be conveniently moved about a room. The finger levers or key strikers correspond with a considerable portion of the manual keys or clavier of a piano. Thus the automatic piano-player comprises a portable cabinet fitted with bellows and operating pedals, a pneumatic and operating pedal-actuating mechanism, a tracker adjusted for the use of a perforated music-sheet, a pneumatic motor and winding-roll mechanism to propel the music-sheet, and a series of levers operated by the pneumatic mechanism, so projecting as to overhang the piano keyboard and play upon it, with rockers or levers for depressing the piano pedals. Subsequently the apparatus was made capable of accelerating or retarding the tempo at the will of the operator. A roll of music, 12 in. wide and varying in length according to the composition, can be placed in position promptly, and when exhausted can be returned upon its original roll by a simple stop, and operated by a mechanical linkage. The complete apparatus was patented in 1886 and followed in 1898, the Apollo 1900. The difference of all these clever contrivances is not conspicuous to the amateur.

While these allied inventions have had to do with a substitute for touch and the necessity for the persevering acquirement of a difficult technique, another, the Virgil Practice Clavier, so called after the inventor, Mr Almon Kineaid Virgil, an American music teacher, is intended to aid the student in acquiring the technique with taste, so that the finger technique is acquired mechanically and unmusically, while value of tone, reading, expression, whatever we understand by musical production existing our response to the ear, is delayed until the player's hand is formed and considerably developed. The opinion of some of the very greatest pianists is brought forward as approving of the system; in the work, for instance, of Vladimir de Fuchsann, the Virgil technique was found to improve the Virgil technique. The Virgil technique was brought to Europe. Bearing in mind that the minimum weight of the touch of a concert piano is not likely to exceed three and a half ounces it is hardly likely that these skilled performers use this dumb keyboard with the graduated weight advised for advancing

**PIANOFORTE**

**Mechanical Playing.**

**Fig. 36.** Modern Pianola.

A, Blowing pedals operated by feet of player connected by metal crank to feeder B, which exhausts air from bellows C, which in turn exhausts air from all working valves and bellows in Pianola.

D, is perforated roll passing over tracker bar E, winding on to spool F operated by a pneumatic motor and controlled by lever G, which is connected to metronome style pointer H. This is used in conjunction with a specially marked roll, giving correct interpretation of tempo.

I, is channel leading to primary pneumatic J operating secondary pneumatic K, which exhausts striking motor L, connected to key lever M to depress piano key.

The melodist device consists of two small holes, one at each end of tracker bar E, connecting with pneumatic valve, which increases power of suction instantaneously when melody notes are being played, by means of an extra perforation at each outside edge near roll D; one hole for bass melody at left, and one at right edge for treble melody.

N, is metal arm or bracket connected to lever in front for purpose of depressing sustaining pedal of piano.

O, is the governing bellows of motor for operating music-roll and prevents pace of roll being accelerated or retarded by hand or soft pedalling, thus allowing great change of expression to be made without interfering with speed of roll.
pianos, namely, from five to eight ounces. It is allowed that the lightest possible touch may be used at first. One high recommendation certainly remains after all that may be said regarding it, namely that it is practically almost noiseless, the up and down clicks that mark the duration of finger attachment being alone audible, a boon to the unwell hearing of ordinary piano practice, scales and five-finger exercises requiring that it be executed in its final form in 1872, the more satisfactory Practice Clavier dates from the completion of the invention, about 1890. It was brought to England in 1895 by Mr. Virgil.

PIANO DE MARCA (anc. Pianosa), an island of Italy, belonging to and forming part of the commune of Marciana (Elba), from which it is 73 m. S.W. Pop. (1881), 774. As its name indicates, it is quite flat, and the highest point is only 95 ft. above sea-level. Its area is 6 sq. m. Augustus banished to it his grandson, Agrippa Postumus, and some ruins of baths near the harbour still bear his name. It changed hands more than once in the wars between Pisa and Genoa in the 13th and 14th centuries; from 1306 it belonged to the prince of Piombino, but was depopulated in 1555 by the Turkish fleet, and only resettled at the beginning of the 19th century. In 1877 a penal colony was established here.

PIARISTS, the popular name of a Catholic educational order, the "clerici regulares scholarum piarum," the Pauline Congregation of the Mother of God, founded by Joseph Calasanz (Josephus a Matre Dei) at Rome in the beginning of the 17th century. Calasanz, a native of Calasanza in the province of Huesca in Aragon, was born on September 11, 1556, studied at Lerida and Alcalá, and after his ordination to the priesthood removed to Rome (1592). Here he organized, in 1607, a brotherhood which ultimately, in 1617, became an independent Congregation, numbering at that time fifteen priests, under Calasanz as their head. To the three usual vows they added a fourth, that of obedience to the gratuitous instruction of young. In 1622 the Congregation received a new constitution from Gregory XV., and had all the privileges of the mendicant orders conferred upon it, Calasanz being recognized as general. In 1643 the jealousy of the Jesuits led to his removal from office; owing to the same cause the Congregation was deprived of its privileges by Innocent X. in 1646. Calasanz, who died on August 22, 1648, was beatified in 1748, and canonized in 1767. The privileges of the Congregation were successively restored in 1660, 1669 and 1698. The Piarists, who are not numerous, are found chiefly in Italy, Spain, the West Indies, Germany, and especially in Austria-Hungary. Before the course of study established by the state, a Piarist establishment contained nine classes: reading, writing, elementary mathematics, schola parva or Rudimentorum, schola Principiorum, Grammatica, Syntaxis, Humanitas or Poesis, Rhetorica. The general provost of the order is chosen by the general chapter, and with a general procurator and four assistants resides at Rome. The members are divided into professors, novices, and lay brethren. Their dress is very similar to that of the Jesuits; their motto "Ad majus pietatis incrementum!"

For Calasanz, see Timon-David, Vie de St Joseph Calasanz (Marseilles, 1884); and on the Piarists, P. Helvét, Hist. des ordres religieux (1745), iv. 218; J. A. Seyffert, Ordensregeln der Piaristen (Halle, 1783); J. Schaller, Gedanken über die Ordensfassung der Piaristen (Prague, 1805); A. Heimbucher, Orden und Krenegungen der Piaristen bei den Deutschen (Berlin, 1851); H. H. Walder, "Das Piaristische in der Geschichte der Religion" (Berlin, 1860). The Piarist establishment is always divided into provinces, of which the most important are: 1. the Province of Genoa, 2. the Province of Tuscany, 3. the Province of Italy, 4. the Province of France, 5. the Province of Spain, 6. the Province of England, 7. the Province of Germany, 8. the Province of Poland, 9. the Province of Hungary. The Piarists are always distinguished by the white hood. The general house in Rome is in the Via della Consolata, 1497 by Leonardo da Vinci. There are saw-mills and textile factories in Piastra, which has a considerable trade in wine and timber. Neamtz is one of the most densely forested regions in Moldavia. Lumber rafts are floated down the Bistritz to the Sereh, and so on to Galatz. There are several monasteries in the neighbourhood.

PIATTI, CARLO ALFREDO (1822–1901), Italian violinist, was born at Bergamo on the 8th of January 1822. He was the son of a violinist, and became a pupil at the conservatorio of Milan. From 1838 onwards he journeyed over Europe, playing with extraordinary success in all the important cities of the continent. In 1844 he appeared before the London public at the Festival of the Popular Concerts, he took up the work with which he was most intimately connected for thirty-nine years, retaining until 1897 the post of first violoncello at these famous concert halls, during the latter
half of each series. His purely classical style, his wide musical sympathies, and his general culture and charm, would have ensured him a high position even without his marvellously finished technical skill. In 1804 the fiftieth anniversary of his first appearance in London was celebrated by a reception given in honour of him and his lifelong friend Joachim. He retired from public life, owing to a severe illness, in 1807, and until his death at Bergamo on the 19th of July 1901 divided his time between his native town and Cadenabbia. As a composer he attained a wide popularity with some graceful and popular songs; he did excellent work as an editor; and he was an enthusiastic collector and musical antiquary.

PIAUHY, or Piauí, a north-eastern state of Brazil, bounded N. and W. by Maranhão, E. by Goias, Pernambuco and Bahia, and S. by Bahia. It has a few miles of Atlantic coast-line on the N., and the Rio Parnahyba forms the boundary line with Maranhão throughout its entire length. Area, 116,523 sq. m.; pop. (1900), 334,428. Part of the state on the Atlantic coast and along the lower Parnahyba is low, swampy and malarial. South of this the country rises gradually to a high plateau with open campos. This plateau region is watered by numerous tributaries of the Parnahyba, chief of which are the Urussuhy, the Canindé and its tributary the Piauí, the Gurugua, and its tributary the Parahim, which drains the large inland lake of Parnaguá, the Longa, and the Poty, which has its source in the state of Ceará. The Parnahyba is navigable for boats of 3 ft. draught up to Nova York, a few miles above the mouth of the Gurugua, and could be made navigable up to the mouth of the Balsas. The climate is hot and humid in the lowlands and along the lower Parnahyba, but in the uplands it is dry with high sun temperatures and cool nights. The principal industry is stock-raising, which dates from the first settlement in 1674 by Domingos Afonso Malfrene, who established here a large number of cattle ranges. A secondary industry is the raising of goats, which are able to stand neglect and a scanty food supply. Sheep have likewise been raised in Piauí, but there is no market for mutton and their wool is not utilized. The agricultural products are: cotton, sugar and tobacco. Of fruit-stuffs the people do not produce enough for their own consumption. Forest products include rubber, cannauba wax and dyewoods. The exports include hides, skins, rubber, wax, tobacco and cotton. The capital is Theresina, on the right bank of the Parnahyba, 250 m. above Parnahyba (town), with which it is connected by a line of light-draught river boats. The town dates from 1852, is attractively situated, and is regularly laid out with broad, straight streets crossing each other at right angles. The population of the município in 1890 was 31,523, which includes a large rural district. Other towns, with their populations in 1890, are Sobradinho (2,500); Parnahyba (1,525); Valença (1,603); and Campo Maior (1,425), the figures given of population being those of the large districts (municipios) in which the towns are situated.

PIAZZA, properly an open square or place in an Italian town (Ital. piazza, from Lat. platea, broad space, Gr. ἡ πλάτεα, broad). These squares were usually surrounded with a colonnade or arcade, and thus the word has been loosely applied to a covered walk or arcade along the front of a building, and in America, to the veranda of a house.

PIAZZA ARNERIMA, a city of Sicily, in the province of Caltanissetta, 39 m. by road E.S.E. from that town, and the same distance S. of the railway station of Assoro-Valguarnera, 43 m. W. of Catania, situated 2,560 ft. above sea-level. Pop. (1901), 24,119. It has a 15th-century cathedral, with a fine campanile, and some of the houses show Norman or Gothic architecture. The foundation of the town dates from the 11th century, and the dialect is Lombard.

See Mauceri in L’Arte (1906), 14.

PIAZZI, GIUSEPPE (1746–1826), Italian astronomer, was born at Ponte, in the Valtellina, on the 16th of July 1746. He entered the Theatine Order in 1764, accepted the chair of mathematics in the academy of Palermo in 1770, and persuaded the viceroy, Prince Caramanico, to build an observatory there. During a visit to England in 1788 he procured from Jesse Ramsden a five-foot alidade, with which he collected at Pisa from 1792–1813, the materials for two admirable star-catalogues, published in 1803 and 1814 respectively. While engaged on this work he discovered, on the 1st of January 1801, the first asteroid or minor planet, to which he gave the name of Ceres, the tutelary deity of Sicily. He died at Naples on the 22nd of July 1826.

PIBRAC, GUY DU FAUB, Seigneur de (1529–1584), French jurist and poet, was born at Toulouse, of an old family of the magistracy. He studied law there with Jacques Cujas, and afterwards at Padua. In 1548 he was admitted to the bar at Toulouse, at once took high rank, and rose to be juge-mage, an office in Languedocian cities about equal to that of prévôt. He was selected in 1562 as one of the three representatives of the king of France at the council of Trent. In 1565 he became general advocate to the parliament of Paris, and extended the renaissance in jurisprudence which was transforming French justice. In 1573 he was sent by Charles IX. to accompany as châtelain his brother Henry (afterwards Henry III.) to Poland, of which country Henry had been elected king. Pibrac's fluent Polish won much applause from the Poles, but his second visit to Poland in 1575, when sent back by Henry III. to try to save the Crown he had deserted, was not so successful. Then he was employed in negotiations with the so-called politiques, and he managed to keep them quiet for a while. In 1578 he became the chancellor of Marguerite of France, queen of Navarre. Although he was fifty, his beauty and intellectual gifts led him to aspire to win her affection; but he was rejected with disdain. He died in 1584. His oratorical style was too pedantic, but quotations from the classics had a fresher meaning in his day. He was the friend of Ronsard, de Thou and L'Hôpital, and left, among other literary remains, elegant and sententious quadrains.

PIBRACH, a form of music as played by the bagpipe. The word is derived from the Gaelic piobaireachd, the art of the bagpiper. This special form of bagpipe music, consisting of a series of variations founded on a theme, was called the srurlar. These variations are generally of a martial or warlike character and include dirges and marches (see BAGPIPE).

PICA, the name of the European representative of a group of diminutive rodent mammals, also known as tailless hares, mouse-hares, or piping hares, constituting the family Ochotonidae with the single genus Ochotona. From the more typical hares and rabbits they differ by the short and rounded ears, the absence of a tail, and the relatively shorter hind-limbs, as well as by complete collar-bones. The soles of the feet are hairy, and the fur is usually soft and thick; while in some cases the last upper molar is absent. Picas are inhabitants of cold and desert regions. They dwell either in the chinks between rocks, or in burrows, although one Himalayan species frequents pine-forests. They are very active, and most of the species utter a piping or whistling cry. They store up a supply of grass for winter use; in Siberia it is stacked in small heaps. The Himalayan Ochotona roylei may be seen in the daytime, but most kinds are nocturnal. The Siberian species, O. altaica ranges into eastern Europe, but Central Asia is the headquarters, although a few species range into Arctic America and the Rocky Mountains. In size pias may be compared to guinea-pigs. Till of late years the group has been generally known by the name of Lagomys. There are several extinct genera.

PICA, the Latin name of a genus of oscine passerine birds, the magpies. The Latin word, by interchange of initial p and k, is possibly the Gr. κλασσα (see MAGNE), and probably the same word as pīcus, the woodpecker (q.v.). Another derivation would connect both pīca and pīcus with the root pīc- of pīnger, to
paint, from the parti-coloured appearance of the bird. It is this "pyed" or black and white look of the page that probably gave the name of *pica*; "pyed" or "pyed" is a word printed in black and white and then read to a size of type in printing coming next to "English" (see Typography). The Gr. κισσα and Lat. *pica* were used of a perverted craving for unnatural foods; and the word has been adopted in this sense in modern medical terminology.

**PICARD** (La Picardie), one of the old provinces of France, bounded on the N. by Hainaut and Artois, on the E. by Champagne, on the S. by the Île de France, and on the W. by Normandy and the English Channel. Its maritime frontier ran from the mouth of the Aa to the cliffs of Caux, and it included the whole of the basin of the Somme and part of that of the Oise. The chief towns of Picardy were Amiens, Boulogne, Abbeville, Laon, Soissons, Montreuil, Péronne, Beauvais, Montdidier, St Quentin and Noyon. Its principal rivers were the Somme and the Oise. Picardy formed part of the archdiocese of Reims, and its bishops were Amiens, Beauvais, Sens, Soissons, Noyon and Laon. In 1789 the province of Picardy was covered by the three bishoprics of Amiens, Noyon and Boulogne. It was one of the provinces of the five great fermanes, districts subject to the tariff of 1664, and in judicial matters was under the authority of the parlement of Paris. Its area now forms the department of the Somme and parts of the departments of Pas de Calais, Aisne and Oise.

The name of Picardy does not appear until the 13th century, but was employed by Matthew Paris and was in general use in the 14th century. In the 13th century the province was divided into the two bailliages of Amiens and Vermandois, but its regular organization as part of the kingdom of France only dates from the beginning of the 16th century. At this time it was divided into north and south Picardy. North Picardy, or Picardy proper, formed one of the great military governments of the kingdom, while south Picardy was included in the Île de France. North Picardy was divided into upper and lower Picardy, the former being the interior part of the province and the latter the district along the coast. Upper Picardy comprised the districts of Amiènois, Santerre, Vermandois and Thiérache, and lower Picardy those of Ponthieu, Vimeu, Boulognais and Calaisis, or the Pays reconquis; south Picardy included the districts of Beauvaisis, Laonnais and Soissonsais.

Under the Romans Picardy was part of Belgica secunda; it was inhabited by the Morini, the Ambiani, the Veromandui, the Bellovaci and the Parisii. The ancient names of Picardy are derived from Amiens, Vermandois, Beauvais and Soissons. The Romans intersected the district with roads and built several castra to defend the valley of the Somme. In the 3rd century Christianity was preached here, and St Quentin and others were martyred. A little later abbeys were founded, among them Corbie, St Valéry and St Riquier. Early in the 5th century Picardy became the centre of Merovingian France, for, as the historian Michelet says, "Thistoire de l'antique France semble entassée en Picardie." Clavix had his first capital at Soissons. Charlemagne had his at Noyon, and Laon was the capital and the refuge of the later and feeble Carolingian sovereigns.

During the later feudal period Picardy was the home of the counts of Vermandois, of Clermont and of Ponthieu, the sire of Coxy and others. The neighbouring duked of Burgundy cast covetous eyes upon the province; in 1435, by the famous treaty of Arras, the royal towns and lands in the valley of the Somme were ceded by King Charles VII. to Burgundy. However, after the death of Charles the Bold in 1477 Picardy was finally united with the crown of France. The province was early an industrial district. Flemish immigrants brought with them the lucrative trade of weaving cloth, and the Somme towns were soon competing with those of Flanders. The Picard towns were noted for their love of independence, which often brought them into collision with the kings of France during the 13th century. At a later time the province received a number of Spanish immigrants. In the middle ages the Picards formed one of the four "nations" at the university of Paris. Picardy has a high place as a home of Gothic art, this being testified to by the superb cathedrals at Amiens and Noyon, while within its borders is the famous château of Coxy.

Picardy has a literature of its own, which was rich and popular in the 11th century. It suffered greatly from the ravages of the Normans, and later during the Hundred Years War and the wars between France and Spain. Within it are the famous battlefields of Crecy, Agincourt and St Quentin, while it also includes places of conference like Guines, Amiens and Ficqquigny. The Picard had a high reputation as a soldier, being sometimes called the "Gascon of the North," and in 1548 Henry II. created the *régiment de Picardie*. Many anthropological remains have been found in the Somme valley.

**PICARESQUE NOVEL, THE.** This special form of the roman à aventures may be defined as the prose autobiography of a real or fictitious personage who describes his experiences as a social parasite, and who satirizes the society which he has exploited. The picaro, or rogue type, is represented by Encolpos, Asylios and Giton in the Satyricon which tradition ascribes to Petronius; it persists in Lucian, in the *Roman de Renart*, in the *faible*, and in other works popular during the middle ages; and it is incarnated in real life by such men of genius as the Archpriest of Hita and François Villon. But in its final form the picaroesque novel may be regarded as a Spanish invention. The word *picaro* is first used, apparently, in a letter written by Eugenio de Saazar at Toledo on the 15th of April 1560; the etymology which derives *picaro* from *picar* (to pick up) is unsatisfactory to philologists, but it suggests the picaro's chief business in life. In the *Tesoro de la lengua castellana* (Madrid, 1611) Sebastian Covarrubias y Orozco, the best of Spanish lexicographers, describes a *picaro* as a man of loose character engaged in menial work and—by extension—a rascal who attains his ends by skilful dissimulation; and the earliest application of the expression *picaro* to a character in fiction occurs in Mateo Alemán's *Cuanad de Alfarache*, the first part of which was published in 1590. But a genuine *novela picaresca* existed in Spain before the word *picaro* became generally current.

The earliest specimen of the kind is *La Vida de Lazarillo de Tormes y de sus fortunas y adversidades*, an anonymous tale long attributed to a high priest of insufficient grounds, to Diego Hurtado de Mendoza (q.v.). The authorship of Lazarillo and the circulation of his work are obscure; however, it was certainly issued not later than 1554, and was thrice reprinted before 1559, when it was placed on the Index. Imitations of so successful a story were inevitable, and so early as 1555 there appeared at Antwerp *La Segunda parte de Lazarillo de Tormes*, an anonymous sequel which completely misinterpreted the irreverent wit of the original. The first part had been prohibited because of its attacks on the
clergy; in the second part the hero is presented as a devout youth transformed into a tawny at the intercession of the Virgin Mary, who thus saved him from death; after many extravagant experiences in this form he is restored to human shape, and proposes to teach the subhuman language at the university of Salamanca. This dull performance naturally failed to please and, meanwhile, many surreptitious copies of the first part were introduced into Spain; the Inquisition finally gave up the attempt to suppress it, and Don Quixote an expurgated edition was authorized. With this mutilated version the Spanish public was forced to be content during the remaining fifteen years of Philip II's reign. Upon the death of this sombre monarch society relaxed its hypocritical pose of austerity, and in 1599 Mateo Alemán (q.v.) published the Primera parte de Guzmán de Alfarache. It is modelled upon Lazarillo de Tormes, being the autobiography of the son of a ruined Genoese money-lender; but the writer indulges in a tedious series of moralizing. This contrasts sharply with the laconic cynicism of Lazarillo de Tormes; but Guzmán de Alfarache is richer in invention, in variety of episode and in the presentation of character. Its extraordinary popularity tempted a Valencian lay erstwhile Juan José Marfil to publish a Segunda parte de la vida del pícaro Guzmán de Alfarache (1600) at the instance of Mateo Luján de Sayavedra. Though partly plagiarized from the manuscript of the genuine second part to which Marfil had somehow obtained access, the continuation was coldly received; in 1604 Alemán brought out the true continuation, and revenged himself by introducing into the narrative a brother of Marfil—a crazy picaroon of the lowest morality who ultimately commits suicide in disgust at his own turpitude. In Lazarillo de Tormes, and still more in Guzmán de Alfarache, it is difficult to distinguish between the invented episodes and the personal reminiscences of the authors. The Viage entretenido (1605) of Agustín de Rojas is a realistic account of the writer's experiences as a strolling actor and playwright, and, apart from its considerable literary merits, it is an invaluable contribution to the history of the Spanish stage as well as a graphic record of contemporary low life; the chief character in the book is called the caballero del milagro, an expression which recurs in Spanish literature as the equivalent of a chevalier d'industrie.

The next in chronological order of the Spanish picaresque tales is La Picara Justina (1605), the history of a woman picaroon, which has long been customary to ascribe to Andrés Pérez, a Dominican monk; there is, however, no good reason to suppose that the name of Francisco López de Uélésa on the title-page is a pseudonym for the author. The Picara Justina is a realistic account of the writer's experiences as a strolling actor and playwright, and, apart from its considerable literary merits, it is an invaluable contribution to the history of Spanish literature; the chief character in the book is called the caballero del milagro, an expression which recurs in Spanish literature as the equivalent of a chevalier d'industrie.

The next in chronological order of the Spanish picaresque tales is La Picara Justina (1605), the history of a woman picaroon, which has long been customary to ascribe to Andrés Pérez, a Dominican monk; there is, however, no good reason to suppose that the name of Francisco López de Uélésa on the title-page is a pseudonym for the author. The Picara Justina is a realistic account of the writer's experiences as a strolling actor and playwright, and, apart from its considerable literary merits, it is an invaluable contribution to the history of Spanish literature; the chief character in the book is called the caballero del milagro, an expression which recurs in Spanish literature as the equivalent of a chevalier d'industrie. The Picara Justina was thrice reprinted during the seventeenth century; this is the only basis for the untenable theory that it is the source of the caverdismo which reaches its climax in Gracian's treatises. The Picara Justina is now read solely by philologists in quest of verbal eccentricities. Ginés de Pasamonte, one of the secondary figures in Don Quixote, is a singularly wittily achieved character from a Spanish rogue, and in the comedy entitled Pedro de Urdemalas Cervantes again presents a brilliant panorama of picaresque existence. He returns to the subject in Rinconete y Cortadillo and in the Coloquio de los perros, two of the best stories in the Novelas ejemplares (1613). The attraction of picaresque life was felt by pious and learned critics, and expounded in print. In the Viage del mundo (1614) the zealous missionary Pedro de Cevallos interpolates amusing tales of what befell him in the slums of Andalusia before he fled from justice to America, where he lived as a sinful soldier till his spiritual conversion was accomplished. Cristóbal Suárez de Figueroa, a caustic critic of his contemporaries and an arbiter of taste, did not think it beneath his dignity to show a disconcerting acquaintance with the ways of professional rogues, and in El Pasagero (1617) he fills in the sketch of the knavish inn-keeper already outlined by Cervantes in Don Quijote. Evidence of the widely diffused taste for picaresque literature is found in Enriquez de Castro (1517), an interminable story written in Spanish by a Frenchman named François Loubayssin de Lamara, who brought out his book at Paris; two years previously Loubayssin had introduced some clever but risky picaresque episodes in his Engaños deste siglo y historia sucedida en nuestros tiempos. But his attempt to fill a larger canvas is a complete failure. The roving instinct of Vicente Martínez Espinel (q.v.) had led him into strange and dangerous company before and after his ordination as a priest, and a great part of his Relaciones de la vida del escudero Marcos de Obrégon (1618) is manifestly the confession of one who has regretfully outlived his pleasant vices. The baffling compound of fact with fiction and the lucid style of which Espinel was a master would suffice to win for Marcos de Obrégon a permanent place in the history of Spanish literature; the fact that it was largely utilized by Le Sage in Gil Blas has won for it a place in the history of comparative literature. Within five months of its publication at Madrid a fragmentary French version by the Sieur d'Audiguier was issued at Paris, and thus the Spanish picaresque story entitled La Desordenada codicia de los bienes ajenos (1618), ascribed conjecturally to a certain Dr Carlos García, who reports his conversation with a garrulous goad-bird, and appends a glossary of slang terms used by the confraternity of thieves; he was not, however, the first worker in this field, for a key to their gross jargon had been given ten years previously by Juan Hidalgo in his Romances de germania (1609), a series of gipsy ballads. Every kind of picaresque is portrayed with intelligent sympathy by Alonso Jerónimo de Salas Barbaullillo, who is always described as a picaresque novelist; yet he so constantly neglects the recognized conventions of the Spanish school that his right to the title is disputable. Thus in La Hijà de Celestina (1617) he abandons the autobiographical form, in El Subtil cordobés Pedro de Urdemalas (1620) he alternates between dialogue and verse, and in El Neco bien afortunado (1621) the chief character is rather a cunning dolt than a successful scoundrel. The pretense of warning newcomers against the innumerable occasions of sin in the capital is solemnly kept up by Antonio Liñán y Verdugo in his Guía y aviso de forasteros que vienen a la corte (1620), but in most of his tales there is more entertainment than decorum.

The profession of a serious moral purpose on the part of many picaresque writers is often a transparent excuse for the introductions of unsavoury characters; very often it is based on a ground for doubting the sincerity of the physician Jerónimo de Málaga Yáñez y Ribera, who at one time thought of taking holy orders, and studied theology under St John of the Cross. An unusual gravity of intention is visible in Alonso, moco de muchos amos (1624–1626), in which the repentant pícaro Alonso, now a lay-brother, tells the story of his past life to the superior of the monastery in which he has taken refuge. It abounds with pointed anecdotes and with curious information concerning the Spanish gipsies, and this last characteristic explains George Borrow's hyperbolical praise of the work as competing with Don Quijote in grave humour, and as unequalled "for knowledge of other men's mind and observation." At about this time there lived in Spain an ex-nun named Catalina de Erauso, who fled from her convent, dressed herself in men's clothes, enlisted, was promoted ensign, and saw more of life than any other nun in history. Broadsides relating the story of this picaresque amazon were circulated during her lifetime, and the details of her adventures attracted the attention of De Quincey, who would seem to have read them in a Spanish original which has been admirably translated since then by the French poet José María de Heredia. The Spanish original, in its existing form, was issued no earlier than 1630 by Joaquín María de Ferrer, whose character is not a satisfactory guarantee of the work's authenticity; but its interest is far from negligible. No such suspicion attaches to the Vida de Alonso de Contreras, first published in 1899; this out-at-elbows soldier faithfully records how he became a knight of the Order of Santiago, how he
broke all the Commandments, how he found himself stranded in Madrid, how his fine air captivated Lope de Vega, who housed him for eight months and dedicated to him a play entitled *Rey sin reino*, and how the ex-capitan ended by "resolving to retire to a lonely spot and there serve God as a hermit." Every convention of the picaresque novel is faithfully observed, and the incidents are no doubt substantially true, though Contreras, like most converts, judges his own past with unnecessary harshness. This subtle form of vanity also pervades the *Comentarios de el desengañado de sí mismo* of Diego duque de Estrada, a rakish soldier and inferior dramatist whose autobiography (begun in 1614 and continued at intervals during many years) was not printed till 1680. A far higher order of talent distinguishes the *Capitelaciones de la vida de la corte y oficios entretenidos en ella*, a bitterly unsparring review of picaresque life written by the great satirist Francisco Gomez de Quevedo y Villegas (q.v.). These thumbnail sketches were the preparatory studies worked up into the more elaborate *Vida del buscón Don Pablo* (1626), the cleverest and most revolting book of its class. There is no attempt to scare the wicked by means of awful examples; the moral lesson is contemptuously thrown aside; the veil of romance is rent in twain, and the *picaro*—the nephew of the public executioner—is revealed as he is, gloating in cruelty and reveling in the conscious enjoyment of crime. But though Quevedo detests mankind, his morose vision of existence rarely degenerates into caricature. In his repugnant, misanthropic masterpiece the sordid genius of the Spanish picaroon finds absolute expression. Nothing further remained to be done in the matter of realism; henceforth the taste for picaresque novels grew less keen, and later writers unconsciously began to humanize their personages.

The *Varia fortuna del soldado Pindaro* (1626) added nothing to the established reputation of Gonzalo Cypleses y Meneses. A clever anonymous story, *Don Raimundo el entretenido* (1627), missed fire, even though it was attributed to Quevedo; yet the author, Diego Tovar y Valderrama, compiled a sprightly diary of the events which make up a picaroon's crowded day, and failed solely because the interest in rogues was waning. Other writers of undoubted gifts were slow to see that the fashion had changed. Alonso de Castillo Solórzano (q.v.) tempted the public with three picaresque stories published in quick succession: *La Nita de los embustes, Teresa de Mamonares* (1634), the *Aventuras del Bachiller Trapaza* (1637) and a sequel to the latter entitled *La Garduña de Sevilla* (1638). Clever as Castillo Solórzano's stories are, their tricks and wiles were not quite as welcome to the public as the enthusiasm in Spain; the *Bachiller Trapaza* was destined to be continued by Mateo da Silva Cabral in Portugal and to be exploited by Le Sage in France, and to these two accidents it owes its survival. Le Sage likewise utilized *Gil Blas* episodes taken from *El Siglo pitagórico* (1644), the work of Antonio Enríquez Gómez (q.v.); but most of *El Siglo pitagórico* is in verse, and as it was published at Paris by an exiled Portuguese Jew, its circulation in Spain must have been limited. The normal primitive rogue returns to the scene in *La Vida y hechos de Estebanillo Gonzales* (1648), which is no doubt the genuine autobiography that it purports to be. If he is still occasionally read by students he owes it to the fact that Le Sage found in these adventures d'Estebanillo Gonzales "by the general public he is completely forgotten, and the same may be said of many subsequent Spanish writers who adopted the picaresque formula. The *Buscón* is the last great book of its kind.

Meanwhile, the rogue had forced his way into other European literatures. The Antwerp continuation (1555) of *Lazarillo de Tormes* brought the original to the notice of northern readers, and this first part was translated into French by Jean Saugrain in 1561. A Dutch version was issued anonymously in 1579, and it seems extremely likely that the book had been translated into English before this date. This follows from a manuscript note written by Gabriel Harvey in a copy of the *Hevaglass* given him by Edmund Spenser; Harvey here mentions that he had received the *Hevaglass*, Skogg, Skelton and *Lazarillo* from Spenser on the 20th of December 1578. The earliest known edition of David Rowland's version of *Lazarillo de Tormes* is dated 1586, but as a licence to print a translation of this tale was granted on the 22nd of July 1568/1569, it is probable that a 1576 edition which appears in the Harleian Catalogue really existed. Numerous reprints (1599, 1639, 1669-1670, 1672, 1677) go to prove that *Lazarillo de Tormes* was very popular, and that Shakespeare had read it seems to follow from an allusion in *Much Ado about Nothing* (Act. i., sc. i): "Now you strike like the blind man; you say that 'twas your transit, and you will beat the post." To Thomas Nashe belongs the credit, such as it is, of being the first to write a picaresque novel in English: *The Unfortunate Traveller; or The Life of Jack-Wilton* (1594). Nashe carefully points out that his work is a new experiment, "being a clean different veine from other my former courses of writing"; the only possible Spanish model that he can have had was *Lazarillo de Tormes,* but he has nothing of his predecessor's sardonic brevity, and he anticipates later Spanish writers by his emphatic insistence on the pleasures of eating and drinking to repletion. Nashe led the way, and a reference to "Spanish picaroes" in Middleton's *Spanish Gipsie* indicates that the picaroon type had speedily become familiar enough for London playwrights to understand the reference. Interest in picaresque literature was kept alive in England by a translation (1622) of a sequel to *Lazarillo de Tormes* published at Paris two years earlier by Juan de Luna, who came to London to supervise the English rendering; by James Mabbe's admirable version (1622) of *Guzmán de Alfarache;* by The Son of the Rogue or the Politic Thief (1638), an anonymous translation, done through the French, of *De la desordenada codicia;* and by another anonymous translation (1657), likewise done through the French, of Quevedo's *Buscón.* The result of this campaign was *The English Rogue described in the Life of Meriton Latoine, a witty Extravagant* (1665), by Richard Head and Francis Kirkman. The authors of this farrago insist on the English nationality of their chief character, and repudiate the idea that they are in any way indebted to Alcán and Quevedo. It is no exaggeration, however, to say that almost all the material in the text is taken from Spanish sources, and even the thieves' vocabulary is stolen from John Awdeley's *Fraternitie of Vascondes or Thomas Harman's Cocket, or Warning for Common Cursetors.* It is not till Defoe's time that the English picaresque novel acquires any real importance, and the picaresque intention informs much of his work that contravenes the accepted rules of composition. There is a female picaroon in *Moll Flanders,* and, as Defoe reads Spanish, it is conceivable that Moll Flanders was suggested by the *Picara Justina,* but this resemblance does not make *Moll Flanders* a real translation of *Moll Flanders.*

The satirical spirit which is lacking in *Moll Flanders* is abundantly present in *Colonel Jack,* which bravely aims at exhibiting "vice and all kinds of wickedness attended with misery." Henceforward the picaroon is naturalized in English literature, and is gloriously reincarnated in Fielding's *Jonathan Wild* and in Smollett's *Ferdinand, Count Fathom.* The classification of Sterne's *Tristram Shandy* and Morier's *Haji Baba* as picaresque novels is not strictly accurate; like *Pickle* and *Oliver Twist* and *Barry Lyndon,* they are rather varieties of the peripatetic novel, but many incidents in all five reveal the implying wiles of the Spanish picaroons.

The Dutch translation of *Lazarillo de Tormes* (1579) did not enable the picaresque novel to strike root in Holland, yet from it is derived one of the best Dutch comedies, *De Spaensche Brabander Jorolimo* (1616) of Gerbrand Brandero. A German translation of *Guzmán de Alfarache* was published by Aegidius Albericus in 1615; both Lazarillo and *Cinconete y Cortadillo* were translated by Nicolas Ulenhart in 1716, and in 1627 there appeared an anonymous version of the *Picara Justina.* The Spanish tradition was followed by Martin Freeden in a continuation (1626) of *Guzmán de Alfarache,* but the only original picaresque novel of real value in German is Grimmelhausen's *Wildenburger.* The attempt to acclimatize the picaresque novel in Italy failed completely. The Spanish novel *Guzmán de Alfarache, Lazarillo de Tormes and the Picara Justina* in 1666, 1662 and 1622 respectively, and Giovanni Pietro Franco did the *Buscón* into Italian in 1634; but there was no important native
development. The same may be said of Portugal; for though Silva Cabral's continuation of the _Bachiiller Trepaso_ is called the most remarkable of Portuguese picaresque romances, it is significant that _O pereibinho de Cordofo_ remains in manuscript.

The case was very different in France, where pictures of low life had always found admirers. The first translation of _Lasarillo de Torment_ appeared, as already noted, at Paris in 1561; the first translation of the first part of _Guzmán de Alfarache_ was issued there by Gabriel Chappuis in 1600, and the dictator Chapelain designed to translate both parts in 1619-1620; the first translation of the _Novelas ejemplares_ was published at Paris in 1618 by Rosset and d'Audiguié; and French translations of _Marcos de Obregón, de La Desordenada codicia, of the Buscón_ and of the _Picaresca Justina_ were printed in 1618, 1621, 1633 and 1635 respectively.

Before this series of translations was completed Charles Sorel recounted in _Francion_ (1622) "the comic mishaps which befell evil-doers," invoking the common excuse that it is "lawful to find pleasure at their expense." Many of the episodes in _Francion_ are picaresque in tone, but unfortunately Sorel wanders from his subject, and devotes no small part of his book to satirizing literature who, though fribbles or paupers, are still these picaresca. The legitimate Spanish tradition is followed more closely and with more ability by Paul Scarron in the _Roman comique_ (1651), in which horseplay is predominant. The framework may have been suggested by Agustín de Rojas or Quevedo, both of whom introduce a strolling company, and such characters as Llandre, Angelique de l'Etoile and Ragotin might be found in any average _nóvela picaresca_.

Scarron frankly mentions Castillo Solórzano's _Gardunha de Sevilla_ in his text, and his _Précaution initiale et Les Hypocrisies_ are convincing proofs of close study of Spanish picaresque stories; the _Précaution initiale_ is taken from _Guzmán de Alfarache_, and _Les Hypocrisies_ is merely a translation of Salas Barbiallo's _IIa de Celestino_. The _Roman bourgeois_ (1666) of Antoine Furettec is generally described as a picaresque novel, but this involves a new definition of the adjective; the _Roman bourgeois_ includes some portraits and more satire which seem suggested by picaresque reading, but it is concerned with the foibles of the middle class rather than with the sly devices of common vagabonds.

The Spanish picaresque lives again in _Gil Blas_, where, with a dexterity almost rarer than original genius, a master of literary manipulation fuses materials unearthed from forgotten and seemingly worthless Spanish sources into a creation of the gentle, sunnier French spirit; like Beaumarchais' _Figaro_ he is a scrappy born, reared and humanized in Paris, and these two are the only picaresca whose relative refinement has not been gained at the cost of verisimilitude. But the old original scoundrel was not yet extinct: in the interval between the appearance of the _Barbier de Steille_ and the _Mariage de Figaro_ Restif de la Bretonne produced a sequel (1776) to the _Buscón_—a sequel so dull as to be well-nigh unreadable. The untamed Spanish rogue had become impossible towards the end of the 18th century: in the 19th he was deliberately rejected when Théophile Gautier wrote his _Capitaine Fracasse_. Yet Gautier conscientiously provides a Spanish atmosphere as well as the personal name Spanish names; the form is Spanish inscription; the host串联es are Spanish and have a Spanish accent; Valombreuse parts from the marquis with a Spanish formula: "beso a vuestra merced la mano, caballero." _Capitaine Fracasse_ is the last important book which continues the picaresque tradition. The possibilities of picaresque fiction can never be exhausted while human nature is unchanged. Pereda (q.v.) in _Pedro Sánchez_ (1884) touches the old theme with the accent of modernity. It may be that instead of one continuous tale, interrupted by episodical digressions, the picaresque fiction of the future will take the form of short stories independent of one another; but this would be nothing more than a convenient mechanical device, a readjustment of means to ends.

**PICAYUNE—PICCINNI**

The name in Florida and Louisiana of the Spanish half-real = 1/6 of a dollar, 3 cents, and hence used of the United States 5 cent piece. The French _picaillons_, from which the word was adapted in America, was an old copper coin of Picmont. Its origin is doubtful, but is possibly related to the Italian _piccolo_, little, small. In America the word is used of anything trifling, petty, mean or contemptible.

**PICCANINNY, or PICKANINNY,** a word applied originally by the negroes of the West Indies to their babies. It is adapted either from Span. _pequeño_, small, or Port. _pequenino_, very small. The word spread with the slave trade to America, and has since been adopted in Australia and in South Africa.

**PICCININO, NICCOLO** (1386-1444), Italian condottiere, born at Perugia, the son of a nobleman. He began his military career in the service of Braccio da Montone, who at that time was waging war against Perugia on his own account, and at the death of his chief, shortly followed by that of the latter's son Oddo, Piccinino became leader of Braccio's _condotta_. After serving for a short period under the Florentine Republic, he went over to Filippo Maria Visconti, duke of Milan (1425), in whose service together with Niccolò Fortebraccio he fought in the wars against the league of Pope Eugenius IV., Venice and Florence. He defeated the papal forces at Castel Bolognese (1434), but another papal army under Francesco Sforza having defeated and killed Fortebraccio at Fierldimonte, Piccinino was left in sole command, and in a series of campaigns against Sforza he seized a number of cities in Romagna by treachery. In 1439 he again fought in Lombardy with varying success against Sforza, who had now entered the Venetian service. Piccinino then induced the duke of Milan to send him to Umbrìa, where he hoped, like so many other condottieri, to carve out a dominion for himself. He was defeated by Sforza at Angiari (1440), but although a number of his men were taken prisoners they were at once liberated, as was usually done in wars waged by soldiers of fortune. Again the war shifted to Lombardy, and Piccinino, having defeated and surrounded Sforza at Martinengo, demanded of the Visconti the lordship of Piacenza at a price of 50,000 ducats. The Visconti's answer of reply concluded a truce with Sforza; but the latter, who, while professing to defend the Papal States, had established his own power in the Marche, aroused the fears of the pope and the king of Naples, as well as of the visconti, who gave the command of their joint forces to Piccinino. Sforza was driven from the Marche, but defeated Piccinino at Montelauro, and while the latter was preparing for a desperate effort against Sforza he was suddenly recalled to Milan, his army was beaten in his absence, and he died of grief and of his wounds in 1444. Short of stature, lame and in weak health, he was brave to the point of foolhardiness, wonderfully resourceful, and never overwhelmed by defeat when he was cruel and treacherous, and had an aim beyond his own aggrandizement. Piccinino left two sons, Jacopo and Francesco, both distinguished condottieri.

A good account of Piccinino is contained in vol. iii. of E. Ricotti's _Storia della compagnie di ventura_ (Turin, 1845); G. B. Poggio, _Vita di N. Piccinino_ (Venice, 1572); see also the general histories of the period.

**PICCININI, NICCOLA** (1725-1800), Italian musical composer, was born at Bari on the 16th of January 1728. He was educated under Leo and Durante, at the Conservatorio di Sant' Onofrio in Naples. For this Piccinini had to thank the intervention of the bishop of Bari, his father, although himself a musician being opposed to his son's following a musical career. His first opera, _Le Donne dispette_, was produced in 1755, and in 1760 he composed, at Rome, the _chef d'œuvre_ of his early life, _La Cecchina, ossia la buona_
PIGGLIO, an opera buffa which attained a European success. Six years after this Piccinni was invited by Queen Marie Antoinette to Paris. He had married in 1756 his pupil Vincenza Sibilla, a singer, whom he never allowed after her marriage to appear on the stage. All his next works were successful; but, unhappily, the directors of the Grand Opéra conceived the mad idea of deliberately opposing him to Gluck, by persuading the two composers to treat the same subject—Hippogène en Dauphine—simultaneously. The Parisian public now divided itself into two rival parties, which, under the names of Gluckists and Piccinnists, carried on an unworthy and disgraceful war. Gluck's masterly Hippogène was first produced on the 18th of May 1770. Piccinni's Hippogène followed on the 23rd of January 1781, and, though performed seventeen times, was afterwards consigned to oblivion. The fury of the rival parties continued unabated, even after Gluck's departure from Paris in 1780; and an attempt was afterwards made to inaugurate a new rivalry with Sacchini. Still, Piccinni held a good position, and on the death of Gluck, in 1787, proposed that a public monument should be erected to his memory—a suggestion which the Gluckists themselves declined to support. In 1784 Piccinni was professor at the Royal School of Music, one of the institutions from which the Conservatoire was formed in 1794. On the breaking out of the Revolution in 1789 Piccinni returned to Naples, where he was at first well received by King Ferdinand IV.; but the marriage of his daughter to a French democrat brought him into irretrievable disgrace. For nine years after this he maintained a precarious existence in Venice, Naples and Rome; but he returned in 1798 to Paris, where the fickle public received him with enthusiasm, but left him to starve. He died at Passy, near Paris, on the 7th of May 1800. After his death a memorial tablet was set up in the house in which he was born at Bari.

The most complete list of his works is that given in the Rivista musicale italiana, viii. 75. He produced over eighty operas, but although his later work shows the influence of the French and German stage, he belongs to the conventional Italian school of the 18th century.

See also P. L. Ginguéné, Notice sur la vie et les ouvrages de Piccinni (Paris, 1801); E. Demoiselles, La Musique française au 18e siècle (Gluck et Piccinni 1770-1800) (Paris, 1872).

PIECOLO (Fr. petite flûte octave; Ger. Pickelflöte; Ital. flauto piccolo or ottavino), a small flute of less than half the dimensions of the large concert flute and pitched an octave higher. The principles of construction and the acoustic properties are the same for the piccolo as for the flute, with the exception that the piccolo does not contain the additional tail-piece with the extra low keys, which give the flute its extended compass. As the pitch of the piccolo is so high, the highest of all orchestral instruments with the exception of a few harmonics on the violin, the music for it is written an octave lower than the real sounds in order to avoid the ledger lines. The piccolo has been used with good effect in imitating the whistling of the wind in storms, as in Beethoven's Pastoral Symphony, Wagner's Flying Dutchman, and in conjunction with the violins in trento to depict the rustling of the leaves in the breeze, as in the "Waldweben" in Siegfried. Verdi employed it to advantage in Falstaff as a comic agent in humorous situations. The piccolo is generally in D, sometimes in E or F.

PIECOLOMINI, the name of an Italian noble family, which was prominent in Siena (q.v.) from the beginning of the 13th century onwards. In 1220 Enghelberto d'Ugo Piccolomini received the fee of Montemart in Val d'Orcia from the emperor Frederick II. as a reward for services rendered. The family acquired houses and towers in Siena and castles in the republic's territories, including Montone and Castiglione; the latter they sold to the commune in 1241. They obtained great wealth through trade, and established counting-houses in Genoa, Venice, Aquileia, Trieste, and in various cities of France and Germany. Supporters of the Guelp cause in the civil wars by which Siena was torn, they were driven from the city in the time of Manfred and their houses demolished; they returned in triumph after the Angevin victories, were expelled once more during the brief

regin of Conradin, and again returned to Siena with the help of Charles of Anjou. But through their riotous political activity the Piccolomini lost their commercial influence, which passed into the hands of the Florentines, although they retained their palaces, castles and about twenty fiefs, some of which were in the territory of Arezzo and Empoli. Many members of the house were distinguished ecclesiastics, three of whom were cardinals; two were archbishops in Siena and elsewhere; two of them were popes, viz. Aeneas Silvius Piccolomini (Pius II., &c.) and Francesco Piccolomini (Pius III., &c.).

See Richter, Die Piccolomini (Berlin, 1874); A. Lisini and A. Liberati, Albero della famiglia Piccolomini (Siena, 1890); and articles by A. Lisini in the Miscellanea storica senese, 3rd series 12, and 4th series, 17 and 189.

PIECOLOMINI, OCTAVIO, Prince (1559-1630), duke of Amalfi, Austrian general, was born on the 11th of November 1559 in Florence, and carried a pike in the Spanish service at the age of sixteen. Two years later, on the outbreak of the Thirty Years' War in Bohemia, he was appointed a captain in a cavalry regiment sent by the grand duke of Tuscany to the emperor's army, and he fought with some distinction under Buquoy at the Weisser Berg and in Hungary. In 1624 he served for a short time in the Spanish army and then as lieutenant-colonel of Pappenheim's cuirassier regiment in the war in the Milanese. In 1627 he re-entered the Imperial service as colonel and captain of the lifeguard of Wallenstein, duke of Friedland. In this capacity he soon fell into disgrace for practising extortion at Stargard in Pomerania, but his adroitness secured him, after no long interval, the rank of "colonel of horse and foot." About this time the appointment of his younger brother to the archbishopric of Siena secured him a position of influence in the diplomatic world. Diplomatic talent was indeed almost the birthright of a member of an Italian family, that had seen two of its members occupying the papal chair, and Wallenstein freely made use of his subordinate's capacity for negotiation and intrigue. In the events of the Mantuan War Piccolomini took a prominent part in the dual rôle of the subtle diplomatist and the plundering soldier of fortune. At this moment came the invasion of Germany by Gustavus Adolphus. Piccolomini was interred at Ferrara as a hostage for the ratification of a treaty, but he added his voice to the general call for Wallenstein's reappointment to the imperial army. He was not, however, included in the list of promotions that followed the duke's reappearance, and he served under General Holk, an officer brought in from the Danish service, in the preliminary operations and in the battle of Lützen. His ambition was gratified when, on reading the official report of the battle, the emperor made him a generalfeldwachtmeister. At the same time, however, Holk was created a field marshal at Wallenstein's instance, much to his rival's chagrin. In the campaign of 1633 Piccolomini held the command of an important detachment posted at Königgrätz to bar the enemy's advance from Silesia into Bohemia. History repeated itself on the same ground in 1756, 1757 and 1766; in the first of these cases it was a Piccolomini, grand-nephew of Octavio, who commanded the Austrians; in the last the victorious Prussians passed over the estate of Nachod, which after 1635 was a hereditary possession of the family. In May Wallenstein entered Silesia with the main army with the unwavoured object of compelling or persuading the electors of Brandenburg and Saxony to make common cause with the emperor against the Swedes. Piccolomini was with him, and, disapproving of the duke's policy, joined in a military conspiracy, out of which grew the drama that ended with the murder of Wallenstein on the 25th of February 1634. Piccolomini's own part in the tragedy has been set forth for all time in the pages of Schiller's Wallenstein.

His reward was his marshal's baton, 100,000 gulden and the beautiful estate of Nachod in the Elkengebirge.

He was Wallenstein's pupil as well as his skater, and had learned the art of war from that master. On the 5th-6th of September in the same year he distinguished himself amongst the foremost in the great victory of Nördlingen. He soon saw the necessity for following out the lines of military policy laid
down by the duke, but neither he nor Gallas, the new lieutenant-general of the emperor, possessed the capacity for carrying it out, and the war dragged on year after year. Piccolomini was in 1635 allied with a Spanish army, and bitterly complained that their sloth and caution marred every scheme that he formed. In 1638 he was made a count of the empire, and in 1639, having been victorious in General Montaigu's battle, he won a great victory over the French (relief of Thionville, July 7, 1639), he was rewarded with the office of privy councillor from the emperor and with the dukedom of Amalfi from the king of Spain. But instead of being appointed, as he hoped, Gallas's successor, he was called in to act as ad iutus to the Archduke Leopold Wilhelm, with whom he was defeated in the second battle of Breitenfeld in 1642. After this he spent some years in the Spanish service and received as his reward the title of grandee and the order of the Golden Fleece. Some years later, having re-entered the Imperial army, he was again dis-appointed of the chief command by the selection of the brave veteran Peter Melander, Count Holzapel. But when in 1648 Melander fell in battle at Zunsmarkhausen, Piccolomini was at last appointed lieutenant-general of the emperor, and thus conducted as generalissimo the final campaign of the weary and desultory Thirty Years' War. Three days after the commission for executing the peace had finished its labours, the emperor addressed a letter of thanks "to the Prince Piccolomini," and awarded him a gift of 114,566 gulden. Piccolomini died on the 11th of August 1656. He left no children (his only son Josef Silvio, the "Max" of Schiller's Wallenstein, was murdered by the Swedes after the battle of Jankau in 1645), and his titles and estates passed to his brother's son. With the death of the latter's nephew Octavio Aeneas Josef in 1757, the line became extinct.

PICENE, \( \text{C}_{4} \text{H}_{8} \), a hydrocarbon found in the pitchy residue obtained in the distillation of peat-tar and of petroleum. This is distilled to dryness and the distillate repeatedly recrystallized from cymene. It may be synthetically prepared by the action of anhydrous aluminium chloride on a mixture of naphthalene and ethylene dibromide (R. Lespieau, Bull. soc. chim., 1891, (3), 6, p. 238), or by distilling a-dinaphthithilene (T. Hirn, Ber., 1899, 32, p. 3341). It crystallizes in large colourless plates which possess a blue fluorescence. It is soluble in concentrated sulphuric acid with a green colour. Glacial acetic acid in glacial acetic acid solution oxidizes it to picene-quione, picene-quinoine, carbonyl acid, and finally to a carbonic acid. This is a typical hydriodic acid and phosphorus it forms hydrides of composition \( \text{C}_{4} \text{H}_{8} \) and \( \text{C}_{4} \text{H}_{9} \) (see E. Bamberger and F. D. Chattaway, Ann., 1895, 284, p. 61).

PICENUM, a district of ancient Italy, situated between the Apenines and the Adriatic, bounded N. by the Senones and S. by the Vestini. The inhabitants were, according to tradition, an offshoot of the Sabines. Strabo (v. 4, 1, 1) gives the story of their migration, led by a woodpecker (\textit{picus}), a bird sacred to Mars, from which they derived their name Picentini (cf. Dion. Hal. i. 14, 3), just as the Hirpini derived theirs from \textit{hirpus}, a wolf. The district was conquered by the Romans early in the 3rd century B.C. and the whole territory was divided up among Latin-speaking settlers by the Lex Flaminius in 232 B.C. Hence we have very scanty records of any non-Latin Language that may have been spoken in the district before the 3rd century. Besides the problematic inscriptions from Belmonte, Nereto and Cupra Maritima (see Sabellico), we have one or two Latin inscriptions (probably of the 2nd or even the 1st century B.C.) which contain certain forms showing a distinct affinity with the dialect of Iguvium (cf. the name \textit{Patub}—Latin \textit{Pedicidii}). Hence there seems some ground for believing that the population which the Romans dispossessed, or held in subjection, really spoke a dialect very much like that of their neighbours in Umbria.

For inscriptions, see R. S. Conway, \textit{The Ithic Dialects}, p. 448, where the place-names and personal names of the district will also be found; see further, Livy, \textit{Epl. xvi.}; B. V. Head, \textit{Historia numorum}, p. 19. (R. S. C.)

It was in Picenum, at Asculum, that the Social War broke out in 90 B.C. At the end of the war the district became connected with Pompeius Strabo, and his son Pompey the Great threw into

the scale on the side of Sulla, in 83 B.C., all the influence he possessed there, and hoped to make it a base against Caesar's legions in 49 B.C. Under Augustus it formed the fifth region of Italy, and included twenty-three independent communities, of which five, Ancona, Firmum, Asculum, Hadria and Interamnia, were \textit{coloniae}. It was reached from Rome by the Via Salaria, and its branch the Via Caecilia. It was also on a branch leading from the Via Flaminia at Nuceria Camellaria to Septempontia. There were also communications from north to south; a road led from Asculum to Urbis Salvia and Ancona, another from Asculum and Firmum and the coast, another from Urbis Salvia to Potentia, while finally along the whole line of the coast there ran a prolongation of the Via Flaminia, the name of which is not known to us.

At the end of the 2nd century A.D. the north-eastern portion of Umbria was divided from the rest and acquired the name Flaminia, from the high road. For the time it remained united with Umbria for administrative purposes, but passed to Picenum at latest in the time of Constantine, and acquired the name of \textit{Picentino et Picenum Annanarium}, the main portion of Picenum being distinguished as \textit{Suburbaricum}. In an inscription of A.D. 304 Ravenna is actually spoken of as the chief town of Picenum. When the exarchate of Ravenna was founded the part of Picenum Annanarium near the sea became the Pentapolis Maritima, which included the five cities of Ariminum, Pisaurum, Fanum Fortunae, Sena Gallica and Ancona. The exarchate was seized by Luitprand in 727, and Ravenna itself was taken by Aistulf in 752. In the next year, however, the emperor Pippin took it from him and handed it over to the pope, a grant confirmed by his son Charlemagne.

PICHEGRU, CHARLES (1761–1804), French general, was born at Arbois, or, according to Charles Nodier, at Les Planches, near Lons-le-Saulnier, on the 16th of February 1761. His father was a labourer, but the friars of Arbois gave the boy a good education, and one of his masters, the Père Partault, took him to the military school of Brienne. In 1783 he entered the first regiment of artillery, where he rapidly rose to the rank of adjutant-sub-lieutenant. When the Revolution began he became leader of the Jacobin party in Besançon, and when a regiment of volunteers of the department of the Gard marched through the city he was elected lieutenant-colonel. The fine condition of his health prevented his taking part in the army of the Rhine, but his organizing ability was made use of by an appointment on the staff, and finally by his promotion to the rank of general of brigade. In 1793 Carnot and Saint Just were sent to find \textit{roturier} generals who could be successful; Carnot discovered Jourdan, and Saint Just discovered Hoche and Pichegru. In co-operation with Hoche and the army of the Moselle, Pichegru, now general of division and in command of the army of the Rhine, had to reconquer Alsace and to reorganize the disheartened troops of the republic. They succeeded; Pichegru made use of the \textit{dans} of his soldiers to win innumerable small engagements, and with Hoche forced the lines of Haguenau and relieved Landau. In December 1793 Hoche was arrested, it is said owing in part to his colleague's machinations, and Pichegru became commander-in-chief of the army of the Rhine-and-Moselle, whence he was summoned to succeed Jourdan in the army of the North in February 1794. It was now that he fought his three great campaigns of one year. The English and Austrians held a strong position along the Sambre to the sea. After vainly attempting to break the Austrian centre, Pichegru suddenly turned their left, and defeated Clerfayt at Cassel, Menin and Courtrai, while Moreau, his second in command, defeated Coburg at Tourcoing in May 1794; then after a pause, during which Pichegru feigned to besiege Ypres, he again dashed at Clerfayt and defeated him at Rouesselle and Hoogledo, while Jourdan came up with the new army of the Sambre-and-Meuse, and utterly routed the Austrians at Fleurus on the 27th of June 1794. Pichegru began his second campaign by crossing the Meuse on the 18th of October, and after taking Nijmegen drove the Austrians beyond the Rhine. Then, instead of going into winter-quarters, he prepared his army for a winter
campaign. On the 28th of December he crossed the Meuse on the ice, and stormed the island of Bommel, then crossed the Waal in the same manner, and, driving the English before him, entered Utrecht on the 9th of January, and Amsterdam on the 20th of January, and soon occupied the whole of Holland. This grand feat of arms was marked by many points of interest, such as the capture of the Dutch ships, which were frozen in the Helder, by the French hussars, and the splendid discipline of the ragged battalions in Amsterdam, who, with the richest city of the continent to sack, yet behaved with a self-restraint which few revolutionary and Napoleonic armies attained. The former friend of Saint Just now offered his services to the Thermidorians, and after receiving from the Convention the title of “Sauveur de la Patrie,” subduted the sans-culottes of Paris, when they rose in insurrection against the Convention on 12 Germinal (April 1). Pichegru then took command of the armies of the North, the Sambre-and-Meuse, and the Rhine, and crossing the Rhine in force took Mannheim in May 1795. When his fame was at its height he allowed his colleague Jourdan to be beaten, betrayed all his plans to the enemy, and took part in organizing a conspiracy for the return of Louis XVIII., in which he was to play, for his own aggrandizement, the part that Monk played from higher motives in the English revolution. His intrigues were suspected, and when he offered his resignation to the Directory in October 1795 it was to his surprise promptly accepted. He retired in disgrace, but hoped to serve the royalist cause by securing his election to the Council of Five Hundred in May 1797. He was there the royalist leader, and planned a coup d’état, but on the 18th Fructidor he was arrested, and with fourteen others deported to Cayenne in 1797. Escaping, he reached London in 1798, and served on General Korsakov’s staff in the campaign of 1799. He went to Paris in August 1803 with Georges Cadoudal to head a royalist rising against Napoleon; but, betrayed by a friend, he was arrested on the 28th of February 1804, and on the 15th of April was found strangled in prison. It has often been asserted that he was murdered by the orders of Napoleon, but there is no foundation for the story.

Pichegru’s campaigns of 1794 are marked by traits of an audacious genius which would not have disgraced Napoleon. His tremendous physical strength, the personal ascendancy he gained by this and by his powers of command made him a peculiarly formidable opponent, and thus enabled him to maintain a discipline which guaranteed the faith of all his troops. He had also a strangely infatuated power of captivating honest men like Moreau. He flattered in turn Saint Just and the Terrorists, the Thermidorians and the Directors, and played always for his own hand—a strange egotist who rose to fame as the leader of an idealist and sentimental crusade.

There is no really good life of Pichegru; perhaps the best is J. M. Gassier’s Vie du général Pichegru (Paris, 1815). For his treason, trial and death, consult Montgaillard’s Mémoires concernant la trahison de Pichegru (1804); Fauche-Borel’s Mémoires: Savary, Mémoires sur la mort de Pichegru (Paris, 1825); and C. Pierret, Pichegru, son procès et sa mort (1826).

PICHLER, CAROLINE (1769—1843). Austrian novelist, was born at Vienna on the 7th of September 1769, the daughter of Hofrat Franz von Greiner, and married, in 1796, Andreas Picker, a government official. For many years her salon was the centre of the literary life in the Austrian capital, where she died on the 9th of July 1843. Her early works, Olivier, first published anonymously (1802), Idyljen (1803) and Ruth (1805), though displaying considerable talent, were immature. She made her mark in historical romance, and the first of her novels of this class, Agathocles (1808), an answer to Gibbon’s attack on that king, was followed by The Decline and Fall of the Roman Empire, attained great popularity, after which her other novels may be regarded as temporary works. Belagerung Wien (1824); Die Schweden in Prag (1827); Die Wiedererobrung Oens (1829) and Henriette von England (1832). Her last work was Zeichbilder (1840).

The edition of Caroline Pichler’s Sämtliche Werke (1829—1845) comprises no less than 60 volumes. Her Denkwürdigkeiten aus meinem Leben (4 vols.) was published posthumously in 1844. A selection of her narratives, Ausgewählte Erzählungen, appeared in 4 vols. in 1844.

PICKENS, ANDREW (1739—1817), American soldier in the War of Independence, was born in Paxton, Bucks county, Pennsylvania, on the 19th of September 1739. His family settled at the Waxhaws (in what is now Lancaster county), South Carolina, in 1752. He fought against the Cherokees in 1764 as a lieutenant. In the War of Independence he rose to brigadier-general (after Cowpens) in the South Carolina militia. He was a captain among the American troops which surrendered at Ninety Six in November 1777. On the 14th of February 1779, with 300—400 men, he surprised and defeated about 700 Loyalists under Colonel Boldy on Kettle Creek, Wilkes county, Georgia; on the 20th of June he fought at Stono Ferry; and later in the same year at Tomasee defeated the Cherokees, who were allied with the British. Upon the surrender of Charleston (May 1780) he became a prisoner on parole, which he observed rigidly until, contrary to the promises made to him, Major James Dunlap plundered his plantation; he then returned to active service. His command (about 150 men) joined General Daniel Morgan immediately before the battle of Cowpens, in which Pickens commanded an advance guard (270—350 men from Georgia and North Carolina) and twice rallied the broken American militia; for his services Congress gave him a sword. With Colonel Henry Lee he harassed Lieut.-Colonel Banastre Tarleton, who was attempting to gather a Loyalist force just before the battle of Guilford Court House; and with Lee and others, he captured Augusta (June 5, 1781) after a siege. At Eutaw Springs (Sept. 8, 1781) he commanded the left wing and was wounded. In 1782 he defeated the Cherokees again and forced them to surrender all lands south of the Savannah and east of the Chattahoochee. After the war he was a member of the South Carolina House of Representatives for a number of years, of the state Constitutional Convention in 1790, and of the National House of Representatives in 1793—1795. He died in Pendleton district, South Carolina, on the 17th of August 1817. He had married in 1763 Rebecca Calhoun, an aunt of John C. Calhoun. Their son, Andrew Pickens (1779—1838), served as a lieutenant-colonel in the War of 1812, and was governor of South Carolina in 1816—1818.

PICKENS, FRANCIS WILKINSON (1805—1860), American politician, was born in Togado, St Paul’s parish, South Carolina, in 1805. He graduated from the College of Charleston in 1825; son of Andrew Pickens (1779—1838) and grandson of General Andrew Pickens (1735—1793). He was educated at Franklin College, Athens, Georgia, and at South Carolina College, Columbia, and was admitted to the bar in 1829. In 1832 he was elected to the state House of Representatives, where, as chairman of a sub-committee, he submitted a report denying the right of Congress to exercise any control over the states. He was a Democratic member of the National House of Representatives in 1834—1843, served in the South Carolina Senate in 1844—1845, was a delegate to the Nashville Southern Convention (see NASHVILLE, TENNESSEE) in 1839, was United States minister to Russia in 1858—1860, and in 1860—1862 was governor of South Carolina. He strongly advocated the secession of the Southern states; signed the South Carolina ordinance of secession; protested against Major Robert Anderson’s removal from Fort Moultrie to Fort Sumter; sanctioned the firing upon the “Star of the West” (Jan. 9, 1861), which was bringing supplies to Anderson, and the bombardment of Fort Sumter; and was a zealous supporter of the Confederate cause. At the close of his term he retired to his home at Edgefield, South Carolina, where he died on the 25th of January 1860.

PICKERING, EDWARD CHARLES (1846— ), American physicist and astronomer, was born in Boston on the 19th of July 1846. He graduated in 1865 at the Lawrence Scientific School, Harvard, where he was for the next two years a teacher of mathematics. Subsequently he became professor of physics at the Massachusetts Institute of Technology, and in 1876 he was appointed professor of astronomy and director of the Harvard College observatory. In 1877 he decided to
devote one of the telescopes of the observatory to stellar photometry, and after an exhaustive trial of various forms of photometers, he devised the meridian photometer (see PHOTOMETRY, STELLAR), which seemed to be free from most of the sources of error. With his first instrument of this kind, having objectives of 1·5 inch aperture, he measured about 4000 stars, including all stars down to the 6th magnitude between the North Pole and -30° declination. With the object of reaching fainter stars, Professor Pickering constructed another instrument of larger dimensions, and with this more than a million observations have been made. The first important work undertaken with it was a revision of the magnitudes given in the Bonn Durchmusterung. On the completion of this, Professor Pickering decided to undertake the survey of the southern hemisphere. An expedition, under the direction of Prof. S. I. Bailey, was accordingly despatched (1859), and the meridian photometer erected successively in three different positions on the slopes of the Andes. The third of these was Arequipa, at which a permanent branch of the Harvard Observatory is now located. The magnitudes of nearly 8000 southern stars were determined, including 1428 stars of the 6th magnitude and brighter. The instrument was then returned to Cambridge (U.S.A.), where the survey extended so as to include all stars of magnitude 7-5 down to -90° declination, after which it was once more sent back to Arequipa. In 1886 the widow of Henry Draper, one of the pioneers of stellar spectroscopy, made a liberal provision for carrying on spectroscopic investigations at Harvard College in memory of her husband. With Professor Pickering's usual comprehensiveness, the inquiry was so arranged as to cover the whole sky; and with four telescopes—two at Cambridge for the northern hemisphere, and two at Arequipa in Peru for the southern—to which a fine 24-inch photographic telescope was afterwards added, no fewer than 75,000 photographs had been obtained up to the beginning of 1901. These investigations have yielded many important discoveries, not only of new stars, and of large numbers of variable stars, but also of a wholly new class of double stars whose binary character is only revealed by peculiarities in their spectra. The important conclusion has been already derived that the majority of the stars in the Milky Way belong to one special type.

PIEKERING, TIMOTHY (1745-1830), American politician, was born in Salem, Massachusetts, on the 17th of July 1745. He graduated from Harvard College in 1763 and was admitted to the bar in 1768. In the pre-revolutionary controversies he identified himself with the American Whigs; in 1773 he prepared for Salem a paper entitled State of the Rights of the Colonists; in 1775 he drafted a memorial protesting against the Boston Port Bill; and in 1776 he was a representative from Salem in the General Court of Massachusetts. In 1766 he had been commissioned lieutenant and in 1790 captain in the Essex county militia; early in 1772 he published An Easy Plan of Discipline for a Militia, adopted in May 1776 by the General Court for use by the militia of Massachusetts, and he was elected colonel of his regiment. In the same year he became judge of the court of common pleas for Essex county, and sole judge of the maritime court for the counties of Suffolk, Essex and Middlesex. In the winter of 1776-1777 he led an Essex regiment of volunteers to New York, and he subsequently served as adjutant-general (June 1777-Jan. 1778) and later as quartermaster-general (1780-1785); he was also a member of the board of war from the 7th of November 1777 until its abolition. With the aid of some officers he drew up, in April 1783, a plan for the settlement of the North-West territory, which provided for the exclusion of slavery. In 1785 he became a commission merchant in Philadelphia; but in October 1786, soon after the legislature of Pennsylvania had passed a bill creating the Wyoming district into the county of Luzerne, he was appointed prothonotary and a judge of the court of common pleas and clerk of the court of sessions and orphans' court for the new county, and was commissioned to organize the county. He offered to purchase for himself the Connecticut title to a farm, and in the following year he was appointed a member of a commission to settle claims according to the terms of an act, of which he was the author, confirming the Connecticut titles (see Wyoming Valley and Wilkes-Bare). Pickering was a member of the Pennsylvania convention of 1787 which ratified the Federal constitution, and of the Pennsylvania constitutional convention of 1789-1790. In November 1790 he negotiated a peace with the Seneca Indians, and he concluded treaties with the Six Nations in July 1791, in March 1792 and in November 1794. Under Washington he was postmaster-general (1791-1795), secretary of war (1795), and after December 1795 secretary of state, to which position he was reappointed (1797) by Adams. In 1793, while he was quartermaster-general, he had presented a plan for a military academy at West Point, and now, as secretary of war, he supervised the West Point military post with a view to its conversion into a military academy. As head of the state department he soon came into conflict with Adams. His hatred of France made it impossible for him to sympathize with the president's efforts to settle the differences with that country on a peaceable basis. He used all his influence to hamper the president and to advance the political interests of Alexander Hamilton, until he was dismissed, after refusing to resign, in May 1800. Returning to Massachusetts, he served as chief justice of the court of common pleas of Essex county in 1802-1803. He was a United States senator in 1803-1811 and a member of the Federal House of Representatives in 1813-1817. As an ultra Federalist—he was a prominent member of the group known as the Essex Junto—he strongly opposed the purchase of Louisiana and the War of 1812. He died at Salem, Massachusetts, on the 29th of January 1829.

The standard biography is that by his son, Octavius Pickering (1791-1868), and C. W. Upham, The Life of Timothy Pickering (2 vols, Boston, 1867-1873). In the library of the Massachusetts Historical Society at Boston, there are sixty-two manuscript volumes of the Pickering papers, an index to which was published in the Collections of the society, 6th series, vol. viii. (Boston, 1890).

His son, JOHN PICKERING (1777-1846), graduated at Harvard in 1796, studied law and was private secretary to William Smith, United States minister to Portugal, in 1797-1799, and to Rufus King, minister to Great Britain, in 1799-1801. He practised law in Salem and (after 1827) in Boston, where he was city solicitor in 1827-1846, and wrote much on law and especially on the languages of the North-American Indians. He was a founder of the American Oriental Society and published an excellent Comprehensive Dictionary of the Greek Language (1826).

See Mary O. Pickering (his daughter), Life of John Pickering (Boston, 1887).

Timothy Pickering's grandson, CHARLES PICKERING (1805-1878), graduated at Harvard College in 1823 and at the Harvard Medical School in 1826, practised medicine in Philadelphia, was naturalist to the Wilkes exploring expedition of 1838-1842, and in 1843-1845 travelled in East Africa and India. He wrote The Races of Man and their Geographical Distribution (1848), Geographical Distribution of Animals and Man (1854), Geographical Distribution of Plants (1861) and Chronological History of Plants (1879).

PIEKERING, a market town in the Whitby parliamentary division of the North Riding of Yorkshire, England, 32 m. N.E. by N. from York by the North Eastern railway, the junction of several branch lines. Pop. of urban district (1901), 3491. The church of St Peter is Norman and transitional Norman, with later additions including a Decorated spire. It contains a remarkable series of mural paintings of the 15th century. The castle, on a hill to the north, is a picturesque ruin, the fragmentary keep and several towers remaining. The work is in part Norman, but the principal portions are of the 14th century. One of the towers is connected in name and story with Fair Rosamond. The castle was held by Earl Morcar shortly before the Conquest; it then came into the hands of the Crown, and subsequently passed to the duchy of Lancaster. It was the prison of Richard II. before his confinement at Pontefract. During the civil wars of the 17th century the castle was held by the Royalists, and suffered greatly in siege. The district
**PICTURE**—**PICO DELLA MIRANDOLA**

surrounding Pickering is agricultural, and the town is a centre of the trade. Agricultural implements are manufactured, and limestone and freestone are quarried in the vicinity.

**PICKET.** Picket or Picquet (Fr. *piqueat*, a pointed stake or peg, from *pique*, to point or pierce), a military term, signifying an outpost or guard, supposed to have originated in the French army about 1660, from the circumstance that an infantry company on outpost duty dispersed its musketiers to watch, the small group of pikemen called *piqueat* remaining in reserve. Thus at the present day the word "*piqueat*" is, in Great Britain at any rate, restricted to an infantry post on the outpost line, from which the sentries or "groups" of watchers are sent out.

In the United States a "*picket*" is synonymous with a sentry, and the "*picket-line" is the extreme advanced line of observation of an army. In the French army picquets are called "grand' gardes," and the phrase "grand guard" is often met with in English military works of the 17th and 18th centuries. A body of soldiers held in readiness for military or police duties within the limits of a camp or barracks is also called a *picquet* or "inlying *piqueat*." These special uses of the word in English are apparently quite modern (after about 1750). "*Picket*" in its ordinary meaning of a peg or stake, has always been in common military use, being applied variously to the picketing pegs in horse-lines, to long pointed stakes employed in palisades or stockades, to straight thin rods used for marking out the line of fire for guns, &c. Of the various spellings "*picquet*" is officially adopted in Great Britain and "*picket*" in the United States, but the latter is now invariably used when a peg or stake is meant.

Two obsolete meanings of the word should also be mentioned. The "*picket*" was a form of military punishment in vogue in the 16th and 17th centuries, which consisted in the offender being forced to stand on the narrow flat top of a peg for a period of time. The punishment died out in the 18th century and was so far unfamiliar by 1800 that Sir Thomas Picton, who ordered a mulatto woman to be so punished, was accused by public opinion in England of inflicting a torture akin to impalement. It was thought, in fact, that the prisoner was forced to stand on the head of a pointed stake, and this error is repeated in the *New English Dictionary*. In the middle of the 19th century, when elongated rifle bullets were a novelty, they were often, and especially in America, called pickets. The ordinary military use of the word gives rise to compound forms such as "*picket boat*" or "*picket launch," large steam launch or pinnae fitted with guns and torpedoes, and employed for watching the waters of harbours, &c. For picketing in strikes, &c., see below.

**PICKETING,** a term used to describe a practice resorted to by workmen engaged in trade disputes, of placing one or more men near the works of the employer with whom the dispute is pending, with the object of drawing off his hands or acquiring information useful for the purposes of the dispute. In England, under the Conspiracy and Protection of Property Act 1875, it is an offence wrongfully and without legal authority to watch or beset the house or place where another resides or works, or carries on business or happens to be, or the approach to such house or place, if the object of the watching, &c., is to compel the person watched, &c., to abstain from doing or to do an act which he is legally entitled to do or to abstain from doing (§ 7). The definition of the offence was qualified by a proviso excluding from punishment those who attend at or near a house or place merely to obtain or communicate information, in other words what is termed peaceful picketing, without intimidation, molestation or direct efforts to influence the course of a trade dispute. This act had the effect of a great deal of litigation between trade unions and employers; and trade unions were in some instances restrained by injunction from picketing the works of employers, the decisions of the courts upon this subject met with severe criticism from the leaders of trade unions, and by the Trades Disputes Act 1906 the proviso above quoted was repealed, and it was declared lawful for one or more persons acting for themselves or for a trade union or for an individual employer to attend at or near a house, &c., "if the attendance is merely for the purpose of peacefully obtaining or communicating information or of peacefully persuading any person to work or abstain from working. The exact effect of this change in the law has not yet been determined by the courts, but during the Bellast carters' strike of 1907 (see below) the efforts of the authorities to counteract the interference with lawful business caused by free use of picketing. The change in the law is supplemented by provisions forbidding actions against trade unions in respect of any tortious acts alleged to have been committed by or on behalf of the union.

**PICKLE.** In the wider sense the term "*pickle*" is applied to any saline or acid preservative solution; in the narrower to vegetables preserved in vinegar. The word appears to be a adaptation of Dutch *pekelen*, brine, pickle; cf. Ger. *Pikel*. The ultimate origin is unknown; connexions with a supposed inventor's name, such as *Beukteler* or *Blichet*, are mere inventions. A solution of copper or zinc sulphate is used as a "*pickle*" for railway-sleepers or other wood, a brine containing salt and saltpetre as a preservative for meat, lime-water as "*pickle*" for eggs. Domestic pickles are made from small cucumbers, onions, cauliflower, cabbages, mangos and unripe walnuts, by either steeping or boiling them in salt-brine and vinegar. On account of the large proportion of water natural to these vegetables, only the strongest vinegar, containing from 5 to 6% of acetic acid, can be used. For the better kinds vinegar made from malted or unmaltend barley is as a rule employed, for cheaper varieties simply dilute acetic acid obtained from acetate of lime. Sauces such as Worcestershire sauce, or Yorkshire relish, consist of fluid pickles, that is of salted and variously spiced vinegar solutions or emulsions containing tissue of vegetables (tomatoes, mushrooms, &c.), or of fish (sardines or anchovies).

**PICKNELL, WILLIAM LAMB** (1854–1897), American landscape-painter, was born at Hinesburg, Vermont, on the 23rd of October 1854. He was a pupil of George Inness in Rome for two years, and of J. L. Gérôme in the Ecole des Beaux Arts, Paris. With Robert Wylie he worked for several years in Brittany, at Pont Aven and Concarneau, where he painted his "*Route de Concarneau*" (Corcoran Art Gallery, Washington, D.C.). His "Morning on the Loïc" received a gold medal at the Paris Salon of 1885. In 1880 he became a member of the Society of American Artists, and in 1891 an associate of the National Academy of Design. He died at Marblehead, Massachusetts, on the 8th of August 1897.

**PICNIC,** a term of entertainment in which the guests are invited to join an excursion to some place where a meal can be taken in the open air. During the first half of the 19th century the essential of a picnic was that the guests should each bring with them a contribution of provisions. At the beginning of the 19th century a society was formed in London called the "*Picnic Society,"* the members of which supped at the Pantheon in Leadenhall Street, and drew lots as to what part of the meal each should supply. By L. Melville, *The Beaux of the Regency, 1808, i. 225*.

The French term *pique-nique* is said to be of recent introduction in 1692 (Ménage, *Dit. etym.*). It is doubtful whether picnic is merely a rhyming word, or can be referred to *pique*, pick, and *nique*, small coin.

**PICO,** an island in the Atlantic Ocean, belonging to Portugal, and forming part of the Azores archipelago. Pop. (1900), 24,628; area 175 sq. m. Pico is a conical mountain, rising to the height of 7612 ft. It consists entirely of pulverized lava. The so-called Fayal vine, though named after an adjacent island, was formerly produced there, and largely exported to Europe. But in 1851 the vines were attacked by the Oidium fungus, and completely destroyed, while the orange-trees suffered almost as much from the *Coccus hesperidum*.* The people were consequently forced to emigrate in great numbers, till the planting of fig-trees and apricots alleviated the evil. Pico also produces a species of wood resembling mahogany, and equal in quality to it. Its chief town is Lages do Pico. Pop. (1907).

**PICO DELLA MIRANDOLA, GIOVANNI, COUNT** (1435–1494), Italian philosopher and writer, the youngest son of Giovanni
PICRIC ACID—PICRITE

Francesco Pico, prince of Mirandola, a small territory about 30 Italian miles west of Ferrara, afterwards absorbed in the duchy of Modena, was born on the 24th of February 1463. The family was illustrious and wealthy, and claimed descent from Constantine. In his fourteenth year Pico went to Bologna, where he studied for two years, and worked, occupied with the Decretals. The traditional studies of the place, however, disgusted him; and he spent seven years wandering through all the schools of Italy and France and collecting a precious library. Besides Greek and Latin he knew Hebrew, Chaldee and Arabic; and his Hebrew teachers (Elia del Medigo, Leo Abarbanel and Jochanan Alemen—see L. Geiger Johann Reuchlin (1871). p. 167) introduced him to the Kabbalah, which had great fascinations for one who loved all mystic and theosophic speculations. His learned wanderings ended (1486) at Rome, where he set forth for public disputations a list of nine hundred questions and conclusions in all branches of philosophy and theology. He remained a year in Rome, but the disputations he proposed was never held. The pope prohibited the little book in which they were contained, and Pico had to defend the impugned theses (De omni re scibili) in an elaborate Apologia. His personal orthodoxy was, however, subsequently vindicated by a brief of Alexander VI. dated 18th June 1493. The suspected theses included such points as the following: that Christ descended ad inferos not in His real presence but quoad effectum; that no image or cross should receive iatria even in the sense allowed by Thomas; that it is more reasonable to regard Origen as saved than as damned; that it is not in a man's will to believe or disbelieve an article of faith as he pleases. But perhaps the most startling thesis was that no science gives surer conviction of the divinity of Christ than "magia" (i.e. the knowledge of the secrets of the heavenly bodies) and Kabbalah. Pico was the first to seek in the Kabbalah a proof of the Christian mysteries and it was by him that Reuchlin was led into the same delusive path.

Pico had been up to this time a gay Italian nobleman; he was tall, handsome, fair-complexioned, with keen grey eyes and yellow hair, and a great favourite with women. But his troubles led him to more serious thoughts; and he published, in his 28th year, the Hebraplus, a mystical exposition of the creation. Next he planned a great seven-fold work against the enemies of the Church, of which only the section directed against astrology was completed. After leaving Rome he again lived a wandering life, often visiting Florence, to which he was drawn by his friends Politian and Marsilius Ficinus, and where also he came under the influence of Savonarola. It was at Florence that he died on the 17th of November 1494. Three years before his death he parted with his share of the ancestral principality, and designed, when certain literary plans were completed, to give away all he had and wander barefoot through the world preaching Christ. But these plans were cut short by a fever which carried him off just at the time when Charles VIII. was at Florence.

Pico's works cannot now be read with much interest, but he himself is still interesting, partly from his influence on Reuchlin and partly from the spectacle of a truly devout mind in the brilliant circle of half-pagan scholars of the Florentine renaissance.

His works were published at Bologna in 1496 by his nephew, Giov. Fran. Pico, with a biography, which was translated by Sir Thomas More as Life of John Pico, Earl of Mirandola (1516). See the essay in Walter Pater's Renaissance (1878) and the study by J. Rigg. prefixed to the reprint of More's Life in the "Tudor Library" (London, 1890).

PICRIC ACID, or Triphenylphosphine, C6H5-CH3O-N(OH)3 [2·4·6], an explosive and dyestuff formerly the action of concentrated nitric acid on indigo, aniline, resins, silk, wool, leather, &c. It is the final product of the direct nitration of phenol, and is usually prepared by the nitration of the mixture of phenol sulphon acids obtained by heating phenol with concentrated sulphuric acid (E. Eisenmann and A. Arche, Eng. pat., 4539 (1888)). It may also be obtained by oxidizing the symmetrical triinitrotoluene with potassium ferricyanide in alkaline solution (P. Hepp, Ann. 1882, 215, p. 352). It crystallizes from water in yellow plates melting at 122-5°C, which sublimes on careful heating, but explode when rapidly heated. It is poisonous and possesses a bitter taste, hence its name from the Greek μυκή, bitter. It has a strongly narcotic action, but almost comparable with the carbolic acids. By the action of bleaching powder it is converted into chloropicrin, CCl3NO2. Phosphorus pentachloride converts it into picryl chloride, C6H5Cl(NO2)3, which is a true acid chloride, being decomposed by water with the regeneration of picric acid and the formation of hydrochloric acid; with ammonia it yields picramide, C6H5NH2(NO2)3. Silver picrate and molybdate yield the methyl ester, which gives with ammonia picramide. Picric acid forms many well-defined salts, of a yellow or red-brown colour. It also yields crystalline compounds with many aromatic hydrocarbons and bases. It imparts a yellow colour to wool and silk. The chief application of picric acid and its salts is in the manufacture of explosives. When ignited, picric acid burns quietly with a smoky flame, and it is very difficult to detonate by percussion; its salts, however, are more readily detonated. The more important picric powders are melinite, believed to be a mixture of fused picric acid and gun-cotton; lyddite, the British service explosive, and shimose, the Japanese powder, both supposed to be identical with the original melinite; Brugère's powder, a mixture of 54 parts of ammonium picrate and 45 parts of sulphate; Designolle's powder, composed of potassium picrate, saltpetre and charcoal; and ammencite, invented by Stephen Emmens, of the United States. It may be detected by the addition of an aqueous solution of potassium cyanide, with which it gives a violet-red coloration, due to the formation of isopurpuric acid. R. Anschatz (Ber., 1884, 17, p. 430) estimates picric acid by precipitation with acridine.

PICRITE (from Gr. πιξόπιτο, bitter, because these rocks are rich in magnesia, a base which forms bitter salts), a rock belonging to the ultrabasic group, and consisting mainly of olivine and augite often with hornblende and biotite and a greater or less amount of plagioclase felspar. The picrites are of "hypabyssal origin and in their natural occurrence are connected with dolerites (diabases and tesanites). The distinction between them and the peridotites, which have an essentially similar composition, is not easy to define, but the peridotites accompany the true plutonic rocks, such as gabbro, norite and pyroxenite, are often very coarsely crystalline, and form large bosses and laccolites, while the picrites usually are found in sills or intrusive sheets.

In hand specimens the picrites are dark green to black; the absence or scarcity of lath-shaped plagioclase felspar distinguishes them from diabases and they rarely have the lustremollting which is a characteristic of the peridotites. Since they contain much olivine they readily decompose, passing into deep green and brown incoherent masses in which are embedded rounded granules of harder consistency. They have a high specific gravity (about 3·6) and may be distinctly magnetic, because they are rich in iron ores. Porphyritic structure is rare though occurring sometimes in the rocks known as picrite-porphyrites; the phenocrysts are olivine and augite. There is seldom any fine-grained or glassy groundmass, and the typical microstructure is holocristalline, moderately fine grained and somewhat poikilitic. Olivine is abundant in rounded pale green crystals. It may form one half of the rock but rarely more than this. The augite is generally brown or reddish-brown, sometimes violet, and tends to enclose the olivine, yielding poecilitic aggre gates. Brown hornblende often occurs as marginal growths around the pyroxene crystals and may be so abundant as to replace the augite to a large extent; rocks of this class are known as hornblende-picrites. Bright green or pale-green hornblende are less frequently present, and in many cases are really of secondary origin. Deep brown biotite is a frequent accessory mineral and both biotite and hornblende sometimes enclose olivine. A small amount of basic plagioclase occurs in many picrites; apatite, iron oxides, chromite and spinels are minor ingredients seldom altogether absent.
The minerals of picrites are very frequently decomposed. Serpentine partly or wholly replaces olivine, forming radiate fibrous masses which are green, yellow or red in microscopic sections. Sometimes hornblende (piite), talc, chlorite and mica appear as secondary products after olivine. The augite passes into chlorite or into green fibrous or platy amphibole. Hornblende and biotite are often fresh while the other components are altered. The felspar is rarely in good preservation but yields epidote, prehnite, sericite, kaolin; calcite and analcite are abundant in some weathered picrites.

Rocks of this type are well represented in Great Britain. In the central valley of Scotland several masses of picrite have been discovered which are composed of olivine hornblende-tektite. One of these forms the island of Inchcolm in the Firth of Forth, another lies near Bathgate (in Linlithgowshire), and there are others at Aberdour (Fife), Ardrossan and Barnston (Midlothian). They belong to the great series of Carboniferous eruptive rocks of the Scottish midland valley. These picrites are not known to be represented in England, but, on the other hand, there are Devonian picrites in Devon and Cornwall as basic members of the diabase and protorobase series of these counties. Some of them contain much augite like the picrite (often called palaepicrite as being of palaeozoic age) at Menheniot Station in Cornwall and the picrite of Highglen near North Ayr, in South Ayrshire. Other Devonian picrites occur in that of Carturther near St Garmans, Cornwall. Hornblende-picrite occurs also in the island of Sark and several beautiful examples have been described from Anglesey and from Penrhyndulas in North Wales, and from Wicklow near Dublin. Picrites occur in several parts of Germany, notably in the Devonian rocks of the Fichtelgebirge and Nassau, where they accompany diabases and protorobases like those of Cornwall and Devonshire. In the diabase districts of the mountainous parts of central and northern Germany picrites are very common.

Some in the continental picrites enstalite is present but is rare. In North America picrites occur among the igneous rocks on the Hudson river and in Alabama and Montana.

PICROTOXIN, a neutral principle obtained from the Cocculus indicus, which is the fruit of the Anamurita paniculata. It is used in medicine externally as an antiparasitic. Internally it has been successfully used to check the night-sweats of phthisis. In large doses it is a powerful poison, causing unconsciousness, delirium, convulsions, gastro-enteritis and stimulation of the respiratory centre followed by paralysis, from which death sometimes results. Formerly low class pubucans sometimes added Cocculus indicus berries to beer to increase the intoxicating effects. Its chemical formula is C_{18}H_{20}O_{4}.H_{2}O.

PICTET DE LA RIVE, FRANCOIS, a Swiss zoologist and malacologist, was born in Geneva on the 27th of September 1809. He graduated B. ès Sc. at Geneva in 1829, and pursued his studies for a short time at Paris, where under the influence of Cuvier, de Blainville and others, he worked at natural history and comparative anatomy. On his return to Geneva in 1830 he assisted A. P. de Candolle by giving demonstrations in comparative anatomy. Five years later, when de Candolle retired, Pictet was appointed professor of zoology and comparative anatomy. In 1846 his duties were restricted to certain branches of zoology, including geology and palaeontology, and these he continued to teach until 1859, when he retired to devote his energies to the museum of natural history and to special palaeontological work. He was rector of the academy from 1847 to 1850, and again from 1866 to 1868. He was for many years a member of the Representative Council of Geneva, and in 1862 President of the Constituent Assembly. His earlier published work related chiefly to entomology, and included Recherches pour servir à l'histoire et à l'anatomie des Phrygianides (1834) and two parts of Histoire naturelle, générale et particulière des insectes Neuroptères (1842-1845). Feeling the want of a hand-book, he prepared his Traité élémentaire de paléontologie (4 vols. 1844–1846). In the first edition Pictet, while adopting the hypothesis of successive creations of species, admitted that some may have originated through the modification of pre-existing species. In his second edition (1853-1857) he enters further into the probable transformation of some species, and discusses the independence of certain faunas, which did not appear to have originated from the types which locally preceded them. He now directed his attention to the fossils of his native country, more especially to those of the Cretaceous and Jurassic

strata, and in 1854 he commenced the publication of his great work, Moutiers pour la paléontologie suisse, a series of quarto memoirs, of which six were published (1854-1873). In this work Pictet was ably assisted by Louis de Rive, and others. Pictet also brought out Mémoues paléontologiques (1863-1868). He died at Geneva on the 3rd of March 1872.

PICTON, SIR THOMAS (1758–1815), British general, was the younger son of Thomas Picton, of Poyston, Pembrokeshire, where he was born in August 1758. In 1771 he obtained an ensign's commission in the 12th regiment of foot, but he did not join until two years afterwards. The regiment was then stationed at Gibraltar, where he remained until he was made captain in the 75th in January 1778, when he returned to England. The regiment was disbanded five years later. On the occasion of its disbandment Picton quelled a mutiny amongst the men by his prompt personal action and courage, and was promised a majority in reward for his conduct. This, however, he did not receive, and after living in retirement on his father's estate for nearly twelve years, he went out to the West Indies in 1794 on the strength of a slight acquaintance with Sir John Vaughan, the commander-in-chief, who made him his aide-de-camp and gave him a captaincy in the 7th foot. Shortly afterwards he was promoted major. Under Sir Ralph Abercromby, who succeeded Vaughan in 1795, he took part in the capture of St Lucia (for which he was promoted lieutenant-colonel) and in that of St Vincent. After the reduction of Trinidad Abercromby made him governor of the island. He administered the island with such success that he was sent out in 1803 to suppress a mutiny of the inhabitants petitioned against the retrocession of the island to Spain, and their protest, with Picton's and Abercromby's representations, ensured the retention of Trinidad as a British possession. In October 1801 he was gazetted brigadier-general. But by this time the rigour of his government, as reported by his enemies, had led to a demand by humanitarians at home for his removal. Colonel William Fullarton (1754-1808) procured the appointment of a commission to govern the island, of which he himself was the senior member, Captain (afterwards Admiral Sir Samuel) Hood the second, and Picton himself the junior. Picton thereupon tendered his resignation, and Hood, as soon as the nature of Fullarton's commission became known, signed it on Picton's behalf (1803). On his way home Picton took part with great credit in military operations in St Lucia and Tobago. Realizing, however, that the attacks upon him were increasing in virulence, he quickly returned to England, and in December 1803 he was arrested by order of the privy council. He was tried in the court of king's bench before Lord Ellenborough in 1806 on a charge of unlawfully applying torture to extort a confession from Luise Calderon, a mulatto woman of loose character who was charged, along with a man, with robbery. The torture consisted in compelling the woman to stand on one leg on a flat-headed peg for one hour. The punishment was ordered under Spanish law (which in default of a fresh code Picton had been appointed to administer in 1823) by the local alcalde, and approved by Picton. On these grounds the court returned a merely technical verdict of guilty, which was superseded in 1808 by a special verdict on retrial. It should be mentioned that the inhabitants of the island, who had already given him a sword of honour, and had petitioned the king not to accept his resignation, subscribed £4000 towards his legal expenses, which sum Picton contributed in return to the relief of the suffering caused by a widespread fire in Port of Spain. He had meanwhile been promoted major-general, and in 1809 he had been governor of Flushing during the Walcheren expedition. In 1810, at Wellington's request, he was appointed to command at Cadiz in Spain. For the remaining years of the Peninsular War, Picton was one of Wellington's principal subordinates. The commander-in-chief, it is true, never reposed in him the confidence that he gave to Beresford Hill and Craufurd. But in the resolute, thorough and punctual execution of a well-defined task Picton had no superior in the army. His début,
owing partly to his naturally stern and now embittered temper, and partly to the difficult position in which he was placed, was unfortunately. On the 23 April 1781 Craufurd’s division became involved in an action, and Picton, his nearest neighbour, refused to support him, as Wellington’s direct orders were to avoid an engagement. Details of the incident will be found in Oman, *Peninsular War*, vol. iii. Shortly after this, however, at Busaco, Picton found and used his first great opportunity for distinction. Here he had a plain duty, that of repulsing the French attack, and he performed that duty with a skill and resolution which indicated his great powers as a troop-leader. After the winter in the lines of Torres Vedras, he added to his reputation and to that of his division, the 3rd, at Fuentes d’Onor. In September he was given the local rank of Lieutenant-general, and in the same month the division won great glory by its rapid and orderly retreat under severe pressure from the French cavalry at El Bordon. In October Picton was appointed to the colonelcy of the 77th regiment. In the first operations of 1812 Picton and Craufurd, side by side for the last time, stormed the two breaches of Ciudad Rodrigo, Craufurd and Picton’s second in command, Major-General Mackinnon, being mortally wounded. At Badajoz, a month later, the successful storming of the fortress was due to his daring self-reliance and penetration in converting the secondary attack on the castle, delivered by the 3rd division, into a real one. He was himself wounded in this terrible engagement, but would not leave the ramparts, and the day after, having recently inherited a fortune, he gave every survivor of his command a guinea. His wound, and an attack of fever, compelled him to return to England to recruit his health, but he reappeared at the front in April 1813. While in England he was invested with the collar and badge of a K.B. by the prince regent, and in June he was made a lieutenant-general in the army. The conduct of the 3rd division under his leadership at the battle of Vittoria and in the engagements in the Pyrenees raised his reputation as a resolute and skilful fighting general to serious weight. Early in 1814 he was offered, but consulting Wellington declined, the command of the British forces operating on the side of Catalonia. He thus bore his share in the Orthez campaign and in the final victory before Toulouse.

On the break-up of the division the officers presented Picton with a valuable service of plate, and on the 24th of June 1814 he received for the seventh time the thanks of the House of Commons for his great services. Somewhat to his disappointment he was not included amongst the generals who were raised to the peerage, but early in 1815 he was made a G.C.B. When Napoleon returned from Elba, Picton, at Wellington’s request, accepted a high command in the Anglo-Dutch army. He was severely wounded at Quatre Bras on the 16th of June, but concealed his wound and retained command of his troops, and at Waterloo on the 18th, while repulsing with impetuous valour “one of the most serious attacks made by the enemy on our position,” he was shot through the head by a musket ball. His body was brought home to London, and buried in the family vault at St George’s, Hanover Square. A public monument was erected to his memory in St Paul’s Cathedral, by order of parliament, and in 1823 another was erected at Carmarthen by subscription, the king contributing a hundred guineas thereto.

See Robinson’s *Life of Sir Thomas Picton* (London, 1836), with which, however, compare Napier’s and Oman’s histories of the Peninsular War as to controversial points.

**PICTOU**, a seaport, port of entry, and capital of Pictou county, Nova Scotia, 90 m. N.E. by N. of Halifax, on a branch of the Intercolonial railway. Pop. (1901), 3235. It has several valuable industries, and is the shipping port for the adjacent coal-mines. The Academy, founded in 1818, played an important part in the early educational history of the province, and still enjoys a high reputation.

**PICUS**, in Roman mythology, originally the woodpecker, the favourite bird and symbol of Mars as the god of both nature and war. He appears later as a spirit of the forest, endowed with the gift of prophecy, haunting springs and streams, with a special sanctuary in a grove on the Aventine. As a god of agriculture, especially connected with manuring the soil, he is called the son of Hercutus (from sterco, dung, a name of Saturn). Again, Picus is the first king of Latium, son of Saturn and father of Faunus. Virgil (*Aen*. vii. 170) describes the reception of the ambassadors of Aeneas by Latinius in an ancient temple or palace, containing figures of his divine ancestors, amongst them Picus, famous as an augur and soothsayer. According to Ovid (*Metam*. xiv., 320), Circe, while gathering herbs in the forest, saw the youthful hero out hunting, and immediately fell in love with him. Picus rejected her advances, and the goddess in her anger changed him into a woodpecker, which pecks impatiently at the branches of trees, but still retains prophetic powers. The purple cloak which Picus were fastened by a golden clasps is preserved in the plumage of the bird; in the simplest form of art, he was represented by a wooden pillar surmounted by a woodpecker; later, as a young man with the bird upon his head.

**PICUMNUS** is merely another form of Picus, and with him is associated his brother and double *PILUMNUS*. Picumus, a rustic deity (like Picus) and husband of Pomona, is specially concerned with the manuring of the soil and hence called *Serumnus*, while Pilumus is the inventor of the pounding of grain, so named from the pestle (*pilum*). Bakers, under a different aspect, the pair were regarded as the guardians of women in childbirth and of newborn children. Before the child was taken up for uncircumcision, a(%)

**PIE** (1) The name of the bird more generally known as the magpie (q.v.). The word comes through the French from Lat. *pica* (q.v.). It is probably from the black and white or spotted appearance of the bird that the name “pie” or “pye” (Lat. *pica*) was given to the ordinal, a table or calendar which afterwards took the place of the *lunae calendar* and *luna* of the ancients. Further, the word was corrupted to “pie,” and pointed out the effect on them of the festivals rendered movable by the changing date of Easter. An English act of 1549 (3 & 4 Edw. VI. c. 19) abolished “pies” with manuals, legends, primers and other service books. The parti-coloured appearance of the magpie also gives rise to the term “piebald,” applied to an animal, more particularly a horse, which is marked with large irregular patches of white and black; where the colour is white and some colour other than black, the more appropriate word is “skew-bald,” i.e. marked with “skew” or irregular patches. (2) A dish made of meat, fish or other ingredients, also of vegetables or fruit, baked in a covering of pastry; in English usage, where “fruit” is the ingredient, the dish is generally called a “tart,” except in the case of “apple-pie.”

The word appears early in the 14th century of meat or fish pies. The expression “to eat humble-pie,” i.e. to make an apology, to retract or recant, is a facetious adaptation of “umbles” (O. Fr. *nombles*, connected with Lat. *lumbus*, loin or umbilicus, navel), the inner parts of a deer, to “humble” (Lat. *humbilis*, lowly). An “umble-pie,” made of the inner parts of a deer or other animal, was once a favourite dish. “Printers’ pie,” i.e. a mass of confused type, is a transferred sense of “pie,” the dish, or of “pie,” the ordinal, from the difficulty of decipherment.

**PIEDMONT** (Ital. *Piemonte*; Low Lat. *Pedomons* and *Pedinum*), a territorial division (comportimenti) of northern
PIENZA—PIER

Italy, bounded N. by Switzerland, W. by France, S. by Liguria and E. by Lombardy. Physically it may be briefly described as the upper gathering-ground and valley of the Tiber, Po, and Arno, which, at the foot of the Alps, are on all sides except towards the Lombard plain by the vast semicircle of the Pennine, Graian, Cottian, Maritime and Ligurian Alps. In 1859 it was divided into the four provinces of Alessandria, Cuneo, Novara and Torino (Turin). It has an area of 11,340 sq. m. The people are chiefly engaged in agriculture: growing wheat, maize and rice, chestnuts, wine and hemp; in the reeling and threshing of silkworm; and in the manufacture of cotton, woolen, and linen. There are other considerable manufactures at Turin, Savigliano, &c. The Piedmontese dialect has been rather strongly influenced by French. The chief towns in the several provinces are: Turin, with their conquests; Alessandria, Savigliano (72,105), Asti (39,251), Casale Monferrato (31,370), Novo Ligure (7,868), Tortona (17,410), Acqui (13,940), Valenza (10,056), Ovada (10,284); total of province 825,745, number of communes 343; Cuneo (26,879), Mondovì (18,082), Fossano (18,179), Savigliano (17,340), Saluzzo (16,028), Brà (15,821), Alba (13,637), Boves (10,137); total of province 670,504, number of communes 263; Novara (44,240), Vercelli (30,470), Biella (10,267), Trino (12,138), Borgomanero (10,131); total of province 765,833; number of communes, 437; Turin (329,601), Fenera (18,630), Carmagnola (11,721), Ivrea (14,606), Moncalieri (11,496). The total population of the kingdom in 1843 was 2,738,814 in 1859, and in 1901, 3,407,403. The large number of communes is noticeable, as in Lombardy, and points to a village life which, owing to greater insecurity and the character of the country, is not to be found in central and southern Italy as a whole. There are numerous summer resorts in the Alpine valleys. The chief railway centres are Turin, communicating with the Mont Cenis line, and with the Riviera by the railway over the Col di Tenda (in process of construction), Novara, Vercelli, Asti, Alessandria, Novi. The communications with Liguria are difficult owing to the approach of the mountains to the coast, and the existing lines from Genoa to Turin and Milan are hardly sufficient to cope with the traffic.

Piedmont in Roman times until 49 B.C. formed a part of Gallia Traspadana, and in Augustus' division of Italy formed with what was later known as Lombardy the 17th region. It formed part of the Lombard kingdom, and it was not till about A.D. 1000 that the house of Savoy (g.v.) arose. The subsequent history of Piedmont is that of its dynasty.

PIENZA, a town of Tuscany, Italy, in the province of Siena, 9 m. west of the town of Montepulciano by road, 1611 ft. above sea-level. Pep. (1001), 2730 (town); 3566 (commune). The place was originally called Cerignone and owes its present name to Aemilia Silvia Piccolomini, Pope Pius II. (g.v.) who was born here in 1405. The buildings which he caused to be erected by Bernardo Rossellino in 1460-1463 form a noble group of early Renaissance architecture round the Piazza del Duomo. The latter retains Gothic details in the interior, but the façade is simple Renaissance work. The other three sides are occupied by the episcopal and municipal palaces, and the Palazzo Piccolomini; the last, resembling the Palazzo Rucellai at Florence, is the finest, and in front of it is a beautiful fountain. The episcopal palace contains a museum with some fine ecclesiastical vestments, enamels and other works of art.

PIER (older forms per or per, from Med. Lat. pera; the word is of obscure origin, and the connexion with Fr. pierre, Lat. petra, stone, is doubtful; equivalents are Fr. piedrot, pilier, trumeau; Ital. pia; Ger. Pfeiler), the term given in architecture to a vertical support in masonry or brickwork, usually rectangular or plan, which carries an arch or superstructure. The term is also sometimes given to the great circular columns which in some English cathedrals and churches carry the nave arches. In early Christian churches, when antique columns, such as those at Abond in Rome, were not procurable, square piers took the place of columns and sometimes alternated with them. The introduction of vaulting, however, in the 11th century, necessitated a support of much greater dimensions than those which had been deemed sufficient when the roof was of timber only, and led to the development of the compound or clustered pier. To give extra support to the subordinate arches of the nave arcade, semicircular shafts or pilasters were added, carried up to the transverse and diagonal ribs of the main vault. In Romanesque work the pier was generally square on plan with semicircular shafts attached, the angles of the pier being worked with smaller shafts. As the rings or circles of the nave arches increased in number, additional shafts were added to carry them, and the pilaster facing the nave had central and side shafts rising to carry the transverse and diagonal ribs of the vault; this development of the compound pier obtains throughout Europe in all its local structures. In the Early English period the piers became lofter and lighter, and in most important buildings a series of clustered columns, frequently of marble, are placed side by side, sometimes set at intervals round a circular centre, and sometimes almost touching each other. These shafts are often wholly detached from the central pier, though grouped round it, in which case they are almost always of Purbeck or Bethersden marbles. In Decorated work the shafts on plan are very often placed round a square set angle-wise, or a lozenge, the long way round the nave; the centre or core itself is often worked into hollows or other mouldings, to show between the shafts, and to form part of the composition. In this and the latter part of the preceding style there is generally a fillet on the outer part of the shaft, forming what has been called a "keel moulding" (g.v.). They are also often tied together by bands, formed of rings of stone and sometimes of metal. About this period, too, these intermediate mouldings run up into and form part of the arch moulds, there being no impost. This arrangement became much more frequent in the Perpendicular period; in fact it was almost universal, the commonest section being a lozenge set with the long side from the nave to the aisle, and not towards the other arches, as in the Decorated period, with four shafts at the angles, between which were shallow mouldings, one of which was in general a wide hollow, sometimes with wave moulds. The small columns at the jambs of doors and windows and in arcades, and also those attached to piers or standing detached, are generally called "shafts" (g.v.).

The term pier is sometimes applied to the solid parts of a wall between windows or voids, and also to the isolated masses of brickwork or masonry to which gates are hung. (R. P. S.)

Piers of Bridges.—The piers of bridges and viaducts on land are constructed of masonry or brickwork and occasionally, in the case of high piers, of open braced ironwork, as exemplified by the old Crumlin viaduct in Wales and the Pecos viaduct in Texas. These piers, besides being proportioned in cross-section to the weight they have to support, are widened out at their base, so as to give a distribution of the load. To this end they are often built of the stratum on which it rests without risk of settlement. Special provisions have to be made for the foundations of piers where the ground is soft for some depth, or loose water-bearing strata are encountered, and especially where the piers of large bridges crossing rivers have to be constructed under water. In soft ground, bearing piles driven down to a firm stratum, and surmounted by a planked floor or a layer of concrete, provide a convenient foundation for a pier; and in places where timber is abundant, wooden cribs filled with rubble stone or concrete have been used in the United States for raising the foundations for piers out of water. For river piers, where a firm, watertight stratum is found at a moderate depth below the river-bed, the site is often enclosed within a coffee-dam or a plate iron caisson carried down into the stratum and raised out of water; and then, after the water has been pumped out and the surface layers removed, the pier is readily built within the enclosure in the open air. When, however, a river-bed consists of silt, sand or other soft materials extending down to a considerable depth, brickwork wells are gradually sunk to a firm stratum by removing the material within them with grabs, and on them the piers are built out of water; or bottomless caissons are carried down by excavating their interiors under compressed air, and the piers are built on top of them within a plate-iron enclosure, a system
adopted for the piers of the Brooklyn, St Louis, Forth and other large bridges, and essential for forming foundations on sloping rock, such as was encountered in places under the Firth of Forth.

The methods indicated above as employed for the foundations of the piers of bridges under favourable conditions belong equally to the foundations of other structures (see Foundations); but there are some methods which, by combining bridge piers and their foundations in a single structure, appertain entirely to piers. Thus iron screw piles, sunk by turning into the soft bed of a river till they reach a firm stratum or one sufficiently consolidated by the superincumbent layers to enable it to support the wide blades of the screws with the weight imposed on them, were formerly often arranged in converging clusters joined together at the top, so as to serve as the piers of bridges having several comparatively small spans, and intended for carrying lightly constructed railways across rivers in India and elsewhere. Hollow, cast-iron, cylindrical piles also, with a broad circular disk at the bottom to increase their bearing surface, have been used for piers founded in sandy or silty strata and subsequently extended; whilst a new pier was completed in 1900 near the site of the old chain pier, 1700 ft. long. The Southport pier, erected in 1859-1860 and afterwards prolonged, furnishes an example of an iron pier supported on disk piles sunk in sand as described above (fig. 1); whilst the much more commonly used iron screw piles, adopted as early as 1837 for an open landing-pier on the Irish coast at Courtown, which was exposed to a great littoral drift of sand, are shown as the mode of support for the pier.

1 The Engineer (1888), i. 380, 381 and 384.
at St Leonards (fig. 3). The length given to these promenade piers depends mainly on the slope of the foreshore, which determines the shape. The shoals at the ends have sufficiently reached for steamers of moderate draught to come alongside the end of the pier. Thus, whereas a length of 900 ft. has sufficed for the St Leonards pier on a somewhat steep, shingly beach, the pier at Stove Harbour, New Brunswick, the shortest of the piers in the vicinity for Wight passengers, has had to be carried out about half a mile across a flat alluvial foreshore to reach water deep enough for the access of the steamboats crossing the Solent. The vast sands, moreover, at the outlet of the Ribble estuary, stretching two or three miles in front of Southport at low water of spring tides, have necessitated the construction of a pier 4395 ft. long merely to get out to an old flood-tide channel, which is now completely severed by the sands at low water from all connexion with the river.

(P. L. F.-V.-H.)

Pierce, Franklin (1804-1869), fourteenth president of the United States, was born at Hillsborough, New Hampshire, on the 23rd of November 1804. His father, Benjamin Pierce (1757-1839), served in the American army throughout the War of Independence, was a Democratic member of the New Hampshire House of Representatives from 1809 to 1823, and was governor of the state in 1827-1829. The son graduated in 1824 at Bowdoin College, at Brunswick, Maine, where he formed a friendship with Nathaniel Hawthorne. Pierce then studied law, and in 1827 was admitted to the bar and began to practise at Hillsborough. He at once took a lively interest in politics, and from 1829 to 1833 served in the state House of Representatives, for the last two years as Speaker. In 1833 he entered the national House of Representatives, and although he achieved no distinction in debate he was a hard worker, and a loyal supporter of the policies of President Jackson. After four years in the House he entered the Senate, being its youngest member. In 1842, before the expiration of his term, he resigned his seat, and at Concord, New Hampshire, began his career in the bar in earnest, though still retaining an interest in politics. In 1845 he declined the Democratic nomination for governor, and also an appointment to the seat in the United States Senate made vacant by the resignation of Judge Levi Woodbury. He accepted, however, an appointment as Federal District Attorney for New Hampshire, as the duties of this office, which he held in 1845-1847, were closely related to those of his profession. In 1846 he again declined public honours, when President Polk invited him to enter the cabinet as attorney-general. Soon after the outbreak of the war with Mexico, in 1846, Pierce entered the United States Senate, and in March (1847) became colonel of the Ninth Regiment (which joined General Winfield Scott at Pueblo on the 6th of August 1847), and later (March, 1847) became a brigadier-general of volunteers. At the battle of Contreras, on the 19th of August 1847, he was thrown from his horse and received severe injuries. At the end of the war he resigned his commission and returned to Concord. In 1850 Pierce became president of a convention assembled at Concord to revise the constitution of his state, and used his influence to secure the removal of those provisions of the constitution of 1792 which declared that only Protestants should be eligible for higher state offices. This amendment passed the convention in April 1852, but was rejected by the electorate of the state; a similar amendment was adopted by popular vote in 1877. In January 1852 the legislature of New Hampshire proposed him as a candidate for the presidency, and when the Democratic national convention met at Baltimore in the following June the Virginia delegation brought forward his name on the thirty-fifth ballot. Although both parties had declared the Compromise of 1850 a futility, the Democrats alone were thoroughly united in support of this declaration, and therefore seemed to offer the greater prospect of peace. This fact, combined with the colourless record of their candidate, enabled them to sweep the country at the November election. Pierce received 254 electoral votes, and General Scott, his Whig opponent, only 42. The Democrats carried every state except Massachusetts, Vermont, Kentucky and Tennessee. No president since James Monroe had received such a vote.

Pierce was the youngest man who had as yet been elevated to the presidency. For his cabinet he chose William L. Marcy of New York, secretary of state; Jefferson Davis of Mississippi, secretary of war; James Guthrie of Kentucky, secretary of the treasury; James C. Dobbin (1814-1857) of North Carolina, secretary of the navy; Robert McClelland (1807-1856) of Michigan, secretary of the interior; James Campbell (1813-1893) of Pennsylvania, postmaster-general; and Caleb Cushing of Massachusetts, attorney-general. This was an able body of men, and is the only cabinet in American history that has continued unbroken throughout an entire administration. Although Pierce during his term in the Senate had severely criticized the Whigs for their removals of Democrats from office, he himself now adopted the policy of replacing Whigs by Democrats, and the country acquiesced. Pierce had no scruples against slavery, and opposed anti-slavery agitation as tending to disrupt the Union. The conduct of foreign relations was on the whole the most creditable part of his administration. The Kosza Affair (1853) gave the government an opportunity vigorously to assert the protection it would afford those in the process of becoming its naturalized citizens. When the British government refused to prevent recruiting for the Crimean War by their representatives in America, their minister, John F. Crampton, received his passports, and the exequaturs of the British consuls at New York, Philadelphia and Cincinnati were revoked. A commercial treaty was negotiated with Japan in 1854 after Perry's expedition in the previous year. As an avowed expansionist, Pierce sympathized with the filibuster government set up in Nicaragua by William Walker, and finally accorded it recognition. It was during this term also that the Gadsden Purchase was consummated, by which 45,535 sq. m. of territory were acquired from Mexico, and that three routes were surveyed for railways from the Mississippi river to the Pacific coast.

When the Democratic national convention met at Cincinnati in June 1856, Pierce was an avowed candidate for renomination, but as his attitude on the slavery question, and especially his subservience to the South in supporting the pro-slavery party in the Territory of Kansas, had lost him the support of the Northern wing of his party, the nomination went to James Buchanan. After retiring from the presidency Pierce returned to Concord, and soon afterwards went abroad for a three years' tour in Europe. Many Southern leaders desired his renomination by the Democratic party in 1860, but he received such a cold reception in that year that he never returned. After his return to America he remained in retirement at Concord until the day of his death, the 8th of October 1869.

Pierce was not a great statesman, and his fame has been overshadowed by that of Benton, Calhoun, Clay and Webster. But he was an able lawyer, an orator of no mean reputation, and a brave soldier. He was a man of fine appearance and courtly manners, and he possessed personal magnetism and the ability to make friends, two qualities that contributed in great measure to his success.

The second volume of Pierce's correspondence has been published in the American Historical Review, x. 110-127, 350-370. D. W. Bartlett's Franklin Pierce (New York, 1882), and Nathaniel Hawthorne's Franklin Pierce (Boston, 1882), are two "campaign" biographies. The best life of Pierce is that of J. F. Rhodes, History of the United States, vols. i. and ii. (New York, 1893-1894); and J. W. Burgess's Middle Period (New York, 1900).

Piero Di Cosimo (1462-1521), the name by which the Florentine painter Pietro di Lorenzo is generally known. He was born in Florence, about 1462, and worked in the bottega of Cosimo Rosselli (from whom he derived his popular name). Other influences that can be traced in his work are those of Filippino Lippi, Luca Signorelli, and Leonardo da Vinci, and, as has been recently suggested by Professor R. Muther, that of Hugo van der Goes, whose Portinari altar-piece (now at the
SPEDALE OF S. MARIA NOVELLA IN FLORENCE) helped to lead the whole of Florentine painting into new channels. From him, most probably, he acquired the love of landscape and the intimate knowledge of the growth of flowers and of animal life. The influence of Hugo van der Goes is especially apparent in the "Adoration of the Shepherds," at the Berlin Museum. He had the gift of a fertile fantastic imagination, which, as a result of a journey to Rome in 1482 with his master, Roselli, became directed towards the myths of classic antiquity. He proves himself a true child of the Renaissance in such pictures as the "Death of Procris," at the National Gallery, the "Mars and Venus," at the Berlin Gallery, the "Perseus and Andromeda" series, at the Uffizi in Florence, and the "Hylas and the Nymphs," belonging to Mr Benson. If, as we are told by Vasari, he spent the last years of his life in gloomy retirement, the cause of which, probably due to Savonarola, under whose influence he turned his attention once more to religious art. The "Immaculate Conception," at the Uffizi, and the "Holy Family," at Dresden, best illustrate the religious fervour to which he was stimulated by the stern preacher.

With the exception of the landscape background in Roselli's fresco of the "Sermon on the Mount," in the Sistine Chapel, we have no record of any fresco work from his brush. On the other hand, he enjoyed a great reputation as a portrait painter, though the only known examples that can be definitely ascribed to him are the portrait of a warrior, at the National Gallery, (No. 395), the so-called "Bella Simonetta," at Chantilly, the portrait of Giuliana di See Velasquez and his father, at the Hague, and a head of a youth, at Dulwich. The most delightful are the portraits of Pierre excelled in designing pageants and triumphal processions, for the pleasure-loving youths of Florence, and gives a vivid description of one such procession at the end of the carnival of 1597, which illustrated the triumph of death. Piero de Cosimo exercised considerable influence upon his fellow pupils Albertinelli and Bartolommeo della Porta and was the master of Andrea del Sarto. Examples of his work are also to be found at the Louvre in Paris, the Harrach and Liechtenstein collections in Vienna, the Borghese Gallery in Rome, the Spedale degli Innocenti in Florence, and in the collections of Mr John Burke and Colonel Cornwallis West in London. A "Magdalene" from his brush was added to the National Gallery of Rome in 1907.

See PIERRE DE COSIMO, by F. Knap; H. (Halle, 1899); PIERRE DE COSIMO, by H. Haberfeldt (Breslau, 1901).

PIERRE, the capital of South Dakota, U.S.A., and the county-seat of Hughes county, situated on the east bank of the Missouri river, opposite the mouth of the Bad river, about 186 m. N.W. of Yankton. Pop. (1905) 2794; (1910) 3626. Pierre is served by the Chicago & North-Western railway; the Missouri is navigable here, but river traffic has been practically abandoned. Pierre is the site of the state capitol (1909) and the post office building. Pierre has a public library, and is the seat of the Pierre Industrial School (co-educational, opened in 1890), a government boarding school (non-reservation) for Indian children. The city has a large trade in livestock, and is a centre for the mining districts of the Black Hills and for a grain-growing country. Natural gas is used for lighting, heating and power. A fur-trading post, Fort La Framboise, was built in 1817 by a French fur-trader (from whom it took its name) at the mouth of the Teton or Little Missouri river (now called the Bad river), on or near the site of the present village of Fort Pierre (pop. in 1910, 792). In 1822 Fort Tecumseh was built about 2 m. up-stream by the Columbia Fur Company, which turned it over in 1837 to the American Fur Company. The washing away of the river bank caused the abandonment of this post and the erection about a mile farther up-stream, and a short distance west of the river, of Fort Pierre Chouteau (later called Fort Pierre), occupied in 1832, and named in honour of Pierre Chouteau, jun. (1789-1863).1 For twenty years thereafter Fort Pierre was the chief fur-trading depot of the Upper Missouri country. In 1855 the United States government bought the post building and other property for $34,500, and laid out around them a military reservation of about 720 sq. m. The fort was the headquarters of General William S. Harney (1800-1889) in his expedition against the Sioux in 1856, and in March of that year an important council between General Harney and the chiefs of all the Sioux bands, except the Blackfeet, was held here. Fort Pierre was abandoned in 1857. Pierre was laid out in 1880, was incorporated as a village in 1883, and was chartered as a city in 1900.

PIERRE DE CASTELNAU (d. 1208), French ecclesiastical, was born in the diocese of Montpellier. In 1199 he was archdeacon of Maguelonne, and was appointed by Pope Innocent III. as one of the legates for the suppression of heresy in Languedoc. In 1202, when a monk in the Cistercian abbey of Fontfoide, Narbonne, he was designated to similar work, first in Toulouse, and afterwards at Viviers and Montpellier. In 1207 he was in the Rhone valley and in Provence, where he became involved in the strife between the count of Baux and Raymond, count of Toulouse, by one of whose agents he was assassinated on the 27th of January 1207. He was beatified in the year of his death by Pope Innocent III.

See De la Bouillerie, Le Bienheureux Pierre de Castelnau et les Abbeiges au XIIIe siècle (Paris, 1866).

PIERREFONDS, a town of northern France, in the department of Oise, 9 m. S.E. of Compiègne by road. Pop. (1906), 1482. It is celebrated for its feudal stronghold, a masterpiece of modern restoration. The building is rectangular in shape, with a tower at each corner and at the centre of each of the walls, which are strengthened by crenelation and machicolation. A lofty keep defends the principal entrances on the south-west. The interior buildings are chiefly modern, but the exterior reproduces faithfully that of the medieval fortress. Pierrefonds has a church dating from various periods from the 11th to the 16th century, and its mineral springs are in some repute. The château was begun in the last decade of the 14th century by Louis d'Orléans, to whom the domain was given by Charles VI., and finished early in the 15th century. It was subsequently held by the Burgundians, the English and the adherents of the League, from whom it passed to Henry IV. It was dismantled in 1522. The ruins, bought by Napoleon I., were restored, by order of Napoleon III., from 1858 to 1865, under the direction, first of Viollet-le-Duc and afterwards of E. Boeswillwald.

PIERREPONT, WILLIAM (c. 1607-1678), English politician, was the second son of Sir Thomas Pierrepont, 1st earl of Kingston. Returned to the Long Parliament in 1649 as member for Great Wenlock, he threw his influence on the side of peace and took part for the parliament in the negotiations with Charles I. at Oxford in 1643. Pierrepont was a member of the committee of both kingdoms, and represented the parliamentary party during the deliberations at Uxbridge in 1645; but from that time, according to Clarendon, he forsook his moderate attitude, and "contracted more bitterness and sourness than formerly."

This statement, however, is perhaps somewhat exaggerated, as Pierrepont favoured the resumption of negotiations with the king in 1647, and in the following year his efforts on behalf of peace at Newport, where again he represented the parliamentarians, brought upon him some slight censure from Cromwell. For his services at Newport he was thanked by parliament; but he retired from active political life soon afterwards, as he disliked the "purging" of the House of Commons by Colonel Pride and the proceedings against the king. In spite of his Company. Chouteau built (in 1830-1831) the "Yellowstone," which went up the river to the present site of Pierre in 1831, and was the first steamboat to navigate the upper waters of the Missouri. Pierre Chouteau died in 1834 in New York City, and while living in St Louis was a member of the convention (1820) which drafted the first constitution of Missouri.
moderate views Pierrepont enjoyed the personal friendship of Cromwell; but, although elected, he would not sit in the parliament of 1656, nor would he take the place offered to him in the Protector's House of Lords. When Richard Cromwell succeeded his father, Pierrepont was an unabtrusive but powerful influence in directing the policy of the government, and after a short period of retirement on Richard's fall he was chosen, early in 1660, a member of the council of state. He represented Nottinghamshire in the Convention Parliament of 1660, and probably was instrumental in saving the lives of some of the parliamentary leaders. At the general election of 1661 he was defeated, and, spending the remainder of his life in retirement, he died in 1678. Pierrepont married Elizabeth, daughter of Sir Thomas Harris, Bart., of Tong Castle, Shropshire, by whom he had five sons and five daughters. His eldest son, Robert (d. 1660), was the father of Robert, 3rd earl, William, 4th earl, and Evelyn, 1st duke of Kingston; and his third son, Gervase (1649-1715), was created in 1714 baron Pierrepont of Han slope, a title which became extinct on his death.

PIERROT (Ital. Pedrotino), the name given to the leading character in the French pantomime plays since the 18th century; transferred from the Italian stage, and revived especially in recent times. He is always in white, both face and costume, with a loose and daintily clownish garb, and is represented as if a freakish disposition. Modern pierrot plays have converted the pierrot into a romantic and even pathetic figure.

PIERSON, HENRY HUGO [properly HENRY HUGH PEARSON], (1815-1873), English composer, was the son of the Rev. Dr Pearson of St John's College, Oxford, where he was born in 1815; his father afterwards became dean of Salisbury. Pierson was educated at Harrow and Trinity College, Cambridge, and was at first intended for the career of medicine. His musical powers were too strong to be repressed, and after receiving instruction from Attwood and A. T. Corfe he went in 1839 to Germany to study under C. H. Rink, Tomaschek and Reissiger. He was elected Reid Professor of Music in Edinburgh in 1844, but, owing to a disagreement with the authorities, he resigned in the following year, and definitely adopted Germany as his country about the same time, making the change in his names noted above. His two operas, Leila (Hamburg, 1848) and Contarini (Hamburg, 1872), have not retained their hold upon the German public as his music to Faust has done, a work which until quite recently was frequently associated with Goethe's drama. He was never recognized in England as he was in Germany, for most of his career fell in the period of the Mendelssohn fashion. His most important work was the oratorio Jerusalem, produced at the Norwich Festival of 1832, and subsequently given in London (Sacred Harmonic Society, 1833) and Würzburg (1832). For the Norwich Festival (at one of the meetings a selection from his Faust music was given with success) he began an oratorio, Hesekiel, in 1860; it was not finished, but was given in a fragmentary condition at the festival of that year. These two large works and a number of Pierson's songs, as well as the three overtures played at the Crystal Palace, reveal undeniable originality and a wealth of melodic ideas. He was weak in contrapuntal skill, and his music was wanting in outline and coherence; but in more fortunate conditions his great gifts might have been turned to better account. He died at Leipzig on the 28th of January 1873, and was buried at Sonning, Berks., of which parish his brother, Canon Pearson, was rector.

PIETAS, in Roman mythology, the personification of the sense of duty towards God and man and the fatherland. According to a well-known story, a young woman in humble circumstances, whose father (or mother) was in prison under sentence of death, without food, managed to gain admittance, and fed her parent with milk from her breast. To commemorate her filial affection a temple was dedicated (181 n.c.) by Manius Aciilii Glabrio to Pietas in the Forum Holitorium at Rome, on the spot where the young woman had formerly lived. The temple was probably originally vowed by the elder Glabrio out of gratitude for the Pietas shown during the engagement by his son, who may have saved his life, as the elder Africanus that of his father at the battle of Ticinus (Livy xxi. 46); the legend of the young woman (borrowed from the Greek story of Mycon and Pero, Val. Max. v. 4, ext. 1) was then connected with the temple by the identification of its site with that of the prison. There was another temple of Pietas near the Circus Flamininus, which is connected by Amatucci ([Rivista di storia antica, 1903]) with the story of the Pietas of C. Flaminius (Val. Max. v. 4, 5), and regarded by him as the real seat of the cult of the goddess, the Pietas of the sanctuary dedicated by Gladrio being a Greek goddess. Pietas is represented on coins as a matron throwing incense on an altar, her attribute being a stork. Typical examples of "piety" are Aeneas and Antoninus Pius, who founded games called Eusebela at Putoeli in honour of Hadrian.

See Val. Max. v. 4, 7; Pliny, Nat. hist. vii. 121; Livy xl. 34; Feuere, Paul. C. Wissowa, Religion und Kultur der Römer (1902); F. Kuntze, "Die Legende von der guten Töchter," in Jahrbücher für das klassische Altertum (1904), xxii. 280.

PIETERMARITZBURG, the capital of Natal, situated in 29° 46’ S., 30° 13’ E., 45 m. is a direct line (71 by rail) W.N.W. of Durban. It lies, 2200 ft. above the sea, north of the river Umsunduzi, and is surrounded by wooded hills. Of these the Town Hill, flat-topped, rises 1600 ft. above the town. Pop. (1904), 31,119, of whom 15,087 were whites, 10,753 Kaffirs, and 5280 Indians. The town is laid out on the usual Dutch South African plan—in rectangular blocks with a central market square. The public buildings include the legislative council chambers and the legislative assembly buildings, government house, the government post offices, colleges, and market buildings.

The town-hall, a fine building in a modified Renaissance style (characteristic of the majority of the other public buildings), has a lofty tower. It was completed in 1901, and replaces a building destroyed by fire in 1898. St Saviour's is the cathedral church of the Anglican community. The headquarters of the Dutch Reformed Church are also in the town. There are monuments of Queen Victoria and Sir Theophilus Shepstone, and various war memorials—one commemorating those who fell in Zululand in 1879, and another those who lost their lives in the Boer War 1899-1902. A large park and botanical gardens were laid out to the attractions of the town. A favourite mode of conveyance is by rickshaw. The climate is healthy and agreeable, the mean annual temperature being 65° F. (55° in June, 71° in February). The rainfall is about 38 in. a year, chiefly in the summer months (Oct.-Mar.), when the heat is tempered by violent thunderstorms.

Pietermaritzburg was founded early in 1839 by the newly-arrived Dutch settlers in Natal, and its name commemorates two of their leaders—Piet Retief and Gerrit Maritz. From the time of its establishment it was the seat of the Volksraad of the Natal Boers, and on the submission of the Boers to the British in 1842 Maritzburg (as it is usually called) became the capital of the country. It was given a municipal board in 1846, and in 1854 was incorporated as a borough. Railway connexion with Durban was made in 1880, and in 1895 the line was extended to Johannesburg. The borough covers 44 sq. m. and includes numerous attractive suburbs. The rateable value is about £4,000,000. Various industries are carried on, including brick-making, tanning, brewing, and cart and wagon building.

See J. F. Ingram, The Story of an African City (Maritzburg, 1898).

PIETERSBURG, a town of the Transvaal, capital of the Zoutpansberg district, and 177 m. N.E. of Pretoria by rail. Pop. (1904), 3276, of whom 1620 were whites. The town is pleasantly situated, at an elevation of 4200 ft., on a small tributary of the Vaal river, and is the place of most importance in the province north of Pretoria. From it roads run to Klein Lelaba and other gold-mining centres in the neighbourhood, and through it passes the old route to Moshana-land, which crosses the Limpopo at Rhodes Drift. The Zout- pansberg district contains a comparatively dense Kaffir population, and a native newspaper is published at Pietersburg.
PIETISM, a movement in the Lutheran Church, which arose towards the end of the 17th and continued during the first half of the following century. The name of Pietists was given to the adherents of the movement by its enemies as a term of ridicule, like that of "Methodists" somewhat later in England. The Lutheran Church had, in continuing Melanchthon's attempt to construct the evangelical faith as a doctrinal system, by the 17th century become a creed-bound theological and sacramentarian institution, which orthodox theologians like Johann Gerhard of Jena (d. 1637) ruled with almost the absolutism of the papacy. Chicanical faith had been discarded from its seat in the heart, where Luther had placed it, to the complete repugnance of the intellect. The dogmatic formulaires of the Lutheran Church had usurped the position which Luther himself had assigned to the Bible alone, and as a consequence only they were studied and preached, while the Bible was neglected in the family, the study, the pulpit and the university. Instead of advocating the priesthood of all believers, the Lutheran pastors had made themselves a despotic hierarchy, while they neglected their practical pastoral work. In the Reformed Church, on the other hand, the influence of Calvin had made less for doctrine than the practical Christianity. The presbyterian constitution gave the people a share in church life which the Lutherans lacked, but it involved a dogmatic legalism which imperilled Christian freedom and fostered self-righteousness.

As forerunners of the Pietists in the strict sense, not a few earnest and powerful voices had been heard bewailing the shortcomings of the Church and advocating a revival of practical and devout Christianity. Amongst them were Jakob Boehme (Behmen), the theosophic mystic; Johann Arndt, whose work on True Christianity became widely known and appreciated; Heinrich Müller, who described the font, the pulpit, the confessional and the altar as the four dumb idols of the Lutheran Church; the theologian, Johann Valentin Andreae, the court chaplain of the landgrave of Hesse; Schappius, who sought to restore to the Bible its place in the pulpit; and Theophilus Grossebauer (d. 1661) of Rostock, who from his pulpit and by his writings raised "the alarm cry of a watchman in Sion". The direct originator of the movement was Philip Jacob Spener, who combined the Lutheran emphasis on Biblical doctrine with the Reformed tendency to vigorous Christian life. Born at Rappoltsweiler, in Alsace on the 13th of, January 1635, trained by a devout godmother, who used books of devotion like Arndt's True Christianity, accustomed to hear the sermons of a pastor who preached the Bible more than the Lutheran creeds, Spener was early convinced of the necessity of a moral and religious reformation of the German Church. He studied theology, with a view to the Christian ministry, at Strassburg, where the professors at the time (and especially Sebastian Schmidt) were more inclined to practical Christianity than to theological dispute. He afterwards spent a year in Geneva, and was powerfully influenced by the strict moral life and rigid ecclesiastical discipline prevalent there, and also by the preaching and the piety of the Waldensian professor, Antoine Leger, and the converted Jesuit preacher, Jean de Labadie. During a stay in Tübingen he read Grossebauer's Alarm Cry, and in 1666 he entered upon his first pastoral charge at Frankfurt-on-the-Main, profoundly impressed with a sense of the danger of the Christian life being sacrificed to zeal for rigid orthodoxy. Pietism, as a distinct movement in the German Church, was then originated by Spener by religious meetings at his house (collegia Pietatis), at which he repeated his sermons, expounded passages of the New Testament, and induced those present to join in conversation on religious questions that arose. They gave rise to the name "Pietists." In 1675 Spener published his Pia desideria, or Earnest Desires for a Reform of the True Evangelical Church. In this publication he made six proposals as the best means of restoring the life of the Church: (1) the earnest and thorough study of the Bible in private meetings, ecclesiola in ecclesia; (2) the Christian priesthood being universal, the laity should share in the spiritual government of the Church; (3) a knowledge of Christianity must be attended by the practice of it as its indispensible sign and supplement; (4) instead of merely didactic, and often bitter, attacks on the heterodox and unbelievers, a sympathetic and kindly treatment of them; (5) a reorganization of the theological training of the universities, giving more prominence to the devotional life; and (6) a different style of preaching, namely, in the place of pleasing rhetoric, the implanting of Christianity in the inner or new man, the soul of which is faith, and its effects the fruits of life. This work produced a deep impression throughout Germany, and although large numbers of the orthodox Lutheran theologians and pastors were deeply offended by Spener's book, its complaints and its demands were both too well justified to admit of their being point-blank denied. A large number of pastors at once practically adopted Spener's proposals. In Paul Gerhardt the movement found a singer whose hymns are genuine folk poetry. In 1686 Spener accepted an appointment to the court-chaplainship at Dresden, which opened to him a wider though more difficult sphere of labour. In Leipzig a society of young theologians was formed under his influence for the learned study and devout piety of those who were not able to go into the theological academy, one of whom was August Hermann Francke, subsequently the founder of the famous orphanage at Halle (1695), commenced courses of expository lectures on the Scriptures of a practical and devotional character, and in the German language, which were zealously frequented by both students and townsmen. The lectures aroused, however, the ill-will of the other theologians and pastors of Leipzig, and Francke and his friends left the city, and with the aid of Christian Thomasius and Spener founded the new university of Halle. The theological chairs in the new university were filled in complete conformity with Spener's proposals. The main difference between the new Pietistic school and the orthodox Lutherans arose from the conception of Christianity as chiefly consisting in a change of heart and consequent holiness of life, while the orthodox Lutherans of the time made it to consist mainly in correctness of doctrine.

Spener died in 1705; but the movement, guided by Francke, fertilized from Halle the whole of Middle and North Germany. Among its greatest achievements, apart from the philanthropic institutions founded at Halle, were the organization of the Moravian Church in 1727 by Count von Zinzendorf, Spener's godson and a pupil in the Halle Orphanage, and the establishment of the great Protestant missions, Ziegenbalg and others being the pioneers of an enterprise which until this time Protestantism had strangely neglected.

Pietism, on the contrary, had its weaknesses. The very earnestness with which Spener had insisted on the necessity of a new birth, and on a separation of Christians from the world, led to exaggeration and fanaticism among followers less distinguished than himself for wisdom and moderation. Many Pietists soon maintained that the new birth must always be preceded by agonies of repentance, and that only a regenerated theologian could teach theology, while the whole school shunned all common worldly appointments and disdained the things of the world. There thus arose a new form of justification by works. Its ecclesiola in ecclesia also weakened the power and meaning of church organization. Through these extravagancies a reactionary movement arose at the beginning of the 18th century, one of the most distinguished leaders of which was Lessner, superintendent at Dresden.

As a distinct movement Pietism had run its course before the middle of the 18th century; by its very individualism it had managed to prepare the way for another great movement, the Illumination (Aufklärung), which was now to lead the world into new paths. Yet Pietism could claim to have contributed largely to the ruddy cheeks, the brisk and active manner, the public spirit once more an affair of the heart and the life, and not merely of the intellect. It likewise vindicated afresh the rights of the Christian laity in regard to their own beliefs and
the work of the Church, against the assumptions and despotism of an arrogant clergy. "It was," says Rudolf Sohm, "the last great surge of the waves of the ecclesiastical movement begun by the Reformation; it was the completion and the final form of the Protestantism created by the Reformation. Then came a time when another intellectual power took possession of the minds of men."

Some writers on the history of Pietism—e.g. Heppe and Ritschl—have included under it nearly all religious tendencies amongst Protestants of the last three centuries in the direction of the "second cultivation of personal piety" that prevailed in the various established churches. Ritschl, too, treats Pietism as a retrograde movement of Christian life towards Catholicism. Some historians also speak of a later or modern Pietism, characterizing thereby a party in the German Church which was probably at first influenced by some remains of Spener's Pietism in Westphalia, on the Rhine, in Wurttemberg, and at Halle and Berlin. The party was chiefly distinguished by its opposition to an independent scientific study of theology, its principal theological leader being Hengstenberg, and its chief literary organ the Evangelische Kirchenzeitung. The party opposed Catherine the Great of Prussia with the whole of Berlin.

Amongst older works on Pietism are J. G. Walch, Historische und theologische Einleitung in die Religionsstreitigkeiten der evangelisch-Lutherischen Kirche (1730); A. Tholuck, Geschichte des Pietismus und des ersten Studenten der Universität Tübingen (1832); Geschichte des Pietismus (1833); M. Goebel, Geschichte des christlichen Lebens in der Rheinisch-Westfälischen Kirche (3 vols., 1849-1866); and the subject is dealt with at length in J. A. Dorner's and W. Gies's Historie der Pietistischen Bewegung (1836); H. Schmid, Die Geschichte des Pietismus und der Mystik in der preussischen Kirche (1879), which is sympathetic; A. Ritschl's Geschichte des Pietismus (3 vols., 1880-1886), which is hostile; and G. Sachse, Die Ursprung und Wesen des Pietismus (1884). See also F. H. J. Nippold's article in Theol. Stud. und Kritiken (1882), pp. 347-392; H. von Schubert, Outlines of Church History, ch. xv. (Eng. trans., 1907); and Carl Mibert's article, "Pietismus," in Herzog-Hauck's Realencyklopädie für prot. Theologie u. Kirche, end of vol. xv.

PIETRO DELLA VIGNA, or PIER DELLE VIGNE [PETRUS DE VINEAS OR DE VINEIS] (c. 1190-1249), chancellor and secretary to the emperor Frederick II, was born at Capua in humble circumstances. He studied law at Padua, and through his classical education, his ability to speak Latin and his poetic gifts, he gained the favour of Frederick II, who made him his secretary, and afterwards iudex magnae curiae, councillor, governor of Apulia, prothonotary, and chancellor. The emperor, "of whose heart he held the keys," as Dante says, sent him to Rome in 1232 and 1237 to negotiate with his backer, the Pope, to Padua, in 1236, and in 1239 to accept imperial protection, to England in 1234-1235 to arrange a marriage between Frederick and Isabella, sister of King Henry III. He proved a skilful and trustworthy diplomat, and he persistently defended the emperor against his traducers and against the pope's menaces. But at the Council of Lyons, which had been summoned by Pope Innocent IV., Pietro della Vigna entrusted the defence of his master to the celebrated jurist Taddeo di Suessa, who failed to prevent his condemnation. Frederick, whose suspicions had been awakened by the slanders of the envious, had him imprisoned and blinded without giving him a chance to rebut his accusers. He committed suicide in his prison at Pisa in 1249. The exact date, place and manner of his death are, however, subject to controversy, and Flaminio del Borgo states that it occurred in the church of S. Andrea, at Pisa, in 1256. The tragic fate of this man gave rise to many legends. The Guelpic tradition accuses Pietro della Vigna, as well as the emperor and the court, of heresy; it was even stated, probably without any foundation, that they were the authors of the famous work, De tribus impositoribus, wherein Moses, Christ and Mahomet are blasphemed.

Pietro della Vigna was a man of great culture; he encouraged science and the fine arts, and contributed much to the welfare of the town of Padua in the time of the reform. He was the author of some delicate verse in the vernacular tongue, of which two canoni and a sonnet are still extant. His letters, mostly written in the name of the emperor and published by Iselin (Epistolae

libri vi, 2 vols, Basel, 1740), contain much valuable information on the history and culture of the 13th century. A collection of the laws of Sicily, a Tractatus de potestate imperiali, and another treatise, "On Consolation," in the style of Boethius, are also attributed to him.

See Huillard-Bre'holles, Vie et correspondance de Pierre de la Vigne (1864); President Pier delle Vigne (Milan, 1880); Capasso and Lanelli, Pier delle Vigne (Caserta, 1882); also FREDERICK II.

PIG (a word of obscure origin, connected with the Low Ger. and Dut. word of the same meaning, "bigge"), a common name given to the domesticated swine of agricultural use. (For the zoology, see SWINE.)

British breeds of pigs are classified as black, white and red. In some places, notably Wales and Gloucester, a remnant of a spotted breed lingers; and a large proportion of common pigs, often parti-coloured, are mongrels. The white breeds are liable to sun-scald, and black pigs (like black men) are much better adapted than white to exposure in strong sunlight, conforming to the rule that animals in the tropics have black skins.

The Large Whites may have in the skin a few blue spots which grow white hair. The head is long, light in the jaw, and wide between the eyes, with long thin ears inclined slightly forward and fringed with long fine hair. The neck is long, but not coarse, the ribs are deep, the loin wide and level, the tail set high, and the legs straight and set well outside the carcass. The whole body, including the back of the neck, is covered with straight silky hair, which denotes quality and lean meat. Pigs of this breed are very prolific, and they may be grown to enormous weights—over 11 cwt. alive.

The Middle Whites are built on a smaller scale than the Large Whites. They are shorter in the heads and legs, and fuller at the jowl, thicker and more compact in the body. The sows are quite as prolific as those of the Large White breed, and, as their produce matures earlier, they are much in demand for breeding porkers.

The Small White pigs are beautifully proportioned. The head and legs are very short, and the body short, thick and wide: the jowl is heavy, the ears pricked, and the thin skin laden with long silky, wavy, but not curly, hair, whilst the tail is very fine. A deficiency of lean meat is a common characteristic of the breed, which is almost extinct.

The above three breeds were designated Yorkshire Whites, and are still so named at times. The Middle White, formed by crossing the large and the small breeds, is not so symmetrical as the parent stocks, and the type is not uniform.

The Lincolnshire Curly Coated or Boston pig is a local breed of great size and capacity for producing pork. It is very hardy and prolific, but somewhat coarse in the bone. It has an abundance of long curly hair, a short face and a straight nose, and the ears, not too long and heavy, fall over the face. It crosses well with the Large White, the Large Black and the Berkshire.

The Large Black breed, which vies with the Large White breed for size, and is probably its superior as a bacon pig, has only since 1800 received national show-yard recognition; but there is ample evidence that, with its characteristic whole black colour, it is the parent of the hue, length, fine hair and long ear, the Large Black existed in the south of England for generations. It has been continuously and carefully bred in Cornwall, Devon, Essex and Suffolk, and from these centres it has rapidly spread all over the country. Large Blacks are exceedingly docile, and the ears, hanging well forward over the eyes, contribute materially to a quietness of habit which renders them peculiarly adapted to field grazing. On account of their hardiness and disposition to early maturity they have proved valuable for crossing purposes. The Large Black Pig Society was incorporated in 1890.

The Berkshire is a black pig with a pinkish skin, and a little white on the nose, forehead, pasterns, and tip to the tail. It has an almost perfectly short head with heavy jowl, a deep, compact carcass, and wide, low and well-developed hind-quarters, with heavy hams. The skin carries an abundance of fine hair. The Berkshire is an early-maturity breed which has been somewhat
ENGLISH BREEDS OF PIG, from photographs of F. Babbage. The comparative sizes of the animals are indicated by the scale of reproduction of the photographs.
in bred, and is not so hardy and prolific as most breeds. The
boars cross well with common stock. It merits the most credit
in raising the quality of Irish pigs. In America it is in the front
rank for numbers and quality as a lard-hog. There it often
grows to be a larger and finer animal than it is in England.
The Small Black or Black Suffolk was produced from the old
Essex pig by crossing with the Neapolitan. It resembles the
Small White, except that the skin is coal-black in colour, and
the coat of hair is not usually profuse. The Small Black, more-
over, is rather longer, and stands somewhat higher, whilst it
yields more lean meat than the Small White. It matures early
and is quick to fatten.
The Berkshire is one of the oldest breeds of pigs. It is hardy,
active and prolific, and nearly related to the wild boar. The
colour is red or chestnut, with at times darkish spots on the
skin. The head, body and legs are long, and the ribs deep and
flat. Originally a local breed in the districts around the Stafford-
shire town from which it takes its name, it is now extensively
bred, and highly valued as a bacon pig. (W. Fr.; R. W.)

In America nearly all the breeds may be classified as lard-
hogs. Bacon-pigs fed on Indian corn degenerate into hard-
hogs, run down in size and become too small in the bone and
less prolific by inbreeding.
The Poland-China, the most popular breed in the United
States, is thus degenerating. It is a black pig like the Berke-
shire, but has short ear-tips, a more pointed, straight nose, a
more compact body, and more white markings. It is a breed of
mixed blood, and is believed to have originated from the
"Big China" pig—a large white hog with sandy spots, taken to
Ohio in 1816, and blended with Irish graziers in 1839, and with
a breed known by Baysides, as well as with Berkshires. In Iowa
the Berkshire is a combined lard and bacon pig in high favour.
The Duroc Jersey or Duroc, of a red or cherry-red colour—
not sandy or dark—is the most popular pig in Nebraska and
equal to any other in Iowa. It is a large prolific lard-hog, easily
making 100 lb in eight months. It has gained rapidity in
popularity since the beginning of this century, and is spilling
to other centres.
The Chester White, named from Chester county, Pennsyl-
vania, is one of the four leading breeds of lard-hogs in America.
It is of mixed origin and bears a strong family resemblance to
the Lincolnshire curly-coated pig. The early English ancestors,
the breed of which is not on record in America, were most probably of Lincoln origin. The sow is a prolific breeder and good mother, weighing, when mature but
not fat, 450 lb— the boar averaging 600 lb, and barrows at six
to eight months 350 lb. At Vermont Station, in a 147 days' test, Chester Whites made an average gain of a
little more than 84 lb. and they can gain fully 1 lb of live
weight for 3 lb of grain consumed.

Management.—The brood sow should be lengthy and of a prolific
strain, known to milk well. She is moderately fed and put to
a boar of her own age when large enough, i.e. seven to eight months old. She remains in a state of oestrus for about three days, and if not pregnant comes in heat again in three weeks. Breeding
swine, male and female, run most of their time at pasture and
receive a liberal allowance of green food or raw roots. The period
of gestation is sixteen weeks. Six to eight pigs are reared of the
first litter, and the second and third litters of the sow. Many breeder sows are fattened to greatest profit after the second or third litter. Two
litters are produced in one year, as pigs are usually weaned at two
months old, and the sow will take the boar at from three to
days after the pigs are removed, according to condition. A
convenient sty to hold five or six pigs has a southern aspect, and
consists of a covered compartment and outer court, each 10 ft.
square. When the animals are fed extensively they may be
cleaned out with a small spade, and the pigs lie. The labouring man's pig
is his bank, and is fed on scraps, small potatoes and waste products.
In connexion with cheese dairies pigs are largely fed on sour whey
thickened with mixed meal produced from any or all of the grain
used in the cheese, depending upon the market price. Food
may with advantage be cooked for very young pigs; but, with
the exception of potatoes, which should never be given raw, roots and
meals are best for creep-food. Meal mixed with milk or
syrup for a few hours improves in digestibility, and a sprinkling of salt
is an improvement. Meal derived from leguminous seeds makes
the flesh firm and improves the quality. Fattening pigs are fed
three times a day and supplied with coal-ashes or a few handfuls
of earth. Of the fattened weight of a pig 83% is butcher's
carcass, and 91% of the increase from 100 to 200 lb is carcass.
From 3 to 5 lb of meal consumed results in an increase of 2 lb of
live weight in a pig, which is the most economical meat producer on
a farm. Concentrated and digestible foods give best results, a pig
has a small stomach. Fjord's Danish experiments show that
for pigs 1 lb of meal is equivalent to 0.5 lb of skimmilk or 12 lb of whey, and 1 lb of meal equivalent to 8 lb of
mangold or 4 lb of potatoes.

PIGALLE, JEAN (1774-1785), French sculptor, was born in Paris on the 26th of January 1774. He was the seven child of a carpenter. Although he failed to obtain the grand prix, after a severe struggle he entered the Academy and became one of the most popular sculptors of his day. His
earlier work, such as "Child with Cage" (model at Sèvres) and
"Mercury Fastening his Sandals" (Berlin, and lead cast in
Louvre), is less commonplace than that of his mature years, but his nude statue of Voltaire, dated 1776 (Institut), and his
tombs of Comte d'Harcout (c. 1764) (Notre Dame) and of
Marshal Saxe, completed in 1777 (Lutheran church, Strassburg), are good specimens of French sculpture in the 18th century.
He died on 18th August 1785.

PIGALLE—PIGEON

PIGALLE-LEBRUN (PIGALU de L'EPINOY), CHARLES
ANTOINE GUILLAUME (1773-1835), French novelist, was born
at Calais (he is said to have traced his pedigree on the mother's
side to Eustache de St Pierre) on the 8th of April 1773. His
youth was stormy. He twice carried off young ladies of some
position, and was in consequence twice imprisoned by lettre de cachet. The first, a Miss Crawford, the daughter of an English
merchant whose office Pigalut had entered, died almost
immediately after her elopement; the second, Mlle de Salens, he
married. He became a soldier in the Queen's Guards, then
a very unsuccessful actor, and a teacher of French. At
the breaking out of the great war he re-enlisted and fought at
Valmy. He wrote more than twenty plays, and a large number
of novels, the first of which appeared in 1785. In his old age
he took to graver work, and executed an abridgment of French
history in eight volumes, besides some other work. His Œuvres
complètes were published in twenty volumes between 1822 and
1824, but much of his work is subsequent to this collection.
He died on the 24th of July 1835. The style of Pigalut's novels is insignificant, and their morality very far from severe.
As almost the father of a kind of literature which later developed
enormously, Pigalut-Lebrun deserves a certain place in literary
history. Among the most celebrated of his novels may be
mentioned L'Enfant du Carnaval (1792) and Angélique et Jeanne-
ton de la place Maubert (1799). His Citator (2 vols., 1803), a
collection of quotations against Christianity, was forbidden and
yet several times reprinted.

PIECE (Fr. pigeon, Ital. piccione and pigeons, Lat. pipio, literally a nesting-bird that pipes or cries out, a "piper"—the
very name now in use among some pigeon-fanciers, though
"squeaker" in the more usual term). The name pigeon, doubtless of Norman introduction, as a polite term, seems to
bear much the same relation to dove, the word of Anglo-Saxon
origin, as "puss" to "kitten". The mutton has to sheep, beef to ox, veal to calf, and pork to bacon; no sharp zoological distinction can be drawn
(see Dove) between dove and pigeon, and the collective members of the group Columbidae are by ornithologists ordinarily called
pigeons. Perhaps the best-known species to which the latter
name is exclusively given in common speech is the wild pigeon

It may be observed that the "rock-pigeons" of Anglo-Indians are Sand-grouse (q.v.), and the "cape pigeon" of sailors is a petrel (q.v.).
or passenger pigeon of North America, Ectopistes migratorius, which is still found in many parts of Canada and the United States, though now almost extinct and never appearing in the countless numbers that it did of old, when a flock seen by A. Wilson was estimated to consist of more than 2250 millions. The often-quoted descriptions given by him and J. J. Audubon of pigeon-haunts in the then “backwoods” of Kentucky, Ohio and Indiana need not here be reproduced. That of the latter was declared by C. Waterton to be a gross exaggeration; but the critic would certainly have changed his tone had he known that, some hundred and fifty years earlier, passenger-pigeons, so swarmed and ravaged the colonists’ crops near Montreal that a bishop of his own church was constrained to exercise them with holy water, as if they had been demons. The passenger-pigeon is about the size of a common turtle-dove, but with a long, wedge-shaped tail. The male is of a dark slate-colour above, and purplish-bay beneath, the sides of the neck being enlivened by violet, green and gold. The female is drab-coloured and dull white beneath, with only a slight trace of the brilliant neck-markings. (See plate illustration under Dove.)

Among the multitudinous forms of pigeons very few can here be noticed. A species which might possibly repay the trouble of domestication is the Wonga-wonga or white-crested pigeon of Australia, Lecosarcia picta, a bird larger than the ring-dove, of a slate-blue colour above and white beneath, streaked on the flanks with black. It is known to breed, though not very freely, in captivity, and is said to be excellent for the table. As regards flavour, the fruit-pigeons of the genus Treron (or Vinog of some authors) and its allies surpass all birds. These inhabit tropical Africa, India, and especially the Malay Archipelago; but the probability of domesticating any of them is very remote. Hardly less esteemed are the pigeons of the genus Ptilopus and its kindred forms, which have their headquarters in the Pacific Islands, though some occur far to the westward and also in Australia. There may be mentioned the strange Nicobar pigeon, Caloenas (see plate illustration under Dove), an inhabitant of the Indian Archipelago, not less remarkable for the long lustrous hackles with which its neck is clothed than for the structure of its gizzard, which has been described by Sir W. H. Flower (Proc. Zool. Soc., 1860, p. 330), though this peculiarity is matched or even surpassed by that of the same organ in the Phaenorrhina gelaeta of New Caledonia (Rév. de zoologie, 1862, p. 138) and in the Carphophaga latrun of Fiji. In this last the surface of the epithelial lining is beset by horn companies, adapted, it is believed, for crushing the very hard fruits of Onocarpus vitensis on which the bird feeds (Proc. Zool. Soc., 1878, p. 102). The modern giants of the group, consisting of about half a dozen species of the genus Goura and known as crowned pigeons (see plate illustration under Dove), belong to New Guinea and the neighbouring islands, and are conspicuous by their large size, beautiful filmy fan-shaped crest, and the reticulated instead of scutellated covering of their “tarsi.”

A very distinct type of pigeon is that represented by Didunculus virgirrostris, the “ Manu-mea” of Samoa, still believed by some to be the next of kin to the Dodo (q.v.), but really presenting only a superficial resemblance in the shape of its bill to that extinct form, from which it differs ostonally quite as much as do other pigeons (Phil. Trans., 1860, p. 340). It remains to be seen whether the Papuan genus Oidiaephos, of which several species are now known, may not belong rather to the Didunculidae than to the true Columbidae. Pigeons are now regarded as belonging to the Charadriiform or plver-like birds (see Brans) and are placed in the sub-order Columbae, near the sand-grouse (q.v.). They are divided into three families, Dididae, which includes the Dodo (q.v.) and Sidaire, the Columbidae, which includes the doves and pigeons, and the Didunculidae, of which the curious tooth-billed pigeon, of Samoa is the only example. The body is always compact, and the bill has a soft skin or cere covering the nostrils. The pigeons are chiefly vegetable feeders and have a hard gizzard, and all drink much water; they perch, and have a note of the nature of a “coo.” The nest is a rough platform or is in holes on the ground, or on rocks, eggs, usually three and white, and the young, which are helpless when hatched, are fed by a secretion from the crop of the parents. (A. N.)

PIGEON-FLYING, the sport of racing homing-pigeons bred and trained for the purpose. It is of very recent date, although the use of birds as a means of carrying messages (see Pigeon Post) is of great antiquity. Belgium may be considered as par excellence the home of the sport, the first birds flown there probably coming from Holland. Long-distance flying began in 1818, with a match of 100 m., while in 1820 there was a race from Paris to Liége, and three years later the first race from London to Belgium. The sport is now a favourite one in Great Britain, the United States, France, and, to a less degree, in some other countries, although nowhere attaining the general popularity which it enjoys in Belgium, where nearly every village has its Société colombophile, millions of pigeons being sent over the French border to be raced back. The annual Belgian concours national, a race of about 500 m. from Toulouse to Brussels, was inaugurated in 1885, in which year the first regular races in Great Britain, from Exeter, Plymouth and Penzance to London, took place. The velocity attained at that time was about 125 0 yds. per minute, but this was soon surpassed in the races of the London Columbrian Society, one of the winners in which attained a speed of 1836 yds. per minute.

The sport was introduced into the United States about the year 1875, although regular racing did not begin until 1878. Since then it has gained widespread popularity, the American record for old birds at 300 m. being 1848 yds. per minute and for young birds (yearlings) 1665 yds., while the distance record is 1900 m. The American “blue ribbon” championships are held at 100, 200, 300, 400, 500 and 600 m. The speed of homing-pigeons depends very greatly upon the state of the atmosphere. In the race from Montargis to Brussels in 1876 in bright and clear weather, all the prize-winners made the distance of 270 m. within three and one-quarter hours, while in the rain and stormy day, thirty hours passed before the first bird arrived.

Training.—The loft should be on a commanding site. It is best made in the shape of a large room, suitably subdivided, protected from vermin, and provided with drinking troughs, rock salt and crushed mortar for the birds’ use. It should be fitted with a sufficient number of nests about 2 ft. long, 20 in. in breadth and height. Arrangements should be made for allowing the pigeons to fly out daily for exercise; and they should be trained to re-enter the loft through bolting wires, which open inwards only, into a small chamber, to which an electric arrangement may be fitted so as to sound a bell and warn the owner of the arrival of a bird. The food of birds in training consists of vetch, beans, maize, peas, broken rice, unpolished, in very small portions. In the latter part of July, the beginnings of autumn, the feeding is reduced, and in the period of mating, the daily allowance for each bird being about 40 grammes weight. Young birds may be fed on rice in the husk and bread. They are called “squeakers” for a week or two after birth, and then “squeakers” until about three months old. Each brood consists of two eggs, on which both parents sit in turn, the cock only for a few hours in the middle of the day. When the young are being brought up, only one of the parent birds is in the loft at a time, and the other, perched on a small perch, are let out in the morning, is sufficient. Training should commence in warm weather, when the bird is about four months old, and continued until the bird is seen to be in a closed position up to the ‘tooting’ it at great distances, the time taken being that taken by the loft in flights of some distance. It is considered better to

1 Voyages du Baron de la Hontan dans l’Amérique septentrionale, i. 93, 94 (2nd ed., Amsterdam, 1709). In the first edition, published at the Hague in 1703, the passage, less explicit in details but to the same effect, is at p. 80. The author’s letter, describing the circumstance, is found in the second volume of the first edition, p. 167.

2 There are several records of the occurrence in Britain of this pigeon, but in most cases the birds noticed cannot be supposed to have found their own way hither. One, which was shot in Fife in 1855, may, however, have crossed the Atlantic unassisted by man.
Pigeon post—pigments

train the young homers alone, so that they may become independent of the older birds. When thoroughly trained they may be flown over long distances about once a week. The Belgian fanciers generally divide their birds into two classes, one for breeding and the other for racing, though the latter are allowed to breed within certain limits. Some fanciers always choose birds with chucks in the nest for long journeys, claiming that they return faster with this method. In some cases a metal ring marked with the owner's name is slipped over the foot of the pigeon when only a few days old, and during its racing career the longer wing-feathers are stamped with the bird's records. At the start of a race the competing birds are collected and taken to the station by a man who takes the time. Upon being released the homer ascends rapidly in spirals until, apparently desiring some familiar landmark on the horizon, it will fly straight and swiftly towards it. As the birds enter their home-lofts the times are taken by a watch. A bird is not considered to have got "home" until it has actually passed through the door of its loft.

Pigeon post. The use of homing pigeons to carry messages is as old as Solomon, and the ancient Greeks, to whom the art of training the birds came probably from the Persians, conveyed the names of Olympic victors to their various cities by this means. Before the electric telegraph this method of communication had a considerable vogue amongst stockbrokers and financiers. The Dutch government established a civil and military pigeon system in Java and Sumatra early in the 19th century, the birds being obtained from Bagdad. Details of the employment of pigeons during the siege of Paris in 1870–71 will be found in "International Pigeon Post" (London and Paris, 1872). This led to a revival in the training of pigeons for military purposes. Numerous private societies were established for keeping pigeons of this class in all important European countries; and, in time, various governments established systems of communication for military purposes by pigeon post. When the possibility of using the birds between military fortresses had been thoroughly tested attention was turned to their use for naval purposes, to send messages between coast stations and ships at sea. They are also found of great use by news agencies and private individuals. Governments have in several countries established lofts of their own. Laws have been passed making the destruction of such pigeons a serious offense; premiums to stimulate efficiency have been offered to private societies, and rewards given for destruction of birds of prey. Pigeons have been used by newspapers to report yacht races, and some yachts have actually been fitted with lofts. It has also been found of great importance to establish registration of all birds. In order to hinder the efficiency of the systems of foreign countries, difficulties have been placed in the way of the importation of their birds for training, and in a few cases falcons have been specially trained to interrupt the service in war-time, the Germans having set the example by employing hawks against the Paris pigeons in 1870–71. No satisfactory substitutes for these homing pigeons seem to have been found, though the Chinese formerly provided their pigeons with whistles and bells to scare away birds of prey.

In view of the development of wireless telegraphy the modern tendency is to consider fortress warfare as the only sphere in which homing pigeons can be expected to render really valuable services. Consequently, the British Admiralty has discontinued its pigeon service, which had attained a high standard of efficiency, and other powers will no doubt follow the example. Nevertheless, large numbers of birds are, and will presumably continue to be, kept at the great inland fortresses of France, Germany and Russia.

See L. du Puy de Podlo, Die Brieftaube in der Kriegskunst (Leipzig, 1872); Brückmeier, Anzucht, Pflege, und Dressur der Brieftauben (Ilmenau, 1891).

Pigeon-shooting, a form of sport consisting of shooting at live pigeons released from traps. The number of traps, which are six-sided boxes, falling flat open at the release of a spring, is usually five; these are arranged 3 yds. apart on the arc of a circle of which the shooter forms the centre. The distance (maximum) is 31 yds., handcapping being determined by shortening the distance. The five traps are each connected by wires with a case ("the puller"); a single string pulled by a man stationed at the side of the shooter works an arrangement of springs and cog-wheels in the "puller," and lets fall one of the traps; it is impossible to know beforehand which trap will be released. At a fixed distance from the centre of the traps the bird is in a boundary within which the birds must fall if they are to count to the shooter. This line varies in distance in the various clubs; the National Gun Club boundary being 65 yds., that of the Monaco Club being only 20 yds. The charge of shot allowed must not exceed 1/4 oz. The best type of pigeon is the blue rock. From the start of the Hurlingham Club at Fulham in 1867 pigeon-shooting was a favourite sport there; it was, however, stopped in 1906. The principal pigeon-shooting centre in England is now at the National Gun Club grounds at Hendon. The great international competitions and sweepstakes take place at Monaco. An artificial bird of clay, now more usually of a composition of pigments, is employed for the live pigeon. These clay birds are also sprung from traps. This sport originated in the United States, where, under the name of "trap-shooting," or innimate bird shooting, it is extremely popular. At first the traps invented threw the birds with too great regularity of curve; now the traps throw the birds at different and unknown angles, and the skill required is great. In clay-bird shooting the traps usually number fifteen, and are out of sight of the shooter. The Innimate Bird Shooting Association in England was started in 1893.

Pigments (Lat. Pigmentum, from pegere, to paint). It is convenient to distinguish between pigments and paints, the latter being prepared from the former by the addition of a vehicle or medium. Nor are pigments and dyes identical, although there are cases in which the same colouring matter which yields a dye or stain may give rise to a pigment. A pigment is, in fact, a substance which is insoluble in the vehicle with which it is mixed to make a paint, while a dye is soluble. Pigments exhibit various degrees of transparency and opacity, and ought to possess such qualities as these: ease in working, chemical indifference to each other and, generally, to the vehicles employed, also stability under exposure to light and air. As a rule, it is desirable that pigments should not be seriously affected in hue by the vehicle; at all events, whatever change does occur ought to admit of calculation. In the case of oil colours it should be remembered that a thorough drying of the paint is preferable to the formation of a surface-skin, and that a few pigments, notably white lead, possess properties conducing to this desirable result. It is scarcely necessary to add to these general observations concerning pigments that their artistic value depends primarily upon the nature and amount of the optical sensation which they are competent to produce.

Although the number of available pigments is great, the number of chemical elements which enter into their composition is not large. Very many richly coloured pigments cannot be employed because they lack the properties of insolubility, inertness and stability. Pigments are drawn from various sources. Some are natural, some artificial; some are inorganic, some organic, some are elements, some mixtures, some compounds. It is not unusual to arrange them into two groups, substantive and adjective. Amongst the members of the former group such a pigment as vermilion, where each particle is homogeneous, may be cited as an example. Amongst the adjective pigments rose-madder may be named, for each particle consists of a colourless base on which a colouring matter (alizarin) has been thrown. Most of the inorganic pigments, whether natural or artificial, belong to the substantive group; while there are many organic pigments, notably those of artificial origin, which are of adjective character. The following table presents a summary classification of pigments according to their source or origin:

<table>

A variety of processes are in use in order to fit natural coloured substances for employment as pigments. The first step is,
in many cases, to select, or "pick over," the raw material, rejecting whatever impurities may weaken or injure the character of the product. It is occasionally necessary to treat the finely-ground substance with water by the method of elutriation or washing-over; the wash-waters will then deposit, on standing, various grades of the coloured body required. With rare exceptions native pigments need careful grading, either by means of a mullet on a slab or by edge rollers, or horizontal mill-stones, or special machines. The substance is usually ground in spirits of turpentine, or alcohol, or water; oil-paints are of course finally ground in a drying-oil, such as linseed oil or poppy oil; water-colours require gum-water, or gum-water and glycerin if they are to be "moist" paints. In the case of all pigments, whether mineral or organic, whether natural or artificial, it is of the highest importance to make sure that they are free from saline matters soluble in water. Such salts are removed by thorough washing with distilled water. A treatment of this kind is essential in the case of a large number of pigments formed by chemical reactions in the "wet way." Characteristic examples are furnished by Prussian blue, viridian and lakes. Sometimes it is necessary to remove certain impurities by solvents other than water, such as carbon bisulphide, which is used to extract free sulphur from cadmium yellow. Mention may here be made of another kind of preparative treatment which is adopted with some pigments: they are subjected to the action of heat—moderate in some cases, strong in others. Thus, a few substances, such as ivory black and yellow ochre, which in ordinary circumstances contain much non-essential moisture, before they are ground in oil may with advantage be gently dried at a temperature not above that of boiling water. Again, there are pigments, such as Prussian brown, light red and burnt sienna, which owe their hues to a process of actual calcination, the first of these being thus made from Prussian blue, the second from yellow ochre, and the third from raw sienna. The pigments known as burnt Carmine and burnt madder are prepared at a much lower temperature, and ought to be described as roasted rather than as burnt.

The substitution of one pigment for another is rarely practised, but it is not so unusual to find that a costly substance has received an admixture of something cheaper, and that an inferior grade of a genuine pigment has had a blue exaltation or enhanced by some unlawful or dangerous agent. In fact, these two kinds of sophistication are often associated. Thus vermillion is adulterated with red lead, with red antimony sulphide, or with baryta white and lead sulphate, and then the hue of the mixture is restored to the proper pitch by the introduction of the powerful but fugitive colouring matter eosin. Amongst other adulterations which may be named here are the addition of chrome-yellow (lead chromate) to yellow ochre, of green ultramarine to terre verte, and of indigo to ivory black; this last mixture being a substitute for vine-black, the natural blue-black. The detection of the above-named sophistications is by no means difficult even in the hands of persons unacquainted with chemical manipulation, but it needs a trained analyst who possesses a qualitative examination required. If we are dealing with an oil-colour, the first step is to remove the oil by means of a solvent, such, for example, as ether. The residual pigment is then allowed to dry, and the dry powder submitted to the appropriate physical and chemical tests. Thus a suspected vermillion, having been freed from oil, is heated in a small hard glass bulb-tube; it should prove practically volatile, leaving a mere trace of residue. In this particular case the presence of a red hue in the ether-extract affords evidence of adulteration with an organic colouring matter, such as eosin. Then, again, we may detect the presence in yellow ochre of lead chromate by pouring a little sulphuretted hydrogen water and dilute hydrochloric acid upon one portion of the dry pigment, and boiling another portion with dilute sulphuric acid and some alcohol: In the former experiment blackening will occur, in the latter the liquid part of the mixture will acquire a greenish tint. So also green ultramarine may be recognized in adulterated terre verte by the addition of dilute hydrochloric acid, which destroys the colour of the adulterant and causes an abundant evolution of the evil-smelling sulphur- etted hydrogen. Moreover, nothing is easier than the recognition of indigo in wine or charcoal-black, for the dry powder, heated in a glass tube, gives off purple vapours of indigo, which condense in the cooler part of the tube into a blackish sublimate. A word must be said here as to the adulteration of white lead, and the examination of this most important pigment. The best variety of white lead or flake white contains two molecules of lead carbonate to one of lead hydrate, and is wholly soluble in dilute nitric acid, while barium sulphate, its most frequent adulterant, is wholly insoluble. China-clay and lead sulphate will also remain undissolved; but whitening or chalk cannot be detected in this way;—indeed, the thorough examination of white lead, not only for sophistications but also for correspondence with the best type in composition, cannot be carried out save by a skilled chemist.

Pigments may be classified on two systems: (1) based on the chemical composition; (2) based on the colour. On the first system pigments fall into nine groups, seven of which are fairly well defined but the eighth and ninth have a somewhat miscellaneous character. The groups of elements, oxides, sulphides, hydrates, carbonates and silicates present this characteristic, namely, that each member of any one group is without action upon the other members of the group; any two or more may therefore be mixed together without fear of mutual injury. The same statement may be made with reference to the various inorganic salts of Group VIII, and to the organic compounds of Group IX., although in this large final group there are two pigments containing copper (verdigris and emerald green) which must be regarded with suspicion. The inertness of the members of the same group towards each other may be explained in the majority of cases by the following consideration. An oxide does not act upon an oxide, nor does a sulphide affect a sulphide, because all the pigment oxides have taken up their full complement of oxygen, and can neither give nor lose this element to similar oxides; so also with sulphur in the sulphides. A few details regarding the several members of the nine groups are now offered:—

**GROUP I. ELEMENTS.—** All the black pigments in ordinary use—ivory black, lamp black, charcoal black, Indian ink, and graphite, are largely composed of carbon. They are not liable to change with time, and as gold, silver, aluminium and platinum, belong here; of these, silver alone is easily susceptible of change, tarnishing by combination with hydrogen sulphide.

**GROUP II. OXIDES.—** The oxides have generally been formed at a high temperature and are not easily amenable to physical or chemical change; they are, moreover, not liable to affect other pigments, being practically inert, red lead only being an exception. The oxides include zinc white, green chromium oxide, burntumber (a mixture of iron and manganese oxide), cobalt green (CoO,2ZnO), cobalt blue (CoO,3Al2O3), coeruleum (CoO,3MnO2), Venetian red, light red, Indian red and burnt sienna (all chiefly composed of ferric oxide), and red lead (Pb3O4).

**GROUP III. SULPHIDES.—** Some of the members of this group are liable to contain free sulphur, and some may give up this element under the action of certain bases of organic pigments. For instance, Prussian black, emerald green, producing copper sulphide. Another pigment of this group, vermillion, is prone to a molecular change whereby the red form passes into the black variety. This change, frequent in water-colour drawings, is scarcely observable in works painted in oil. The sulphides comprise cadmium yellow (CdS), king's yellow (As4S4), realgar (As4S4), antimony red (Sb2S3) and orpiment (As2S3). It is convenient to give places in the same group to the various kinds of arsenic black, antimony black, cadmium black and native, for in all of them a part of the sulphur present occurs in the form of a sulphide. It may be stated that the sulphides of arsenic and antimony are dangerous and changeable pigments not suited for artistic painting.

**GROUP IV. HYDRATES or HYDROXIDES.—** Several native earths belong here, notably yellow ochre, raw timber, raw sienna and terre lave; and these earths are of great importance in the production of reds, violets, and carmines. They are obtained by the treatment of hydrates and oxides of iron and of manganese, but the presence of a colourless body such as white clay or barium sulphate is usual with the pale pigments. A false yellow ochre from Cyprus is really a basic ferric sulphate, and does not properly belong to this.
group. Besides the yellow and brown pigments, there is a magnifi-
cent deep green pigment in this group, known as emerald oxide of
chromium or viridian. The blue copper preparation which goes
upwards to a brilliant blue, and is very useful in general painting as
a rich pigment, is also essentially a hydrate, though by no means pure.
It should be stated that all the earthy or native hydrates belonging
to this group, and represented by cobalt blue, are essentially
loosely-attached and constitutional. Besides lead white, may be
excluded from this group in the reduction in the amount of the hygroscopic moisture by means of a
current of dry air or a gentle warmth often improves the hue and
duration of these pigments.

Group V. Carbonates.—There is but one really important member of this group, namely, the old and typical variety of white lead (\(2\text{PbCO}_3\cdot\text{Pb(OH)}_2\)). Like green verditer (\(2\text{CuCO}_3\cdot\text{Cu(OH)}_2\)), and like the verdigris or verditer blue of the old time, this pigment is obtained as a product of the decomposition of the salts of the carbonate of lead.

Group VI. Silicates.—Terre verte, which is a natural green oxide of iron, may be considered as a silicate of iron, potassium and magnesium, and one other silicate, yellow ochre, which is essentially a silicate of cobalt and potassium, constitute this small group. However, some of the ochreous earths contain silicates of iron, magnesium and aluminium, and are therefore referred to as hydrates of the two former metals, and so have some claim to be ranked with the silicates.

Group VII. Chrome Oxides.—These are rich in oxygen. When in contact with some of the more alterable organic pigments belonging
to Group IV, these pigments may lose oxygen, acquiring a
somewhat greenish or greyish hue, owing to the formation of the
lower or green oxide of chromium. The chromates cannot be
trusted as pigments. The yellow chromates, those of barium, strontium, or lead, are represented by the general formular \(\text{M}_2\text{CrO}_4\); chrome red is basic, and is \(\text{Pb}_2\text{CrO}_4\).

Group VIII. Various Inorganic Salts.—This group is intended to include only those pigments that are solubilised, or at least, are soluble in some of the inorganic salts. There is the magnesium nitrate, aureolin (\(\text{K}_2\text{CO}_3\cdot\text{K}_2\text{O}_3\cdot\text{K}_2\text{O}_3\cdot\text{H}_2\text{O}\)), associated with one or more molecules of water, called sometimes cobalt yellow; one antimonate, that of lead, true Naples yellow; another, the colour of petroleum; these known as tungsten green; a metaphosphate of manganese, which goes under the name of Nürnberg or manganese violet; and several mixolytic cobalt compounds containing arsenates and phosphates of that metal, and represented by cobalt violet and cobalt white.

Two sulphates also belong here, namely, baryta white (\(\text{BaSO}_4\)) and lead sulphate (\(\text{Pb}_2\text{SO}_4\)); also Schweinfurt green, a basic copper arsenite.

It is obvious that the majority of these inorganic pigments is used only for the preparation of other pigments, and are thus not of much importance.

But it may be stated that the two sulphates, the tungstate and the cobalt compounds are practically inert and unalterable, while the compounds of the arsenic and the antimonite are sensitive to the action of sulphur and of sulphides. The cobaltinitrite, aureolin, cannot be safely mixed with some of the organic pigments belonging to the next and last group.

Group IX. Copper Compounds.—Most of the members of this large and unwieldy group of pigments possess this character in common, proneness to oxidation and consequent deterioration in
the presence of light, moisture and air. Such oxidation is acceler-
ated in most cases, especially in very highly saturated pigments, in other groups, such as the chromates of Group VII, and aureolin of Group VIII, this action being particularly marked in the case of the yellow lakes, the cochineal lakes and indigo. There are two pigments of this group—blue lakes and copper salts of Group IX. The
both the blue-green and the green varieties being basic copper compounds—and the pigment known in England as emerald-green, which is a basic cupric acetate. These copper pigments present the usual weakness to the attack of sulphur which distin-

guishes compounds of this metal, and cannot therefore be safely mixed with the members of Group III, and more particularly with the cadmium colours. About nine members of Group IX may be regarded as substantive pigments. These include Indian yellow (mainly magnesium and calcium euxanthes), gamboge, sap green, indigo, Prussian blue, bitumen or asphalt, bister, sephia, and the bluish purple of azurite and sandeyke. The last-named contains a number of yellow lakes where different kinds of colouring matters of more or less acid character have been thrown upon a base, generally of colourless aluminium hydrate, aluminium phosphate, stannous hydrate, stannic oxide, baryta or lime; sometimes coloured bases containing such metals as copper, chromium, magnesium, manganese or iron are introduced in small quantities. The colouring matters used are both natural and artificial. The yellow lake from the resinous exudation produced in certain trees by the attacks of Coccus lacca; carmine, crimson and purple lake, from the colouring matter obtained from the scale insects Coccus aurantium and Coccus lacca; lake from the alizarin and allied bodies derived from the root of the ordinary madder plant Rubia tinctorum; and yellow lakes, from quercitron bark (Quercus tinctoria), and from Persian and Avignon barks, from the fruits of the madder plant, from the root, from kalut root, archil, Brazil wood, and red sanders wood are of very small interest and value. The same judgment may be pronounced upon the large number of artificial lakes which owe their colours to coal-tar derivatives, with the single exception of

the important class of pigments obtained from artificial alizarin, and from its congeners and derivatives. Of these, alizarin (\(\text{C}_9\text{H}_8\text{O}_3\)), itself, in its purest state and associated with a little lime, lends its hues to those pigments which take a pink or rosy hue. When purpurin and its isomers, anthrapurpurin and flavopurpurin, are present, the red hue is more pronounced, and may even tend towards a golden colour; or, when some copper or iron or manganese compound is added, the grinding action of this variant paints the crimson so sold as paints are not made from alizarin itself, but from the sulphonic acids of alizarin. These lakes present a wide range of hues. Another derivative of alizarin, known as \(\beta\)-nitro-alizarin, yields those orange lakes to which such names as pure orange, orange madder and marigold have been applied.

Stability.—Some notion of the relative stability of pigments is made in the remarks already made under "Classification." But as permanence is of no less importance than chromatic quality in the case of pigments used in the fine art of painting, to which the present article is mainly devoted, further particulars concerning certain selected pigments may profitably be given here. Beginning with white pigments, these three may be named as useful: white lead, Freeman's white, zinc white. As an oil-colour, white lead of the old type is generally the best to use, but among water-colours its place must be taken by zinc white in the condensed form known as Chinese white. Zinc white, in spite of the qualities which recommend its use in oil, namely, the fact of its being not only unaffected by sulphur, but colourless and non-poisonous, lacks toughness as an oil-paint, and has a tendency to scale. Freeman's white, which consists essentially of lead sulphite, is the best substitute for white lead yet devised. The small percentages of zinc white and baryta white which it contains are not to be regarded as adulterations, for they greatly increase its body, and of less specific gravity than lead sulphate, actually raise the weight per cubic foot of the dry pigment. Out of a dozen or more similar yellow paints, a selection may be made of these six: yellow ochre, raw sienna, maro orange, cadmium yellow, aureolin and baryta yellow. Concerning two of these, cadmium yellow and aureolin, the following observations may be set down. Cadmium sulphide, CdS, exists in two forms, which in some measure correspond to the two modifications of mercuric and antimonious sulphides. One of these forms is yellow and the other reddish orange. When sulphuretted hydrogen is sent into a weak, cold, and neutral solution of cadmium salt, the sulphide which separates is pale and yellow—the orange variety is obtained from a strong, hot, and acid solution. The pale variety is more prone to change than the darker one; but as oil colours are usually made from the purest of these ironless sulphides, it is desirable that they should be pure. The value of aureolin as a pigment depends much upon its mode of preparation. A new variety of bright yellow hue was described by Adie and Wood in 1900, and is represented by the formula \(\text{K}_2\text{NaCo}_3\cdot\text{NO}_3\cdot\text{H}_2\text{O}\). Of red pigments, six claim special mention. These are vermilion, light red, Venetian red, Indian red, red ochre, and the red lakes derived from madder or alizarin. Vermilion is stable in oils, but as water-colour

paint is prone to change, under exposure to strong light, into the black modification of mercuric sulphide. The iron-reds named above, whether natural or artificial, are quite permanent, but so much cannot be said of the various madder-paints. They are incapable of undergoing oxidation without deteriorating, and are therefore inferior to the above red organic pigments, and are absolutely necessary to the artist.

It must be noted that those madder and alizarin lakes which contain an element of yellow and brown are less stable than those of a crimson hue. Five green pigments may be re-

commended, namely, viridian, or the emerald oxide of chromium, the ordinary green oxide, cobalt green, green ultramarine, and terre verte. Except for minor decorative work, where perma-

nence is of secondary moment, one is obliged to exclude from the palette emerald green, green verditer, verdigris, sap-green, and the numerous preparations which owe their colour to mixtures of Prussian blue and chrome yellow, and are sold under the names of verditer, Prussian blue, lake, and Prussian blue, alizarin. The same observation may be made in the case of reds and purples. All these pigments usually contain much barium sulphate. Similarly, amongst blue pigments, ultramarine, cobalt blue and coeruleul may be retained, while small, indigo and all
copper blues should be rejected. Prussian blue, or the mixture of this pigment with a white base which is usually called Antwerp blue, can scarcely be spared, but care should be taken to choose a sample containing no potassium compounds. Coeruleum, which may be described as cobalt stannate presents the peculiarity of appearing a greenish blue in artificial light, not a purplish blue like that of ordinary cobalt blue. Cobalt violet is a sound pigment, while manganese metaphosphate or Nürnberg violet may be dispensed with. Most Indian, artificially prepared feric oxide, is dull in hue but permanent. Passing to the black pigments, it is matter for regret that there are no permanent colours possessing the artistic capacities of asphalt, madder brown, and the old bituminous Vandyke brown. Cappagh brown, burnt sienna, and raw and burnt umber may be employed safely. Little need be said as to the selection of black pigments, for all are permanent. The soot from burning acetylene, which has recently been introduced, forms a black pigment of remarkable intensity.

Uses.—Hitherto pigments have been considered chiefly in relation to the requirements of the painter of pictures. In many merely decorative arts, such as the manufacture of wall-papers and the painting of woodwork and of iron, the pigments available are in one direction, that of cost, more restricted, but, on the other hand, many alterable or weak pigments are commonly employed. In paints intended for the protection of iron-work, the nature of the pigment introduced is a matter of great moment, for red lead, zinc white and white lead are found to exert a strong protective influence, which is not observed in the case of the vast majority of pigments. There are a number of other uses besides those just named for which special pigments, or, more precisely, special paints, are employed. Amongst such preparations may be named luminous paints, anti-fouling paints, metallic paints, damp-proof paints, and asbestos and other fire-proof paints.

PIGOT, GEORGE, Baron (1779-1777), English governor of Madras, was born on the 4th of March 1739 and entered the service of the East India Company in 1756; after nineteen years he became governor and Commander-in-Chief of Madras in 1775. Having defended this place against the French in 1756-9 and occupied Pondicherry on behalf of the company, he resigned his office in November 1765 and returned to England, being made a baronet in 1764. In the following year he obtained a seat in parliament, and this he retained until his death; in 1766 he was created an Irish peer as Baron Pigot. Returning to India in 1775 to occupy his former position at Madras, Pigot was at once involved in a fierce quarrel with the majority of his council, which arose out of the proposed restoration of the raja of Tanjore. The governor was arrested by order of his opponents, and was still a prisoner when he died on the 11th of May 1777. Meanwhile the Pigot was censored by the court of directors in England and the order for his restoration was followed immediately by another for his recall. This happened about a month after his death, but before the news had reached England. In 1779 the matter was discussed in parliament, and four of those who were responsible for his arrest were tried and were fined £1000 each. Pigot, who left several illegitimate children, was never married, and his barony became extinct.

Two of the governor's brothers were men of repute. Sir Robert Pigott (1747-1796), who succeeded to the baronetcy, commanded his regiment (the 10th) in the Battle of Bunker Hill during the War of American Independence. He became a lieutenant-general in 1782. The other brother, Hugh Pigott (c. 1721-1792), was a captain in the 55th. After 20 years of service he became an admiral and commander-in-chief in the West Indies, 1779. One of his sons was General Sir Henry Pigott (1750-1840), and another was Hugh Pigott (1769-1797), a captain in the navy, who was murdered during a mutiny in September 1797 while in command of the "Hermione."

PIG-STICKING, or Hog-Hunting, the chase of the wild boar, as a sport, on horseback with the spear. The chase on horseback is common among ancient peoples, and in central Europe has lasted to the present day, although, on account of the introduction of fire-arms, the spear has gradually become an auxiliary weapon, used to give the coup de grâce to a wounded animal. The modern sport is the direct descendant of bear-spearng which was popular in Bengal until the beginning of the 19th century, when the bears had become so scarce that wild pigs were substituted as the quarry. The weapon used by the Bengalese was a short, heavy, broad-bladed javelin. British officers introduced the spear or lance and this has become the recognized method of hunting wild pigs in India. The season for hunting in northern India, the present headquarters of the sport, is from February to July. The best horses should be quiet and not too big. Two kinds of weapon are used. The long, or underhand, spear, weighing from two to three pounds, has a light, tough bamboo shaft, from seven to eight feet long, armed with a small steel head of varying shape. This spear is held in the hand about two-thirds the distance from the point, with the knuckles turned down and the thumb along the shaft. The short, or jogging, spear is from six to six and a half feet long, and somewhat heavier than the longer weapon. It is grasped near the butt, with the thumb up. Although easier to handle in the jungle, it permits the nearer approach of the boar and is therefore more dangerous to man and mount.

When the hunting arrived at the bush-grown or marshland haunt of the pigs, the quarry is "reared," i.e. chased out of its cover, by a long line of beaters, usually under the command of a mounted shikari. Sometimes dogs and guns loaded with small shot are used to induce an animal to break cover. The mounted sportmen, placed on the edge of the cover, attack the pig as soon as it appears, the honour of "first spear," or "spear of honour," i.e. the thrust that first draws blood, being much coveted. As a startled or angry wild boar is a fast runner and a desperate fighter the pig-sticker must possess a good eye, a steady hand, a firm seat, a cool head and a courageous heart. For these reasons the military authorities encourage the sport, which is for the most part carried on by the tent clubs of the larger Indian stations.

ordered to restore to their homes 50 Osages, redeemed by the United States government from Potawatami, and to explore the country. He started on the 15th of July; and went north along the Missouri and the Osage into the present state of Kansas and probably to the Republican river in the south of the present Nebraska, where on the 29th of September he held a grand council of the Pawnees. Then (early in October), turning nearly south, he marched to the Arkansas river, which he reached on the 14th of October, and up which (after the 28th with only 16 men) he went to the Royal Gorge (Dec. 7), having first seen the mountain called in his honour Pike's Peak on the 23rd of November; and then went north-west, probably up Oil Creek from Cañon City. In searching for the red river he came to the South Platte, marched through South Park, left it by Trout Creek pass, struck over to the Arkansas, which he thought was the Red River for which he was searching, and, going south and south-west, came to the Rio Grande del Norte (about where Alamoss, Conejos county, Colorado, is now) on the 30th of January 1807. There on the 26th of February he and a small number of his men were taken prisoners by Spanish authorities, who sent him first to Santa Fé, then to Chihuahua to General Salcedo, and by a roundabout way to the American frontier, where he was released on the 1st of July 1807. He was promoted captain (August 1806), major (May 1808), lieutenant-colonel (Dec. 1809) and colonel (July 1812). In 1808 he tried in vain to get an appropriation from Congress for himself and his men. He was military agent in New Orleans in 1809-1810, was deputy quartermaster-general in April-July 1812, and was in active service in the War of 1812 as adjutant and inspector-general in the campaign against York (now Toronto), Canada, and in the attack on York on the 27th of April 1813 was in immediate command of the troops in action and was killed by a piece of rock which fell on him when the British garrison in its retreat set fire to the magazine.

His Account of an Expedition to the Sources of the Mississippi and through the Western Parts of Louisiana, and a Tour through the Interior Parts of New Spain was published at Philadelphia in 1810; was reprinted and rearranged in London in 1811; and was published in a French version in Paris in 1812, and a Dutch version at Amsterdam in 1812-1813. The standard edition with memoir and notes by Elliott Coues was published in three volumes in New York in 1895. Some of Pike's papers taken from him in Mexico are now in the Mexican archives (Seccion de Asuntos Inter-nacionales caxa 1817-1824), and the more important were published by H E. Bolton in the American Historical Review, (1907-1908), xiii. 798-827. See the sketch by Henry Whiting in vol. v., series 2, of Jared Sparks's Library of American Biography.

PIKE, fresh-water fishes generally distributed over the rivers and lakes of Europe, northern Asia, and North America, and forming a small family (Esocidae) of soft-rayed fishes. They are readily recognized by their elagite compressed body covered with small scales, a long head, long and spatulate snout, and very large mouth armed with strong and long teeth in the jaws and broad bands of smaller teeth on the palate and tongue. The teeth point backwards or can be depressed so as to offer no obstruction to any object entering the gape, but prevent its withdrawal in the opposite direction. The dorsal and anal fins are placed far back on the tail, this greatly increasing the propelling power of the fish, and, although pike are bad swimmers and lead rather a sedentary than a roving life, they are excelled by no other fresh-water fish in rapidity of motion when, by a single stroke of the tail, they dash upon their prey or dart out of reach of danger. In the Old World one species only is known (Essox lucius), which prefers lakes and sluggish reaches of rivers to strong currents or agitated waters. Its eastward range in northern Asia is not known; it extends into Lapland in the north and into central Italy and the vicinity of Constantinople in the south, but is absent in the Iberian Peninsula. The European species occurs also in North America, and is common in the eastern United States southwards to northern Ohio. But North America is tenanted by other species of pike besides, of which the largest is the muskellunge or maskinong of the Great Lakes (Essox nubilus); it commonly attains to the large size which is exceptionally recorded of Essox lucius. The other American pike are of smaller size, and generally named “pickeral”, but opinions as to the distinction of the species differing widely among American ichthyologists. The European pike, like its brethren, is the most voracious of fresh-water fishes; it probably exceeds the shark, to which it has been compared by many writers, in the relative quantity of food it consumes. Large specimens will seize rats or water-voles, and are said to attack even foxes and small dogs. Individuals of from 40 lb. to 50 lb. are not scarce, but captures of much larger ones are on record. Pike are wholesome food, and much esteemed in inland countries—the smaller (of 20 to 24 in. in length) being preferred to the larger individuals. They are prolific, and not easily exterminated, so that in many cases they have become once allowed to spawn. According to season and climate they spawn in April or May, and sometimes as early as February.

PIKE, a word which, with its collateral forms “pick” and “peak,” has as its basic meaning that of anything pointed or tapering to a point. The ultimate etymology is much disputed, and the interrelation of the collaterals is very confused. In Old English there are two forms (pic, one with a long and the other with a short vowel, which give “pike” and “pick” respectively. The first form gave in the 15th century the variant “peak,” first with reference to the peaked shoes then fashionable, pekēd schone. In Romanic languages are found Fr. píc, Span. pic, Ital. piccare, to pierce, &c. There are also similar words in Welsh, Cornish and Breton. The Scandinavian forms, e.g. Swed. and Nor. pik, are probably taken from English. While some authorities take the Celtic as the original, others look to Latin for the source. Here the woodpecker, pícus, is referred to, or more probably the root seen in spíc, ear of corn, and spína, prickle (English spike, spine). The current differentiation in meanings attached to pike, pick and peak are more or less clearly marked, though in dialects they may vary. (1) Pike: Apart from the use as the name of the fish (see above), probably a shortened form of pike-fish, from its sharp, pointed teeth, which are the common means of killing its food, the sharply pointed head of iron or steel, the common weapon of the foot-soldier till the introduction of the bayonet (see Spear and Bayonet), and for a hill with a pointed summit, appearing chiefly in the names of such hills in Cumberland, Westmorland and North West Lancashire. It may be noticed that the proverbial expression “plain as a pike-staff” appears originally as “plain as a pack-staff,” the flat plain sided staff on which a pedlar carried and rested his pack. The use of “pike” for a highway, a toll-gate, &c., is merely short for “turnpike.” (2) Pick: As a substantive this form is chiefly used of the common tool of the navy and the miner, consisting of a curved double-ended head set at right angles to the handle, one end being squared with a chisel edge, the other pointed, and used for loosening and breaking hard masses of earth, coal, &c. (see Tools). The other name for this tool, “pickaxe,” is a corruption of the earlier pikobs, Fr. picois, M. Lat. picosium, formed from Fr. pic, the termination being adapted to the familiar English “axe.” The sense-development of the verb “to pick” is not very clear, but the following meanings give the probable line: to dig into anything like a bird with its beak, in order to extract or remove something, to gather, pluck, hence to select, choose. (3) Peak: The chief uses are for the front of a cap or hat projecting sharply over the eyes, for the part of a ship’s...
Pike perch—Pilate

hold where it narrows towards the bows, the fore-peak, or towards the stern, the after-peak, for the top corner of a sail extended by a gaff, or for the projecting end of the gaff itself, and for a pointed or conical top of a hill or mountain. The name of the high table-land district in Derbyshire is not to be connected with this word, but probably retains the name of an old English demon, Peac (see Peak, The).

Pike perch (Lucioperca), fresh-water fishes closely allied to the perch, but with strong canine teeth standing between the smaller teeth of the jaws and palate. They resemble the pike in their elongate body and head, and they are also most dangerous enemies to other fresh-water fishes, though they compensate for their destructiveness by the excellent flavour of their flesh. In Europe two species occur, the more celebrated being the "Zander" of North Germany or "Schiel" of the Danube (Lucioperca sandra); strange to say, it is absent in the system of the Rhine. It prefers the quiet waters of large lakes and clear deep lakes, in which it reaches a weight of 25 lb or 50 lb. The second (Lucioperca wolgensis) is limited to rivers in southern Russia and Hungary. In North America several pike-perches have been described, but in the most recent works only two are distinguished, viz. Lucioperca americana, which grows to a weight of 20 lb, and the much smaller Lucioperca canadensis; both are abundant in the Canadian lakes and rivers and Ohio.

Pike's Peak, a famous peak of the Rampart range of the Rocky Mountains in El Paso county, Colorado, U.S.A., about 6 m. W. of Colorado Springs. Though surpassed in altitude (14,108 ft.) by many summits in the state, no other is so well known. The commanding appearance of the peak is very fine. To the south are Cameron Cone (10,685 ft.), Mt. Sachett, Mt. Bald (13,974), Mt. Rosa (11,427), and Mt Cheyenne (9427). From the summit the magnificent Sangre de Cristo range is in the foreground, while on a clear day not only its southernmost summit, Blanca Peak (14,350 ft.) is visible, but also the Spanish Peaks (14,700 and 13,623 ft.) 100 m. to the south, and Long's Peak nearby to the north, and between them Mt. Lincoln, Gray's Peak and other giants. At the base of the mountain are Manitou and Colorado Springs, whence tourists can make the ascent of the peak (in summer safe and relatively simple) on horseback or by a cog-railway, 8-75 m. long (opened in 1891), which makes a total ascent of 8100 ft. (maximum gradient 1 in 4) to the summit. In 1905 a powerful searchlight was erected on the summit.

Pike's Peak was discovered in November 1806 by Lieut. Zebulon M. Pike. He attempted to scale it, but took the wrong path and found himself at the summit of Cheyenne Mountain. In Europe two species occur, the more celebrated being the "Zander" of North Germany or "Schiel" of the Danube (Lucioperca sandra); strange to say, it is absent in the system of the Rhine. It prefers the quiet waters of large lakes and clear deep lakes, in which it reaches a weight of 25 lb or 50 lb. The second (Lucioperca wolgensis) is limited to rivers in southern Russia and Hungary. In North America several pike-perches have been described, but in the most recent works only two are distinguished, viz. Lucioperca americana, which grows to a weight of 20 lb, and the much smaller Lucioperca canadensis; both are abundant in the Canadian lakes and rivers and Ohio.

Pilaster (Fr. pilastre, med. Lat. pilastrum, from pila, a pillar), in architecture, an engaged pier projecting slightly from the wall, and employed to divide up and decorate a wall surface or to serve as respond to a column. One of the earliest examples (c. 100 B.C.) exists in the propylaea at Priene in Asia Minor, where it tapers towards the top. Pilasters have bases and capitals and are frequently fluted like columns. The Romans would seem to have preferred semi-detached columns, but for their amphitheatres the latterwise pilasters are employed, as in the upper story of the Colosseum. In the revival of Classic architecture, and especially in Italy, architects seem to have considered that no building was complete without a network of pilasters on every storey, and France and England followed their example; and not only externally but inside the great cathedrals and churches the pilaster is adopted as the simplest and best way of dividing the bays.

Pilate, Pontius, the Roman governor of Judea under whom Jesus Christ suffered crucifixion. Of equestrian rank, his name Pontius suggests a Samnite origin, and his cognomen in the gospel, Pilatus (if derived from the pilus or cap of liberty), descent from a freeman. In any case he came in A.D. 26 from the household of Tiberius, through the influence of Sejanus, to be procurator over part of the imperial province of Syria, viz. Judaea, Samaria and Idumea. He ruled ten years, quarrelled almost continuously with the Jews—whom Sejanus, diverging from the Caesar tradition, is said to have disliked—and in A.D. 36 was recalled. Before he arrived Tiberius died, and Pilate disappears from history. Eusebius relates (Hist. ecc. ii. 7)—but three centuries later and on the authority of earlier writers unnamed—that he was exiled to Gaul and committed suicide at Vienne.

Pilate kept the Roman peace in Palestine but with limited understanding of the people. Sometimes he had to yield; as when he had sent the standards, by night, into the Holy City, and had besieged for five days by suppliants who had rushed to Caesarea (Jos. Ant. 31: 3; B. J. ii. ix. 1). But he sometimes made a bold stand, as when he hung up inscribed shields in Jerusalem, and was ordered by Tiberius to remove them to the other city (Philos ad Gaium 38). Sometimes he struck more promptly; as when the mob protested against his using the temple treasure to build an aqueduct for Jerusalem, and he disguised his soldiers to disperse them with clubs (Jos. Ant. xviii. 3, 2); or when he "mingled the blood" of some unknown Galileans "with their sacrifices" (Luke xiii. 1); or slew the Samaritans who came to Mt Gerizim to dig up sacred vessels hidden by Moses there (Jos. Ant. xviii. 4, 1)—an incident which led to his recall. Philo, who made his acquaintance in Egypt, says of Pilate that he was "a Roman of the highest order among Romans, at home in every country, with every nation, and in all languages."

A more discriminating light is thrown upon him by the New Testament narratives of the trial of Jesus. They illustrate the right of review or recognitio which the Romans retained, at least in capital causes; the charge brought in this case of acting adversus majestatem populi romani; the claim made by Jesus to be a king; and the result that his judge became convinced that the claimant was opposed neither to the public peace nor to the civil supremacy of Rome. The result is explained only by the dialogue, recorded exclusively in John, which shows the accused and the Roman meeting on the highest levels of the thought and conscience of the time. "I am come to bear witness unto the truth . . . Pilate answered, What is truth?" Estimates of Pilate's attitude at this point have varied infinitely, from Tertullian's, that he was "already in conviction a Christian"—from pro sua conscientia Christianus—to Bacon's "jesting Pilate," who would not stay for a reply. We know only that to his persistent attempts thereafter to get his proposed verdict accepted by the people, came their fatal answer, "Thou art not Caesar's friend," and that at last he unwillingly ascended the bema (in this case a portable judgment-seat, brought for the day outside the Praetorium), and in such words "This ad cruceum . . . delivered Him to be crucified." Pilate's place in the Christian tragedy, and perhaps also in the Creed, stimulated legend about him in two directions, equally unhistorical. The Gospel of Nicodemus, written by a Christian (possibly as early, Tischendorf thought, as the middle of the 2nd century), repeats the trial in a dull and diluted way; but adds not only alleged evidence of the Resurrection, but the splendid vision of the descensus ad inferos—the whole professing to be recorded in the Acta Pilati or official records of the governor. The Epistola Pilati gives Pilate's supposed account to Tiberius of the Resurrection; and the Paradisi Pilati relates how Tiberius condemned him and his wife Proca or Procula, both Christian converts. All this culminates in Pilate being canonized in the Abyssinian Church (June 29), and his wife in the Greek (Oct. 27). On the other hand the Mors Pilati tells how when condemned by the emperor he committed suicide; and his body, thrown first into the Tiber and then the Rhone, disturbed both waters, and was driven north into "Losaenia," where it was plunged in the gulf near Lucerne and below Mt Pilatus (originally no doubt Pilatus or cloud-capped), from whence it is raised every Good Friday to sit and wash unavailing hands.

Bibliography.—For legends see Tischendorf's Evangelia apocrypha (1863) and Apocryphal Gospels, Ante-Nicene Lib. (1880).

**PILATUS**, LEÓN, or LEONTIUS [LEONIO PILATO] (d. 1366), one of the earliest promoters of Greek studies in western Europe, was a native of Thessalonica. According to his own account, he was a Calabrian, who posed as a Greek in Italy and as an Italian abroad. In 1360 he went to Florence at the invitation of Boccaccio, by whose influence he was appointed to a lectureship in Greek at the Studio, the first appointment of the kind in the west. After three years he accompanied Boccaccio to Venice on a visit to Petrarch, whom he had already met at Padua. Petrarch, disgusted with his manners and habits, despatched him to Constantinople to purchase MSS. of classical authors. Pilatus soon tired of his mission and, although Petrarch refused to pay his bill, again sailed for Venice. Just outside the Adriatic Gulf he was struck down by lightning. His chief importance lies in his connexion with Petrarch and Boccaccio. He made a bald and almost word for word translation of Homer into Latin prose for Boccaccio, subsequently sent to Petrarch, who owed his introduction to the poet to Pilatus and was anxious to obtain a complete translation. Pilatus also furnished Boccaccio with the material for his genealogy of the gods, in which he made an ostentatious display of Greek learning.

**PILAUS**, a favourite Eastern dish, consisting essentially of rice, boiled with mutton or other meat, fowl or fish, and flavoured with spices, raisins, etc. The word appears in Persian, Turkish, and Urdu, and has been adopted in European languages. The form *pilaff*, showing the Turkish pronunciation, is also common.

**PILCHARD** (in earlier 16th century forms *pizcher, pilchar;* of unknown origin; the Fr. *pilseir* is adapted from Eng.), *Clupea pilchardus*, a fish of the herring family (*Clupeidae*), abundant in the Mediterranean and on the Atlantic coasts of Europe, north to the English Channel. Sardine is another name for the same fish, which on the coast of Brittany and Normandy is also called *cilan* or *cilorer*. It is readily distinguished from the other European species of *Clupea*. The operculum is sculptured with ridges radiating and descending towards the subpericardium; the scales are large, about thirty along the lateral line, deciduous; the ventral fins are inserted below, or nearly below, the middle of the base of the dorsal fin; the dorsal fin has seventeen or eighteen, the anal from nineteen to twenty-one rays. A small blackish spot in the scapular region is very constant, and sometimes succeeded by other similar marks. There are no teeth on the palate; pyloric appendages exist in great numbers; the vertebrae number fifty-three. The pilchard is one of the most important fishes of the English Channel. It spawns at a distance from the shore, and its eggs are buoyant, like those of many other marine fishes and unlike those of the herring, which are adhesive and demersal, i.e. develop under water. The egg of the pilchard is very slightly dis. Engulished from other pelagic eggs by the unusually large space separating the vitelline membrane from the contained ovum. Spawning takes place in summer, the season extending from June to October. When commencing their migrations towards the land the schools consist of countless numbers, but they break up into smaller companies near the shore. Pilchards feed on minute crustaceans and other pelagic animals and require two or three years before they attain their full size, which is about 10 in. in length. The sardines of the west coast of France, which are tinned in oil for export, are immature fish of the same stock as those taken on the coasts of Cornwall; they are 5 to 7½ in. in length, and though such fish occur also on the Cornish coast it is only in small numbers and for brief periods. In the Mediterranean the sardine does not exceed 7½ in., in length when mature. On the Pacific coast of America in New Zealand and in Japan a pilchard occurs (*Clupea sagax*) which in its characters and habits is so similar to the European pilchard that its general utilization is deserving of attention. Immense shoals are reported to visit the east coast of Otago every year in February and March. *Clupea scombrina* is the "oil sardine" of the east coast of India. (J. T. C.)

**PILE**, an homonymous word, of which the main branches are (1) a heap, through Fr. from *pile*, pillar; (2) a heavy beam used in making foundations, literally a pointed stake, an adaptation of Lat. *pilum*, in Hebrew a pointed stone (*pilat*); (3) the Lat. *pila*, hair. In the first branch the Lat. *pila* (for *pilis*, from *pangere, to fasten*) meant also a pier or mole of stone, hence any mass of masonry, as in Fr. *pile*. In English usage the word chiefly means a "heap" or "mass" of objects laid one on the top of the other, such as the heap of faggots or other combustible material on which a dead body is cremated, "funeral pile," or on which a living person is burnt as a punishment. It also is applied to a large and lofty building, and specifically, to a stand of arms, piled "in military fashion, and to the series of plates, "trussel" or "volcanic piles," in an electric battery. The modern "head and tail of a coin," was formerly "head and pile," Fr. *croix et pile*, in modern Fr. *face et pile*. In the older apparatus for minting the die for the reverse was placed on a small upright pillar, *pile*, the other on a punchen known as a "trussel" (Fr. *trousseau*). The common name of the disease of haemorrhoids (q.v.) or "piles" is probably an extension of this word, in the sense of mass, swelling, but may be referred to the Lat. *pila*, ball. The name of the *pileum*, or heavy javelin (lit. pounder, pestle, from *pinnere, pisere, to beat), the chief weapon of the ancient Roman infantry, was adopted into many Teutonic languages in the sense of dart or arrow, cf. Germ. *Pfeil;* in English it was chiefly used of a heavy stake with one end sharpened, and driven into swampy ground or in the bed of a river to form the first foundations for a building; the primitive lake-dwellings built on "piles" are also known as "pile-dwellings." For the use of piles in building see *FOUNDATIONS and BRIDGES.* In heraldry a charge represented by two lines meeting in the form of an arrow head is known as a "pile," a direct adaptation probably of the Lat. *pilum*. The division of this intricate word, followed here, is that adopted by the *New English Dictionary*; other etymologists (e.g. Skeat, *Etym. Dict.,* 1858) arrange the words and their Latin originals somewhat differently.

**PILGRIM**, a wanderer, traveller, particularly to a holy place (see PILGRIMAGE). The earliest English forms are *piligrime or pelegrem*, through Fr. *pelerin* (the original O. Fr. *peleger* is not found), from Lat. *peregrinus*, a stranger, foreigner, particularly a resident alien in Rome (see PRAETOR, and ROMAN LAW). The Lat. *peregrer*, from which *peregrinus* is formed, meant, "from abroad," "travelled through many lands" (per, through, and ager, country).

It was customary for pilgrims to bring back as proof of their pilgrimage to a particular shrine or holy place a badge, usually made of lead or pewter, bearing some figure or device identifying it with the name or place. These "pilgrim signs" are frequently alluded to in literature—notably in the *Canterbury Tales* and in *Piers Plowman*. The British Museum and the Musée Cluny in Paris have fine collections of them, mainly dredged from the Thames and the Seine. The badges were generally worn fastened to the pilgrim's hat or cape. Among the best known are those of the cockle or scallop shell of St. James of Compostella in Spain; the "vernicile," a representation of the miraculous head of Christ; the *vera icon*, true image, on St Veronica's handkerchief, at Rome, or of the Abgar portrait at Genoa, of a "vernicile hadde he sowed on his cappe" (*Canter. Tales, *"Pro."* 683); the Amiens badge of the head of John the Baptist on the charger, the cathedral claiming the custody of the relic from 1206 (fig. 1); and the palm branches or cross of palm leaf, the
Pilgrimage

PILGRIMAGE

The most common of the English pilgrims' signs are those of the shrine of Thomas Becket at Canterbury, the greatest centre of pilgrimage in England. These take a variety of forms, sometimes a simple T, sometimes a bell marked 

*campana Thome*, the Canterbury bell, most often a figure of the saint, sometimes seated, sometimes riding on a horse, and carrying his episcopal cross, and with hand uplifted in benediction (fig. 2). Sometimes the badges took the shape of small *ampullae*, or vases, as in the case of the badges of the shrine of Our Lady of Walsingham, which were marked with a W and cross. See W. Andrews, *Church Treasury* (1898), article "*Pilgrims' Signs*," by Rev. G. S. Tyack; and *Guide to Medieval Room, British Museum*, p. 69.

*The English "Pilgrims' Way."*—From Winchester, in Hampshire, to Canterbury, in Kent, runs a road or way which can still be traced, now on the present made roads, now as a lane, bridle path, or cart track, now only by a line of ancient yews, hollies or oaks which once bordered it. To this old track the name of "*pilgrims' way*" has been given, for along it passed the stream of pilgrims coming through Winchester from the south, and west of England and from the continent of Europe by way of Southampton to Canterbury Cathedral to view the place of the martyrdom of Thomas Becket, in the north transept, to the relics in the crypt where he was first buried after his murder, in 1170, and the shrine in the Trinity Chapel which rose above his tomb after the translation of the body in 1220. There were two festivals for the pilgrimage, on the 29th of December, the day of the martyrdom, and on the 7th of July, the day of the translation. The summer pilgrimage naturally became the most popular. In 1538 the shrine was destroyed and the relics of the saint scattered, but the great days of the pilgrimage had then passed. Erasmus gives a vivid picture of the glories of the shrine and of all that was shown to the pilgrims on his visit with Colet to Canterbury in 1534.

The principal villages, towns and places near or through which the way passed are as follow: Winchester, Alresford, Ropley, Alton, Farnham (here the way follows the present main road), Scale, Puttenham, by the ruined chapel of St Catherine, outside Guildford, near where the road crosses the Wey above Shalford, and by the chapel of St Martha, properly of "*the martyr*," now restored and used as a church, Albury, Shere, Gomshall, Dorking (near here the Mole is crossed), along the southern slope of Boxhill to Reigate, then through Gatton Park, Merstham, Oxted, Wrotham, after which the Medway was crossed, Burham, past the megalithic monument Kit's Coty House, and the site of Boxley Abbey, the oldest after Waverley Abbey of Cistercian houses in England, and famous for its miraculous image of the infant saint Rumbold, and the still more famous winking rock or crucifix. The road passes next by Hollingbourne, Lenham and Charing. At Oxted, Wrotham and Charing were manor-houses or rather palaces of the archbishops of Canterbury; at Hollingbourne was a manor of the priors of Christchurch.

1 Shalford Fair, the chapels on the two hills and the Surrey hills are probably the scene of Bunyan’s *Pilgrim’s Progress*, see E. Rénouard James, *Notes on the Pilgrim’s Way on West Surrey* (1871).

Hollingbourne come Westwell, Eastwell, Boughton Aluph, Godmersham, Chilham Castle, and then at Harbledown, where are the remains of the Hospice of St Nicholas, the road joins Watling Street, by which came the main stream of pilgrims from London, the North and the Midlands.

This road, although its name of the Pilgrims’ Way has for long confined it to the road by which the pilgrims came to Canterbury from Winchester, follows a far older track. Right back into British and even older times the main direction which commerce and travellers followed across southern and western England to the Straits of Dover and the Continent lay from Canterbury along the southern chalk slope of the North Downs to near Guildford, then by the Hog’s Back to Farnham. At this point the oldest track went across Salisbury Plain towards Stonehenge and so on to Cornwall. From Farnham westward the only portion of this the oldest track that can now he traced is a small portion that still bears the name of the Harrow (i.e. hoary, old) road. It was in early times abandoned for the road from Winchester to which the stream of travel and commerce from the Continent and the south and south-west of England was diverted.

The 18th-century 'pilgrims' way' has been traced fully in Mrs Ady’s book *The Pilgrim's Way* (1893), and the older track in the fullest detail in Hilaire Belloc’s *The Old Road* (1904).

*The American "Pilgrim Fathers."*—In American history the name "*Pilgrims*" is applied to the earliest settlers of the colony of Plymouth, Massachusetts, and more specifically to the first company of emigrants, who sailed in the "Mayflower" in 1620. They were from the beginning Separatists from the Church of England; they had established Independent (Congregational) churches at Scrooby and Gainsborough early in the 17th century, and some of them had fled to Amsterdam in 1608 to avoid persecution, and had removed to Leiden in the following year. They sailed from Delfshaven late in July 1620, from Southampton on the 5th of August, from Plymouth on the 6th of September, and late in December 1620 founded the colony of Plymouth, Massachusetts. See *Massachusetts; Plymouth, and Mayflower.*

PILGRIMAGE (Fr. *pèlerinage*, Lat. *peregrinatio*), a journey undertaken, from religious motives, to some place reputed as sacred. These journeys play an important rôle in most pre-Christian and extra-Christian religions: in the Catholic Church their acceptance dates from the 3rd and 4th centuries.

I. The Pilgrimage in pre-Christian and non-Christian Religions.

—To the Germanic religions the pilgrimage is unknown. On the other hand, it is an indigenous element, not only in the two great religions, but in those of the ancient seats of civilization on the Mediterranean. The fundamental conception is always that the Deity resides—or exercises a peculiarly powerful influence—in some definite locality; and to this locality the devout repair, either in reverence of their god, or in quest of his assistance and bounty. Thus, as the cult of a particular divinity spreads farther and farther, so the circle expands from which are drawn those who visit his sanctuary.

One of the oldest homes of the pilgrimage is India. There the army of devotees tends more especially to the Ganges—the hallowed river of Hindu belief. On the Ganges lies Benares, the holy city of Brahminism; and to look on Benares, to visit its temples, and to be washed clean in the purifying river, is the yearning of every pious Indian. Even Buddhism—originally destitute of ceremonial—has adopted the pilgrimage and the secondary tradition makes Buddha himself determine its goals: the place where he was born, where he first preached, where the highest insight dawned on him, and where he sank into Nirvana. The four ancient sacred resorts are Kapilavastu, Gaya, Benares and Kusinagara.

In Syria, the temple of Atargatis in Hierapolis was an immunorial memorial of pilgrims. In Phoenicia, a similar significance was enjoyed by the shrine of Astarte, on the richly-watered source of the river Adonis, till, as late as the 4th century after Christ, it was destroyed by Constantine the Great. In Egypt, the great annual and monthly festivals of the indigenous gods
gave rise to all manner of religious expeditions. Even among the Israelites, the visitation of certain cult-centres prevailed from remote antiquity; but, when the restriction of Yahweh-worship to Jerusalem had doomed the old shrines, the Jewish pilgrimages were directed solely to the sanctuary on Mt. Moriah.

Among the Greeks the habit was no less deeply rooted. Just as the inhabitants of each town honoured their tutelary deity by solemn processions to his temple, so, at the period of the Olympic games, the temple of Zeus at Olympia formed the goal of multitudes from every Hellenic country. No less powerful was the attraction exercised by the shrines of the oracular divinities, though the influx of pilgrims was not limited to certain days, but, year in and year out, a stream of private persons, or embassies from the city-states, came flowing to the temple of Zeus in Dodona or the shrine of Apollo at Delphi.

The unification of the peoples of antiquity in the Roman Empire, and the resultant amalgam of religions, gave a powerful impetus to the custom. For, as East and West still met at the old sanctuaries of Greece, so—and yet more—Greece and Rome repaired to the temples of the southern and eastern deities. In the shrine of Isis at Philae, Europeans set up votive inscriptions on behalf of their Christian family at home, and it may be surmised that even among the festival crowds at Jerusalem a few Greeks found place (John xii. 20).

The pilgrimage, however, attained its zenith under Islam. For Mahomet proclaimed it the duty of every Mussulman, once at least in his life, to visit Mecca; the result being that the birthplace of the Prophet is now the religious centre of the whole Mahommedan world (see MAHOMMEDAN RELIGION; CARAVAN; MECCA).

II. The Pilgrimage under Christianity.—The pilgrimages of Christianity presuppose the existence of those of paganism; but it would be an error to maintain that the former were a direct development of the latter. For primitive Christianity was devoid of any point by which these journeys of devotion might naturally have been suggested. It was a religion without temples, without sanctuaries, and without ceremony. The saying of the Johannine Gospel—that God is to be adored neither in Jerusalem nor on Gerizim, but that His true worshipper must worship Him in spirit and in truth—is in complete harmony with the old Christian piety. And, accordingly, in the ancient Christian literature, we find no trace of a conception that the believer should visit a definite place in order to pay homage to his Master. The evolution of the Christian pilgrimage moved on other lines.

The pilgrim, of course, finely observes that, in Athens, the glorious architecture caused him less pleasure than did the thought of the great men whose work was done in its midst—"how here one had lived, and there fallen asleep; how here another had disputed, and there lay buried" (De Legg. ii. 2). This feeling was not weakened by the advent of Christianity, in fact, we may say that it was largely strengthened. Ciceron had already compared the sites consecrated by the memory of some illustrious name with those hallowed by recollections of a loved one. But with the Christian, when his Redeemer was in question, both motives coincided: for there the greatest was also the dearest.

In this devotion to the memory of Jesus and the key to the origin of the Christian pilgrimage: the faithful repaired to those places which were invested with memories of their Lord's earthly life. And these journeys must certainly date from the 2nd century. For Origen (d. 254) mentions that in Bethlehem the cave was shown where Christ was born, and in it the manger in which Mary made the bed of her child. The site must have been much visited long before this, since Origen remarks that it was common knowledge, even among the infidels, that there was the birthplace of that Jesus whom the Christians worshipped (Contra Celts. i. 51). But those who visited Bethlehem must certainly have visited Jerusalem and the places there, so rich in memorials of their Master. And the sympathy of Christendom soon let them beyond this immediate circle. The anonymous author of the Cohortatio ad Graecos, a work of the 2nd century, visited the remnants of those cells, in which—so legend related—the seventy interpreters laboured on their version of the Old Testament: nor, when he came to Cuma in Campania, did he fail to have shown him the old shrine of the Sibyl (Col. ad Gr. 13 and 37). Soon we begin to hear the names of the pilgrims.

In the course of the 3rd century, as Jerome relates, Firmilian, bishop of Caesarea in Cappadocia, travelled to Palestine to view the sacred places (De Vir. ill. 54); while, according to Eusebius, a second bishop from Cappadocia, Alexander by name, visited Jerusalem in order to pray and acquaint himself with the holy sites, and was there invited by the community to remain with them and assume the episcopate of the aged Narcissus (Hist. eccl. vii. 12). With regard to the West, the early years of the 4th century—the same authority recounts that believers kept streaming to Palestine from all regions, there to offer their prayers at a cavern shown on the Mount of Olives (Demonstr. evang. vi. 18).

This statement, that the Christians of the 3rd and 4th centuries were in the habit of visiting Jerusalem for prayer, proves that the non-Christian conception of the religious pilgrimage had already entered the sphere of Christian thought. That men travelled for purposes of prayer implies acceptance of the heathen theory of sanctuaries which it is an act of piety to visit. We may assume that the journey to Jerusalem was contemporary with Christian thought. Nevertheless, it is clear that the development was inevitable. As soon as the non-Christian ideas of priests, sacrifices, houses of the god, and so forth, were naturalized in the Christianity of the 3rd century, it was but a short step to the belief in holy places.

III. The Pilgrimage in the Ancient Church.—In the passages cited above, Bethlehem and the Mount of Olives figure as the main goal of the pilgrim: and on the Mount of Olives the mind must naturally turn to the Garden of Gethsemane and the scene of the Agon. It may seem surprising that there is no mention of Golgotha and the Sepulchre. But the visitation of these sites was rendered impossible to the Christians by the destruction of Jerusalem and the erection of the town of Aelia Capitolina. They had not forgotten them; but the grave was concealed under a mound of earth and stones—a profanation probably dating from the siege of the city and Titus's attack on the second wall. On the summit of this mound there stood, in the days of Eusebius, a sanctuary of Venus (Eus. Vit. Const. iii. 26, 30). The Sepulchre and the Hill of the Crucifixion were lost to the Christian pilgrim; and, consequently, before the era of Constantine, the one holy site in the town of Jerusalem was the so-called Conoculum, which received its name in later years. It lay south of the city, near the outer wall, and, if Epiphanius is to be believed, was already in existence when Hadrian (130–131) visited Jerusalem (De mens. 14). It was regarded as the house, in which —according to the Acts of the Apostles (xii. 12 sqq.)—Mary, the mother of John Mark, lived; and the belief was that there the Lord held the Last Supper, and that there the eleven assembled after the Ascension. It was there, also, that the scene of the Pentecostal effusion of the Spirit was laid (cf. Cyrill. Hlerus. Cat. xvi. 4).

The pilgrimage to Palestine received a powerful impetus from the erection of the memorial churches on the holy sites, as described by Eusebius in his biography of the emperor (iii. 25 sqq.). At the order of Constantine, the shrine of Venus above mentioned was destroyed, and the accumulated rubbish removed, till the ancient rock-foundation was reached. There the cave was discovered in which Joseph of Arimathea had laid the body of Jesus; and above this cave and the Hill of the Crucifixion the imposing church of the Holy Sepulchre was built (A.D. 326–336). The churches in Bethlehem and on the Mount of Olives were erected by Helena, the mother of Constantine, who herself undertook the pilgrimage to the Holy Land. These churches were then endowed with new sanctuaries of miraculous powers, and relics of Christ were found, including the shape of the Cross and the nails.

Eusebius, the contemporary of Constantine, is silent on this point. To his continuators, on the other hand, it is an established fact that Helena brought all three crosses to light, and ascertained...
the genuine Cross by the instrumentality of a miracle, in addition to discovering the nails of the Crucifixion (Ruini, i. 7; Socr. i.17; Sozomen, ii. 1; Theod. i. 17). It is impossible to fix the date at which the supposititious relics were introduced into the church of the Sepulchre: it is certain, however, that in the 5th century the Cross was there preserved with scrupulous reverence, and accounted the highest treasure of the sanctuary.

After the 4th century, monks and nuns begin to form no inconsiderable part of the pilgrimages—a fact which is especially manifest from the numerous notices to be found in Jerome, and the narratives of Theodoret in the Historia religions. In fact, many were inclined to regard a journey to Jerusalem as the bounden duty of every monk—an exaggerated view which led to energetic protests, especially from Gregory of Nyssa, who composed a monograph on the pilgrimages (De ipsis qui aduent Hierosol.). Jerome, like Gregory, insists on the point that residence in Jerusalem has in itself no religious value: it is not locality, but character, that avails, and the gates of Heaven are as open in Britain as in Jerusalem (Ep. 58, 3). These utterances, however, must not be misinterpreted. They are not directed against the pilgrimage in itself, nor even against the belief that prayer possesses special efficacy, since there are many equally inconsiderable pilgrimages, but solely against the exaggerated development of the system.

The theologians of the 4th and 5th centuries were at one with the masses in recognizing the religious uses of the pilgrimages. Jerome in particular considered it an act of faith for a man to offer his prayers where the feet of the Lord had stood, and the traces of the Birth, of the Cross, and of the Passion were still to be seen (Ep. 47, 2).

We may gain some impression of the mood in which the pilgrims completed their journey, when we read how Paula, the friend of Jerome, expresses herself on her visit to the church of the Sepulchre: "As oft as we enter its precincts we see the Saviour laid in the shroud, and the angel seated at the feet of the dead!" (Hieron. Ep. 46, 2). She assured Jerome that, in the church of the Nativity at Bethlehem, she beheld, with the eye of faith, the Christ-child wrapped in swaddling clothes (Ep. 108, 10). But with these thoughts, others of an entirely different stamp were frequently blended. Pilgrimages were conceived as means to ensure an answer to particular prayers. So, for example, Eudocia, the wife of Theodosius II., vowed to undertake a pilgrimage to Jerusalem, if she should see her daughter married. (Socr. Hist. eccl. vii. 47). And, as closely as this approaches to the pagan ideas, the distinction between paganism and Christianity is completely obliterated when we find the hermit Julian and his companions travelling to Sinai in order to worship the Deity there resident (Theod. Hist. rel. 2).

With the number of the pilgrims the number of pilgrim-resorts also increased. Of Jerusalem alone Jerome relates that the places of prayer were so numerous that it was impossible to visit them all in one day (Ep. 46, 6). In the Holy Land the list was still longer: the natives were ready to show everything for which the foreigners inquired, and the pilgrim was eager to credit everything. In her expedition to the East, the Paula mentioned above visited, among other places, the tombs of Caesarea. In the first-named place she was shown the tower of Elijah; in the second, the house of Cornelius, that of Philip, and finally the grave of the four virgins. At Bethlehem she saw, in addition to the church of the Nativity, the grave of Rachel; at Hebron the hut of Sarah, in which the swaddling clothes of Isaac and the remains of Abraham's oak were on view (Hieron. Ep. 108). A similar picture is given in the Travels of the so-called Silvia Aquitana, who seems, in reality, to have been a Spanish nun, named Etheria or Eucheria. She went as a pilgrim to Jerusalem (c. 380), and from there traced the supposed sites of Palestine, in order to visit every site which was consecrated by memories of the Lord's earthly life. Nor did she neglect the scenes of patriarchal history. Of greater antiquity is the concise account of his travels by an anonymous pilgrim, who, in a.d. 333, undertook the journey from Bordeaux to Palestine. The Itinerary of the African Theodosius who visited the East between a.d. 520 and a.d. 530 is of later date (P. Geyer, Itin. hierosol. sacet. iv-viii.).

While pilgrim-resorts were thus filling the East, their counterparts began to emerge in the West. And here the starting-point is to be found in the veneration of martyrs. In the west, care for the tombs of martyrs was sanctioned by immemorial custom of the Church; but, in this case also, a later age strove to preserve the primitive conception in its purity. Hence, and Augustine himself was obliged to defend the usage of the Church from the imputation that it implied a transference of heathen ceremonial to the sphere of Christianity (Contr. Faust. xx. 21). The martyrs were the local heroes of particular communities; but there were men whose life and death were of significance for the whole of Christendom—the apostles. Of these Peter and Paul had suffered martyrdom in Rome, and it was inevitable, from the nature of the case, that their graves should soon become a resort, not only of Romans born, but of strangers also. True, the presbyter Caius (c. 200) who first mentions the situation of the apostolic tombs on the Vatican and the 'departure' to Ostia in reference to the memorials there erected, is not far from saying nothing to foreign Christians regarding to time in order to visit them. And though Origen travelled to Rome, it was not to view the graves of dead men, but to establish relations with the living flock (Euseb. Hist. eccl. ii. 25, 7; vi. 14, 10); still, it is certain that the Roman cemeteries were visited by numerous pilgrims even in the 3rd century: for the earliest graffiti in the papal crypt of the Eccezmerium Callistii must date from this period (De Rossi, Roma sotter. i. 253 sqq.; Krauss, Rom. Sot. 148 sqq.). And if the tombs of the popes were thus visited, so much more must this hold of the tombs of the apostles. After these, the most frequented resort at Rome in the 4th century was the grave of Hippolytus. The poet Prudentius describes how, on the day of the martyr's death, an innumerable multitude of pilgrims flocked round the site. Even on ordinary days arrivals and departures were almost incessant—foreigners being everywhere seen mingled with the native Latins. They poured balsam on the sepulchre of the saint, washed it with their tears, and covered it with their kisses, in the belief that they were thus assuring themselves of his intercession or testifying their gratitude for his assistance. Prudentius says of himself, that whenever he was sick in soul or body, and prayed there, he found help and returned in cheerfulness: for God had vouchsafed His saint the power to confer a share of his own strength (p. 125 sqq.). Paulinus of Nola (d. 431) concurs—his custom being to visit Syria, Egypt, and Rome on the apostolic anniversaries (Ep. 20, 2; 45, 1). Next to Rome the most popular religious resort was the tomb of Felix of Nola (August. Ep. 78, 3); while in Gaul the grave of St Martin at Tours drew pilgrims from all quarters (Paul. Nol. Ep. 17, 4). Africa possessed no sanctuary to compete with these; but we learn from Sulpicius Severus (c. 400) that the tomb of Cyprian seems to have been visited even by a Gaul (Dial. i. 3).

The motive that drew the pilgrims to the graves of the saints is to be found in the conviction, expressed by Prudentius, that the sepulchral succour was certain; and hence came the belief in a never-ending series of miracles there performed (cf. lives of the saints, e.g. Eutrope. Hist. Lib. pro syn. p. 315). Doubt was unknown. St Augustine observes that, though Africa was full of martyrs' tombs, no miracle had been wrought at them so far as his knowledge extended. This, however, did not lead him to doubt the truth of those reported by others—a fact that is somewhat surprising when we reflect that the phenomenon caused him much disquiet and perplexity. Who, he asks, can fathom the design of God in ordaining that this should happen at one place and not at another? And eventually he acquiesces in the conclusion that God, who gives every man his individual gift at pleasure, has not willed that the same powers should have efficacy at every sepulchre of the saints (Ep. 78, 3).

IV. The Pilgrimage in the Middle Ages.—The medieval Church
adopted the custom of the pilgrimage from the ancient Church. The young Germanic and Romance nations did precisely as the Greeks and Romans had done before them, and the motives of these devotional journeys—now much more difficult of execution in the general decay of the great world-system of commerce—remained much the same. They were undertaken to the honour of God (Pipp. Cap. 754–755, c. 4), for purposes of prayer (Ann. Hild. 992), or in quest of assistance, especially health (Vita Galli, ii. 37; Vita Liudg. iii. 10). But the old causes were reinforced by others of at least equal potency. The medieval Church was even more profoundly convinced than its predecessor that the miraculous power of Deity attached to the bodies of saints and their relics. But the younger nations—French, English and German—were scantily endowed with saints; while, on the other hand, the belief obtained that the home-countries of Christianity, especially Rome and Jerusalem, possessed an inexhaustible supply of these sanctified bodies. Pilgrimages were consequently undertaken with the intention of securing relics. At first it was enough to acquire some object which had enjoyed at least a mediatic connexion with the hallowed corpse. Gregory of Tours (d. 594) mentions one of his deacons who made a pilgrimage into the East, in order to collect relics of the Oriental saints; and, on his return, visited the grave of the Bishop of Seligenstadt (St Nizier, d. 573) in Lyons, where he still further increased his store. His testimony showed how relics came to be distributed among the populace: one enthusiast took a little wax dropped from the taper; another, a portion of the dust which lay on the grave; a third, a thread from the cloth covering the sarcophagus; and he himself plucked the flowers which visitors had planted above the tomb. Such were the memorials with which he returned; but the universal belief was that something of the miraculous virtue of the saint had passed into these objects (Vit. patr. 8, 6). Before long, however, these humble trophies failed to content the pilgrims, and they began to devote their efforts to acquiring the actual bodies, or portions of them—frequently by honest means, still oftener by trickery. One of the most attractive works of early medievalism—Einhard's little book, Translatio Marcellini et Petri—gives a vivid description of the methods by which the bodies of the two saints were acquired and transported from Rome to Seligenstadt on the Main.

Far more important consequences, however, resulted from the fact that the medieval mind associated the pilgrimage with the forgiveness of sins. This conception of the pilgrimage, as a means of expiation or a source of pardon for wrong, was foreign to the ancient Church. It is quite in accordance with the keener consciousness of sin, which prevailed in the middle ages, that the expiatory pilgrimage took its place side by side with the pilgrimage to the glory of God. The pilgrimage became an act of obedience; and, in the books of penance (Poenitentialia) which date from the early middle ages, it is enjoined—whether for a definite period (e.g. Poen. Valicell. i. c. 19; Theod. Cant. i. 2, 16) or for life (Poen. Cummeeani, vii. 12; Casin. 24)—as an expiation for many of the more serious sins, especially murder or the less venial forms of unchastity. The place to be visited was not specified; but the pilgrim, who was bound by an open letter of his bishop to discourse himself as a penitent, lay under the obligation, wherever he went, to repair to the churches and—more especially—the tombs of the saints, and so offer his prayers. Occasion, a chain or ring was fastened about his body, that his condition might be obvious to all; and soon all manner of fables gained currency: how, here or there, the iron had sprung apart by a miracle, in token that the sinner was thereby absolved by God. For instance, the Vita Liudgeri recounts the history of a fraticide who was condemned to this form of pilgrimage by Jonas, bishop of Orleans (d. 843); he wore three iron rings round his body and arms, and travelled bare-footed, fasting, and devoid of linen, from church to church till he found pardon, the first ring breaking by the tomb of St Gertrude at Nivelles, the second in the crypt of St Peter, and the third by the grave of Liudger. The pilgrim—age with a predetermined goal was not recognized by the books of penance; but, in 1059, Peter Damianii imposed a pilgrimage to Rome or Tours on the clerics of Milan, whom he had absolved (Auct. mediol. patroL lat. 145, p. 98).

As the system of indulgences developed, a new motive came to the fore which rapidly overshadowed all others: pilgrimages were now undertaken to some sacred spot, simply in order to obtain the indulgence which was vested in the respective church or chapel. In the 11th century the indulgence consisted in a remission of part of the penance imposed in the confessional, in return for the discharge of some obligation voluntarily assumed by the penitent. Among these obligations, a visit to a particular church or temple bestowing a pious gift upon it, held a prominent place. The earliest instance of the indulgential privilege conferred on a church is that granted in 1216 by Pontius, archbishop of Arles, to the Benedictine abbey of Montmajour (Mons Major) in Provence (d'Achery, Spicil. iii. 383 seq.). But these dispensations, which at first lay chiefly in the gift of the bishops, then almost exclusively in that of the popes, soon increased in an incessant stream, till at the close of the middle ages there were thousands of churches in every western country, by visiting which it was possible to obtain an almost indefinite number of indulgences. But, at the same time, the character of the indulgence was modified on the ground that it was, in the 13th century, to a release from the temporal punishment exacted by God, whether in this life or in purgatory, from the repentant sinner. And, from an abolution from the consequences of guilt, it became, in the 14th and 15th centuries, a negation or the guilt itself; while simultaneously the opportunity was offered of acquiring an indulgence for the souls of those already in purgatory. Consequently, during the whole period of medievalism, the number of pilgrims was perpetually on the increase.

So long as the number of pilgrims remained comparatively small, and the difficulties in their path proportionately great, the service was confined almost exclusively to the clergy or the nobility, and to a limited number of rich and learned mendicants. But when their numbers had increased to a point where they could signify that they were worthy of the indulgence, they obtained it; and they were encouraged to bestow it on the clergy and laity, which ensured them lodging in convents and charitable foundations, in addition to the protection of public officials. An instance is preserved in Markulf's formulaium (i. 49). To receive the pilgrim and supply him with alms was always considered the duty of every Christian: Charlemagne, indeed, made it a legal obligation to withhold neither roof, hearth, nor fire from them (Admon. gent. 789, c. 75; Cap. Miss. 802, c. 27).

The most important places of resort both for voluntary and involuntary pilgrimages, were still Palestine and Rome. On the other hand, the old Iria and Iria, the abbot Adamnan of Iona (d. 704) now composed his monograph De locis sanctis, which served as the basis of a similar book by the Venerable Bede (d. 735)—both works being edited in the Itin. hierosol. His authority was a Frankish bishop named Arculf, who resided for nine months as a pilgrim in Jerusalem, and visited the remaining holy sites of Palestine in addition to Alexandria and Constantinople. Of the later itineraries the Descriptio terrae sanctae, by the Dominican Burchardus de Monte Sion, enjoyed the widest vogue. This was written between the years 1285 and 1295; but books of travel in the modern tongues had already begun to make their appearance. The initiative was taken by the French in the 14th and 15th centuries, and the Germans followed in the 14th and 15th; while the Book of Wayes to Jerusalem of John de Maunscleve (c. 1336) attained extreme popularity, and was translated into almost all the vernacular languages. Most pilgrims, probably, contented themselves with the brief guide-books which seem to have originated in the catalogues of indulgences. In later periods, that of Romberch a Kyrsepe, printed at Venice (1519), stood high in favour.

A long list might be compiled of men of distinction who performed the pilgrimage to Palestine. In the 8th century one of the most famous is the Anglo-Saxon Willibald, who died in 781 as bishop of the Frisian diocese of Bremen. He left his home in the spring of 770, accompanied by his father and brother. The pilgrims traversed France and Italy, visiting
every religious resort; in Lucca the father died, and the brother remained behind in Rome. Early in 1122 Willibald began his expedition to the Holy Land alone, except for the presence of two companions. He travelled past Naples to Syracuse, then on shipboard by Cos and Samos to Ephesus, and thence through Asia Minor to Damascus and Jerusalem. On St Martin's day, in 724, he arrived in the Holy City. After a prolonged stay in the town and its environs, Willibald proceeded (727) to Constantinople, and in 729 returned to Italy. Such is the account given by the nun of Heidenheim in her biography of Willibald; and her version is probably based on notes by the pilgrim himself (Mon. Germ. hist. ser. xxv. 80 sqq.). In 966 the French monk Bernard visited Palestine with two companions, and afterwards wrote a simple and trust-worthy account of his journey (Patrol. lat. 121, 569 sqq.).

In the 10th century Conrad, bishop of Constance (934-976), performed the pilgrimage to Jerusalem three times (Vita Chov. 7), and to the same period belong the first women-pilgrims to Jerusalem of whom we have any cognisance—Hidda, mother of Gero, archbishop of Cologne (Thl. Chron. ii. 16), and the countess Hademod of Elbersberg (Chron. ebersb.). The leaders, moreover, of the monkish reform movement in the 10th and 11th centuries, Richard of St Vaast in Normandy (d. 1045), and St Bernard of Clairvaux, saw the Holy Land with their own eyes (Vita Rich. 17; Vita Popp. 3). In the year 1028 Archbishop Poppo of Trier (d. 1047) undertook a pilgrimage which led him past Jerusalem to the banks of the Euphrates, his return taking place in 1030 (Gesta Trevir. Cont. i. 4 seq.). But the most celebrated devotional expedition before the Crusades was that of the four bishops—Sigrifd of Mainz, Gunther of Bamberg, William of Utrecht, and Otto of Regensburg. They set out in 1064, with a company whose numbers exceeded seven thousand. The major portion, however, fell in battle against the Mahomedans, or succumbed to the privations of the journey, and only some two thousand saw their homes again (Annal. Alth., Lamb., Disib., Marian. Scot. k.c.). Among the followes of the bishops were two clerics of Bamberg, Ezzo and Wille, who composed on the way the beautiful song on the miracles of Christ—one of the oldest hymns in the German language. The text was due to Ezzo, the tune to Wille (Müllenhoff and Scherer, Denkmäler, i. p. 78, No. 31). A few years later Count Dietrich of Trier began a pilgrimage to Jerusalem with 113 companions, in atonement for the murder of Archbishop Kuno. The ship, however, which conveyed them went down with all hands in a storm (Berth. Ann. 1573).

As a result of this steady increase in the number of pilgrims, the old arrangements for their accommodation were found deficient. Consequently hospices arose which were designed exclusively for the pilgrim. Those on the Alpine passes are common knowledge. The oldest, that on the Septimer pass, dates from the Carolingian period, though it was restored in 1120 by the bishop Wido of Chur: that on the Great St Bernard was founded in the 10th century, and reorganized in the 13th. To this century may also be assigned the hospice on the Simplon; to the 14th those on the St Gothard and the Lukmanier. Similarly, the Mediterranean towns, and Jerusalem in particular, had their pilgrim-refuges. Service in the hospices was regularly performed by the hospital-brothers—that is to say, by associations working under the authorization of the Church. The most important of these was the fraternity of the Hospitalis hierosolymitanum, founded between 1065 and 1075; for hence arose the order of St John, the earliest of the orders of knighthood. In addition to the hospital of Jerusalem, numerous others were under its charge in Acre, Cyprus, Rhodes, Malta, &c. Associations were formed to assist pilgrims bound for the East; one being the Confere de Flesier de Terre-Sainte in Paris, founded in 1325 by Louis de Bourbon, count of Clermont (afterwards first duke of Bourbon). Its church was in the rue des Cordeliers. Similar institutions existed also in Amsterdam, Utrecht, and elsewhere in the Low Countries.

But since, in the middle ages, the Holy Land was no longer held by a Christian Power, the protection of the pilgrims was no less necessary than their sustenance. This fact, after the close of the 11th century, led to the Crusades (q.v.), which in many respects are to be regarded as armed pilgrimages. For the old dream of the pilgrim, to view the country where God had walked as man, lived on in the Crusades—a fact which is demonstrated by the letters of Bernard of Clairvaux, with the songs of Walther von der Vogelweide and other Crusaders. And, since the strongest motive in the pilgrimage was the acquisition of indulgences, unnumbered thousands were moved to assume the Cross, when, in 1095, Urban II. promised them plenary indulgence (Conc. Clerom. c. 2). The conquest of Jerusalem, and the erection of a Christian empire in Palestine, naturally well the influx of pilgrims. And though in 1187 the Holy City again fell into the hands of the infidel, while in 1291 the loss of Acre eliminated the last Christian possession in Palestine, the pilgrimages still proceeded. True, after the fall of the city and the loss of Acre, they were forbidden by the Church; but the veto was impracticable. In the 12th century these religious expeditions were still so common that, every Sunday, prayers were offered in church for the pilgrims (Honor. Aug. Spec. ecc. p. 828). In the 13th century the annual number of those who visited Palestine amounted to many thousands: in the 14th and 15th it was accurately known. In fact, between the year 1300 and 1600, no fewer than 1400 men of distinction can be enumerated from Germany alone who travelled to the Holy Land (Röhrich and Meissner, Deutsche Pilgerreisen, pp. 465-456). It was not till the Reformation, the wars of the 16th century, and the loss of Rhodes, Candia and Cyprus to the Turks, that any appreciable alteration was effected. When Ignatius de Loyola (q.v.) set sail in 1523 from Venice to Palestine, only some thirteen souls could be mustered on the pilgrimage-ship, while eight or nine others sailed with the Venetian state- vessel as far as Cyprus. A considerable number had abandoned their pilgrimage and returned home on the news of the fall of Rhodes (Dec. 25, 1522: see Acta sanct. vil. 642 seq.).

For pilgrimage overseas, as it was styled, the permission of the Church was still requisite. The pilgrims made their journey in grey cloaks fastened by a broad belt. On the cowl they wore a red cross; and a broad-brimmed hat, a staff, sack and gourd completed their equipment. During their travels the beard was allowed to grow, and they prepared for departure by confession and communion. Of their hymns many are yet extant ("Jerusalen mirabilia, "In gottes namen faren wir," &c.). The embarkation took place either in France or Italy. In France, Marseilles was the main harbour for the pilgrims. From there ships belonging to the Knights of St John and the knights (temples) conducted the commerce with Palestine, and carried annually some 6000 passengers. In the Italian ports the number of shipments was still greater—especially in Venice, whence the regular passagium started twice a year. The Venetian pilgrim ships, moreover, carried as many as 1500 souls. The pilgrims formed themselves into unions, elected a "master" and concluded their agreements, as to the outward voyage and return, in common. After Venice, Genoa and Pisa occupied the most prominent position. The voyage lasted from six to eight weeks, the stay in Jerusalem averaging ten days. The visitation of the holy places was conducted in processions headed by the Franciscans of the Convent of Zion.

The expenses of the journey to Palestine were no light matter. In the 12th century they may be estimated at 100 marks of silver (£200) for the ordinary pilgrim. This was the amount raised in 1147 by one Goswin von Randerath to defray the expenses of his pilgrimage (Niederh. Urk. Bch. i. No. 361). Later the cost was put at 280-300 ducats (£140-£150). In the 13th century a knight with two squires, one groom, and the requisite horses, had to disburse 8½ marks of silver for his passage, while for a single pilgrim the rate was rather less than 1 mark. In the 16th century Ignatius de Loyola calculated the cost of the voyage from Venice to Jaffa at some 6 or 7 gold florins (£3). The expenses of the princes and lords were, of course, much heavier. Duke William of Saxony, who was in Jerusalem in 1401, spent no less than £10,000 on his journey (see Prutz.
In France St Martin remained the chief goal of the pilgrimage; while Notre Dame de Sous-Terre in Chartres (with a portrait of the "black Virgin"), Le Puy-en-Velay (dep. Haute Loire), and others, also enjoyed considerable celebrity. In England pilgrimages were made to the tomb of the murdered archbishop, Thomas Becket, in Canterbury Cathedral. The setting of Chaucer's Canterbury Tales gives a vivid idea of the motley company of pilgrims; but it seems probable that Germany also sent a contingent (Gervas. Cantuar. ehr. ann. 1183; Ralph de Diceto, Ymag. hist. ann. 1184). In addition, Walsingham, Peterborough, St Davids, Holywell, and St Andrews in Scotland were much frequented. In lower Germany, Cologne and Aix-la-Chapelle were practically a local resort.

In Italy the church of the Archangel on Mt Gargano was one of the most ancient centres of the pilgrimage, being visited even by the monk Bernard (side s.64). Later the Portiuncula church at Assisi displaced all other religious resorts, with the exception of Rome; but in the 15th century it was overshadowed in turn by the "Holy House" at Loretto on the Adriatic. According to an extravagant legend, the house of Joseph and Mary in Nazareth was transported by angels, on the night of the 9th–10th of May 1291 to Dalmatia, then brought to the Italian coast opposite (Dec. 10, 1294), till, on the 7th of September 1295 it found rest on its present site. The pilgrimage thither must have attained great importance as early as the 13th century; for the popes of the Renaissance found themselves constrained to erect an imposing pilgrimage church above the "Holy House."

The significance of the pilgrimage for the religious life of later medievalism cannot be adequately estimated. The possession of an extraordinary relic, a bloody Host, or the like, was everywhere considered a sufficient claim for the privileges of indulgence; and wherever this privilege existed, there the pilgrims were gathered together. All these pilgrimages, great and small, were approved and encouraged by the Church. And yet, during the whole of the middle ages, the voice of suspicion in their regard was never entirely stifled. Earnest men could not disguise from themselves the moral dangers almost inevitably consequent upon them; they recognized, moreover, that many pilgrims were actuated by extremely dubious motives; and they mistrusted the exaggerated value set on outward works. The Roman papacy had no more zealous adherent than Boniface; yet he absolutely rejected the idea that Englishwomen should make the journey to Rome, and would willingly have seen the princes and bishops veto these pilgrimages altogether (Ep. 78). The theologians who surrounded Charlemagne held similar views. When the abbess Ethelburga of Fladbury (Worcestershire) found her projected pilgrimage impracticable, Alcuin wrote to her, saying that it was no great loss, and that God had better designs for her: "Expend the sum thou hast gathered, for the journey on the support of the poor; and if thou givest as thou canst, thou shalt reap as thou wilt." (Ep. 300). Bishop Theodulf of Orleans (d. 821) made an energetic protest against the delusions that to go to Rome availed more than to live an upright life (Carm. 67). To the same effect, the synod of Chalon-sur-Saône (813) repudiated the superstition which was wedded to the pilgrimage (c. 13); and it would be easy to collect similar judgments, delivered in every centre of medievalism. But, fundamentally, pilgrimages in themselves were rejected by a mere handful: the protest was not against the thing, but against its excesses. Thus Frideswide, for instance, in spite of his emphatic declaration that most pilgrims returned worse than they went, himself participated in the crusade of Frederick II.

V. The Modern Pilgrimage.—The Reformation eradicated the belief in the religious value of visits to a particular locality. It is only pious memory that draws the Protestant to the sites consecrated by ecclesiastical history. On the other hand, while in the Eastern Church things have undergone little change,—the pilgrims, in addition to the Holy Land, visiting Mt Athos and Kiev—the developments in the Roman Church show important divergences. The Year of Jubilee, in 1325, was unprecedented in its scant attendance, but the jubilees of 1375 and 1600 again saw great armies of pilgrims marching to Rome.
Fresh pilgrim resorts now began to spring up, and medieval shrines, which had fallen on evil days, to emerge from their obscurity. In the 16th century we must mention the pilgrimages to the “Holy Mount” at Görlz on the Austrian coast, and to Montserrat in the Spanish province of Barcelona: in the 17th century, those to Luxembourg, Kevelaer (Gelderland), Notre Dame de Fourvrière in Lyons, Heiligenberg in Bohemia, Rocronne in the Netherlands, &c. The 18th century, which witnessed the religious Aufklärung, was not favourable to the pilgrimage. Enlightened bishops and princes prohibited it altogether: so, for instance, Joseph II. of Austria. Archbishop Clement Wenzeslaus of Trier forbad, in 1777, the much-frequented, medieval “leaping-procession” of Echternach (duchy of Luxembourg). The progressive theologians and clergy, moreover, assumed a hostile attitude, and, in 1800, even the Curia omitted the Year of Jubilee. The 19th century, on the other hand, led to an extraordinary revival of the pilgrimage. Not only did new resorts spring into existence—e.g. La Salette in Dauphiné (1846), and more particularly Lourdes (1858) in the department of Hautes-Pyrénées—that the numbers more attained a height which enables them to compete with the medieval figures. It is computed that 60,000 pilgrims were present in La Salette on the 29th of September 1847, the first anniversary of the appearance of Mary which gave rise to the shrine. The dedication of the church of Lourdes, in 1876, took place in the presence of 30 bishops, 3,000 priests and 100,000 pilgrims. In 1877 the number rose to 250,000; and similar statistics are given of the German and Austrian devotional resorts. The sanctuaries of Aix-la-Chapelle are said to have been visited by 65,000 pilgrims on the 15th of July 1860; and on the following Sunday by 52,000. From 25,000 to 30,000 persons take part each year in the resuscitated “leaping-procession” at Echternach; and the annual visitants to the “Holy Mount” at Görlz are estimated at 50,000. No new motives for the pilgrimage emerged in the 19th century, unless the ever-increasing cultus of the Virgin Mary may be classed as such, all of the new devotional sites being dedicated to the Virgin. For the rest, the desire of acquiring indulgences maintains its influence: but doubting voices are no more heard within the pale of the Roman Catholic Church.

PILIBHIT, a town and district of British India, in the Bareilly division of the United Provinces. The town—pop. (1901), 33,490—contains the mosque of Hafiz Rahmat Khan, the Rohilla chieftain, built in the second half of the 18th century. Trade is mainly in agricultural produce, and in the products of the town’s neighbour, the large Rayalaiy area.

The District of Pilibhit has an area of 1,350 sq. m.; pop. (1901), 470,339, showing a decrease of 3% in the decade. Though so near the Himalayas it is entirely a plain. In its midst is the Malwa swamp. The east is forest-clad, poor and unhealthy; on the other side of the Malwa the land becomes more fertile. The chief river is the Sarda, and the Gomti rises in the east. The principal crops are rice, pulses, wheat and sugar-cane. Sugar-refining is carried on, and sugar, wheat, rice and hemp are exported. The Lucknow-Bareilly section of the Oudh & Köhlkhand railway runs through the district, a portion of which is watered by the Rohil, Malwa and Bareilly canals.

PILLAR (O. Fr. pilier, Mod. pilier, Late Lat. pilare, from pila, column), an upright, isolated structure of narrow width in relation to its height, which is either employed as a support for a superincumbent load of some sort or is set up for commemorative or ornamental purposes. In the first sense the word has many common applications, as to columns supporting the girders of a warehouse floor or the deckbeams of a ship, to the single central support or pedestal of a table, machine-tool, &c., and to the masses of coal which the miner leaves in certain methods of working as supports to the roof (see Coal): it is also used figuratively of persons in such phrases as a pillar of the state.” In architecture it has strictly the second sense. The column erected at the foot of the statue of Alexander at Alexandria is known as Pompey’s pillar, and the so-called columns of Trajan and Antoninus are in reality pillars, performing no structural function beyond that of carrying a statue. In India the only example is the iron pillar at Delhi, which is an extraordinary specimen of the ironworker’s art considering the remote date at which it was made. Up to the middle of the 19th century the term “pillar” was employed to designate the masses of masonry in a church, which carry the arcades, but now the term “pier” is invariably adopted in preference.

PILLAUV, a seaport and watering-place of Germany, in the Prussian province of East Prussia, on the spit of land (Neurenburg) which separates the Frische Haff from the Baltic, on the north of the entrance channel, and 29 m. by rail from Königsberg. Pop. (1905), 7,374. It is fortified and has a harbour, which serves as the outer port of Königsberg, and to some extent also of Elbing and Braunsberg. A new navigable channel was in 1900-1901 constructed across the Frische Haff from Pillauv to Königsberg. Pillauv has a school of navigation, and is a well-known pilot station. Ship-building, sail-making, fishing and the working of amber are carried on.

Pillau is memorable as the place where Gustavus Adolphus of Sweden landed in 1626. It did not obtain civic privileges until 1725, but was fortified shortly after that date. In 1807 it offered a stout resistance to the French. By a treaty of the 24th of February 1812 it was ceded to Napoleon, but on the 6th of February in the following year it was restored to Prussia.

PILLON, a light saddle without pommel or bow, especially a pad fastened to the back of an ordinary saddle, as a seat for another person, generally a woman. Pillions were also used to support baggage. They were in common use from the 16th to the 18th centuries. The word appears to have been adopted into English from the Irish pillin, cushion, formed from Lat. pellis, skin. In the sense of a hat worn by a priest or doctor of divinity, “pillon” or “pylon” occurs in the 15th and 16th centuries. This is probably from Lat. pillicus, a conical felt hat or cap. See Tr. 790.

PILLNITZ, a village in the kingdom of Saxony, situated on the right bank of the Elbe, 5 m. above Dresden. Pop. (1905), 770. The new palace of the king of Saxony was built in 1818 on the site of a building which was destroyed by fire. The place became a residence of the electors of Saxony about 1700, and the different parts of the palace were erected at various times during the 18th century. By the convention of Pillnitz in August 1791 the emperor Leopold II. and Frederick William II., king of Prussia, agreed to take common action against any attack on the part of France; this compact may be regarded as the basis of the first coalition against that country. (See A. von Minischit, Geschichte von Pillnitz (Dresden, 1892).

PILLORY (O. Fr. pilori, Prov. espidiori, from Lat. speculatorium, a place of observation or “peep-hole”), an instrument of punishment which consisted of a wooden post and frame fixed on a platform raised several feet from the ground, behind which the culprit stood, his head and his hands being thrust through holes in the frame (as are the feet in the stocks) so as to be held fast, exposed in front of it. This frame in the more complicated forms of the instrument consisted of a perforated iron circle, which secured the heads and hands of several persons at the same time, but it was commonly capable of holding only one.

In the statutes of Edward I. it is enacted that every pillory or “stretch-neck” should be made of convenient strength, from that condition might be less endured by the bodies than by the heads of offenders without peril of their bodies. It was customary to shave the heads wholly or partially, and the beards of men, and to cut off the hair and even in extreme cases to shave the heads of female culprits. Some of the offences punished in England by the pillory will be found enumerated in
a statute of Henry III. (1266). By this "Statute of the Pillory" it was ordered as the penalty for "forestallers and registrators, users of deceitful weights, perjurers and forgers." Stow, describing Cornhill pillory, says: "On the top of the cage (a strong prison of timber) was placed a pillory for the punishment of bakers offending in the assay of bread, for millers stealing corn at the mill, for bawds, scolds and other offenders." Until 1637 this was the last resort for such offenders. In that year some attack was made on the Press, and the pillory became the recognized punishment of those who published books without a licence or libelled the government. Alexander Leighton, John Lilburn, Pryyne and Daniel Defoe were among those who suffered. These were popular favourites, and their exposures in the pillory were converted into public triumphs. Titus Oates, however, was put in the pillory in 1685 and nearly killed. In 1816 the pillory was abolished except for perjury and subornation, and the perjurer Peter James Bossy was the last to stand in the pillory at the Old Bailey for one hour on the 22nd of June 1835. It was finally abolished in 1837 at the end of William IV's reign. In France the pillory, called carcan, was employed till 1832. In Germany it was known as strangr. The pillory was used in the American colonies, and provisions as to its infliction existed in the United States statute books until 1839; it survived in the state of Delaware until 1905.

Finger-pillories were at one time in common use as instruments of domestic punishment. Two stout pieces of oak, the top being hinged to the bottom or fixed piece, formed when closed a number of holes sufficiently deep to admit the finger to the second joint, holding the hand imprisoned. A finger-pillory is preserved in the parish church of Ashby-de-la-Zouch, Leicestershire, and there is one, still in its original situation against the wall, at Littlecote Hall, Wilts.

PILOFIA (O. Eng. pylu; Lat. pilosinus, a cushion), a support for the head during sleep or rest. The pillow of Western nations is a cushion of linen or other material, stuffed with feathers, down, hair or wool. In the East it is a framework made of bamboo or rattan with a depression in the top to receive the neck; similarly blocks of wood with a concave-shaped top are used by the natives of other countries. The word is found in various technical uses for a block or support, as for a brass bearing for the journal of a shaft, and in architecture the term "pillowed," or "pulvinated," is given to the frieze of an order which bulges out in the centre and is convex in section. It is found in friezes of some of the later works of the Roman school and is common in Italian practice.

PILOCARPIN, C₈H₁₆N₂O₄, an alkaloid found, together with isopilocarpine and other related compounds, in the leaves of jaborandi (Pilocarpus pennatifolius). It was first isolated by E. Hardy in 1875 (Ber., 8, p. 1954), and is a crystalline, very hygroscopic solid. It is a strong poison. It has the properties of a monocaspide base and contains the methylamino group, -NCH₃. When heated with hydrochloric acid it gives isopilocarpine. Isopilocarpine was isolated in 1900 by H. A. D. Jowett (Journ. Chem. Soc., 77, p. 473), and is a colourless oil which boils at 261° C. (10 mm.). It is a monocaspide base which is readily soluble in solutions of the saline alkaloids. Jowett is of the opinion that pilocarpine and isopilocarpine are stereo-isomers of the structure:

 Nilew, a town of northern Spain, in the province of Oviedo; between the right bank of the river Pilona, a left-hand tributary of the Sella, and the Sierra de Abes (3268 ft.). Pop. (1900), 18,828. Though officially classed as a town, Pilona is rather a densely populated mining and agricultural district. It is served by the railway from Infesto, on the river Pilona, to Oviedo and Gijon.

PILOT, the name applied either to a particular officer serving on board a ship during the course of a voyage and having the charge of the helm and the ship's route, or to a person taken on board at a particular place for the purpose of conducting a ship through a river, road or channel, or from or into a port. The latter kind is the only one to which the term is now applied either in British or foreign countries. The word "pilot" is not the early name for the man who guides or steers a ship. In Old English the name is leadan, i.e. the man who leads the way. "Pilot" does not appear in English till the 16th century. The origin of the word has been much debated. Many etymologists find it in the Dutch pijlout (Hexham's Dictionary, 1639). This has been identified with pellood, pel-luth, sounding lead, cf. German pelleen, to sound; the last part of these words is the same as English "lead," the metal; the first part, pelleen, is for peggen, to mark with pegs or points for measuring, cf. pegel, gauge. The New English Dictionary, on the other hand, finds that the Dutch pijlout, the earlier form, is taken from the French. The source is, therefore, to be looked for in Romance languages. Du Cange (Gloss. Med. et Inf. Lat.) gives Pedotta, defined as quorum est sciire intrare et extrare portus, a gloss on pedotte e timonieri in F. Ubaldini's edition, 1640, of I documenti d'amore by Francesco da Barberino (1264-1348). It is therefore conjectured that the Italian pilota is a popular conception of pedotta, and a possible source may be found in the Greek πηλώο, ait.

In England, formerly, pilots were subject to the jurisdiction of the lord high admiral; and in the 16th century there are many instances of the admiralty court dealing with pilots disciplinarily as well as civilly, holding them liable in damages to owners of ships lost or damaged by their negligence. For some considerable time throughout the United Kingdom the appointment and control of pilots have been in the hands of numerous societies or corporations established at the various ports by charter or act of Parliament, such as the Trinity Houses of Deptford Strond (London), Kingston-upon-Hull, Newcastle-on-Tyne, and Leith, and the Society of Cinque Ports Pilots and Court of Lodemanager (now extinct). These societies had jurisdiction over the pilots exercising their employment within the limits of such ports, and in many cases made it compulsory for ships resorting thereto to employ them. By degrees the London Trinity House acquired a leading position, which was confirmed and extended by the general Pilotage Acts passed in the 18th and 19th centuries, with the object of introducing a uniform system throughout the realm. At the present day the United Kingdom is divided into districts for the purpose of pilotage jurisdiction. The (London) Trinity House has jurisdiction over the London district, which extends from Orfordness to Dungeness and comprises the Medway up to London and Rochester bridges; the English Channel district, comprising the sea between Dungeness and the Isle of Wight; and the Trinity outport districts, which include any pilotage districts for the appointment of pilots within which no particular provision is made by act of Parliament or charter, and the number of which is 40, all English and Welsh. There are 66 other districts, within which other pilotage authorities have jurisdiction.

The present general pilotage law is contained in the Merchant Shipping Acts 1894 to 1906. Pilotage authorities are defined as bodies or persons authorized to appoint or license pilots, or to fix and alter rates of pilotage or to exercise any jurisdiction in respect of pilotage. They are subject to the control of the Board of Trade as the supreme mercantile marine authority. Those bodies, however, which existed at the time of the passing of the act retain their powers and jurisdiction, so far as is consistent with it. The board has power to appoint new pilotage authority in any area where there is none, and to include a new area where there is none within an already existing one (but in either case pilots cannot be made compulsory), or to transfer pilotage jurisdiction over a port other than that where the pilotage authority for that port resides, from that pilotage authority to the Board of Trade, or to a new authority; and the board has all powers necessary to effectuate such transfer and constitute the new authority. The board may also, by provisional order (which requires parliamentary confirmation), provide for the representation of pilots or shipowners on the pilotage authority...
of any district, and the exemption of ships from compulsory pilotage in any district. Where pilotage is not compulsory, and the power of obtaining pilotage licences unrestricted, the board can in the same way give the pilotage authority powers with respect to licences, amount of pilotage rates, and the like. Pilotage authorities may, by by-laws under the (or where expressly empowered), exempt wholly or partly any ships or classes of ships from compulsory pilotage, and regulate the means of obtaining licences, and the amount of pilotage rates, subject to a maximum limit. They must make yearly returns to the Board of Trade of their by-laws, the names, ages and services of their licensed pilots, the rates of pilotage, the amounts received for pilotage and their receipts and expenditure; and if they fail to do so, the board may suspend their authority, which is then exercised by the Trinity House.

The statutes also provide generally for the qualifications of pilots. A "qualified" pilot is one duly licensed by a pilotage authority to conduct ships to which he does not belong. On his appointment he receives a licence, which is registered with the chief officer of customs at the nearest place to the pilot's residence, and must be delivered up by the pilot whenever required by the licensing pilotage authority. On his death this licence must be returned to that authority. By an act of 1906 no pilotage certificate shall be granted to the master or mate of a British ship unless he is a British subject; this does not, however, refer to the renewal of a certificate granted before 1906 to one not a British subject. Pilotage dues are recoverable summarily from the owner, master, or consignees of the ship, after a written demand for them has been made. A pilot may not be taken beyond the limits of his district without his consent, and if so taken he is entitled to a fixed daily sum in addition to the dues; if he cannot board the ship, and leads her from his boat, he is entitled to the same dues as if he were on board; and he must be truly informed of the ship's draught of water. An unqualified pilot may in any pilotage district take charge of a ship without subjecting himself or his employer to any penalty, where no qualified pilot has offered himself, or where a ship is in distress, or in circumstances where the master must take the best assistance he can, or for the purpose of changing the moorings of any ship in port on docking or undocking her; but after a qualified pilot has offered himself any unqualified pilot continuing in charge of the ship, or in charge of the ship, is liable to a penalty. A qualified pilot may not be directly or indirectly interested in licensed premises or in the selling of dutiable goods, or in the unnecessary supply of gear or stores to a ship for his personal gain or for the gain of any other person. He can be punished for quitting a ship before the completion of his duty without the consent of the master, refusing or delaying to perform his duty without reasonable cause when required by lawful authority, lending his licence, acting as pilot when suspended or when intoxicated, and any pilot who through wilful breach of or neglect of duty, or by reason of his drunkenness, endangers ship, life or limb, is guilty of a misdemeanour and liable to suspension or dismissal; but the pilot has an appeal in cases of fines over £2, of suspension or dismissal, suspension or revocation of his licence, or the application of a pilotage fund to which he has contributed. This appeal lies in England to a county court judge having jurisdiction over the port where he is licensed, or a metropolitan police magistrate or stipendiary magistrate with the like power; in Scotland, to a sheriff; in Ireland, to a county court judge, chairman of quarter sessions, recorder, or magistrate. Pilotage certificates may also be granted by pilotage authorities, available within their districts, to masters and mates of ships; and the holder of such a certificate may pilot any ship in respect of which it is available without incurring any penalty for non-pilotage of such a ship.

The statute further makes special provision for Trinity House pilots. Every such pilot, on his appointment, must execute a bond for £500 conditioned for due observance of the Trinity House regulations and by-laws, and thereupon he is not liable for neglect or want of skill to anybody beyond the penalty of the bond and the amount payable to him for pilotage on the voyage on which he was engaged at the time of his so becoming liable. The licence may be revoked or suspended by the Trinity House when it thinks fit; it only continues in force for a year, and the Trinity House has absolute discretion whether it shall be renewed or not.

A pilot boat is approved and licensed by the district pilotage authority who appoints or removes the master thereof. In order to be easily recognized, she has painted on her stern in legible white letters the name of her owner and her port, and on her bows the number of her licence; the remainder of the boat is usually black. The pilot flag is a red and white-horizontal flag of a comparatively large size, and is flown from a conspicuous position. When the flag is flown from a merchant vessel, it indicates that a licensed pilot is on board or that the master or mate holds a certificate entitling him to pilot the ship. By order in council of 1806, and on and after the 1st day of January 1807 the signals for a pilot displayed together or separately are: In daytime, there is (1) hoisted at the fore the pilot flag (Union Jack having round it a white border, one-fifth of the breadth of the flag); (2) the international code pilotage signal indicated by P.T.; (3) the international code flag S. (white with small blue square centre), with or without the code pennant; (4) the distant signal consisting of a cone point upwards, having above it two balls or shapes resembling balls. By night, (1) the pyrotechnic light commonly known as a blue light, every fifteen seconds; (2) a bright white light, flashed or shown at short or frequent intervals just above the bulwarks, for about a minute at a time.

Pilotage in British waters may be either compulsory or free for all or certain classes of ships. From parliamentary pilotage returns, it appears that it is compulsory in about 64 districts of the United Kingdom (of which two-thirds are the Trinity House districts), free in 32, free and compulsory in 8, while in 3 cases (Berwick, Dingwall and Caledonia) no particulars are given. British war-ships in British waters are not compelled to employ a pilot, the navigating officer becoming the pilot under the direction of the captain. If a pilot be employed, the captain and navigating officer are not relieved from responsibility. They supervise the pilot, and should, if necessary, remove him from the ship. In the majority of foreign ports British war-ships are exempted from employing pilots, but the Suez Canal and the ports of France are exceptions. The Merchant Shipping Act 1854 continues the compulsory employment of pilots in all districts where it was already compulsory, and also the already existing exemptions; and there is no power in any pilotage authority or the Board of Trade to increase the area of compulsory pilotage, though there is to diminish it. Compulsion is enforced by a provision in the act, that within a district where compulsory pilotage exists, the master of an unlicensed ship who pilot her himself without holding the necessary certificate, after a qualified pilot has offered or signalled to take charge of the ship, shall be liable for each offence to a fine of double the amount of the pilotage dues demandable for the conveyance of the ship. The exemptions from compulsory pilotage still existing in and in terms of France are as follows: Ships or vessels with British registers trading to Norway or the Cattegat or the Baltic (except vessels on voyages between any port in Sweden or Norway and the port of London), or round the North Cape, or into the White Sea on their inward or outward voyages, whether coming up by North or South Channels; any constant British traders inwards from ports between Boulogne inclusive and the Baltic coming up by North Channel, and any British ships or vessels trading to ports between the same limits on their outward passages and when coming up by the South Channels; Irish traders using the navigation of the Thames and Medway; ships engaged in the regular movement of the exchange of the London bills of exchange against the ships or vessels wholly laden with stone produced in the Channel Islands and Isle of Man, and bringing thence; ships or vessels not exceeding 60 tons, whether British or belonging to a foreign country specified by order in council; ships within the limits of the port or place to which they belong, if
PILOT

613

this is not a place particularly provided for by act of Parliament or charter as regards the appointment of pilots; ships passing through the limits of any pilotage district in their voyages from one port to another port, and not being bound to any port or place within such limits or anchoring therein, but not including ships being at any time at any place situate within the district, or at any place situate along the district on the same river or its tributaries. Ships whose masters or mates are owners or part-owners of them, and living at Dover, Deal, or the Isle of Thanet, may be piloted by them from any of these places up and down the Thames or Medway, or into or out of any place or port within the jurisdiction of the Cinque Ports. The following ships in the London district and Trinity outports districts are also exempt when not carrying passengers, namely: Ships employed in the coasting trade of the United Kingdom; ships of not more than 60 tons burden; ships trading to or from any port in Great Britain within the above districts or from the port of Brest in France, and any port in Europe (which does not include the United Kingdom) north and east of Brest, or to the Channel Islands or Isle of Man; and ships navigating within the limits of the port to which they belong. The port to or from which the ship must be "trading" in this provision has been interpreted by the decisions to mean the port where the cargo is substantially discharged or loaded respectively; and the word "coaster" similarly has been held to apply only to a vessel carrying to one port of the United Kingdom a cargo which has been taken in at another. Every ship carrying passengers between any place in the British Islands and any other place so situate must carry a compulsory pilot, unless her master or mate have a pilotage certificate. The effect in law of the ship (British or foreign) being in charge of a compulsory pilot under the act is that her owner and master are not answerable to any person whatever for any loss or damage occasioned by the fault or incapacity of any qualified pilot acting in charge of such ship within any district where the employment of such pilot is compulsory by law. In order to take advantage of this privilege, the shipowner must show (1) that a properly qualified pilot was acting in charge of the ship; there are, however, various kinds of qualified pilots—the qualified pilot who is always capable of acting, and the qualified pilot who is liable to be superseded if a better can be obtained; (2) that that charge was compulsory; the pilot, however, must take the charge compulsorily employed at the place where the accident happened, so long as he is compulsorily employed within the district where it happens; (3) that it was solely the pilot's fault or incapacity which caused the damage. Similarly, under the Harbours, Piers and Docks Clauses Act, the owner of a vessel is not liable for damage done thereby to docks or piers when she is in charge of a duly licensed pilot.

This statutory exemption of a ship in charge of a compulsory pilot from any liability for her negligent navigation by that pilot, is only declaratory of the common law of England, and is based on the principle that the pilot is a state official put in charge of a ship, and is not the servant of the shipowner so as to make him liable for his negligence; and a British court gives the same effect to any foreign or colonial law which makes it compulsory on shipowners to put a pilot in charge of their ship when within their jurisdiction. Most foreign codes, however, while agreeing with English law in making the presence of a pilot on board compulsory, differ from it in not putting him in charge of the ship; and in this case the defence of compulsory pilotage cannot be pleaded successfully in British courts. Judicial decisions have established that French, Suez Canal, Danube and Dutch pilots are not compulsory pilots in the British sense of the word, being only advisers of the master, or "living charts." But if the pilot is put in charge by the foreign law or colonial law, the shipowner surrendering the charge of the ship to the claimant, the shipowner must still be liable, a British court will hold the owner free from liability, on the ground that to make any person liable for a tort committed abroad, the act complained of must be wrongful not only according to the foreign law, but also by English law. This consequence which English law attaches to the employment of a compulsory pilot has been much criticized in recent times, and it would seem that the foreign view is much more satisfactory in regarding the pilot merely as the adviser and not the superior of the master. Moreover, the adoption of the foreign law on this point would restore the old general maritime law. The policy of the law was at one time inclined to extend this principle of compulsory pilotage to the ground that it was for the benefit of commerce and the safety of seamen's lives, but it now restricts it within as narrow limits as possible, e.g. the presence of a compulsory pilot on board a tug who is directing the navigation of a tug does not protect the tug-owner from liability for negligent navigation. As already pointed out, pilotage authorities have no power to extend its scope.

A pilot who is compulsorily in charge of a ship under English law has supreme control over her navigation, superseding the master for the time being; and if she is a tow he has also control of the navigation of her tug. The judicial decisions establish that it is within his province to decide whether the ship shall get under way, the proper time and place for her to anchor, the way of carrying her anchor, the proper orders for the helm, her rate of speed, and whether the statutory rules of navigation shall be complied with; and the master and crew must not interfere with his control, and only remain liable for the proper execution of the pilot's orders and the trim and general efficiency as to look-out, &c., of the ship. The master, however, is bound to supersede the pilot in case of his intoxication or manifest incapacity, and to interfere if there is a clear and plain prospect of danger to the ship following the pilot's directions, e.g. getting under way in a thick fog. The pilot is entitled to receive from the master assistance in having his attention called to anything which a competent mariner would see that he ought to know.

A pilot taken voluntarily, and not by compulsion of law, is considered as the servant of the shipowner, and as such renders him liable for his acts of negligence towards third parties. He does not, it seems, supersede the master in the control of the ship, but only advises him. The Admiralty and the Board of Trade and the Trinity House all take the view that the captain or master is bound to keep a vigilant eye on the navigation of the vessel by the pilot, and insist on all proper precautions being taken. For the purposes of a policy of marine insurance a ship is not seaworthy without a pilot in compulsory pilotage waters; and where there is no legal compulsion to have one, but the locality requires navigation by a person having local knowledge, it has been said that a ship must take a pilot, certainly when leaving a port, and probably on entering a port if a pilot is available.

A pilot can sue for his pilotage fee at common law or in Admiralty (g.v.), in the latter case provided that the contract was made and the work done not within the body of a county; but he has a 'summary remedy by statute which is of easier application. He cannot be sued in Admiralty for damage done by a collision caused by his negligence (e.g. on the Admiralty side of a county court having Admiralty Jurisdiction); but he can be made liable at common law or in the Admiralty Division of the High Court, although in the case of a Trinity House pilot his liability is limited to the amount of his bond and pilotage fee then being earned (see above); but the court has refused to join him as a defendant to an action in rem brought against the ship of which he had the charge. A pilotage authority cannot be made liable for the negligent navigation of a ship by a pilot which it has licensed, for he is not its servant, though it has been held liable for the negligence of a person not licensed by it as a pilot, but employed by it for wages to pilot ships into a harbour under its jurisdiction, itself taking the pilotage dues and applying them for harbour purposes. A pilot is not in common employment with the master and crew of a ship, and can recover for any injury done him by their negligence. He may be entitled to claim salvage from a ship of which he has charge, if the services he renders are beyond the scope of his pilotage contract, either from the outset or owing to supervening circumstances, but not otherwise, whether he is on board her or leading her from his boat. (See Salvage.)

In the United States pilotage laws are regulated by the respective
PILOT-FISH—PIMENTO

614

states. If the waters are the boundary between two states a duly licensed pilot of either state may be employed, but no discrimination can be made in the rates of piloting between vessels of different states. In the German Empire the piloting laws are very complicated. In the majority of the maritime states each one has its own regulations and laws. In Prussia there are government pilots who enter the service as apprentices, and are placed under a department of state. In France the general organization of pilots is regulated by the Statute on Pilots of the 12th of December 1856, and the piloting regulations for each port are made by the minister of marine at the request of his local representative and the Chamber of Commerce. French pilots are exempt from military service.

PILOT-FISH (Naukrites doctor), a pelagic fish of the family of horse-mackerels or Carangidæ, well known to sailors from its peculiar habit of keeping company with ships and large fishes, especially sharks. It occurs in all tropical and sub-tropical seas, and is common in the Mediterranean, but becomes scarcer in higher latitudes. In summer pilots will accompany ships as far north as the south coast of England into port. This habit was known to the ancients, who describe the Pomplius as a fish which points out the way to dubious or embarrassed sailors, and by its sudden disappearance indicates to them the vicinity of land; the ancient seamen of the Mediterranean regarded it, therefore, as a sacred fish. That the pilot accompanies sharks is an observation which first appears in works of travel of the 17th century, the writers asserting that it is of great use to its big companion in conducting it and showing the way to its food. It is, however, extremely doubtful whether the pilot's connexion with a shark serves a more special purpose than its temporary attachment to a ship. It accompanies both on account of the supply of food which it derives from them. The pilot, therefore, stands to both in the relation of a so-called "commensal," like the Echeines or sucking-fish. All observers, however, agree that neither the pilot nor the sucker is ever attacked by the shark. The pilot attains to a length of about 12 in. In the shape of its body it resembles a mackerel, but is rather shorter, especially in the head, and covered with small scales. A sharp keel runs along the middle of each side of the tail. The first dorsal fin consists of a few short spines not connected by a membrane; the second dorsal and the anal are composed of numerous rays. The teeth, which occupy the jaws, vomer and palatine bones, are all small, in villiform bands. The coloration of the pilot renders it conspicuous at a distance; on a bluish ground-colour from five to seven dark-blue or violet cross-bands traverse the body from the back to the belly. The pilot-fish spawns in the open sea, and its fry is constantly caught in the tow-net. But young pilot-fish differ considerably from the adult, having the spines of the first dorsal connected by a membrane, and some bones of the head armed with projecting spines. These little fishes were therefore long considered to be a distinct genus, Naucerus.

PILOTY, KARL VON (1826-1886), German painter, was born at Munich, on the 1st of October 1826. His father, Ferdinand Piloty (d. 1844), enjoyed a great repute as a lithographer. In 1840 he was admitted as a student of the Munich Academy, under the artists Schorn and Schnorr. After a journey to Belgium, France and England, he commenced work as a painter of genre pictures, and in 1853 produced a work, Die Amme ("The Wet Nurse"), which, on account of its originality of style, caused a considerable sensation in Germany at the time. But he soon forsook this branch of painting in favour of historical subjects, and produced in 1854 for King Maximilian II. The Adhesion of the Germans to the Catholic League in 1860. It was succeeded by "Soni at the Dead Body of Wallenstein" (1855), which gained for the young painter the membership of the Munich Academy, where he succeeded Schorn (his brother-in-law) as professor. Among other well-known works by Piloty are the "Battle of the White Mountain near Prague," "Nero Dancing upon the Ruins of Rome" (1861), "Godfrey of Bouillon on a Pilgrimage to the Holy Land" (1861), "Galileo in Prison" (1864), and "The Death of Alexander the Great" (unfinished), his last great work. He also executed a number of mural paintings for the royal palace in Munich. For Baron von Schach he painted the justly celebrated "Discovery of America." In 1874 he was appointed keeper of the Munich Academy, before being afterwards ennobled by the king of Bavaria. Piloty was the foremost representative of the realistic school in Germany. He was a most successful teacher, and among his more famous pupils may be mentioned Makart, Lenbach, Defregger, Max and Grützner. He died at Munich on the 21st of July 1886.

PILSEN (Czech, Pilsen), a town of Bohemia, Austria, 68 m. W.S.W. of Prague by rail. Pop. (1890), 68,392, of which 94% are Czech. It is the second town of Bohemia, and lies at the confluence of the Radhusa and the Mies. It consists of the town proper, which is regularly built and surrounded with parapets, and the suburbs, and of three wawas. The most prominent buildings are the Gothic church of St Bartholomew, said to date from 1202, whose tower (325 ft.) is the highest in Bohemia, and the fine Renaissance town hall dating from the 16th century. The staple article of manufacture and commerce is beer, which is exported to all parts of the world. Other industrial products are machinery, enamelled thinware, leather, alum, paper, earthenware, stoves and spirits, while a tolerably brisk trade is carried on in wool, leathers, cattle and horses. In the neighbourhood are several coal-pits, iron-works and glass-works, as well as large deposits of kaolin.

Pilsen first appears in history in 976, as the scene of a battle in the war between Prince Bolenaus and the emperor Otto II., and it became a town in 1272. During the Hussite wars it was the centre of Catholic resistance to the Hussites; it was three times unsuccessfully besieged by Prokop the Great, and it took part in the league of the Romanist lords against King George of Podebrad. During the Thirty Years' War the town was taken by Mansfeld in 1618 and not recaptured by the Imperialists till 1621. Wallenstein made it his winter-quarters in 1633, and it was in the great hall of the Rathaus that his generals took the oath of fidelity to him (January 1634). The town was unsuccessfully besieged by the Swedes in 1637 and 1649. The first Bohemian printing press was established in the house in 1453, and the whole of its productions were of great importance in the spread of the Reformation, and the publication of the works of Vondel, and of three suburbs.

PIIMA, a tribe and stock of North American Indians. Their range was southern Arizona and northern Mexico. The ruined Pima village, known to the Spanish as Casa Grande on the south bank of the Gila, is an example of their early civilization and skill in building. Driven out of their homes by neighbouring tribes, they lived a more or less nomadic life. They were always good farmers, showing much skill in irrigation. At first submitting to the Spaniards, they revolted in 1751, destroying all the missions. The war lasted two years, but since then the Pima Indians have been friendly with the settlers. As a race they are brave, honest and hard working. They number some 5000 on two reservations in Arizona. The Piman stock includes such tribes as the Papago, Huichol, Opata, Tarumari, and numbers upwards of a hundred thousand.

PIMENTO, also called Allspice (from a supposed combination of various flavours) and Jamaica pepper, the dried immature fruit of Eugenia pimento or Pimenta officinalis, an evergreen tree about 30 ft. high, belonging to the natural order Myrtaceae. It is indigenous in the West India Islands, growing on limestone hills near the sea, and is especially grown in Jamaica. The spice derives its name from the Portuguese pimenta, Spanish pimienta, pepper, which was given to it from its resemblance to

Pilot-fish.
pepper-corus. The berries are gathered in July and August, when of full size, but still unripe—the small branches bearing fruit being broken off and dried in the sun and air for some days, when the straw is removed and the berries are ready for packing. These owe their aromatic properties to an essential oil present to the extent of 3 to 4% and consisting largely of eugenol or allyl guaiacol, HO(CHOH)C₂H₃C₆H₅. The chief use of pimento is as a spice. The oil, the action of which resembles that of cloves, is occasionally used in medicine, and is also employed in perfumery.

The "bay rum" used as a toilet article is a tincture scented with the oil of the leaves of an allied species, Pimenta acris, commonly known as the bayberry tree.

**PIN (a doublet with "pen" from Lat. *pinna*, feather, pinnacle, which is said to contain the same root as *fissur*, pine tree, and properly to mean a sharp point or a slender point of metal or wood, not necessarily pointed, employed as fastening to connect together different parts of an article, as a stop to limit the motion of some moving piece in a machine, as a support on which a smaller wheel may turn, &c., but most commonly as a small metal spike, used for fastening portions of fabrics together, having one end pointed and at the other a bulbous head, or some other arrangement for preventing the spike from passing entirely through the cloth or other material with which it is employed. In one form or another pins of this kind are of the highest antiquity, the earliest form doubtless being a natural thorn. Pins of bronze, and bronze brooches in which the pin is the distal feature, are among the earliest marks of the bronze age. The ordinary domestic pin had become in the 15th century an article of sufficient importance in England to warrant legislative notice, as in 1483 the importation of pins was prohibited by statute. In 1540 Queen Catherine received pins from France, and again in 1543 an act was passed providing that "no person shall put to sale any pins but only such as shall be double headed, and have the heads soldered fast to the shank of the pinnes, well smothed, the shank well shapen, the points well and round filed, canted and sharpened." At that time pins of good quality were made of brass; but a large proportion of those against which the legislative enactment was directed were made of iron wire blanched and passed as brass pins. To a large extent the supply of pins in England was received from France till about 1626, in which year the manufacture was introduced into Gloucestershire by John Tilsey. His business flourished so well that he soon gave employment to 1500 persons, and Stroud pins attained a high reputation. In 1636 the pinmakers of London formed a corporation, and the manufacture was subsequently established at Bristol and Birmingham, the latter town ultimately becoming the principal centre of the industry. So early as 1775 the attention of the enterprising colonists in Carolina was drawn to the manufacture by the offer of prizes for the first native-made pins and needles. At a later date several pin-making machines were invented in the United States. During the war of 1812, when the price of pins rose enormously, the manufacture was actually started, but the industry was not fairly successful till about the year 1836 when the Howe Manufacturing Company was formed at Birmingham, Connecticut. Previous to this an American, Lemuel W. Wright, had in 1824 secured in England a patent for a machine to make solid-headed pins, which established the industry on its present basis.

The old form of pin consisted of a shank with a separate head of fine wire twisted round and secured to it. Fine wire for heads was the first wound on a lathe round a spilt the exact circumference of the pin shanks to be headed. In this way a long elastic spiral was produced which had next to be cut into heads, each consisting of two complements of the spiral. These heads were softened by heating and made into a heat for the heading boy, whose duty it was to thrust a number of shanks into the heat and let them as many as might be fit themselves with heads. Such shanks as came out must next be passed to the headers, who with a falling block and die arrangement compressed together shank and head of such a number as his die-block was fitted for. All the other operations of straightening the wire, cutting, pointing, &c., were separately performed and the finished pin connected with a proper fastening. A common pin were seized on by Adam Smith as one of the most remarkable illustrations of the advantages of the division of labour.

The beautiful automatic machinery by which pins are now made of single pieces of wire is an invention of the 19th century. In 1817 a communication was made at the Patent Office by Seth Hunt, describing a machine for making pins with "head, shaft and point in one piece." The "blistering iron" was cut off and held in a die till a globular head was formed on one end by compression, and the other end was pointed by the revolution of it of a roughened steel wheel. This machine does not require a workman to carry it. The plant passed into the hands of F. Taylor of Birmingham, who obtained an extension of Wright's patent for five years from 1838, and his firm was the first to carry on the production of pins on a commercial basis. In a modern pin-making machine wire of suitable gauge running off a reel is drawn in and straightened by passing between straightening pins or studs set in a table. When a pin length has entered it is caught by lateral jaws, beyond which enough of the end projects to form a pin-head. Against this end a steel punch advances and compresses the metal by a die arrangement into the form of a head. The pin length is immediately cut off at the point of the die so that the finished pin is passably finished with the wire through but retain the head. The pins are consequently suspended by the head while their projecting extremities are held together by a knife-block, which is passed over them next cleaned by being boiled in weak beer, and then arranged in a copper pan in layers alternating with layers of grated tin. The contents of the pan are covered with water over which a quantity in the form of a rain of iron pins is sprinkled. After several hours the bars pins are coated with a thin deposit of tin, which gives them their silvery appearance. They are then washed in clean water, dried and polished by being revolved in a barrel, and then with a heavy brush or one made of iron wire, and finally polished by being polished on a stone, the finished pins. A large proportion of the pins sold are stuck into paper by an automatic machine not less ingenious than the pin-making machine itself. Pleasing pins are made of iron wire, finished by immersing in black lacquer and drying in a stove. A considerable variety of pins, including the ingeniously coiled, bent and twisted nursery safety pin, ladies' hairpins, &c., are also technically good. The size of a pin or brooch varies from the 3½-in. stout blanket pin down to the finest slender gilt pin used by entomologists, 4500 of which weigh about an ounce.

**PINA, RUY DE (1440-1521), Portuguese chronicler, was a native of Guarda. He acted as secretary of the embassy sent by King John II. to Castile in the spring of 1482, and in the following September returned there as sole envoy. He was present at the execution of the duke of Braganza at Evora in 1483, and in 1484 went to Rome as secretary of an embassy to Pope Innocent VII. On his return, the king charged him to write a history of his reign and gave him a pension for his support. Following the arrival of Columbus from his first voyage in 1493, Pina was one of the commissaries despatched to Barcelona by John II. to negotiate with the Catholic sovereigns respecting the limits of their respective jurisdictions. In September 1495 he attested the will of John II. in his capacity as a notary public, and on the 25th of October of the same year he was present at his master's death at Alvor and opened and read his testament. John Manoel confirmed his pension and appointed him in 1497 chronicler of the kingdom, keeper of the archives and royal librarian, with a suitable salary. By 1504 Pina had completed his chronicles of Alphonso V. and John II. King John III. charged him with a history of his father, Manoel, and at his death Pina had carried it down to the capture of Azamor, as we know from Damião de Gois, who used it in preparing his own chronicle of that monarch.

It is probable that the chronicles of the early kings of Portugal from Sancho I. to Alphonso IV. which were published under Pina's name in the 18th century were written by Fernão Lopes and edited by Pina, while that of King Duarte seems to have been written by Duarte de Albuquerque and Antonio de Paiva, Pina being as the editor only. Pina was a favourite of fortune during his life, for, apart from royal benefactions, he received presents from public men who wished to figure well in his books, and after his death he obtained the credit for work that was not his. His authority as an historian is considerable, and his frankness is said to have provoked remark from contemporaries.

Pina's chronicle of King Alphonso IV. was first published in Lisbon in 1583; those of King Duarte and King Alphonso V. in vol. i. of the *Collección de libros inéditos de la historia portuguesa*.
PINACOTHECA—PINCKNEY, C. C.

(Lisbon, 1790), and his chronicle of John II. in vol. ii. of the same collection (Lisbon, 1792). The introduction to the chronicle of King Duarte contains the fullest account of Pina's life. (E. P.)

**PINACOTHECA**, a picture-gallery (Gr. παναθήκη, from πᾶν, a tablet or picture). The name is especially given to the building containing pictures which formed the left wing of the Propylæum on the Acropolis at Athens. Though Pausanias (Bk. II., xxii. 6) speaks of the pictures "which time had not effaced," which seems to point to fresco painting, the fact that there is no trace of any preparation for stucco is rather shown that the paintings were cast pictures (J. G. Frazier, Pausanias's Descriptions, p. 168, 1808, ii. 259). The Romans adopted the term for the room in a private house containing pictures, statues, and other works of art. It is used for a public gallery on the continent of Europe, as at Bologna and Turin. At Munich there are two galleries known as the Old and New Pinakothek.

**PINAR DEL RIO**, capital of Pinar del Rio Province, Cuba, about 107 m. S.W. by railway from Havana. Pop. (1907), 16,634. The city is in the fertile valley of the Guama. It is the centre of the tobacco industry of the Vuelta Abajo region. Its port is La Coloma, on the southern coast. The pueblo was created after 1773; but the historical settlement goes back to the 16th century. The principal church dates from 1710.

**PINCKNEY, CHARLES** (1757–1824), American statesman, was born on the 26th of October 1757 at Charleston, South Carolina; he was the son of Charles Pinckney (1731–1784), first president of the South Carolina Provincial Congress (Jan. to June 1775), and a cousin of Charles Cotesworth Pinckney and Thomas Pinckney. He was studying law at the outbreak of the War of Independence, served in the early campaigns in the South, and in 1770 was elected to the South Carolina House of Representatives. He was captured by the British at the fall of Charleston (1780), and received a pardon under the close of hostilities in 1784. He was elected a delegate to the Congress of the Confederation in 1784, 1785 and 1786, and in 1786 he moved the appointment of a committee "to take into consideration the affairs of the nation," advocating in this connexion an enlargement of the powers of Congress. The committee having been appointed, Pinckney was made chairman of a sub-committee which prepared a plan for amending the articles of confederation. In 1787 he was a delegate to the Federal constitutional convention, and on the same day (May 29) on which Edmund Randolph (q.v.) presented what is known as the Virginia plan, Pinckney presented a draft of a constitution which is known as the Pinckney plan. Although Randolph's resolution was adopted in the convention, Pinckney's plan seems to have been much drawn upon. Furthermore, Pinckney appears to have made valuable suggestions regarding phrasing and matters of detail. On the 18th of August he introduced a series of resolutions, and to him should probably be accredited the authorship of some thirty-one or thirty-two provisions of the constitution.1 Pinckney was president of the State Convention of 1790 that framed a new constitution for South Carolina, was governor of the state from 1790 to 1792, a member of the State House of Representatives in 1792–1796, and again governor from 1796 to 1798. From 1790 to 1801 he was a member of the United States Senate. He entered public life as a Federalist, but later became the leader in organizing the Democratic-Republican party in his state, and contributed largely to the success of Thomas Jefferson in the presidential election of 1800. By Jefferson's appointment he was American minister to Spain from 1801 to 1805. In general his mission was a distinct failure, his arrogance created friction finally among the Spanish government to request his recall. He was elected to the State House of Representatives in 1805, was again governor of South Carolina from 1806 to 1808, in 1810–1814 was once more a member of the State House of Representatives, in which he defended President Madison's war policy, and from 1819 to 1821 was a member of the National House of Representatives, in which he opposed the Missouri Compromise in a brilliant speech. He died at Charleston, South Carolina, on the 20th of October 1824.

His son, **HENRY LAURENS PINCKNEY** (1794–1863), was a member of the state House of Representatives in 1816–1832, founded in 1819 and edited for fifteen years the Charleston Mercury, the greatest exponent of state's rights principles, and was a member of the National House of Representatives in 1833–1837.

**PINCKNEY, CHARLES COTESWORTH** (1746–1825), American statesman, was born in Charleston, South Carolina, on the 25th of February 1746, the son of Charles Pinckney (d. 1758),2 by his second wife, the celebrated girl planter, Eliza Lucas. When a child he was sent to England, like his brother Thomas after him, to be educated. Both of them were at Westminster and Oxford and were called to the bar, and for a time they studied in France at the Royal Military College at Caen. Returning to America in 1769, C. C. Pinckney began the practice of law at Charleston, and soon became deputy-governor of South Carolina. He was a member of the first South Carolina provincial congress in 1775, served as colonel in the South Carolina militia in 1776–1777, was chosen president of the South Carolina Senate in 1779, took part in the Georgia expedition and the attack on Savannah in the same year, was captured at the fall of Charleston in 1780 and was kept in close confinement until 1782, when he was exchanged. In 1783 he was commissioned a brevet brigadier-general in the continental army. He was an influential member of the constitutional convention of 1787, advocating the counting of all slaves as a basis of representation and opposing the abolition of the slave-trade. He opposed as "impracticable" the election of representatives by the people, and also opposed the election of senators, who, he thought, should be men of wealth. Subsequently Pinckney bore a prominent part in securing the ratification of the Federal constitution in the South Carolina convention called for that purpose in 1788 and in framing the South Carolina State Constitution in the convention of 1790. After the organization of the Federal government, President Washington offered him at different times appointments as associate justice of the Supreme Court (1791), secretary of war (1795) and secretary the document sent by Pinckney to Adams in 1818 is a genuine copy of his luggage. It is as a result of their efforts to reconstruct his original plan chiefly from his speeches, or alleged speeches, that the walls rather showed that the paintings were cast pictures. J. F. Jameson, Studies in the History of the Federal Convention of 1787," in the Annual Report of the American Historical Association for 1902, vol. i.; A. C. McLaughlin, "Outline of Pinckney's Plan for a Constitution," in The Nation, April 28, 1904; an article entitled "Sketch of Pinckney's Plan for a Constitution," in the American Historical Review for July 1904; and C. C. Nott, The Mystery of the Pinckney Draft (New York, 1908), an attempt by a former chief-justice of the U.S. Court of Claims to prove that

1 The "Pinckney Plan" has been the subject of considerable discussion. When, in 1818, John Quincy Adams was preparing the journal of the convention for publication, and was convinced that the Pinckney plan was missing, he wrote to Pinckney for a copy, and Pinckney sent him what he asserted was either a copy of his original draft or a copy of a draft which differed from the original in no essential particular. This was apparently to be a class to the draft reported by the committee of detail, Madison and others, who had been members of the convention, as well as historians, treated it as spurious, and for years Pinckney received little credit for his work in the convention. Later historians, however, notably J. Franklin Jameson and Andrew C. McLaughlin, have accredited to him the suggestion of a number of provisions of the constitution as a result of their efforts to reconstruct his original plan chiefly from his speeches, or alleged speeches, that the walls rather showed that the paintings were cast pictures. J. F. Jameson, Studies in the History of the Federal Convention of 1787," in the Annual Report of the American Historical Association for 1902, vol. i.; A. C. McLaughlin, "Outline of Pinckney's Plan for a Constitution," in The Nation, April 28, 1904; an article entitled "Sketch of Pinckney's Plan for a Constitution," in the American Historical Review for July 1904; and C. C. Nott, The Mystery of the Pinckney Draft (New York, 1908), an attempt by a former chief-justice of the U.S. Court of Claims to prove that

2 Charles Pinckney, the father, was long prominent in colonial affairs; he was attorney-general of the province in 1733, speaker of the assembly in 1736–1738 and in 1746, chief justice of the province of Antigua, of which he was governor, and a member of the British army, who about 1738 removed from Antigua to South Carolina, where he acquired several plantations. He was almost immediately recalled to Antigua, and his daughter under-took the management of the plantation. She is said to have been the first to introduce into South Carolina (and into continental North America) the cultivation and manufacture of indigo, and she also imported silkworms—in 1753 she presented to the princess of Wales a dress made of silk from her plantations. She was married to Charles Pinckney in 1744. See Harriott H. Ravenel, Eliza Pinckney (New York, 1896), in the "Women of Colonial and Revolutionary Times." series.
of state (1795), each of which he declined; but in 1796 he succeeded James Monroe as minister to France. The Directory refused to receive him, and he retired to Holland, but in the next year, Elbridge Gerry and John Marshall having been appointed to act with him, he again repaired to Paris, where he is said to have made the famous reply to Berthenoux, "I must have a loan" (in reality for a gift), "Millions for defense, but not one cent for tribute,"—another version is, "No, not a sixpence."

The mission accomplished nothing, and Pinckney and Marshall left France in disgust, Gerry (q.v.) remaining. When the correspondence of the commissioners was sent to the United States Congress the letters "X," "Y" and "Z," were inserted in place of the names of the French agents with whom the commission treated—hence the "X Y Z Correspondence," famous in American history. In 1800 he was the Federalist candidate for vice-president, and in 1804 and again in 1808 for president, receiving 14 electoral votes in the former and 47 in the latter year. From 1805 until his death, on the 16th of August 1825, he was president-general of the Society of the Cincinnati.

PINCNEY, THOMAS (1750-1828). American statesman and diplomat, was born in Charleston, South Carolina, on the 23rd of October 1750, a younger brother of Charles Cotesworth Pinckney (q.v.). Educated in England, he returned to Charleston in 1773, and was admitted to the bar in 1774. During the War of Independence his early training at the French military college at Caen enabled him to render effective service to General Benjamin Lincoln in 1778-1779, to Count d'Estaing (1779), to General Lincoln in the defence of Charleston and afterwards to General Horatio Gates. In the battle of Camden he was badly wounded and captured, remaining a prisoner for more than a year. Subsequently he was governor of South Carolina in 1787-1789; presided over the state convention which ratified the Federal constitution in 1788; was a member of the state legislature in 1791; and was United States minister to Great Britain in 1792-1796. During part of this time (1794-1795) he was also envoy extraordinary to Spain, and in this capacity negotiated (1795) the important Treaty of San Lorenzo el Real; by that treaty the boundary between the United States and East and West Florida and between the United States and "Louisiana" was settled (Spain relinquishing all claims east of the Mississippi above 31° N. lat.), and the United States secured the freedom of transportation to the Mississippi to its mouth with the right of deposit at New Orleans for three years, after which the United States was to have the same right either at New Orleans or at some other place on the Mississippi to be designated by Spain. In 1796 Pinckney was the Federalist candidate for vice-president, and in 1797-1801 he was a Federalist representative in Congress. During the War of 1812 he was a major-general. In 1825 he succeeded his brother as president-general of the Society of the Cincinnati. He died in Charleston on the 2nd of November 1828. Pinckney, like many other South Carolina revolutionary leaders, was of aristocratic birth and politics, closely connected with England by ties of blood, education and business relations. This renders the more remarkable their attitude in the War of Independence, for which they made great sacrifices. The Men of Pinckney's type were not in sympathy with the progressive democratic spirit of America, and they began to withdraw from politics after about 1800.

See C. C. Pinckney, Life of General Thomas Pinckney (Boston, 1895).

PINDAR (Gr. Πίνδαρος, c. 522-443 B.C.), the great lyric poet of ancient Greece, was born at Cynocephaelae, in Boeotia, at the time of the Pythian games (fr. 175, Bergk 4, 103), which is taken by Böck to be 522 B.C. He would thus be some thirty-four years younger than Simonides of Ceos. He was the son of Daliphants and Cleodice (or Cleidice). The traditions of his family have left too much room for poetry, and are not without some chance of a correct estimate of his relation to his contemporaries. The clan of the Aegidae—tracing their line from the hero Aegus—belonged to the "Cadmean" element.

1 The references are to the edition of Pindar by C. A. M. Fennell (1893-1899), and the fourth edition of Bergk's Poetae lyrici graeci.

2 According to others, his latest poem is the eighth Pythian ode, 450 or 446.

3 Πίνδαρος ψιθυρίς, in ed. Ald.
victory of the Athenian Megacles; he begins thus: “Fairest of preludes is the renown of Athens for the mighty race of the Alcaimonides. What home, or what house, could I call mine by a name that should sound more glorious for Hellas to hear?” Referring to the fact that an Aeginetan victor in the games had been trained by an Athenian, he says (Nem. v. 49) “meet it is that a shaper of athletes should come from Athens”—and recollecting how often Pindar compares the poet's efforts to the athlete's, we may well believe that he was thinking of his own entry among the victors at Aegina.

Pindar's versatility as a lyric poet is one of the characteristics remarked by Horace (Odes, iv. 2), and is proved by the fragments, though the poems which have come down entire represent only one class of compositions—the Epinicia, or odes of victory, commemorating successes in the great games. The lyric types to which the fragments belong, though it cannot be assumed that the list is complete, are at least numerous and varied.

(1) Τυρών, Ημέρας to deities—as to Zeus Ammon, to Persephone, to Fortune. The fragmentary hymn entitled Οἰδίπων seems to have celebrated the deities of Thebes. (2) Πινδάρον, Fragments: πατρίδα, expressing prayer or prayer for the help of a protecting god, especially Apollo, Artemis or Zeus. (3) Παναίδες, a form of Dithyramb, the Panhellenic kind, sung by choruses in honour of Dionysus (cf. Pind. Ol. xii. 18, ταὶ δέοντα κλαθέντα γαίροντας σεθεντω ἴδρας ἔωιςβάθμια—where Pindar alludes to the choral form given to the dithyramb, by Arion; cf. xi. 161, ἵππον πατρίς αὐξάνοντας ἐκ τιμής." (4) Νυσταλία, Processional Songs, choral chants for worshippers approaching a shrine. One was written by Pindar for the Delians, another for the Aeginetans. (5) Πυθικά, Choral Songs or Māides. The reference in Pyth. iii. 78 to maidens worshipping Cybele and Pan near the poet's house is illustrated by the fact that one of these Nysaiae invoked Pan, lord of Arcadia, attendant of the Great Mother, watcher of the Pythian Games (vii. 22, 72, Bergk, 95). (6) Τραγούδια, Choral Dance-Songs, adapted to a lively movement, used from an early date in the cult of Apollo, and afterwards in that of other gods, especially Dionysus. Thus belonging to the finest fragments (84, Bergk's 107). written for the Thebans in connection with propitiatory rites after an eclipse of the sun, probably that of the 30th of April 463 B.C. (7) Επινίξεια, Songs of Praise (for men, while ἤμφειρα for gods), to be sung by a σῶμα or festal company. In strictness Επινίξεια was the genus of which Πνίκεις was a species; but the latter is more conveniently treated as a distinct kind. Pindar wrote encomia for Theron, despot of Acragas, and for his grandfather of Pegase. A number of small fragments, which cannot be certainly classified, are usually given as Επινίξεια or Επινίξεια, "of uncertain class." On comparing the above list with Horace, Odes, iv. 2, it will be seen that he alludes to No. 3 (dithyrambo), No. 2 (_panathenaic), and 7 (epinicia). One of the smaller fragments (Pyth. i. 157) in memory of an Athenian who had been initiated into the Eleusinian mysteries (ἰὼν εἴρηκα)—has been conjecturally referred to the Οἰδίπων which Pindar is said to have written (schol. Pyth. vii. 18) for Hippocrates, the grandfather of Pegase. A number of small fragments, which cannot be certainly classified, are usually given as Επινίξεια or Επινίξεια, "of uncertain class." On comparing the above list with Horace, Odes, iv. 2, it will be seen that he alludes to No. 3 (dithyrambo), No. 2 (Panathenaic), and 7 (Epinicia). One of the smaller fragments (Pyth. i. 157) in memory of an Athenian who had been initiated into the Eleusinian mysteries (ἰὼν εἴρηκα) has been conjecturally referred to the Οἰδίπων which Pindar is said to have written (schol. Pyth. vii. 18) for Hippocrates, the grandfather of Pegase. A number of small fragments, which cannot be certainly classified, are usually given as Επινίξεια or Επινίξεια, "of uncertain class."
of Corinth, in honour of Poseidon, once in two years, the first and third of each Olympiad. The Greek way of citing an ode is by its number, followed by the numeral, e.g. “the ninth Olympian” is “Οἰμικοσκεύη 9ος.” The chronological range of the collection (so far as ascertainable) is from 602 B.C. (Pyth. x) to 452 B.C. (Ol. v.). With respect to the native places of the victors, the geographical distribution is as follows: for the mainland of Greece proper, 13 odes; for Aegina, 11; for Sicily, 15; for the Epizephyrian Locrians (southern Italy), 2; for Cyrene (Africa), 3.

The general characteristics of the odes may be briefly considered under the following heads: (1) language; (2) treatment of theme; (3) sentiment—religious, moral and political; (4) relation to contemporary events.

The reason of Pindar is distinct in character from that of every other Greek poet, being almost everywhere marked by the greatest imaginative boldness. Thus (a) metaphor is used even for the expression of common ideas, or the translation of familiar phrases, as when a cloak is called (Ol. ix. 97) “a warm remedy for winds.” (b) Images for the highest excellence are drawn from the farthest limits of travel or navigation, or from the fairest of natural objects; as when the superlative hospitality of a man who kept open house all year round is described by saying, “far as to Phasis was his voyage in summer days, and in winter to the shores of Nile” (Isthm. ii. 41); or when Olympian, the “crown” or “flower of festivals,” is said to be excellent as water, bright as gold, brilliant as the noonday sun (Ol. i. ad init.). This trait might be called the Pindaric imagery of the superlative. (c) Poetical inversion of ordinary phrase is frequent; as, instead of, “he struck fear into the beasts,” “he gave the beasts to fear” (Pyth. v. 50). (d) The efforts of the poet’s genius are represented under an extraordinary number of similitudes, borrowed from javelin-throwing, chariot-driving, leaping, rowing, sailing, ploughing, building, with the bow, sharpening a knife on a whetstone, mixing wine in a bowl, and many more. (e) Homely images, from common life, are not rare; as from account-keeping, usury, sending merchandise over sea, the σώματα or secret dispatch, &c. And we have such homely proverbs as, “he hath his foot in this shoe,” i.e. stands in this case (Ol. vi. 8). (f) The natural order of words in a sentence is often boldly deranged, while, on the other hand, the syntax is seldom difficult. (g) Words not found except in Pindar are numerous, many of these being compounds which (like ἐναριμβρότος, καταφυλλορεῖν, &c.) suited the dactylic metres in their Pindaric combinations. Horace was right in speaking of Pindar’s “nova verba,” though they were not confined to the “audaces dithyrambii.”

2. The actual victory which gave occasion to the ode is seldom treated at length or in detail—which, indeed, only exceptional incidents could justify. Pindar’s method is to take some heroic myth, or group of myths, connected with the victor’s city or family, and, after a brief prelude, to enter on this, returning at the close, as a rule, to the subject of the victor’s merit or good fortune, and interspersing the whole with moral comment. Thus the fourth Pythian is for Arcesilas, king of Cyrene, which was said to have been founded by men of Thera, descendants of one of Jason’s comrades. Using this link, Pindar introduces his splendid narrative of the Argonauts. Many odes, again, contain shorter mythical episodes—as the birth of Iamus (Ol. vi.), or the vision of Bellerophon (Ol. xii.)—which form small pictures of masterly finish and beauty. Particular notice is due to the skill with which Pindar often manages the return from a mythical derivation to his immediate theme. It is bold and swift, yet is not felt as harshly abrupt—justifying his own phrase at one such turn—καὶ τῶν ὀλίγων ὑπακοή Βραχίων (Pyth. iv. 247). It has been thought that, in the parenthesis about the Amazons’ shields (quibus Mos unde deducitur quaevere distulti, Odes, iv. 4, 18), Horace was imitating a Pindaric transition; if so, he has illustrated his own observation as to the peril of imitating the Theban poet.

3. The religious feeling of Pindar is strongly marked in the odes. “From the gods are all means of human excellence.” He will not believe that the gods, when they dined with Tantalus, ate his son Pelops; rather Poseidon carried off the youth to Olympus. That is, his reason for rejecting a scandalous story about the gods is purely religious, as distinct from moral; it shocks his conception of the divine dignity. With regard to oracles, he inculcates precisely such a view which would have been most acceptable to the Delphic priesthood, viz. that the gods do illumine their prophets, but that human wit can foresee nothing which the gods do not choose to reveal. A mystical doctrine of the soul’s destiny after death appears in some passages (as Ol. ii. 66 sqq.). Pindar was familiar with the idea of metempsychosis (cf. ibid. 68), but the attempt to trace Pythagoreanism in some phrases (Pyth. ii. 34, iii. 74) appears unsafe. The belief in a fully complex cosmology, and in the state, determined by the character of the earthly life, entered into the teaching of the Eleusinian and other mysteries. Comparing the fragment of the Οἰνοπός (114, Bergk, 173), we may probably regard the mystic or esoteric element in Pindar’s theology as due to such a source.

b. The moral sentiment pervading Pindar’s odes rests on a constant recognition of the limits imposed by the divine will on human effort, combined with strenuous exhortation that each man should strive to reach the limit allowed in his own case. Native temperament (φυσις) is the grand source of all human excellence (ἀρετή), while such excellences as can be acquired by study (διδασκαλία ἀρετῆς, Ol. ix. 100) are of relatively small scope—the sentiment, we may remark, of one whose thoughts were habitually conversant with the native qualities of a poet on the one hand and of an athlete on the other. The elements of τρίγυρα δίδοντος—"sane happiness," such as has least reason to dread the jealousy of the gods—are substance sufficient for daily wants and good repute (ἀθλογία). He who has these should not “seek to be a god.” “Wealth set with virtues” (πλοῦτος ἀρετῆς διδόμενος), as gold with precious gems, is the most fortunate lot, because it affords the amplest opportunities for honourable activity. Pindar does not rise above the ethical standard of an age which said “love thy friend and hate thy foe” (cf. Pyth. ii. 83; Isthm. iii. 65). But in one sense he has a moral elevation which is distinctively his own; he is the glowing prophet of generous emulation and of reverent self-control.

c. The political sentiments of the Theban poet are suggested by Pyth. xi. 52; “In politics I find the middle state crowned with more enduring good; therefore praise I not the despotic portion; those virtues move my zeal which serve the folk.” If in Pyth. ii. 87, a democracy is described as ἅδικος στρατός, “the raging crowd,” it is to be noted that the ode is for Hiero of Syracuse, and that the phrase clearly refers to the whole of those of his speeches hostile to part of the 5th century B.C., more than once convulsed Sicilian cities. At Thbes, after the Persian wars, a “constitutional oligarchy” (Ἀγαρχία λεσθομένου, Thuc. iii. 62) had replaced the narrower and less temperate oligarchy of former days (δυναστεία ὡς μετὰ νόμων); and in this we may probably recognize the phase of Greek political life most congenial to Pindar. He speaks of a king’s lot as unique in its opportunities (Ol. i. 113); he sketches the character of an ideal king (Pyth. iii. 71); but nothing in his poetry implies liking for the τυραννία as a form of government. Towards the Greek princes of Sicily and Cyrene his tone is ever one of manly independence; he speaks as a Greek citizen whose lineage places him on a level with the proudest of the Dorian race, and whose office invests him with an almost sacred dignity. In regard to the politics of Hellas at large, Pindar makes us feel the new sense of leisure for quiet pursuits and civilizing arts which came after the Persian wars. He honours “Tranquillity, the friend of cities” (Ἀστυφυλάκεια, Ol. iv. 16). The epic poet sang of wars; Pindar celebrates the “rivalries of peace.”

4. Pindar’s genius was boldly original; at the same time he was an exquisite artist. “Mine be it to invent new strains, mine the skill to hold my course in the chariot of the Muses; and may courage go with me, and power of ample grasp” (Ol.)
ix. 80). Here we see the exulting sense of inborn strength; in many other places we perceive the feeling of conscious art—as in the phrase ἀλλὰ ἄνθρωπος, so apt for his method of inlaying an ode with mythical subjects, or when he compares the opening of a song to the front of a stately building (Ol. vi. 3). The symphony of sound with external nature was deeper and keener than is often discernible in the poetry of his age. It appears, for example, in his welcome of the season when "the chamber of the hours is opened, and delicate plants perceive the fragrant spring" (fr. 53, Bergk 4, 75); in the passage where Jason invokes "the rushing strength of waves and winds, and the nights, and the paths of the deep" (Pyth. iv. 193); in the lines on the eclipse of the sun (fr. 84, Bergk 4, 107); and in the picture of the eruption, when Etna, pillar of the sky, nurse of keen snow all the year," sends forth "pure springs of fire unapproachable" (Pyth. i. 29). The poet's feeling for colour is often noticeable—as in the beautiful story of the birth of Iamus—when Evadne lays aside her silver pitcher and her girdle of scarlet web; the babe is found, "its delicate body steeped in the golden and deep purple rays of pansies" (Ol. vi. 55).

"The spirit of art, in every form, is represented for Pindar by χάρας—"the source of all delights to mortals" (Ol. i. 30)—or by the personified Charites (Graces). The Charites were often represented as young maidens, decoying themselves with early flowers—the rose, in particular, being sacred to them as well as to Aphrodite. In Pindar's mind, as in the old Greek conception from which the worship of the Charites sprang, the instinct of beautiful art was inseparable from the sense of natural beauty. The period from 500 to 460 B.C. to which most of Pindar's extant odes belong, marked a stage in the development of Greek sculpture. The schools of Argos, Sicyon and Aegina were effecting a transition from archaic types to the art which was afterwards matured in the age of Pheidias. Olympia forms the central link between Pindar's poetry and Greek sculpture. From about 560 B.C. onwards sculpture had been applied to the commemoration of athletes, chiefly at Olympia. In a striking passage (Nem. v. ad. init.) Pindar recognizes sculpture and poetry as sister arts employed in the commemoration of the athlete, and contrasts the merely local effect of the statue with the wide diffusion of the poem. "No sculptor I, to fashion images that shall stand for one pedestal for aye; no, go thou forth from Aegina, sweet song of mine, on every freighted ship, on each light bark." Many particular subjects were common to Pindar and contemporary sculpture. Thus (1) the sculptures on the east pediment of the temple at Aegina represented Heracles coming to seek the aid of Telamon against Troy—a theme brilliantly treated by Pindar in the fifth Isthmian; (2) Hiero's victory in the chariot-race was commemorated at Olympia by the joint work of the sculptors Onatas and Calamis; (3) the Gigantomachia, (4) the wedding of Heracles and Hebe, (5) the war of the Centaurs with the Lapithae, and (6) a contest between Heracles and Apollo, are instances of mythical material treated alike by the poet and by sculptors of his day. The contemporary improvements in town architecture, introducing spacious and well-paved streets, such as the στρωμή ὄδοι at Cyrene (Pyth. v. 87), suggests his frequent comparison of the paths of song to broad and stately causeways (παλαιὰς πρόσδος—ἐκκοιμώμενοι κλεόβοι, Nem. vi. 47; Isthm. vi. 22). A song is likened to cunning work which blends gold, ivory and coral (Nem. vii. 78). Pindar's feeling that poetry, though essentially a divine gift, has a technical side (σοφία), and that on this side it has had an historical development like that of other arts, is forcibly illustrated in his early attempts to found new metres (ten trochees) which Corinth had early been famous. He instances (1) the development of the dithyramb, (2) certain improvements in the harnessing and driving of horses, and (3) the addition of the pediment to temples (Ol. xii. 21).

In the development of Greek lyric poetry two periods are broadly distinguished. During the first, from about 600 to 500 B.C., lyric poetry is local or tribal—as Alcaeus and Sappho write for Lesbians, Alcman and Steichochorus for Dorian. During the second period, which takes its rise in the sense of Hellenic unity created by the Persian wars, the lyric poet addresses all Greece. Pindar and Simonides are the great representatives of this second period, to which Bacchylides, the nephew of Pindar, belongs. The works of these poets are classed by German writers as die universalen Meliche. The Greeks usually spoke, not of "lyric," but of "melic" poetry (i.e. meant to be sung, and not, like the epic, recited); and "universal melic" is lyric poetry addressed to all Greece. But Pindar is more than the chief extant lyricist. Epic, lyric and dramatic poetry succeeded each other in Greek literature by a natural development. Each of them was the spontaneous utterance of the age which brought it forth. In Pindar we can see that phase of the Greek mind which produced Homeric epics passing over into the phase which produced Athenian drama. His spirit is often thoroughly dramatic—witness such scenes as the interview between Jason and Pelias (Pyth. iv), the meeting of Apollo and Chiron (Pyth. ix.), the episode of Castor and Polydeuces (Nem. x.), the entertainment of Heracles by Telamon (Isthm. v.). Epic narrative alone was no longer enough for the men who had known that great trilogy of national life, the Persian invasions; they longed to see the heroes moving and to hear them speaking. The poet of Olympia, accustomed to see beautiful forms in vivid action or vivid art, was well fitted to be the lyric interpreter of the new dramatic impulse. Pindar has more of the Homeric spirit than any Greek lyric poet known to us. On the other hand, he has a genuine, if less evident, kinship with Aeschylus and Sophocles. Pindar's work, like Homer itself, illustrates the spiritual unity of Greek art.

The fact that certain glasses and lacunae are common to all our MSS. of Pindar makes it probable that these MSS. are derived from a common archetype. Now the older scholia on Pindar, which appear to have been compiled mainly from the commentaries of Didymus (15 c.e.), sometimes presuppose a purer text than is to be gathered from our best MSS. But the corruption of Didymus is often less than the corruption of his MSS. (A.D. 160). The archetype of our MSS. then, cannot have been older than the end of the 2nd century. Our MSS. fall into two general divisions: (1) those presenting a text which, though often corrupt, is comparatively free from interpolation; and (2) the later, which exhibit the traces of a Byzantine recension, in other words, of lawless conjecture, down to the 14th or 15th century. To the first class belong Parisinus 7, breaking off in Pyth. v.; Ambrosianus 1, which has only Ol. i.—xii.; Mediceus 2; and Vaticanus 2—the two last-named being of the highest value. The editio princeps is the Aldine (Venice, 1513). A modern study of the text of Pindar is best seen in A. F. Schwyzer, Pindar. The edition (1773). Hermann did much to advance Pindaric criticism. But August Böckh (1811–1821), who assisted in his commentary by L. Dissen, is justly regarded as the founder of a scientific treatise on the poet. The text of the Schwyzer edition, new ed. by O. Schröder, 1900) is marked by considerable boldness of conjecture, as that of Tycho Mommsen (1864) by a sometimes excessive adherence to MSS. A recession in W. Chrystal, has been published in Teubner's series (2nd ed., 1896), also with the Prolegomena and commentary (1896); and by O. Schröder (1908). The complete edition of J. W. Donaldson (1841) has many merits; but that of C. A. and E. Fennell (1879–1883; new ed. 1883–1899) is better adapted to the needs of English students. The Olympia and Pythia have been edited by B. L. Gildersleeve (1885), the Nemesis and Isthmia by J. B. Bury (1890–1892); the Scholia by J. Abel (1890, unfinished) and A. B. Brackmann (1903). There is a special lexicon by J. Rumpel (1883). The translation into English prose by Ernest Myers (2nd ed., 1883) is excellent; verse translation by T. C. Baring (1875), and of the Olympic Odes by F. J. D. Girdlestone (1903). The first book of the Olympic Odes was edited by J. H. Schmidt, in Die Kunstformen der griechischen Poesie (Leipzig, 1868–1872). On Pindar generally, see monographs by A. V. Villenmann (1839), L. Schmidt (1862), G. Lübbert (1882), E. Croiset (1880), W. Christ, Geschichte der griechischen Literatur (1888); and the little volume by F. D. Morice in Blackwood's Ancient Classics for English Readers. Exhaustive bibliographical information on the earlier literature will be found in Engemann, Scriptores (1836); see also Schwyzer, cit. (cxi. 1904), with special reference to chronological questions and Pythia, i., ii., iii. Some considerable fragments of the poems were discovered in 1906 by B. F. Grenfell and A. S. Hunt (see Oxyrhynchus papyri, pts. iv. 24–28); some notes will be found in Classical Review, Feb. 1908 (A. E. Hausman). (R. C. J.; X.)

PINDARICS, the name by which was known a class of loose and irregular odes greatly in fashion in England during the close
of the 17th and the beginning of the 18th century. The invention is due to Abraham Cowley, who, probably in Paris—"a place where he had no other books to direct him"—and perhaps in 1659, found a text of Pindar and determined to imitate the Greek poetry in English, without having comprehended the system upon which Pindar's prosody was built up. Cowley published, however, in 1656, fifteen Pindarique Odes, which became the model on which countless imitators founded their pindarics. The erroneous form of these poems, which were absolutely without discipline of structure, was first exposed by Congreve, exactly half a century later, he very justly describing them as "bundles of rambling incoherent thoughts, expressed in a like parcel of irregular stanzas, which also consist of such another complication of disproportionately, uncertain and perplexed verses and rhymes." This is harsh, but it describes a pindaric with absolute justice. Cowley had not been aware that "there is nothing more regular than the Odes of Pindar," and that his poems were constructed in harmony with rigid prosodical laws in strophe, antistrophe and epode; "the liberty which Pindar took in his numbers, which has been so much misunderstood and misapplied by his pretended imitators, was only in varying the stanzas in different odes; but in each particular ode, the stanzas corresponded to anthems of tunes, and according to the order of the ode." These excellent critical remarks were made by Congreve in his Discourse on the Pindarique Ode of 1706, and from that date forward the use of pindarics ceased to be so lax and frantic as it had been during the previous fifty years. The time had now passed in which such a critic as Sprat could praise "this loose and unconfined measure" as having "all the grace and harmony of the most confined." It began to be felt that the English pindaric was a blunder founded upon a misconception. If we examine Cowley's "Resurrection," which was considered in the 17th century to be a model of the style, and "truly pindarical," we find it to be a shapeless poem of 64 lines, arbitrarily divided, not into strophes, but into six stanzas of four lines each, of which these stanzas are of lengths varying from three feet to seven feet, with rhymes repeated in wilful disorder, the whole forming a mere vague caricature of Pindar's brilliant odes. The very laxity of these pindarics attracted the poets of the unlyrical close of the 17th century, and they, with much of the purpose not only of Dryden and Pope, but of a score of lesser poets, among whom Oldham, Mrs Behn, Otway, Sprent, Flatman and many others were prominent. The pindaric became the almost necessary form in which to induce a poem of compliment on a birth, a wedding or a funeral. Although the vogue of these forms hardly survived the age of Anne, something of the vicious tradition of them still remained, and even in the odes of Wordsworth, Coleridge, from the broken versification of Cowley's pindarics occasionally survives. Tennyson's Ode on the Death of the Duke of Wellington (1852) is the latest important specimen of a pindaric in English literature. (E. G.)

PINDARIS, a word of uncertain origin, applied to the irregular horsemen who accompanied the Mahratta armies in India during the 18th century when the Mughal Empire was breaking up; loosely organized under self-chosen leaders, each band was usually attached to one or other of the great Mahratta chieftains. Their special characteristic was that they received no pay, but rather purchased the privilege of plundering on their own account. The majority of them seem to have been Mahomedans: when the regular forces of the Mahrattas had been broken up in the campaigns conducted by Sir Arthur Wellesley and Lord Lake in 1802–04, the Pindaris made their headquarters in the Doon Valley, under the tacit protection of Sindhi and Holkar. They were accustomed to assemble every year at the beginning of November, and sally forth into British territory in search of plunder. In one such raid upon the Marsupatam coast they plundered 339 villages, killing or wounding 682 persons, torturing 3600 and carrying off property worth a quarter of a million. In 1808–09 they plundered Gujarat, and in 1812 Mirzapur. In 1814 they were reckoned at 25,000 to 30,000 horsemen, half of them well armed. At last the evil became intolerable, and in 1817 the marquis of Hastings obtained the consent of the East India Company to the organized campaign, known as the Pindari War. The Pindaris were surrounded on all sides by a great army, consisting of 120,000 men and 300 guns, which converged upon them from Bengal, the Deccan and Gujarat under the supreme command of Lord Hastings in person. Sindhi was overawed and forced to sign the treaty of Gwalior, consenting to aid in the extirpation of the Pindaris, whom he had hitherto protected. The Peshawa at Poona, the Bhonsla raja at Nagpur and the army of the infant Holkar each took up arms, but were separately defeated. The Pindaris themselves offered little opposition. Amir Khan, by far their most powerful leader, accepted the conditions offered to him; and his descendant is now Nawab of the state of Tonk in Rajputana. The rest surrendered or were hunted down, the fate of Chitu, one of the most notorious, being to perish in a tiger's den. These military operations were followed by the pacification of Central India under the administration of Sir John Malcolm.

See J. Grant Duff, History of the Mahrattas (1826); and Major Ross of Bladensburg, Marquess of Hastings (Rulers of India Series) (1893).

PIND DADAN KHAN, a town of British India, in the Jhelum district of the Punjab, situated near the right bank of the river Jhelum, on the Sind-Sugar branch of the North-Western railway. Pop. (1901), 13,770. It is an important centre of trade, and its manufactures include boats, brass-ware, pottery, embroidered scarves and riding-whips.

PINDUS, the ancient name of the rugged group of mountains which separates Thessaly from Epirus, and branches south in various directions. The geographical name is sometimes extended over all these branches, and so reaches from Actolia to the Gulf of Lamia. The northern part of the ridge was known as Laemon. There is no modern name covering the whole range, but its different parts have separate names. Several of these have a height of 2000 ft. or more.

PINE (Lat. Pinus, Gr. πίνους), a name given by the ancients to some of the resinosum cone-bearing trees to which it is now applied, and, as limited by modern botanists, the designation of a large genus of true conifers, differing from the firs in their hard woody cone-scales being thickened at the apex, and in their slender needle-shaped leaves growing from a membranous sheath, either in pairs or from three to five together—each tuft representing an abortive branch, springing from the axil of a partially deciduous scale-leaf, the base of which remains closely adherent to the stem. The numerous male catkins are generally arranged in dense whorls around the bases of the young shoots; the anther-scales, surmounted by a crest-like appendage, shed their abundant pollen by longitudinal slits; the two ovules at the base of the inner side of each fertile cone-scale develop into a pair of winged seeds, which drop from the opening scales when mature—as in the allied genera.

The pines are widely distributed over the north temperate zone, in the southern portions chiefly confined to the mountains, along which, in Central America, a few are found within the tropic; in more northern regions they frequently form extensive forests, sometimes hardly mingled with other trees. Their soft, straight-grained, resinous and often durable wood gives to many kinds a high economic value, and some are among the most esteemed of timber trees.

Of the two-leaved species, P. sylvestris, the pine of northern Europe, may be taken as a type. When growing in perfection it is one of the finest of the group, and perhaps the most picturesque of all forest trees; attaining a height of from 70 to 120 ft., it is of conical growth when young, but in maturity acquires a spreading cedar or mushroom-like top, with a straight trunk of from 2 to 4 ft. in diameter at the base, and gnarled twisted boughs, densely clothed at the extremities with glaucous green foliage, which contrasts strongly with the fiery red-brown bark. The leaves are rather short, curved, and often twisted; the male catkins, in dense cylindrical whorls, fill the air of the forest with their sulphur-like pollen in May or June, and fecundate the purple female flowers, which, at first sessile and erect, then
become recurved on a lengthening stalk; the ovate cones, about the length of the leaves, do not reach maturity until the autumn of the following year, and the seeds are seldom scattered until the third spring; the cone-scales terminate in a pyramidal

recurred point, well marked in the green state and in some varieties in the mature cone, but in others scarcely projecting. *P. sylvestris* is found, in greater or less abundance, from the hills of Finmark and the plains of Bothnia to the mountains of Spain and even the higher forest-slopes of Etna, while in longitude its range extends from the shores of the North Sea to Kamchatka. Nowhere more abundant than in the Scandinavian peninsula, this tree is the true fir (*fur, furu*) of the old Norsemen, and still retains the name among their descendants in Britain, though botanically now classed as a pine. It grows vigorously in Lapland on the lower ground, and is found even at an elevation of 700 ft., while in south Norway it occurs up to 3000 ft., though the great forests from which "Norway pine" timber is chiefly derived are on the comparatively lower slopes of the south-eastern dales; in the highest situations it dwindles to a mere bush. It furnishes the yellow deal of the Baltic and Norway. In Germany, both on the mountains and the sandy plains, woods of "kiefer" are frequent and widely spread, while vast forests in Russia and Poland are chiefly composed of this species; in many northern habitats it is associated with the spruce and birch. In Asia it abounds in Siberia and on the mountains of the Amur region; on the European Alps it occurs at a height of 3600 ft., and on the Pyrenees it is found at still higher elevations; on the northern side of Etna it is said to grow at above 7000 ft. In British natural forests of Scotch fir of any extent are only now found in the Highlands, chiefly on the declivities of the Grampians. In former ages the tree covered a large portion of the more northern part of the island, as well as of Ireland; the numerous trunks found everywhere in the mosses and peat-bogs

of the northern counties of England attest its abundance there in prehistoric times; and in the remoter post-Glacial epoch its range was probably vastly more extended. The tree is not at present indigenous in southern Britain, but when planted in suitable ground multiplies rapidly by the wind-sown seeds; on many of the sandy moors and commons natural pine woods of large extent have been thus formed during the last fifty years.

The Scotch fir is a very variable tree, and certain varieties have acquired a higher reputation for the qualities of their timber than others; among those most prized by foresters is the one called the Braemar pine, the remaining fragments of the great wood in the Braemar district being chiefly composed of this kind; it is mainly distinguished by its shorter and more glaucous leaves and ovoid cones with blunt recurved spines, and especially by the early horizontal growth of its ultimately drooping boughs; of all varieties this is the most picturesque. On the European continent the Hagenau pine of Westphalia is esteemed for the straightness and good quality of its timber. The heartwood of the finer kinds of Scotch fir is of a deep brownish-red colour, abounding in the resin to which its durability is probably due. For all indoor and most outdoor purposes it is as lasting as oak, and for ship planking is perhaps little inferior; from its lightness and elasticity it is well adapted for the construction of yachts and other small fast-sailing craft, and is said to be the best of all wood for masts and large spars; its weight varies from 30 to 40 lb. the cubic foot. The sap-wood is more perishable, but it is useful for fences, casks and a variety of other purposes; soaking in lime-water renders it more lasting; great numbers of young pines are annually cut for railway sleepers, mining timber and numerous agricultural applications; large quantities are consumed for wood-pavement. The quality of the timber

depends greatly on the soil and position in which the trees are grown; the dry slopes of granite or gneissic mountains, or the deep well-drained sandy gravels of the lower country seem to answer equally well; but on clay or wet peat the tree rarely

flourishes, and the timber is always indifferent; it is usually said that the wood is best in the cold climate of its more northern habitats, but a trunk (4 ft. in diameter) grown on the sands of Surrey had heart-wood quite equal to any produced in Glenmore or Rothiemurchus. The rapidity of growth is still more variable: in Britain full maturity is attained from seventy to one hundred and twenty years, but in Norway the trunk increases much more slowly. Schjelderup suggests that a tree felled in the Alten district (about 70° lat.), measuring 2 ft. 10 in. in diameter without the bark, showed four hundred circles of annual growth. In Norway the tree, growing in dense forests, is generally of but moderate girth, and probably this pine nowhere reaches a greater size than in the Scottish woods; a plank from Glenmore forest measured nearly 5 ft. across, and from 3 to 4 1/2 ft. is not an unusual diameter for a British pine tree.

Vast numbers of Scotch firs are raised in nurseries for artificial planting; the seed is sown in the spring, being just covered with earth, and the seedlings transplanted in the second year into rows for further culture, or taken direct from the seed-bed for final planting; sometimes the seed is sown where the trees are intended to grow. A plantation of Scotch fir requires frequent and careful thinning as the young trees increase in size; but pruning should be avoided as much as possible, excepting for the removal of dead wood. Plantations in England are generally ready for final cutting in from sixty to seventy years, and many are cleared at a much earlier stage of growth. P. sylvestris in Britain is liable to many insect depredations: the pine-chafer, Hylurgus piniperda, is destructive in some places, the larva of this beetle feeding on the young succulent shoots, especially in young plantations; Hyllobius abietis, the fir-weep, eats away the bark, and numerous lepidopterous larvae devour the leaves; the pine-barberry is also injurious in some seasons; the removal of all dead branches from the trees and from the ground beneath them is recommended, as most of these insects lay their eggs among the decaying bark and dead leaves. In common with other pines, P. sylvestris is subject to the attacks of various fungi. Trameles radiciperda attacks the roots and penetrates to the stem, causing rotting of the wood; the disease is difficult to eradicate, as the mycelium of the fungus travels from root to root in the soil. Rotting of the wood at the base of the trunk is also caused by Agaricus melleus, which spreads from root to root in the soil by means of its long purple-black, cord-like mycelium; it is, however, less destructive than Peridermium. Damage is often caused by species of Peridermium, which often invade the cortex and cambium to such an extent as to "ring" the stem or branch, or to cause an abnormal formation of turpentine which seeps into the wood and stops the upward passage of water; this causes the parts above the diseased area to perish. In England the pine is largely employed as a "nurse" for oak trees, its conical growth when young admirably adapting it for this purpose; its dense foliage renders it valuable as a shelter tree for protecting land from the wind; it stands the sea gales better than most conifers, but will not flourish on the shore like some other species.

The pine is an important tree in the economy of the northern nations of Europe. In Scandinavia and Russia houses are chiefly constructed of its timber; and log-huts are made of the smaller trunks and lined and roofed with the bark. The inner bark is twisted into ropes, and, like that of the spruce, is kih dried, ground up, and mixed with meal in times of scarcity; in Kamchatka it is macerated in water, then pounded, and made into a kind of substitute for bread without any admixture of flour. In recent days the fibre of the leaves has been extracted in some quantity and applied to textile purposes under the name of waldquelle, both in Germany and Sweden. It is prepared by boiling the needles in a solution of soda to remove the resin, which process loosens the fibre and renders its separation easy; it has some resemblance to coarse wool, and is spun and woven into blankets and garments that are said to be warm and durable; it is also used for stuffing cushions; an essential oil, obtained by a previous distillation of the leaves, has medicinal virtues attributed to it by some German practitioners.

Large quantities of turpentine are extracted from this pine in Sweden and Russia by removing a strip of bark, terminating below in a deep notch cut in the wood, into which the turpentine runs, and from which it is scooped as it accumulates; but the product is not equal to that of the silver fir and other species. Tar is prepared largely from P. sylvestris; it is chiefly obtained from the roots, which, mingled with a few logs, are arranged in a kiln at a distance of a few feet apart, and covered with a mound of straw or turf. After allowing the tar to render for some months, it is drawn off into vats lined with lead; after filling up, the whole is covered with turf and fired at the top, when the tar exudes slowly and runs into an iron vessel placed below, from the spout of which it is conveyed into barrels. Most of the so-called Stockholm tar is thus prepared, chiefly in the province of Bothnia.

Closely allied to the Scotch pine, and perhaps to be regarded as a mere alpine form of that species, is the dwarf P. montana (or P. Pumilio), the "krummholz" or "knieholz" of the Germans—a trunk 1 to 2 ft. high, with a few wide branches, growing in the Alps in the higher grassy pastures. It is apt to develop into a tall tree in the Mediterranean region, where it is known as P. Pinus aquifolius, and is liable to form thickets where it rests upon the ground. The foliage much resembles that of the Scotch fir, but is shorter, finer and more rigid; the cones are smaller but similar in form. Abounding on the higher valleys of the Bavarian and Tirolese Alps, it is a favourite shelter for the chamois; the hunters call it the "latschen," from its recumbent straggling branches. Krummholz fir, valued in Germany as an outlet for the production in rhizomatous and for bristles and sprains, is distilled from the young branches, and a fragrant white resin that exudes in some quantity from the buds is used for similar purposes and as a disinfectant. It is said that the wood is employed in the manufacture of ropes, in the province of Styria. In the rock towns of Germany, being probably obtained from the Carpathians.

The red pine of Canada and New England (so called from the colour of its bark), P. resinosa, is a tree of considerable size, some-what resembling the P. sylvestris in the character of its trunk and branches, and differing only in the glaucous leaves form dense tusfs at the ends of the branches, and are 4 or 5 in. long; the ovate blunt cones are about half that length. The tree is of quick growth and the wood strong and durable, but is less esteemed for shipboard than Scotch fir, though sometimes employed in ship-building; according to Emerson, trunks exist in Maine 4 ft. in diameter. A sandy soil seems to suit it best, and the quality of the wood varies with the nature of the ground. Red pines abound in Nova Scotia and Newfoundland, and the tree is rather widely distributed over the northern parts of the continent; it rarely forms extensive woods, but grows chiefly in open situations on poor soil. The cones are usually three to four in number, and are very durable, though less strong than those of P. sylvestris; the heart-wood is of a brownish-tint. In southern Europe it has been planted with success on the drift-sands of the Bay of Biscay, though it does not bear the full force of the sea-blast as well as the pine. In England it grows well in sheltered situations and well-drained soils; the Scotch pine, P. sylvestris, generally now regarded as a variety of P. Laricio, derives its name from the extreme depth of its foliage tints—the sharp, rigid, rather long leaves of a dark green hue giving a sombre effect to the tree, its light-green, glossy, twisted cones are generally in pairs, but sometimes three or four together. The tree is conical when young, but when old forms a spreading head; it often attains a large size. Southern Europe is the home of the species, and it is said to be not so rapid in growth. The silver pine, P. pumilio, has recently been brought to this country; it seems to flourish best on rocky mountain sides, but in England grows well on sandy soils. The timber is valued in its native country, and is said to be durable and to stand exposure to the weather well. The yellow pine, P. pseudostrobus, resembles the Scotch pine in that its cones are solitary, oblong, conical and of a yellow tint. The timber is used in Spanish dockyards, but opinions vary as to its quality. In plantations its bright foliage, with the orange cones and resinous shoots, render it an ornamental tree, hardy in southern Britain. P. brutia, the Calabrian pine, is regarded as the same.
PINE species. *P. halepensis*, another Mediterranean form, is valued for its timber, which, though not tall or second-rate for panelling or resinous timber, the cluster pine or pinaster, is an important species from its vigorous growth in the sand-drifts of the coast, for the purpose of binding which it has been grown more extensively and successfully than any other tree on the coast of Biscay. Growing to a height of from 40 to 80 ft., the deeplyfurrowed trunk occasionally reaches a diameter of 3 ft. or more at the base, where, like most sand trees, it usually curves upward gradually. Many other trees, especially on the dunes of long, open sand, are better the strain of the sea gale; when once established, the tree is rarely overthrown even on the loosest sand. The branches curve upwards like the stem, with their thick covering of long, rounded leaves growing to the tree; the ovate cones are from 4 to 6 in. long, of a light shining brown hue, with thick scales terminating in a pyramidal apex; they are arranged around the stem like the ridges of a windmill, and the resin is kept in a sort of bag under the leaves. The Pinaster grows naturally on sandy soils around the Mediterranean from Spain to the Levant. On the drift-sands of France, especially in the Gironde, forests have been formed mainly for the manufacture of firewood, but by progressive analogous to that of the Landes.
PINE-APPLE.  

Pine-apple (Ananas sativus) much reduced.

PINEL, PHILIPPE (1745-1826), French physician, was born at the château de Rascas, Saint-André, in the department of Tarn, France, on the 20th of April 1745. He studied at Laval and afterwards at the university of Toulouse, where he took his doctor’s degree in 1773. From Montpellier he removed in 1778 to Paris, engaging there chiefly in literary work connected with his profession. His first publication was a French translation of William Cullen’s Nosology (1783); it was followed by an edition of the works of G. Baglivi (1788), and in 1791 he published a Traité médico-philosophique de l’aliénation mentale. In 1792 he became head physician of the Bicêtre, and two years afterwards he received the corresponding appointment at the Salpêtrière, where he began to deliver a course of clinical lectures; these formed the basis of his Nosographie philosophique (1798; 6th ed., 1818), which was further developed in La Médecine clinique (1802). Pinel was made a member of the Institute in 1803, and soon afterwards was appointed professor of pathology in the École de Médecine. His fame rests entirely upon the fact that he was among the first to introduce the humane treatment of the insane. He died at Paris on the 26th of October 1826.

PINERO, SIR ARTHUR WING (1855— ), English dramatist, was born in London on the 24th of May 1855, the son of John Daniel Pinero, a Jewish solicitor, whose family was of Portuguese origin, long established in London. A. W. Pinero was engaged in 1874 as an actor at the Theatre Royal, Edinburgh, and came to London in 1876, to play at the Globe Theatre. Later in the year he joined the Lyceum company, of which he remained a member for five years. The first piece of his to see the footlights appears less suitable for it, probably from the want of summer heat, and it can hardly be recommended for British planting otherwise than for ornamental purposes.

Nearly approaching this is P. excelsa, the Bhotan pine, which differs chiefly in its longer cones and drooping glaucous foliage. It is the type of the genus in Kashmir and on some of the Nepa1 ranges, but does not grow in the moist climate of the Sikkim Himalayas, is found at a height of 7000 to 12,000 ft., and attains large dimensions; the wood is highly resinous, and is said to be durable; great quantities of tar pitch are exuded from the branches when injured. The Bhotan pine is quite hardy in southern England, and has been largely planted of late as an ornamental tree.

P. Lamberiana, the giant pine or sugar pine of California, is the largest of the genus, rising to a height of 900 ft., with branches 20 to 30 ft. in girth, and, it is said, occasionally attaining much larger dimensions. The head is of a pyramidal form, the lower branches drooping like those of a Norway spruce; its foliage is of a dark green colour. The pendent cones are very large, sometimes 18 in. long and 4 in. in diameter, with large nut-like seeds, which, pounded and baked, are eaten by the Indians. The tree abounds in some sandy districts, but more generally occurs singly or in small groups dispersed through the woods, attaining its greatest dimensions in light soils. The wood is soft and nearly white, but contains much resin, which when fire has run through the forest exudes, and, having in this half-burnt condition a sweetish taste, has given the common name to the tree; the wood seems to be formed slowly; from its smooth grain it is valued for indoor carpentry; the succarine burnt resin is used as a laxative in California.

P. Cembra is the stone pine of Siberia and central Europe. It abounds on the Alps, the Carpathians and the Siberian ranges, in Switzerland being found at an altitude of 4000 to 6000 ft. It is a tall, straight-growing tree, with grey bark and whorls of horizontal branches giving a cyindro-conical outline; the leaves are short, rigid and glaucous; the cones, oblong and rather pointing upwards, grow only near the top of the tree, and ripen in the second autumn; the seeds are city like those of P. Pinus, and are eaten both on the Alps and by the inhabitants of Siberia; a fine oil is expressed from them which is used both for food and in lamps, but, like that of the Italian pine, it soon turns rancid. The growth of P. Cembra is slow, but the wood is of remarkably even grain, and is employed by the Swiss wood-carvers in preference to any other. The Cembra is the "zirbel" or "zirbel-kieler" of the Germans, and is known locally in Switzerland as the "aroile," "aleise," and "arve." P. occidentalis, a five-leaved pine with pale-green foliage and small ovate cones, is found on the high mountains of Santo Domingo and Cuba. Many members of the group occur on the American continent, of which P. cembroides, produces edible seeds; another, P. Montesmea, is a valuable timber tree. P. Ayacucho, the common white pine of Mexico, spreads southwards on to the mountains of Guatemala, it is a large tree with glaucous foliage like P. Strobus, and yields a valuable resin. P. fitiloto and P. macrophylla, likewise natives of Central America, are remarkable for the extreme length of their leaves; the former is said to attain a large size. (C. P. J.)

PINE-APPLE—PINERO

Pine (Pinus sp.), a city and the county-seat of Jefferson county, Arkansas, U.S.A., situated at an altitude of about 200 ft. in the alluvial bottoms of the Arkansas river, about 107 m. from its mouth, and about 42 m. S. by E. of Little Rock. Pop. (1910), 15,102. It has an active river trade with St Louis, Memphis and New Orleans, and five railway outlets—the Missouri Pacific and its branch, the Pine Bluff & Western, and the St Louis South-Western and its two branches, the Pine Bluff & Arkansas River and the Altheimer. The city has many schools, and a business college, the state normal school for negroes, and Merrill institute, endowed by Joseph Merrill of Pine Bluff with $100,000. Large quantities of cotton and lumber are shipped from the city. Among the manufactures are cotton-seed oil, lumber and staves, and furniture. Pine Bluff has shops of the St Louis South-Western railway. The city's factory products were valued at $2,989,242 in 1903, an increase of 94% over their value in 1900. Pine Bluff was laid out in 1832 and chartered as a city in 1885.
was £200 a year, played in October 1877 at the Globe Theatre for the benefit of Mr F. H. Macklin. The first play to make a hit was The Money Spinner (Theatre Royal, Manchester, Nov. 1880); but in The Squire (St James’s Theatre, Dec. 1881) he attempted serious drama, and gave promise of the qualities of his later work. In 1883 and 1884 Pinero produced seven pieces, but the most important of his works at this period were the successful farces produced at the Court Theatre: The Magistrate (March 1883), which ran for more than a year; The Schoolmistress (March 1886); Dandy Dick (Jan. 1887), revived in February 1900; The Cabinet Minister (April 1890), and The Amazons (March 1893). Two comedies of sentiment, Sweet Lavender (Terry’s, March 1888) and The Weaker Sex (Theatre Royal, Manchester, Sept. 1888), met with success, and Sweet Lavender has enjoyed numerous revivals. With The Prodigal (Garrick, April 1889) he returned to the serious drama which he had already touched on in The Squire. Out of deference to the wishes of John Hare the play was fitted with the conventional “happy ending,” but the original dénouement was restored, with great advantage to the unity of the play, in the printed version. The Second Mrs Tanqueray (St James’s, May 27, 1893) dealt with the conversion of the question propounded in The Prodigal, but with more art and more courage. The piece aroused great discussion, and placed Pinero in the front rank of living dramatists (see DRAMA: Recent English). It was translated into French, German and Italian, and the part of Paula Tanqueray, created in the first place by Mrs Patrick Campbell, attracted many actresses, among others Eleonora Duse. His later plays were The Notorious Mrs Ebbsmith (Garrick, March 13, 1893), The Benefit of the Doubt (Comedy, Oct. 1893), The Princess and the Butterfly (St James’s, April 7, 1897), Trelawney of the Wells (Court, Jan. 30, 1898), The Gay Lord Ques (Globe, April 8, 1899), Iris (Garrick, Sept. 21, 1901), Letty (Duke of York’s, Oct. 8, 1903), A Wife Without a Smile (Wyndham’s, Oct. 9, 1904), His House in Order (St James’s, Feb. 1, 1906), The Thunderbolt (St James’s, May 9, 1908) and Mid-Channel (St James’s, Sept. 2, 1909). Pinero was knighted in 1909.

His Plays (11 vols. 1861-1895) have prefaces by M. C. Salaman. See also H. Hamilton Fyle, A. W. Pinero (1902).

PINERO (Pinerolo), a city and episcopal see of Piedmont, Italy, in the province of Turin. Pop. (1901), 12,608 (town); 16,639 (commune). It is built on a hill-side just above the valley of the Chisone and the Tanaro, at a height of 1234 ft. above the sea, 24 m. by rail S.W. of Turin. The railway goes on to Torre Pellice; and steam tramways run from Pinerolo to Perosa, and to Cavour and Saluzzo. Till 1696 it was strongly fortified with a citadel on Santa Brigida, a castle on S. Maurizio, and city walls constructed by Thomas I. of Savoy. It has a cathedral (St Donatus), the palace of the princes of Acaya and other buildings of some interest. Cotton, silk, wool and hemp are among the local manufactures.

Pinero was bestowed on the bishops of Turin by Otto III. in 966; but in 1078 the countess Adelaide made it over to the Benedictine abbey of St Maria in, in whose possession it remained till 1159. Thomas I. of Savoy captured the castle in 1188, and in 1246 the commune formally recognized the supremacy of Savoy. Passing in 1293 into the hands of Philip, son of Thomas III., Pinero became his residence and capital, a distinction which it retained under Amadeus VIII. of Savoy. Francis I. of France obtained possession of the town in his descent into Italy, but Emmanuel Philibert received it back from Henry III. in 1574. A second occupation by the French occurred under Cardinal Richelieu; the French language was imposed on the people, great fortifications were constructed, and the fortress (Pinerolo) was used as a state prison for such men as Fourquet-de Cavoy and the Man with the Iron Mask (see IRON MASK). Victor Amadeus I. restored the place in 1633, and ultimately compelled Louis XIV. to retract his promise on it; but before the withdrawal of the French troops the defences were demolished. In 1748 the town was made a bishop’s see.

PINERO—PINK

PIN-EYED, a botanical term for flowers which occur in two forms, one of which shows the stigma at the mouth of the corolla, as in the primrose; the term is contrasted with thrum-eyed.

PING-PONG, or TABLE-TENNIS, a miniature variety of lawn-tennis played on a table, which may be of any size not less than 53 ft. long by 3 ft. broad. Various attempts were made to adapt lawn-tennis to the house, but the real popularity of the game began when, near the close of the 19th century, celluloid balls were introduced, and the game was called ping-pong from the sound of the balls as they were struck by the racket or rebounded from the table. In 1900 the ball was improved and made heavier, and for the next two years ping-pong enjoyed a popularity never before attained by a game in so short a time, not only in Great Britain but in France, the British Colonies and America. Two leagues were formed, the “Table-Tennis Association” and the “Ping-Pong Association,” whose laws were practically identical. The regular tournament table is 9 ft. long by 5 ft. broad, and the net is a little less than 7 in. high. The balls, which are of hollow celluloid, are about 1 in. in diameter. The racket has a blade, shaped like a lawn-tennis racket, about 6 in. long and a handle long enough to grasp comfortably, all in one piece. The racket and balls are made either wholly of wood covered with vellum, cork, sand-paper or rubber, or of light frames covered with vellum or some other material. The table was at first marked out in courts, but is now plain. It should be unpollished and stained. In serving, a player must stand directly behind his end of the table and use an underhand motion only. The ball must clear the net and strike the table anywhere on the other side. The game is then continued until the ball misses the table or fails to pass over the net. Only one service is allowed, except in case of a let. The scoring is the same as in lawn-tennis.

See Ping-Pong, by Arnold Parker (London, 1902); Table Tennis, by A. Sinclair (London, 1902).

PINK, in botany, the common name corresponding to a genus of Caryophyllaceae, the Dianthus of botanists. It is characterized by the presence of simple leaves borne in pairs at the thickened nodes, flowers terminating the axis and having a tubular calyx surrounded by a number of overlapping bracts, a showy corolla of five free long-stalked petals, ten stamens proceeding, together with the petals, from a short stalk supporting the ovary, which latter has two styles and stigmas into a cylindrical or oblong pod-like one-chambered many-seeded capsule which opens at the apex by four courts or valves. The species are herbaceous perennials of low stature, often with very showy flowers. They are chiefly confined to the Mediterranean region, a few being found in temperate Asia and South Africa. Four species are wild in Britain. Of these, D. armeria, Deptford pink and D. deltoides, maiden pink, are generally distributed, D. caesius, Cheddar pink, occurs only on the limestone rocks at Cheddar. Two others, D. plumarius and D. caryophyllus, are more or less naturalized, and are interesting as being the originals of the pinks and of the carnations and picotees of English gardens. Garden pinks are derivatives from Dianthus plumarius, a native of central Europe, with leaves rough at the edges, and with rose-coloured or purplish flowers. The use of “pink” for a colour is taken from the name of the plant.

The plant is a favourite garden flower of hardy constitution. It has been in cultivation in England since 1620, and is a great favourite with florists, those varieties being preferred which

1 The etymology of “pink” is disputed; it may be connected with pink (apparently a naturalized form of “pikk”) properly to pick out; “pink” may be used as a state prison for such men as Fourquet-de Cavoy and the Man with the Iron Mask (see IRON MASK). Victor Amadeus I. restored the place in 1633, and ultimately compelled Louis XIV. to retract his promise on it; but before the withdrawal of the French troops the defences were demolished. In 1748 the town was made a bishop’s see.

1 The etymology of “pink” is disputed; it may be connected with pink (apparently a naturalized form of “pikk”) properly to pick out; “pink” may be used as a state prison for such men as Fourquet-de Cavoy and the Man with the Iron Mask (see IRON MASK). Victor Amadeus I. restored the place in 1633, and ultimately compelled Louis XIV. to retract his promise on it; but before the withdrawal of the French troops the defences were demolished. In 1748 the town was made a bishop’s see.
have the margin of the petals entire, and which are well marked in the centre with bright crimson or dark purple. Its grassy but glaucous foliage is much like that of the carnation, but the whole plant is smaller and more tufted. Pinks require a free loamy soil deeply trenched, and well enriched with cow-dung. They are readily increased by cuttings (pippings), by layers and by seed. Cuttings and layers should be taken as early in July as practicable. The former should be rooted in a cold frame or in a shady spot out of doors. When rooted, which will be about August, they should be planted 4 in. apart in a nursery bed, where they may remain till the last of October or the early part of November. The chief attention required during winter is to press them down firmly should they become lifted by frosts, and in spring the ground should be frequently stirred and kept free from weeds. The pink is raised from seeds, not only to obtain new varieties, but to keep up a race of vigorous-growing sorts. The seeds may be sown in March or April in pots in a warm frame, and the young plants may be pricked off into boxes and sheltered in a cold frame. They should be planted out in the early part of the summer in nursery beds, in which, if they have space, they may remain to flower, or the alternate ones may be transplanted to a blooming bed in September or the early part of October; in either case they will bloom the following summer. These will grow in any good garden soil, but the richer it is the better.

The border varieties are useful for forcing during the early spring months. These are propagated from early pippings and grown in nursery beds, being taken up in October, potted in a rich loamy compost, and wintered in a cold pit till required for the forcing house.

The following varieties are among the best. For borders and forcing: Alba, Carmen, Delice, De la Herma, Hércules, Anna Bolena, Lady Blanche, Mrs Sinkins, Mrs James Welsh, Pilrig Park, Rubens, Snowdon, Tom Welsh. Florists' show and laced varieties: Attraction, Beauty of Bath, Clara, Cheese, Charm, Ensign, John Ball, Malcolm Dunn, Mrs D. Gray, Reliance, William Paul.

The Carnation (g.v.) and Pioette are modifications of Dianthus Caryophyllus, the Clove Pink. This is a native of Europe, growing on rocks in the south, but in the north usually found on old walls. Its occurrence in England on some of the Old Norman castles, as at Rochester, is supposed by Canon Elliscombe to indicate its introduction by the Normans; in any case the plant grows in similar situations in Normandy. The carnation includes those flowers which are streaked or striped lengthwise—the picotees are those in which the petals have a narrow band of colour along the edge, the remainder of the petal being free from stripes or blotches. These were called "cliffy-flowers." The Sweet William of gardens is a product from Dianthus barbatus. The Sea-Pink, or Thrift, Statae Armeria (Armeria vulgaris), is a member of the same family. Under Plowman's Brief it is a well-distributed plant found on rocky and stony sea-shore and on rocky mountains. There are many improved varieties of it now in cultivation, one with almost pure white flowers.

PINKERTON, ALLAN (1819-1884), American detective, was born in Glasgow, Scotland, on the 25th of August 1819. His father, a sergeant of the Glasgow municipal police, died in 1828 of injuries received from a prisoner in his custody. In 1842 Allan emigrated to Chicago, Illinois. In 1843 he removed to Dundee, Kane county, Illinois, where he established a cooperation business. Here he ran down a gang of counterfeiters, and immediately afterwards of Kane county, with headquarters in Chicago. There he organized a force of detectives to capture thieves who were stealing railway property, and this organization developed in 1852 into Pinkerton's National Detective Agency, of which he took sole charge in 1853. He was especially successful in capturing thieves who stole large amounts from express companies. In 1866 his agency captured the principals in the theft of $500,000 from Adams Express Company safes on a train of the New York, New Haven & Hartford railway, and recovered all but about $12,000 of the stolen money. In February 1861 Pinkerton found evidence of a plot to assassinate President-elect Lincoln upon his arrival in Baltimore on his way to Washington; as a result, Lincoln passed through Baltimore on his way to Washington in the morning without stopping. In April 1861 Pinkerton, on the suggestion of General George B. McClellan, organized a system of obtaining military information in the Southern states. From this system he developed the Federal secret service, of which he was in charge throughout the war, under the assumed name of Major E. J. Allen. One of his detectives, James McParlan, in 1873-1876 lived among the Molly Maguires (g.v.) in Pennsylvania and secured evidence which led to the breaking up of the organization. In 1869 Pinkerton suffered a partial stroke of paralysis, and thereafter the management of the detective agency devolved chiefly upon his sons, William Allan (b. 1846) and Robert (1846-1907). He died in Chicago on the 1st of July 1884. He published The Molly Maguires and the Detectives (1877), The Spy of the Rebellion (1885), in which he gave his version of President-elect Lincoln's journey to Washington; and Thirty Years a Detective (1884).

PINKERTON, JOHN (1758-1826), Scottish archaeologist, numismatist and author, was born at Edinburgh on the 17th of February 1758. He was articled as a law clerk in Edinburgh, and his Elegy on Craigmillar Castle (1776) was printed during his clerkship. In 1781 he removed to London to devote himself to literary work, publishing in the same year a volume of Rimes of no great merit, and Scottish Tragic Ballads. These were reprinted in a new volume, Dismal Ditties, Boks and Ensemle Laughter, and by a series of Tales in Verse. Under the title of Select Scottish Ballads he reprinted in 1783 his tragic ballads, with a supplement comprising Ballads of the Comic Kind. Ritson pointed out in 1784 that the so-called ancient ballads were some of them of modern date, and Pinkerton confessed that he was the author of the second part of Hardy Kanute and part-author of some others. He published an Essay on Medals in 1784, and in 1785, under the pseudonym of "Robert Horon," his bold but eccentric Letters of Literature deprecating the classical authors of Greece and Rome. In 1786 he edited Ancient Scottish Poems from the MS. collections of Sir Richard Maitland of Lethington—a genuine reproduction. It was succeeded in 1787 by a compilation, under the new pseudonym of "H. Bennet," entitled The Treasury of Wit, and by his first important historical work, the Dissertation on the Origin and Progress of the Scythians or Goths, which Gibbon acknowledged himself indebted. Pinkerton next collected and printed in 1789 certain Vitae sancorum scoitae, and, a little later, published his Enquiry into the History of Scotland preceding the Reign of Malcolm III. His assertion that the Celtic race was incapable of assimilating the highest forms of civilization excited "violent disgust," but the Enquiry was twice reprinted, in 1794 and 1814, and is still of value for its accurate facts embodied in it. His edition of Barrow's Bruce and a Medallie History of England to the Revolution appeared in 1790; a collection of Scottish Poems reprinted from scarce Editions in 1792; and a series of biographical sketches, the Iconographia scoitae, in the years 1795-1797. In 1797 he published a History of Scotland from the Accession of the House of Stuart to that of Mary, containing much valuable material. A new biographical collection, the Gallery of Eminent Persons of Scotland (1799), was succeeded after a short interval by a Modern Geography digested on a New Plan (1802; enlarged, 1807). About this time he left London for Paris, where he made his headquarters until his death on the 10th of March 1826. He died at Lyons, and was buried in the churchyard of the Couvent des Feuillants. His edition of Barrow's Bruce and a very useful General Collection of Voyages and Travels (1808-1814); a New Modern Atlas (1808-1810); and his Petroleo (1811).

PINKNEY, WILLIAM (1764-1832), American lawyer and statesman, was born in Annapolis, Maryland, on the 17th of March 1764. He was admitted to the bar in 1786, and in 1788-1792 practised in Harford county. In 1788 he was a member of the state convention which ratified the Federal constitution for Maryland, in 1788-1792 and in 1795 of the House of Delegates (where in 1788 and 1789 he defended the right of slave-owners to manumit their slaves), and in 1792-1795 of the state executive council. In 1796-1797, as a member of the committee of 6 of the 7 of Jay's Treaty of 1794 to determine the claims of American merchants for damage through "irregular or illegal captures
or condemning," and during this time adjusted on behalf of Maryland a claim of the state to stock in the Bank of England. In May 1806, with James Monroe, then minister at London, he was commissioned to treat with the British government concerning the capture of neutral ships in time of war; in 1807-1811, after Monroe's return to America, he was resident minister in London. He was elected to the Maryland senate in September 1811, and from December 1811 to January 1814 was attorney-general of the United States. In August 1814 he was wounded at Bladensburg. He served in the National House of Representatives in January–April 1816, and in 1825-1818 was minister plenipotentiary to Russia and special minister to Naples, where he attempted to secure indemnity for the losses to American merchants by seize and confiscation during the rule of Murat in 1809. From 1820 until his death, at Washington, on the 25th of February 1822, he was a member of the United States Senate. He was a member of the conference committee on the bill for the admission of Maine and Missouri, which in its final form embodied what is known as the Missouri Compromise. Finney was a remarkably able lawyer and an orator of the old school. See The Life of William Pinnock (New York, 1853) by his nephew, William Finney (1810-1883), who was Protestant Episcopal bishop of Virginia in 1879-1883; and Henry Wheaton, Some Account of the Life, Writings, and Speeches of William Pinnock (New York, 1831).

PINNACE—PINNACLE

PINNACE, the name of two types of vessel or boat, one a light sailing vessel with two schooner-rigged masts, the other a heavy eight-oared man-of-war's boat. The word is usually referred to Lat. *pinus*, pin, but this derivation is at variance with the earlier form “spine.”

PINNACLE (from Lat. *pinnaculum*, a little feather, *pinnas*; the Gr. *πηνασι, diminutive of *περας*, wing, is also used in this sense), an architectural ornament originally forming the cap or crown of a buttress or small turret, but afterwards used on parapets at the corners of towers in many other situations. Sometimes it is defined that there are no pinnacles in the Romanesque styles, but conical caps to circular buttresses, with finial terminations, are not uncommon in France at very early periods. Viollet-le-Duc gives examples from St. Germer and St. Remi, and there is one of similar form at the west front of Rochester Cathedral. In the 12th-century Romanesque two examples have been cited, one from Bredon in Worcestershire, and the other from Cleeve in Gloucestershire. In these the buttresses run up, forming a sort of square turret, and crowned with a pyramidal cap, very much like those of the next period, the Early English. In this and the following styles the pinnacle seems generally to have had its appropriate uses. It was a way to counteract the thrust of the masonry, particularly when there were flying buttresses; it stopped the tendency to slip of the stone copings of the gables, and counterpoised the thrust of spires; it formed a pier to steady the elegant perforated parapets of later periods; and in France especially served to counterbalance the weight of overhearing corbel tables, huge gargoyles, &c. In the Early English period the small buttresses frequently finished with gables, and the more important with pinnacles supported with clustered shafts. At this period the pinnacles were often supported on these shafts alone, and were open below; and in larger work in this and the subsequent periods they frequently form niches and contain statues. About the Transition and during the Decorated period, the different faces above the angle shafts often finish with gables. Those of the last-named period are much richer, and are generally decorated with crockets and finials, and sometimes with flowers. Very fine groups are found at Beverley Minster and at the rise of the spire of St. Mary's, Oxford. Perpendicular pinnacles differ but little from Decorated, except that the crockets and finials are of later character. They are also often set angle-ways, particularly on parapets, and the shafts are panelled. In France pinnacles, like spires, seem to have been in use earlier than in England. There are small pinnacles at the angles of the tower in the abbey of Saints, at Roulet there are pinnacles in a similar position, each composed of four small shafts, with caps and bases surmounted with small pyramidal spires. In all these examples the towers have semicircular-headed windows.

PINNOCK, WILLIAM (1782-1843), English publisher and educational writer, was born at Alton, Hampshire, on the 3rd of February 1782, and was at first a schoolmaster, then a bookseller. In 1817 he went to London and, in partnership with Samuel Mander, began to publish cheap educational works. The firm's first productions were a series of *Catechisms*, planned by Pinnock, consisting of short popular manuals, arranged in the form of question and answer, of the different departments of knowledge. They were followed by abridged editions of Goldsmith's histories of England, Greece and Rome, and a series of county histories which were no less profitable. Pinnock lost nearly all his money in outside speculation, and died in London on the 21st of October 1843. His son, William Henry Pinnock (1813-1885), a clergyman, was the editor and author of several elementary textbooks and scriptural manuals, and of various works on ecclesiastical law and usage.

PINNOCHLE, or PENNOCH (Ger. *Pinochel* or *Binochel*, of uncertain etymology), a game of cards probably invented by Germans in the United States about the middle of the 19th century. It bears a general resemblance to *Bésique* (q.v.), and has almost entirely superseded the plain card game of Pinochle. Pinochle may be played by two, three, or four persons. Two packs, from which all cards below the nines have been deleted, are shuffled together, forming one pack of 48 cards. The object of the game is to make 1000 points. The cards rank as follows: ace 11, ten 10, king 4, queen 3, knave 2. The nine counts nothing unless it be turned for trumps, when it scores 10. The last trick scores 10. The term "to meld" (Ger. *melden*, to announce), as used in pinochle, means "to declare." "Melds" are combinations which are declared during the play of the hands. They are of three classes: (1) "melded," and "melded;" (2) "melds" and "melds;" (3) "melds," and "melds." The "melds" of the first class score as follows: "marriage" (king and queen of any plain suit), 20; "royal marriage" (king and queen of trumps), 40; "sequence" (the five highest trumps), 150. In the second class the "melds" are "pinochle" (queen of spades and knave of diamonds), 40; "double pinochle" (two queens of spades and knaves of diamonds), 50; "grand pinochle" (king and queen of spades and knave of diamonds), 80; this "meld" is not often played in America. Of the third class the "melds" are: four aces of different suits, 100; four kings of different suits, 80; four queens of different suits, 60; four knaves of different suits, 40; eight aces, 1000; eight kings, 800; eight queens, 600; eight knaves, 400.

In single pinochle (two players) each player receives twelve cards, four at a time, the twenty-fifth being turned up beside the stock for trumps. The non-dealer leads a card, to which the dealer plays. There is no obligation either to take, follow suit or trump. The winner of the trick leads again, before which, however, he may "meld" any one combination he holds. After he has "melded," or refused to do so, he draws a card from the top of the stock and adds it to his hand without showing it, his adversary doing the same, so that each player continues to hold twelve cards. Playing, announcing, and drawing then go on until the stock is exhausted. All combinations "melded" must be laid face upward on the table but still belong to the player's hand, though they may not be taken up until the stock is exhausted. When the stock has all been produced, all announcements cease, and all cards exposed are replaced in the hands. The last tricks are then played, but now both players must follow suit and must win the trick if possible, either with a superior card or a trump. A failure to do this is a "revoke" and is penalized by the loss of all points made by "cards," i.e. for the five highest cards in each suit, which after all the tricks have been counted for the player holding them. Ace counts 11 points, ten 10, king nine, queen seven, and knave four. In this way it happens that 240 points for "cards" are divided between the two players. Though points are not counted during the play, a mental count is made by them whenever a player sees that, by adding the value of his "melds" to what he thinks his cards will count, he has enough to win the game, namely 1000, he "calls out" or knocks on the table, and proceeds to expose his cards. If he fails to show enough to win, he loses the game. If neither player knows the game continues until one of them scores 1250; if still a tie, 1500. If a player fails to make good a "meld" he is set back that number of points. The game is scored by counters or on a cribbage-board.
PINSK—PINTO

629

In three-handed pinochle the "melds" are exposed before a card is played, and no player may "meld" after he has played to the first trick. A rule is sometimes made that an overlooked combination may be scored by the other players. Four-handed pinochle is played either with partners or each player for himself.

PINSK, a town of Russia, in the government of Minsk, at the confluence of the Strunen and Pina rivers, 156 m. S.W. by rail of Minsk. Pop., 27,938, two-thirds being Jews. The town carries on considerable trade, due to the navigable river Pina, which connects it with the fertile regions in the basin of the Dnieper, and, by means of the Dnieper-and-Bug canal, with Poland and Prussia, while the Oginsky canal connects it with the basin of the Niemen. Pottery, leather, oil, soap and beer are the chief products of the local industries. The draining of the marshes around Pinsk was partly done by the government in 1872, and by 1897 8,000,000 acres had been drained at an average cost of 3s. per acre. Pinsk (Pinesk) is first mentioned in 1069 as a town belonging to Sviatopolk, prince of Kiev. In 1132 it formed part of the Minsk principality. After the Mongol invasion of 1239-42 it became the chief town of a separate principality, and continued to be so until the end of the 13th century. In 1320 it was annexed to Lithuania, and in 1369, after the union of Lithuania with Poland, it was chief town of the province of Brest. During the rebellion of the Cossack chief, Bogdan Chmielnicki (1649), the Poles took it by assault, killing 14,000 persons and burning 5000 houses. Eight years later the town was burned by the Russians. Charles XII took it in 1706, and burned the town with its suburbs. Pinsk was annexed to Russia in 1795.

PINSUTI, GIRO (1829-1888), Anglo-Italian composer, was born at Siena, and was educated in music, for a career as a pianist, partly in London and partly at Bologna, where he was a pupil of Rossini. From 1848 he made his home in England, where he became a teacher of singing, and in 1856 he made a professor at the Academy of Music in London. He became well known as a composer of numerous favourite songs and part-songs, as well as of three operas brought out in Italy, and it is by the former that he is still remembered. He was appointed to the Hanoverian Civil List, and conducted a diplomatic mission to China, to which he was attached in 1831. In 1832 he visited the United States, and in 1833-40 he was a diplomatist in the Court of St James's. He died in 1888.

PINT (derived probably through Spanish, from Lat. picture, pixel, a painted or marked vessel), a liquid measure of capacity, equivalent to ⅛ of a gallon. The imperial British pint = ⅗ of a litre, 34ⅹ66 cub. in. The United States standard pint = ⅕ of a litre, 28ⅸ cub. in. The word appears in French as pinte for a liquid measure as early as the 13th century.

PINTO, ANIBAL (1825-1884), Chilean president, was born at Santiago, Chile. After a diplomatic training in the legation at Rome he learned the practice of administration as intendent of Concepcion, and from 1871 to 1876 was minister of war and marine under Errázuriz. During his term of office as president (1876-81) he was bound to defend the country against a financial crisis, and then to conduct the struggle with Peru and Bolivia in which he displayed great coolness of judgment and devotion to duty.

PINTO, FERNANDO MENDES (1500-1583), Portuguese adventurer, was born at Montemór-o-Velho, of poor and humble parents, and entered the service of a noble lady in Lisbon, being afterwards for two years page to the duke of Aveiro in Setubal. Desiring to try his fortune in the East, he embarked for India in 1537 in a fleet commanded by the son of Vasco da Gama, and for twenty-one years travelled, fought and traded in China, Tartary, Fugus and the neighbouring countries, sailing in every sea, while in 1542-43 he was one of the first Europeans to visit Japan, where he introduced the musket. Though he was thirteen times a captive and seventeen times sold into slavery, his gay and dauntless spirit brought him through every misfortune. He was soldier and sailor, merchant and doctor, missionary and ambassador; moreover, as the friend and traveling companion of St Francis Xavier, he lent the apostle of the Indies the money with which to build the first Jesuit establishment in Japan. In January 1554 Mendes Pinto was in Goa, waiting for a ship to take him to Portugal, when he took a sudden resolution to enter the company of Jesus and devote a large part of the capital he had accumulated to the evangelization of Japan.

The viceroy appointed him ambassador to the king of Bungo in order to give the mission an official standing, and on the 18th of April he set sail with the provincial, Father Belchior Nunes. Owing to bad weather and contrary winds, however, the missionaries did not reach Japan until July 1556, but the success of the mission represented a notable service to the cause of Christianity and civilization. On the 14th of November 1556 Father Belchior and Mendes Pinto began their return voyage and reached Goa on the 17th of February 1557. During his stay of a twelve-month there, the latter left the company, being dispensed from his vows for want of vocation at his own request, though a modern authority states that he was expelled because he was suspected of having taken the name of a Jesuit i.e. to possess Jewish blood. He finally returned to Portugal on the 3rd of September 1558, and settled at Fragal near Almada, where he married and wrote his famous book, the Peregrination; the MS., in fulfilment of his wishes, was presented by his daughter to the Casa Pia for penitent women in Lisbon, and it was published by the administrators in 1614. When Philip II. of Spain came to Portugal as its king, he listened with pleasure to the account of Mendes Pinto's travels, and by letter of the 15th of January 1563 gave him a pension for his services in the Indies. But the reward came too late, for the great traveller died on the 8th of October.

In the light of our present-day knowledge of the East, Pinto is regarded as having been on the whole a careful observer and truthful narrator, but this was not always the case. Some witty countryman of his own parodied his name into Fernão, mentes? Minto! ("Ferdinand, do you lie? I do!"); and the English dramatist Congreve only expressed the general opinion of the unlearned when he wrote in Love for Love "Mendez Pinto was but a type of thee, thou liar of the first magnitude." It must be remembered that Pinto wrote the Peregrination long subsequent to the events he records, and this fact and a certain fertility of imagination sufficiently account for inexactitudes. Furthermore, as the book was only published posthumously, he never had the opportunity of correcting the proofs. Some of his most marvellous stories are expressly given on the authority of writers belonging to the countries he describes; others he tells from hearsay, and Oriental informants are prone to exaggeration. But if he somewhat adorned the truth, he did not wilfully misrepresent it. The book itself gives the impression of sincerity, and the editors of the first edition bear witness to the probity, good faith and truthfulness of Mendes Pinto as a man. Herrera Maldonado prefaced his Spanish translation of the Peregrination (1620) by a lengthy and erudite apology to demonstrate its authenticity, and Castillo has reinforced his assertions by modern discoveries. In the narrative portions of his work Pinto's style is simple, clear and rich, particularly in sea terms, and appropriate to his various subjects. There is an entire absence of artifice about the book, which must always rank as a classic, and it might fairly be argued that Mendes Pinto did for the prose of Portugal what Camoens did for its poetry; this is the more remarkable, because it does not appear that he ever received any education in the ordinary sense. He wrote the book for his children to learn to read by, and modestly excused its literary defects by alleging his rudeness and lack of talent. Tradition has it that the MS. was entrusted to the chronicler Francisco de Andrade for the purpose of being polished in style and made ready for press, but that all he did was to divide it into chapters.

The Peregrination has gone through many editions subsequent to that of 1614, and in 1869 Castillo published excerpts in his Literaria clásica portuguesa with an interesting notice of Mendes Pinto's life and writings, and wrote an essay on the book in French (3 editions), Spanish (4 editions), and in English by Henry Cogan, London (1663, 1692 and—abridged and illustrated, with introduction by Arminius Vambré—1891). Cogan omits the chapters relating to Mendes Pinto's intercourse with, and the last days of, St Francis Xavier, presumably as a concession to anti-Catholic prejudice.

PINTO—PINTURICCHIO

PINTO. The remarkable brown, black and blue spots of discoloration of the whole body met with endemically in Mexico, Peru, and Colombia, known as the name of "pinto" or "mal de los pintos," were first claimed by Gastambide (Prase med. Belge, 1881, Nos. 33-41) as due to the presence of a vegetable parasite, whose spores and even mycelial filaments may be detected among the deeper rows of cells of the retic mucosum. The disease appears to be one of the many forms of morbus misericiae; but it is contagious, and is sometimes seen in the well-to-do. In some villages of the western districts of Tabasco (Mexico) it has been estimated that 90% of the inhabitants suffer from the pinto; M'Clennan says that in 1826 in the City of Mexico he saw a whole regiment of troops affected with it.

PINTURICCHIO (1454-1513), Italian painter, whose full name was Bernardino di Betto, the son of a citizen of Perugia, Benedetto or Betto di Biagio, was one of a very important group who inherited the artistic traditions and developed the style of the older Perugian painters, such as Bongfigli and Florenzo di Lorenzo. According to Vasari he was a pupil of Perugino; and so in one sense no doubt he was, but rather as a paid assistant than as an apprentice. The strong similarity both in design and methods of execution which runs through the works of this later Perugian school is very striking; paintings by Perugino, Pinturicchio, Lo Spagna and Raphael (in his first manner) may often be mistaken for one another. He is said to have been in the execution of large frescoes, pupils and assistants had a large share in the work, either in enlarging the master's sketch to the full-sized cartoon, in transferring the cartoon to the wall, or in painting backgrounds, drapery and other accessories. After assisting Perugino in the execution of his frescoes in the Sistine Chapel, Pinturicchio was employed by various members of the Della Rovere family and others to decorate a whole series of chapels in the church of S. Maria del Popolo in Rome, where he appears to have worked from 1484, or earlier, to 1492 with little interruption. The earliest of these is an altarpiece of the "Adoration of the Shepherds," in the first chapel (from the west) on the south, built by Cardinal Domenico della Rovere; a portrait of the cardinal is introduced as the foremost of the kneeling shepherds. In the lunettes under the vault Pinturicchio painted small scenes from the life of St Jerome. The frescoes which he painted in the next chapel, that built by Cardinal Innocenzo Cibo, were destroyed in 1700, when the chapel was rebuilt by Cardinal Alderano Cibo. The third chapel on the south is that of Giov. della/Rovere, duke of Sora, nephew of Sixtus IV., and brother of Giuliano, who was afterwards Pope Julius II. This contains a fine altarpiece of the "Madonna enthroned between Four Saints," and on the east side a very nobly composed fresco of the "Miracles of the Virgin." The vault and its lunettes are richly decorated with small pictures of the life of the Virgin, surrounded by graceful arabesques; and the dado is covered with monochrome paintings of scenes from the lives of saints, medallions with prophets, and very graceful and powerfully drawn female figures in full length in which the influence of Signorelli may be traced. In the fourth chapel Pinturicchio painted the Four Latin Doctors in the lunettes of the vault. Most of these frescoes are considerably injured by damp, but happily have suffered little from restoration; the heads are painted with much minuteness of finish, and the whole of the pictures depend very largely for their effect on the final touchings a secco. The last paintings completed by Pinturicchio in this church were the frescoes on the vault over the retable-a very rich and well-designed piece of decorative work, with main lines arranged to suit their surroundings in a very skillful way. In the centre is an octagonal panel of the coronation of the Virgin, and round it medallions of the Four Evangelists—the spaces between them being filled up by reclining figures of the Four Sibyls. On each pendant is a figure of one of the Four Doctors enthroned under a niced canopy. The hands which separate these pictures have elaborate arabesques on a gold ground, and the whole is painted with broad and effective touches, very telling when seen (as is necessarily the case) from a considerable distance below. No finer specimen of the decoration of a simple quadripartite vault can anywhere be seen.

In 1492 Pinturicchio was summoned to Orvieto, where he painted two Prophets and two of the Doctors in the duomo. In the following year he returned to Rome, and was employed by Pope Alexander VI. (Borgia) to decorate a suite of six rooms in the Vatican, which Alexander had just built. These rooms, called after their founder the Appartamenti Borghia, now form part of the Vatican library, and five of them still retain the fine series of frescoes with which they were so skilfully decorated by Pinturicchio. The upper part of the walls and vaults, not only covered with painting, but further enriched with delicate stucco work in relief, are a masterpiece of decorative design and arrangement. In the grandiose byzantine style, the panelled ornament is a much better model for imitation in that respect than the more celebrated Stanze of Raphael immediately over the Borghia rooms. The main subjects are: (1) the Annunciation, the Nativity, the Magi, and the Resurrection; (2) Scenes from the lives of St Catherine, St Antony and other saints; (3) allegorical figures of music, arithmetic and the like; (4) four figures in half length, with rich arabesques; (5) figures of the planets, the occupations of the various months, and other subjects. The sixth room was repainted by Perino del Vaga.

Though not without interruption, Pinturicchio, assisted by his pupils, worked in these rooms from 1492 till 1498, when they were completed. His other chief frescoes in Rome, still existing in a very genuine state, are those in the Cappella Bufalini at the south-west of S Maria in Ara Coeli, probably executed from 1497 to 1500. These are well-designed compositions, noble in conception, and finished with much care and refinement. On the altar wall is a grand painting of St Bernardino of Siena between two other saints, crowned by angels; in the upper part is a figure of Christ in a vesca-glory, surrounded by angel musicians; on the left wall is a large fresco of the miracles done by the corpse of St Bernardino, very rich in colour, and full of very carefully painted heads, some being portraits of members of the Bufalini family, for whom these frescoes were executed. In one group of three females, the central figure with a child at her breast, is of especial beauty, recalling the grace of Raphael's second manner. The composition of the main group round the saint's corpse appears to have been suggested by Giotto's painting of St Francis on his bier in S. Croce at Florence. On the vault are four noble figures of the Evangelists, usually attributed to Luca Signorelli, but certainly, like the rest of the frescoes in this chapel, by the hand of Pinturicchio. On the vault of the sacristy of S. Cecilia in Trastevere, Pinturicchio painted the Almighty surrounded by the Evangelists. During a visit to Orvieto in 1496 Pinturicchio painted two more figures of the Last Doctors in the choir of the duomo—now, like the rest of his work at Orvieto, almost destroyed. For these he received fifty gold ducats.

Among his panel pictures the following are the most important. An altarpiece for S Maria de' Fossi at Perugia, painted in 1496-1498, now moved to the picture gallery, is a Madonna enthroned among Saints, graceful and sweet in expression, and very minutely painted; the wings of the relatable have standing figures of St Augustine and St Jerome; and the predella has paintings in miniature of the Annunciation and the Evangelists. Another fine altarpiece, similar in delicacy of detail, and probably painted about the same time, is that in the cathedral of San Severino—the Madonna enthroned looks down towards the kneeling donor. The angels at the sides in beauty of face and expression recall the manner of Lorenzo di Credi or Da Vinci. The Vatican picture gallery has the largest of Pinturicchio's panels—the Coronation of the Virgin, with the apostles and other saints below. Several well-executed portraits occur among the kneeling saints. The Virgin, who kneels at Christ's feet to receive her crown, is a figure of great tenderness and beauty, and the lower group is composed with great skill and grace in arrangement. Other important panel paintings by Pinturicchio exist

1See Guattani, Quadri nell' appart. Borghia (Rome, 1820).
in the cathedral of Spello, in the Siena gallery, at Florence, at Perugia, and in other collections.

In 1501 Pinturicchio painted several fine frescoes in S. Maria Maggiore at Spello——all very decorative and produced with elaborate and architectonic accessories. One of these is the Annunciation, signed "Bernardinis Pinturichii Persius." The most striking of all Pinturicchio's frescoes, both for colour and their wonderful state of preservation, are those in the cathedral library at Siena, a large room built in 1495 by Cardinal Francesco Piccolomini, afterwards Pius III. In 1502 the cardinal contracted with Pinturicchio to decorate the whole room with arabesques on the vault, and on the walls ten scenes from the life of Acneas Sylvius Piccolomini, Pius II., the uncle of Cardinal Francesco.

The contract specially provided that the cartoons, their transference on to the wall, and the heads, were to be by Pinturicchio's own hand, thus contradicting Vasari's assertion that the cartoons were the work of Raphael. The document provides for the price of these frescoes, namely, one thousand gold ducats, to be paid in various installments. The work was begun early in 1503, but was interrupted for a while by the death of Pius III. His will, however, provided for the completion of the work by his executors, and the whole series was finished in 1507.

In 1508 Pinturicchio painted another panel of the Madonna enthroned among saints for the church of the Minori Conventuali at Spello, over the altarpiece of our lady of sunlight. On his return to Siena he painted a whole series of frescoes on the walls of the Palazzo Petrucci, now all destroyed except one scene of the return of Ulysses to Penelope (or possibly Collatinus and Lucretia), which is now in the National Gallery of London, transferred to canvas. One of his last works, painted in 1523, the year of his death, is a very beautiful and highly finished panel with Christ bearing His Cross, now in the Palazzo Borromeo in Milan. Pinturicchio married Grazia di Niccolò, and had by her two sons and four daughters; there is probably no truth in the story of his being starved by his wife during his last illness. Pinturicchio's worth as a painter has been for the most part undervalued, partly owing to the very strong prejudice and dislike which tinged Vasari's biography of him. Even Crowe and Cavallascialle hardly did him justice. A fairer estimate of his position in the history of art is given by Vermiglioni, Memorie di Pinturicchio (Perugia, 1837); and in the valuable notes and appendix of Milanesi's edition of Vasari, iii., 493-531 (Florence, 1878). See also Schnitzer, Raphael and Pinturicchio in Siena (Stuttgart, 1880), and Pinturicchio in Rom (Stuttgart, 1882), both well illustrated by photo-lithography.

PINWELL, GEORGE JOHN (1842-1875), British water-colour painter, was born at Wycombe, and educated at Heatherley's Academy. He is one of the most interesting personalities in the little group of water-colour painters which included Frederick Walker and A. B. Houghton, a group whose style was directly derived from the practice of drawing upon wood for book illustration. He was one of the most delightful book illustrators of his day, poetic in imagination and possessing a considerable inventive power. As he died young his works are few, but their promise was so great that had he lived he would probably have attained a very high position. His early life was one of considerable privation. In 1862 he entered at Heatherley's studio and there obtained his art education. His earliest drawings appeared in Lilliputus Legere. He did a little work for Fun and executed several designs for the silversmiths, Elkingtons. In 1863 his first drawing appeared in Once a Week, and from that time his work was in constant demand. There are many of his compositions in Good Words, The Sunday Magazine, The Quiver and London Society, but his most important production was made for the Daliel brothers were illustrations of Goldsmith, of Jean Ingelow's poems, Robert Buchanan's Ballads of the Affections, and the Arabian Nights.

Of Pinwell's pictures in colour, which are distinguished by a remarkable, jewel-like quality and marked by his strong love of pure, bright colour and opalescent effect, the chief are the two scenes from The Pied Piper of Hamelin, Gilbert & Becket's Thoth, of Tune or The Old Cross, A Seat in St James' Park, and The Elixir of Life.

In 1874 Pinwell fell seriously ill and went to Africa for the winter. He painted several remarkable pictures at Tangier, but his strength gradually broke down and he returned to die in his wife's arms on the 8th of September 1875. Pinwell was an exhibitor at the Dudley gallery, and in 1869 was elected associate of the Royal Water-colour Society and full member in 1870; to this gallery he contributed fifty-nine works. A posthumous exhibition of his works was held in 1876 in Bond Street.

See Life of George J. Pinwell, by George C. Williamson, 1876. (G. C. W.)

PINZON, a family of wealthy Spanish navigators, of Palos in Andalusia, three members of which—Martin Alonzo, Francisco and Vicente Yáñez, brothers—were associated with Columbus in the discovery of America.

Martin Alonzo Pinzón, born about the middle of the 15th century, gave material assistance to Columbus in carrying out his project. "If Colon was the head, Pinzon was the right arm" (Asensio). In the expedition of 1492 he commanded the "Pinta," on which his brother Francisco was pilot; another brother, Vicente Yáñez, commanded the "Nina." On the 6th of October Martin Alonzo suggested to Columbus (when already in the longitude of the Bermudas) to change the course of the expedition from due west to south-west; on the 7th of October this suggestion—strengthened by the observation of a flight of birds to the south-west—was adopted, bringing the fleet, four days later, to the landfall at Gibrabahni (San Salvador, Watling Island) in the Bahamas (Oct. 12, 1492). On the 21st of November 1492, near the east end of the north coast of Cuba, Martin Alonzo left Columbus, making eastward in search of the gold-land of which they had heard the natives speak. On the 6th of January 1493 he rejoined the admiral, who accepted his excuses. But on the return journey he again left his leader, and when Columbus arrived at Palos on the 15th of March 1493 he learned that Alonzo had already landed at Bayona in Galicia. If his object was to forestall Columbus and pose as discoverer of the New World, he was foiled; audience was refused him by Ferdi- nand and Isabella; and soon after he died, perhaps of chan- ging his mind. Vicente Yáñez Pinzón, who sailed with Columbus in 1492-1493, also gave Columbus material help and remained loyal to his leader throughout. In after years he made important discoveries on his own account. Late in December 1490 he sailed with four caravels across the Atlantic to the south-west, and on the 7th of February 1500 he struck the South American continent at Cape S. Agostinho, near its most easterly projection (called by him Cape Santa Maria de la Consolacion) almost three months before the Portuguese navigator Cabral reached Brazil, the discovery of which is generally attributed to him. Proceeding southwards a short distance, he then turned north, followed the coast to the north-west, discovered the Amazon estuary, and went at least as far as what is now Costa Rica. After touch- ing at Haiti, and losing two of his vessels among the Bahamas, Vicente returned to Palos in the end of September 1500. Although concessions were made to him, and he was created governor of the newly discovered lands by Ferdinand and Isabella, he does not seem to have ever taken possession. In 1507 we find Vicente sailing with Juan Diaz de Solis along the east coast of Central America. In 1509, again with De Solis, he coasted the Atlantic side of South America as far as the La Plata estuary, hoping to find an opening westwards leading to the Spice Islands. According to Herrera, he even reached 40ºS.
passing the La Plata without recognizing it, and turning back about the 13th of the Rio Negro but this is probably an exaggeration. After 1523 all traces of Vicente are lost.

PIO DI SAVIO, an ancient noble Italian family, first mentioned by good authorities in the 14th century. From the house of Este (q.v.) they received the lordship of Carpi, and later they acquired the fiefs of Moldola, Sassuolo, &c. Many members of the family were distinguished as condottieri, diplomats and ecclesiastics. Alberto Pio obtained from the house of Savoy in 1450 the privilege of adding "di Savoia" to his name as a reward for his military services. Another Alberto Pio (1475–1531), who was French ambassador in Rome, won fame as a man of learning, and Cardinal Rodolfo Pio (1576–1654) was a trusted adviser to Pius V and helped to establish the Inquisition at Milan. Ascanio Pio (d. 1649) was a dramatic poet of some merit. Spain conferred the title of prince on the family, and one branch of it is to this day established in Spain.

See P. Litta, Le Famiglie celebri italiane (Milan); G. Campori, Memorie storiche di Marco Pio di Savoia (Modena, 1876); A. Ceriani and G. Porro, Il Rotolo epigrafico dei principi Pio di Savoia, in the Studi storici, ser. an. XI. fasc. 1, ser. III. an. VIII. 96, and III. an. XIX. 453.

PIOMBINO, a seaport of Tuscany, Italy, in the province of Pisa, 8 m. by rail W.S.W. of Campiglia Marittima (which is 53 m. S.S.E. of Pisa), 62 ft. above sea-level, at the southern extremity of the peninsula of the Monte Massoncello. Pop. (1901), 5979 (town); 7703 (commune). It is surrounded by old walls, and contains some interesting Renaissance works by a master of about 1458 under the influence of Alberti. It is the port of embarkation for Elba, the nearest point of which is about 6 m. to the south-west, and originally belonged to Pisa. It gives the title of prince to the Buoncompagni Ludovisi family, who, however, no longer own it.

PIONEER, properly a foot-soldier (Med. Lat. pedo, pedonis, through O. Fr. peonier, pension, cf. "paw"") who with spade, axe and other implements, precedes an army or smaller military body, and clears or makes a road, digs intrenchments, prepares a camping ground, &c. The word is thus applied to all who, actually or figuratively, are first in exploring or working an undiscovered or undeveloped country or field of inquiry.

PIOtkow (Ger. Petrikau), a government of Russian Poland, bounded by the government of Warsaw on the N., Radom and Kielce on the E., Kaliasz on the W. and Prussian Silesia on the S. Area, 4729 sq. m.; pop. (1906, estimate), 1,675,200. Geologically it represents a continuation of Upper Silesia, and is built up of Upper Carboniferous deposits, containing near Bendzin a bed of coal 205 sq. m. in extent. Permian and Jurassic deposits, containing zinc ores, as also lignite and limonite iron ores, overlie the Carboniferous. The surface consists of a series of heights, 1000 to 1600 ft. above sea-level, intersected by ravines, and stretching from south-west to north-east. The government is drained by the Warta and the Pilica, and was formerly covered with thick forests. It was colonized by Mazurs and Poles (Veliko-Polans and Malo-Polans). The government, which is the most densely peopled in the Russian Empire, is divided into 26 counties, of which the largest are: Piotrkow, Bendzin, Brzeziny, Czarnstochowa, Lask, Lodz, Novo-Radom and Rawa. Agriculture and cattle-breeding are extensively carried on; and coal and iron are mined. Textile industries developed with extraordinary rapidity during the closing years of the 19th and the opening years of the 20th centuries, the towns of Lodz, Pabianice, Zgerz and Bendzin all being important centres. Other branches of productive industry are distilleries, breweries, flour-mills, brickyards, sugar, cement, glass and candle factories. Granica and Sosnowice, in this government, are two of the most important custom-houses in Russia, and the annual trade is estimated at £12,000,000.

Piotrkow, a town of Russian Poland, capital of the government of the same name, and formerly the seat of the high court of Poland, on the railway from Warsaw to Vienna, 90 m. south-west of the former and 5 m. west of the river Pilica. Pop. (1900), 32,173. It is a well-kept town, with numerous gardens, and has flour-mills, saw-mills, tanneries, agricultural machinery works, and breweries. One of the oldest towns in Poland, Piotrkow was in the 15th and 16th centuries the place of meeting of the diets, and here the kings were elected. In the 14th century Casimir the Great built here a castle (now a military church) and surrounded the town with walls. Here in 1790 the Russians defeated the Polish army. In 1863 it was damaged by fire. There are several important churches and synagogues.

PIOZZI, HESTER LYNCH (1744–1821), English writer, well known as the friend (Mrs Thrale) of Samuel Johnson (q.v.), was born on the 10th of January 1741, her father being John Salusbury of Bobbel, Carnarvonshire. Her maternal uncle, Sir Robert Salusbury Cotton, contemplated providing for his niece, but he died without having carried out his intention. She and her mother lived in London, and amongst her childish recollections were meetings with James Quin and David Garrick. She received a solid education, for she was acquainted with Latin as well as with French, Italian and Spanish. In 1763 she was married to Henry Thrale, a rich Southwark brewer, whose house stands at Streatham on the south-east corner of Tooting Bec Common. There was very little sympathy between the lively girl and Thrale, who was thirteen years her senior, but gradually she drew round her a distinguished circle of friends. She was introduced to Samuel Johnson in 1765 by Arthur Murphy, who was an old friend of her husband's. In 1766 Johnson paid a long visit to Streatham, and from that time was more or less domesticated with the Thrales. In time it became his custom to spend the middle of the week at Streatham, devoting the remaining days to his own heterogeneous family. He was genuinely attached to his hostess, and thoroughly appreciated the luxury in which the Thrales lived. They were able to soften some of his eccentricities, and they certainly made him happy. He travelled with them in Wales in 1774, and in France in 1775. Dr Burney gave lessons to one of the Miss Thrales, and in 1778 he brought his daughter Fanny to Streatham. She became a warm friend of Mrs Thrale, and has left an account of the Streatham household in her diary. This friendship was by no means always unclouded. Fanny Burney was very sensitive, and sometimes thought that Mrs Thrale gave herself airs of patronage. Meanwhile, in 1772, Thrale's business was seriously injured, and he was threatened with bankruptcy. The situation was saved by his wife's efforts, and in the next year Thrale travelled, leaving her in charge of his affairs. He was twice returned for the borough of Southwark, chiefly through her efforts. In 1781 Mr Thrale died, and Dr Johnson helped the widow with her business arrangements, advising her to keep on the brewery, until she "cured his honest heart of its incipient passion for trade, by letting him into some, and only some, of its mysteries." The brewery was finally sold for £33,000. Mrs Thrale had met Gabriele Piozzi, an Italian musician, in 1780. Johnson was now in failing health, and soon began to feel himself slighted. His suspicions were definitely aroused when she had aside her mourning for Thrale in 1782, and the Streatham house was sold. In 1783 her engagement to Piozzi was announced. The objections of her daughters and her friends induced her to break it off for a time, but it was soon resumed, and in 1784 they were married. Johnson told Miss Burney that he knew the memory of Mrs Thrale from his mind, burning every letter of hers on which he could lay his hand. The Piozzis presently left England to travel in Italy. At Florence they fell in with Robert Merry and the other "Della Cruscan" writers ridiculed by William Gifford in his Maedias and Bvidia, and she contributed some verses to their Florence Miscellany in 1785. In 1786 she published Anecdotes of the late Samuel Johnson, during the last twenty years of his life, which was severely criticized by Boswell. She was ridiculed by "Peter Pindar" in Bosvoy and
PIECE; or the British Biographers, A Town Edologue (1756). But though Miss Burney and some others held aloof, the Piozzis found plenty of friends when they returned to London in 1787. Piozzi died at Brynbella, a villa he had built on his wife's Carnarvonshire estate in 1809, and Mrs Piozzi gave up her Welsh property to her husband's son, and spent most of her life at Bath and Clifton. When long past seventy she took a fancy to William Augustus Conway, the actor. She retained her vivacity to the last, celebrating her 80th birthday by a ball to six or seven hundred people at Bath. She died at Clifton on the 2nd of May 1821.

From 1776 to 1809 she kept a note-book which she called "Thraliana." Her well-known poem of the "Three Warnings" is to be found in many popular collections. Letters to and from the late Samuel Johnson appeared in 1788: Observations and Reflections made in the course of a Journey, through France, Italy and Germany, in 1799; and in 1801 she published Retrospection; or a review of the most striking and important events, characters, and situations... which the last eighteen years have presented to the view of mankind (1801).

See Letters and Literary Remains of Mrs Piozzi (Thrale), edited with notes and an Introductory Account of Her Life and Writings by A. Haywood (1861); Piozziana; or Recollections of the late Mrs Piozzi by a Friend (1853), the anonymous friend being Edward Manig (1772–1852); B. Beslow, Thrale, afterwards Mrs Piozzi... (1891), and G. Birkbeck Hill, Johnsonian Miscellanea (1897). Also works noted in bibliography to Johnson, Samuel.

PIE. A term used of a musical wind-instrument of tubular form, and hence of any cylindrical hollow tube. The original application of the term is to the musical instrument (see PIPE and TABOR below), and the source is to be found in Lat. piper, to chirp, of a bird. The general meaning of "pipe," in the sense of a tube for such purposes as carrying water, gas, sewage, &c., is treated under TUBE. Among specific uses of the word are those for the hollow stem of clay, wood or other material with a bowl at one end in which tobacco is smoked (see below); for the metal or wooden sound tubes in an organ (q.v.); and for various forms of cylindrical veins, hollows, channels, &c., in mining and geology.

The Great Roll of the Exchequer was known as the "Pipe Roll"; this contained the various "pipes" or enrolled accounts of the sheriffs, &c., which were so called either from being set in a cylindrical case or as resembling a pipe in shape when rolled (see RECORDS).

TOBACCO PIPE.—The smoking of tobacco in pipes is a custom which prevailed in America for a period of unknown duration previous to the discovery of that continent by Columbus. The most ancient pipes of which remains exist have been found in mounds or tumuli called pipe mounds, principally in Ohio, Indiana, Illinois and Iowa. These mound pipes, which are carved in porphyry and other hard stones, are very uniform in type. The pipe, cut out of a single piece of stone, consists of a slightly convex platform or base, generally from 3 to 4 in. in length, and about an inch broad, with the bowl on the centre. A fine hole is pierced from one end of the platform to the bottom of the bowl, the opposite end being obviously for holding in the hand while the pipe is being smoked.

In the commonest forms the bowl is a simple cylinder of urn (fig. 1), but in many cases remarkable artistic skill has been displayed in carving the bowls into miniature figures of birds, mammals, reptiles and human heads, often grotesque and fantastic, but always vigorously expressed (fig. 2). These mound or platform pipes with carved human and animal forms are objects of the highest ethnographic interest and importance, being among the most characteristic remains of the ancient inhabitants of the Mississippi valley. The wide area over which they, as well as remains of baked clay pipes, are found throughout the American continent testifies to the universal prevalence of smoking in the pre-Columbian era. Many of the ancient clay pipes found in Mexico, &c., are elaborately moulded and ornamented, while others show considerable similarity to the early clay pipes of Europe. Among the North-American tribes of the period, pipe smoking occupies a position of peculiar symbolic significance in connexion with the superstitious rites and usages of the race. The calumet, peace pipe or medicine pipe, is an object of the most profound veneration, entrusted to the care of a highly honoured official, and produced and smoked with much ceremony only on occasions of great importance and solemnity. It is remarkable that, whilst the most ancient American pipes had no separate stem, it is the stem only of the medicine pipe which is the object of veneration among the Indians, the bowl used being a matter of indifference. The favourite material for Indian pipe bowls is the famous red pipe stone (catlinite), a fine-grained easily-worked stone of a rich red colour of the Côteau des Prairies, west of the Big Stone Lake in S. Dakota. The quantities were formerly neutral ground among the warring Indian tribes, many sacred traditions being associated with the locality and its product.

It is disputed whether pipes for smoking were at all known in Europe previous to the discovery of America. That tobacco-smoking was unknown is certain; but pipes of iron, bronze and clay have been so frequently found associated with Roman remains and other antiquities as to lead many authorities to maintain that such pipes must have been anciently used for burning incense or for smoking aromatic herbs or hemp. Throughout Great Britain and Ireland small clay pipes are frequently dug up, in some instances associated with Roman relics. These are known amongst the people as elfin, fairy or Celtic pipes, and in some districts supernatural agencies have been called in to account for their existence. The elfin pipes have commonly flat broad heels in place of the sharp spur now found on clay pipes, and on that flat space the mark or initials of the maker is occasionally found. There is no reason to believe that these pipes are older than the 17th century. The introduction of the tobacco pipe into Europe is generally ascribed to Ralph Lane, first governor of Virginia, who in 1586 brought an Indian pipe to Sir Walter Raleigh, and taught that courtier how to use the implement. The pipe-makers of London became an incorporated body in 1619, and from England the other nations of Europe learned the art of making clay pipes.

The habit of smoking with pipes spread with incredible rapidity; and among the various peoples the pipe assumed special characteristics, and its modifications became the medium of conveying social, political and personal allusions, in many cases with no little artistic skill and humour. The pipe also became the object of much inventive ingenuity, and it varied as greatly in material as in form—wood, horn, bone, ivory, stone, precious and other metals, amber, glass, porcelain and, above all, clay being the materials employed in various forms. By degrees pipes of special form and material came to be associated with particular people, e.g. the elongated painted porcelain bowls and pendulous stem of the German peasantry, the red clay bowl and long cherry wood stem of the Turk, and the very small metallic bowl and cane stem of the Japanese, &c. Among other kinds of pipe which have been popular at various times are the "corn-cob," where the bowl is made of the cob of maize or Indian corn, and the "calabash" with the bowl of a small gourd. The "churchwarden" is a clay pipe with a slender stem, some 16 or 20 in. long. The most luxurious and elaborate form of pipe is the Persian kalydah, Turkah or water tobacco pipe. This consists of three pipes, the head or bowl, the water bottle or base, and the snake or long flexible tube ending in the mouthpiece. The tobacco, which must be previously prepared by steeping in water, is placed in the head and lighted with live charcoal, a wooden stem passes from its bottom down into the water which fills the base, and the tube is fitted to a stem which ends in the bottle above the water. Thus the smoke is cooled and washed before it reaches the smoker by passing through the water in...
the bottle, and by being drawn through the coil of tube frequently some yards in length. The bottles are in many cases made of carved and otherwise ornamented coco-nut shells, whence the apparatus is called nargile, from nargil, a coco-nut. Silver, gold, damascened steel and precious stones are freely used in the making and decoration of these pipes for wealthy smokers.

Pipe Manufacture.—The regular pipe-making industries divide into many branches, of which the more important are the clay pipe, meerschaum (real and artificial), and wooden bowl trades. Clay pipes are made in prodigious numbers by hand labour with an iron mould and a steel wire for forming the tube of the stem. Pipe-moulding is a very simple operation in pottery, and the work is performed with a astonishing celerity. A number of machines have been devised for automatic pipe-moulding; but the manual operations are so rapid and inexpensive that there is little margin for saving by the substitution of machinery. The pipes are very slightly fired so as to keep them soft and porous; and so cheaply made are they that the commoner kinds can be retailed at a profit for a farthing each. The principal early centres of the clay-pipe industry were at Broseley in Staffordshire, where the trade has been established since the early part of the 17th century, and at Amesbury in Wiltshire. The manufacture is still carried on at Broseley. Meerschaum pipes (see Meerschaum) are the luxury of the European smoker. The favourite wooden pipe generally known as a briar-wood or briar-root pipe is really made from the roots of the tree heath, Erica arborea (Fr. bruyère), principally obtained on the hills of the Maremma and taken thence to Leghorn. There the roots are shaped into blocks each of which is suitable for a pipe, and the outer part of the wood so as to avoid waste requiring considerable skill. These blocks are simmered in a vat for twelve hours, which gives them the much-appreciated yellowish-brown hue of a good 'briar-root.' So prepared the blocks are exported for boring and finishing. Many devices have been invented for the purpose of preventing the nicotine liquor from reaching the smoker's mouth or collecting in and fouling the pipe.

Pipe and Tabor (Fr. galoubet; Ger. Schwebel or Stamentenspil) is a popular medieval combination of a small pipe or flageolet and a small drum. The favourite wooden pipe, generally known as a briar-wood or briar-root pipe is really made from the roots of the tree heath, Erica arborea (Fr. bruyère), principally obtained on the hills of the Maremma and taken thence to Leghorn. There the roots are shaped into blocks each of which is suitable for a pipe, and the outer part of the wood so as to avoid waste requiring considerable skill. These blocks are simmered in a vat for twelve hours, which gives them the much-appreciated yellowish-brown hue of a good 'briar-root.' So prepared the blocks are exported for boring and finishing. Many devices have been invented for the purpose of preventing the nicotine liquor from reaching the smoker's mouth or collecting in and fouling the pipe.

Pipe-Fishes (Syngnathus), small fishes, which with the Sea-horses form a distinct family, Syngnathidae, of Lophobranchiate narrow and small mouth which opens upwards and is toothless. The body and tail are long and thin, snake-like, encased in hard integuments which are divided into regularly arranged segments. This dermal skeleton is composed of longitudinal ridges, so that a vertical section through the body represents an angular figure, not round or oval as in the majority of other fishes. A dorsal fin is always present, and is the principal (in some species, the only) organ of locomotion. The ventral fins are as constantly absent, and the other fins may or may not be developed. The gill-openings are extremely small and placed near the upper posterior angle of the Gill-cover. Most of the pipe-fishes are marine, only a few being freshwater. Pipe-fishes are abundant on such coasts of the tropical and temperate zones as offer by their vegetation shelter to these defenseless creatures. They are very bad swimmers, slowly moving through the water by means of the rapid undulatory movement of the dorsal fin.

Their tail, even when provided with a caudal fin, is of no use in swimming, and not prehensile as in sea-horses. Specimens, therefore, are not rarely found at a great distance from land, having been resistlessly carried by currents into the open sea; one species, Syngnathus pelagicus, has an extraordinarily wide range over the tropical seas, and is one of the common fishes inhabiting the vegetation of the Sargasso Sea. The colour of these fishes often changes with the sea-weeds among which they may be found, passing from brown to green or even brick-red. In pipe-fishes the male is furnished with a pouch—in some species on the abdomen, in others on the lower side of the tail—in which the ova are lodged during their development. This marsupial pouch is formed by a fold of the skin developed from each side of the trunk or tail, the free margins of the fold being firmly united in the median line throughout the period during which the eggs are being hatched. When the young are hatched the folds separate, leaving a wide slit, by which the young gradually escape when quite able to take care of themselves. Nearly a hundred different species of pipe-fishes are known, of which Siphonostoma typhle, Syngnathus acus (the Great Pipe-fish up to 18 in. in length), Nerophis aquorosus (Ocean Pipe-fish), Nerophis opilion (Slit-nosed Pipe-fish), and Nerophis lumbriciformis (Little Pipe-fish) are British species. The most abundant are Syngnathus acus, with the young ready to leave the pouch. One side of the membrane of the pouch is pushed aside to admit of a view of its interior. (Nat. size.)

PIPER, CARL, Count (1647-1716), Swedish statesman, was born at Stockholm on the 29th of July 1647. He entered the foreign office after completing his academic course at Upsala, accompanied Benedict Oxenstjerna on his embassy to Russia in 1673, and attracted the attention of Charles XI. during the Scanian War by his extraordinary energy and ability. In 1679 he was appointed secretary to the board of trade and enumerated. In 1680 he was made one of the secretaries of state, and Charles XI. recommended him on his deathbed to his son and successor, Charles XII. Piper became the most confidential of the new sovereign's ministers. In 1692 he was made a senator and set over domestic affairs while still retaining his state-secretaryship. In 1698 he was created a count, in 1702 appointed chancellor of Upsala University, and during the first half of the Great Northern War, as the chief of Charles’ parambulating chancellery, he was practically prime minister. It was his misfortune, however, to be obliged to support a system which was not his
own. He belonged to the school of Benedict Oxenstierna and was therefore an avowed advocate of a pacific policy. He protested in vain against nearly all the military ventures of Charles XII., e.g. the War of Deposition against Augustus of Saxony and Poland, the invasion of Saxony, the raid into the Ukraine. Again and again he insisted that the pacific overtures of Peter the Great should at least be fairly considered, but his master was always immovable. Piper's career came to an end at Poltava (1709), where he was among the prisoners. The last years of his life were spent in exile in Russia. He died at Schlüsselburg on the 29th of May 1716.

See W. L. Svedelius, Count Carl Peter (Stockholm, 1869).

PIPERAZIN, a substance formed by the action of sodium glycol on ethylene-diamine hydrochloride, consisting of small alkaline deliquescent crystals with a saline taste and soluble in water. It was originally introduced into medicine as a solvent for uric acid. When taken into the body the drug is partly oxidized and partly eliminated unchanged. Outside the body piperazin has a remarkable power of dissolving uric acid and producing a soluble urate, but in clinical experience it has not proved equally successful. Lycetol, lysidine and sidonial are bodies having similar action.

PIPERINE, C₅H₇NO₂, an alkaloid found in the fruits of Piper nigrum and P. longum. It forms white prisms, which melt at 128°-210°. It is almost insoluble in water, but readily soluble in alcohol and ether. It is a very weak base, salts being only formed with mineral acids, and these are dissociated by water. Alcoholic potash decomposes it into piperidine, C₅H₇N, and piperic acid, C₅H₇O₄. The constitution of piperic acid was elucidated by R. Fittig and his pupils (Ann., vols. 152, 159, 168, 216, 227) and shown to be (1). Piperine consequently is (2).

\[
\begin{align*}
\text{CH}_3 & \quad \text{CH}\text{-CH}\text{-CH}\text{-COOH} \\
\text{CH}_3 & \quad \text{CH}\text{-CH}\text{-CH}\text{-CO-N(CH}_3)_2
\end{align*}
\]

Oxidation with potassium permanganate converts piperic acid into pipernol, C₅H₈O₃, and pipernonol, C₅H₈O₄. The latter when heated with hydrochloric acid to 170°, or water to 200°, separates in a very pure form the formation products of the incomplete oxidation, 

1-2-dioxy-3-benzoic acid, C₆H₅(OH)₂COOH. Conversely, by heating protocatechuic acid with potash and methylene iodide, pipernic acid was regained. These results show that piperonyl acid and its methylene ether of protocatechuic acid, Piperonal (q.v.), is the corresponding aldehyde. Piperic acid differs from pipernic acid by the group C₅H₅, and it was apparent that these carbon atoms must be attached to the carbon atom which appears in the carbonyl group of piperonic acid, for if they were directly attached to the benzene ring polycarboxylic acids would result in oxidation. The above formula for piperic acid was confirmed by its synthesis by A. Ladenburg and M. Schötz (Ber., 1894, 27, p. 2958) from piperonyl acrolein (the condensation product of piperonal and acetaldehyde) and acetic acid. The synthesis of piperine follows from the interaction of piperyl chloride (formed from piperic acid and phosphorus pentachloride) and pipidine (L. Röhssinger, Ber., 1882, 15, p. 1330.)

PIPERINO (anc. Privernum), a town of the province of Rome, Italy, 61 m. S.E. of Rome by rail. Pop. (1901), 6736. The medieval town was founded in the 10th century (?) on a hill 400 ft. above sea-level, by refugees from the Roman town of Privernum, lower down (118 ft. above sea-level) on the highroad, 1½ m. to the north, at the mouth of a low pass leading through the Volscian mountains to the valley of the Sacco. Here are remains of an arch crossing the road and other ruins (mostly buried) of the Roman period, but the remains above ground are largely medieval. It is improbable, however, that the ancient Volscian town should have occupied so easily accessible a site; it is not unlikely that it stood on the site occupied by the medieval and modern town, but there is no proof of this. Privernum was a Volscian town, and took up arms against Rome after the foundation of a Latin colony at Setia in 382 B.C. It was finally captured in 320 B.C. and eleven years later the

tribus Oufentina was founded, taking its name from the river Oufens (mod. Uffente) in the territory of Privernum. Little is known of it subsequently. The medieval town has a picturesqueness piazza, with a Gothic cathedral (1283), which preserves a fine porch, though the interior was modernized in 1782; a Gothic palazzo publico; and other Gothic churches exist in the town. Polygonal terrace walls of the Roman or pre-Roman period exist at various places in the vicinity (G. B. Giovenale and L. Mariani in Notizie degli Scoi., 1809, 88).

PIPERONAL (heliotropine, protocatechuic aldehyde methylene ether), C₆H₈O₃, an aromatic aldehyde. It is prepared by oxidizing piperic acid with potassium permanganate (R. Fittig, Ann., 1806, 152, p. 35); by condensing methylene iodide with protocatechuic aldehyde (R. Wegscheider, Monats., 1893, 14, p. 388); or by oxidizing isosafrole with chromic acid. It forms long colourless crystals which melt at 37° C. and boil at 263° C. It has an agreeable smell, resembling that of heliotrope, and is much used in perfumery. It is only slightly soluble in cold water, but is readily soluble in alcohol and in ether. When heated with dilute hydrochloric acid to 200° C. it yields protocatechuic aldehyde, C₅H₈O₄, and carbon. It readily combines with sodium bisulphite and with various bases (ammonia, aniline, methylamine, &c.).

PIPET (cognate with the Lat. Pipio; see PIGEON), the name applied by ornithologists to a group of birds having a great resemblance both in habits and appearance to the larks (q.v.). Many species however differ from larks in several important characters, and, having been first separated to form the genus Anthus, which has since been much broken up, are now generally associated with the wagtails (q.v.) in the Passerine family Motacillidae. Pipits, of which over fifty species have been described, occur in almost all parts of the world, but in North America are represented by only two species—Neocorys spraguii, the prairie-lark of the north-western plains, and Anthus ludovicianus, the American titlark, which last is very nearly allied to the so-called water-pipit of Europe, A. sipekota. To most English readers the best known species of pipit is the titlark or meadow-pipit, A. pratensis, a bird too common to need description, and abundant on pastures, moors, and uncultivated districts generally; but in some localities the tree-pipit, A. trivialis, or A. arboreus of some authors, takes its place, and where it does so it usually attracts attention by its loud song, which is not unlike that of a canary, but delivered (as appears to be the habit of all the pipits) on the wing and during a short circuitous flight. Another species, the rock-lark, A. obscurus, scarcely ever leaves the sea-coast and is found almost all round the British Islands. The South-African genus Macronyx, remarkable for the extreme length of its hind claw, is generally placed among the pipits, but differs from all the rest in its brighter coloration, which has a curious resemblance to the American genus Sturnella (see IC TERUS), though the bird is certainly not allied thereto.

PIPPIN, or PEPPIN, the name of three members of the Carolingian family.

PIPPIN I. (d. 640), incorrectly called Pippin of Landen, was mayor of the palace to the youthful Dagobert I., whom Clotaire II. had placed over the kingdom of Austrasia. He was disgraced when Dagobert became sole king in 629, and had to seek refuge in Aquitaine. Returning at Dagobert's death (639), he governed Austrasia in Sigebert's name, but died in the following year.

PIPPIN II. (d. 714), incorrectly called Pippin of Herstal, was son of Adalgiselus (son of Arnulf, bishop of Metz) by a daughter of Pippin I., called in later documents Begga. Towards 678 he placed himself at the head of the great nobles in Austrasia to combat Ebroin, the mayor of the palace, and Neustria. After some reverses he gained a great victory after Ebroin's death at the battle of Tetrty, not far from St Quentin. This victory made Pippin almost entire master of Gaul. He appointed one of his sons mayor of the palace of Neustria, reserving for another of his sons the mayoralty of Austrasia. He made war
on the Frisians and defeated their duke Radbod; and part of this people became converts to Christianity. He also defeated Willari, the duke of the Alamanni, and subdued his country. The Bavarians, too, recognized the Frankish suzerainty. The plans he had formed for reforming the church and convoking councils were interrupted by his death, which took place on the 16th of December 714.

Pippin III. (d. 768), the Short, 1 was son of Charles Martel. Before his death in 741 Charles Martel had divided the Frankish kingdom between his two sons, Carloman and Pippin, giving Carloman the eastern part and Pippin the western. Since 737 there had been no king in the Frankish realm; in the diplomas then Pippin bears the title of magister palatii, which the chroniclers call them simply principes. In 743, however, the mayors decided to appoint a king in the person of Childeric III., who was apparently connected with the Merovingian family. But Childeric was a mere figure-head, and had no power. The two brothers presided over the tribunals, convoked the councils at which the Frankish Church was reformed, assembled the host and made war, jointly defeating and subduing Duke Hunald of Aquitaine. In 747 Carloman unexpectedly abdicated, became a monk, and retired to a monastery near Rome, subsequently founding on Mt Soracte the monastery of St. Paul’s outside Rome. From the time of the abdication 747 was sole master; and in 751, after consulting Pope Zacharias, he took the title of king and removed the feebler Childeric to a monastery. He then got himself crowned by St Boniface, a ceremony which was new to France and which gave the sovereign immense prestige; henceforth the king of the Franks called himself Gratia Dei rex Francorum. Pippin’s reign is marked by many important events. He received in France a personal visit from Pope Stephen II., who conferred on him the title of Patrician of the Romans and recrowned him. In return for these honours Pippin, at the appeal of the pope, made two expeditions into Italy, in 754 and 756; and he became the very representative of the papal state by conferring on the pope the exarchate of Ravenna, which he had wrested from Aistulf, the king of the Lombards. Pippin took Septimania from the Arabs, and after a stubborn war of nearly eight years’ duration (760–68) succeeded in taking Aquitaine from its duke, Waifer. He also intervened in Germany, where he forced the duke of Bavaria, Tassilo, to become his vassal. In 763, however, Tassilo abandoned Pippin during an expedition against Aquitaine. Pippin made several expeditions against the Saxons, but failed to subdue them. He entered into relations with the Eastern Empire, exchanging ambassadors with the emperor Constantine V. Copronymus. During Pippin’s reign Frankish institutions underwent some modification. The Frankish assemblies, previously held in the month of March (champs de maïs), came to be more numerous, and served the king of the Franks as a means of receiving the gifts of his subjects and of promulgating his capitularies. At the head of the administration was placed the archchaplain, and an ecclesiastical chancellor was substituted for the ancient referendarii. Ecclesiastical reform was continued under Pippin, Bishop Chrodegang of Metz uniting the clergy of Metz in a common life and creating canons (see Canons). Pippin died on the 24th of September 768 at St Denis, leaving two sons, Charles (Charlemagne) and Carloman.

Oesler, Jahrbücher des fränkischen Reiches unter König Pippin (Leipzig, 1857); J. F. Böhmer and E. Mühbacher, Regesta des Kaiserreiches unter den Karolingern (pp. ed., 1881); and E. Mühbacher, Deutsche Geschichte unter den Karolingern (Stuttgart, 1896).

PIPRÁWA, a village on the Birdpur estate in the Basti district, United Provinces, India. It lies on the Uska-Nepal road at mile 197-75; and about half a mile south of the boundary pillar numbered 44 on the frontier line between British and Nepalese territory. The village is celebrated as the site of the following discovery:

In 1866 interest having been aroused by the discovery, only twelve miles away, of the Buddha’s birthplace (see LUMBIAH), William Peppe, then resident manager of the Birdpur estate, opened a ruined tope or burial mound situat at Piprâwa, but nothing of importance was found. In January 1867 he carried the work of excavation farther. A well, 20 ft. sq., was dug down the centre of the mound. After digging through 18 ft. of solid brickwork set in clay a massive stone cofar was found lying due magnetic north and south. Its dimensions were, 4 ft. 10 in. by 2 ft. 85 in. and 2 ft. 21 in. high. The stone lid of the cofar was split into four pieces, but the cofar remained perfectly closed, so accurately was the lid fitted into flanges on the sides of the box. The pieces were thus firmly held in their place, and the contents of the cofar were found intact. These consisted of five vessels, two vases, a bowl and a casket being made of steatite, and the fifth, also a bowl, of crystal. All these vessels are beautifully worked, the crystal bowl especially, with its fish-shaped cover handle, being as a work of art of high merit. The cofar is of fine hard sandstone of superior quality, and has been hollowed out, at the cost of vast labour and expense, from a solid block of rock. Peppe calculates its weight, lid included, at 65 lb. It is only the greater solidity of this cofar which has preserved the contents. A cover of one of the vases was found dislodged and lying on the bottom of the stone cofar. As this cover fits very well it must have required a quite violent shock to remove it. This was almost certainly the shock of an earthquake, and the same shock probably caused the split in the stone lid of the cofar itself.

The vessels contained a dark dust, apparently disintegrated ashes, small pieces of bone, and a number of small pieces of jewelry in gold, silver, white and red cornelian, amethyst, topaz, garnet, coral and crystal. Most of these are perforated for mounting on threads or wires, and had been, no doubt, originally connected together to form one or more of the elaborate pendants, necklaces and breast ornaments then worn by the women. On the bottom of the stone box there was similar dust, pieces of bone and jewelry, and also remains of what had been vessels of wood. The knob forming the handle of one of these wooden receptacles was still distinguishable. The total quantity of scraps of bone may have amounted to a wineglassful.

An inscription ran round one of the steatite vases just below the lid. The words mean: This shrine for ashes of the Buddha, the Exalted One, is the pious work of the Sakhyas, his brethren, associated with their sisters, and their children, and their wives. The thirteen words, in a local dialect of Pall, are written in very ancient characters and are the oldest inscription yet discovered in India. Twelve out of the thirteen are well-known words, the interpretation of which is not open to doubt. One word, rendered above by “pious work,” has not been found elsewhere, and its derivation is open to discussion. The explanation here adopted as most probable was put forward by Professor Pischel of Berlin. The phrase “pious work” probably had a precise technical connotation like the English “benefaction.”

The monument must have been of imposing appearance. The diameter (on the ground level) of the dome is 116 ft. For 8 ft. from the summit of the ruin it was not possible to trace the outline. At that point the outer wall, if one may so call it, of the solid dome could be traced, and had a diameter of 68 ft. The dome, therefore, sloped inwards 1 ft. for every 3 ft. in height; in other words, it was, like all the most ancient of these artificial burial domes in India, a shallow dome, and cannot have been more than about 35 ft. high exclusive of the ornament or “tee” on the summit. We have in bas-reliefs of the 3rd century representations of what these ornaments were like—small 7 An illustration from a photograph is given in Rhys Davids’ Buddhist India, p. 131.

For figures of the jewelry found see the plate in Mr Peppe’s article reproduced in Rhys Davids’ Buddhist India, p. 80. For the jewelry of the time, ibid., pp. 90, 91.

1 See illustration ibid., p. 129.

PIQUA—PIQUET

637

square erections, like a shrine or small temple, surmounted by a canopy called from its shape a T. They were then more than a third of the height of the dome itself. The total height of this Śākyi tope will therefore have been approximately a little under 50 ft. It was probably surrounded by a carved wooden railing, but this has long since disappeared.

All such monuments hitherto discovered in India were put up in honour of some religious teacher, not in memory of royal persons, generous benefactors, politicians, or soldiers or private persons, however distinguished. And we need have no hesitation in accepting this as a monument put up over a portion of the ashes from the funeral pyre of Gotama the Buddha. The account of the death and cremation of the Buddha, preserved in the Buddhist canon, states that one-eighth portion of the ashes was presented to the Śākyi clan, and that they built a śākya, or memorial mound, over it.1

Mr Peppe presented the coffers and vases with specimens of the jewelry to the museum at Calcutta where they still are. He also gave specimens of the trinkets to the Asiatic Society in London.

Peppe's original article is in the Journal of the Royal Asiatic Society for 1898, pp. 573 seqq. Comments upon it, one or two of them suseptible, are in the same journal 1898, pp. 579, 580, 587, 588; 1899, pp. 398, 399; 1906; 1908. See also A. Barth, Comptes rendus de l'académie des inscriptions (1899), xxxvi, 147, 233; Sylvain Levy, Journal des savants (1905) pp. 540 seqq; and R. Pichelin and Rhys Davids as quoted above. (T. W. W.)

PIQUA, a city of Miami county, Ohio, U.S.A., on the Miami River and the Miami & Erie Canal, 73 m. W. by N. of Columbus. Pop. (1890), 9090; (1900), 12,172, of whom 901 were foreign-born and 487 were negroes; (1910 census), 13,388. It is served by the Pittsburg, Cincinnati, Chicago & St Louis, and the Cincinnati, Hamilton & Dayton railways, and by inter-urban electric lines to Lima, Dayton and Covington. It has a park, a public library and a public hospital. There are remains of blue limestone in the vicinity. The city has various manufactories, the factory products being valued in 1905 at $4,035,706. The municipality owns and operates its waterworks. On or near the site of Piqua was one of the principal villages of the Chillicothe division of the Shawnee tribe; the village also was called Chillicothe. It was destroyed by George Rogers Clark in 1783. A town was laid out here in 1809 under the name of Washington, and the present name, that of another division of the Shawnee tribe, was substituted in 1823. Piqua was chartered as a city in 1846. During the French and Indian War, in 1763, a battle was fought in this vicinity chiefly between the Miami, Wyandots, Ottawas and other Indian allies of the French, and the Delawares, Shawnees, Cherokees, Catawbas and other Indian allies of the English, the English allies making an unsuccessful attempt to drive the French allies from their fortified position, Fort Piqua.

See Henry Howe, Historical Collections of Ohio (Columbus, 1891).

PIQUET, a game at cards, probably a development of ranfa, a game mentioned by Berni in 1526; la ranfol (included in Rabelais's list, c. 1530) may be regarded as the same game. The point at piquet was ancienly called ranfle. The Spanish name of the game was cantos (cantum, a hundred). Piquet was played in England under the name of cent, or sant, probably as early as 1539 (contemporaneously with the marriage of Mary to Philip of Spain). About the middle of the 17th century (shortly after the marriage of Charles I to Henrietta Maria of France) the name cent was dropped in England, and the French equivalent, piquet, adopted. It is played by two persons, with a pack of thirty-two cards—the sixes, fives, fours, threes and twos being thrown out from a complete pack. At one time the partie was the best of five games of a hundred up (a player not obtaining fifty losing a double game). But now the partie is generally determined in six hands, the player making the largest aggregate score being the winner. The number of points won is the difference between the two scores, with a hundred added for the game. If, however, the loser fails to make a hundred in six hands, the number of points won is the sum of the two scores, with a hundred for the game. Piquet played in this way is called Rubicon Piquet.

The dealer deals twelve cards to his adversary and twelve to himself, two at a time, or three at a time. He then places the cards in suit, face downwards, and discards two cards to the table, the top five being for the elder hand (non-dealer) to take from first in exchange for his own. The players now look at their cards, and may, or may not, substitute them if they think advisable in order to improve their hands, and take in an equivalent number from the stock. Each player must discard at least three cards. The elder hand discards first. If he finds the elder hand has more than five cards, he must state how many he leaves. He is entitled to look at the cards he leaves, replacing them face downwards on the top of the stock. The younger hand then makes the exchange from the remainder of the stock. If the elder hand leaves any of the five, the younger may exchange as many as remain in the stock, discarding an equal number. If the younger hand leaves any cards, he announces the number left. He may look at the cards he leaves. If he looks at them he must show them to the elder hand, after the elder has named the suit he will lead first, or has led a card.

The younger hand elects not to look at the cards left the elder cannot see them. The younger hand must make his election before he plays to the card first led, or, if so required, after the dealer has named the suit he will lead first. Each player may examine his hand at any time during the hand; but he must keep it separate from his other cards.

The elder hand next makes a declaration of what he has in his hand.

The "point" must be called first or the right to call it is lost. It is scored by the player who announces the suit of greatest strength, valued thus; ace 11; court cards, each 10; other cards, the number of pips on each. Thus if the elder hand's best suit is ace, king, nine, eight, he calls "five cards." If the younger hand has no suit of five cards, he says "good." The elder hand then says "in spades," or whatever the suit may be, or shows his point if he has none of more than four cards. If the younger hand has four or more, he says "good." If the younger hand has also five cards, he says "equal" or "what do they make?" when the elder calls "forty-eight" (or making eight, short for forty-eight), and asks whether the points on the elder hand will make an equal number of cards. If the younger hand's five cards make less than forty-eight he says "good;" if exactly forty-eight, he says "equal;" if more than forty-eight he says "not good." The player whose point is good reckons one for each to the elder hand; if the points are equal neither player scores for point.

"Sequences" are usually called next, the elder hand stating whether his sequences of younger, or older, or of "good," or "not good," as in the case of the point. Any three or more consecutive cards of the same suit held in hand constitute a sequence. The order of the cards is as follows: ace (highest), king, queen, jack (nine), eight (seven), seven (six), six (five), five (four), four (three), three (two), two (one). A sequence of three cards is called a "tiers;" of four, a "quart;" of five, a "quint;" of six, a "sixième;" of seven, a "septième;" of eight, a "huitième." A tiers of ace, king, queen, is called a "tiers major;" a tiers of king, queen, jack, is called a "tiers minor;" a tiers of queen, jack, nine, is called a "tiers of nine." Sequence of four or more cards follow the same nomenclature: e.g., ace, king, queen, knave is a quart major; knave, ten, nine, eight, is a quart to a knave; and so on. A sequence of a greater number of cards is good against a sequence of a smaller number; thus, a quart minor is good against a tierce major. As between sequences containing the same number of cards, the one headed by the highest card is good; thus, a quart to a king is good against a quart to a knave. Only identical sequences can be equal. The number of tiers to a sequence is reckoned by counting the pips, and ten in addition for quints or higher sequences. Thus a tierce counts three; a quart, four; a quint, fifteen; a sixième, sixteen; and so on. If the elder hand's sequence is good, he names the suit, or shows how it exceeds the sequence of his adversary. If the elder hand's sequence is good, all lower sequences can be reckoned, notwithstanding that the adversary has a sequence of intermediate value. For example, A has a quart to a king (good), and a tierce minor. He can name his sequence as equal, because he has a tierce minor; or tiers of nine, seven, six, five, four, three, two and one, all good, and"quarte" is the next number. "Quatorzes" are composed of four aces, four kings, four queens, four knaves or four tens, in order of value; "trios" of three of any of these. A "quarte," "quarte and a trio," and one that is good establishes any smaller quatorzes or trios in his hand.

When the elder hand has done calling he leads a card. Before
PIRAM—PIRATE AND PIRACY

playing to this card, the younger hand reckons all that he has gained of spades, clubs and diamonds, as composed, or showing the cards claimed for; The elder hand leads any card he pleases; the younger player to it. The younger hand must follow suit if he can; otherwise he may play any card he thinks fit. If he cannot, the elder hand takes the trick, and so many cards are counted off, for which each card led, whether it wins the trick or not. If the second player wins the trick he also counts one. The winner of the last trick counts an additional one for the last card. The tricks are left face upwards in front of the player who wins them. They may be examined by either player.

If each player wins six tricks the cards are divided, and there is no adverse play. If the player wins six tricks but six times he wins the cards, and adds ten to his score. If one player wins every trick, he wins a capo, and scores forty for the cards, instead of twenty.

During the play of the hand, a player is entitled to be informed as to any cards his adversary holds which he has reckoned as good, or has declared to be equal. A player may require his adversary to take up the cards. But if a player, having played on the cards of a sixthime, declared as a quint, is asked how many he has left, he need only reply "Two."

During the progress of the hand each player repeats aloud the amount of his score for the time elapsed. The scores are written on cards, which are distributed among the players.

A (elder hand) has dealt him ace, king, knave of spades; ace, queen, knave, eight of hearts; knave, eight, seven of clubs; and nine, eight of diamonds. He discards king of spades; eight, seven of clubs; and nine, eight of diamonds. He takes eight, seven of spades; king of hearts; nine of clubs; and king of diamonds.

B (younger hand) has seven, ten of spades; ten, nine, seven of hearts; nine of clubs; and queen of diamonds. He discards seven of spades; and nine, seven of hearts. He takes in queen of spades; ace of clubs; and seven of diamonds.

The hand then proceeds. A (calling his point) five cards.

B says "forty-nine," and makes nine. B "good."

A (counting his point) five and, counting his sequence, which is good "a quart major, nine. Three knaves." B "not good."

A (continues) "sixteen, fourteen, and three queens." B answers, "plays the ten of hearts."

A (leaves the remaining hearts and says) eleven, twelve, thirteen, fourteen.

B (plays seven, ten, knave, queen of diamonds, and repeating his score says) seventeen.

A has now five tricks, and in order to win the cards should lead any card but a high spade. He leads king of diamonds, and says "nineteen."

B (with ace and says) "sixteen." A (then having the winning clubs, saying) "nineteen, twenty, twenty-one, twenty-two."

A (keeps ace, knave of clubs, and repeating his score says) "fifteen." B (with ace of spades) "twelve.

A (with ace and says) sixteen and (leaves knave, saying) "eighteen" (and adding ten for the cards) "twenty-eight."

A then writes on his scoring card 28; B writes on his 23; the former is correct, and the latter is incorrect. The hand terminates.

Three scores (omitted in order to simplify the description of the game) have yet to be mentioned.

If a player has no king, queen or knave in the hand dealt him, he holds carte blanche, for which he scores ten. As soon as a player discovers he has a carte blanche, he must tell his adversary; this he usually does by saying "discard for carte blanche."

The adverse discard is then made (as explained under discarding), after which the carte blanche is shown, the cards, face upwards on the table; they are then taken back into the hand.

Pirates.—If the elder hand scores, in hand, play, thirty or more, before the younger hand counts anything in that deal, he gains a pique, for which he scores thirty.

Repique.—If a player scores in hand alone thirty or more before his adversary has any score at all, he gains a repique, for which he adds sixty to his score. Equalities do not prevent piques or repiques.

A player who has an equal point or sequence scores nothing for it. Therefore if, notwithstanding the equality, a player makes thirty, in hand and play; or in hand, by scores which reckon in order before anything his adversary can count, he gains a pique or a repique.

In the order in which the scores accrue is of importance. For the sake of convenience, the elder hand finishes his reckoning before the younger begins. The scores, however, whether made by the elder or younger hand are recordable in the following order: (1) cards played; (2) points made in play; (3) scoring points; (4) points made in play; (5) the cards. This will often affect a pique or repique. Thus, a pique can only be made by the elder hand, as the one he reckons in play when he leads his first card counts before points subsequently made in play by the younger hand. The younger, therefore, cannot make thirty in hand and play before the elder scores one. But the one reckoned by the elder hand when he leads his first card does not prevent his being repiqued, because scores made in hand have precedence of points made in play. The elder leads his first card and counts for it before the younger reckons, simply as a convenient way of stating after the play of the hand is over. A player who reckons nothing that hand as a penalty is not piqued or repiqued if he holds any cards which, but for the penalty, would have been reckoned before his account was reached.

PIRAM, or PERIM, an island in the Gulf of Cambay, forming part of Ahmadabad district, Bombay. Formerly notorious as the stronghold of a pirate chieftain, it has attained fame among palaeontologists for the large quantity of fossil remains discovered here in 1836, similar to the better-known Siwalik faunas.

PIRANESI, GIOVANNI BATTISTA, Italian engraver of ancient architectural subjects, was born in the earlier half of the 18th century, and studied his art at Rome. The great remains of that city kindled his enthusiasm and demanded portrayal. His hand faithfully imitated the actual remains of a fabric; his invention, catching the design of the original architect, supplied the parts that were wanting; his skill introduced groups of vases, altars, tombs; and his broad and scientific distribution of light and shade completed the picture, and threw a striking effect over the whole. One engraving after another was executed with much brilliancy; and, as the work went on, the zeal of Piranesi was increased, and four thousand turned out. In course of time it was found necessary to call in the aid of all his children and of several pupils. He did not, in fact, slacken in his exertions till his death in 1778.

The plates of Piranesi, in which the severity of burial work is largely supplemented by the freer lines of the etching-needle, were collected and preserved by his son and coadjutor Francesco. They were published, to the number of about 2000, in 29 vols. fol. (Paris, 1835-1837).

PIRANO, a seaport of Austria, in Istria, 22 m. S.W. of Trieste by rail. Pop. (1900), 13,330, mostly Italians. In addition to viticulture and the cultivation of the olive, its principal resources are ship-building and fishing. In the neighbourhood are the most extensive works in Istria for the extraction of salt from the sea-water, which produce about 50,000 tons of salt annually. Pirano is celebrated for the victory of the Venetians over the fleet of the emperor Frederick Barbarossa in 1177. It passed under the domination of Venice in 1183 and became definitely incorporated with Austria, together with the other possessions of Venice in the Istrian Peninsula, in 1813.

PIRATE AND PIRACY. Sir Edward Coke (Inst. iii, 113) describes a pirate (Lat. pirata, from Gr. παραπταμός, παρά to attempt or attack), as hostis humani generis, and as a robber upon the sea. Sir J. Fitzjames Stephen in his Digest of Criminal Law defined piracy as follows: "Taking a ship on the High Seas or within the jurisdiction of the Lord High Admiral from the possession or control of those who are lawfully entitled to it and carrying away the ship itself or any of its goods, tackle, apparel or furniture under circumstances which would have amounted to robbery if the act had been done within the body of an English county." (See also C. F. G. for Hong Kong and Kow-Sing, 5th P.C., 254; C. F. G. for the United States, 5 P.C., 254.) That any particular state but against all mankind, may be punished in the competent court of any country where the offender may be found or into which he may be carried. But, whilst the practice of nations gives to every one the right to pursue and exterminate pirates without any previous declaration of war (pirates holding no commission or delegated authority from any sovereign or state), it is not allowed to kill them without trial except in battle. Those who surrender or are taken prisoners
PIRATE AND PIRACY

must be brought before the proper tribunal and dealt with according to law.

Piracy has been dealt with in a large number of English statutes, from 1356 down to the Territorial Waters Jurisdiction Act 1878 (41 & 42 Vict., c. 73), which provided for the maintenance of the existing jurisdiction for the trial of "any act of piracy as defined by the law of nations."

During the Spanish-American War the Spanish government issued (1898) a decree declaring that "captains, masters and officers of vessels, which, as well as two-thirds of their crew, are not American, captured while committing acts of war against Spain, even if they are provided with letters of marque issued by the United States" would be regarded and judged as pirates. This was not in accordance with the international practice on the subject.

A public ship or one which is entitled to fly the flag of a belligerent and navigates under the cover of state papers, by the very sense of the term, is not a pirate. Again, during the Russo-Japanese War, the word "piracy" was freely applied in British newspapers to the seizure of the "Malacca" and other vessels held up by the "Petersburg" and "Smolensk," two cruisers belonging to the Russian Black Sea volunteer fleet, which in July 1904 passed as merchantmen through the Bosphorus and Dardanelles and were transformed to their real character on the open sea.

The application of the term in this case was equally inaccurate.

The conversion of merchant into war ships was one of the subjects dealt with by the second Hague Conference (1907), but it was agreed that "the question of the place where such conversion is effected remains outside the scope of the agreement."

Piracy is essentially a crime under international law, and although any state may apply its penalties to its own subjects by analogy, as was done by Great Britain and the United States in connexion with the repression of the slave trade, they cannot be lawfully applied to subjects of other states.

Historical Sketch.—It has at all times been more difficult to enforce good order on the sea than on the land; or perhaps we ought to say that the establishment of law and order on the sea has in all ages of the world's history followed, but has not accompanied, and has still less preceded, the creation of a good police on the land. The sea robber, or pirate, cannot make a profit from any part of his booty except the food which he consumes, or the vessels which he may use, unless he can find a market. But so long as he is sure that he will somewhere meet a purchaser for the goods he has taken by violence, he has every encouragement to pursue his trade. Therefore from the times described in the Odyssey, down to the days when Sir Henry Keppel sailed in H.M.S. "Dido" to suppress the pirates of Borneo, and when Rajah Brooke of Sarawak co-operated with him on land, we find that the prevalence of piracy and the suppression of it have been closely dependent on the efforts made to rout it out from its lurking-places on the coast, and the degree of success achieved.

Very different types of men have been named pirates. They have in fact been so unlike that to class them all together would be in the last degree unjust. The Greek in the youth of the world, and the Malay of Borneo in the 19th century, knew of no rule of morals which should restrain them from treating all who lay outside the limits of their city or their tribe as enemies, to be traded with when strong and plundered when weak. They might be patriotic, and law-abiding men towards the only authority they recognized. Their piracy was a form of war, not without close moral analogies to the seizure of Silesia by Frederick the Great, the attempted seizure of Spain by Napoleon. Indeed the story of this latter venture, with its deceitful preliminary successes and its final disaster, may fairly be compared with the fall of Ulysses and his companions on the Cicones, as told in the ninth book of the Odyssey. Yet it would be highly uncritical to class Ulysses or Napoleon with Captain Avery, or Captain Kidd, or Bartholomew Roberts. We are not here concerned with the legal aspects of piracy, but with the true character of the persons to whom the name pirate has been applied at various times. The term was applied by the Romans to the adventurers against whom Pompey was commissioned to act by the Gabian Law, by the English of the 9th and 10th centuries to the Vikings, and by the Spaniards to the English, French and Dutch who were found sailing beyond the line. Sufferers by naval commerce-destroyers call it a piratical form of warfare. But the pirates of the Roman Republic were no mere "gang of robbers." They were the victims of a time of conquest and "general overture"—"the ruined men of all nations, the hunted refugees of all vanquished parties, everyone that was wretched and daring—and where was there not misery and violence in this unhappy age? It was no longer a gang of robbers who had flocked together, but a compact soldier state, in which the freemasonry of exile and of crime took the place of nationality, and within which crime redeemed itself, as it so often does in its own eyes, by displaying the most generous public spirit." Such men are akin to the corsairs or pirata, and not the same reproach against Admiral Lord Howe for the Don Luis de Córdoba, who with a fleet captures whole convoys.

The pirate pure and simple is that member of an orderly community who elects to live on the sea, by violence and robbery, making no distinction between his own city or tribe and any other. The old adage, that "war makes thieves and peace hangs them" has ever been peculiarly true of the sea. War has always been conducted there by the capture of an enemy's property, and by division of the spoil. A portion of the naval forces of all nations has been composed of privateers, letters of marque or corsairs, who plundered with a licence. They have ever found a difficulty in drawing the line between enemy and neutral; when peace returned some of them found it hard to be content with honest wages earned by dull industry. Nelson declared that all privateers were no better than pirates. He was borne out by the experience of Great Britain, which at the beginning of the Seven Years' War had to take strong measures to repress the excesses of its privateers, and to hang a good few of them as mere pirates. The pirates suppressed by Pompey did not all submit to remain in the settlements he made. Some continued to rob at sea. If we can trust the Pastoral of Longus, and the other Greek romances, the pirate was a known type even under the Roman peace, but it is highly probable that he was more of a stock literary figure than a reality. Before the Roman peace, and during long centuries after it had been given, that piracy was common. It grew out of a state of war.

In modern times—even down to 1815—a recrudescence of piracy has followed regular hostilities. But there are other conditions which have a material influence, such as the need for a lurking-place and for a receiver of the plundered goods. An archipelago provides the best lurking-places, and next to it a coast of many inlets. Therefore the Greek Islands, the British Isles, the Antilles, the Indian Ocean, the coast of Cilicia in Asia Minor, of Dalmatia, of Malabar and of Norway, have all at one time or other, and some of them for centuries, been haunts of pirates. The convenience of the place had to be completed by the convenience of the time. In the ancient world, and the middle ages, the market never failed. One city or tribe had little care for the sufferings of another. The men of the Cinque Ports who plundered the men of Yarmouth knew that their own townsmen would never call them to account, and therefore they had a safe refuge. Even when the medieval anarchy had come to an end on land, the sea was lawless. When peace was made with Spain after the death of Queen Elizabeth there were many who could not settle down to a life of industry. Some took the
plain course of betaking themselves to Algiers or Salee. But there were many who provided nearer home. Sir William Monson, in his Naval Traits, tells how he was sent in 1605 to hunt pirates out of the Channel. He found them, not at sea near Scotland, but some unemployed, whom he shipped and used as guides and informers, on the coast of Ireland. At Broad Haven he discovered an Irish gentleman of the name of Cormat (presumably Cormac) living in some dignity. His house was "the well-head of all pirates," and their captains were the lovers of his daughters. Monson found agents of merchants of London and of Galway, who came to buy the goods which the pirates had to sell at a bargain. He put that interesting family under the gallow, and frightened them into turning king's evidence. It was his boast that he had cleared the Irish coast of pirates, but we know that they were common late in the reign of Charles I., and that under the name of "sea Tories" they abandoned during the Civil War both in Ireland and in the Scilly Isles. Their existence was prolonged by the weakness of the government, which when piracy became very rampant took the disastrous course of offering pardon to all who would come in by a certain date. As a matter of course many did, and when their booty was spent returned to their piratical trade. Monson says that the pirates he caused to be executed had already tasted of the king's mercy. While there were friendly harbours to anchor in, purchasers to be met and a very fair prospect of a free pardon, piracy was not likely to cease.

As the 17th century drew on the law and the police became 100 strong for such persons as Mr Cormat at Broad Haven, and his pirate friends. But the pirate class did not cease. It was only driven to a wider field of operations—to a field which in fact stretched from the Red Sea to New England. On this wide portion of the earth's surface everything combined to favour the pirate. In the West Indies there was a "well-head" of immense capacity. Spain was forced late and reluctantly to recognize the legitimacy of any foreign settlement. She would rather put up with the lawless adventurers known as the "Brothers of the Coast" and the "Buccaneers" than co-operate with foreign governments to suppress them. Even when she renounced her full pretensions, several of the islands remained unoccupied except by the lingering remnants of the native races. Swine and cattle had been let loose on many of them, and had multiplied. The turtle was abundant and succulent. There was no want of food. A population with predatory instincts had been formed in the early days of hostile settlement and buccaneering. Jamaica was full of the so-called "private men-of-war" whose doings are prominent in the correspondence of the early governors, who were not uncommonly their associates. Add to this that the commercial policy of Spain denied to her colonists the right of trading with foreigners, and yet that she could not supply their needs herself. Hence arose a smuggling trade which had affinities with piracy. The lawless trader was not liable to be asked awkward questions, as to the origin of his cargo, by the Spanish American who purchased it on the sly for money or by barter. Nor were any questions asked him when he brought his cargo to Jamaica, San Domingo, the Carolinas, New England or even Europe. In the decay of Spain her navy was not to be feared. But it was not the commercial policy of Spain alone which helped the pirate. Great Britain, and France also, insisted that their colonists should trade exclusively with or through them. The colonists were always ready to buy "good cheap" from the smuggler, and never ask him whether the East Indian produce—tea, silk, spices and so forth—he offered for sale were purchased or plundered in the Red Sea or on the coast of Malabar or of Coromandel. Add to all this that the police and patrol work of regular navies was but superficially done even in peace, and hardly at all in war, and that in the British colonies there was no judicial machinery for trying pirates till the 11th and 12th years of William III. (1700, 1701), and it will be seen that all the conditions favoured the pirate. In the East the decadence of the Mogul Empire was plunging India into anarchy, and it had no navy. Yet a large native trade existed, conducted by "Moors," as they were called, and Madagascar, a great "no-man's-land," afforded ample anchorage and food. To get plunder outside the East India Company's sphere, the Moors," to sell the booty in New England or the Carolinas, to spend the produce in riotous living, and go to sea on the same errand again, was the round of life of the large class of known pirates, who formed a recognized element of the population of Massachusetts and New York at the end of the 17th century. These are the men we know best, for they were encouraged by the tolerance shown them to come into the light. Others are buried in, or only dimly visible in, obscurity. Some trace of these latter may be found in the Letter Books of the Old Providence Company, a puritan society formed in the reign of Charles I., of which Pym and the Earl of Warwick, afterwards the Parliamentary admiral of the Civil War, were governors. It was founded to colonize Old Providence on the coast of Honduras, a place not to be confused with another pirate haunt, New Providence in the Bahamas. It took to plain piracy and was suppressed by the Spaniards in 1638. Warwick made a regular business and large profits by fitting out "privateers," which were in fact pirates on the "Spanish main," not the seas of America, as some have thought, but the coast of the mainland.

The lives of the later and better known pirates may be illustrated by the career of Captain Avery, or Every (alias Bridgman), whose renown was great at the end of the 17th century, and who has the greater part of inspired Defoe's Life, Adventures and Piracies of Captain Singleton. He was master of a Bristol ship hired by the Spaniards in 1694 to serve as a coastguard vessel in South America. She was called the "Charles II," commanded by one Captain Gibson, and mounted 40 guns. While the "Charles II." was lying at Corunna, in company with another vessel also hired by the Spaniards, waiting for the payment of wages which was delayed, Avery persuaded part of the two crews to seize her and sail with her on a piratical voyage to the East. The enterprise was carried out without bloodshed or, apparently, coercion of those who were unwilling to go. Avery and his crew sailed to Madagascar, a regular haunt of the pirates. Many of them ended by remaining for life among the natives. The adventurers in the "Charles II.," who had already made some small prizes, English and Danish, were joined at the island by others of the same character who had come from the West Indies. From Madagascar they went to the Straits of Bab-el-Mandeb, to lie in wait for the trade from India. Several prizes were taken, and finally a large and valuable ship, belonging "to the Great Mogul and his subjects," was captured about ten miles from Surat. Avery and his crew now hastened to New England to sell their booty. The "Charles II." was disposed of as a privateer at Providence, and the pirates bought a sloop in which they sailed along the coast of the English colonies, selling their spoil, with the consent of the colonists and the connivance of the officials, who were bribed. In an evil hour for themselves they decided to come to England. The Indian governments, exasperated by the piracy practised at the expense of their subjects, were threatening reprisals on the East India Company. The Company made complaints to the government at home, and energetic measures of repression were taken. Avery himself escaped capture, but several of his men were brought to trial, condemned and executed. It is to be noted that when first tried, on the 19th of October 1696, they were acquitted. They were, however, re-tried on other counts, on the 31st of October. The charge of which is the record of the jury, and the address of Sir Charles Locket, the justice, who pronounced the sentence. He pronounced the sentence "in the name of God, and for the safety of the kingdom, held both the importance and the uncertainty of securing a verdict.

The cruise of Avery is not only a typical example of a piratical venture, but it is an important date in the history of the policing of the sea. The English government was roused to a sense of the necessity for strong measures to repress piracy. All the steps taken were not according to knowledge. The extraordinary private venture of Lord Bellamont and his associates who sent out Captain Kidd (q.v.), a man of piratical antecedents,
to suppress pirates in the Eastern seas, brought deserved discredit upon them. The decision taken on the advice of Burchett, the secretary of the admiralty, to offer a pardon to all who would surrender by a given date—for all pirates committed before the 30th of April to the east of the Cape of Good Hope, and the 30th of June 1699 to the west—was an error. It induced many to come in, but it also gave all pirates the hope that they would in the future be provided with similar means of escape. The establishment of admiralty courts in the East Indies and America and the despatch of warships were more effectual methods. Yet it was long before piracy was thoroughly checked; indeed the signing of the Peace of Utrecht was followed by a recrudescence of this form of crime. The privateers who swarmed in the West Indies and, as long as the war lasted, used, in the phrase of the time, to join the squadrons of war-ships “on the plundering account,” could not settle down to dull industry. They leagued themselves into a species of pirate republic, with its capital at Providence in the Bahamas. In 1718 a special force had to be sent against them under Woodes Rogers, who is best remembered now for having taken Alexander Selkirk from the island of Juan Fernandez, in the course of a privateering voyage into the Pacific with the “duke” and “duchess” of Bristol. Rogers broke up the Providence settlement, and did a similar piece of service on the coast of Madagascar. Piracy did not, however, die. The Asiento (q.v.) Treaty having given Great Britain a monopoly of the slave trade with Spanish America, the monopolists, i.e. the South Sea Company and Royal African Company, were of course subject to the competition of interlopers. The interlopers were the natural friends of the pirates, who divided their activity between the Antilles and the west coast of Africa, plundering in the second, selling and re-fitting, not without further plunder, in the first. The most notorious of these free-booters was Bartholomew Roberts, who was introduced to piracy by Howel Davis. Roberts was the nearest known approach to the pirate of romance, ostentations, brave, not without touches of generosity. He was killed in action with Captain Chaloner Ogle, of H.M.S. “Swallow,” on the coast of Africa, in 1722.

As the American colonies grew more settled piracy became intolerable to them. Yet it lingered on the coast of North Carolina, where the pirates could either terrorize the scattered inhabitants, or were encouraged by dishonest officers. Here flourished the grotesque brute known as Blackbeard, Edward Teach. He strolled down the coast of South Carolina in 1718. It was noted that several of those who helped to suppress him afterwards “went a-pirating” themselves. So strong was the piratical tradition of the New World that even men of some standing fell into it. “Major” or Captain Stede Bonnet, who was condemned and executed at Charleston, South Carolina, as a pirate, in 1718, was a gentleman of some property in Barbadoes, who first ventured to sea in a ship of his own. Stede Bonnet had taken advantage of an act of grace, had come in on a proclamation, and had returned to a pirate's life. The last great explosion of piracy in the West Indies followed the peace of 1713. Here again we find the old corsairs remembered on the stage and in song as the safe-luck-landing and the receiver. The refuge and the market were supplied by the Spanish colonies, which were plunged into anarchy by their revolt against Spain. The pirates were able to masquerade as “patriot” navies. The sloth and corruption of Spanish captains-general of Cuba were no less favourable to the pirates. The south coast of the island became a haunt of these villains till the British and American governments were driven to combine for their suppression. When they had been followed into their hiding-places and their vessels sunk, they took to brigandage on land, and were gallantly fought by the Spanish authorities in self-defence. The pirates were freed and were re-embarked in vessels, and the Malays were not named till nearly 1850. On the coast and the rivers of China piracy was and is endemic, but the sailing junk has no chance with the modern steamer. When cases of piracy have occurred in the Straits of Malacca or in the China seas, by which Europeans have been the sufferers, the crime has generally been perpetrated by men who shipped as passengers or as crew, and who surprised the vessel. The pirate has been as useful to the author of modern tales and poems as to the writers of the Greek romances. When he is seen in authentic evidence he is found to have been for the most part a pitiful rogue. His gains were but small. A share of £2,000 was wealth to a mere sailor, and one of £1,000 wealth beyond the dreams of average privateers. War-ships he could help it, and indeed nothing is more surprising than his readiness to surrender when before the fate against him was told.

Authorities.—The pirates of the ancient world are admirably dealt with in Mommsen's History of Rome. For the modern pirate, see Monson’s “Naval Tracts” in Churchill’s Voyages, v. 5 (London, 1726). Here are also the voyages of the N. W. Passage; but the best accounts are to be found in the State Trials, vols. xiii., xiv., xv. (London, 1812). Captain Charles Johnson’s General History of the Pyrates (London, 1724) must be used with caution. He doubtless learnt much from pirates who, having come in on a proclamation, were free to talk, but he cannot always be reconciled with authentic records. The Documents relative to the Colonial History of the State of New York (Albany, 1856-1858) contain many curious details; for the eastern coast, see Lord Clive’s History of the Indian Wars; with an account of the Rise, Progress, Strength and Forces of Angria, the Pyrate, &c., by Clement Downing (London, 1757), is useful. (J. T. K.)

ABOTH. The penultimate tract of the fourth part of the Mishnah is the book of proverbs in five chapters called Maasechet Aboth (tractatus patrum), better known with a sixth chapter as Pirke Aboth (capitula patrum). For Pirke Aboth in English see The Authorized Daily Prayer Book of the united Hebrew congregations of the British Empire, with a new translation by the Rev. S. Singer. The six chapters are there appointed to be read one on each Sabbath afternoon between Passover and New Year. Formerly they were read, in places at least, on the six Sabbaths between Passover and Pentecost only. The subsections of the chapters are hereinafter numbered as in the Authorized Prayer Book.

Chapters i., ii.—The Mosiac succession has first to be established. Moses (i. 1-3) having received the Torah from Sinai, it was handed down to Joshua, the Elders (Josh. xxiv. 31), the Prophets and the men of the Great Synagogue, from one of the last of whom, Simon b. Justus, it was received by Antigonus of Socho. Next are named (i. 4-15), without any title, as links in the chain of tradition, five pairs of teachers, the last Hillel and Shammai, elsewhere in the Mishnah called muni patres (Surehm. iv. 232). Rabban Jochanan ben Zacchai (n. 9) “received from Hillel and Shammai.” Sayings of these teachers are next given (i. 16-21), some of the words of their somewhat younger contemporary, Rabbi Tarphon (Toprhon), to the effect Aris longa vita brevis. These sections (i. 1-15, ii. 9-21) contain the Tarn der Summahin (Sobek), Mommsen’s Compendius edition (1856-1858), etc.; the Mishnah (i. 16-ii. 8) of Rabban Gamaliel I., Rabban Simeon, “Rabbi,” i.e. R. Jehudah ha-Nasi (cent. a.d. 1-2), the traditional redactor of the Mishnah, Rabban Gamaliel II. and Hillel, which broke the sequence.

Chapters iii., iv.—Maxims of numerous authorities, mostly Mishnah teachers and called Rabbis (Matt. xxii. 7 seq.; J. F. p. 27), not in exact chronological order.

Chapters v., vi. Chap. v. which is sui generis, is presumably of later date than what precedes. Naming no teacher until the end, it combines historical, legendary and didactic elements. It touches upon the miraculous and its place in nature (v. 9). In form it is essentially a didactic work, for it is arranged from the ten creative Sayings to the trials of qualities which differentiate the disciples of Balaam and Abraham. R. Jacob ben Shimshon's commentary makes Aboth end with the saying of Jehudah ben Tema (v. 23), the word of the Lord, and Balaam and Abraham remain, and strong as a lion, to do the will of thy Father who is in heaven.” Chapter vi., on acquisita legis, is thought to have been added for use on the last of the six sabbaths above-mentioned (Strock, J. F. Ap. p. 61). In some manuscripts there are seven chapters.

Pirke Aboth serves as a primer to the student of rabbinic Judaism. For the most part in simple Hebrew, it has a few sayings in Aramaic (i. 13-ii. 7, v. 25, 26) and some adopted Greek (v. 10, 35, 36). The entire book, even in the Orit (Phil.), to which it is usually attached, is an attempt to fulfill the dicta of Aboth (Baba Kam. 30a). It gives favourable aphorisms of leading Jewish teachers who flourished in or before the earliest Christian centuries, and supplies material for some interesting illustrations of the New Testament. Too heterogeneous to be represented by a few extracts, the collection
must be read through to be appreciated. Among the sayings of Hillel we miss the best known one, What is hateful to thee do not do not, &c. (J. F. p. 142), with which we may now compare Exclus. xxxi. 15 Heb., "Know (thy) neighbour as thyself, and consider what thou hastest." Of the precept, "Make a fence to the 'Torah" (i.1; cf. iii. 17) it may be said that "every Jewish thinker, at some period of his development and as an ethical principle it is reflected in Clement of Alexandria's view of philosophy as a φαρµακιον of the vineyard (Strom. i. 20), and Polyarp's saying, "He that has love is far from all sin." The use of Abot in the synagogues stamps it as authoritative, and, with its intrinsic excellence, has led to its being "the most popular of all rabbinical writings." For midrashic comments upon it see the Abot of Rabbi Nathan (ed. S. Schechter, Vienna, 1887), or the rendering of it (new ed., New York, 1900) in M. L. Redkindson's translation of the Babylonian Talmud into English. (See also Apocryphal Literature, § Old Testament, II. d.)

Pirimases, a town of Germany, in the Bavarian Palatinate, 40 m. W. by S. of Spire, on the railway from Biebermühle. Pop. (1905), 34,002. The only noteworthy buildings are the town-hall and the principal Evangelical church, which contains a fine monument to Louis IX. (d. 1270), landgrave of Hesse-Darmstadt, who made the town his residence. The staple industry is the production of boots and shoes; but musical instruments, leather and machines are also manufactured. Pirimases owes its name to a St Firmin, who is said to have preached Christianity here in the 8th century. It originally belonged to the count of Hanau-Lichtenberg, but passed to Hesse-Darmstadt in 1736. In September 1793 the Prussians gained a victory here over a body of French troops. See T. Weiss, Pirimases in der Franzosenzeit (Pirimases, 1905).

Pirimaze, Octave (1832-1883), Belgian author, was born at Châtelaine in 1832. He belonged to a well-known Belgian family, and his cousin, Édouard Pirmez, was distinguished for his works on literary and political subjects. He lived an unhappy life at his château of Acoz, in Hainaut, where he died in May 1883. Pirmez was an ardent admirer of the French romanticists. His works include Les Feuillées: pensées et maximes (1862); Victor Hugo (1863); Jours de solitude (1866); Rémois; Souvenirs d'un frère (1880); Heures de philosophie (1881); and the posthumous Lettres à José (1884). These books form a history of his emotional life, and reveal an extreme melancholy. See Vie et correspondance d'Octave Pirmez (1888), by Adolphe Siret and Jules de Coppin.

Pirna, a town in the kingdom of Saxony, on the left bank of the Elbe, 11 m. above Dresden, and on the railway to Bodenbach and Prague. Pop. (1905), 19,220. The town is regularly built, with promenades covering the site of the old fortifications; the most notable edifices are the fine Gothic parish church, built in the 16th century and restored in 1890, and the old town-hall. Excellent sandstone is found on both banks of the Elbe. There are manufactories of glass, machinery, cigars, pottery and enamelled goods; and there is a trade in grain, fruit and timber, mainly carried on by river, and a little shipbuilding. Pirna, originally a Slavonic settlement, was for many years in the alternate possession of Bohemia and Meissen, but it became permanently united with the latter, and thus with Saxony, in 1405. The Sonnenstein, a fortress on a commanding eminence above the town, was erected in the 16th century on the site of an older castle by the elector of Saxony, Augustus I. It was once considered the most important fortress on the Elbe, and successfully withstood the Swedes in 1639, but it was captured and dismantled by the Prussians in 1758, and in 1813 was occupied by the French.

Pirog, or Pirogova (the French and Spanish forms respectively of a Carabbean word for this type of vessel; it has at various times adopted many corrupt forms, e.g. paragua, petilagonu, petilago), originally the native name of a vessel made by hollowing out the trunk of a tree, a "dug-out" ; hence applied to many different developments of this type of vessel used in the West Indies and along the American coast. An early improvement was to split the "dug-out" into two sections and inset a flat bottom of planking to widen it; another form had a leeboard, was decked in at either end, and had two masts.

Piron, Alexis (1689-1773), French epigrammatist and dramatist, was born at Dijon on the 9th of July 1689. His father, Aimé Piron, was an apothecary, who wrote verse in the Burgundian patois. Alexis began life as clerk and secretary to a banker, and then studied law. In 1719, when nearly thirty years old, he went to seek his fortune at Paris. An accident brought him money and notoriety. The jealousy of the regular actors produced an edict restricting the Théâtre de la Foire, or licensed booths at fair times, to a single character on the stage. None of the ordinary writers for this theatre would attempt a monologue-drama for the purpose, and Piron made a great success with a piece called Arlesquin Deucalion, representing Deucalion immediately after the Deluge, amusing himself with recreating in succession the different types of man. In 1728 he produced Les Fils ingrats (known later as L'Ecole des pères) at the Comédie française. He attempted tragedy in Callisthène (1720), Gustave Vasa (1723) and Fernand Cortés (1744), but none of these succeeded, and Piron returned to comedy with La Métamorphose (1738), in which the hero, Damis, suffers from the verse mania. His most intimate associates at this time were Mlle Quinault, the actress, and her friend Marie Thérèse Quenandon, known as Mlle de Bar. This lady was slightly older than Piron and not beautiful, but after twenty years' acquaintance he married her in 1741. He died on the 21st of January 1773, in his eightieth year. He was elected in 1753 to the Academy, but his enemies raked up a certain Ode à Priape, dating from his early days, and induced Louis XV. to interpose his veto. Piron however was pensioned, and during the last half-century of his life was never in any want. His best title to remembrance lies in his epigrams. The burlesque epistle on himself, in which he ridicules the Academy—

"C'est Piron, qui ne fut rien,
Pas même académicien"

—is well-known, while many others are as brilliant. Grimm called him a "machine à salissures." Piron published his own theatrical works in 1758, and after his death his friend and literary executor, Rigoléy de Juvigny, published his Oeuvres complètes. M. Bonhomme produced a critical edition in 1859, completed by Polèses choisies et pièces inédites in 1868.

Piroht (Turkish Şehr-Kecy), a Servian town, 124 m. from the Bulgarian frontier at Tsaribrod, on the railway line between Nish and Sofia. Pop. (1900), 10,428. Piroh is the seat of the prefecture for the department of the same name, with a tribunal, several schools and a custom-house. It is the only proper industrial town in Servia, having numerous small factories for the manufacture of thin cloth (şayak), woollen braid (gaiyan), and especially carpets. Its carpets have a great reputation in the Balkan Peninsula for their quaint designs, durability and freshness of colour. Piroh has a medieval fortress, believed to be the best built on any site in Servia. The town was in the military roads leading from Olt Naissus to Philippopolis. The town is of great strategical importance, for which reason the Russian plenipotentiaries at the Berlin congress (1878) stubbornly tried to include it within the Bulgarian frontier, while Austria and some other Powers insisted that it should be given to Servia. In the war between Servia and Bulgaria in 1885 the Bulgarians occupied and held it until the conclusion of peace.
PISA, a town, archiepiscopal see and capital of a province of the same name, Tuscany, Italy, on the Arno, 7 m. from the sea, and 40 m. west of Florence by rail. Pop. (1881), 42,779; (1900), 61,279. It still retains its ancient walls, 63 m. in circuit, and is defended by a citadel on the south-west. The principal streets run alongside the river, and are lined with fine buildings. Besides the cathedral, the baptistery and the famous leaning tower, the city possesses several notable churches, as the Renaissance church of St Stephen, built in 1562 from plans by Vasari; San Niccolo, with a four-storied tower (1330), built by Niccola Pisano, and the tomb of John of Aragon, bishop; Santa Caterina (1626); Santa Maria della Spina, in the Italo-Gothic style, built in 1320 and restored in 1872; San Sepolcro, erected in 1150 by Diotisalvi; San Francesco, with frescoes by Taddeo Gaddi; and the basilica of San Michele (1018). Amongst the secular buildings may be mentioned the royal palace; the archiepiscopal palace; the palace of the order of St Stephen, built by Niccola Pisano and reconstructed by Vasari; the Upezzinghi (formerly Lanfreducci) palace, built of Carrara marble in 1590; the Lanfranchi, Agostini and other palaces; the university (1472); a large hospital (1528); and fine market halls. The chief architects of the city were Giotto (Fravaccilla), Archduke Leopold, and Ferdinand I. The city possesses an academy of the fine arts, with a gallery of paintings; and the university a library of 120,000 volumes, a natural history museum, botanical garden and agricultural schools. The university, founded in 1338, has faculties of law, medicine, mathematics and philosophy and literature, and is to this day one of the most famous in Italy.

The architects of the cathedral were Boschetti and Rinaldo, both Italians, probably Pisans. It is in plan a Latin cross, with an internal length of 314 ft. and a breadth of 252 ft. The nave, 100 ft. high, has eight divisions, and the transept terminating arches; and at the intersection of nave and transept there is a cupola. The basilica is still the predominant type, but the influence of the domed churches of Constantinople and the mosques of Palermo is also apparent. The pillars which support the nave are of marble from Elba and Giglio; those of the side aisles are the spoils of ancient Greek and Roman buildings brought by the Pisan galleys. Externally the finest part of the building is the west front, in which the note struck by the range of arches running round the base is repeated by four open arcades. Of the four doors three are by John of Bologna, who was greatly helped by Francavilla, Tacca and others; the fourth is much more Italian in character, and is generally supposed to be the work of Bonanno. Of the interior decorations there is a great deal to mention the altars of the nave, said to be after designs by Michelangelo, and the mosaics in the dome and the apse, which were among the most famous of their kind. The façade was restored only in 1278, and marred in the 14th century by the introduction of Gothic details. The building is a circle 100 ft. in diameter, and is covered with a cone-surfaced dome 190 ft. high on which stands a lantern 100 ft. high. The range of secondary arches consists of twenty columns and the second of sixty; and above this is a row of eighteen windows in the same style separated by as many pilasters. The interior, which is supported by four pilasters and eight columns, the most striking features are the octagonal font and the hexagonal pulpit, erected in 1260 by Niccola Pisano. The campanile or "leaning tower of Pisa" is a round tower, the noblest, according to Freeman, of the southern Romanesque work. Through the walls at the base are 22 ft. thick, and at the top about half as much, they are constructed throughout of marble. The basement is surrounded by a range of semi-circular arches supported by eight columns and divided by six pilasters and thirty columns each. The eighth storey, which contains the bells, is only 15 ft. smaller in diameter than the rest of the tower, and has only twelve columns. The height of the tower is 179 ft., but the ascent is easy, and one need only climb a short distance (311 ft. when measured in 1829, and 165 ft. in 1910). There is no reason to suppose that the architects, Bonanno and William of Innabruck, intended that the campanile should be built in an oblique position; it is an error that has been assumed, and worked up into a local tradition. The foundations are not more than 10 ft. deep, and their circumference only that of the tower. The Campo Santo, lying to the north of the cathedral, owes its origin to Archbishop Ubaldo (1188-1200), who made the spot peculiarly sacred by bringing fifty-three ships loads of earth from Mount Calvary. The building, erected in the Italian Gothic style between 1278 and 1283, by Giovanni Pisano, is of special interest chiefly for its famous frescoes.

There are numerous industries, the most important being the manufacture of cottons. In the vicinity are the royal stud-farm (horses and dromedaries) of Cascine di San Rossore, and the mineral baths of San Giuliano, alkaline-ferruginous, with temperatures ranging from 95° to 105° Fahr. At the mouth of the Arno, joined to the city by a steam tramway, is the seaside resort of Marina di Pisa, also known as Bocca d'Arno, a well-known centre for landscape painters.

The old town occupied the site of the ancient Pisa on the right bank of the Arno. The foundation of Pisa is by tradition ascribed to a very remote period, and it was often (possibly only owing to the similarity of name) believed to have been founded from Pisa in Ely. It is first mentioned in history as the place at which a Roman army from Sardinia landed in 225 B.C., its harbour being at the mouth of the south branch of the Arno, north of Livorno. Being situated on the coast road (Via Aemilia), it was important as a frontier fortress against Liguria, to which, and not to Etruria, it really belonged, perhaps, up to the time of Sulla, the actual boundary lying between it and Vada Volterrana (mod. Vada). It became a colony in 180 B.C., and was important for the fertility of its territory, for its quarries, and for the timber it yielded for ship-building. Augustus gave it the name of Colonia Julia Pisana; his grandsons Gaius and Lucius were patrons of the colony, and after their death monuments were erected in their honour, as is recorded in two long inscriptions still extant. Greek vases have been found within the city itself, seeming to point to the presence of Etruscan tombs (G. Ghirardini in Notizie degli Scavi, 1893, 147), but no remains now exist except of the Roman period—some scanty ruins of baths and of a temple, while the Piazza dei Cavalieri follows the outline of the ancient theatre.

See E. Bormann, Corp. inscr. lat. xi. 272 (1888).

Little is known of the history of Pisa during the barbarian invasions, but it is an ascertained fact that it was one of the first towns to regain its independence. Under the Byzantine dominion Pisa, like many other of the maritime cities of Italy, profited by the weakness of the government at Constantinople to reassert its strength. And even during the first years of the harsh Lombard rule the need recognized by these oppressors of defending the Italian coast from the attacks of the Byzantines was favourable to the development of the Pisan navy. Few particulars are extant concerning the real condition of the town; but we occasionally hear of it as a port of call. Although it was an independent city, at moments when Italy was overwhelmed by the greatest calamities. According to Amari's happy expression, "it was already independent by itself, while still enslaved on land." Its prosperity notably declined after the establishment of the Lombard rule and under the Franks. It again began to flourish under the marquises of Tuscany, who governed it in the name of the emperor.

In 1003 we find records of a war between Pisa and Lucca, which, according to Muratori, was the first waged between Italian cities in the middle ages. But the military development and real importance of Pisa in the 14th century must be attributed to the continuous and desperate struggle it maintained against the tide of Saracenic invasion from Sicily. And, although the numerous legends and fables of the oldchronicles disguise the true history of this struggle, they serve to attest the importance of Pisa in those days. In 1294 the Saracens forced the gates and sacked a quarter of the town; and in 1011 they renewed the attack. But the Pisans repulsed them and assumed the offensive in Calabria, Sicily, and even in Africa. Still more memorable was the expedition afterwards undertaken by the united forces of Pisa and Genoa against Mogadid, better known in the Italian chronicles as Mugetto. This Moslem chief had made himself master of Sardinia, and was driven thence by the allied fleets in 1015. Again invading the island, he was again attacked and defeated by the same adversaries, leaving a
brother and son, or, as some authorities aver, a wife and son, prisoners in their hands. Sardinia continued to be governed by native "judges" who were like petty sovereigns, and were now subject to the sway of Pisa. This was the primary cause of the jealousy of the Genoese, and of the wars afterwards made by them upon Pisa and carried on until its power was crushed. Meanwhile the Pisans flourished more and more, and continued hostilities against the Saracens. In 1063, their ships returned from Palermo laden with spoil by the It is not surprising that Pisa should already have had its own code of laws (Consuetudini di mare), which in 1075 were approved by Gregory VII., and in 1081 confirmed by a patent from the emperor Henry IV., a document which mentions for the first time the existence of a magistrate analogous to the consuls of the republic, although the latter, according to some writers, already existed in Pisa as early as the year 1098; the point, however, is doubtful, and other writers place the first authentic mention of the consuls in the year 1194.1 The oldest of Pisan statutes still extant is the Breve dei consoli di mare of 1162.

In 1099 the Pisans joined in the second crusade, proved their value at the capture of Jerusalem, and derived many commercial advantages from it; for within a short time they had banks, consuls, warehouses and privileges of all kinds in every Eastern port. Thus, while the commune of Pisa was still under the rule of the marquises of Tuscany, all negotiations with it were carried on as with an independent state officially represented by the archbishop and consuls. The aristocrats were the dominant party, and filled the highest offices of the republic, which, in the 12th century, rose to great power, both on sea and land, by its wars with the Lucchese, Genoese and Moslems. In 1170 Pisa made peace with Lucca after six years of continuous hostilities. And in the years 1113 and 1115 it achieved a still greater enterprise. The Pisan fleet of three hundred sail, commanded by the archbishop Pietro Moriconi, attacked the Balearic Isles, where as many as 20,000 Christians were said to be held captive by the Moslems, and returned loaded with spoil and with a multitude of Christian and Moslem prisoners. The former were set at liberty or ransomed, and among the latter was the last descendant of the reigning dynasty. The chief enuch who had governed Majorca perished in the siege. Immediately afterwards the fourteenth years' war with Genoa broke out. The two republics contested the dominion of the sea, and both claimed supreme power over the islands of Corsica and Sardinia. At first awed by the supremacy of Corsica to the Pisan church proved sufficient for the defence of the war, which went on from 1118 to 1132. Then Innocent II. transferred the supremacy over part of Corsica to the Genoese church, and compensated Pisa by grants in Sardinia and elsewhere. Accordingly, to gratify the pope and the emperor Lothair II., the Pisans entered the Neapolitan territory to combat the Normans. They aided in the vigorous defence of the city of Naples, and twice attacked and pillaged Amalfi, in 1135 and 1137, with such effect that the town never regained its prosperity. It has been said that the copy of the Pandects then taken by the Pisans from Amalfi was the first known to them, but in fact they were already acquainted with the civil laws. The effect of these laws. Genoa never came to a real end. Even after the retaking of Jerusalem by the Moslems (1187) the Pisans and Genoese again met in conflict in the East, and performed many deeds of valour. They were always ready to come to blows, and gave still more signal proofs of their enmity during the Sicilian War in behalf of the emperor Henry VI. From that moment it was plain that there could be no lasting peace between these rival powers until the one or the other should be crushed. The greatness and wealth of the Pisans at this period of their history is proved by the erection of the noble buildings by which their city is adorned. The foundation of the cathedral were laid in 1063, and its consecration took place in 1118; the baptistry was begun in 1152, and the campanile (the famous leaning tower) in 1174. And all three magnificent structures were mainly the work of Pisan artists, who gave new life to Italian architecture, as they afterwards renewed the art of sculpture.

It is asserted by some authors, especially by Tronci, that in the 12th century Pisa adopted a more democratic form of government. But in fact the chief authority was still vested in the nobles, who, both in Pisa and in Sardinia, exercised almost sovereign power. They formed the real strength of the republic, and kept it faithful to the empire and the Ghibelline party. The Guelph and popular element which constituted the force and prosperity of Florence was hostile to Pisa, and led to its downfall. The independence of the former city was of much later origin, only dating from the death of Countess Matilda (1115), but it rapidly rose to an ever-increasing power, and to inevitable rivalry with Pisa. Owing to the political and commercial interests binding Florence to the Roman court, the Guelph elements naturally prevailed there, while the growth of its trade forced it to cultivate friendly relations with the commercial cities; but in Pisa this was more particularly the case, when the Pisan empire was already in process of being crushed. However, in 1186 Pisa was able to repel another enterprise of the Genoese and Lucca, and to preserve its independence. But in 1187 the Genoese, with three ships, set sail for the city, and by a feigned treaty, obtained permission to build a fort on the castle of the Pisans which overlooked the town. The two parties were soon at war, and the Genoese, after a long siege, captured the city. But its situation being endangered, the Pisans, who had been driven from their ships by a storm, came to terms with their conquerors. In 1194 the Genoese, who had occupied the whole city, were expelled, and the Pisans restored to their lawful possession. In 1197 the Genoese captured the city again, and overthrew it. In 1198 the Pisans laid siege to Genoa, and in 1200 they defeated them.
Guelphs and the popular party, in spite of the Ghibelline traditions of his race. He was supported by his kinsman Giovannì Visconti, judge of Gallura; but almost all the other great families vowed eternal hatred against him, and proclaimed him a traitor to his party, his country, and his king. So in 1274 the Visconti were driven into exile. Both then joined the Florentines, took part in the war against their native city, and laid waste its surrounding territories. In 1276 the Pisans were compelled to agree to very grievous terms—to exempt Florentine merchandise from all harbour dues, to yield certain strongholds to Lucca, and to permit the return of Count Ugolino, whose houses they had burnt, and whose lands they had confiscated. Thus the count again became a powerful leader in Pisa. Visconti, however, was dead.

This was the moment chosen by Genoa for a desperate and decisive struggle with her perpetual rival. For some years the hostile fleets continued to harass each other and engage in petty skirmishes, as if to measure their strength and prepare for a final effort. On the 6th of August 1284 the great battle of Meloria took place. Here seventy-two Pisan galleys engaged eighty-eight Genoese, and half the Pisan fleet was destroyed. The chroniclers speak of 5000 killed and 17,000 prisoners; and, although these figures must be exaggerated, so great was the number of captives taken by the Genoese as to give rise to the saying—"To see Pisa, you must now go to Genoa." This defeat crushed the power of Pisa. She had lost her dominion over the sea, and the Tuscan Guelphs again joined in attacking her by land. Count Ugolino had taken part in the battle of Meloria and was accused of treachery. At the height of his country's disasters he sought to confirm his own power by making terms with the Florentines, by yielding certain castles to Lucca, and by neglecting to conclude negotiations with the Genoese for the release of the prisoners, lest these should all prove more or less hostile to himself. This excited a storm of opposition against him. The archbishop Ruggieri, having put himself at the head of the nobles, was elected podesta by the Lanfranchi, Simondi and Gualandi, and a section of the popular party. The city was plunged into civil war. The great bell of the commune called together the adherents of the archbishop; the bell of the people summoned the partisans of the count. After a day's fighting (July 1, 1288) the count, his two sons and his two grandsons were captured in the palazzo del popolo (or town hall), and cast into a tower belonging to the Gualandi and known as the Tower of the Seven Streets." Here they were all left to die of hunger. Their tragic end was afterwards immortalized in the Divina commedia. The sympathies of Dante Alighieri, the Florentine patriot and foe of Rome, were naturally in favour of the victims of an aristocratic prelate, opposed to all reconciliation with Florence.

The Florentines were now allied with Lucca and Genoa, and a few of their vessels succeeded in forcing an entry into the Pisan port, blocked it with sunken boats, and seized its towers. Their own internal dissensions of 1263 put a stop to the campaign, but not before they had concluded an advantageous peace. They and all the members of the Guelph league were freed from all imposts in Pisa and its port. In addition to these privileges the Genoese also held Corsica and part of Sardinia; and throughout the island of Elba they were exempted from every tax. They likewise received a ransom of 160,000 lire for their Pisan prisoners. These were no longer numerous, many having succumbed to the hardships and sufferings of all kinds to which they had been exposed.

In 1312 the arrival of the emperor Henry VII. gladdened the hearts of the Pisans, but his sudden death in 1313 again overthrew the city, left it without a sovereign, and endangered the faggia. Guicciardini, remaining as imperial lieutenant, was elected podesta and captain of the people, and thus became virtual lord of the city. As a Ghibelline chief of valour and renown he was able to restore the military prestige of the Pisans, who, under his command, captured Lucca and defeated the Florentines at Montecatini on the 29th of August 1315. So tyrannical, however, 'was his rule that in 1316 he was expelled by the popular fury. But Pisa's freedom was for ever lost. He was succeeded by other lords or tyrants, of whom the most renowned was Castruccio Castracane, a political and military adventurer of much the same stamp as Ugolino himself. With the help of Louis IV. of Bavaria, Castruccio became lord of Luca and Pisa, and was victorious over the Florentines; but his premature death in 1328 again left the city a prey to the conflicts of opposing factions. New lords, or petty tyrants, rose to power in turn during this period of civil discord, but the military valour of the Pisans was not yet extinguished. By sea they were almost impotent—Corsica and Sardinia were lost to them for ever; but they were still formidable by land. In 1347 they besieged Lucca in order to prevent the entry of the Florentines, to whom the city had been sold for 250,000 florins by the powerful Mastino della Scala. Aided by their Milanese, Mantuan and Paduan allies, they gave battle to their rivals, put them to rout at Altopascio (Oct. 5), and then again excluded them from their port. Thereupon the Florentines obtained Porto Talamone from Siena and established a navy of their own. By this means they were enabled to capture the island of Giglio, and, attacking the Pisan harbour, carried off its chains, bore them in triumph to Florence, and suspended them in front of the baptismery, where they remained until 1848. Then, in pledge of the brotherhood of all Italian cities, they were given back to Pisa, and placed in the Campo Santo.

The war was now carried on by the free companies with varying fortune, but always more or less to the hurt of the Pisans. In 1360 Lucca was taken from them by the emperor Charles IV.; and afterwards Giovanni Galeazzo Visconti, known as the count of Virtù, determined to forward his ambitious designs upon the whole of Italy by wrestling Pisa from the Gambacorti. For at this time the conflicts of the Raspanti faction, headed by the Gherardesca, with the Bergolìni led by the Gambacorti, had left the latter family masters of the city. At Visconti's instigation Piero Gambacorti, the ruler of the moment, was treacherously assassinated by Jacopo d'Appiano, who succeeded him as tyrant of Pisa, and bequeathed the state to his son Gherardo. The latter, a man of inferior ability and daring, sold Pisa to the count of Virtù, receiving in exchange 200,000 florins, Fiambino, and the islands of Elba, Pianosa and Monte Cristo. Thus in 1399 Visconti took possession of Pisa, and left it to his natural son Gabriele Maria Visconti, who was afterwards expelled from its gates. But even during this century of disaster the Pisans continued to cherish not only commerce, but also the fine arts. In the year 1278 they had entrusted the erection of their fine Campo Santo to Niccola and Giovanni Pisano, by whom the architectural part of it was completed towards the end of the century. In the following year the first artists of Italy were engaged in its decoration, and the celebrated frescoes attributed to Orcagna (q.v.) were painted on its walls. Others were afterwards supplied by Benozzo Gozzoli and men of lesser note, and the labour of ornamentation was only discontinued in 1464.

Meanwhile, in 1496, the Florentines made another attack upon Pisa, besieging it simultaneously by sea and land. Owing to the starving condition of its defenders, and aided by the treachery of Giovanni Gambacorti, they entered the city in triumph on the 9th of October, and sought to "crush every germ of rebellion and drive out its citizens by measures of the utmost harshness and cruelty." Such were the orders sent by the Ten of War to the representatives of the Florentine government in Pisa, and such was then the established policy of every Italian state. Consequently for a long time there was a continual stream of emigration from Pisa. The Medici pursued a humane course. In 1472 Lorenzo the Magnificent tried to restore the ancient renown of the Pisan university. To this end he invited the celebrated scholars, and, with only a few chairs of letters and philosophy in Florence, compelled the Florentines to resort to Pisa for the prosecution of their studies. But nothing could now allay the inextinguishable hatred of the conquered people. When Charles VIII. made his descent into Italy in 1494, and came to Sarzana on his way to Tuscany, he was welcomed by the Pisans with the greatest demonstrations of joy. And, although that monarch was ostensibly the friend of Florence, they did not
hesitate, even in his presence, to assert their own independence, and, casting the Florentine ensign, the Marzocco, into the Arno, made instant preparations for war. Between 1499 and 1501 they heroically withstood three sieges and repulsed their attacking armies. But their adversaries always returned to the assault, and, what was worse, yearly laid waste their territories and destroyed all their crops. Soderini, who was perpetual gonfalonier of Florence, and Machiavelli, the secretary of the Ten, urged on the war. In 1500 Florence encamped her forces on three sides of the distressed city, which at last, reduced to extremity by famine, was compelled to surrender on the 8th of June 1500. Thenceforth the Florentines remained lords of Pisa. But now, mainly owing to the efforts of Soderini and Machiavelli, the conquerors showed great magnanimity. They brought none of their stores of war, which were freely distributed to all; they tried to succour the suffering populace in every way, and gave other assistance to the wealthier classes. Nevertheless, emigration continued even on a larger scale than in 1406, and the real history of Pisa may be said to have ended. In Naples, in Palermo, in all parts of Italy, Switzerland and the south of France, we still find the names of Pisan families who quitted their beloved home at that time. The Florentines immediately built a new citadel, and this was a great bitterness to the Pisans. The Medici, however, remained well disposed towards the city. Leo X. was an active patron of the university, but it again declined after his death, and the grand duke of Tuscany, as a genuine statesman, not only restored the university, but instituted the "uffizio dei fossi," or drainage office for the reclamation of marsh lands, and founded the knighthood of St Stephen. This order played a noble part in the protection of Tuscan commerce, by fighting the Barbary pirates and establishing the prestige of the grand-ducal navy (see Medici). Under the succeeding Medici, Pisa's fortunes steadily declined. Ferdinand I. initiated a few public works there, and above all restored the cathedral, which had been partly destroyed by fire in 1593. These dreary times, however, are brightened by one glorious name—that of Galileo Galilei.

The population of Pisa within the walls had been reduced in 1551 to 8,574 souls, and between 1745 it had only risen to the number of 12,406. Under the house of Lorraine, or more correctly during the reign of that enlightened reformer the grand duke Peter Leopold (1765-1790), Pisa shared in the general prosperity of Tuscany, and its population constantly increased. By 1840 it contained 21,670 souls, exclusive of the suburbs and outlying districts.

Authorities.—Paolo Tronci, Annali di Pisa, edited by E. V. Montario (2 vols., Lucca, 1842-1843), which comes down to 1840; Ranzieri Grassi, Pisa e la sua indisciplina (Pisa, 1851), which contains a useful historical guide; Roncioni, "Istorie Pisane," in the Archivio storico italiano, vol. vii., pt. 1; "Cronache Pisane," in the same Archivio, vol. vii., pt. 2; for the early constitution of the city, see G. Volpe's Stati e istituzioni, comunali di Pisa (Pisa, 1902), and for the laws, F. Bonaiuti's Stati e ordinamenti della città di Pisa (3 vols., Floence, 1851, &c.). The maritime and commercial history of the republic is dealt with in A. Schaubie's Das Konzulat des Meeres in Pisa (Leipzig, 1888) and in Pawiński's "Zur Entstehungsgeschichte des Konzulats in den Communen Nord- und Mittel-Italens" (Berlin, 1867); for the monuments and inscriptions see A. Madeo, Il Ponente (Leghorn, 1717 and 1718); and C. R. de Fleury, in his Les monuments de Pise au moyen âge (Paris, 1866); also Repetti's Dizionario geografico della Toscana, s.v. "Pisa." For Dante's connexion with Pisa, see Dante e i Pisani, by Giovanni Sforza (Pisa, 1858). Among the more recent historical guides to Pisa, of a popular character is The Story of Pisa and Lucca, by Janet Ross and Nellie Erichsen, in Dent's "Medieval Towns" (London, 1907), and T. B. Supino's Pisa, in the "Italia artistica Series" (P. V.).

PISA, COUNCIL OF (1409). The great schism of the west had already lasted thirty years, and the efforts which had been made to restore unity with the simultaneous resignation of the two rival pontiffs had been in vain, when in the spring of 1408, the state of affairs being desperate, the idea arose of assembling a council to effect a union without the co-operation of the popes. The initiative came from those cardinals who had one after the other ceased either from Gregory XII. or Benedict XIII. They were forestalled by the popes, who each summoned a council, the former to Civitadela (in Friuli), the latter to Pérpignan, so the dissident cardinals sent out anated letters inviting the English, French, and other cardinals to meet at Pisa in May of 1409. Their appeal met with a response in a great part of Italy, France, Navarre, Portugal and England, and in Germany in the states subject to Wenceslas king of the Romans, the electors of Cologne and Mainz, the margrave of Brandenburg, &c. For a time the number of the fathers exceeded five hundred.

The day after the opening of the council, proceedings were started against the two popes, who, it was agreed, were to be eliminated. An act of accusation, containing in 37 articles the chief complaints against them, was read out to the people; not that they polluted themselves and sodomy, but that they were not only abusive to the holy see, but that they were of the fourteenth year of the pontificate of Pope Urban VIII. The appeal met with a response in a great part of Italy, France, Navarre, Portugal and England, and in Germany in the states subject to Wenceslas king of the Romans, the electors of Cologne and Mainz, the margrave of Brandenburg, &c. For a time the number of the fathers exceeded five hundred.

In order to complete their task the cardinals present at Pisa, authorized by delegation of the council, shut themselves up in conclave, and elected one of their number, Peter Philarges, cardinal of Milan, as the new pope, who assumed the name of Alexander V. They had hoped to save the Church, but unfortunately the result of their efforts, generous as they were, was that the schism increased in bitterness, and that instead of the unity for which the Church craved, three popes continued to flourish. Both the deposed pontiffs protested against the legality of the council of Pisa; each had numerous partisans, and the thesis, constructed rather to meet the exigencies of the Church and the popes, was far from being established.

Originally the council of Pisa was to have occupied itself not only with effecting the union, but also with the reform of the Church. As a matter of fact, it confined itself to expressing certain desiderata in a "libellus supPLICATORIUS" which it submitted to the new pope. Alexander V. only partially acceded to these demands, many of which constituted serious encroachments on the prerogatives of the Holy See; he then declared the work of reform suspended, and dissolved the council (August 7, 1409).

PIŠACA LANGUAGES, the name which has been given to a family of languages spoken immediately to the south of the Hindu Kush, and north of the frontier of British India. The family included the group of Kafir languages spoken in Kafiristan, Khwar, spoken in the Chitral country, and the group of Shina languages, which includes the Shināt of Gilgit, Kōfāstān, spoken in the Khoostans of the Indus and Swat rivers, and Kashmīr. Of all these Kashmiri is the only one which has received any literary cultivation, and of which the number of speakers is known. The Pišaca languages are Aryan by origin, but are neither Iranian nor Indo-Aryan. (See Indo-Aryan Languages and Kashmiri.)
PISACANE, CARLO, duke of San Giovanni (1818-1857), Italian revolutionary, was born at Naples, and entered the Neapolitan army in 1839; but having become imbued with Mazzinian ideas he emigrated in 1847, and after a short stay in England and France served in the French army in Algeria. The revolution of 1848 recalled him to Italy; he played a part in the brief but glorious history of the Roman Republic, and was the life and soul of the war commission in the defence of the city. After its capture by the French he again went into exile, first to London and then to Genoa, maintaining himself by teaching. He regarded the rule of the house of Savoy as no better than that of Austria. When Mazzini, undeterred by the failure of the abortive Milan rising on the 6th of February 1853, determined to organize an expedition to provoke a rising in the Neapolitan kingdom, Pisacane offered himself for the task, and sailed from Genoa with a few followers (including Giovanni Nicotera) on board the "Cagliari" on the 25th of June 1857. They landed on the island of Ponza, where the guards were overpowered and some hundreds of prisoners liberated, and on the 28th arrived at Sapri in Calabria and attempted to reach the Cilento. But hardly any assistance from the inhabitants was forthcoming, and the invaders were quickly overpowered, Pisacane himself being killed.

See P. M. Bilotti, La Spedizione di Sapri (Salerno, 1907).

PISAN, CHRISTINE DE (1364-1419), French poet, of Italian birth, was born at Venice in 1364. When she was four years old she was brought to her father, a councillor of the Venetian Republic, in Paris, where he held office as an astrologer and a tutor to Charles V. At fifteen Christine married Étienne du Castel, who became Charles's notary and secretary. After the king's death in 1388 her father lost his appointment, and died soon after; and when Christine's husband died in 1389 she found herself without a protector, and with three children depending on her. This determined her to have recourse to letters as a means of livelihood. Her first ballads were written to the memory of her husband, and as love poems the fashion she continued to write others—lais, virelais, rondeaux and jeux à vendre—though she took the precaution to assure her readers (Cent balades, No. 50) that they were merely exercises. In 1399 she began to study the Latin poets, and between that time and 1405, as she herself declares, she composed some fifteen important works, chiefly in prose, besides minor pieces. The earl of Salisbury, who was in Paris on the occasion of the marriage of Richard II. with Isabella of France (1396), took her elder son, Jean du Castel (b. 1384), and reared him as his own; the boy, after Salisbury's death (1400), being received by Philip of Burgundy, at whose desire Christine wrote Le Livre des faits et bonnes mœurs du sacye roy Charles (1405), valuable as a first-hand picture of Charles V. and his court. Her Mutation de fortune, in which she finds room for a great deal of history and philosophy, was presented to the same patron on New Year's Day, 1404. It possesses an introduction of great autobiographical interest. In La Vision (1405) she tells her own history, by way of defence against those who objected to her pretensions as a moralist. Henry IV. of England desired her to make his court her home, and she received a like invitation from Galeazzo Visconti, tyrant of Milan. She preferred, however, to remain in France, where she enjoyed the favour of Charles VI., the dukes of Berry and Burgundy, the duchess of Bourbon and others.

Christine was a champion of her own sex. In her Dit de la rose (1402) she describes an order of the rose, the members of which bind themselves by vow to defend the honour of women. Her Épître au dieu d'amour (1399) is a defence of women against the satire of Jean de Meun, and initiated a prolonged dispute with two great scholars of her time, Jean de Montemueil (d. 1415) and Gonthier Col, who undertook the defence of the Roman de la rose. Christine wrote about 1407 two books for women, La Clôture des femmes et Le Livre de la clôture des femmes. She was dedicated to her adopted country. During the civil wars she wrote a Lamentation (1410) and a Livre de la paix (1412-1413), but after the disasters of the campaign of Agincourt she retired to a convent. We have no more of her work until 1429, when she broke her silence to write a song in honour of Joan of Arc. Of the circumstances of her death nothing is known but it probably took place about this time. Her Clôture des dames contains many interesting contemporary portraits, and her Livre des trois versus contains details of domestic life in the France of the early 15th century not supplied by more formal historians.

Her poems were edited by Maurice Roy for the Société des anciens Textes français (1886, &c.), and her Livre du chemin du long estude, by Paschel (Berlin, 1887). There are monographs by Raimond Thomassy (Paris, 1839); E. M. D. Robineau (Saint-Omer, 1882); and Friedrich Koch (Goslar, 1883). It is possible that Jean Castel, who was chronicler of France under Louis XI., was Christine's grandson. Hoccleve imitated her Épître au dieu d'amour, in his "Letter of Cupid" (Chaucerian and other Pieces, ed. W. D. Skeat, 1897). A translation of her Épître d'Othée was made (c. 1440) by Stephen Scrope for his stepfather, Sir John Fastolf, and is preserved in a MS. at Longleat. This was edited (1904) for the Roxburghe Club by W. C. Warner as The Epistle of Othée to Hector, or the Boke of Knighthode. The Moral Proverbs of Christyne de Pise, translated by Earl Rivers, was printed in 1478 by Caxton, who himself translated, by order of Henry VII., her Livre des faits d'armes, et de chevalerie, a treatise on the art of war, based chiefly on Vegetius. Her Clôture des dames was translated by Brian Anslay (London, 1521).

PISANI, VETTOR (d. 1380), Venetian admiral, was in command of the Venetian fleet in 1378 during the war against the Genoese, whom he defeated off Capo d'Anzio; subsequently he recaptured Cattaro, Senbenco and Arbe, which had been seized by the Hungarians, the allies of the Genoese. But the Genoese fleet completely defeated Pisani at Pola in May 1379, and on his return to Venice he was thrown into prison. The enemy now pressed home their victory, and besieged and captured Chioggia, whereby Venice itself was in danger. The people thereupon demanded the liberation of Pisani, in whose skill they had the fullest confidence. The government gave way and appointed the aged commander admiral of the fleet once more. Through his able strategy and daring he recaptured Chioggia, defeated the Genoese and threatened Genoa itself until that republic agreed to peace terms. Pisani died in 1380 while on his way to Manfredonia with a squadron to ship provisions.

PISANO, ANDREA, also known as ANDREA DA PONTADERA (c. 1270-1348), Italian sculptor, was born about 1270, and first learned the trade of a goldsmith. He became a pupil of Giovanni Pisano about 1300, and worked with him on the sculpture for S. Maria della Spina at Pisa and elsewhere. But it is at Florence...
that his chief works were executed, and the formation of his mature style was due rather to Giotto than to his earlier master. Of the three world-famed bronze doors of the Florentine baptistery, the earliest one—that on the south side—was the work of Andrea; he spent many years on it; and it was finally set up in 1336. 1 It consists of a number of small quatrefoil panels—the lower eight containing single figures of the Virtues, and the rest scenes from the life of the Baptist. Andrea Pisano, while living in Florence, also produced many important works of marble sculpture, all of which show strongly Giotto's influence. In some cases probably they were actually designed by that artist, as, for instance, the double hand of beautiful panel-reliefs which Andrea executed for the great campanile. The subjects of these are the Four Great Prophets, the Seven Virtues, the Seven Sacraments, the Seven Works of Mercy and the Seven Planets. The duomo contains the chief of Andrea's other Florentine works in marble. In 1347 he was appointed architect to the duomo of Orvieto, which had already been designed and begun by Lorenzo Maitani. The exact date of his death is not known, but it must have been shortly before the year 1349.

Andrea Pisano had two sons, Nino and Tommaso—both, especially the former, sculptors of considerable ability. Nino was very successful in his statues of the Madonna and Child, which are full of human feeling and soft loveliness—a perfect embodiment of the Catholic ideal of the Divine Mother. Andrea's chief pupil was Andrea di Cione, better known as Orcagna (q.v.). Balduccio di Pisa, another, and in one branch (that of sculpture) equally gifted pupil, executed the wonderful shrine of St. Eustorgio at Milan—a most magnificent mass of sculptured figures and relics.

PISSANO, GIOVANNI (c. 1250–1330), Italian architect and sculptor, was the son of Niccola Pisano. Together with Arnolfo del Cambio and other pupils, he developed and extended into other parts of Italy the renaissance of sculpture which in the main was due to his father's talent. After he had spent the first part of his life at home as a pupil and fellow worker of church of S. Domenico in 1304, but little of the original structure remains. The north transept, however, still contains his beautiful tomb of Benedict XI. With a sleeping figure of the pope, encircled by angels who draw aside the curtain, Ornate with the most beautiful architectural works was the little chapel of S. Maria della Spina (now rebuilt, "restored"), on the banks of the Arno in Pisa; the actual execution of this chapel, and the sculpture with which it is adorned, was mostly the work of his pupils. 2 The influence of his father Niccola is seen strongly in all Giovanni's works, but especially in the pulpit of S. Andrea at Pistoia, executed about 1300. Another pulpit, designed on the same lines, was made by him for the nave of Pisa Cathedral between 1310 and 1311. The last part of Giovanni's life was spent at Pistoia, near Florence, where with many pupils he worked on the cathedral till his death in 1339.

See M. Sauerlandt, Über die Bildwerke des Giovanni Pisano, &c. (1903); A. Brach, Nicola und Giovanni Pissano und die Plastik des XIV. Jahrhunderts in Siena (1905).

PISSANO, NICCOLA (c. 1266–1278), Italian sculptor and architect. Though he called himself Pissanus, from Pisa, where most of his life was spent, he was not a Pisan by birth. There are two distinct accounts of his parentage, both derived mainly from existing documents. According to one of these he is said to have been the son of "Petrus, a notary of Siena;" but this statement is very doubtful, especially as the word "Siena" or "de Senis" appears to be a conjectural addition. Another document among the archives of the Sienese Cathedral calls him son of "Petrus de Apulia." Most modern writers accept the latter statement, and believe that he was not only a native of the province of Apulia in southern Italy, but also that he gained there his early instruction in the arts of sculpture and architecture. Those, on the other hand, who, with most of the older writers, prefer to accept the theory of Niccola's origin being Tuscan, suppose that he was a native of a small town called Apulia near Lucca.

Except through his works, but little is known of the history of Niccola's life. As early as 1221 he is said to have been summoned to Naples by Frederick II, to do work in the new Castel del'Uovo. This fact supports the theory of his southern origin, though not perhaps very strongly, as, some years before, the Pisano Bonannus had been chosen by the Norman king as the sculptor to cast one of the bronze doors for Monreale Cathedral, where it still exists. The earliest existing piece of sculpture which can be attributed to Niccola is a beautiful relief of the Deposition from the Cross in the tympanum of the arch of a side door at San Martino at Lucca; it is remarkable for its graceful composition and delicate finish of execution. The date is about 1237. In 1260, as an incised inscription records, he finished the marble pulpit for the Pisan baptistery; this is on the whole the finest of his works.

It is a high octagon, on semicircular arches, with trefoil cusps, supported by nine marble columns, three of which rest on white marble lions. In design it presents that curious combination of Gothic forms with classical details which is one of the characteristics of the medieval architecture of northern Italy; though much enriched with sculpture both in relief and in the round, the general line of the design is not sacrificed to this, but the sculptural is kept subordinate to the whole. In this respect it is superior to the more magnificent pulpit at Siena, one of Niccola's later works, which suffers greatly from want of repose and purity of outline, owing to its being overloaded with reliefs and statuettes. Five of the sides of the main octagon have panels with subjects—the Nativity, the Adoration of the Magi, the Presentation in the Temple, the Crucifixion and the Dormition. These are all, especially the first three, works of the highest beauty, and a wonderful advance on anything of the sort that had been produced by Niccola's predecessors. The drapery is gracefully arranged in broad simple folds; the heads and hands are full of significant beauty. The stately beauty of the Madonna could hardly be surpassed. The panel with the Adoration of the Magi is perhaps the one in which Niccola's study of the antique is most apparent (see figure). The veiled, and tiaraed figure of the Virgin, seated on a throne, recalls the Roman Juno; the head of Joseph behind her might be that of Vulcan; while the youthful beauty of an Apollo and the mature dignity of a Jupiter are suggested by the standing

1 The date on the door, 1330, refers to the original wax model.
PISANO, V.—PISCICULTURE

and kneeling figures of the Magi. Certain figures in others of the panels are no less deeply imbued with classical feeling.

The next important work of Niccola in date is the Arca di San Domenico, in the church at Bologna consecrated to that saint, who died in 1221. Only the main part, the actual sarcophagus covered with sculptured reliefs of St. Dominic's life, is the work of Niccola and his pupils. The sculptured base and carved roof, with its fanciful ornaments are later additions. This "Arca"

The Adoration of the Magi, one of the panels in the pulpit of the Pisan Baptistery, by Niccola Pisano, was made when St. Dominic was canonized, and his bones translated; it was finished in 1267, not by Niccola himself, but by his pupils. The most magnificent, though not the most beautiful, of Niccola's works is the great pulpit in Siena cathedral (1268). It is much larger than that at Pisa, though somewhat similar in general design, being an octagon on cusped foliage and columns. Its stairs, and a large landing at the top, with carved balusters and panels, rich with semi-classical figures, are an addition of about 1500. The pulpit itself is much overloaded with sculpture, and each relief is far too crowded with figures. An attempt to gain magnificence of effect has destroyed the dignified simplicity for which the earlier pulpit is so remarkable.

Niccola's last great work of sculpture was the fountain in the piazza opposite the west end of the cathedral at Perugia. This is a series of basins rising one above another, each with sculptured bas-reliefs; it was begun in 1274, and completed, except the topmost basin, which is of bronze, by Niccola's son and pupil Giovanni.

Niccola Pisano was not only pre-eminent as a sculptor, but was also the greatest Italian architect of his century; he designed a number of very important buildings, though not all which are attributed to him by Vasari. Among those now existing the chief are the main part of the cathedral at Pistoia, the church and convent of Sta. Margherita at Cortona, and Sta. Trinità at Florence. The church of Sant' Antonio at Padua has also been attributed to him, but without reason. Unfortunately his architectural works have in most cases been much altered and modernized. Niccola was also a skilled engineer, and was compelled by the Florentines to destroy the great tower, called the Guademorto, which overshadowed the baptistery at Florence, and had for long been the scene of violent conflicts between the Guelphs and Ghibellines. He managed skilfully so that it should fall without injuring the baptistery. Niccola Pisano died at Pisa in the year 1278, leaving his son Giovanni a worthy successor to his great talents both as an architect and sculptor.

Though his importance as a revival of the old traditions of beauty in art has been to some extent exaggerated by Vasari, yet it is probable that Niccola, more than any other one man, was the means of starting that "new birth" of the plastic arts which, in the years following his death, was so fertile in countless works of the most unrivalled beauty. Both Niccola and his son had many pupils of great artistic power, and these carried the influence of the Pisani throughout Tuscany and northern Italy, so that the whole art of the succeeding generations may be said to have owed the greater part of its rapid development to this one family.

See SCULPTURE, and general histories of Italian art; Symonds, Renaissance in Italy; A. Brach, Nicola und Giovanni Pisano und die Plastik des XIV. Jahrhunderts in Siena (Strassburg, 1904).

PISANO, VITTORE (c. 1380-1450), commonly called PISANELLO, Italian medalist, was a native of San Vigiolo sul Lago in the territory of Verona. Specimens of his work as a painter are still extant in Rome, Venice, Verona and Pistoia, and entitle him to a place of some distinction in the history of that art. The National Gallery in London possesses a very fine specimen of Pisanello's work—a panel painted with miniature-like delicacy. During the latter portion of his life he lived in Rome, where he enjoyed great repute.

PISARUM (mod. Pesaro, q.v.), an ancient town of Umbria on the Via Flaminia, 26 m. from Ariminum and 8 from Fanum Fortunae. A Roman colony was founded here in the territory of the Gallo Senones in 854 B.C., at the mouth of the river Pisarum (mod. Foglia); the sea has since then receded about half a mile. Whether it took the place of an earlier town or not, is not known: an important Gaulish cemetery has been discovered near the village of Novilara between Pisarum and Fanum, but to which of these centres (if either) it belonged is uncertain (E. Brizio in Monumenti dei Lincei [1805], v. 835q.v.). In 174 B.C. we hear that the censors built a temple of Jupiter here and paved a road. T. Accius, the counsel who opposed Cicero in the case when he defended Cluentius in a still extant speech, was a native of Pisarum. Catullus refers to the town as decadent or unhealthy, but this may be merely malicious, and does not seem to be borne out by facts: for it is not infrequently mentioned by classical authors. It was occupied by Caesar in 49 B.C., and was made a colony under the second triumvirate. Hence it bears the name Colonia Julia Felix. We hear little of it under the empire. It was destroyed by the Goths in 539, and restored by Belisarius in 545. From the inscriptions, nearly 260 in number, an idea of the importance of the town may be gained. Among them are a group of cippi found on the site of a sacred grove of the matrons of Pisarum, bearing dedications to various deities, and belonging probably to the date of the foundation of the colony. There are some remains of the town walls, and an ancient bridge over the Foglia. It was, like Ariminum, a considerable place for the manufacture of bricks and pottery, though the factories cannot always be precisely localized.

PISCES (the fishes), in astronomy, the twelfth sign of the zodiac (q.v.), represented by two fishes tailed together by their tails, and supported by the symbol Ω. It is also a constellation, mentioned by Eudoxus (4th century B.C.) and Aratus (3rd century B.C.); and catalogued by Ptolemy (35 stars), Tycho Brahe (36) and Hevelius (39). In Greek legend Aphrodite and Eros, while on the banks of the Euphrates, were surprised by Typhon, and sought safety by jumping into the water, where they were changed into two fishes. This fable, however, as in many other similar cases, is probably nothing more than an adaptation of an older Egyptian tale. α Piscium, is a fine double star of magnitude 3 and 4; 35 Piscium, is another double star, the components being a white star of the 6th magnitude and a purplish star of the 8th magnitude.

Piscis australis, the southern fish, is a constellation of the southern hemisphere, mentioned by Eudoxus and Aratus, and cata-

catalogued by Ptolemy, who described 18 stars. The most important star is a Piscis australis or Formalhaut, a star of the first magnitude. Piscis volans, the flying fish, is a new constellation introduced by John Bayer in 1603.

PISCICULTURE (from Lat. piscis, fish). The species of fish which can be kept successfully in captivity throughout their lives from egg to adult is exceedingly limited in number. The various breeds of goldfish are familiar examples, but the carp is almost the only food-fish capable of similar domestication. Various other food-fishes, both marine and fresh-water, can be kept in ponds for longer or shorter periods, but refuse to breed, while in other cases the fry obtained from captive breeders will not develop. Consequently there are two main types of pisciculture to be distinguished: (1) the rearing in confinement of young fishes to an edible stage, and (2) the stocking of natural waters with eggs or fry from captured breeders.
PISCICULTURE

Fish-rearing.—Of the first type of pisciculture there are few examples of commercial importance. The pond-culture of carp is an important industry in China and Germany, and has been introduced with some success in the United States, but in England it has long fallen out of use, and is not likely to be revived so long as fresh fish can be obtained and distributed so readily as is now the case. Other examples are to be found in the cultivation of the lagoons of the Adriatic, and of the salt-marshes of various parts of France. Here, as in ancient Greece and Rome, it is the practice to admit young fish from the sea by sluices, into artificial enclosures or “viviers,” and to keep them there until they are large enough to be used. An interesting modification of this method of cultivation has been introduced into Denmark. The entrances to the inner lagoons of the Limfjord are naturally blocked against the immigration of flatfish by dense growths of sea-grass (Zostera), although the outer lagoons are annually invaded by large numbers of small plaice from the North Sea. The fishermen of the district consequently combined to defray the expenses of transplanting large numbers of small plaice from the outer waters to the inner lagoons, where they were found to thrive far better than in their natural habitat. The explanation has been shown by Dr. Petersen to be due to the abundance of food, coupled with the lack of overcrowding of the small fish. This transplantation of plaice in Denmark has been annually repeated for several years with the most successful results, and a suitable subvention to the cost is now an annual charge upon the government funds.

As a result of the international North Sea fishery investigations, it has been proposed to extend the same principle to the development of the deep sea fishery in the neighbourhood of the Dogger Bank. Experiments with labelled plaice, carried out in 1904 by the Marine Biological Association, showed that small plaice transplanted to the Dogger Bank in spring grew three times as rapidly as they grew grounded on the same ground with insignificant variations, has been obtained by similar experiments in each succeeding year. In this case the deep water round the Dogger Bank acts as a barrier to the emigration of the small plaice from the shores. It has consequently been proposed that the small plaice should be transplanted in millions to the Bank by well vessels every spring. It is claimed, as a further result of the experiments, that from May to October the young fish would be practically fished on the shallow part of the Bank from the risk of premature capture by trawlers, and that the increased value of the fish, consequent upon their phenomenal growth-rate, would greatly exceed the cost of the transplanted.

The methods of oyster- and mussel-culture are similar in principle to those just described. A breeding stock is maintained to supply the ground, or the “collectors,” with spat, and the latter, when sufficient, is transferred to the transplanter, then transplanted to the feeding-grounds, care being taken to avoid the local over-crowding which is so commonly observed among shell-fish under natural conditions.

Fish-hatching.—The second, and more familiar, type of pisciculture is that known as fish-hatching, with which must be associated the various methods of artificial propagation.

The fertilization of the spawn is very easily effected. The eggs are collected either by "stripping" them from the mature adult immediately after capture, or by keeping the adults alive until they are ready to spawn, and then stripping them alive or by keeping them in reservoirs of sea-water and allowing them to spawn of their own accord. In the two former cases a little milt is allowed to fall from a male fish into a vessel containing a small quantity of water—fresh or salt as required—and the eggs are pressed from the female fish into the same vessel. In fresh-water culture the eggs thus fertilized may be at once distributed to the waters to be stocked, or they may be kept in special receptacles provided with a suitable stream of water until the fry are hatched, and then distributed, or again they may be reared in the hatchery for several months until they are fry or parr.

The hatching of eggs, whether of fresh-water or salt-water fishes, presents no serious difficulties, if suitable apparatus is employed; but the rearing of fry to an advanced stage, without serious losses, is less easy, and in the case of sea-fishes with pelagic eggs, the larvae of which are exceedingly small and tender, is still an unsolved problem, although recent work, carried out at the Plymouth laboratory of the Marine Biological Association, is at least promising. It has been found possible to grow pure cultures of various diatoms, and by feeding these to delicate larvae kept in sterilized sea-water, great successes have been attained. In fresh-water culture little advantage, if any, has been found to result from artificial hatching, and this is followed by a successful period of rearing. Thus the Howetown Fishery Company recommend to their customers to stock their streams either with unhatched ova or with three-month-old fry. Their experience is "that there is no half-way house between ova sown in redds and three-month-old fry. Younger fry may do, but only where ova would do as well, and at half the cost." In marine hatcheries, on the other hand, it is the invariable practice to hatch the eggs, although the fry have to be put into the sea at the most critical period of their lives. If it is a risky matter to plant out the robust young fry of trout under an age of three months, it would seem to be an infinitely more speculative proceeding to plant out the delicate week-old larvae of sea-fishes in an environment which teems with predaceous enemies.

Objects and Utility of Fish-hatcheries.—The earlier advocates of artificial propagation and fish-hatching seem to have been under the impression that the thousands of fry resulting from a single act of artificial propagation meant a corresponding increase in the numbers of edible fish when once they had been deposited in suitable waters; and also that artificial fertilization ensured a greater proportion of fertilized eggs than the natural process. For the second of these propositions there is no evidence, while the first proposition is now everywhere discredited. It is recognized that the great fertility of fishes is nature's provision to meet a high mortality—greater in sea-fishes with minute pelagic eggs than in fresh-water fishes with larger-yolked eggs, partly because of the greater risks of marine pelagic life, and partly because of the greater delicacy of marine larvae at the time of hatching. Artificially propagated eggs and fry after planting must submit to the same mortality as the other eggs and fry around them. Consequently it is useless to plant out eggs or fry unless in numbers sufficiently great to appreciably increase the stock of eggs and fry already existing.

It is this, combined always with the suitability of the external conditions, which accounts for the success of the best hatcheries—whether fish-cultivists or pisciculturists. The artificially propagated eggs of the shad far outnumber all the wild eggs in the waters of the United States were planted in those of California and the Mississippi, where the species did not naturally occur. The conditions were suitable, and the species became at once acclimatized. Similarly reservoirs and streams can be stocked with various kinds of fish not previously present. But in the case of indigenous species the breeding stock must be very seriously reduced before the addition of the eggs or fry of a few score or hundreds of fish can appreciably increase the local stock.

In the case of sea-fishes it is becoming increasingly recognized that the millions of cod fry which are annually turned out to sea from the artificial hatcheries of Norway and Sweden are but an insignificant fraction of the billions of fry which are naturally produced. A single female cod liberates, according to its size, from one to five million eggs in a single season. Yet the annual output of fry from each of these hatcheries rarely exceeds 200 millions, i.e. the natural product of a few hundred cod at most. In Britain marine hatcheries have been established by the Fishery Board for Scotland in the bay of Nigg, near Aberdeen, by the Lancashire Sea Fisheries Committee at Peel, and by the government of the Isle of Man at Port Erin. These establishments have been principally devoted to the hatching of the eggs of plaice. But again the maximum output of fry from any one of these establishments has not exceeded 50 millions in any single year. As a single female plaice produces about 200,000 eggs per annum, this output does not exceed the natural produce of a few hundred fish. Under these circumstances the probable utility of the operations could be
admitted only if the fry were sedentary and could be planted in suitable localities where young fish were naturally scarce. But the fry drift with the currents as helplessly as the eggs, and the a priori objections to the utility of the operations have in no case been met by evidence of tangible results. The place fry hatched in the Scottish establishment have been distributed for many years in the waters of Loch Fyne. Yet in this area, according to the investigation of Mr Williamson (Report of the Scottish Fishery Board for 1898), nearly 500 millions of place eggs are naturally produced in one spawning season. Evidence is still lacking as to whether the 20 to 30 million fry annually added from the hatchery have appreciably increased the quantities of young place on the surrounding shores. Supposing this could be established, the question would still remain whether the same result could not be obtained at far less expense by dispensing with the hatchery operations and distributing the eggs directly after fertilization.

In the United States the utility of the cod-hatching operations has been constantly asserted by representatives of the Bureau of Fisheries, but practically the only evidence adduced is the occasional appearance of unusual numbers of cod in the neighbourhood. It has not been established that the fluctuations in the local cod fisheries bear any fixed relation to the extent of the hatchery operations, while the earlier reports of the Commissioners of Fisheries contain evidence that similar fluctuations occurred before the hatching of "fish commission cod" had begun.

The situation may be summed up in the words of Mr Fryer, H.M. Superintending Inspector of Fisheries, who critically examined the evidence bearing upon the operations of the Newfoundland Hatchery at Dildo (Reports x.—xii. of the Inspectors of Sea Fisheries, E. & W.): "Where the establishment of a hatchery, even on the smallest scale, is followed by an increased take of fish, there is a tendency to connect the two as cause and effect on insufficient evidence, and without any regard to the many conditions which have always led to fluctuations in the case of any particular kind of fish."

The most exact investigations bearing upon this problem are those which have been recently undertaken in Norway in connexion with the cod-hatching operations at A rendal under Captain Dannevig. Four fjords were selected in the south coast of Norway in proximity to the hatchery, and the usual number of fry (a million each) were planted in alternate fjords, leaving the intermediate fjords untried. The relative number of young cod in the various fjords was then carefully investigated throughout the succeeding summer and autumn months. It was found that there was no relation between the abundance of young fish and the presence or absence of "artificial" fry. In 1904, 33 million fry were planted in Sondefjord and young fish were exceptionally abundant in the following autumn (three times as abundant as in 1903 when no fry were planted). But their abundance was equally striking in other fjords in which no fry had been planted, while in 1905 all the fjords were deficient in young cod whether they had been planted with fry from the hatchery or not.

For a summary of these investigations see papers on "Artificial Fish-hatchery in Norway" by Captain Dannevig and Mr Dahl, in the Report of the Lancashire Sea Fisheries Laboratory for 1906 (Liverpool, 1907).

It would thus seem clear that the attempts hitherto made to increase the supply of sea-fish by artificial hatching have been unsuccessful. The experience gained has doubtless not been wasted, but the direction to be taken by future work is plain. The energy and money devoted to hatching operations should be diverted to the serious attempt to discover a means of rearing on a large scale the just-hatched fry of the more sedentary species to a sturdy adolescence. When that has been done (it has been achieved by the present writer in the case of the sea fish Cottus with demersal eggs) it would be possible to deposit the young fish in suitable localities on a large scale, with a reasonable prospect of influencing the local abundance of the species of fish in question.

For further details, see J. T. Cunningham, Natural History of the Marketable Marine Fishes of the British Islands (London, 1896); Memorandum of Fish-Collecting (Washington, 1897); Roché, La Culture des ours (Paris, 1898); W. Garstang, Experiments on the Transplantation of Marked Places (First Report of the North Sea Fisheries Investigation Committee, 1905).

PISCINA, a Latin word first applied to a fish-pond, and later used for any pool of water for bathing, &c., either natural or artificial, and also for a tank or reservoir. In ecclesiastical usage the term was given to a shallow stone basin (the French casse) placed near the altar in a church, with drains to take away the water used in the ablutions at the mass. "Pisicinae" seem at first to have been mere cups or small basins, supported on perforated stems, placed close to the wall, and afterwards to have been recessed therein and covered with niche heads, which often contained shells to serve as aumbries. They are rare in England till the 13th century, after which there is scarcely an altar without one. They frequently take the form of a double niche, with a shaft between the arched heads, which are often filled with elaborate tracing.

PISEK, a town of Bohemia, 55 m. S. of Prague by rail. Pop. (1900), 13,668, mostly Czech. It lies on the right bank of the Wottawa, which is here crossed by an interesting stone bridge of great antiquity. The most prominent buildings are the church of the Nativity, the town-hall, and a castle dating from the 13th century. The industries are iron and brass founding, brewing, and the manufacture of shoes, paper, cement and Turkish fezes. Feldspar, quartz and granite are quarried in the environs. The name of Pisek, which is the Czech for sand, is said to be derived from the gold-washing formerly carried on in the bed of the Wottawa (1571-1621).

In 1619 it was captured by the imperialist general, Karl Bonaventura de Longueval, Graf von Burquoy, and suffered so severely that the citizens opened their gates to his opponent, Ernst von Mansfeld. This was punished in October of the following year, when Duke Maximilian of Bavaria sacked the town and put nearly all the inhabitants to the sword. Pisek was one of the chief centres of the Hussites. It was occupied by the French in 1741.

PISIDIA, in ancient geography, the name given to a country in the south of Asia Minor, immediately north of Pamphylia by which it was separated from the Mediterranean, while it was bounded on the N. by Phrygia, on the E. by Lyconia, and on the W. and S. by Cilicia, and on the W. and S. by Lycia and a part of Phrygia. It is a region of Phrygia, with the district, comprising some of the loftiest portions of the great range of Mt. Taurus, together with the offshoots of the same chain towards the central table-land of Phrygia. Such a region was naturally occupied from a very early period by wild and lawless races of mountaineers, who were either imperfectly reduced to subjection by the powers that successively established their dominion in Asia Minor. The Pisidians are not mentioned by Herodotus, either among the nations that were subdued by Croesus, or among those that furnished contingents to the army of Xerxes, and the first mention of them in history occurs in the Anabasis of Xenophon, when they furnished a pretext to the Persians for the invasion of Europe, and the sacking of the town, which they used to subvert his brother's throne, while he pretended only to put down the Pisidians who were continually harassing the neighbouring nations by their lawless forays (Anab. i. 1, 11; ii. 1, 4, &c.). They are afterwards mentioned frequently by later writers among the inland nations of Asia Minor, and assume a more prominent part in the history of Alexander the Great, to whose march through their country they opposed a determined resistance. In Strabo's time they had passed under the Roman dominion, though still governed by their own petty chiefs and retaining to a considerable extent their predatory habits (giving rise to such wars as that carried on by Quirinius, about A.D. 18). The boundaries of Pisidia, like those of most of the inland provinces or regions of Asia Minor, were not clearly defined, and appear to have fluctuated at different times. This was especially the case on the side of Lycia, where the upland
district of Milyas was sometimes included in Pisidia, at other times assigned to Lycia. Some writers, indeed, considered the Pisidians as the same people with the Milyans, while others regarded them as descendants of the Solymi, but Strabo speaks of the language of the Pisidians as distinct from that of the Solymi, as well as from that of the Lydians. The whole of Pisidia is an elevated region of table-lands or upland valleys in the midst of the ranges of Mt Taurus which descends abruptly on the side of Pamphylia. It contains several small lakes, and two of large size, Bey-Sheher Lake, the ancient Karalís, and the double lake now called the Egerdir Geul, of which the ancient name was Limnai. The latter is a fresh-water lake of about 30 m. in length, situated in the north of Pisidia on the frontier of Phrygia, at an elevation of 300 ft. Karalís is a larger body, also of fresh water, and at a distinctly higher level above the sea. The only rivers of importance are the Cestrus and the Eurymedon, both of which take their rise in the highest ranges of Mt Taurus, and flow down through deep and narrow valleys to the plain of Pamphylia, which they traverse on their way to the sea.

Notwithstanding its rugged and mountainous character, Pisidia contained in ancient times several considerable towns, the ruins of which have been brought to light by the researches of recent travellers (Arundell, Hamilton, Daniell, G. Hirschfeld, Radet, Sterrett, Lanckoronski, Ramsay, &c.), and show them to have attained under the Roman Empire to a degree of opulence and prosperity far beyond what we should have looked for in a country of predatory mountaineers. The most important of them are Ternessus, near the frontier of Lycia, a strong fortress in a position of great natural strength and commanding one of the principal passes into Pamphylia; Cremona, another mountain fortress, north of the preceding, impeding over the valley of the Cestrus; Sagalassus, a little farther north, a large town in a strong position, the ruins of which are among the most remarkable in Asia Minor; Selege, on the right bank of the Eurymedon, surrounded by rugged mountains, notwithstanding which it was in Strabo's time a large and opulent city; and Antioch, known for distinction's sake as Antioch of Pisidia, and celebrated for the visit of St Paul. This was situated in the extreme north-east of the district immediately on the frontier of Phrygia, between Lake Egerdir and the range of the Sultán Dagh and was reckoned in the Greek and earlier Roman period, e.g. by Strabo, as a city of Phrygia.

Besides these there were situated in the rugged mountain tract west of the Cestrus Cretopolis, Olbasa, Pogla, Isinda, Ettena and Comama. Pednelissus was in the upper valley of the Eurymedon above Selege. The only place in the district at the present day deserving to be called a town is Isbarta, the residence of a pasha; it stands at the northern foot of the main mass of Mt Taurus, looking over a wide and fertile plain which extends up to the northern chain of Taurus. North of this and immediately on the borders of Phrygia stood Apollonia, called also Mordaeum. Large estates in Pisidia and the adjoining parts of Phrygia belonged to the Roman emperors; and their administration has been investigated by Ramsay and others.

We have no clue to the ethnic character and relations of the Pisidians, except that we learn from Strabo that they were distinct from the neighbouring Solymi, who were probably a Semitic race, but we find mention in an early period in these mountain districts of various other tribes, as the Cabali, Milyans, &c., of which, as well as the neighbouring Isaurians and Lycaonians, the origin is wholly unknown, and the absence of monuments of their languages must remain so. A few short Pisidian inscriptions have been published by Ramsay in Revue des études anciennes (1895, pp. 355-362). No inscriptions in these languages are known (W. M. RA.).

PISO—PISSARRO

1. Lucius Calpurnius Piso Caesoninus, Roman statesman, was the father-in-law of Julius Caesar. In 58 B.C., when consul, he and his colleague Aulus Gabinius entered into a compact with P. Clodius, with the object of getting Cicero out of the way. Piso's reward was the province of Macedonia, which he administered from 57 to the beginning of 55, when he was recalled, perhaps in consequence of a pack made up against Cicero in the senate in his speech De fragmentis conturbatus. On his return Piso addressed the senate in his defence, and Cicero replied with the coarse and exaggerated invective known as In Pisonem. Piso issued a pamphlet by way of rejoinder, and there the matter dropped, Cicero being afraid to bring the father-in-law of Caesar to trial. At the outbreak of the civil war Piso offered his services as mediator, but when Caesar marched upon Rome he left the city by way of protest. He did not, however, definitely declare for Pompey, but remained neutral, without forfeiting the respect of Caesar. After the murder of the dictator he insisted on the provisions of his will being strictly carried out, and for a time opposed Antony. Subsequently, however, he became one of his supporters, and is mentioned as taking part in an embassy to Antony's camp at Mutina with the object of bringing about a reconciliation.

2. Lucius Calpurnius Piso, surnamed Frugi (the worthy), Roman statesman and historian, was tribune in 149 B.C. He is known chiefly for his lex Calpurnia repetundarum, which brought about the system of quaestiones perpetuae and a new phase of criminal procedure. As praetor (136) and consul (133) Piso fought against the slaves in Sicily. He energetically opposed Gaius Gracchus, especially in connexion with his corn law. See ANNALIST; C. Chichorius in Pauly-Wissowa's Realencyclopädie (1897), vol. iii., pt. 1; H. Peter, Historiorum romanorum reliquiae (1870), vol. i.; Teuffel-Schwabe, Hist. of Roman Lit. (Eng. trans.), i. 152-4. On the lex Calpurnia, Corpus inscr. latinarum, i., No. 692, with Mommsen's commentary; A. H. J. Greenidge, Hist. of Rome, 123-105 B.C. (1904).

3. Gnaeus Calpurnius Piso, Roman statesman, was consul in 7 B.C., and subsequently governor of Spain and proconsul of Africa. In A.D. 17 Tiberius appointed him governor of Syria, with secret instructions to thwart Germanicus, to whom the eastern provinces had been assigned. The indignation of the people at the death of Germanicus, and the suspicion that Piso had poisoned him, forced Tiberius to order an investigation. Piso committed suicide, though it was rumoured that Tiberius, fearing incriminating disclosures, had put him to death. See H. Schiller, Geschichte der römischen Kaiserzeit (1881), vol. i.

4. Gaud Calpurnius Piso, Roman statesman, orator and patron of literature in the 2nd century. He is known chiefly for his share in the conspiracy of A.D. 65 against Nero (q.v.). He was one of the most popular men in Rome, partly for his skill in poetry and music, partly for his love of luxury and generosity. It is probably the last-named which is referred to by Calpurnius Siculus under the name of Meliboeus, and he is the subject of the panegyric De laude Pisonis.

PISSARRO, Camille (1830-1903), French painter, was born at St Thomas in the Danish Antilles, of Jewish parents of Spanish extraction. He went to Paris at the age of twenty, and was on the staff of Cabanel, then occupied with the Barbizon masters. Though at first he devoted himself strenuously to the study of the kind which will ever be associated with the name of Millet, his interest was entirely absorbed by the landscape, and not by the figures. He subsequently fell under the spell of the rising impressionist movement and threw in his lot with Monet and his friends, who were at that time the butt of public ridicule. Like Monet, he made sunlight, and the effect of sunlight on the objects of nature, the chief subjects of his paintings, whether in the country or on the Paris boulevards. About 1885 he took up the laboriously scientific method of the pointillists, but after a few years of these experiments he returned to a broader and more attractive manner. Indeed, in the closing years of his life he1 succeeded so well in using the tints that he set down with admirable truth the peculiar atmosphere and colour and teeming life of the boulevards, streets and bridges of Paris and Rouen. He died in Paris in 1903.
PISTACHIO NUT—PISTOIA, SYNOD OF

Pissarro is represented in the Cijollebotte room at the Luxembourg, and in every collection of impressionists. A number of his finest works are in the collection of M. Durand-Ruel in Paris.

PISTACHIO NUT, the fruit of Pistacia vera (natural order Anacardiaceae), a small tree which is a native, of Syria and generally cultivated in the Mediterranean region. Although a delicious nut and much prized by the Greeks and other Eastern nations, it is not well known in Britain. It is not so large as a hazel nut, but is rather longer and much thinner, and the shell is covered with a somewhat wrinkled skin. The pistachio nut is the species named in Gen.xiii. 11 (Heb. 194. Ar. bhim) as forming part of the present which is most tasted by them from Canaan, and in Egypt it is still often placed along with sweetmeats and the like in presents of courtesy. The small nut of Pistacia Lentiscus, not larger than a cherry stone, also comes from Smyrna, Constantinople and Greece. P. Lentiscus is the mastic tree, a native of the Mediterranean region, forming a shaggy or stumpy tree with evergreen pinnately-compound leaves with a winged stalk. "Mastic" (from masticare, to chew) is an aromatic resinous exudation obtained by making incisions in the bark. It is chiefly produced in Asia Minor and is used by the Turks as a chewing gum. It is also used as a varnish for pictures. P. Terebinthus, the Cyprus turpentine tree, a native of southern Europe, Asia Minor and North Africa, yields turpentine from incisions in the trunk. A gall is produced on this tree, which is used in dyeing and tanning.

PISTIL, a term in botany for the female or seed-bearing organ of a flower (q.v.). The Lat. pistillum (diminutive from pinnare, pistum, to pound), a pestle, a club-headed instrument used for crushing or braying substances in a mortar (q.v.), was taken as the name for this organ from its similarity in shape, and thence adapted in Fr. pêtil about the middle of the 18th century. In its complete form a pistil consists of three parts—ovary, at the base, containing the body which becomes seeds, the style ( traveller's pillar), and stigmas (Gr. steugma, mark, stigwos, to brand), the part which in impregnation receives the pollen.

PISTOIA, or Pistoia (anc. Pistoriae), a town and episcopal see of Tuscany, Italy, in the province of Florence, from which it is 21 m. N.W. by rail. Pop. (1906), 27,127 (town); 68,131 (commune). It is situated on a slight eminence (210 ft.) near the Ombrone, one of the tributaries of the Arno. It is on the site of the Roman Pistoriae, which is hardly mentioned in ancient times, except for the destruction of Catiline's forces and the slaughter of their leader near it in 62 B.C., and as a station on the road between Florentia and Luca; and earlier still by Plautus, but only with jesting allusion to the similarity of the name to the word pistor (baker). Harleian's any inscriptions of the ancient town have been found; but excavations in 1900 (see G. Pellegrini in Notizie degli Scavi, 1904, p. 241) in the Piazza del Duomo led to the discovery of a large private house, which belonged to the end of the 1st century B.C. Some mosaic pavements were found, belonging perhaps to the 3rd century A.D., while the house appears to have fallen into ruin at the beginning of the 5th. Remains of four subsequent periods were discovered above it. It was found that the tradition that the cathedral occupied the site of a temple of Mars was groundless; for the house appears to have been built over it. Ammianus Marcellinus (5th century) mentions Pistoriae as a city of Tuscia Annonnaia. During the middle ages Pistoia was at times a dangerous enemy to Florence, and the scene of constant conflicts between the Guelphs and Ghibellines; it was there that the great party struggle took place which resulted in the creation of the Bianchi and Neri factions (see Dante, Inferno, xxiv. 121 to end). In 1302-06 it was besieged and eventually taken by the armies of Florence and Lucca, and in 1325 it became subject to Castruccio of Lucca. In 1350 it was obliged to surrender to Florence, and thenceforth shared its fate.

The city is still surrounded by walls, dating from shortly after the siege of 1302-06; while two inner lines of streets represent two earlier and inner lines of wall. In the early development of architecture and sculpture Pistoia played a very important part; these arts, as they existed in Tuscany before the time of Niccolò Pisano, can perhaps be better studied in Pistoia than anywhere else; nor is the city less rich in the later works produced by the school of sculptors founded by Niccola. In the 14th century Pistoia possessed a number of the most skilful artists in silver-work, a wonderful specimen of whose powers exists now in the cathedral—the great silver altar and frontal of St James, originally made for the high altar, but now placed in a chapel on the south side. The cathedral is partly of the 12th century, with a porch and façade with small arcades—in black and white marble, as is the case with several other churches of Pistoia—but was remodelled in the 15th century, and modernized inside and out. The silver altar it contains many fine works of sculpture; the chief are the monument of Cino da Pistoia, lawyer and poet, Dante's contemporary (1337), by Cellino di Nese, surrounded by his scholars, and Verrocchio's finest work in marble, the monument to Cardinal Forteguerra (1474), with a large figure of Christ, surrounded by angels, in high relief. The clay model for it is in the South Kensington Museum. The monument has unfortunately been altered. The octagonal baptistry is by Cellino di Nese (1339). Among the earlier churches the principal is Sant' Andrea, enriched with sculpture, and probably designed by Gruamos and his brother Adoesdatus in 1158. In the nave is Giovanni Pisano's magnificent pulpit, imitated from his father's pulpit at Pisa. Other churches of almost equal interest are S. Giovanni Fuorcivitas (so called because it was outside the line of the earliest, pentagonal, eccentie of the middle ages), with one of the long sides elaborately adorned with small arcades in the Pisan style, in black and white marble, also with sculpture by Gruamos (1162) on the façade. Within is a beautiful group of the Visitatio by Luca della Robbia. There is also a fine pulpit by Fra Guglielmo dell' Agnello of Pisa (1270). S. Bartolomeo in Panton is an interesting basilica of 1107. San Francisco al Prato is a fine church of the end of the 13th century with interesting frescoes of the school of Giotto. San Domenico, a noble church, begun in 1204, contains the beautiful tomb of Filippo Lazari by Bernardo and Antonio Rossellino (1466-1468). In addition to its fine churches, Pistoia contains many noble palaces and public buildings. The Palazzo del Commune and the Palazzo Pretorio, once the residence of the podestà, are both fine specimens of 14th-century domestic architecture, in good preservation. The quadrangle of the latter contains many well-painted armorial bearings of the podestàs. The Osbedale del Ceppo, built originally in the 13th century, but remodelled in the 15th, is remarkable for the reliefs in enameled and coloured terra-cotta with which its exterior is richly decorated. Besides various warlike figures there is a picture of the sieges by the town, with the citizens being dragged along the front, over its open arcade. The reliefs consist of a series of groups representing the Seven Works of Mercy and other figures; these were executed by Giovanni Della Robbia between 1514 and 1525, and, though not equal to the best work of Luca and Andrea, are yet very fine in conception and modelling, and extremely rich in their general decorative effect. The last on the right was added in 1585 by Paladini.

The industries of Pistoia include iron and steel works, especially manufactures of glass, silk, macaroni, woollens, olive oil, ropes, paper, vehicles and fire-arms. The word "pistol" is derived (apparently through pistolese, a dagger—dagger and pistol being both small arms) from Pistòia, where that weapon was largely manufactured in the middle ages.

PISTOIA, SYNOD OF, a diocesan synod held in 1786 under the presidency of Scipione de' Ricci (1741-1810), bishop of Pistoia, and the patronage of Leopold, grand-duke of Tuscany, with a view to preparing the ground for a national council and a reform of the Tuscan Church. On the 26th of January the grand-duke issued a circular letter to the Tuscan bishops suggesting certain reforms, especially in the matter of the restoration of the authority of diocesan synods, the purging of the missals and breviaries of legends, the assertion of episcopal as against papal authority, the curtailing of the privileges of the monastic orders, and the better education of the clergy.
PISTOL

In spite of the hostile attitude of the great majority of the bishops, Bishop de' Ricci issued on the 31st of July a summons to a diocesan synod, which was solemnly opened on the 18th of September. It was attended by 233 beneficed secular and 13 regular priests, and decided with practical unanimity on a series of decrees which, had it been possible to carry them into effect, would have involved a drastic reform of the Church on the lines advocated by " Ebranatus " (see EBRANISM).

The first decree (Decretum de fide et ecclesia) declared that the Catholic Church has no right to introduce new dogmas, but only to preserve in its original purity the faith once delivered by Christ to His apostles, and is infallible only so far as it conforms to Holy Scripture and true tradition; the Church, moreover, is a purely spiritual body and has no authority in things secular. Other decrees denounced the abuse of indulgences, of festivals of saints, and of processions and suggested reforms; others again enjoined the closing of shops on Sunday during divine service, the issue of service-books with parallel translations in the vernacular, and recommended the abolition of all monastic orders except that of St Benedict, the rules of which were to be brought into harmony with modern ideas; nuns were to be forbidden to take the vows before the age of 40. The last decree proposed the convocation of a national council.

These decrees were issued together with a pastoral letter of Bishop de' Ricci, and were warmly approved by the grand-duke, at whose instance a national synod of the Tuscan bishops met at Florence on the 23rd of April 1787. The temper of this assembly was, however, wholly different. The bishops refused to allow a voice to any not of their own order, and in the end the decrees of Pistoia were supported by a majority of only three. They were finally condemned at Rome by the bull Auctorem fidei of the 28th of August 1794. De' Ricci, deprived of the personal support of the grand-duke (now the emperor Leopold I.), exposed to pressure from Rome, and threatened with mob violence as a suspected destroyer of holy relics, resigned his see in 1791, and lived in Florence as a private gentleman until his death in 1810. In May 1805, on the return of Pope Pius VII. from Paris, he had signed an act of submission to the papal decision of 1794.

De' Ricci's own memoirs, Memorie di Scipione de' Ricci, sessono di Prato e Pistoia, edited by Antonio Galli, were published at Florence in 2 vols. in 1805. Besides this his letters to Antonio Marini were published by Cesare Guasti at Prato in 1857; these were promptly put on the Index. See also De Potter, Vie de Scipione de' Ricci (3 vols., Brussels, 1825), based on a MS. life and a MS. account of the synod placed on the Index in 1823. There are many documents in Zobi, Storia civile della Toscana, vols. ii. and iii. (Florence, 1856). The acts of the synod of Pistoia were published in Italian and Latin at Pavia in 1788.

PISTOL, a small fire-arm designed for quick work and personal protection at close quarters, and for use in one hand. It was originally made as a single and also double-barrelled smooth bore muzzle-loader, involving no departure in principle from the ordinary fire-arms of the day. With the introduction of revolvers and breech-loading pistols and the application of " rifling " to musket barrels, came also, in the early half of the 19th century, the rifling of pistol-barrels.

History.—Pistols are understood to have been made for the first time at Pistoia in Italy, whence they receive their name. Caminello Vitelli, who flourished in 1540, is the accredited inventor. The first pistols, in the 16th century, had short single barrels and heavy butts, nearly at right angles to the barrel. Shortly afterwards the pattern changed, the butts being lengthened out almost in a line with the barrels. These early pistols were usually fitted with the wheel-lock (see Gun). Short, heavy pistols, called " daggs," were in common use about the middle of the 17th century, with butts of ivory, bone, hard wood or metal. A chiselled Italian dagg of 1650, for example, had a slightly bell-nosed barrel of about 8 in. in length and 14 bore. The German wheel-lock military pistols used by the Reiters, and those made for nobles and gentlemen, were profusely and beautifully ornamented. Pistols with metal butts were common in the 16th and 17th centuries, many beautiful specimens of which, silver-mounted, were made in Edinburgh and used by Highlanders. Duelling, when in vogue, caused the production of specially accurate and well-made single-barrelled pistols, reliable at twenty paces. The pattern of this pistol seldom varied, its accuracy at short range equalling that of many modern ones, the principle of a heavy bullet and light charge of powder being employed. The first double-barrelled pistols were very bulky weapons made with the barrels laid alongside one another, necessitating two locks and two hammers. There was also the " over and under " pistol, one barrel being laid over the other. This was a more portable weapon, only requiring one lock and hammer, the second barrel being turned round by hand, after the first had been fired, or, as an alternative, the flash-hole being adjusted to the second barrel by a key. These pistols were first made with flint and steel locks and subsequently for percussion caps. Double " over and under " pistols were also made with a trigger mechanism that served to discharge both barrels in turn.

Revolvers.—A revolver is a single-barrelled pistol with a revolving breech containing several chambers for the cartridges, thus enabling successive shots to be rapidly fired from the same weapon without reloading. The ordinary pistol is now, and has been for many years past, superseded by the revolver. The first revolver, fired with the percussion cap, was made with the whole of the barrels, six, seven or eight, revolving in one piece, and was known as the " pepper-box." It was " single action," i.e. the hammer was raised and the barrels revolved by the pull of the trigger. This weapon was cumbersome and no accurate aim could be taken with it owing chiefly to the strength and resistance of the main-spring and the consequent strong pull required on the trigger. The principle of a revolving breech to one barrel, which superseded the " pepper-box," is an old one in the history of fire-arms, dating from the 16th century. At

ordinary fire-arms of the day. With the introduction of revolvers and breech-loading pistols and the application of " rifling " to musket barrels, came also, in the early half of the 19th century, the rifling of pistol-barrels.

1 For the use of long heavy pistols by cavalry in the 16th and 17th centuries, see Army: History; and Cavalry.
Tower of London, but this was subsequently improved by introducing geared mechanism, by which the pull of the trigger or the cocking of the hammer, or both, do the work. There exists a pistol of the time of Charles I. which is rotated automatically as the hammer is raised.

In 1814 a self-acting revolver mechanism of a crude pattern was produced in England. Four years later Collier used a separate spring to rotate the chamber. In 1835, an American, Samuel Colt, produced and patented the first practical revolving pistol, the idea of which was obtained by him, it is stated, from an ancient "revolving" weapon in the Tower of London. The chambers of the first Colt revolver were loaded with powder and bullets from the muzzle end, and each chamber had a nipple that required to be capped. It was the invention of the copper cap that made the Colt revolver possible. Under the old priming system with exposed powder in a pan the difficulty of separate and effective ignition with the revolving cylinder was almost insuperable.

The first American revolver makers caused the cocking of the hammer to revolve the cylinder, while the English makers effected this by the pull of the trigger. In 1855, Adams of London, and also Tranter of Birmingham, brought out the double-action revolver, in which the revolution of the cylinder could be effected by both these methods. When the revolver is cocked and fired by pressing the trigger, greater rapidity of fire is obtained than when the hammer is cocked with the thumb, but accuracy is impaired, as the trigger requires a long pull and considerable force in order to compress the mainspring and revolve the cylinder. The double action revolver was, therefore, a great advance on the single action, enabling the first and also following shots, if desired, to be accurately fired by a moderate pressure of the trigger after the hammer had been cocked by the thumb; or, alternatively, the revolver could be rapidly fired, if necessary, by the trigger action alone. Many revolvers on the Colt principle were in use during the Crimean War and the Indian Mutiny, and proved of valuable service to British officers.

As rim-fire, pin-fire and central-fire cartridges were successively introduced, breech-loading revolvers were constructed to use them. Messrs Smith & Wesson, of Springfield, U.S.A., produced the first metal cartridges for revolvers. Pin-fire cartridges, paper and metallic, were used on the continent of Europe for Lefaucheux and other revolvers, and these and rim-fire cartridges are still used for revolvers of small calibre. But since the central-fire cartridge has proved its superiority for guns, its principle has been generally applied to pistol cartridges, at first to the larger bores.

The alteration of the muzzle-loading to the breech-loading chamber in the revolver involved no decided change of type. The original Colt, as a breech-loader, remained practically the same weapon as before, with a changed chamber. A hinged flap uncovered the breech-chamber on the right, and as each chamber reached that point the empty cartridge case was ejected by means of an ejecting-rod carried in a tube attached to the under side of the barrel and kept in place by a spiral spring, and the chamber reloaded. The next improvement was greater ease and rapidity of extraction, obtained first by Thomas's invention of making the barrel and chamber slide forward on the frame of the pistol. The extractor, being fast to the pivot, retained the cartridges until the chamber was pushed clear of them. Then the chamber was made to swing on one side, as in the Colt pistol illustrated, enabling all the cartridges to be simultaneously extracted. Finally, self-extracting revolvers with jointed frames were introduced, in which the dropping of the barrel forces out the extractor as in an ordinary double gun, the extractor acting simultaneously in all the chambers of
PISTOL

the pistol. A spring returns the extractor to its place when the empty cartridge cases have been ejected, and brings the barrel to an angle of about 45°, for convenience in loading. The soundness and rigidity of the weapon depend upon the efficiency of the connexion between the barrels and the standing breech, and a top snap bolt has proved the strongest and handiest with the pistol, as with the shot-gun.

This type of revolver originated with Messrs Smith & Wesson and other makers, have greatly improved upon the original model. Between the American pattern and the English, as made by Messrs F. Webley & Son, the chief difference is that in the Smith & Wesson the holding-down bolt or catch is upon the barrel, and it engages with the top of the standing breech; whereas in the Webley the bolt is upon the standing breech and grips the extremity of the hinged barrel. Neither mechanism is as strong as could be wished if heavy charges of smokeless nitro-compounds are to be used. This hinged type of revolver is most convenient for use on horseback, as the pistol can be opened, the cartridges extracted and the weapon reloaded with one hand.

The Colt's Double-action Revolver, calibre .38, model 1896, used in the United States army, consists (figs. 7 and 8) of the barrel (B), the cylinder (C) with six chambers, the frame (F), and the firing mechanism, all of steel. The muzzle velocity, with a charge of 16 grains of black powder and a bullet of 150 grains of lead, is about 708 ft. per second, giving at 25 yards a penetration of about 5 in. in pine.

The lock mechanism consists of the hammer (h), with its stirrup (r), stirrup pin (p), strut (i), strut pin (o), strut spring (g); the trigger (t), the rebound lever (l); the hand (a) with the rear end of the cylinder bolt (b), with its spring (s); the locking lever (e); the main spring (m), and rebound lever spring (n). The hammer (h), trigger (t), and rebound lever (l) are pivoted on their respective pins, which are fastened in the left side of the frame. The lower end of the rebound lever spring (n) is secured to the frame and the free end bears against the rear end of the rebound lever so that the latter, when the trigger is released, cams the hammer back to its safety position, and forces the trigger forward. The trigger mechanism causes its upper edge to engage the strut, and thereby raises the hammer until nearly in the full-cock position, when the strut will escape from the trigger, and the hammer, under the action of the mainspring, will fall and strike the cartridge. A projection on the upper part of the trigger, working in a slot in the frame, prevents the cylinder from making more than one-sixth of a revolution at a time by entering one of the grooves near the rear end of the surface of the cylinder. When the cylinder is swung out of the frame, the parts are arranged to prevent the cocking of the hammer. The cylinder bolt is pivoted on the trigger pin, and its spring, bearing on the rebound lever arm, causes the nose of the bolt to project through a slot in the frame ready to enter one of the rectangular cuts in the cylinder surface. During the first movement of the trigger in cocking the revolver, the nose of the bolt is withdrawn, allowing free rotation of the cylinder. The object of the bolt is to prevent rotation of the cylinder in transportation. The hand is attached by its pivot to the trigger, and, as the latter swings on its pin when the hammer is being cocked, the hand is raised and revolves the cylinder, and also serves to lock the cylinder in position at the time of firing. An abutment on the side plate supports the hand spring in rear. The spring ensures the engagement of the hand with the ratchet (y). The revolver is cocked by hand by withdrawing the hammer by the pressure of the thumb until its full-cock notch engages in the rear sharp corner of the trigger. Pulling the trigger then releases the hammer, allowing its firing pin (f) to move forward and strike the cartridge.

The locking lever is pivoted by its screw in a recess in the left side of the frame, and so connected with the latch that it locks the hammer and trigger when the latch is pushed to the rear for opening the cylinder, and does not unlock them until the cylinder is positively closed and is locked by the latch. The cylinder revolves and is supported on a central arbour of the crane (E). The crane fits in a recess in the frame below the barrel and turns on its pivot arm (A). The ejector rod with its spring passes through the centre of the cylinder arbour and is terminated in rear by the ejector with a ratchet (y). Pushing against the front end of the ejector rod will empty the chambers, the cylinder being swung out for loading. The thumb-piece of the latch (j) slides to the rear in the left side of the frame, unlocking the cylinder for opening, but upon closing the cylinder, the body of the latch firmly enters a recess in the ejector, locking the cylinder in position for firing.

One great disadvantage of revolvers is the escape of gas at the opening between the breech of the barrel and the cylinder.

![FIG. 5.—Percussion-lock pistol (Royal United Service Institution).](image1)

This escape corrodes the surrounding parts and also materially diminishes the pressure in the barrel and the consequent velocity of the bullet. In the Nagant revolver, adopted by Russia, this disadvantage has been overcome by employing a long cartridge case which extends beyond the nose of the bullet and bridges the gap between barrel and cylinder as the cylinder is moved forward. A "mitrailleuse" pistol has also been constructed by the Braendlin Armoury Co., Ltd., on the "pepper-box" principle, with fixed barrels, either four or six, arranged in pairs, and a special striking mechanism, in which there is no revolving chamber and no escape of gas at the breech.

It gives stronger shooting than a revolver, but is more cumbersome, and has the serious defect that the shock of the discharge of one barrel sometimes prematurely fires a second barrel.

In 1865, Sharp, an American, patented an invention to remedy the escape of gas, in which the four barrels of the pistol were drilled the full length out of one block of metal. The barrels were slid forward by an under lever to load, and the firing was effected by a revolving head to the hammer, set by the action of cocking the pistol.

About 1878 Messrs Lancaster introduced both two- and four-barrelled hammerless pistols, in which an internal hammer was worked by the pull of the trigger. In all the three weapons
PISTOL

above mentioned, extraction and reloading were slow processes, which made them unsuited for use on horseback.

Hammerless Revolver.—The Smith & Wesson pocket pistol is one of the safest weapons of the size made. There is no hammer or equivalent protuberance to catch as the pistol is drawn from the pocket; or to entangle if the weapon falls. An automatic safety bolt, whose length lies half across the palm of the hand, and ensures certainty of freedom at the time of shooting, blocks the action until the pistol is firmly gripped for use.

Breech-loading Pistols.—Although the revolver has for many years practically superseded the pistol, some breech-loading varieties of pistols are still made—the small pocket pistol, for example, and occasionally the heavy double-barrelled horse pistol. At one time these latter were much used, of .57 bore, as well as the well-known short, large-bore pistol known as the Derringer, usually of .41 calibre. The double horse pistol is now usually made for a 20-bore cartridge and spherical bullet, and weighs about 3½ lb. It is a clumsy, but effective weapon, and fires a charge of 1¼ drams of powder without unpleasant recoil. The duelling pistol, as made by Gartinne Renette of Paris, is capable of wonderfully accurate shooting, firing a 9 millimetre spherical bullet and about 12 grs. of powder. This weapon is far superior in accuracy to a revolver. Single-barrelled pistols, chambered for the .22 or 297/250 calibre cartridges, with a barrel of from 6 to 10 in. in length, are also made, and when fitted with a detachable metal stock form excellent little weapons for target practice.

Automatic Revolver.—The Webley-Fosbery automatic revolver is a weapon of a distinctly new design, in which for the first time the principle of utilizing the recoil of each shot to operate the mechanism is applied to the revolver. In appearance the weapon is very similar to the Webley service model. The simple pressure of the forefinger on the trigger, the pressure being released between each shot, is all that is required to fire the six successive shots of the revolver. It is supplied with a safety bolt worked by a thumb-piece, and Messrs Webley have introduced a clip loader which enables the six chambers to be reloaded at the same time. This weapon has met with considerable success, and is made in two calibres, the .455, 6 shot, 2 lb 3½ oz. in weight; and the .38 model, 8 shot, 2 lb 3 oz. in weight.

Automatic Pistols.—These weapons are the latest and most advanced type of pistol, and it is anticipated by experts that they will ultimately supersede the revolver. They are made with one barrel and a magazine, on the principle of the repeating rifle, thus doing away with the escape of gas that takes place in revolvers between the chamber and the barrel.

Automatic pistols are so constructed that the force of the recoil is utilized to open the breech, extract the empty case, cock the pistol, reload the chamber with the top cartridge from the magazine, and close the breech, leaving the pistol ready to fire on again pressing the trigger.

The Mauser “self-loading” pistol (fig. 9) is one of the easiest of the successful automatic weapons. It is usually .300 calibre, 10 shot, with a metal clip loader from which the cartridges are “stripped” into the magazine, weight 2¾ lb, length of barrel 5½ in.; bullet 85 grains, initial velocity about 1394 ft.s.

The barrel (1) and bolt (2) are in one piece; the latter contains the bolt (3). The barrel and bolt slide on the frame (4); the 10-shot magazine (5) and the stock are in one piece with the frame, and the lock frame (6) and lock-work are contained in the rear part of it. The bolt (3), which is square, slides in the body, and is kept pressed up to the chamber by the bolt spring (8); the rear end of this bolt spring bears against the block (9). The striker and extractor are contained in the bolt. The bolt is locked by the bolt-lock (10). This is slotted through the centre and fits on to the projection (11) under the body; it is supported at the moment of firing by a projection on the lock frame (12); the top of the bolt-lock has two teeth (13), which in the loaded and cocked position fit into two recesses in the bottom of its front end, and in front of the body attachment (11) has another tooth (14) which bears on the rocker (15). This rocker is pivoted at its bottom corner. The main-spring (16) bears in front against the rocker, and in rear against the hammer mechanism. The action of the mechanism is
PISTOL

as follows: on pressing the trigger, the trigger nose lifts the lever (18) which is attached to the sear (19), the lifting of the sear allows the main-spring to act backwards on the hammer, which impinges on the striker and ignites the cartridge. At this moment the bolt is locked by the upper two teeth (13) of the bolt-lock, which is itself held up by the lock frame projection (13). But, the barrel body and bolt recoiling together 13 of an in., the rear end of the bolt-lock is no longer supported, the rocker (15) acting on the forward tooth (14) pulls down the bolt-lock and its upper teeth, the nose of the bolt-lock falling into the recess just behind the projection (12). Thus the barrel and body come to a standstill and the remaining recoil energy is used in driving back the bolt (now free) and extracting the cartridge case. When this energy is used up the bolt spring (8) reasserts itself, drives the bolt forward and pushes another cartridge into the chamber as in the magazine, and the main-spring, acting on the rocker, pulls up the bolt-lock again and engages the teeth (13) in the bolt, locking it for

the next shot. The releasing of the trigger brings the sear (19) to its former position, cocking the pistol.

This pistol is usually supplied with a wooden holster which can also be attached to the grip of the pistol and so form shoulder-stock for long-range shooting. It is sighted from 50 to 1000 yards.

The Colt Automatic Pistol, calibre .38 (fig. 10) consists of four main parts, namely the frame (F), the barrel (B), and the magazine (M). The frame forms, at its rear and lower part, the handle (A), which is hollow, and contains the seat for the magazine. After being charged with seven cartridges, the magazine is seated from below and held in place by the magazine catch (c) which slightly projects from the bottom of the handle. This projection serves to release the magazine from the catch, when it can be readily drawn from the handle for re-charging. In front of the handle is the trigger guard (g), in which the trigger (h) is found, and in the rear and above the Grip the firing mechanism is placed in the part of the frame called the receiver (K). The firing mechanism consists of the hammer (b), the sear (c), the trigger (h), a safety device, this recovers the spring (5) and sear spring (6), lower part of the latter serving to operate the magazine catch. The top of the receiver extends forward from the handle, and to it the barrel is attached by two short links, (f) near the front end of the barrel, and the other at its rear end; these links are pivoted to the receiver and also to the barrel, and allow the barrel to swing rearwards thereon. As both links are of the same length, the rearward movement of the barrel in swinging on these links carries the barrel slightly downwards, but keeps its longitudinal axis in parallel positions during all its movements. Below the handle the receiver forms a tubular seat for the retractor spring (s), which in front is closed by a plug (u) fastened in the receiver by the lower pivot-pin (i) of the front barrel-link. The upper surface of the receiver and two longitudinal grooves on its sides form the seat for the slide, which is guided therein in its rearward and forward movements. The rear part of the slide forms the locking block (K), and the front part forms a partly tubular cover (1) which encloses the barrel. In the forward part of the receiver is a transverse mortice extending through the retractor spring seat, and behind this mortice a transverse mortice is formed in the frame, consisting of a spiral spring (r) at the rear end of which rests against the receiver, and the front end of which carries a piston (p). The rear face of the key (m) has a slight recess, and when the key is in its place the front end of the retractor spring seat is brought into contact with the rear end of the transverse mortice, thereby pressing the spring (r). The tension of the retractor spring is exerted to force the key and the slide to their forward position. Upon the barrel are provided three transverse ribs (b), and in the interior of the slide are three corresponding recesses; these serve to lock the barrel in the slide, and the slide firmly together when in their forward position. Between the locking recesses and the bolt, the slide has an opening on its right side for the ejection of the cartridge cases (j), and the bolt is provided with an extractor, a firing pin (f), a firing pin retraction

spring (g), and a firing pin lock (y). This latter is pivoted at the rear end in the top of the slide, and when depressed, locks the firing pin in its retracted position, thus preventing its point from coming in contact with the cartridge primer. When raised, the firing pin lock releases the firing pin, and in this position also serves as the rear sight, being provided on the top with a sighting notch.

The operation of the pistol is as follows: When a charged magazine (M) is inserted, the slide (S) is drawn once to the rear by hand, thereby cocking the hammer (h). In this position of the slide, the carrier (c) and carrier spring in the magazine raise the topmost cartridge into the chamber so as to bring it into the path of the bolt (K). On releasing the slide, it, with the bolt, is carried forward by the retractor spring (r), and during this movement the bolt forces the topmost cartridge into the barrel (B). As the slide approaches its forward position the front of the bolt encounters the rear end of the barrel and forces the latter to its forward position. During this forward movement the barrel swings forward and upward on the links (a, s), and thus the locking ribs (b) on the barrel are carried into the corresponding recesses in the slide. The barrel and slide are thereby interlocked, and the pistol ready for firing.

A slight pull on the trigger (1) now serves to move the sear (c) to release the hammer (h) and fire. The force of the powder gases driving the bolt from the barrel is exerted rearwards against the bolt, and, overcoming the inertia of the slide and the tension of the retractor spring, causes the slide and the barrel to recoil together. After moving rearwards together, for a distance, enough to ensure the bullet having passed from the barrel, the downward swinging movement of the bolt releases the latter from the slide and stops the barrel in its rearmost position. The rearward movement of the slide is continued by the forward movement, thereby again cocking the hammer and compressing the retractor spring, until, as the slide arrives at its rearmost position, the empty shell is ejected from the slide of the pistol and another cartridge raised in front of the bolt. During this rearward movement of the slide, caused by the retractor spring, the cartridge is driven into the barrel, and the slide and barrel are interlocked, thus making the pistol ready for another shot. These operations may be continued so long as there are cartridges in the magazine, each discharge requiring only the slight pull on the trigger. The pistol is provided with a safety device (d) which makes it impossible to release the hammer unless the slide and barrel are in their first forward position and interlocked.

In the Borchardt-Leuger pistol (fig. 11) the bolt is solidly supported

at the moment of firing by a toggle joint. The barrel (1 A) and body (1 B) slide in the frame (1 C), the bolt (2) slides in the body and is held up to the breech by the toggle joint 3 and 4 and the pins 5 and 7, which secure the links of the toggle to the body. The centre of pin (6) is below those of the other pins so that the joint cannot bend at the moment of firing. On the rear link (4) there is a swivel (9) which is connected to the recoil spring (10) in the grip. This pistol is fired by a spring striker, like a rifle, instead of by a hammer.

The striker is within the bolt; it is cocked in the rear position by a claw on the end of the front link (3 A) and held thus when ready to fire by the nose of the trigger sear, these engaging with a projection (8 A) on the side of the striker. The magazine (6 shot) is in the grip. The action is as follows: the first cartridge is loaded from the magazine by pulling back the toggle joint. As soon as the toggle joint is released the recoil spring acts and forces the bolt home, with the cartridge in front of it. On pressing the trigger the barrel and body recoil a little. Then the toggle joint comes

FIG. 10.—Colt automatic pistol.

FIG. 11.—Borchardt-Leuger (Text-book of Small Arms, by permission of the Controller of H. M. Stationery Office).
against curved rumps on the sides of the non-recoiling frame and is forced up, so that thereafter the bolt alone recoils (the ejector is similar in principle to that of a rifle). The recoil spring then acts as before on reloading.

Other varieties of the automatic pistol are the "Mannlicher," the "Mars," the "Bergmann" and the "Webley." The last, being simple in construction, small and light, weight 18 oz. and length over all only 6½ in., may be classed as a pocket pistol.

**Qualities of Automatic Pistols.**—In reference to the general qualities of automatic pistols, while these weapons have the advantage over revolvers of longer range and greater rapidity of fire and recharging, on the other hand they are necessarily more complicated in their mechanism, which has to do the work of cocking, winding, and cocking that in the revolver is done by hand. A stoppage may occur through cartridge missing, fire, or continuous uncontrolled fire may take place through the trigger spring breaking until the magazine is exhausted. Their action is also to some extent uncertain, as it depends on the recoil of the discharge, which may be affected by variables in the cartridge; also the effective automatic working of the moving parts depends upon their cleanliness and lubrication. As automatic pistols, like revolvers, are intended for personal defence at short range and for sudden use in emergencies, simplicity of mechanism and certainty of action are in their case of paramount importance. There is usually no time to rectify a check or cocking, and if after this the mechanism is out of gear, it can not be moved. Thus, before the revolver is altogether superseded by the automatic pistol, it is most desirable that the latter should be as certain in its action under service conditions as the former. Some automatic pistols, as already stated, are sighted up to 1000 yards, and provided with attachable butts. The practical value of these improvements is open to question, as the sighting of a pistol differs materially when used with and without a butt, and under no circumstances can the accuracy of shooting of a pistol, even with a butt, equal that of a carbine.

The tendency in automatic pistols has been to reduce the bore to .3 in., and increase the muzzle velocity, on the lines of modern small arms. These, again, would appear to be advantages of minor importance in a weapon intended for use at short range in the field, where a heavy bullet of fairly large diameter, with a moderate muzzle velocity, has a more immediate and paralyzing effect, and is therefore, from this point of view, and particularly in savage warfare, preferable to a small projectile of high muzzle velocity.

**PISTOLE**—The French name given to a Spanish gold coin in use from 1537; it was a double escudo, the gold unit, and was worth 16s. 11d. sterling. The name was also given to the *lois d'or* of Louis XIII. of France, and to other European gold coins of about the value of the Spanish coin.

**PISTON**—(through Fr. from It., *pistone* or *pistone*, a great pestle, from Late Lat. *pistare*, to push) is a perpendicular form of classical Latin. *Pistore* in the steam engine, a disk or partition placed inside the cylinder, from end to end of which it moves alternately under the pressure of the steam. By means of the "piston-rod" attached to it this forward and backward motion is communicated to the machinery which the engine is employed to drive, and is in most cases converted into rotary motion by a "connecting-rod," one end of which is jointed to the "cross-head" carried at the end of the piston-rod, while the other turns the crank on the crank-shaft. The piston in gas, oil and air engines has a similar function, but in a pump, instead of imparting motion, it has motion imparted to it by some prime-mover. In every case the piston must fit the cylinder so accurately that as little as possible of the working fluid, whether it be steam, gas or water, can escape past it, packing of various forms being commonly placed round its periphery in order to secure this fit. In music, the valves which in certain wind instruments, such as the cornet, enable the player to increase the length of the air-column and thus lower the note produced, are known as pistons. (See VALVES.)

**PIT**—(O. E. *pyt*, cognate with Du. *pul*, Ger. *Pflze*, &c., all ultimately adaptations of Lat. *pulvis*, well, formed from root *pu*- to cleanse, whence *parus*, clean, pure), a term of wide application for a hole, cavity or excavation in the earth or other surface; thus it is applied to the excavations made in the ground for the purpose of extracting minerals, e.g. chalk, gravel or sand, or for carrying on some industry, e.g. tan-pit, saw-pit or to the group of shafts which form a coal-mine. Roots and other vegetables can be stored in the winter in a pit, and the term is thus transferred to a heap of such vegetables covered with earth or straw. The word is also used of any hollow or depression in a surface, as in the body, the arm-pit, the pit of the stomach, or on the skin, as the scars left by small-pox or chicken-pox. As applied to a portion of a building or construction, the word first appears for an enclosure, often sunk in the ground, in which cock-fighting was carried on, a "cock-pit." It would seem a transference of this usage that gave the common name to that now called "the Chinese trade-oolong" and "the Chinese chaffer," the French *pasterre.* In the United States a special usage is that of its application to that part of the floor space in an exchange where a particular branch of business is transacted; thus in the Chicago Board of Trade, transactions in the grain trade are carried on in what is known as the "Wheat Pit."

In Scottish legal history there was a baronial privilege which in Latin is termed *fures et fossa,* "fork (i.e. gallows) and pit;" here the term has usually been taken to refer to the drowning-pit, in which women criminals were put to death; others take it to refer to an ordeal pit. There is a parallel phrase in M. Dutch, *putte ends goelhen*; here *putte* is the pit in which women were buried alive as a punishment.

**PITCAIRN,** an island in the mid-eastern Pacific Ocean, in 25° 3' S., 136° 6' W., belonging to Great Britain. It lies south of the Paumotu archipelago, 1000 m. from the nearest member of this group. Unlike the majority of the islands in this region, it is without coral reefs, but rises abruptly with steep and rugged cliffs of dark basaltic lava. The extreme elevation is over 2000 ft., and the area 2 sq. m. The soil in the valleys is volcanic and fertile, but the gradual utilization of natural timber increases the liability to drought, as there are no streams. The climate is variable and rainy. Stone axes, remains of carved stone pillars similar to those of Easter Island, and skeletons with a pearl-mussel beneath the head have been found in the islands, though it was uninhabited when discovered by Philip Carteret in 1767. Pitcairn was the name of the midshipman who first observed it.

The island was destined to become the scene of a curious social experiment. On the 28th of April 1789 a mutiny broke out on board the "Bounty," then employed by the British government in conveying young bread-fruit trees from Tahiti to the West Indies. The commander, Lieutenant William Bligh, was set adrift in the launch with part of the crew, but managed to make his way to Timor in the Malay Archipelago. The twenty-five mutineers at first all returned to Tahiti. Some were killed and six of the remainder joined up with the British in England, three being executed in 1792. Meanwhile in 1790 a party consisting of Fletcher Christian, the leader of the mutiny, eight Englishmen, six Polynesian men and twelve Polynesian women had taken possession of Pitcairn Island and burned the "Bounty." Treachery and debauchery filled the first years of the annals of the beautiful island. By 1800 all the men were dead except Alexander Smith, afterwards known as John Adams, who rose to a sense of his responsibility and successfully trained up the youthful generation left in his charge. An American vessel, the "Topaze," discovered the strange colony in 1808; again, by accident, it was visited by the "Brion," Captain Sir F. Staines, and the "Tagus," Captain Pipo, in 1817; and by the exploring ship "Blossom" in 1825. On the death of John Adams on the 29th of March 1829 George Hunn Nobbs, who had settled at Pitcairn in 1828, was appointed pastor and chief magistrate. Through fear of drought the islanders removed to Tahiti in 1830, but disapproved of both the climate and the morals of this island, and returned to Pitcairn in 1831. Shortly after this an adventurer named Joshua Hill appeared, and, claiming government authority, tyrannized over the islanders till his removal by a British man-of-war in 1838. In 1856 the whole of the islanders—60 married persons and 134 young men, women and children—were landed on
Norfolk Island, but in 1858 two families chose to return, and their example was afterwards followed by a few others. Visited in 1873 and 1878 the colony was found in excellent order, but by the end of the century it was stated that intermarriage was bringing a deterioration of intellect, morals and energy, and that the islanders would probably drift into improcerty. Latter accounts make it appear that this was an exaggeration, although the standard of morality was unquestionably low on the whole.

In religion the islanders are Seventh Day Adventists. "They have adopted an extraordinary patois, derived from the language of the Chaldeans, who accost the muuniters of the "Bounty" to Pitcairn Island, although most of the adults can speak the English language fairly well" (R. T. Simons, Report, 1905). The island is a British colony by settlement, and is within the jurisdiction of the High Commissioner for the Western Pacific (since 1898). There is a governing body chosen from among the islanders, the constitution of which has been altered more than once owing to internal jealousies, &c. The island produces sweet potatoes, yams, melons, bananas and other fruits, arrowroot and coffee. Goats and chickens run wild. Some trade is carried on with Mangareva in a vessel owned by the islanders. The population is about 100.

PITCAIRNE, ARCHIBALD (1652-1713), Scottish physician, was born at Edinburgh on the 25th of December 1652. After obtaining some classical education at the school of Dalkeith, Pitcairne entered Edinburgh University in 1668, and took his degree of M.A. in 1671. Having been sent to France for the benefit of his health, he was induced at Paris to begin the study of medicine, and after courses at Edinburgh and Paris he obtained in 1680 the degree of M.D. of Rhenish Heims. He began practice at Edinburgh, and in a short time acquired so great a reputation that in 1692 he was appointed physician of medicine at Leiden. Among his pupils were Richard Mead and H. Boerhaave, and both of them attributed much of their skill to Pitcairne. He wrote a number of treatises on medical subjects, and in 1703 Pitcairne returned to Scotland to marry a daughter of Sir Archibald Stevenson, an eminent physician in Edinburgh. The family objected to her going abroad, so he did not return to Leiden, but settled once more in Edinburgh. He rose to be the first physician in Scotland, and was frequently called into consultation both in England and Holland. Soon after his return to Edinburgh, feeling the great want of the means of anatomical study, he imporunited the town council to permit himself and certain of his medical friends to treat without fee the sick paupers in "Paul's Work," on condition of being allowed to dissect such of the bodies as were unclaimed by their relatives, and therefore had to be buried at the town's expense. Strangely enough, this proposal was strongly opposed by the chief surgeons of the place, but ultimately the town council had the good sense to comply with Pitcairne's request, and in this way he may be said to have the credit of laying the foundation of the great Edinburgh school of medicine. Pitcairne's medical opinions are chiefly contained in a volume of Dissertationes medicae which he published in 1701 (2nd ed. 1713). In these he discusses the application of geometry to physic, the circulation of the blood in the smaller vessels, the difference in the quantity of the blood contained in the lungs of animals in the womb and of the same animals after birth, the motions by which food becomes fit to supply the blood, the question as to inventors in medicine (in which he repels the idea of certain medical discoveries of modern times having been known to the ancients, especially vindicating for Harvey the discovery of the circulation of the blood, and refuting the view that it was known to Hippocrates), the cure of fevers by evaucuating medicines, and the effects of acids and alkalis in medicine. Pitcairne was a good classical scholar, and wrote Latin verses, occasionally with something more than mere imitative cleverness and skill. He was supposed to be the author of a comedy, The Assembly, or Scotch Reformation, and of a satirical poem, Bess of the Borders, of which many copies in Edinburgh and Amsterdam. The wit of the divines of the time, whom, as a loudly avowed Jacobite, he strongly disliked. He was prone to irreverent and ribald jests, and thus gained the reputation of being an unbeliever and an atheist, though he was a confessed deist. The stories about his over-indulgence in drink are probably exaggerated. He was repeatedly involved in violent quarrels with his medical brethren and others, and once or twice got into scrapes with the government on account of his indirect political utterances. Among his friends, however, he was evidently well liked, and he is known to have acted with great kindness and generosity to deserving men who needed his help. Thomas Ruddiman, the Scottish scholar, for example, was rescued from a life of obscurity by his encouragement and assistance, and by no one was his memory more gratefully cherished. Mead, too, appears never to have forgotten what he owed to his old teacher at Leiden. A son of Pitcairne's had gone out in the rebellion of 1715, and, having been condemned to death, was saved by the earnest interposition of Mead with Sir Robert Walpole. He pleaded, very artfully, that if Walpole's health had been bettered by his skill, or if members of the royal family were preserved by his care, it was owing to the instruction he had received from Dr Pitcairne. Pitcairne died in Edinburgh on the 20th of October 1715. He had been a great collector of books, and his library, which is said to have been of considerable value, was, through the influence of Ruddiman, disposed of to Peter the Great of Russia.

PITCH. (1) (O. Eng. pic, an adaptation of Lat. pīx, pīcis, Gr. πίσα, πήσα, allied with Gr. πίειν, pine-tree, Lat. pinus, the name of various substances of dark colour and of extremely viscous and tenacious consistency when subjected to heat. Strictly the term is applied to the resinous substance obtained as a solid residuum by the distillation of wood-tar (see Tar), or the non-resinous substance similarly produced from Coal-tar (q.v.). The name is also applied to the natural mineral substances, i.e. asphalt or bitumen (q.v.).) (2) A noun of various meanings which are somewhat difficult to connect with the verb from which they apparently must be derived. "To pitch" means primarily to thrust in or fix a stake or other pointed object into the ground, hence to place in a fixed position, set in order, cast or throw, hence to incline or slope. The etymology is obscure, but it appears in Northern dialects as "pick," of which it may be a variant; there is some difficulty in connecting this form with "pick," variant of "pike" (q.v.).

PITCH, Musical. The pitch of a musical sound is aurally defined by its absolute position in the scale and by its relative position with regard to other musical sounds. It is precisely defined by a vibration number recording the frequency of the pulsations of a tense string, a column of air, or other vibrator, in a second of time. In Great Britain and the United States the vibration to and fro (swing both ways of a pendulum) is taken as the unit; elsewhere the vibration in one direction only (swing one way of the pendulum). The only official standard is the French, dating from 1859, preserved by a tuning-fork vibrating 870-9 (double vib. 435·45) at a temperature of 15° Centigrade (50° Fahr.) in a second. The vibration number stated in the edict establishing the Diapason Normal is 870 (435), which for comparison will be here adhered to. The natural basis for a standard musical pitch is the voice, particularly the male voice, which has been of greater importance historically. There is no reason to suppose the human voice has varied, during the several thousand years of its existence, from its original fixed place in the physical universe. The only difference to be reckoned with may be in recent tendencies of solo vocalists to sing for effect, and so to
extend the compass of the voice upwards. Otherwise we may assume no disturbing alteration has taken place for more than 2000 years in its position and extent. Vibrations increase in rapidity as they rise and decrease as it falls. Any note may be a pitch note; for orchestras custom has settled upon $a^4$ in the treble clef, for organs and pianos in Great Britain $c^2$, and for modern brass instruments $b^1$.

We are not without a clue to the pitch usual in the classic Greek and Alexandrian ages: the vocal octave to which the lyre was adapted was noted as from $e$ to $e'$. As in choruses baritone and low tenor singers always prevail, $d-d'$, at French or at medium pitch, would really be the Greek singing octave; we may therefore regard it as a tone lower than that to which we are accustomed. But to sing the lower Greek modes in or near the vocal octave it was necessary to transpos(e) ($ujarokh$) a fourth upwards, which is effected in modern notation by a flat placed upon the $b$ line of the staff; thus modulating our major key of $C$ to that of $F$. This transposition has had, as we shall see, much to do with the history of our subject, ultimately influencing the ecclesiastical chant and lasting until the 17th century of our era. It does not appear from any evidence that the keyboards,—when there were more than one,—of the early organs were arranged for transposition, but it is certain that the Flemish harpsichords to 1650 were made with double keyboards to accommodate it (see Hipkins's History of the Pianoforte, 1807). But a positive identity of pitch cannot be claimed for any period of time, and certainly not for the early organs; the foot-rule of the organ-builder, which had to do with the lengths of the pipes, and which varied in every country and province, could easily cause a difference of a semitone. Scale and wind-pressure are also important factors. But with all these often opposed conditions, we find less variation than might be expected, the main and really important divergence being due to the necessity of transposition, which added a very high pitch to the primarily convenient low one.

The first attempt to define pitch would seem to have been Arnold Schlick (Musica ausgesetzte und ausgezogen, Heidelberg, 1521), who gives a measure, a line of 48 Rhenish inches, which, he says, multiplied sixteen times, should be the lowest $F$ of a small organ. He gives no diameter or wind-pressure. Dr A. J. Ellis used this indication to have an organ pipe made which with one-sixteenth diameter and a wind-pressure of 31 in., at one-fourth Schlick's length, gave $f^2$ 301-6, from which he derived a just major third of $a^4$ 377, which would compare very well with an old Greek $a^4$. Schlick goes on to say the organ is to be suited to the choir and properly tuned for singing, that the singer may not be forced to sing too high or too low and the organist have to play chromatics, which is not handy for every one. Further, he says pitch cannot be exactly defined, because voices vary; he nevertheless gives the measure above mentioned for the low $F$, if a larger organ must to increase our still lower $C$, then this $C$ must be of the same measurement, the reason being that a greater part of church music ends in "grandus," a word understood by Schlick's editor to mean the transposition of a fourth. The larger high-pitch organ will therefore be at $a^4$ 302-6. The Halberstadt organ, about which so much has been written, was, according to Praetorius (Syntagma musicum, Wöllfenbüttel, 1618), built in 1561, and repaired or rebuilt 1495. He gives the longest pipe of this organ, $B$ natural, as 31 Brunswick feet, and the circumference 3$\frac{1}{2}$ ft. He further tells us this pitch was a tone, nearly a tone and a half, higher than a suitable church pitch (Chorton), for which he gives a diagram. Dr Ellis had pipes (now preserved in the Royal Institution, London) made to reproduce both these pitches at 3$\frac{1}{2}$ in. wind-pressure. The Halberstadt pitch was found to be $a^4$ 509-8; the Chorton, 424-2. Ellis used mean-tone temperament in calculating this lower pitch; but as he used just intonation for the Halberstadt, it seems preferable to substitute it for the Chorton, thus reducing it to $a^4$ 422-8. Praetorius's Cammerton, or chamber pitch, formulated in his dialogues for voices and instruments, is, he says, a whole tone higher; equivalent, therefore, to $a^4$ 475-6. Nearly all the German organs in his time were tuned to this higher pitch. Ellis offered the suggestion of a much higher pitch for this Cammerton in his lecture "On the History of Musical Pitch," read before the Society of Arts, London (Journ. Soc. Arts, March 5, 1880), but the present writer is unable to accept it. The lower vibration number is justified by due consideration of the three divisions of the male voice, bass, tenor and alto, as given by Praetorius, whose Cammerton very closely corresponds with Bernhardt Schmidt's Durham organ, 1663-1668, the original pitch of which has been proved by Professor Armes to have been $a^4$ 474-1. The Halberstadt pitch is nearly a semitone higher, which again agrees with the statement of Praetorius, and also Schlick's high $C$ organ. Yet it would seem there had been a still higher pitch used in the old ecclesiastical music. Upon this interesting question Praetorius is confused and difficult to understand, but he never wavers about the transposition of a fourth. In one passage he distinctly says the old organ in this high pitch had it in the sign of his Cammerton, with which we shall find his tertia minora combines to make the required interval. The term tertia minore, or inferior, is used by Praetorius to describe a low pitch, often preferred in England and the Netherlands, in Italy and in some parts of Germany. An organist, instead of transposing a whole tone down from the Cammerton, would for the tertia minore have to transpose a minor third. A corroboration of this pitch is found in A. Silbermann's great organ in Strasburg minster (1713-1716), the pitch of which, taken in 1880 and reduced to 59$\frac{1}{2}$ Fehr. (as are all pitches in this article), is $a^4$ 393-2. An old organ at Echternach (1718) reported 395-8.

Sir Frederick Gore Ouseley (side Ellis's lecture) regarded the French ton de chapelle as being about a minor third below the Diapason Normal, $d^4$ 435, and said that most of the untouched organs in the French cathedrals were at this low pitch. Strasbourg was French territory in 1713, but Silbermann's organ is not quite a whole tone below. Ellis quotes an organ at Lille, $d^4$ 374-2, but no other instance of the very low Schlick pitch is recorded, although trial of the French cathedral organs might perhaps result in the finding of examples. Ellis gives Dom Bédos (L'Art du facture d'orgues, Paris, 1766) as authority for a mean tone $a^4$ 376-6. To return to the tertia minora, Dr R. Smith, of Cambridge, in 1759, had the organ of Trinity College, built by Bernhardt Schmidt, lowered a whole tone, to reduce it to certain Roman pitch pipes made about 1720. His determinations of pitch by a weighted wire are not trustworthy; Ellis thinks they are not safe within four or five vibrations per second, but gives a mean pitch for this organ, when altered, of $a^4$ 392-2. St Michael's church at Hamburk, built as late as 1762 and unaltered in 1886, had a 17th-century pitch, $a^4$ 407-9. This is about a semitone below the Diapason Normal, and a just minor third lower than the St Jacobi organ in the same city (1688), measured by Herr Schmahl, $a^4$ 450-2. What was the old pitch of this organ had it been in our sign of an equal minor third lower, $a^4$ 411-1. The difference of a minor third, or, as we shall see later, a whole tone, had replaced the earlier fourth. Sir Frederick Gore Ouseley's comparison of the church and chamber pitches of Orlando Gibbons (side Ellis's lecture) clearly shows the minor third in Great Britain in the first half of the 17th century. But the narrowing continued. Bernhardt Schmidt, better known in England as Father Smith, was invited about 1660 to build the organ for the Chapel Royal, Whitehall; two years later he built the organ in Durham Cathedral $a^4$ 474-1, difference a whole tone, and practically agreeing with the Cammerton of Praetorius. The Hampton Court organ of 1656 shows that Schmidt had further lowered his pitch a semitone, to $a^4$ 441-7. What happened at Durham was that at some subsequent date the pipes were shifted up a semitone to bring the organ into conformity with this lower pitch, with which it is probable Schmidt's organs in St Paul's and the Temple, and also Trinity College, Cambridge, agreed. This lowering tendency towards the low pitch, and the final adoption of the latter as a general mean pitch throughout the 18th century, was no doubt influenced by the introduction of the violin, which would not bear the high tension to which the
lutes and viola had been strained. Harpsichords had long been preferred at the tertia minore. The Chorton of Praetorius, a\textsuperscript{1} 422-8, is practically the same pitch as that of the fork of the possession of which has been attributed to Handel, a\textsuperscript{1} 422-5. It is a very fair mean between G. Silbermann's 18th-century Dresden pitch, a\textsuperscript{1} 415, and the organs of Renatus Harris, a\textsuperscript{1} 428-7. Stein tuned Mozart's piano to a fork a\textsuperscript{1} 421-6, and the Broadwood pianos used at the London Philharmonic Society in its first concerts (1813) were tuned to a fork c\textsuperscript{2} 506-8, which gives a mean tone a\textsuperscript{1} 423-7.

According to Schindler (Niederrheinische Musik-Zeitung, 1855, Nos. 8 and 9) and the report of the French Commission, 1859, the rise in pitch began at the Congress of Vienna in 1814, the military bands being the cause. With the improvements in wind instruments this continued, as a more brilliant effect was gained. In 1823 Weber's Euryanthe is recorded as having been played in Vienna at a\textsuperscript{1} 437-5, and in 1834 Kreutzer's Nachtlager at a\textsuperscript{1} 440. The measurements are doubtful, but the upward tendency is clear. Scheibler, by his simple and accurate tonometer, has recorded pitches in Vienna about 1834 from a\textsuperscript{1} 433-9 to 440-2. About that time, or it may be a few years earlier, Sir George Smart established a fork for the Philharmonic Society, a\textsuperscript{1} 433-2. Forks intended for this vibration number, stamped Philharmonic as above said as 435, but about the year the performing pitch of the Society had reached 435-5. Sir Michael Costa was the conductor 1846-1854, and, from his acceptance of that high pitch the fork became known as Costa's, and its inception was attributed to him, though on insufficient grounds. In 1874 a further rise in the fork to a\textsuperscript{1} 454 was instigated by Sir Charles Hallé. The British army is bound by His Majesty's Rules and Regulations to play at the Philharmonic pitch, and a fork tuned to a\textsuperscript{1} 452-5 in 1890 is preserved as the standard for the Military Training School at Kneller Hall. But the Philharmonic Society adopted the Diapason Normal in 1866, and the military bands have not gone with it. In point of fact, they are only going higher, and the brass bands, which are so important in the North of England and in Wales, are not behind them.

It was the irreplaceable upward tendency that caused the French government in 1859, acting with the advice of Halévy, Meyerbeer, Aubert, Ambroise Thomas and Rossini, to establish by law the Diapason Normal. Other countries have gradually followed, and, with few exceptions, the low pitch derived from the Diapason Normal may be said to prevail throughout the musical world. Great Britain has been the last to fall in, but the predominance of the low pitch, introduced at Covent Garden Opera, in 1826, is assured. The proprietors of Queen's Hall, London, did much when they undertook the alteration, at a great expense, of their large concert organ, which had only just been erected. In 1866 the Philharmonic Society decided upon a performing pitch, ostensibly at 68\textdegree Fah., of a\textsuperscript{1} 459; and in 1899 Messrs Broadwood made a successful effort to get this vibration number accepted by their competitors in Great Britain. The high pitch remains only where there are large concert organs not yet lowered, and with the military and brass bands.

The consideration of temperature as affecting the use of a standard pitch was not attended to when the French government issued its ordinance. The 15\textdegree Centigrade attached to the description of the standard fork in Paris was intended for the definition and verification of the fork only. The alteration of the fork due to heat is scarcely perceptible, but wind instruments, and particularly the organ, rise almost proportionately to the increase in temperature of the surrounding air, because sound travels at an enhanced rate as the temperature rises. The coefficient of this rise is equivalent to half a vibration (o.5) per degree Fah. per second. D. J. Blakley (Essay on Musical Pitch, Catalogue of the Royal Military Exhibition, Chelsea, 1890), and Victor Mahillon (Catalogue descriptif et analytique du Musée, Bruxelles, troisième volume, appendice, 1900) have recorded the experience of wind instruments under changes of temperature. The French Commission, in establishing the Diapason Normal, should have chosen a temperature of 20\textdegree C.

There would then have been less disturbance owing to the breath of the players and heat of the theatres or concert-rooms. It would be a great advantage to get this higher grade generally adopted. It was proposed in the Stimm-Conferenzt at Vienna in 1885, but not carried. Table III, showing orchestral pitches obtained in 1899, for the measurements of which the writer is responsible, prove how chimerical it is to hope for greater accuracy than is found between 435 and 440 vibrations a second for a\textsuperscript{1}, insomuch as temperature must always be reckoned with.

Balangoda in Sabaragamuwa province, Ceylon, has also no doubt been derived from crystalline rocks. On the other hand, the mineral found in metalliferous veins, and to which the name pitchblende is more properly restricted, never occurs as crystals, but as compact masses rendered more or less impure by admixture of other minerals, the specific gravity being sometimes as low as 6.5; thorium, cerium, &c., are absent, and molybdenum and helium are present in smaller amounts. This variety occurs with ores of silver, lead, copper, nickel, cobalt, bisnuth, &c., at Johannegeorgensstadt, Marienberg and Schneeberg in Saxony, Joachimsthal and Pitzbram in Bohemia, Rehbnia in Bihar Mountains in Hungary, Gilpin county in Colorado, St. Just, in Penwith, Redruth, Grampound Road and elsewhere in Cornwall.

Often associated with pitchblende, and resulting from its alteration, is an orange-yellow, amorphous, gum-like mineral called gummithe, which is a hydrous uranous oxide with small amounts of lead, calcium, iron, &c. (L. J. S.)

PITCHER. (1) A large vessel for holding liquids, derived through Fr. from Med. Lat. picarium; the Lat. variant bicarium, Gr. βικορα, has given the Ger Becher, Eng. beaker (q.v.). (2) One who "pitchers," i.e. throws, casts, fixes; the name of the player in the game of base-ball who pitches or delivers the ball to the striker.

PITCHER PLANTS. In botany, the name given to plants in which the leaves bear pitcher-like structures or are pitcher-like in form. The plant generally understood by this name is Nepenthes, a genus containing nearly sixty species, natives of tropical Asia, north Australia and (one only) of Madagascar. North Borneo is especially rich in species. They are shrubby plants climbing over surrounding vegetation by means of tendril-like prolongations of the midrib of the leaf beyond the leaf-tip.

A, Honey-gland from attractive C, Transverse section of the surface of lid, same.
B, Digestive gland from interior A, B, and C magnified about 100 diameters. Present of epidermis, opening downwards.

The pitcher is a development at the end of the tindril. It is generally tubular in form, but in some species two forms are produced on the same plant, lower or terrestrial goblet-shaped pitchers and upper suspended pitchers retaining the more primitive more or less tubular form; in a few species a third form—funnel- or cornucopia-shaped pitchers—occurs in the upper part. In the terrestrial type a pair of well-developed wings traverse the length of the pitcher; in the tubular or funnel-shaped form the wings are narrow or ridge-like. The mouth of the pitcher has a corrugated rim (peristome) formed by incurving of the margin, the convex surface of which is firm and shining. It is traversed by more or less prominent parallel

**Fig. 1.**—Pitcher of *Nepenthes distillatoria*.

A, Honey-gland from attractive C, Transverse section of the surface of lid, same.
B, Digestive gland from interior A, B, and C magnified about 100 diameters. Present of epidermis, opening downwards.

The pitcher is a development at the end of the tindril. It is generally tubular in form, but in some species two forms are produced on the same plant, lower or terrestrial goblet-shaped pitchers and upper suspended pitchers retaining the more primitive more or less tubular form; in a few species a third form—funnel- or cornucopia-shaped pitchers—occurs in the upper part. In the terrestrial type a pair of well-developed wings traverse the length of the pitcher; in the tubular or funnel-shaped form the wings are narrow or ridge-like. The mouth of the pitcher has a corrugated rim (peristome) formed by incurving of the margin, the convex surface of which is firm and shining. It is traversed by more or less prominent parallel
ridges, which are usually prolonged as teeth beyond the infolded margin. Above the mouth is the lid (operculum), which varies in size from a small narrow process to a large heart-shaped expansion. A study of the development of the pitcher, especially in the young pitchers of seedling plants, shows that the inflated portion is a development of the midrib of the leaf, while the wings, which are especially well represented in the terrestrial type of pitcher, represent the upper portion of the leaf-blade which has become separated from the lower portion by the tendril; the lid is regarded as representing two leaflets which have become fused. The short straight or curved process from the back of the pitcher behind the lid represents the organic apex of the leaf (A in fig. 1).

The size of the pitcher varies widely in the different species, from an inch to a foot or more in depth. The colour also varies considerably, even in different pitchers of the same individual, according to age, light exposure or soil conditions. It is uniformly green or more or less spotted, blotched or suffused with red or crimson, or sometimes, as in N. sanguinea or N. Edwardsiana, largely or wholly of a rich scarlet or crimson colour. Insects are attracted to the mouth of the pitcher by a series of glands, yielding a sweet excretion, which occurs on the stem and also on the leaf from the base of the leaf-stalk to the lid and peristome. Embedded in the incurved margin of the rim which affords a very insecure foothold to insects, are a number of large glands excreting a sweet juice. The cavity of the pitcher is in some species lined throughout with a smooth glistening surface over which glands are uniformly distributed; these glands secrete a liquid which is found in the pitcher even in the young state while it is still hermatically closed by the lid. In other species the glands are confined to the lower portion of the cavity surface, while the upper part bear a smooth waxy secretion on which it is impossible, or at any rate extremely difficult, for insects to secure a foothold. This area is termed the "conductive" area, as distinguished from the lower or "detentive" gland-bearing area. It has been proved that the secretion contains a digestive ferment capable of rendering protein matter soluble. Insects, especially running insects, which have followed the track of honey glands upwards from the stem along the leaf, reach the mouth of the pitcher, and in their efforts to sip the attractive marginal glands fall over into the liquid. The smooth walls above the liquid afford no foothold, and they are drowned; their bodies are digested and the products of digestion are ultimately absorbed by the glands in the pitcher-wall. Thus Nepenthes secures a supply of nutritious food from the animal world in a manner somewhat similar to that adopted by the British sundew, butterwort, and other insectivorous plants.

The side-saddle plant, Sarracenia, native of the eastern United States, is also known as a pitcher-plant. There are about seven species, herbs with clusters of radical leaves some or all of which are more or less trumpet- or pitcher-shaped. The leaf has a broadly sheathing base succeeded by a short stalk bearing the pitcher, which represents a much enlarged midrib with a wing-like lamina. Above the rim of the pitcher is a broad flattened lid, which is also a laminar development. The surface of the leaf, especially the laminar wing, bears glands which in spring exude large glistening drops of nectar. The lid and mouth of the pitcher are brighter coloured than the rest of the leaf, which varies from yellow-green to deep crimson in different species and in individuals according to exposure to sunlight and other conditions. This forms the attractive area, and the inner surface of the lid also bears numerous glands, as well as downward-pointing hairs, each with a delicately striated surface (fig. 2, A). Below it is the conducting surface (B) of glassy epidermal cells, with short downward-directed points, which facilitate the descent, but impede the ascent of an insect. Then come the glandular surface (C), which is formed of smooth polished epidermis with numerous glands that secrete the fluid contents of the pitcher, and finally the detentive surface (D), of which the cells are produced into long and strong bristles which point downwards and meet in the centre of the diminishing cavity so as to render escape impossible. The secretion wets an insect very rapidly, but, so far as is known, seems to be completely destitute of digestive power—indeed, rather to accelerate decomposition. The pitchers accumulate vast quantities of insects in the course of a season, and must thus abundantly manure the surrounding soil when they die. Moreover, the
iferous, they are allMICROSCOPIC and occur in the ground substance, as globulites or trichites, among the crystals. They grow in colonies, and are arranged in thin sheets.

**PITCHSTONE** (German *Pechstein*, from its resemblance to pitch), in petrology, a glassy igneous rock, having a resiny lustre, and a very close and glassy, earthy fracture; it differs from obsidian principally in its rather dull lustre, for obsidian is bright and vitreous in appearance; all pitchstones also contain a considerable quantity of water in combination amounting to from 5 to 10% of their weight or 10 to 20% of their volume. The majority of the rocks of this class occur as intrusive dikes or veins; they are glassy forms of quartz porphyry and other dike rocks. Their dull lustre may be connected with the great abundance of minute crystals and microlites they nearly always contain. These are visible only in microscopic sections, and their varied shapes make pitchstones very interesting to the microscopist. In some cases, pitchstones occur at Chernitz and Meissen in Saxony. They are brown or dark green, very often perlitic (see PETROLOGY, Plate I., fig. 5), and show progressive devitrification starting from cracks and joints and spreading inwards through the mass. For a long time the pitchstone dikes of Arran in Scotland have been famous among geologists for the great beauty and variety of skeleton crystals they contain. These pitchstones are dull green in hand specimens. Some of them contain phenocrysts in a massive matrix, while others are简直 crystalline, and consist of a thin layer of glass, being essentially vitreous. In the majority of cases the pitchstone dikes are formed in a window-pane. It is supposed that the mineral they consist of is hornblende. In addition to these larger growths there are many small microlites scattered through the glass, also hair-like trichites, and fine rounded globulites. When phycocysts are present the small crystals are planed out, and their surfaces like grass growing from a turf-covered wall. These pitchstones are believed to proceed from the great eruptive centres which were active in western Scotland in early Tertiary times. Another pitchstone, with a holocrystalline texture, is found in the island of Egg (Scotland). At one time regarded as a lava flow occupying an old stream channel it has recently been described as an intrusive sheet. It is from 200 to 300 ft. thick. The rock is a dark grey or black pitchstone-porphyry, with glowing idiomorphic crystals of felspar in a vitreous base. It contains no quartz; the felspars are anorthoclase, and with them there are numerous crystals of green augite. The ground mass contains small crystals of felspar, and is of a rich brown colour in thin section with well developed perlitic structure (see PETROLOGY, Plate II., fig. 1).

The chemical composition of this rock resembles the trachytes rather than the rhyolites. In Egg and Skye there are many dikes of pitchstone, mostly of intermediate rather than of acid character, all connected with great eruptive activity which characterized that region in early Tertiary times. The following analyses give the chemical composition of a few well-known pitchstones:

Not only are these pitchstones of acid character, but the island of Arran is rich in basalts and andesites, and a thin layer of glassy basalt forms a great crater-like ridge or scree in the island of Egg (Scotland). At one time regarded as a lava flow occupying an old stream channel it has recently been described as an intrusive sheet. It is from 200 to 300 ft. thick. The rock is a dark grey or black pitchstone-porphyry, with glowing idiomorphic crystals of felspar in a vitreous base. It contains no quartz; the felspars are anorthoclase, and with them there are numerous crystals of green augite. The ground mass contains small crystals of felspar, and is of a rich brown colour in thin section with well developed perlitic structure (see PETROLOGY, Plate II., fig. 1). In

The first two of these contain much water for rocks the ingredients of which are but little decomposed. They are of acid or rhyolitic character, while the third is richer in alkalies and contains less silica; it belongs more naturally to the intermediate rocks (andesites).

**PITSCSI** (Petisci, also written Pitestiti and Pitstest, the capital of the department of Argos, Rhumé; situated among the outlying hills of the Carpathians, on the river Arghes, which is here joined by several smaller streams. Pop. (1900), 15,570. The surrounding uplands produce good wine, fruit and grain, besides being rich in petroleum and salt; and, as the main Walachian railway is met at Pitesi by lines from Câmpulung and Hermannstadt in Transylvania, the town has a considerable importance. It has manufactures of lacquer and varnish.

**PITH** (O.E. *pithe*, cognate with Du. *pith*, kernel of a nut), properly the medulla, the central column of spongy cellular tissue, in the stems of dicotyledonous plants (see PLANTS: Anatomy). The word is thence applied to the spinal cord or marrow in animals, to the medullary end of a hair, and to that which forms the central part or core of any object or substance; hence, figuratively, vigour, energy, concentrated force. Very light hats or helmets are made of the dried pith of the Indian spongwood or hat plant (*Aeschynomene aspera*, the native name being *Saloah*). These pith hats are worn by Europeans in India and the East Indies. (Petiole, *Peltis*, the petiole of *Papaver*), from the pith of which the delicate white film known as "rice-paper" is made, is also known as the pith-plant.

**PITHECANTHROPS ERECTUS** (Erect Ape-Man), the name given by Dr Eugene Dubois, of the Dutch army medical service, to the imaginary creature which he constructed from fossilized remains found by him in Java. These fragments consisted of a thigh-bone, two teeth, and the upper part of a skull, and were unearthed in 1891-1892 on the left bank of the Bengawan River near Trinil. The skull appears to have been low and depressed with strong supraciliary ridges; the teeth are very large, and the femur is quite human. The teeth and parts of the skull were found together, the femur a few yards away a year afterwards. The discoverer, however, stated it as his belief that the fragments were portions of the same skeleton and belonged to a creature half-way between man and the higher apes and of the Pleistocene age. Much discussion followed the "find," and many authorities have given an opinion adverse to Dr Dubois's theory. The prevailing opinion is that the bones are human. They are not held to represent what has been called "the missing link," bridging over the gulf between man and the apes; but almost all authorities are agreed that they constitute a further link in the chain, bringing man nearer his Simian prototype. L. Manouvrier concludes that Homo javanicus walked erect, was of about medium height, and was a true precursor, possibly a direct ancestor, of man. He calls attention to the fact that the cranial capacity decreases in proportion to the antiquity of the human skulls found, and that the pithecanthropus skull has a capacity of from 900 to 1000 cc.—that is, "stands at the level of the smallest which have been occasionally found amongst the reputedly lowest savage peoples."

See Dubois, *Pithecanthropus erectus* (Batavia, 1894); a later paper read by Dr Dubois before the Berlin Anthropological Society was translated in the *Smithsonian Report* for 1896. Also a paper read by Dr D. J. Cunningham before the Royal Dublin Society, January 23, 1895 (reported in *Nature*, February 26, 1895): O. C. Marsh,

PITHIVIERS, a town of north central France, capital of an arrondissement in the department of Loiret, 28 m. N.N.E. of Orleans, on the railway to Malesherbes. Pop. (1896), 5767. The church of St Solomon, chiefly in the Renaissance style, and remains of the ancient ramparts are of interest. Statues have been erected of the mathematician Denis Poisson (d. 1840), and of the physician and agriculturist Duhamel de Monceau (d. 1782), natives of Pithiviers. The town is an agricultural market, and an important centre for the affixon of the region of Gâtinais the cultivation of which, originally introduced by the monks of Avignon in the 11th century was fostered by Louis XIV. The shrine of St Solomon in the 9th century and that of St Gregory, an Armenian bishop, in the 1oth, formed the nuclei of the town; and the donjon built at the end of the 10th century for Hélène, lady of Pithiviers, was one of the finest of the period.

PITOM, one of the "treasure cities" stated to have been built for Pharaoh by the Hebrews in Goshen during the oppression (Exod. i. 11). We have here the Hebrewized form of the Egyptian Petôn " House of (the sun-god) Etôm," in Greek, Patuômos, capital of the 9th nome of Lower Egypt and situated in the Wadi Tumilat on the canal from the Nile to the Sea. Successively (Egyptian Thuq) was identical with it or was in its immediate neighbourhood. The site, now Tell et Maskhuta, has yielded several important monuments, including the best preserved of the trilingual stela of Darius which commemorated his work on the canal. The earliest name yet found is that of Rameses II. of the XIXth Dynasty, but in one case he has usurped earlier work, apparently of the XIIth Dynasty (a sphinx), and the city was evidently very ancient. Several of the monuments from Pitom have been removed to Ismailia on the Suez Canal.

PITHOU, PIERRE (1539-1596), French lawyer and scholar, was born at Pithiviers, November 30, 1539. His taste for literature was early seen, and his father Pierre (1496-1556) cultivated it to the utmost. He was called to the Paris bar in 1560. On the outbreak of the second war of religion in 1567, Pithou, who was a Calvinist, withdrew to Sedan and afterwards to Basel, whence he returned to France on the publication of the edict of pacification. Soon afterwards he accompanied the duc de Montmorency on his embassy to England, returning shortly before the massacre of St Bartholomew, in which he narrowly escaped with his life. Next year he followed the example of Henry of Navarre by abjuring the Protestant faith. Henry, shortly after his own accession to the crown of France, recognized Pithou's talents and services by bestowing upon him various legal appointments. The most important work of his life was his co-operation in the production of the Satire Ménippée (1593), which did so much to damage the cause of the League; the harangue of the Sieur d'Aubray is usually attributed to his pen. He died at Nogent-sur-Seine on the 1st of November 1596. His valuable library, specially rich in MSS., was for the most part transferred to what is now the Bibliothèque Nationale in Paris.

Pithou wrote a great number of legal and historical books, besides preparing editions of several ancient authors. His earliest publication was De legibus subsecivorum lib. II. (1565). Perhaps his edition of the Leges Visigothorum (1579) was his most valuable contribution to historical science; in the same line he edited the Capitula of Charlemagne, Louis the Pious, and Charles the Bald in 1586, and he also assisted his brother François in preparing an edition of the Corpus juris canonici (1687). His Libri de l'église gallicense (1594) is reprinted in his Opera sacra juridica his oris miscellanea collecta (1609). In classical literature he was the finder who made the world acquainted with the Faules de Phedrus (1566); he also edited the Persilgium Veneris (1587), and Juvenal and Persius (1585).

Three of Pithou's brothers acquired distinction as jurists: Jean (1524-1602), who was the author of Traité de la résistance du gouvernement des répub., in collaboration with his twin brother Nicolas (1524-1598), of Institution du mariage chrétien; and François (1543-1624), author of Glossarium ad libros capitularium (1588), Traité de l'exemption et des divorces (1624).

PITIGLIANO, a town in Italy, province of Grosseto. Pop. (1891), 4186. It is the cathedral city of the bishopric named after the neighbouring town of Sovana, and possesses a 16th-century cathedral and a church of the 11th-12th centuries, Pitigliano was originally a fief of the countship of Sovana, which in 1903 came by marriage into the possession of the Orsini. In 1140 Sovana was taken by the Siennes, but by the terms of a peace concluded in 1417 the Orsini retained Pitigliano, Gentile Orsini (assassinated 1434) assuming the title of count of Pitigliano. The most famous of the line of counts was Niccolo III (1442-1510), a celebrated condottiere. Under his successors Pitigliano became the scene of ceaseless family feuds culminating in the assassination of the Marchese Matteo in 1542. The Medicis, Florence scoured parts of their territories, and acquired the rest by exchange in 1560. The Orsini stronghold still stands in the town.

PITLOCHRY, a village of Perthshire, Scotland, 28m. N.W. of Perth by the Highland railway. Pop. (1901), 1541. It lies on the left bank of the Tummel, a little below the confluence of that river and the Garry, 350 ft. above the sea. It is a favourite health resort and tourist centre. Among the immediate attractions are the pass of Killiecrankie, the falls of Tummel, the exquisite prospect called "Queen's View" (named after Queen Victoria) and Loch Tummel, 8 m. to the west. One m. S.E. of the village is the Black Spout, a waterfall of 60 ft., formed by the Grearad.

PITMAN, SIR ISAAC (1813-1897), English phonographer, was born at Trowbridge, Wiltshire, on the 4th of January 1813, and was educated at the local grammar school. He started in life as a clerk in a cloth factory, but in 1831 he was sent to the Normal College of the British and Foreign School Society in London. Between 1832 and 1839 he held masterships at Barton-on-Humber and Wotton-under-Edge, but he was dismissed by the authorities when he became a Swedeboroughian, and from 1839 to 1843 he conducted a private school of his own at Bath. In 1829 he took up Samuel Taylor's system of shorthand, and from that time he became an enthusiast in developing the art of shorthand and phonography. In 1832 he published Taylor's system and offered it to Samuel Bagster (1771-1852). The publisher did not accept the work, but suggested that Pitman should invent a new system (see Shortland) of his own. The result was his Stenographic Soundhand (1837). Bagster's friendship and active help had been secured by Pitman's undertaking to verify the half-million references in the Comprehensive Bible, and he published the inventor's books at a cheap rate, thus helping to bring the system within the reach of all. Pitman devoted himself to perfecting phonography and propagating its use, and established at Bath a Phonographic Institute and a Phonographic Journal for this purpose; he printed in shorthand a number of standard works, and in his book with the title Phonography (1845) went through many editions. He was an enthusiastic spelling reformer, and adopted a phonetic system which he tried to bring into general use.

Pitman was twice married, his first wife dying in 1857, and his second, whom he married in 1861, surviving him. In 1894 he was knighted, and on the 22nd of January 1897 he died at Bath. Sir Isaac Pitman popularized shorthand at a time when the advance of the newspaper press and modern business methods were making it a matter of great commercial importance. His system adapted itself readily to the needs of journalism, and of the general use revolutionized the work of reporting. He was a non-smoker and a vegetarian, and advocated temperance principles.

His Life was written by Alfred Baker (1908) and (1902) by his brother, Benn Pitman (1822-1911).
PITONI, GIUSEPPE OTTAVIO (1657–1743), Italian musical composer, was born at Rieti on the 18th of March 1657. He came to Rome as a boy and sang in the choir of SS Apostoli. Foggia gave him instructions in counterpoint, and he became maestro di Cappella, first at Terra di Rotondo and later (1673) at Assisi. In 1670 he went to Rieti, and in 1677 to Rome, where he held various appointments, dying on the 1st of February 1743 as maestro di Cappella at St Marco, where he was buried. Pitoni appears to have devoted himself exclusively to church music, and although he did not disdain the modern style with instrumental accompaniment, he is best known by his Masses and other works in the manner of Palestrina.

Several volumes of his autograph composition are in the Santiniana Library at Münter.

PITT, THOMAS (1653–1726), British East India merchant and politician, usually called "Diamond Pitt," was born at Blandford, Dorset, on the 5th of July 1653. In early life he went to India, and from his headquarters at Balasore he made trading journeys into Persia and soon became prominent among those who were carrying on business in opposition to the East India Company. Twice he was arrested by order of the company, the second time being when he reached London in 1683, but after litigation and detained him for some years in England he returned to India, and to his former career. Unable to send him the East India Company took him into its service in 1695, and in 1697 he became president of Fort St George, or Madras. Pitt was now very zealous in defending the interests of his employers against the new East India Company, and in protecting their settlements from the attacks of the natives; in directing the commercial undertakings of the company he also appears to have been very successful. Soon, however, he had a serious quarrel with William Fraser, a member of his council, and consequently he was relieved of his office in 1709, although he was afterwards consulted by the company on matters of importance. During his residence in India Pitt bought for about £50,000 the fine diamond which was named after him; in 1717 he sold this to the regent of France, Philip duke of Orleans, for £80,000 or, according to another account, for £150,000. It is now the property of the French government. During his stay in England Pitt had bought a good deal of property, including the manor of Old Sarum, and for a short time he had represented this borough in parliament. After his final retreat from India in 1710 he added to his properties and again became member of parliament for Old Sarum. He died at Swallowfield near Reading on the 28th of April 1726.

PITT, WILLIAM (1759–1806), English statesman, the second son of William Pitt, earl of Chatham, and of Lady Hester Grenville, daughter of Hester, Countess Temple, was born at Hayes, near Bromley, Kent, on the 28th of May 1759. The child inherited a name which, at the time of his birth, was the most illustrious in the civilized world, and was pronounced by every Englishman with pride, and by every enemy of England with mingled admiration and terror. During the first year of his life every month had its illuminations and bonfires, and every wind brought some messenger charged with joyful tidings and hostile standards.

In Westphalia the English infantry won a great battle which arrested the armies of Louis XV. in the midst of a career of conquest; Boscowen defeated one French fleet on the coast of Portugal; Hawke put to flight another in the Bay of Biscay; Johnson took Niagara; Amherst took Ticonderoga; Wolfe died by the most enviable of deaths under the walls of Quebec; Clive destroyed a Dutch armament in the Hugli, and established the English supremacy in Bengal; Coote routed Lally at Wandsworth, and established the English supremacy in the Carnatic. The nation, while loudly applauding the successful warriors, considered them all, on sea and on land, in Europe, in America, and in Asia, merely as instruments which received their direction from one superior mind. It was the great William Pitt who had vanquished the French marshal in Germany and French admirals on the Atlantic—who had conquered for his country one great empire on the frozen shores of Ontario and another under the tropical sun near the mouths of the Ganges. It was not in the nature of things that popularity such as he at this time enjoyed should be permanent. That popularity had lost its gloss before his children were old enough to understand that the earl of Chatham was a great man. The energy and declamation which had eminently fitted him for the direction of war were not needed in time of peace. The lively and spirit-stirring eloquence which had made him supreme in the House of Commons often fell dead on the House of Lords. Chatham was only the ruin of Pitt, but an awful and majestic ruin, not to be contemplated by any man of sense and feeling without emotions resembling those which are excited by the remains of the Parthenon and of the Colosseum. In respect the old statesman was eminently happy. Whatever might be the vicissitudes of his public life, he never failed to find peace and love by his own heart. He loved all his children, and was loved by them; and of all his children the courtier whom he educated in the art of whose position was the child's genius and ambition displayed themselves with a rare and almost unnatural precocity. At seven the interest which he took in grave subjects, the ardour with which he pursued his studies, and the sense and vivacity of his remarks on books and on events amazed his parents and instructors. One of his sayings of this date was reported to his mother by his tutor. In August 1766, when the world was agitated by the news that Mr Pitt had become earl of Chatham, little William exclaimed, "I am glad that I am not the eldest son. I want to speak in the House of Commons like papa." At fourteen the lad was in intellect a man. Hayley, who met him at Lyme in the summer of 1773, was astonished, delighted, and somewhat overawed, by hearing wit and wisdom from so young a mouth. The boy himself had already written a tragedy, bad, of course, but not worse than the tragedies of his friend. This piece (still preserved) is in some respects highly curious. There is no love. The whole plot is political; and it is remarkable that the interest, such as it is, turns on a contest about a regency. On one side is a faithful servant of the Crown, on the other an ambitious and unprincipled conspirator. At length the king, who had been missing, reappears, resumes his蹂inable manner, and all are happy. One who should judge only by internal evidence would have no hesitation in pronouncing that the play was written by some Pittite poetaster at the time of the rejoicings for the recovery of George III. in 1789.

The pleasure with which William's parents observed the rapid development of his intellectual powers was alloyed by apprehensions about his health. He shot up alarmingly fast; he was often ill, and always weak; and it was feared that it would be impossible to rear a striping so tall, so slender, and so feeble. Port wine was prescribed by his medical advisers; and it is said that he was, at fourteen, accustomed to take this agreeable physic in quantities which would, in our more abstemious age, be thought much more than sufficient for any full-grown man. It was probably on account of the delicacy of his frame that he was not educated like other boys of the same rank. Almost all the eminent English statesmen and orators to whom he was afterwards opposed or allied—North, Fox, Shelburne, Windham, Grey, Wellesley, Grenville, Sheridan, Canning—went through the training of great public schools. Lord Chatham had himself been a distinguished Etonian; and it is seldom that a distinguished Etonian forgets his obligations to Eton. But William's infirmities required a vigilance and tenderness such as could be bestowed only at home. He was therefore bred under the paternal roof. His studies were superintended by a clergyman named Wilson; and those
PITT, WILLIAM

studies, though often interrupted by illness, were prosecuted with extraordinary success. He was sent, towards the close of the year 1773, to Pembroke Hall, in the university of Cambridge. The governor to whom the direction of William's academical life was confided was a bachelor of arts named Pretyman,1 who had been senior wrangler in the preceding year, and, who though not a man of prepossessing appearance or brilliant parts, was eminently acute and laborious, a sound scholar, and an excellent geometrician. A close and lasting friendship sprang up between the pair. The disciple was able, before he completed his twenty-eighth year, to make his preceptor bishop of Lincoln and dean of St Paul's; and the preceptor showed his gratitude by writing a life of the disciple, which enjoys the distinction of being the worst biographical work of its size in the world. Pitt, till he graduated, had scarcely one acquaintance, attended chapel regularly morning and evening, dined every day in hall, and never went to a single evening party. At seventeen he was admitted, after the fashion of those times, by right of birth, without any examination, to the degree of master of arts. But he continued during some years to reside at college, and to apply himself vigorously, under Pretyman's direction, to the study of the place, while mixing freely in the best academic society.

The stock of learning which Pitt laid in during this part of his life was certainly very extraordinary. The work in which he took the greatest delight was Newton's Principia. His liking for mathematics, indeed, amounted to a passion, which, in the opinion of his instructors, themselves distinguished mathematicians, required to be checked rather than encouraged. Nor was the youth's proficiency in classical learning less remarkable. In one respect, indeed, he appeared to disadvantage when compared with even second-rate and third-rate men from public schools. He had never, while under Wilson's care, been in the habit of composing in the ancient languages; and he therefore never acquired the knack of versification. It would have been utterly out of his power to produce such charming elegiac lines as those in which Wellesley bade farewell to Eton, or such Virgilian hexameters as those in which Canning described the pilgrimage to Mecca. But it may be doubted whether any scholar has ever, at twenty, had a more solid and profound knowledge of the two great tongues of the old civilized world. He had set his heart on being intimately acquainted with all the extant poetry of Greece, and was not satisfied till he had mastered Lycophron's Cæsandra, which seems to have comparatively little attention. He knew no living language except French; and French he knew very imperfectly. With a few of the best English writers he was intimate, particularly with Shakespeare and Milton. The debate in Pandemonium was, as it well deserved to be, one of his favourite passages; and his early friends used to talk, long after his death, of the just emphasis and the melodious cadence with which they had heard him recite the incomparable speech of Belial. He had indeed been carefully trained from infancy in the art of managing his voice, a voice naturally clear and deep-toned. At a later period the wits of Brooke's, irritated by observing, night after night, how powerfully Pitt's sonorous eloquence and the vehemence of views which he so earnestly approached him with having been "taught by his dad on a stool".

His education, indeed, was well adapted to form a great parliamentary speaker. The classical studies of Pitt had the effect of enriching his English vocabulary, and of making him wonderfully expert in the art of constructing correct English sentences. His practice was to look over a page or two of a Greek or Latin author, to make himself master of the meaning, and then to read the passage straight forward into his own language. This practice, begun under his first teacher Wilson, was continued under Pretyman. Of all the remains of antiquity, the orations were those on which he bestowed the most minute examination. His favourite employment was to compare harangues on opposite sides of the same question, to analyse them, and to observe which of the arguments of the first speaker were refuted by the second, which were evaded, and which were left untouched. Nor was it only in books that he at this time studied the art of parliamentary fencing. When he was at home he had frequent opportunities of hearing important debates at Westminster; and he heard them, not only with interest and enjoyment, but with close scientific attention. On one of these occasions Pitt, a youth whose abilities were as yet known only to his own family and to a small knot of college friends, was introduced on the steps of the throne in the House of Lords to Fox, his senior by eleven years, who was already the greatest debater, and one of the greatest orators, that had appeared in England. Fox used afterwards to relate that, as the discussion proceeded, Pitt repeatedly turned to him, and said, "But surely, Mr Fox, that might be met thus," or "Yes; but he lays himself open to this retort." What the particular criticisms were Fox had forgotten; but he said that he was much struck at the time by the peculiarity of a lad of 20, through the whole sitting, seemed to be thinking only how all the speeches on both sides could be answered.

He had not quite completed his nineteenth year when, on the 7th of April 1778, he attended his father to Westminster. A great debate was expected. It was known that France had recognized the independence of the United States. The duke of Richmond was about to declare his opinion that all thought of subjugating those states ought to be relinquished. Chatham had always maintained that the resistance of the colonies to the mother country was justifiable. But he conceived, very erroneously, that on the day on which their independence should be acknowledged the greatness of England would be at an end. Though sinking under the weight of years and infirmities, he determined, in spite of the entreaties of his family, to be in his place. His son supported him to a seat. The excitement and exertion were too much for the old man. In the very act of addressing the peers, he fell back in convulsions. A few weeks later his corpse was borne, with gloomy pomp, from the Painted Chamber to the Abbey. The favourite child and namesake of the deceased statesman followed the coffin as chief mourner, and saw it deposited in the transept where his own was destined to lie. His elder brother, now earl of Chatham, had been sufficiently, and barely sufficient, to support the dignity of the peerage. The other members of the family were poorly provided for. William had little more than £300 a year. It was necessary for him to follow a profession. He had already begun to "eat his terms." In the spring of 1780 he came of age. He then quitted Cambridge, was called to the bar, took chambers in Lincoln's Inn, and joined the western circuit. In the autumn of that year a general election took place; and he offered himself as a candidate for the university; but he was at the bottom of the poll. He was, however, at the request of an hereditary friend, the duke of Rutland, brought into parliament by Sir James Lowther for the borough of Appleby. The settlers of the country were at that time such as might well have disturbed the Army. Pitt, by whom he had been sent in vain against the rebellious colonies of North America. Meanwhile the house of Bourbon, humbled to the dust a few years before by the genius and vigour of Chatham, had seized the opportunity of revenge. France and Spain had united against England, and had recently been joined by Holland. The command of the Mediterranean had been for a time lost. The British flag had been scarcely able to maintain itself in the British Channel. The northern powers professed neutrality; but their neutrality had a menacing aspect. In the East, Hyder Ali had descended on the Carnatic, had destroyed the little army of Bailleul, and had spread terror even to the ramparts of Fort St George. The discontent of Ireland threatened nothing less than civil war. In England the authority of Lord North's government had sunk to the
lowest point. The king and the House of Commons were alike unpopular. The cry for parliamentary reform was scarcely less loud and vehement than afterwards in 1830.

The Opposition consisted of two parties which had once been hostile to each other, but at this juncture seemed to act together with cordiality. The larger of these parties consisted of the great body of the Whig aristocracy, headed by Charles, marquess of Hertford, and Rockingham. In the House of Commons the adherents of Rockingham were led by Fox, whose dissipated habits and ruined fortunes were the talk of the whole town, but whose commanding genius, and whose sweet, generous and affectionate disposition, extorted the admiration and love of those who most lamented the errors of his private life. Burke, superior to Fox in largeness of comprehension, in extent of knowledge, and in splendour of imagination, but less skilled in that kind of logic and in that kind of rhetoric which convince and persuade great assemblies, was willing to be the lieutenant of a young chief who might have been his son. A smaller section of the Opposition was composed of the old followers of Chatham. At their head was William, earl of Shelburne, distinguished both as a statesman and as a lover of science and letters. With him were leagued Lord Camden, who had formerly held the Great Seal, and whose integrity, ability and constitutional knowledge commanded the public respect; Barré, an eloquent and acrimonious declaimer; and Dunning, who had long held the first place at the English bar. It was to this party that Pitt was naturally attracted.

On the 26th of February 1781 he made his first speech in favour of Burke’s plan of economical reform. Fox stood up at the same moment, but instantly gave way. The lofty yet animated deportment of the young member, his perfect self-possession, the readiness with which he replied to the orators who had preceded him, the silver tones of his voice, the perfect structure of his unpremeditated sentences, astonished and delighted his hearers. Burke, moved even to tears, exclaimed, “It is not a chip of the old block; it is the old block itself.” “Pitt will be one of the first men in parliament,” said a member of the Opposition to Fox. “He is so already,” answered Fox, in whose nature envy had no place. Soon after this debate Pitt’s name was put up by Fox at Brookes’s Club. On two subsequent occasions during that session Pitt addressed the house, and on both fully sustained the reputation which he had acquired by his speeches in the House of Lords. From that period he again went the western circuit, held several briefs, and acquitted himself in such a manner that he was highly complimented by Buller from the bench, and by Dunning at the bar.

On the 27th of November the parliament reassembled. Only forty-eight hours before had arrived tidings of the surrender of Cornwallis and his army. In the debate on the report of the address Pitt spoke with even more energy and brilliancy than on any former occasion. He was warmly applauded by his allies; but it was remarked, that no person on his own side of the house was so loud in eulogy as Henry Dundas, the lord advocate of Scotland, who spoke from the ministerial ranks. From that night dates the connexion with Pitt, a connexion which soon became a close intimacy, and which lasted till it was dissolved by death. About a fortnight later Pitt spoke in the committee of supply on the army estimates. Symptoms of dissension had begun to appear on the treasury bench. Lord George Germaine, the secretary of state who was especially charged with the direction of the war in America, had held language not easily to be reconciled with declarations made by the first lord of the treasury. Pitt noticed the discrepancy with much force and keenness. Lord George and Lord North began to whisper together; and Welbore Ellis, an ancient placeman who had been drawing salary almost every quarter since the days of Henry Pelham, bent down between them to put in a word. Such interruptions sometimes discompose veteran speakers. Pitt stopped, and, looking at the group, said with admirable readiness, “I shall wait till Nestor has composed the dispute between Agamemnon and Achilles.” After several defeats, or victories hardly to be distinguished from defeats, the ministry resigned. The king, reluctantly and ungraciously, consented to accept Rockingham as first minister. Fox and Shelburne became secretaries of state. Lord John Cavendish, one of the most upright and honourable of men, was made chancellor of the exchequer. Thurlow, whose abilities and force of character had made him the dictator of the House of Lords, continued to hold the Great Seal. To Pitt was offered, through Shelburne, the vice-treasurership of Ireland, one of the easiest and most highly paid places in the gift of the Crown; but the offer was without hesitation declined. The young statesman had resolved to accept no post which did not entitle him to a seat in the cabinet; and a few days later (March 1782) he announced that resolution in the House of Commons.

Pitt gave a general support to the administration of Rockingham, but omitted, in the meantime, no opportunity of curtailing that ultra-Whig party which the persecution of Wilkes and the Middlesex election had called into existence, and which the disastrous events of the war, and the triumph of republican principles in America, had made formidable both in numbers and in temper. He supported a motion for shortening the duration of parliaments. He made a motion for a committee to examine into the state of the representation, and, in the speech (May 7, 1782) by which that motion was introduced, avowed himself the enemy of the close boroughs, the strongholds of that corruption to which he attributed all the calamities of the nation, and which, as he phrased it in one of those exact and sonorous sentences of which he had a boundless command, had grown with the growth of England and strengthened with her strength, but had not diminished with her diminution or decayed with her decay. On this occasion he was supported by Fox. The motion was lost by only twenty votes in a house of more than three hundred members. The Reformers never again had so good a division till the year 1831.

The new administration was strong in abilities, and was more popular than any administration which had held office since the first year of George III., but was hated by the king, hesitatingly supported by the parliament, and torn by internal dissensions. It was all that Rockingham could do to keep the peace in his cabinet; and before the cabinet had existed three months Rockingham died. In an instant all was confusion. The adherents of the Whig party, who had been ranged against Portia’s chief, the king placed Shelburne at the head of the treasury. Fox, Lord John Cavendish, and Burke immediately resigned their offices; and the new prime minister was left to constitute a government out of very defective materials. It was necessary to find some member of the House of Commons who could confront the great orators of the Opposition; and Pitt alone had the eloquence and the courage which were required. He was offered the great place of chancellor of the exchequer and he accepted it (July 1782). He had scarcely completed his twenty-third year.

The parliament was speedily prorogued. During the recess a negotiation for peace which had been commenced under Rockingham was brought to a successful termination. England acknowledged the independence of her revolted colonies; and she ceded to her European enemies some places in the Mediterranean and in the Gulf of Mexico. But the terms which she obtained were quite as advantageous and honourable as the events of the war entitled her to expect, or as she was likely to obtain by persevering in a contest against immense odds. There is not the slightest reason to believe that Fox, if he had remained in office, would have hesitated one moment about concluding a treaty on such conditions. Unhappily Fox was, at this crisis, hurried by his passions into an error which made his gentleman and his eloquence useless to his country. He saw that the great body of the House of Commons was divided into three parties—his own, that of North, and that of Shelburne; that none of those three parties was large enough to stand alone; that, therefore, unless two of them united there must be a miserably feeble administration,
or, more probably, a rapid succession of miserably feeble administrations, and this at a time when a strong government was essential to the prosperity and representativity of the nation. It was then necessary and right that there should be a coalition. To every possible coalition there were objections. But of all possible coalitions that to which there were the fewest objections was undoubtedly a coalition between Shelburne and Fox. It would have been generally applauded by the followers of both. It might have been made without any sacrifice of public principle on the part of either. Unfortunately, recent bickerings had left in the mind of Fox a profound dislike and distrust of Shelburne. Pitt attempted to mediate, and was authorized to invite Fox to return to the service of the Crown. "Is Lord Shelburne," said Fox, "to remain prime minister?" Pitt answered in the affirmative. "It is impossible that I can act under him," said Fox. "Then negotiation is at an end," said Pitt; "for I cannot betray him." Thus the two statesmen parted. They were never again in a private room together. As Fox and his friends would not treat with Shelburne, nothing remained to them but to treat with North. That fatal coalition which is emphatically called "The Coalition" was formed. Not three quarters of a year had elapsed since Fox and Burke had threatened North with impeachment, and had described him night after night as the most arbitrary, the most corrupt, and the most incapable of ministers. They now allied themselves with him for the purpose of driving from office a statesman with whom they cannot be said to have differed as to any important question. Nor had they even the prudence and the patience to wait for some occasion on which they might, without inconsistency, have combined with their old enemies in opposition to the government. That nothing might be wanting to the scandal, the great orators who had, during seven years, thundered against the war determined to join with the authors of that war in passing a vote of censure on the peace.

The parliament met before Christmas 1782. But it was not till January 1783 that the preliminary treaties were signed. On the 17th of February they were taken into consideration by the House of Commons. There had been, during some days, floating rumours that Fox and North had coalesced; and the debate indicated but too clearly that those rumours were not unfounded. Pitt was suffering from indisposition—he did not rise till his own strength and that of his hearers were exhausted; and he was consequently less successful than on any former occasion. His admirers owned that his speech was feeble and petulant. He said so far for lost hopes as to advise Sheridan not to confine himself to amusing theatrical audiences. This ignoble sarcasm gave Sheridan an opportunity of retorting with great felicity. "After what I have seen and heard to-night," he said, "I really feel strongly tempted to venture on a competition with so great an artist as Ben Jonson, and to bring on the stage a second Angry Boy." On a division, the address proposed by the supporters of the government was rejected by a majority of sixteen. But Pitt was not a man to be disheartened by a single failure, or to be put down by the most lively repartee. When, a few days later, the Opposition proposed a resolution directly censuring the treaties, he spoke with an eloquence, energy, and vehemence which raised his name higher than ever. To the coalition of Fox and North he alluded in language which drew forth tumultuous applause from his followers. "If," he said, "this ill-omened and unnatural marriage be not yet consummated, I know of a just and lawful impediment; and, in the name of the public weal, I forbid the bans." The ministers were again left in a minority, and Shelburne consequently tendered his resignation (March 31, 1783). It was accepted; but the king struggled long and hard before he submitted to the terms dictated by Fox, whose faults he detested, and whose high spirit and powerful intellect he detested still more. The first place at the board of treasury was given Pitt, but Pitt himself offered, thought temporarily, to resign, and that no statesman would venture to brave such a majority was thought impossible. No prince of the Hanoverian line had ever, under any provocation, ventured to appeal from the representative body to the constituent body. The ministers, therefore, notwithstanding the sullen looks and muttered words of displeasure with which their suggestions were received in the closet, notwithstanding the roar of obloquy which was rising louder and louder every day from every corner of the island, thought themselves secure. Such was their confidence in their strength that, as soon as the parliament had met, they brought forward a singularly bold and original plan for the government of India. Pitt's bill was that the whole authority which till that time had been exercised over those territories by the East India Company should be transferred to seven commissioners, who were to be

several weeks the country remained without a government. It was not till all devices had failed, and till the aspect of the House of Commons became threatening, that the king gave way. The duke of Portland was declared first lord of the treasury. Thurlow was dismissed. Fox and North became secretaries of state, with power ostensibly equal. But Fox was the real prime minister. The year was far advanced before the new arrangements were completed; and nothing very important was done during the remainder of the session. Pitt, now seated on the Opposition Bench, brought the question of parliamentary reform a second time (May 7, 1783) under the consideration of the Commons. He proposed to add to the house at once a hundred county members and several members for metropolitan districts, and to enact that every borough of which an election committee should report that the majority of voters appeared to be corrupt should lose the franchise. The motion was rejected by 293 votes to 149.

After the prorogation Pitt visited the Continent for the first and last time. His travelling companion was one of his most intimate, friends, William Wilberforce. That was the time of Anglomania in France; and at Paris the son of the great Chatham was absolutely hunted by men of letters and women of fashion, and forced, much against his will, into political disputation. One remarkable saying which dropped from him during this tour has been preserved. A French gentleman expressed some surprise at the immense influence which Fox, a man of pleasure, ruined by the dice-box and the turf, exercised over the English nation. "You have not," said Pitt, "been under the wand of the magician."

In November 1783 the parliament met again. The government had irresistible strength in the House of Commons, and seemed to be scarcely less strong in the House of Lords, but was, in truth, surrounded on every side by dangers. The king was impatiently waiting for the moment at which he could emancipate himself from a yoke which gallèd him so severely that he had more than once seriously thought of retiring to Hanover; and the king was scarcely more eager for a change than the nation. Fox and North had committed a fatal error. They ought to have known that coalitions between parties which have long been hostile can succeed only when the wish for coalition pervades the lower ranks of both. At the beginning of 1783 North had been the recognized head of the old Tory party, which, though for a moment prostrated by the disastrous issue of the American war, was still a great power in the state. Fox, on the other hand, had been the idol of the Whigs, and of the whole body of Protestant dissenters. The coalition at once alienated the most zealous Tories from North and the most zealous Whigs from Fox. Two great multitudes were at once left without any head, and both at once turned their eyes on Pitt. One party saw in him the only man who could rescue the king; the other saw in him the only man who could purify the parliament. He was supported on one side by Archbishop Markham, the preacher of divine right, and by Jenkinson, the captain of the praetorian band of the king's friends; on the other side by Jebb and Priestley, Sawbridge and Cartwright, Jack Wilkes and Horne Tooke. On the benches of the House of Commons, Pitt had, on the other hand, the backs of the Wigs, and that and any statesman would venture to brave such a majority was thought impossible. No prince of the Hanoverian line had ever, under any provocation, ventured to appeal from the representative body to the constituent body. The ministers, therefore, notwithstanding the sullen looks and muttered words of displeasure with which their suggestions were received in the closet, notwithstanding the roar of obloquy which was rising louder and louder every day from every corner of the island, thought themselves secure. Such was their confidence in their strength that, as soon as the parliament had met, they brought forward a singularly bold and original plan for the government of India. Pitt's bill was that the whole authority which till that time had been exercised over those territories by the East India Company should be transferred to seven commissioners, who were to be
named by parliament, and were not to be removable at the pleasure of the Crown. Earl Fitzwilliam, the most intimate personal friend of Fox, was to be chairman of this board, and the eldest son of North was to be one of the members.

As soon as the outlines of the scheme were known all the hatred which the coalition had excited burst forth with an astounding explosion. Burke, who, whether right or wrong, could in conclusion, as he came, had more at stake for the bill and his enemies than had some of the hearers of that mighty population whose daily rice might depend on a vote of the British parliament. He spoke with even more than his wonted power of thought and language, about the desolation of Rohulcund, about the spoliation of Benares, about the evil policy which had suffered the tanks of the Carnatic to go to ruin; but he could scarcely obtain a hearing. The contending parties, to their shame it must be said, would listen to none but English topics. Out of doors the cry against the ministry was almost universal. Town and country were united. Corporations exclaimed against the violation of the charter of the greatest corporation in the realm. Tories and democrats joined in pronouncing the proposed board an unconstitutional body. It was to consist of Fox's nominees. The effect of his bill was to give, not to the Crown, but to him personally, whether in office or in opposition, an enormous power, a patronage sufficient to counterbalance the patronage of the treasury and of the admiralty, and to decide the elections for fifty boroughs. He knew, it was said, that he was hateful alike to king and people; and he had devised a plan which would make him independent of both. Some nicknamed him Cromwell, and some Carlo Khan. Wilberforce, with his usual felicity of expression, and with very unusual bitterness of feeling, described the scheme as the genuine offspring of the coalition, as marked with the features of both its parents, the corruption of one and the violence of the other. In spite of all opposition, however, the bill was supported in every stage by great majorities, was rapidly passed, and was sent up to the Lords. To the general astonishment, when the second reading was moved in the upper house, the Opposition proposed an adjournment, and carried it by eighty-seven votes to seventy-nine. The cause of this strange turn of fortune was soon known. Pitt's cousin Earl Temple, had been in the royal closet, and had there been authorized to let it be known that his majesty would consider all who voted for the bill as his enemies. The ignominious commission was performed, and instantly a troop of lords of the bedchamber, of bishops who wished to be translated, and of Scotch peers who wished to be re-elected, made haste to change sides. On a later day the Lords rejected the bill. Fox and North were immediately directed to send their seals to the palace by their under-secretaries; and Pitt was appointed first lord of the treasury and chancellor of the exchequer (December 1783).

The general opinion was that there would be an immediate dissolution. But Pitt wisely determined to give the public feeling time to gather strength. On this point he differed from his kinsman the Temple. The consequence was that Temple, who had been appointed one of the secretaries of state, resigned his office forty-eight hours after he had accepted it, and thus relieved the new government from a great load of unpopularity; for all men of sense and honour, however strong might be their dislike of the India Bill, disapproved of the manner in which that bill had been thrown out. The fame of the young prime minister preserved its whiteness. He could declare with perfect truth that, if unconstitutional machinations had been employed, he had been no party to them.

He was, however, surrounded by difficulties and dangers. In the House of Lords, indeed, he had a majority; nor could any orator of the Opposition in that assembly be considered as a match for the Temple. The consequence was that Temple, who had cordially supported the son of his old friend Chatham. But in the other house there was not a single eminent speaker among the official men who sat round Pitt. His most useful assistant was Dundas, who, though he had not eloquence, had sense, knowledge, readiness and boldness. On the opposite benches was a powerful majority, led by Fox, who was supported by Burke, North and Sheridan. The heart of the young minister, stout as it was, almost died within him. But, whatever his internal emotions might be, his language and deportment indicated nothing but unconquerable firmness and haughty confidence in his own powers. His contest against the House of Commons lasted from the 17th of December 1783 to the last day of March 1784. In sixteen divisions the Opposition triumphed. Again and again the king was requested to dismiss his ministers; but he was determined to go to Germany rather than yield. Pitt's resolution never wavered. The cry of the nation in his favour became vehement and almost furious. Addresses assuring him of public support came up daily from every part of the kingdom. The freedom of the city of London was presented to him in a gold box. He was sumptuously feasted in Grocers' Hall; and the shopkeepers of the Strand and Fleet Street illuminated their houses in his honour. These things could not but produce an effect within the walls of parliament. The ranks of the majority began to waver; a few passed over to the enemy; some skulked away; many were for capitulating while it was still possible to capitulate with the honours of war. Negotiations were opened with the view of forming an administration on a wide basis, but they had scarcely been opened when they were closed. The Opposition demanded, as a preliminary article of the treaty, that Pitt should resign the treasury; and with this demand Pitt steadfastly refused to comply. While the contest was raging, the clerkship of the Pells, a sinecure place for life, worth three thousand a year, and tenable with a seat in the House of Commons, became vacant. The appointment was with the chancellor of the exchequer; nobody doubted that he would appoint himself, and nobody could have blamed him if he had done so; for such sinecure offices had always been defended on the ground that they enabled a few men of eminent abilities and small incomes to live without any profession, and to devote themselves to the service of the state. Pitt, in spite of the remonstrances of his friends, gave the Pells to his father's old adherent, Colonel Barré, a man distinguished by talent and eloquence, but poor and afflicted with blindness. By this arrangement a pension which the Rockingham administration had granted to Barré was saved to the public. Pitt had his reward. No minister was ever more rancourously abused; but where the votes on every bill it was supposed that six thousand were passing through his hands, when the wealthiest magnates of the realm were soliciting him for marquises and garters, his bitterest enemies did not dare to accuse him of touching unlawful gain.

At length the hard-fought fight ended. A final remonstrance, drawn up by Burke with admirable skill, was carried on the 8th of March by a single vote in a full house. The supplies had been voted; the Mutiny Bill had been passed; and the parliament was dissolved. The popular constituent bodies all over the country were in general enthusiastic on the side of the new government. A hundred and sixty of the supporters of the coalition were returned. The first lord of the treasury himself came in at the head of the poll for the university of Cambridge. Wilberforce was elected knight of the great shire of York, in opposition to the whole influence of the Fitz-williams, Cavendishes, Dundases and Selves. In the midst of such triumphs Pitt completed his twenty-fifth year. He was now the greatest subject that England had seen during many generations. He dominated absolutely over the cabinet, and was the favourite at once of the sovereign, of the parliament and of the nation. His father had never been so powerful, nor Walpole, nor Marlborough.

Pitt's first administration (1784-1801) lasted seventeen years. That long period is divided by a strongly marked line into two almost exactly equal parts. The first part Pitt's First ended and the second began in the autumn of 1792. Admission. Throughout both parts Pitt displayed in the highest degree the talents of a parliamentary leader. During the first
part he was fortunate and in many respects a skilful administrator. With the difficulties which he had to encounter during the second part he was altogether incapable of contending; but his eloquence and his perfect mastery of the tactics of the House of Commons concealed his incapacity from the multitude.

The eight years which followed the general election of 1754 were as tranquil and prosperous as any eight years in the whole history of England. Her trade increased. Her manufactures flourished. Her exchequer was full to overflowing. Very idle apprehensions were generally entertained that the public debt, though much less than a third of the debt which we now bear with ease, would be found too heavy for the strength of the nation. But Pitt succeeded in persuading first himself and then the whole nation, his opponents included, that a new sinking fund, which, so far as it differed from former sinking funds, differed for the worse, would, by virtue of some mysterious power of propagation belonging to money, put into the pocket of the public creditor great sums not taken out of the pocket of the tax-payer. The minister was almost universally extolled as the greatest of financiers. Meanwhile both the branches of the house of Bourbon found that England was as formidable an antagonist as she had ever been. France had formed a plan for reducing Holland to vassalage. But England interposed, and France receded. Spain interrupted by violence the trade of the English merchants with the regions near the Oregon. But England armed, and Spain receded. Within the island there was profound tranquillity. The king was, for the first time, popular. From the day on which Pitt was placed at the head of affairs there was an end of secret influence. Any attempt to undermine him at court, any mutinous movement among his followers in the House of Commons, was certain to be at once put down. He had only to tender his resignation and he could dictate his own terms. For he, and he alone, stood between the king and the coalition. The nation loudly applauded the king for having the wisdom to repose entire confidence in so excellent a minister. His people heartily prayed that he might long reign over them; and they prayed the more heartily because his virtues were set off to the best advantage by the vices and follies of the prince of Wales, who lived in close intimacy with the chiefs of the Opposition.

How strong this feeling was in the public mind appeared signally on one great occasion. In the autumn of 1788 the king became insane. The Opposition, eager for office, committed the greatest of errors. Pitt, the heir apparent, by the fundamental laws of England, a right to be regent with the full powers of royalty. Pitt, on the other hand, maintained it to be the constitutional doctrine that when a sovereign is, by reason of insanity, disease or absence, incapable of exercising the regal functions, it belongs to the estates of the realm to determine who shall be the vicegerent, and with what portion of the executive authority such vicegerent shall be entrusted. A long and violent contest followed, in which Pitt was supported by the great body of the people with as much enthusiasm as during the first months of his administration. Tories with one voice applauded him for the benefit of a unhappy sovereign against a disloyal faction and an undutiful Whig. Whigs applauded him for asserting the authority of parliaments and the principles of the Revolution, in opposition to a doctrine which seemed to have too much affinity with the servile theory of indefeasible hereditary right. The middle class, always zealous on the side of decency and the domestic virtues, looked forward with dismay to a reign resembling that of Charles II. That the prince of Wales must be regent nobody ventured to deny. But he and his friends were so unpopular that Pitt could, with general approbation, propose to limit the powers of the regent by restrictions to which it would have been impossible to succeed had a prince been chosen instead.

The nature of the great Revolution which followed was long very imperfectly understood in England. Burke saw much further than any of his contemporaries; but whatever his sagacity described was refracted and discoloured by his passions and his imagination. More than three years elapsed before the principles of the English administration underwent any material change. Nothing could as yet be milder or more strictly constitutional than the minister's domestic policy. Not a single act indicating an arbitrary temper or a jealousy of the people could be imputed to him. In office, Pitt had redeemed the pledges which he had, at his entrance into public life, given to the supporters of parliamentary reform. He had, in 1785, brought forward a judicious plan for the representative system, and had prevailed on the king, not only to refrain from talking against that plan, but to recommend it to the houses in a speech from the throne.1 This attempt failed; but there can be little doubt that, if the French Revolution had not produced a violent reaction of public feeling, Pitt would have performed, with little difficulty and no danger, that great work which, at a later period, Lord Grey could accomplish only by means which for a time loosened the very foundations of the commonwealth. When the atrocities of the slave trade were first brought under the consideration of parliament, no abolitionist was more zealous than Pitt. A humane bill, which mitigated the horrors of the middle passage, was, in 1788, carried by the eloquence and determined spirit of Pitt, in spite of the opposition of some of his own colleagues. In 1791 he had concluded a treaty with France secured with Fox in maintaining the sound constitutional doctrine that an impeachment is not terminated by a dissolution. In the course of the same year the two great rivals contended side by side in a far more important cause. They are fairly entitled to divide the high honour of having added to the statute-book the inestimable law which places the liberty of the press under the protection of juries. On one occasion, and one alone, Pitt, during the first half of his long administration, acted in a manner unworthy of an enlightened Whig. In the debate on the Test Act he stooped to gratify the master whom he served, the university which he represented, and the great body of clergymen and country gentlemen on whose support he rested, by talking, with little heartiness or eloquence, with much laughter, the language of a Tory. With this single exception, his conduct from the end of 1783 to the middle of 1792 was that of an honest friend of civil and religious liberty.

Nor did anything, during that period, indicate that he loved war, or harboured any malevolent feeling against any neighbouring nation. Those French writers who have represented him as a Hannibal sworn in childhood by his father to bear eternal hatred to France, as having, by mysterious intrigues and lavish bribes, instigated the leading Jacobins to commit those excesses which dishonoured the Revolution, as having been the real

1 The speech with which the king opened the session of 1785 concluded with an assurance that his majesty would heartily concur in every measure which could tend to secure the true principles of the constitution. These words were at the time understood to refer to Pitt's Reform Bill.
author of the first coalition, know nothing of his character or of his history. So far was he from being a deadly enemy to France that his laudable attempts to bring about a closer connexion with that country by means of a wise and liberal treaty of commerce brought on him the severe censure of the Opposition. He was told in the House of Commons that he was a degenerate son, and that his partiality for the hereditary foes of our island was enough to make his great father's bones stir under the pavement of the Abbey.

And this man, whose name, if he had been so fortunate as to die in 1792, would have been associated with peace, with freedom, with plott antagonists, with temperate reform, with mild and constitutional administration, lived to associate his name with an arbitrary government, with harsh laws harshly executed, with alien bills, with gagging bills, with suspensions of the Habeas Corpus Act, with cruel punishments inflicted on some political agitators, with unjustifiable prosecutions instigated against others and with the most costly and most sanguinary wars of modern times. He lived to be held up to obloquy as the stern oppressor of England and the indefatigable disturber of Europe. Poets, contrasting his earlier with his later years, likened him sometimes to the apostle who kissed in order to betray, and sometimes to the evil angels who kept not their first estate. By the French press and the French tribune treaty had disgraced and every calamity that afflicted France was ascribed to the monster Pitt and his guignes. While the Jacobins were dominant it was he who had corrupted the Gironde, who had raised Lyons and Bordeaux against the Convention, who had suborned Paris to assassinate Lapelleter, and Cecilia Regnault to assassinate Rosper. When the Thermidorean reaction came, all the atrocities of the Reign of Terror were imputed to him. Collot D'Herois and Fouquier Tinville had been his pensioners. It was he who had hired the murderers of September, who had dictated the pamphlets of Marat and the pamphlets of Barere, who had paid Lebon to deluge Arras with blood and Carrier to choke the Loire with corpses. The truth is that he liked neither war nor arbitrary government. He was a lover of peace and freedom, driven, by a stress against which it was hardly possible for any will or any intellect to struggle, out of the course to which his inclinations pointed, and for which his abilities and acquirements fitted him, and forced into a policy repugnant to his feelings and unsuited to his talents.

Between the spring of 1789 and the close of 1792 the public mind of England underwent a great change. If the change of Pitt's sentiments attracted peculiar notice, it was not because he changed more than his neighbours, for in fact he changed less than most of them, but because his position was far more conspicuous than theirs, because he was, till Bonaparte appeared, the individual who filled the greatest space in the eyes of the inhabitants of the civilized world. During a short time the nation, and Pitt as one of the nation, looked with interest and approbation on the French Revolution. But soon vast confiscations, the violent sweeping away of ancient institutions, the domination of clubs, the barbarities of mobs maddened by famine and hatred, produced a reaction. The court, the nobility, the gentry, the clergy, the manufacturers, the merchants, in short nineteen-twentieths of those who had good roofs over their heads and good coats on their backs, became eager intolerant Anti-jacobins. This feeling was at least as strong among the minister's advisers as among his supporters. Fox in vain attempted to restrain his followers. All his genius, all his vast personal influence, could not prevent them from rising up against him in general mutiny. Burke set the example of revolt; and Burke was in no long time joined by Portland, Spencer, Fitzwilliam, Loughborough, Carlisle, Melshbury, Windham, Elliot. In the House of Commons the followers of the great Whig statesman and orator diminished from about a hundred and sixty to fifty. In the House of Lords he had but ten or twelve adherents left. There can be no doubt that there would have been a similar mutiny on the ministerial benches if Pitt had obstinately resisted the general wish. Pressed at once by his master and by his colleagues, by old friends and by old opponents, he abandoned, slowly and reluctantly, the policy which was dear to his heart. He laboured hard to avert the European war. When the European war broke out he still flattered himself that it would not be necessary for this country to take either side. In the spring of 1792 he congratulated the parliament on the prospect of long and profound peace, and proved his sincerity by proposing large remissions of taxation. Down to the end of that year he continued to cherish the hope that England might be able to preserve neutrality. But the passions which raged on both sides of the Channel were not to be restrained. The Republicans who ruled France were inflamed by a fanaticism resembling that of the Mussulmans, who, with one hand and the sword in the other, went forth conquering and converting, eastward to the Bay of Biscay, westward to the Pillars of Hercules. The higher and middle classes of England were animated by zeal not less fiery than that of the crusaders who raised the cry of Deus vult at Clermont. The impulse which drove the two nations to a collision was not to be arrested by the abilities or by the authority of any single man. As Pitt was in front of his fellows, and towered high above them, he seemed to lead them. But in fact he was violently pushed on by them, and, had he held back but a little more than he did, would have been thrust out of their way and compelled to retire.

He yielded to the current; and from that day his misfortunes began. The truth is that there were only two consistent courses before him. Since he did not choose to oppose himself, side by side with Fox, to the public feeling, he should have taken the advice of Burke, and should have availed himself of that feeling to the full extent. If it was impossible to preserve peace, he should have adopted the only policy which should lead to victory. He should have proclaimed a holy war for religion, morality, property, order, public law, and should have thus opposed to the Jacobins an energy equal to their own. Unhappily he tried to find a middle path; and he found one which united all that was best in both extremes. He went to war; but he could not understand the peculiar character of that war. He was obstinately blind to the plain fact that he was contending against a state which was also a sect, and that a new quarrel between England and France was of quite a different kind from the old quarrels about colonies in America and fortresses in the Netherlands. It was pitiable to hear him, year after year, proving to an admiring audience that the wicked republic was exhausted, that she could not hold out, that her credit was gone, that her emissaries were not worth more than the paper on which they were made—as if credit was a Koran to be read and the principle was rapine, and as if Albion could not turn Italy into a desert till he had negotiated a loan at 5%, as if the exchequer bills of Attila had been at par. It was impossible that a man who so completely mistook the nature of a contest could carry on that contest successfully. Great as Pitt's abilities were, his military administration was that of a driller. In such an emergency, and with such means, such a statesman as Richelieu, as Louvois, as Chatham, as Wellesley, would have created in a few months one of the finest armies in the world, and would soon have discovered and brought forward generals worthy to command such an army. Germany might have been saved by another Blenheim; Flandres recovered by another Ramillies; another Poitiers might have delivered the Royalist and Catholic provinces of France from a yoke which they abhorred, and might have spread terror even to the barriers of Paris. But the fact is that, after eight years of war, after a vast destruction of life, after an expenditure of wealth far exceeding the expenditure of the American War, of the Seven Years' War, of the War of the Austrian Succession and of the War of the Spanish Succession united, the English army under Pitt was the laughing-stock of all Europe. It could not boast of one single brilliant exploit. It had never shown itself on the Continent but to be beaten, chased, forced to re-embark or forced to capitulate. To take some sugar island in the West Indies, to scatter some mob of half-naked Irish peasants—such were the most splendid victories.
won by the British troops under Pitt's auspices. The English navy no mismanagement could ruin. But during a long period whatever mismanagement could do was made, by fraternal partiality, first lord of the admiralty, and was kept in that great post during two years of war in which the event of the battle depended on the efficiency of the fleet. Fortunately he was succeeded by George, Earl Spencer, one of those chiefs of the Whig party who, in the great schism caused by the French Revolution, had followed Burke. Lord Spencer, though inferior to many of his colleagues as an orator, was decidedly the best administrator among them. To him it was owing that a long and gloomy succession of days of fasting, and most emphatically of humiliation, was interrupted, twice in the short space of eleven months, by days of thanksgiving for great victories.

It may seem paradoxical to say that the incapacity which Pitt showed in all that related to the conduct of the war is, in some sense, the most decisive proof that he was a man of very extraordinary abilities. Yet this is the simple truth. While his schemes were confounded, while his predictions were falsified, while the coalitions which he had laboured to form were falling to pieces, while the expeditions which he had sent forth at enormous cost were ending in rout and disgrace, while the enemy against whom he was feebly contending was subjugating Flanders and Brabant, the elector of Mainz and the elector of Trèves, Holland, Piedmont, Liguria, Lombardy, his authority over the House of Commons was constantly becoming more and more absolute. There was his empire. There were his victories—his Lodi and his Arcola, his Rivoli and his Marengo. Of the great party which had contended against him during the first eight years of his administration more than one-half now marched under his standard, with his old competitor the duke of Portland at their head; and the rest had, after many vain struggles, quitted the field in despair.

Session followed session with scarcely a single division. In the eventful year 1799 the largest minority that could be mustered against the government was twenty-five.

In Pitt's domestic policy there was at this time assuredly no want of vigour. While he offered to France Jacobinism a resistance so feeble that it only encouraged the enemy, he wished to strengthen, perhaps to mend, England Jacobinism with a strong hand. The Habeas Corpus Act was repeatedly suspended. Public meetings were placed under severe restraints. The government obtained from parliament power to send out of the country aliens who were suspected of evil designs; and that power was not suffered to be idle. Writers who propounded doctrines adverse to monarchy and aristocracy were proscribed and punished without mercy. The old laws of Scotland against sedition, laws which were considered by Englishmen as barbarous, and which a succession of governments had suffered to rust, were now furbished up and sharpened anew. Men of cultivated minds and polished manners were, for offences which at Westminster would have been treated as mere misdemeanours, sent to herd with felons at Botany Bay. Some reformers, whose opinions were extravagant, and whose language was intemperate, but who had never dreamed of subverting the government by physical force, were indicted for high treason, and were saved from the gallows only by the righteous verdicts of juries.

One part only of Pitt's conduct during the last eight years of the 18th century deserves high praise. He was the first English minister who formed great designs for the benefit of Ireland. Had he been able to do all that he wished, it might have been possible to say that his policy would have averted the rebellion of 1798. But the difficulties which he encountered were great, perhaps insurmountable; and the Roman Catholics were, rather by his misfortune than by his fault, thrown into the hands of Jacobins. There was a third great rising of the Irishry against the English, a rising not less formidable than the risings of 1641 and 1689. The English remained victorious; and it was necessary for Pitt, as it had been necessary for Oliver Cromwell and William of Orange before him, to consider how the victory should be used. He determined to make Ireland one kingdom with England, and, at the same time, to relieve the Roman Catholic isity from civil disabilities, and to grant a public maintenance to the Roman Catholic clergy.

Had he been able to carry these noble designs into effect the union would have been a union indeed. But Pitt could execute only one-half of what he had projected. He succeeded in obtaining the consent of the parliaments of both kingdoms to the union; but that reconciliation of races and sects without which the union could exist only in name was not accomplished. The king imagined that his coronation oath bound him to refuse his assent to any bill for relieving Roman Catholics from civil disabilities. Dundas tried to explain the matter, but was told to keep his Scotch metaphysics to himself. Pitt and Pitt's ablest colleagues resigned their offices (March 14, 1801).

It was necessary that the king should make a new arrangement. But by this time his anger and distress had brought back the malady which had, many years before, incapacitated him for the discharge of his functions. He actually assembled his family, read the coronation oath to them, and told them that, if he broke it, the crown would immediately pass to the house of Savoy. It was not until after an interregnum of several weeks that he regained the full use of his small faculties, and that a ministry after his own heart was at length formed. In an age pre-eminently fruitful of parliamentary talents, a cabinet was formed containing hardly a single man who in parliamentary talents could be considered as even of the second rate. Henry Addington was at the head of the treasury. He had been, an early, indeed an hereditary friend of Pitt, and had by Pitt's influence been placed, while still a young man, in the chair of the House of Commons. He was universally admitted to have been the best Speaker that had sat in that chair since the retirement of Onslow. But nature had not bestowed on him very vigorous faculties; and the highly respectable situation which he long occupied with honour had rather unifttted than fitted him for the discharge of his new duties. Nevertheless, during many months, his power seemed to stand firm. The nation was put into high good humour by a peace with France. The enthusiasm with which the upper and middle classes had rushed into the new wars spent itself. Jacobinism was no longer formidable. Everywhere there was a strong reaction against what was called the atheistical and anarchical philosophy of the 18th century. Bonaparte, now first consul, was busied in constructing out of the ruins of old institutions a new ecclesiastical establishment and a new order of knighthood. The treaty of Amiens was therefore hailed by the great body of the English people with extravagant joy. The popularity of the minister was for the moment immense. His want of parliamentary ability was, as yet, of little consequence; for he had scarcely any adversary to encounter. The old Opposition, delighted by the peace, regarded him with favour. A new Opposition had indeed been formed by some of the late ministers, and was led by Grenville in the House of Lords and by Windham in the House of Commons. But the new Opposition could scarcely muster ten votes, and was regarded with no favour by the country.

On Pitt the ministers relied as on their firmest support. He had not, like some of his colleagues, retired in anger. He had expressed the greatest respect for the conscientious scruple which had taken possession of the royal mind; and he had promised his successors all the help in his power. But it was hardly possible that this union should be durable. Pitt, conscious of superior powers, imagined that the place which he had quitted was now occupied by a mere puppet which he had set up, which he was to govern while he suffered it to remain, and which he was to fling aside as soon as he wished to resume his old position. Nor was it long before he began to pine for the power which he had relinquished. Addington, on the other hand, was by no means inclined to descend from his high position. He took his elevation quite seriously, attributed it
to his own merit, and considered himself as one of the great triumvirates of English statesmen, worthy to make a third with Pitt and Fox. Meanwhile Pitt’s most intimate friends exerted themselves to effect a change of ministry. His favourite disciple, George Canning, was indefatigable. He spoke; he wrote; he intrigued; he tried to induce a large number of the supporters of the government to sign a round robin desiring a change; he made game of Addington and of Addington’s relations in a succession of lively pasquinades. The minister’s partisans retorted with equal acrimony, if not with equal vivacity. Pitt could keep out of the affair only by keeping out of politics altogether; and this it soon became impossible for him to do.

The treaty of Amiens had scarcely been signed when the restless ambition of Pitt became apparent. The First Consul convinced the great body of the English people that the war was not only an elegant curiosity and a meagre living, but also an inextricable and impenetrableFix

Pitt’s Second

The treasury he reserved for himself; and to Fox he proposed to assign a share of power little inferior to his own. The plan was excellent; but the king would not hear of it. Dull, obstinate, unforgiving, and at that time half mad, he positively refused to admit Fox into his service. In an evil hour Pitt yielded. All that was left was to construct a government out of the wreck of Addington’s administration. The small circle of Pitt’s personal retainers furnished him with a very few useful assistants, particularly Dundas (who had been created Viscount Melville), Lord Harrowby and Canning.

Such was the inauspicious manner in which Pitt entered on his second administration (May 12, 1804). The whole history of that administration was of a piece with the commencement. Almost every month brought some new disaster or disgrace.

To the war with France was soon added a war with Spain. The opponents of the ministry were numerous, able and active. His most useful coadjutors he soon lost. Sickness deprived him of the help of Lord Harrowby. It was discovered that Lord Melville had been guilty of highly culpable laxity in transactions relating to public money. He was censured by the House of Commons, driven from office, ejected from the privy council and impeached of high crimes and misdemeanours.

The blow fell heavy on Pitt. His difficulties compelled him to resort to various expedients. At one time Addington was persuaded to accept office with a peerage; but he brought no additional strength to the government. While he remained in place he was jealous and punctilious; and he soon retired again. At another time Pitt renewed his efforts to overcome his master’s aversion to Fox, and it was rumoured that the ministry was gradually giving way. But, meanwhile, it was impossible for the minister to conceal from the public eye the decay of his health and the constant anxiety which gnawed at his heart. All who passed him in the park, all who had interviews with him in Downing Street, saw misery written in his face. The peculiar look which he wore during the last months of his life was often pathetically described by Wilberforce, who used to call it the Austerlitz look.

Still the vigour of Pitt’s intellectual faculties and the intrepid haughtiness of his spirit remained unaltered. He had staked everything on a great venture. He had succeeded in forming another mighty coalition against the French ascendancy. The united forces of Austria, Russia and England might, he hoped, oppose an insurmountable barrier to the ambition of the common enemy. But the genius and energy of Napoleon prevailed. While the English troops were preparing to embark for Germany, while the Russian troops were slowly coming up from Poland, he, with rapidity unprecedented in modern war, moved a hundred thousand men from the shores of the ocean to the Black Forest, and compelled a great Austrian army to surrender at Ulm. To the first faint rumours of this calamity Pitt would give no credit. He was irritated by the alarms of those around him. “Do not believe a word of it,” he said; “it is all a fiction.” The next day he received a Dutch newspaper containing the
capitulation. He knew no Dutch. It was Sunday, and the public offices were shut. He carried the paper to Lord Malmesbury, who had been minister in Holland; and Lord Malmesbury translated it. Pitt tried to bear up, but the shock was too great; and he went away with despair in his face.

The news of the battle of Trafalgar arrived four days later, and seemed for a moment to revive him. Forty-eight hours after that most glorious and most mournful of victories had been announced to the country came the Lord Mayor's Day; and Pitt dined at Guildhall. His popularity had declined. But on this occasion the multitude, greatly excited by the recent tidings, welcomed him enthusiastically, took off his horses in Cheapside, and drew his carriage up King Street. When his health was drunk, he returned thanks in two or three of those stately sentences of which he had a boundless command. Several of those who heard him laid up his words in their hearts; for they were the last words that he ever uttered in public:

"Let us hope that England, having saved herself by her energy, may save Europe by her example."

This was but a momentary rally. Austerlitz soon completed what Ulm had begun. Early in December Pitt had retired to Bath, in the hope that he might there gather strength for the approaching session. While he was languishing there on his sofa arrived the news that a decisive battle had been fought and lost in Moravia, that the coalition was dissolved, that the Continent was at the feet of France. He sank down under the blow. Ten days later he was so emaciated that his most intimate friends hardly knew him. He came up from Bath by slow journeys, and on the 11th of January 1806 reached his villa at Putney. Parliament was to meet on the 21st. On the 20th was to be the parliamentary dinner at the house of the first lord of the treasury in Downing Street; and the cards were already issued. But the days of the great minister were numbered. On the day on which he was carried into his bedroom at Putney, the Marquess Wellesley, whom he had long loved, whom he had sent to govern India, and whose administration had been eminently able, energetic and successful, arrived in London after an absence of eight years. The friends saw each other once more. There was an affectionate meeting and a last parting. That it was a last parting Pitt did not seem to be aware. He fancied himself to be recovering, talked on various subjects cheerfully and with an unclouded mind, and pronounced a warm and discerning eulogium on the marquis's brother Arthur. "I never," he said, "met with any military man with whom it was so satisfactory to converse." The excitement and exertion of this interview were too much for the sick man. He fainted away; and Lord Wellesley left the house convinced that the close was fast approaching.

And now members of parliament were fast coming up to London. The chiefs of the Opposition met for the purpose of considering the course to be taken on the first day of the session. It was easy to guess what would be the language of the king's speech, and of the address which would be moved in answer to that speech. An amendment condemning the policy of the government had been prepared, and was to have been proposed in the House of Commons by Lord Henry Petty (afterwards 3rd marquess of Lansdowne). He was unwilling, however, to come forward as the accuser of one who was incapable of defending himself. Lord Grenville, who had been informed of Pitt's state by Lord Wellesley, and had been deeply affected by it, earnestly recommended forbearance; and Fox, with characteristic generosity and good nature, gave his voice against attacking his now helpless rival. "I am not in any hurry," he said, "et mentem mortalla tangunt." On the first day, therefore, there was no move. It was rumoured that evening that Pitt was better. But on the following morning his physicians pronounced that there were no hopes. It was asserted in many after-dinner speeches, Grub Street elegies and academic prize poems and prize declamations that the great minister died exclaiming, "Oh my country!" This is a false, but it is true that the last words which he uttered, while he knew what he said, were broken exclamations about the alarming state of public affairs. He ceased to breathe on the morning of the 23rd of January 1806, the twenty-fifth anniversary of the day on which he first took his seat in parliament.

It was moved in the House of Commons that Pitt should be honoured with a public funeral and a monument. The motion was opposed by Fox in a speech which deserves to be studied as a model of good taste and good feeling. The task was the most invidious that ever an orator undertook; but it was performed with a humanity and delicacy which were warmly acknowledged by the mourning friends of him who was gone. The motion was carried by 288 votes to 89. The 22nd of Feb-

ruary was fixed for the funeral. The corpse, having lain in state during two days in the Painted Chamber, was borne with great pomp to the northern transept of the Abbey. A splendid train of princes, nobles, bishops and privy councillors followed. The grave of Pitt had been made near to the spot where his great father lay, near also to the spot where his great rival was soon to lie. Willerforce, who carried the banner before the hearse, described the awful ceremony with deep feeling. As the coffin descended into the earth, he said, the eagle face of Chatham from above seemed to look down with consternation into the dark house which was receiving all that remained of so much power and glory.

Pitt was emphatically the man of parliamentary government, the type of his class, the minister, the child, the spoiled child, of the House of Commons. He was a distinguished member of the House of Commons at twenty-five. The ability which he had displayed in the House of Commons made him the most powerful subject in Europe before he was twenty-five. It was when the House of Commons was to be convinced and persuaded that he put forth all his powers. Of those powers we must form our estimate chiefly from tradition; for, of all the eminent speakers of that age, Pitt has suffered most from the reporters. Even while he was still living, critics remarked that his eloquence could not be preserved, that he must be heard to be appreciated. They more than once applied to him the sentence in which Tacitus describes the fate of a senator whose rhetoric was admired in the Augustan age: "Hateri canorum illustre, et profusius cum ipso simul extinctum est." There is, however, abundant evidence that nature had bestowed on Pitt the talents of a great orator; and those talents had been developed in a very peculiar manner, first by his education, and secondly by the high official position to which he rose early, and in which he passed the greater part of his public life.

At his first appearance in parliament he showed himself superior to all his contemporaries in command of language. He could pour forth a long succession of round and stately periods, without premeditation, without ever pausing for a word, without ever repeating a word, in a voice of silver clearness, and with a pronunciation so articulate that not a letter was slurred over. He had less amplitude of mind and less richness of imagination than Burke, less ingenuity than Windham, less wit than Sheridan, less perfect mastery of dialectical fence and less of that highest sort of eloquence which consists of reason and passion fused together than Fox. Yet the almost unanimous judgment of those who were in the habit of listening to that remarkable race of men placed Pitt, as a speaker, above Burke, above Windham, above Sheridan and not below Fox. His declamation was copious, polished and splendid. In power of sarcasm he was probably not surpassed by any speaker, ancient or modern; and of this formidable weapon he made merciless use. In two parts of the oratorical art which are of the highest value to a minister of state he was singularly expert. No man knew better how to be luminous or how to be obscure. When he wished to be understood, he never failed to make himself understood. Nothing was out of place; nothing was forgotten; minute details, dates, sums of money, were all faithfully preserved in his memory. On the other hand, when he did not wish to be explicit—and no man who is at the head of affairs always wishes to be explicit—he had a marvellous power
of saying nothing in language which left on his audience the impression that he had said a great deal.

The effect of oratory will always be a great extent depend on the character of the orator. There perhaps never were two speakers whose eloquence had more of what may be called the race, more of the flavour imparted by moral qualities, than Fox and Pitt. The speeches of Fox owe a great part of their charm to that warmth and softness of heart, that sympathy with human suffering, that admiration for everything great and beautiful, and that hatred of cruelty and injustice, which interest and delight us even in the most defective reports. No person, on the other hand, could hear Pitt without perceiving him to be a man of high, intrepid and commanding spirit, proudly conscious of his own strength, indomitable, incapable of the low vices of fear and envy, but too prone to feel and to show disdain. Pride, indeed, pervaded the whole man, was written in the harsh, rigid lines of his face, was marked by the way in which he walked, in which he sat, in which he stood, and above all, in which he bowed. Such pride, of course, inflicted many wounds. But his pride, though it made him bitterly disliked by individuals, inspired the great body of his followers in parliament and throughout the country with respect and confidence. It was that of the magnanimous man so finely described by Aristotle in the Ethics, of the man who thinks himself worthy of great things, being in truth worthy. It was closely connected, too, with an ambition which had no mixture of low curiosity. There was something noble in the cynical disdain with which the mighty minister scattered riches and titles to right and left among those who valued them, while he spurned them out of his way. Poor himself, he was surrounded by friends on whom he had bestowed three thousand, six thousand, ten thousand a year. Plain Mister himself, he had made more lords than any three ministers that had preceded him. The garter, for which the first dukes in the kingdom were contending, was repeatedly offered to him, and offered in vain.

The correctness of his private life added much to the dignity of his public character. In the relations of son, brother, uncle, master, friend, his conduct was exemplary. In the small circle of his intimate associates he was amiable, affectionate, even playful. He indulged, indeed, somewhat too freely in wine, which he had early been directed to take as a medicine, and which use had made a necessary of life to him. But it was very seldom that any indication of undue excess could be detected in his tones or gestures; and, in truth, two bottles of port were little more to him than two dishes of tea. He had, when he was first introduced into the clubs of St James's Street, shown a strong sense for play; but he had the prudence and the resolution to stop before this taste had acquired the strength of habit. From the passion which generally exercises the most tyrannical dominion over the young he possessed an immunity, which is probably to be ascribed partly to his temperament and partly to his situation. His constitution was feeble; he was very shy; and he was very busy. The strictness of his morals furnished such buffoons as Peter Pindar and Captain Morris with an inexhaustible theme for merriment of no very delicate kind. But the great body of the middle class of Englishmen could not see the joke. They warmly praised the young statesman for commanding his passions, and for covering his frailties, if he had frailties, with decorous obscurity.

The memory of Pitt has been assailed, times innumerable, often justly, often unjustly; but it has suffered much less from his assailants than from his eulogists. For, during many years, his name was the rallying cry of a class of men with whom, at one of those terrible conjunctures which confound all ordinary distinctions, he was accidentally and temporally connected, but to whom, on almost all great questions of principle, he was diametrically opposed. The haters of parliamentary reform called themselves Pittites, not choosing to remember that Pitt made three motions for parliamentary reform, and that, though he thought that such a reform could not safely be made while the passions excited by the French Revolution were raging, he never uttered a word indicating that he should not be prepared at a more convenient season to bring the question forward a fourth time. The toast of Protestant ascendency was drunk on Pitt's birthday by a set of Pittites who could not but be aware that Pitt had resigned his office because he could not carry Catholic emancipation. The defenders of the Test Act called themselves Pittites, though they could not be ignorant that Pitt had laid before George III. unanswerable reasons for abolishing the Test Act. The enemies of free trade called themselves Pittites, though Pitt was far more deeply imbued with the doctrines of Adam Smith than either Fox or Grey. The very negro-drivers invoked the name of Pitt, whose eloquence was never more conspicuously displayed than when he spoke of the wrongs of the Negro. This mythical Pitt, who resembles the genuine Pitt as little as the Charlemagne of Ariosto resembles the Charlemagne of Eginhard, has had his day. History will vindicate the real man from calumny disguised under the semblance of adulation, and will exhibit him as what he was—a minister of great talents, honest intentions and liberal opinions, pre-eminent qualities, intellectually and morally, for the part of a parliamentary leader, and capable of administering with prudence and moderation the government of a prosperous and tranquil country, but unequal to surprising and terrible emergencies, and liable in such emergencies to err grievously, both on the side of weakness and on the side of violence.

AUTHORITIES.—Lord Macaulay's article, a classic on its subject, written in 1839 for this Encyclopædia and included in the 9th edition unaltered, is preserved above in its essentials, but has been shortened and readjusted. Among standard biographies are the 5th Earl Stanhope's important Life (4 vols., 2nd ed., 1862), and Lord Rosebery's masterly study in the "Twelve English Statesmen Series" (1891). See also the bibliographical note to the Rev. William Hunt's article on Pitt in the Dict. Nat. Bio., and also the same historian's app. i., pp. 461-462, to his vol. x. (for the years 1760-1801) of The Political History of England (1905), dealing with the authorities for the period.

PITTA, in ornithology, from the Telugu pitta, meaning a small bird, latinized by Vieillot in 1816 (Analyse, p. 42) as the name of a genus, and since adopted by English ornithologists as the general name for a group of birds, called by the French Brêves, and remarkable for their great beauty.1 For a long while the pittas were commonly supposed to be allied to the Turdidae, and some English writers applied to them the name of "water-thrushes" and "ant-thrushes," though there was no evidence of their having aquatic habits or predilections, or of their preying especially upon ants; but the fact that they formed a separate

1 In ornithology the word is first found as part of the native name, "Fomunuy pitta," of a bird, given in 1713 by Pithou, in the "mantisia," to Ray's Synopsis (p. 128), on the authority of Buckley (see Ornithology). This bird is the Pitta bengalensis of modern ornithologists, and is said by Jerdon (Birds of India, i. 503) now to bear the Telugu name of Pena-inki.
family was gradually admitted. Their position was partly determined by A. H. Garrod, who, having obtained examples for dissection, in a communication to the Zoological Society of London, printed in its proceedings for 1876, proved (pp. 512, 513) that the Pittidae belonged to that section of Passerine birds which he named Mesomyoiidae, since their syrinx, like that of the Tyrannidae (see KING-BIRD), has its muscles attached to the middle of its half-rings, instead of to their extremities as in the higher Passerines or Acromyoiidae. They are now placed as a separate family Pittidae of the Clamatorid division of the Anisomyoide Passeres. There are about fifty species, divided into a number of genera, confined to the Old World, and ranging from India and North China to Australia, New Guinea and New Britain, with one species in West Africa, the greatest number being found in Borneo and Sumatra. Few birds can vie with the pittas in brightly-contrasted coloration. Deep velvety black, pure white and intensely vivid scarlet, turquoise-blue and beryl-blue—mosty occupying a considerable extent of surface—are found in a great many of the species—to say nothing of other composite or intermediate hues; and, though in some a modification of these tints is observable, there is scarcely a trace of any blending of shade, each patch of colour standing out distinctly. This is perhaps the more remarkable as the feathers have hardly any lustre to heighten the effect produced, and in some species the brightest colours are exhibited by the plumage of the lower parts of the body. Pittas vary in size from that of a jay to that of a lark, and generally have the bill long and thin; the legs and feet are naked, the tarsi appearing on which is surmounted on which is surmounted of a knob, and a very short talon. In many of the forms there is little or no external difference between the sexes.

Placed originally among the Pittidae, but now created to form an allied family Philepittidae, is the genus Philepis, consisting of two species peculiar to Madagascar. The two species which compose it have little outward resemblance to the pittas, not having the same style of coloration and being apparently of more arboreal habits. The sexes differ greatly in plumage, and the males have the skin round the eyes bare of feathers and carunculated.

PITTACUS, of Mytilene in Lesbos (c. 650–570 B.C.), one of the Seven Sages of Greece. About 611, with the assistance of the brothers of the poet Alcaeus, he overthrew Melanchrus, tyrant of Lesbos. In a war (606) between the Mytileneans and Athenians for the possession of Sigeum on the Hellespont he slew the Athenian commander Phrynon in single combat. In 588 his fellow citizens entrusted Pittacus with despotic power (with the title of Asyssmetes) for the purpose of protecting them against the exiled nobles, at the head of whom were Alcaeus and his brother Antimenides. He resigned the government after holding it for ten years, and died ten years later. According to Diogenes Laërtius, who credits him with an undoubtfully spurious letter to Ctesias (with whom his connexion was probably legendary), Pittacus was a writer of elegiac poems, from which he quotes five lines. His favourite sayings were: "It is hard to be good," and "Know when to act."

See Herodotus v. 27, 94; Diog. Laërt. i. 4; Lucian, Macrobii, 18; Strabo xiii. 600, 617–618; Aristotle, Politics, ii. 12, iii. 14; T. Bega's, Poetæ lyrici graeci.

PITTANCE (through O. Fr. ptissance, from Lat. pietas, loving-kindness), properly a gift to the members of a religious house for masses, consisting usually of an extra allowance of food or wine on occasions such as the anniversary of the donor's death, festivals and the like. The word was early transferred to a charitable donation and to any small gift of food or money.

PITT-RIVERS, AUGUSTUS HENRY LANE-FOX (1827–1900), English soldier and archaeologist, son of W. A. Lane-Fox, was born at Lyndhurst, Hants, on 14 April 1827, that he assumed the name of Pitt-Rivers, on inheriting the Dorsetshire and Wiltshire estates of his great-uncle, the second Lord Rivers. Educated at Sandhurst, he received a commission in the Grenadier Guards in 1845, being captain 1859, lieutenant-colonel 1857, colonel 1867, major-general 1877 and lieutenant-general 1882. He served in the Crimean War, and was at the Alma and the siege of Sebastopol. His talent for experimental research was utilized in investigation into improvements of the army rifle, and he was largely responsible for starting the Hythe School of Musketry. It is not, however, for his military career, but for his work as an anthropologist and archaeologist, that General Pitt-Rivers will be remembered. His interest in the evolution of the rifle early extended itself to other weapons and instruments in the history of man, and he became a collector of articles illustrating the development of human invention. His collection became famous, and, after being exhibited in 1874–1875 at the Bethnal Green Museum, was presented in 1883 to the university of Oxford. When, in 1880, General Pitt-Rivers obtained possession of his great-uncle's estates—practically untouched by the excavator since they had been the battleground of the West Saxons, the Romans and the Britons—he devoted himself to exploring them. His excavations round Rushmore resulted in a valuable "finds"; he founded a local museum and published several illustrated volumes. As a scientific archaeologist he attained high rank. Oxford gave him the D.C.L. in 1886; he was president of the Anthropological Institute, and F.R.S. He married, in 1853, Alice Margaret, daughter of the second Lord Stanley of Alderley, and had a numerous family; his second daughter became in 1884 the wife of Sir John Lubbock (Lord Avebury). General Pitt-Rivers died at Rushmore on the 4th of May 1900.

PITTSBURG, a city of Crawford county, Kansas, U.S.A., about 130 m. S. of Kansas City. Pop. (1880), 624; (1890), 6,897; (1900), 10,112, of whom 560 were foreign-born; (1910) census, 14,775. It is situated at the intersection of four great railway systems—the Atchison Topeka & Santa Fe, the St. Louis & San Francisco, the Kansas City Southern (which maintains shops here), and the Missouri Pacific, and is served by inter-urban electric railways. The city is the seat of the State Manual Training Normal School (1903) and of the Pittsburg Business College. Pittsburg is situated near the lead and zinc region of southeast Kansas and south-west Missouri, is in the midst of a large and rich bituminous coalfield, and lies near natural gas and oil fields. Among the manufactures are zinc smelter—there are large smelters here—clay products (chiefly vitrified brick, sewer pipe and tile; the clay being obtained from a great underlying bed of shale), blowing powder, packing-house products and planing-mill products. The total value of the city's factory products in 1905 was $1,824,929. Pittsburg was settled about 1879, was chartered as a city in 1880, and became a city of the first class in 1908.

PITTSBURG, or PITTSBURGH, the second largest city of Pennsylvania, U.S.A., and the county-seat of Allegheny county, on the Allegheny, Monongahela and Ohio rivers, 440 m. by rail W. by S. of New York City, 366 m. W. by N. of Philadelphia, 366 m. N.W. of Washington and 468 m. E. by S. of Chicago. Pop. (1890), 328,617, (1900), 321,616, of whom 84,878 were foreign-born, 17,040 were negroes and 154 were Chinese; (1910 census, after the annexation of Allegheny), 533,925. Of the 84,878 foreign-born in 1900, 21,222 were natives of Germany, 18,620 of Ireland, 8902 of England, 6243 of Russian Poland, 5709 of Italy, 4107 of Russia, 3553 of Austria, 3515 of German Poland, 2535 of Wales, 2264 of Scotland, 2124 of Hungary, 1072 of Sweden and 1023 of Austrian Poland. Area (including Allegheny, annexed in 1906), 46-67 sq. m. Pittsburg is served by the Pennsylvania (several divisions), the Baltimore & Ohio, the Pittsburg & Lake Erie (controlled by the New York Central System), the Pittsburg, Cincinnati, Chicago & St Louis (controlled by the Pennsylvania Company), the Pittsburg, Chartiers & Youghiogheny (controlled jointly by the two preceding railways; 21 m. of track), the Buffalo, Rochester & Pittsburg, and the Whiskey & Pittsburg Terminal (converted to Pittsburg, Junction, Ohio; controlled by the Wabash railway), and the Pittsburg Terminal (also controlled by the Wabash and operating the

1 "Pittsburgh" is the official spelling of the charter and seal; but "Pittsburg" is the spelling adopted by the U.S. Geographic Board and is in more general use.

2 In previous census years the population was as follows: (1880), 10,112; (1890), 11,413; (1890), 12,115; (1890), 42,221; (1880), 15,389.
West Side Belt, from Pittsburg to Clairton, 21 m.) railways, and by river boats on the Ohio, Monongahela and Allegheny.

Picturesque rolling plateaus, the three rivers and narrow valleys, from which rise high bluffs or precipitous bluffs, are the principal natural features of the district over which the city extends. Retail houses, wholesale houses, banks, tall office buildings, hotels, theatres and railway terminals are crowded into the angle, or “The Point,” formed at the confluence of the Allegheny and Monongahela rivers, with Fifth Avenue as the principal thoroughfare, especially for the retail houses, and Fourth Avenue as the great banking thoroughfare. Factories extend for miles along the banks of all three rivers into the tributary valleys, and are the cause of Pittsburg’s nickname, “The Smoky City. The more attractive residential districts are on the plateau in the eastern portion of the district between the Allegheny and Monongahela rivers and on the hills overlooking the Allegheny river from the north. Overlooking the Monongahela river is Schenley Park (about 422 acres), the first city park, of which about 400 acres were given to the city in 1890 by Mrs. Mary E. Schenley. About 2 m. to the north, overlooking the Allegheny river, is Highland Park (about 366 acres), which contains the city reservoirs and a picturesque lake. Adjacent to Schenley Park are Homewood and Calvary cemeteries; and adjacent to Highland Park is Allegheny cemetery. Across the Allegheny river, in the Allegheny district, are the beautiful Riverview Park (129 acres), in which is the Allegheny Observatory, and West Park (about 100 acres). A number of bridges span the rivers.

The city has some fine public buildings, office buildings and churches. The Allegheny county court-house (1834–1888) is one of H. H. Richardson’s masterpieces. The Nixon theatre is also notable architecturally. The high Frick Office building has exterior walls of white granite; in its main hall is a stained-glass window by John La Farge representing Fortune and her wheel. A large government building of polished granite contains the post office and the customs offices. St. Paul’s Cathedral (Roman Catholic, 1903–1906) is largely of Indiana limestone. The city is the see of a Roman Catholic and a Protestant Episcopal bishop. In Schenley Park is the Carnegie Institute (established by a gift of $70,000,000 from Andrew Carnegie, who made further contributions of $9,000,000 for its maintenance), with a main building containing a library, a department of fine arts, a museum (see MUSEUMS OF SCIENCE) and a music hall, and several separate buildings for the technical schools, which had 2102 students in 1909. The main building, dedicated in April 1907, is 660 ft. long and 400 ft. wide; in its great entrance hall is a series of mural decorations by John White Alexander, a native of the city. The library, in which the institution had its beginning in 1855, contains about 306,000 volumes. The Phipps Conservatory was presented to the city in 1893 by Henry Phipps (b. 1839), a steel manufacturer associated with Andrew Carnegie. It is the largest in America, and, with its Hall of Botany, which is utilized in instructing school children in botany, is situated in Schenley Park. The conservatory is maintained by municipal appropriations. There is a botanical garden in Highland Park. In December 1907 it was decided that the several departments of the Western University of Pennsylvania, then in different parts of the city, should be brought together on a new campus of 43 acres near the Carnegie Institute. In July 1908 the name was changed to “The University of Pittsburg.” The university embraces a college and engineering school, the Western Pennsylvania School of Mines and Mining Engineering, a graduate department, an evening school of economics, accounts and finances, a summer school, evening classes, Saturday classes and departments as the Allegheny Observatory, in the Allegheny district, law (the Pittsburg Law School), medicine (the Western Pennsylvania Medical College), pharmacy (the Pittsburgh College of Pharmacy) and dentistry (the Pittsburgh Dental College). The institution had its beginning in the Pittsburgh Academy, which was opened about 1770 and was incorporated in 1787. It was incorporated as the Western University of Pennsylvania in 1889, but was only a college from that date until 1892, when the Western Pennsylvania-Medical College became its department of medicine. In 1895 the department of law was added, the Pittsburgh College of Pharmacy was united to the university, and seven colleges, which were the first time admitted. In 1896 the department of dentistry was established, there being then 151 instructors and 1243 students. In the east end is the Pennsylvania College for Women (Presbyterian; chartered in 1889), with preparatory, collegiate and musical departments. In the Allegheny district are the Allegheny Theological Seminary (United Presbyterian, 1825), the Western Theological Seminary (Presbyterian, opened 1827), and the Reformed Presbyterian Theological Seminary (1836). Although Allegheny is now a part of Pittsburg, the two public school systems remain independent. The Pittsburg High School (five buildings in 1910) has a normal course; and there are various private schools and academies.

The Pittsburg Gazette-Times is probably the oldest newspaper west of the Allegheny Mountains; the Gazette was founded in 1786 and in 1906 was consolidated with the Times (1879). Other prominent newspapers of the city are the Dispatch (1846), the Chronicle Telegraph (1841), the Post (1792; daily, 1842), which is one of the few influential Democratic newspapers in Pennsylvania, the Leader (Sunday, 1864; daily, 1870) and the Press (1883). Two German dailies, one Slavonic daily, one Slavonic weekly, two Italian weeklies, and iron, building, coal and glass trade journals are published in the city. In Pittsburg is the publishing house of the United Presbyterian Church, and The Christian Advocate (weekly, Methodist Episcopal, 1834) is published here under the auspices of the general conference.

The oldest hospital is the Reimener (private; 1803) for maternity cases; the municipal hospital (1878) is for contagious diseases; the Sisters of Charity, the Sisters of Mercy, the Institution of Protestant Deaconesses, the Presbyterian Church and the United Presbyterian Woman’s Association each have charge of a hospital; and there is also an eye, ear and throat hospital (1895). The Western Pennsylvania Institution for the instruction of the deaf and dumb (1876), in Edgewood Park, is in part maintained by the state. And the state assists the Home for Aged and Infirm Colored Women (1885), and the Home for Colored Children (1881). Among other charitable institutions are the Curtis Home (1894) for destitute women and girls, the Bethesda Home (1890) for homeless girls and their children, the Florence Crittenton Home (1893) for homeless and unfortunate women, the Roselia Foundling Asylum and Maternity Hospital (1891), the Protestant Home for Incurables (1883), the Pittsburg Newsboys’ Home (1894), the Children’s Aid Society of Western Pennsylvania, the Pittsburg Association for the Improvement of the Poor and the Western Pennsylvania Humane Society.

Pittsburg is in the midst of the most productive coalfields in the country; the region is also rich in petroleum and natural gas. The city is on one of the main lines of communication between the east and the west, is the centre of a vast railway system, and has freight yards with a total capacity for more than 60,000 cars. Its harbour has a total length on the three rivers of 27.2 m., and an average width of about 1000 ft., and has been deepened by the construction (1877–1885) of the Davis Island dam, by dredging, under a federal project of 1890. Slack water navigation has been secured on the Allegheny by locks and dams (1890 and 1896 sq.,) at an expense up to July 1909 of $1,658,804; and up to that time $263,625 had been spent for open-channel work. The Monongahela from Pittsburg to the West Virginia state line (91.5 m.) was completed in 1856 sq., by a private company which built seven locks and dams; this property was condemned and bought for $3,767,615 by the United States government in 1897, and, under the project of 1899 for rebuilding three of the locks and enlarging another, and that of 1907 for a new lock and dam and for other improvements, $2,675,602 was spent up to July 1900. Coal is brought to the city from the coalfields by boats on the Allegheny and Monongahela rivers as well as by rail, and
great fleets of barges carry coal and other heavy freight, such as steel rails, cotton ties, sheet iron, wire and nails, down the Ohio in the winter and spring. A ship canal to provide water communication between Pittsburg and Lake Erie has been projected. The railway have a heavy tonnage of coal, coke and iron and steel products, and a large portion of the iron ore that is produced in the Lake Superior region is brought to Pittsburg. In 1908 the river traffic amounted to 9,090,146 tons, most of which was carried on barges down the Ohio. Pittsburg is also a port of entry; in 1907 the value of its imports amounted to $2,416,357, and in 1909 to $2,662,172.

The value of the factory products in 1905 was $165,428,881, and to this may be added $45,830,272 for those of the city of Allegheny, making a total of $211,259,153. In the manufacture of iron and steel products Pittsburg ranks first among the cities of the United States, the value of these products amounting in 1905 to $88,295,805 or 53.3% of the total for all manufactures; if the manufactures of Allegheny be added they amounted to $93,039,860 or 43.7%. Several neighbouring cities and towns are also extensively engaged in the same industry, and in 1902 Allegheny county produced about 24% of the pig-iron, nearly 34% of the Bessemer steel, more than 44% of the open-hearth steel, more than 53% of the crucible steel, more than 24% of the steel rails, and more than 59% of the structural shapes that were made in that year in the United States. In 1903 the value of Pittsburg's foundry and machine shop-products was $6,631,541; of the product of steam railway repair shops, $3,726,090 (being 424.8% more than in 1900); of malt liquors, $1,168,829; of slaughtering and meat-packing products, $723,027; of cigars and cigarettes, $2,207,228; of glass, $2,130,540; and of tin and terne plate, $1,645,570. Electrical machinery, apparatus and supplies were manufactured largely in the city (value in 1905, $1,706,557), and there was another large plant for their manufacture immediately outside of the city limits. Coke, cut cork, rolled brass and copper were other important products in 1905. In 1900, and for a long period preceding, Pittsburg ranked first among American cities in the manufacture of glass, but in 1905 it was outranked in this industry by Muncie, Indiana, Millville, New Jersey, and Washington, Pennsylvania; but in the district outside of the city limits of Pittsburg much glass is manufactured, so that the Pittsburg glass district is the greatest in the country, and there are large glass factories at Washington (18 m. south-west), Charleroi (20 m. south) and Tarentum (15 m. north-east). In Pittsburg or the immediate vicinity are the more important plants of the United States Steel Corporation, including that of the Carnegie Company. Here, too, are the plants of the Westinghouse Company for the manufacture of electrical apparatus, of air brakes invented by George Westinghouse (born 1840), and of devices for railway signals which he also invented. In the Allegheny district the H. J. Heinz Company has its main pickle plant, the largest establishment of the kind in the country. The Pittsburg charter of 1816 vested the more important powers of the city government in a common council of 15 members and a select council of 9 members, and until 1834 the mayor was appointed annually by these city councils from their own number. By the Wallace Act of the state legislature in 1874 a form of government was provided for cities of three classes, and Pittsburg became a city of the second class (population between 100,000 and 300,000); under the act of 1805 a new classification was made, under which Pittsburg remains in the second class. An act of 1887 had amended the provisions of the Wallace Act in regard to second class cities by changing the term of select councilmen from two to four years and of common councilmen from one to two years. In 1901 a new act was passed for the government of cities of the second class. It provided that the executive be a "city recorder"; this provision was repealed in 1903, when the title of mayor again came into use. The mayor holds office for three years, has the powers and jurisdiction of a justice of the peace, appoints the heads of departments (public safety, public works, collector of delinquent taxes, assessors, city treasurer, law, charities and correction, and sinking fund commission), and may remove any of the officers he has appointed, by a written order, showing cause, to the select council. The city controller is elected by popular vote. The legislative bodies are the select and common council, elected under the law of 1887; by a three-fifths vote it may pass resolutions or ordinances over the mayor's veto. The department of public safety controls the bureaus of police, detectives, fire, health, electricity and building inspection; the department of public works controls bureaus of surveys, construction, highways and sewers, city properity, water, assessment of water rents, parks, deed registry, bridges and light. In 1909 the taxable valuation was $100,771,321, and the tax rate was 13.8 mills for city property, 0.2 mills on rural property and 6.9 mills on agricultural property. The tax rate for separate indebtedness varied from 6 mills in Allegheny to 16.2 mills in Westmoreland. Pittsburg ships annually about 39,000,000 tons of coal, taken from the Allegheny river and pumped into reservoirs, the highest of which, in Highland Park, is 367 ft. above the river; and there is a slow sand filtration plant for the filtration of the entire supply.

Pittsburg owes its origin to the strategic value of its site in the struggle between the English and the French for the possession of the North American continent. A few Frenchmen attempted to establish a settlement here in 1731, but were soon driven away by the Indians. In 1753, after the French had laid formal claim to this region and the Ohio Land Company had been formed with a view to establishing a settlement within it, the former Duquesne, governor of Virginia and a shareholder in the Ohio Company invented George Washington to "the commandant of the French forces on the Ohio" (then stationed at Fort Le Boeuf, near the present Waterford, about 115 m. north of the head-waters of that river) asking him to account for his invasion of territory claimed by the English. This was Washington's first important public service. He reached the present site of Pittsburg on the 24th of November 1753, and subsequently reported that what is now called "The Point," i.e. the tongue of land formed by the confluence of the Monongahela and Allegheny rivers, was a much more favourable situation for a fort and trading post than the one about two miles up the Monongahela (near the present site of McKees Rocks) which had been tentatively selected by the Ohio Company. Accordingly, on the 17th of February 1754, a detachment of about 40 soldiers, under the command of Captain William Trent, reached "The Point," and began to build a fortification (under the auspices of the Ohio Company), which it seems to have been the intention to call Fort Trent, and which was the beginning of the permanent settlement here by whites. On the 17th of the following April, however, Ensign Edward Ward, commanding the soldiers, in the absence of Captain Trent, was forced to evacuate the unfinished fortification by a party of about 1000 French and Indians, under Captain Contrecoeur, who immediately occupied the works, which he reinforced and completed, and named Fort Duquesne, in honour of Duquesne de Meunville, governor of New France in 1722–1755. In the following summer Washington attempted to recover this fort, in a campaign which included the skirmish

1 His Journal, published in 1754, gives a concise and lucid account of the expedition.
2 William Trent (c. 1715–1778) was a native of Lancaster county, Pennsylvania, became a captain in the state militia in 1746 and served against the French and Indians, was for many years, after 1749, a justice of the peace in the common pleas and general sessions of the peace for Cumberland county, Pennsylvania, and in 1750–1756 was the partner of George Croghan in an extensive trade with the Indians. According to one account, he visited the site of Pittsburg, and camped for the night by Fort Duquesne before the arrival of Washington. In 1755 he became a member of the council of Lieut.-Governor Robert H. Morris, and in 1754 was appointed to the company of privateers against Fort Duquesne. He acted many times as Indian agent; his lucrative trade with the Indians, conducted from a trading house near Fort Pitt, was ruined during Pontiac's conspiracy. At the beginning of the War of Independence he was given a major's commission to raise troops in Western Pennsylvania. See Journal of Captain William Trent (Cincinnati, Ohio, 1871), edited by Alfred T. Goodman.
PITTSBURG 681

(commonly considered the beginning of the French and Indian—Seven Years—War) on the 28th of May 1754, at Great Meadows (in what is now Wharton township, Fayette county, Pennsylvania), about 50 m. south-east of Pittsburg, was a engagement under his command and a scouting party under N. Coulon de Jumonville, in which Jumonville and several of his men were killed; the building, at Great Meadows, by Washington, of Fort Necessity, and its capitulation (July 3); and the retreat of Washington to Virginia. Another expedition, led by Major-General Edward Braddock, resulted in the engagement known as "Braddock's Defeat" (July 9, 1755), fought within the present borough of Braddock (about 8 m. east of Fort Duquesne), in which Braddock's force was practically annihilated, and Braddock was mortally wounded, dying four days later. The fort was finally recaptured by the English in 1758, as the result of an elaborate expedition (involving about 7000 troops) planned by Brigadier-General John Forbes (1710-1759), and prosecuted, with the assistance of Colonel George Washington and Colonel Henry Bouquet, in the face of great difficulties. General Forbes himself was so ill that he had to be carried in a litter throughout the campaign. The troops having rendezvoused during the summer (of 1758) at Ray's Town (now Bedford, Pennsylvania), and at Loyalhanna creek (now in Westmoreland county), about 30 m. to the north-west (where Fort Ligonier was built), Colonel Bouquet, commanding the division at the latter place, despatched Major James Grant (1720-1806) at the head of about 800 men to reconnoitre the fort. Grant advanced to a hill (still known by his name, and upon the crest of which the court-house now stands) within about a quarter of a mile of the fort. Here he rashly divided his force, and in a sortie of French and Indians, on the morning of the 14th of September, one of his divisions was surrounded, and a general rout ensued in which about 270 of Grant's men were killed, about 40 were wounded, and others (including Grant) were taken prisoners. Forbes's army advanced to within about 15 m. of the fort on the 24th of November, whereupon the French blew up part of the works, set fire to the buildings and retreated down the Ohio in boats. The English occupied the place on the next day and General Forbes ordered the immediate erection of a stockade fort near the site of the old one. In reporting to Lieut.-Governor William Denny (Nov. 26) the success of the expedition he dated his letter from Fort Duquesne "or now Pitts-Bourgh," and this name, with its subsequent modification "Pittsburgh," was thereafter more commonly used than that of Fort Pitt, which, as designating the fortification proper appears to have been first applied by General John Stanwix to the enlarged fort built (at a cost, it was estimated, of $60,000) chiefly under his direction during 1759-1760.

The first considerable settlement around the fort sprang up in 1760; it was composed of two groups of houses and cabins, the "lower town," near the fort's ramparts; and the "upper town," built chiefly along the banks of the Monongahela, and extending as far as the present Market Street. In April 1761, according to a census of the settlement, outside of the fort, taken for Colonel Bouquet, there were 332 inhabitants and 104 houses.

Fort Pitt was one of the important objective points of Pontiac's conspiracy (1763), and as soon as the intentions of the Indians became evident, Captain Simeon Ecuyer, the Swiss officer in command of the garrison (which then numbered about 300), had the houses outside the ramparts levelled and prepared for a siege. The Indians attacked the fort on the 22nd of June (1763), and kept up a continuous, though ineffective, fire upon it from the 27th of July until the 1st of August, when they drew off and advanced to meet the relieving party. Bouquet was defeated, Forbes of the Run, and Colonel Bouquet relieved the fort on the 10th of August (see Pontiac). In 1764 Colonel Bouquet added to the fort a redoubt, the "Block House," which still stands, the sole remaining trace of Fort Pitt, and is owned and cared for by the Daughters of the American Revolution.

A second town, laid out in 1764, by Colonel John Campbell (with the permission of the commandant at Fort Pitt), is bounded in

the present city by Water Street, Market Street, Second Avenue and Ferry Street, and comprises four blocks. In November 1768, at a general council of the Six Nations with Sir William Johnson and representatives of Pennsylvania and Virginia, held at Fort Stanwix, on the site of the present city of Rome, New York (q.v.), at which was signed a treaty establishing the boundary line between the English possessions and the territory claimed by the Six Nations, the Indians sold for $10,000 to Thomas Penn (1702-1775) and Richard Penn (1706-1771), respectively, the second and third sons of William Penn—the founder of Pennsylvania—by his second wife, the remaining land in the province of Pennsylvania to which they claimed title, namely the tract lying south of the west branch of the Susquehanna river and of a straight line from the north-west corner of what is now Cambria county to the present Kittanning (in Armstrong county), and all of the territory east of the Allegheny river below Kittanning and south of the Ohio river. To this transaction the commissioner from Virginia seems to have made no objection, though the tract included the Fort Pitt region and other territory then claimed by Virginia. In January-March 1769 the Penns caused to be surveyed the "Manor of Pittsburgh," a tract of about 5700 acres, including much of the original city, intending to reserve it for their private use; but in the following April they offered at public sale the lands in the remainder of their purchase of the preceding year. At this time the settlement about Fort Pitt consisted of about twenty houses, occupied chiefly by Indian traders. By order of General Thomas Gage the fort was abandoned as a military post in October 1777, and was partly dismantled. In January 1774 it was occupied by an armed force under Dr John Connolly, a partisan of Lord Dunmore, governor of Virginia, and by him was named Fort Dunmore (which name, however, was never formally recognized), this being one of Dunmore's overt acts ostensibly in support of his contention that the Fort Pitt region was included in Augusta county, Virginia. In the following April Connolly took forcible possession of the court-house at Hanson's Town (near the present Greensburg), the county-seat of Westmoreland county (which then included the Fort Pitt region), a few days afterwards arrested the three justices who lived in Pittsburgh, and for the remainder of the year terrorized the settlement. Lord Dunmore himself issued a proclamation dated "Fort Dunmore," 17th September (1774), in which he called upon the inhabitants to ignore the authority of Pennsylvania, and to recognize only that of Virginia. A year afterwards Fort Pitt was occupied by a company of Virginia soldiers by order of the Virginia Provincial Convention (assembled at Williamsburg in August 1773), but this move apparently was more for the defence of the frontier in the coming war than an expression on the Pennsylvania-Virginia boundary dispute; and, in November, Connolly was arrested at Fredericksburg, Maryland, on the charge of furthering Dunmore's plans for invading the western frontier. The boundary itself was in controversy until 1780, and the marking of the boundary lines was not completed until 1785. During the War of Independence the fort was maintained as a frontier Indian post, and as a protection against the British at Detroit. Soon after the close of the war it was neglected, and by 1791 it was in bad repair; therefore at the time of the Indian hostilities of 1792 another stockade fort was built near the bank of the Allegheny river and about a quarter of a mile above the site of Fort Pitt, this new fort being named Fort Lafayette, or, as it was more commonly called, Fort Fayette. After General Anthony Wayne's defeat of the Indians, at Fallen Timbers, Ohio (Aug. 20, 1794), Pittsburg lost its importance as a frontier post.

Then in early 1794, about 12 m. south of the land included in the "Manor of Pittsburgh" was begun by the grands of William Pitt, John Penn (1720-1792), the second son of Richard Penn and lieutenant-governor of Pennsylvania in 1765-1771 and in 1773-1776, and John Penn (1760-1834), the fourth son of Thomas Penn; and in the following June a new series of town lots was laid out in which was incorporated Colonel Campbell's survey. Thereafter, settlers, chiefly Scotch and Irish, came rapidly.

1 This tract was confiscated by Pennsylvania in 1779.
Pittsburg and its vicinity witnessed much of the disorder, and some of the violence against person and property, incident to the Whisky Insurrection of 1791-94. Delegates from Allegheny, Westmoreland, Washington and Fayette counties met here on the 7th of September 1791, and passed an act severely denouncing the excise tax; and a similarly constituted gathering, on the 24th of August 1792, voted to proscribe all persons who assisted in the enforcement of laws taxing the manufacture of liquor. Thereafter various persons who had paid the excise tax, or had assisted in collecting it, were tarred and feathered or had their houses or barns burned. General John Neville (1731-1803), having accepted the office of chief excise inspector for Western Pennsylvania, his fine country residence, about 7 m. south-west of Pittsburg, was attacked by a mob of about 500 men on the 16th and 17th of July 1794. The defenders of the property (who included a squad of soldiers from the garrison at Pittsburg) killed two and wounded several of the attacking party, but they were finally forced to surrender, and General Neville's mansion and other buildings were burned to the ground. A mass meeting of about 5000 citizens of the above-mentioned counties (many of them armed militiamen), at Braddock's Field, on the 1st and 2nd of August 1794, threatened to take possession of Fort Lafayette and to burn Pittsburg, but cooler counsel prevailed, and after voting to proscribe several persons, and marching in a body through the streets of the town, the crowd dispersed without doing any damage. Upon the arrival in the following November of the troops sent by President Washington, a military court of inquiry, held at Pittsburg, caused the arrest of several persons, who were sent to Philadelphia for trial, where some of them were found guilty and sentenced to terms of imprisonment, but the sentences were not enforced.

The town was made the county-seat in 1791, it was incorporated as a borough in 1794, the charter was revived in 1804, and the borough was chartered as a city in 1816. As early as the year of its incorporation as a borough Philadelphia and Baltimore merchants had established an important trade with it. Their goods were carried in Conestoga wagons to Shippensburg and Chambersburg, Pennsylvania, and Hagerstown, Maryland, taken from there to Pittsburg on pack horses, and exchanged for Pittsburg products; these products were carried by boat to New Orleans, where they were exchanged for sugar, molasses, &c., and these were carried through the gulf and along the coast to Baltimore and Philadelphia. Boat-building was begun in Pittsburg in 1797 or earlier; the galley "President Adams," built by the government, was launched here in 1798, and the "Senator Ross," completed in the same year, was launched in 1799. In 1797 glassworks which were the first to use coal as a fuel in making glass were built here; later Pittsburg profited greatly by the use of its great store of natural gas in the manufacture of glass. In 1806 the manufacture of iron was well begun, and by 1825 this had become the leading industry. On the 10th of April 1845 a considerable portion of the city was destroyed by fire, and in July 1877, during the great railway strike of that year, a large amount of property was destroyed by a mob. The commercial importance of the city was increased by the canal from Pittsburg to Philadelphia, built by the state in 1834 at a cost of $10,000,000. The first petroleum pipe line reached Pittsburg in 1875. A movement to consolidate the cities of Pittsburg and Allegheny, together with some adjacent boroughs, was begun in 1853-1854. It failed entirely in that year but in 1867 Lawrenceville, Peebles, Collins, Liberty, Pitt and Oakland, all lying between the two rivers, were annexed to Pittsburg; in later years another annexation of 27 sq. m. south of the Monongahela river; in 1906 Allegheny (g.r.), although a large majority of those voting in the question in that city were opposed to it, was annexed, and in November 1907 the Supreme Court of the United States declared valid the act of the state legislature under which the vote was taken.

**PITTSFIELD,** a city and the county-seat of Berkshire county, Massachusetts, U.S.A., in the western part of the state among the Berkshire Hills, and about 250 m. W. of Boston. Pop. (1800), 17,281; (1900), 21,766, of whom 4344 were foreign-born; (1910 census), 32,121. Area, about 41 sq. m. It is served by the New York, New Haven & Hartford and the Boston & Albany (New York central & Hudson River) railways, and by two inter-urban electric lines. Pittsfield is a popular summer resort; it lies in a plain about 1000 ft. above sea-level, is surrounded by the picturesque Berkshire Hills, and is situated in a region of numerous lakes, one of the largest—Lake Pontoosuc—being a summer pleasure resort. On either side of the city flow the east and west branches of the Housatonic river. Standing in the public green, in the centre of the city, is the original statue (by Launt Thompson) of the "Massachusetts Color Bearers," which has been reproduced on the battlefield of Gettysburg, Pennsylvania. The principal institutions are the House of Mercy Hospital, with which is connected the Henry Blood School of Training for Nurses, the Berkshire Home for aged women, the Berkshire Athenaeum, containing the public library, the Crane Art Museum and a Young Men's Christian Association. Prominent buildings are St Joseph's Cathedral and the buildings of the Berkshire Life Insurance Company, the Agricultural National Bank and the Berkshire County Savings Bank. In the south-western part of Pittsfield, on the boundary between it and Hancock, is Shaker Village, settled about 1790 by Shakers. Pittsfield has water-power and important manufacturing industries. In 1905 its factory products were valued at $8,573,335, or 49.7% more than in 1900. Fully half of the manufactures consist of textile goods.

The first settlement in what is now Pittsfield was made in 1743, but was soon abandoned on account of Indian troubles. In 1749 the settlement was revived, but the settlers did not bring their families to the frontier until 1752. The settlement was first called "Boston Plantation," or "Pontoosuck," but in 1761, when it was incorporated as a township, the name was changed to Pittsfield, in honour of the elder William Pitt. In 1807 Pittsfield was chartered as a city. It was here, in the Appleton (or Plunkett) House, known as "Elm Knoll," and built by Thomas Gold, father-in-law of Nathan Appleton, that in 1845 Henry W. Longfellow (who married Nathan Appleton's daughter) wrote his poem "The Old Clock on the Stairs." For thirty years (1842-1872) Pittsfield was the home of the Rev. J. Franklin Stairs. In 1860-1861, the author of numerous books, of which Lectures to Children (1834; 2nd series, 1838) and The Student's Manual (1835) were once widely read. From 1807 to 1816 Elkanah Watson (1758-1842), a prominent farmer and merchant, lived at what is now the Country Club, and while there introduced the merino sheep into Berkshire county and organized the Berkshire Agricultural Society; he is remembered for his advocacy of the building of a canal connecting the Great Lakes with the Atlantic Ocean, and as the author of Memoirs: Men and Times of the Revolution (1853), edited by his son, W. C. Watson.

**PITTSTON,** a city of Luzerne county, Pennsylvania, U.S.A., on the Susquehanna river just below the mouth of the Lackawanna about 11 m. S.W. of Scranton and about 9 m. N.E. of Wilkes-Barre. Pop. (1890), 10,302; (1900), 13,556, of whom 3394 were foreign-born; (1910 census), 16,627. It is served by the Erie, the Lehigh Valley, the Delaware, Lackawanna & Western, the Central of New Jersey, the Delaware & Hudson, and the Lackawanna & Wyoming Valley railways; there is an electric railway from Pittston to Scranton, and a
belt-line electric railway connects Pittston with Avoca, Nanticoke, Plymouth and Wilkes-Barre. Two bridges connect the city with the borough of West Pittston (pop. 1910, 68,428). Pittston is in the midst of the richest anthracite coal region of the state, and fire-clay also abounds in the vicinity. In 1905 the value of the factory products was $1,474,028 (47.8% more than in 1900). Pittston, named in honour of William Pitt, earl of Chatham, was one of the five original towns founded in the Wyoming Valley by the Susquehanna Company of Connecticut; it was first settled about 1770 and was incorporated as a borough in 1803. It was chartered as a city in 1894.

**PITYRIASIS VERSICOLOR** (Gr. *pterygium*, scurf, from *pteryg-, bran*), a skin disease, consisting of patches of brownish discolorations of various sizes and shapes, mostly on the front of the body, and often attended with itching, especially after heating exercise. The pigmentation seems to radiate from the orifices of hair-follicles. The epidermis is in a scaly condition over the patch, and among the *dèbris* of the epidermic cell there may be seen minute oval spores due to a vegetable parasite, the *Microsporon furfur*. The disease is mostly one of adult age, found all over the world, and not associated in any special way with poor general health. The treatment consists of rubbing in an ointment of potassium sulhide or one of the mercurial ointments, or using sulphur-soap habitually.

**PIURA**, the northernmost maritime department of Peru, bounded north by the Gulf of Guayaquil, N.E. by Ecuador, S. by the departments of Cajamarca and Lambayeque, and W. by the Pacific. Area, 14,849 sq. m.; pop. (1906, estimate), 154,080—both totals exclusive of the province of Tumbes; or Tumbez (area, about 19,820 sq. m.; pop., in 1906, about 80,000), which has been administratively separated from the department for military reasons. The department belongs partly to the arid coastal plain that extends from the Gulf of Guayaquil southward nearly to Valparaiso, and partly to a broken mountainous region belonging to the Western Cordilleras. The coastal zone is traversed by the Tumbes, Chira and Piura rivers, which have their sources in the melting snows of the higher Andes and flow westward across the desert to the coast. The valleys of the Chira and Piura are irrigated and maintain large populations. Rough cotton, called “vegetable wool,” and tobacco are the principal products, and are also produced in the valley of the Tumbes and in some of the elevated mountain districts. On the upland pastures cattle have long been raised, and goat-breeding has been added in modern times. Mules also are reared. Petroleum is an important product, and there are wells at a number of places along the coast, from Tumbes to Sechura, the most productive being those of Talara and Zorritos. There are sulphur deposits in the Sechura desert, and salt is manufactured at some places on the lower western coast. The making of Panama hats from the fibre of the “toquilla” palm is a household industry. The capital is Piura (est. pop. 9,100 in 1906), on the Piura river, about 35 m. (direct) E.S.E. of Piata, and 164 ft. above sea-level. It was founded by Pizarro in 1531 under the name of San Miguel, at a place called Tangarara, nearer Piata, but the present site was afterwards adopted. A railway (60 m. long) by way of Sullana connects with the port of Piata, and an extension of 6 m. runs S.S.E. to Catacos. Other towns of the department, with their estimated populations in 1906, are: Tumbes, or Tumbez (2,900), the most northern port of Peru, on the Gulf of Guayaquil, celebrated as the place where Pizarro landed in 1531; Piata (6,540), on Sechura Bay in the southern part of the department, with exports of salt and sulphur; Sechura (3,500), an inland town with railway connexions in the fertile Chira valley; Morropon (3,800) on the upper Piura; Huanacabamba, the centre of a tobacco district in the mountains; and Tambo Grande (6,100) and Chulucanas (4,600), both in the fertile Piura valley above the capital.

**Pius**, the name of ten popes.

Prus I., pope from about 141 to 154. He was the brother of Hermas, author of the *Shepherd*.

Prus II. (Enea Silvio de' Piccolomini, known in literature as Aeneas Silvius), pope from 1458 to 1464, was born on the 18th of October 1455, at Corsignano (afterward called Pienza after him), near Siena. His family, though poor, was noble, and claimed to trace descent from Romulus. The eldest of eighteen children, he had to work on the farm with his father, until a priest taught him the rudiments of letters, which enabled him, at the age of eighteen, to go as a poor student to Siena, dividing his time between severe humanistic studies and a life of sensual pleasure. He was attracted to Florence by the teaching of Filippo. His father urged him to become a lawyer, but he accepted the position of secretary to Domenico Capranica, bishop of Ferro, and went with him to the council of Basel, where he stayed several years (1431-1433), changing masters whenever he could improve his position. As secretary of the bishop of Fermo, he wrote a celebrated letter to Pope Eugenius IV.; his master was caught and imprisoned, and Aeneas only saved himself by a hasty flight. He was next (1435) employed as secretary of Cardinal Nicholas Albergati (d. 1443) at the congress of Arras, where peace was made between France and Burgundy. From here he took a long journey to Scotland and England, on a secret diplomatic mission; he had numerous adventures, in one of which he nearly lost his life. In 1436 he was back at Basel, and, although a layman, obtained a seat in the council and exercised considerable influence. In order to control it better Eugenius tried to get the council to move to Florence, a minority agreed and seceded; the majority, however, stayed where they were and took vigorous measures against the pope, culminating in his deposition on the 25th of June 1438. Aeneas took an active part in the council; and though he still declined to take orders, he was given a position on the conciliar concile which elected Amadeus of Savoy as pope under the title of Felix V. In return for his services Felix made Aeneas papal secretary.

A new period of his career opened in 1442, when he was sent by the council to take part in the diet of Frankfort-on-Main. Here he met Frederick III. of Germany, who made him poet laureate and his private secretary. He ingratiated himself with the chancellor, Kaspar Schlick, at Vienna, one of whose adventures he celebrated in *Luctetia et Euriolus*, a novel in the style of Boccaccio. At this period he also wrote his witty but immoral play, *Chrisis*. In 1446 he took orders as subdeacon, and wrote that he meant to reform, “forsaking Venus for Bacchus,” chiefly on the ground of saniety, and also, as he frankly wrote, because the clerical profession offered him more advantages than he could secure outside it.

Aeneas was useful to Frederick as a diplomatist, and managed to give all parties the impression that he was the devoted advocate of each. During the struggle between pope and council he induced Frederick to be neutral for a while. He took part in the siege of Nuremberg (1444), and was made on an embassy to Eugenius in the following year he made his peace with the pope. At the diet of Frankfort (Sept. 1446) Aeneas was instrumental in changing the majority of the electors from their hostile position towards pope and emperor into a friendly one. He brought the good news to Eugenius shortly before his death (Feb. 7, 1447), and made friends with the new pope, Nicholas V., by whom he was made bishop of Siena. He was an agent of Frederick in making the celebrated concordat of Vienna (also called concordat of Aschaffenburg) in February 1448. His services to pope and emperor brought him the titles of prince of the empire and cardinal, positions which he used rather unscrupulously to get as many lucrative benefices into his hands as possible. Those in Germany brought him two thousand ducats a year.

The death of Calixtus III. (who succeeded Nicholas V.) occurred on the 5th of August 1458. After a hot fight in the conclave, in which it seemed that the wealthy French cardinal, Guillaume d'Estouteville, archbishop of Rouen and bishop of Orléans, would be elected, the intrigues of Aeneas and of his friend Rodrigo Borgia (later the notorious Alexander VI.) gave the victory to the cardinal of Siena, who took the title Pius II., with a reminiscence of Virgil's "Pius Aeneas." The humanists hailed his election with joy, and flocked around to secure a share
of the good things, but they were bitterly disappointed, as Pius did not even himself the liberal and indiscriminating patron they hoped. The fall of Constantinople in 1453 had made a deep impression upon Pius, and he never ceased to preach the crusade against the Turk. In September 1459 he opened a congress at Mantua for the purpose of considering what could be done in this direction. His proposals for the raising of troops and money met with general opposition. The French were angry because Pius had crowned the Spanish claimant, Ferdinand, king of Naples, and thus disposed of the pretensions of René of Anjou. The Germans also objected to Pius's plans, but finally agreed to furnish some troops and money, promises which they did not carry out. Pius felt how much the position of the papacy had fallen in importance since the days of Urban and Innocent III., and, believing that the change was due to the general councils which had asserted power over the popes, he changed his position, which before his election to the papal throne had been that of a warm advocate of the conciliar claims, and issued (Jan. 1460) the bull Exsorbibilis et in pristinis temporibus inauditus, in which he condemned as heretical the doctrine that the councils were superior to the popes, and proclaimed the anathema against any one who should dare to appeal to one. He issued another bull at the same time, promising forgiveness of sins to those who would take part in the crusade, and thus dissolved the congress.

While Pius was at Mantua war broke out between the French and Spanish in southern Italy, and a rising of the barons devastated the Campagna. Hurrying back to Rome Pius succeeded in quelling the disorders, and sent his nephew Antonio Todeschini to the aid of Ferdinand, who made him duke of Amalfi and gave him his natural daughter Maria in marriage. This measure still further alienated the pope from the French, with whom he was at that time negotiating for the abrogation of the Pragmatic Sanction. When Louis XI. came to the throne (Nov. 1461), he sent to Pius saying that he had abolished the French envoys in Rome in return to get the kingdom of Naples for his countryman René of Anjou. When Pius refused to do anything to the prejudice of Ferdinand, Louis changed his attitude, and allowed the protests of the university of Paris and the parlement to persuade him to restore the ancient liberties of the Gallican Church. At the same time a serious quarrel with the Germans prevented anything being done towards a crusade. George Podiebrad, king of Bohemia, was plotting to depose the emperor Frederick III., who was supported by Pius. Diether, archbishop of Mainz, took the side of Podiebrad, and replied to Pius's measures by appealing to a general council. He was declared deposed by the papacy, and in 1464 compelled the pope to recognize him again. The quarrel with Podiebrad, who was accused of supporting the Utraquist heresy, continued with increasing bitterness, but without any decisive result, until the death of Pius. In the meantime the pope did what he could to further the cause of the crusade. The discovery of alum mines at Tolfa gave him an unexpected pecuniary resource, and to stimulate the zeal of Christendom, Pius took the cross on the 18th of June 1464. He set out for Venice, where he intended to sail for the East, but he was attacked with a fever, and on the 14th of August 1464 he died.

Pius II. was a voluminous author. Besides poems, a novel and a play, he wrote a number of orations, which were considered models of eloquence in their day. His most valuable work, however, is his Commentaries, a history of his own life and times, told in an interesting and rational manner. He is very frank about himself, and most of the adverse judgments which have been pronounced on his character have been based on his own confessions. He was an opportunist, sailing along with any favourable breeze, and not quite enough in earnest about anything to pursue the same tack steadily for long. We must give him the credit, however, of advocating a statesman-like policy in the interests of the whole of Europe in trying to get the powers to unite against the Turks, who threatened to overwhelm them all.

See Herzog-Hauck, Realencyclopedia (1904), vol. xv., where a full bibliography will be found; M. Creighton, History of the Papacy during the Reformation, vol. ii. (London, 1882); L. Pastor, History of the Popes from the close of the Middle Ages (Eng. trans., 1896, vol. ii.); Voigt, Pius II. (1856-1863). The Commentaries of Pius were published in 1854, under the name of Gobelinus Persoma. His other works are found in Aeneae Silvii opera omnia (Bassel, 1851).

PIUS III. (Francesco Nani-Todeschini-Picolomini); pope from the 22nd of September to the 18th of October 1503, was born at Siena on the 6th of May 1459. After studying law at Perugia, he was made archbishop of Siena and cardinal-deacon of St Eustachio, when only twenty-two years of age, by his uncle Pius II., who permitted him to assume the name and arms of the Piccolomini. He was employed by subsequent popes in several important legations, as by Paul II. at the diet of Regensburg, and by Sixtus IV. to secure the restoration of ecclesiastical authority in Umbria. He bravely opposed the policy of Alexander VI., and was elected pope, amid the disturbances consequent upon the death of the latter, through the interested influence of Cardinal della Rovere, afterwards Julius II., and was crowned on the 8th of October, 1503. He permitted Cesare Borgia to return to Rome, but promptly took in hand the reform of the curia: Pius was a man of blameless life, and would doubtless have accomplished much had he lived. His successor was Julius II.

PIUS IV. (Giovanni Angelo Medici, or "Medighino"), pope from 1550 to 1555, was born at Milan on the 31st of March 1499, of an obscure family, not related to the Medici of Florence (a claim to such relationship was advanced after Giovanni Angelo had attained to prominence). The fortune of the family was established by an elder brother, Gian Giacomo, who fought his country's battles and was made marquisate of Montemurlo and distinguished himself in the service of the emperor. Giovanni Angelo studied in Bologna and Pavia, and for some time followed the law. Entering the service of the church, he found favour with Paul III., who entrusted him with the governorship of several important towns, and in 1549 made him a cardinal. Julius III. sent him upon missions to Germany and Hungary. With Paul IV. he was out of favour, because not in sympathy with his policy, and accordingly retired to Milan. In the protracted and momentous concile that followed the death of Paul the election of Pius (Dec. 25, 1550) was due to a compromise between the Spanish and French factions.

His temperament and habit Pius was the antithesis of his predecessor: affable, vivacious, convivial. He was, moreover, astute, diplomatic and experienced in affairs. He allowed the reform movement free course, but tried to repair certain injustices of Paul IV. (for example, releasing and reinstating Morone, who had been imprisoned on a charge of heresy), and mitigated some of his extreme decrees. But to the nephews of Paul he showed no mercy: they were charged with various crimes, condemned, upon testimony of suspicious validity, and executed on the 5th of March 1551. The Colonninci, who had been active in the prosecution, recovered Paliano. But under Pius V. judgment was reversed, the memory of the Caraffa rehabilitated, and restitution made to the family. Pius IV. himself was not guiltless of nepotism; but the bestowment of the cardinalate and the archbishopric of Milan upon his nephew, the pure and upright Carlo Borromeo, redounded to the honour of his pontificate and the welfare of the church.

With England lost to the papacy, Germany overwhelmingly Protestant, and France on the verge of civil war, Pius realized how fatal was the anti-Spanish policy of his predecessor. He therefore recognized Ferdinand as emperor, and conciliated Philip II. with extensive ecclesiastical privileges. But subsequently, antagonized by Philip's arrogance, he inclined towards France, and gave troops and money for the war against the Huguenots.
After a suspension of ten years the council of Trent reconvened on the 18th of January 1562. Among the demands presented by the various nations were, the recognition of the equality of the episcopate, communion in both kinds, clerical marriage, and the use of the vernacular in Church services. It required all the pope's subjects to arrive at compliance on one hand, and a decision on the other with the pope on the basis of the Tridentine creed, of which Borromeo, however, he achieved his end. The council was dissolved on the 4th of December 1563, and its decrees and definitions confirmed by the pope (Jan. 26, 1564), who reserved to himself the sole right of interpretation. The decrees were immediately accepted by most of the Catholic states; only tardily, however, and with reservation by France and Spain. Various measures were taken for carrying the decrees into effect: residence was strictly enjoined; plurality of benefices prohibited; the Inquisition resumed, under the presidency of Ghislieri (afterwards Pius V.); a new edition of the Index published (1564); and the "Tridentine creed" promulgated (Nov. 13, 1564).

After the termination of the council Pius indulged his desire for ease and pleasure, to the great offence of the rigorists. A certain fanatic, Benedetto Accolti, brooding over the pope's unworthiness, felt inspired to remove him, but his plot was discovered and punished (1565). Pius fortified Rome, and contributed much to the embellishment of the city—among other works, the church of Sta Maria degli Angeli in the Baths of Diocletian; the Porta Pia; the Villa Pia in the Vatican Gardens; and the Palace of the Conservatori. He died on the 9th of December, and was succeeded by Pius V.,

See Panvinio, continuator of Platina, De vitis pontific. (a contemporary of Pius); Ciacconius, Vita e res gestae summorum pontific. rom. (Rome 1601–1602; also contemporary); T. Müller, Das Konklave Pius IV. (Gotha, 1888; more comprehensive than the title suggests); Ranke, Popes (Eng. trans. Austin), i. 323 seq., 328 seq.; and v. Reumont, Gesch. der Stadt Rom, lii. 2, 534 seq., 730 seq. (T. F. C.).

PIUS V. (Michele Ghislieri), pope from 1566 to 1572, was born on the 27th of January 1504, in the Milanese. At the age of fourteen he became a Dominican monk. His austere life, his vehemence in attacking heresy and his rigorous discipline as prior of several monasteries proved his fitness for the work of reform, and he was appointed inquisitor in Como, where his zeal provoked such opposition as to compel his recall (1559). The chief inquisitor, Caraffa, convinced of his value, straightway sent him upon a mission to Lombardy, and in 1551 appointed him commissary-general of the Holy Office. When Caraffa became pope, Ghislieri was made bishop of Nepi and Sutri, cardinal (1557), and finally grand inquisitor, which office he discharged in a manner to make the name of "Fra Michele dell' Inquisizione" a terror. In this office he was continued by Pius IV., whom, however, he repelled by his excessive severity, and antagonized by his censoriousness and obstinacy. But the movement with which he was so fully identified was irresistible; and, after the death of Pius IV., the rigorists, led by Borromeo, had no difficulty in making him pope (Jan. 7, 1566).

Though pope, Pius did not cease to be a monk: his ascetic mode of life and his devotions suffered no interruption. Without delay he applied himself to the work of reform. Decrees and ordinances were issued with astonishing rapidity; the papal court was rid of everything unseemly, and became a model of sobriety; prostitutes were driven from the city, or confined to a certain quarter; severe penalties were attached to Sunday desecration, profanity and animal baiting; clerical residence was enforced; conventuals were compelled to live in strict seclusion according to their vows; catechetical instruction was enjoined. A new catechism appeared in 1566, followed by an improved breviary (1568), and an improved missal (1570). The use of indulgences and dispensations was restricted, and the penitential system reformed.

Pius was the avowed enemy of nepotism. One nephew, it is true, he made cardinal, but allowed him no influence: the rest of his relatives he kept at a distance. By the constitution Admonet nos (March 29, 1567), he forbade the reinvestiture of fiefs that should revert to the Holy See, and bound the cardinals by oath to observe it. In March 1569 Pius ordered the expulsion of the Jews from the states of the Church. For commercial reasons they were allowed to remain in Rome and Ancona, but only upon humiliating conditions. In February 1571, the Unilatii, a degenerate monastic order of Milan, was dissolved, and the pope issued an infamous decree in complicity in an attempt upon the life of the archbishop, Carlo Borromeo.

The election of Pius to the papacy was the enthronement of the Inquisition: the utter extinction of heresy was his darling ambition, and the possession of power only intensified his passion. The rules governing the Holy Office were sharpened; old charges, long suspended, were revived; rank offered no protection, but rather exposed its possessor to fiercer attack; none were pursued more relentlessly than the cultured, among whom many of the Protestant doctrines had found acceptance; princes and states withdrew their protection, and courted the favour of the Holy See by surrendering distinguished offenders. Cosmo de' Medici handed over Pietro Narbonesi (and two years later received in reward the title of grand duke, Sept. 1569); Venice delivered Guido Zanetti; Philip II., Bartolomé de Carranza, the archbishop of Toledo. In March 1571 the Congregation of the Index was established and greater thoroughness introduced into the pursuit of heretical literature. The result was the flight of hundreds of printers to Switzerland and Germany. Thus heresy was hunted out of Italy: the only regret of Pius was that he had sometimes been too lenient. In 1567 Pius condemned the doctrines of Michael Baius, a professor of Louvain, who taught just the opposite by dint, among other things, of the sufficiency of the Scriptures, and disparaged outward forms. Baius submitted; but his doctrines were afterwards taken up by the Jansenists.

The political activities of Pius were controlled by one principle, war upon the heretic and infidel. He spurred Philip II. on in the Netherlands, and approved the bloody work of Alva. He denounced all temporizing with the Huguenots, and commanded their utter extermination (ad interexionem usque). While it cannot be proven that he was privy to the massacre of St Bartholomew, still his violent counsels could not fail to stir up the most savage passions. He exclaimed loudly against the emperor's toleration of Protestantism, and all but wished his defeat at the hands of the Turks. He urged a general coalition of the Catholic states against the Protestants; and yet published, in sharper form, the bull In coena domini (1568), which was regarded by these very states as an attack upon their sovereignty. One of his cherished schemes was the invasion of England and the dethronement of Elizabeth, whom he excommunicated and declared a usurper (Feb. 25, 1570); but he was obliged to content himself with abetting plots and fomenting rebellions. He did, however, effect an alliance with Spain and Venice against the Turks, and contributed to the victory of Lepanto (Oct. 6, 1571).

Thus lived and wrought Pius, presenting "a strange union of singleness of purpose, magnanimity, austerity and profound religious feeling with sour bigotry, relentless hatred and bloody persecution" (Ranke). He died on the 1st of May 1572; and was canonized by Clement XI. in 1712.

See Ciacconius, Vita e res gestae summorum pontific. rom. (Rome, 1601–1602; a contemporary of Pius); Acta sanctorum, maij, tom. i. pp. 616 seq., containing the life by Gabuzzo (1668), based upon an earlier one by Catena (1566); Fabry, Histo. de St Fie V. (3rd ed., Paris, 1858), eulogistic; Mendham, Life and Pontificate of St Pius V. (London, 1852), a bitter polemic. The life of Pius has also been written by Fuenmayor (Madrid, 1590); Paolo Angeraner Medici (Rome, 1712), and by T. M. Graneto (Bologna, 1877). His letters have been edited by Catena (vide supra), Goubau (Antwerp, 1640), and a select number in a French translation, by de Potter (Paris, 1826). See also the works of M. F. Angler, O. P. History of Pius V. (London); Kranke, Popes (Eng. trans., Austin), i. 561 seq., 834 seq.; and von Reumont, Gesch. der Stadt Rom, lii. 2, 557 seq. (T. F. C.).
skill in the conduct of a mission to the court of Naples won him the esteem of Benedict XIV., who appointed him one of his secretaries and canon of St Peter's. In 1758 he was raised to the prelature, and in 1760 to the treasurership of the apostolic chamber by Clement XIII. Those who chafed under his conscientious economies cunningly induced Clement XIV. to create him cardinal-priest of San Onofrio on the 26th of April 1773, a promotion which rendered him for the time innocuous. In the four months' conclave which followed the death of Clement XIV., Spain, France and Portugal at length dropped their objection to Braschi, who was after all one of the more moderate opponents of the anti-Jesuit policy of the previous pope, and he was elected to the vacant see on the 15th of February 1775. *

* His earlier acts gave fair promise of liberal rule and reform in the defective administration of the papal states. He showed discrimination in his benevolences, reprimanded Potenziani, the governor of Rome, for unsuppressed disorders, appointed a council of cardinals to remedy the state of the finances and relieve the pressure of imposts, called to account Nicolò Bischi for the expenditure of money intended for the purchase of grain, reduced the annual disbursements by the suppression of several pensions, and adopted a system of bounties for the encouragement of agriculture. The circumstances of his election, however, involved him in difficulties from the outset of his pontificate. He had received the support of the ministers of the Crowns and the anti-Jesuit party upon a tacit understanding that he would continue the action of Clement, by whose brief Dominus ac redemptor (1773) the dissolution of the Society of Jesus had been pronounced. On the other hand the zelani, who believed him secretly inclined towards Jesuitism, expected from him some reparation for the alleged wrongs of the previous reign. As a result of these complications Pius was led into a series of half measures which gave little satisfaction to either party: although it is perhaps largely due to him that the order was able to escape shipwreck in White Russia and Silesia; at but one juncture did he even seriously consider its universal re-establishment, namely in 1792, as a bulwark against revolutionary ideas. Besides facing dissatisfaction with this temporizing policy, Pius met with practical protests tending to the limitation of papal authority. To be sure "Febronius," the chief German literary exponent of the old Gallican Ideas, was himself led (not without scandal) to retract; but his positions were adopted in Austria. Here the social and ecclesiastical reforms undertaken by Joseph II. and his successors bore fruit. The confessions of the oath of allegiance, that in the hope of staying them Pius adopted the exceptional course of visiting Vienna in person. He left Rome on the 27th of February 1783, and, though magnificently received by the emperor, his mission proved a fiasco; he was, however, able a few years later to curb those German archbishops who, in 1786 at the Congress at Ems, had shown a tendency towards independence. In Naples difficulties necessitating certain concessions in respect of feudal homage were raised by the minister Tannucci, and more serious disagreements arose with Leopold I. and Scipione de' Ricci, bishop of Pistola and Prato, upon the questions of reform in Tuscany; but Pius did not give way. The conclusion of the Concordat of 1797 between Pistoia and Rome (1786) till nearly eight years had elapsed. At the outbreak of the French Revolution Pius was compelled to see the old Gallican Church suppressed, the pontifical and ecclesiastical possessions in France confiscated and an effigy of himself burnt by the populace at the Palais Royal. The murder of the republican agent, Hugo Bassville, in the streets of Rome (January 1793) gave new ground of offence; the papal court was charged with complicity by the French Convention; and Pius threw in his lot with the league against France. In 1796 Napoleon invaded Italy, defeated the papal troops and occupied Ancona and Loreto. Pius sued for peace, which was granted at Tolentino on the 19th of February 1797; but on the 31st of December of that year, in a riot created by some Italian and French Jacobin revolutionists, General Dufot of the French embassy was killed and a new pretext furnished for invasion. General Berthier marched to Rome, entered it unopposed on the 13th of February 1798, and, proclaiming a republic, demanded of the pope the renunciation of his temporal authority. Upon his refusal he was taken prisoner, and on the 20th of February was escorted from the Vatican to Siena, and thence to the Certosa near Florence. The French declaration of war against Tuscany led to his removal by way of Parma, Piacenza, Turin and Grenoble to the citadel of Valence, where he died six weeks later, on the 29th of August 1799. Pius VII. succeeded him. The name of Pius VI. is associated with many and often unpopular attempts to revive the splendour of Leo X. in the promotion of art and public works—the words "Manifastation Pii VI. P. M." graven in all parts of the city, giving rise amongst his impoverished subjects to such satire as the insertion of a minute loaf in the hands of Pasquin with that inscription beneath it. He is best remembered in connexion with the establishment of the museum of the Vatican, begun at his suggestion by his predecessor, and with an unpractical and expensive attempt to drain the Pontine marshes.

Pius VII. (Luigi Barnaba Chiaramonti), pope from 1800 to 1823, the son of Count Scipione Chiaramonti and the deeply religious Countess Ghini, was born at Cesena on the 14th of August 1740 (not 1742). After studying at Ravenna, at the age of sixteen he entered the Benedictine monastery of St Mary in his native town: here he was known as Gregorio. Almost immediately he was sent by his superiors to Padua and to Rome for a further course of studies in theology. He then held various teaching appointments in the colleges of his order at Parma and at Rome. He was created an abbot of his order by his relative Pius VI., who also appointed him bishop of Tivoli on the 16th of December 1782, and on the 14th of February 1785, because of excellent conduct of office, raised him to the cardinalate and the see of Imola. At the death of Pius VI. the conclave met at Venice on the 30th of November 1799, with the result that Chiaramonti, the candidate of the French cardinal-archbishop Maury, who was most skilfully supported by the secretary of the conclave Ercole Consalvi, was elected pope on the 14th of December. He had held the office of Roman governor of the 21st of that month; in the following July he entered Rome, on the 12th of August appointed Consalvi cardinal-deacon and secretary of state, and busied himself with administrative reforms.

His attention was at once directed to the ecclesiastical anarchy of France, where, apart from the broad schism on the question of submission to the civil constitution of the clergy, discipline had been so far neglected that a large proportion of the churches were closed, dioceses existed without bishops or with more than one; Jansenism and clerical marriage were on the increase, and indiscipline or hostility widely prevailed amongst the people. Encouraged by Napoleon's desire for the re-establishment of the Roman Catholic religion in France, Pius negotiated the celebrated Concordat of 1801, which, by 1907, had been ratified by Pius on the 14th of August 1801 (see Concordat). The importance of this agreement was, however, considerably lessened by the "articles organiques" appended to it by the French government on the 8th of April 1822. In 1804 Napoleon opened negotiations to secure at the pope's hands his formal consecration as emperor. After some hesitation Pius was induced to perform the ceremony at Notre Dame and to extend his visit to Paris for four months; but in return for these favours he was able to obtain from Napoleon merely one or two minor concessions. Pius, who arrived in Rome on the 16th of May 1805, gave to the college of cardinals a rose-coloured report of his experiences; but disillusionment was rapid. Napoleon soon began to disregard Pius, and in 1807, by an edict, decreed the dissolution of the marriage of his brother Jerome with Miss Patterson of Baltimore. The irritation between France and the Vatican increased so rapidly that on the 2nd of February 1808 Rome was
occupied by General Molliès; a month later the provinces of Ancona, Macerata, Fermo and Urbino were united to the kingdom of Italy, and diplomatic relations between Napoleon and Rome were broken off; finally, by a decree issued from Schönbrunn on the 17th of May 1809, the emperor united the papal states to France. Piis retaliated by a bull excommunicating the invaders; and, to prevent insurrection, Molliès—either on his own responsibility, as Napoleon afterwards asserted, or by order of the latter—employed General Radet to take possession of the pope's person. The palace on the Quirinal was broken open during the night of July 5th, and, on the persistent refusal of Piis to rescind the bull of excommunication and to renounce his temporal authority, he was carried off, first to Grenoble, thence after an interval to Savona on the Gulf of Genoa. Here he steadfastly refused canonical institution to the bishop nominated by Napoleon; and, when it was discovered that he was maintaining a secret correspondence, he was deprived of all books, even of pencil and ink. At length, his nerves shattered by insomnia and fever, he was willing to give satisfactory oral assurances as to the institution of the French bishops.

In May 1812, Napoleon, on the pretext that the English might liberate the pope if he were left at Savona, caused the aged and sick pontiff to be transferred to Fontainebleau, where he was placed under arrest. However, at Fontainebleau, he was lodged in a suite of regal magnificence to await the return of the emperor from Moscow. When Napoleon arrived, he entered into personal negotiations with the pope, who on the 25th of January 1813 assented to a concordat so degrading that his conscience found relief till the 24th of March, when, on the advice of the cardinal Pecca and Consalvi, he abrogated it; and on the 9th of May he proceeded to defy the emperor by declaring invalid all the official acts of the new French bishops. In consequence of the battle of Leipzig and the entry of the allied forces into France, Napoleon ordered in January 1814 that the pope be returned to Savona for safe-keeping, and, in protest of this course of conduct, he determined to liberate the pope and give back the States of the Church. On the 19th of March Piis left Savona, and was received with rejoicing at Rome on the 24th of May. While Consalvi at the Congress of Vienna was securing the restitution of nearly all the papal territory, reaction had full swing at Rome; the Jesuits were restored; the French legislation, much of which was of great social value, was repealed; the Index and the Inquisition were revived. On his return Consalvi conducted a more enlightened and highly centralized administration, based largely on the famous st. 1816; nevertheless the finances were in a desperate condition. Discontent centred perhaps in the Council, a Liberal secret society commanded by the Cardinal of Chigi, by the removal of Consalvi with the negotiation of a series of valuable concordats with all the Roman Catholic powers save Austria. In the latter years of Piis's life autumn he came to Rome; the pope was very gracious to exiled kings and showed notable magnanimity toward the family of Napoleon. He also attracted many artists to the city, including the greatest sculptors of the time, one of whom, the Protestant Thorwaldsen, prepared the tomb in which repose the remains of the gentle and courteous pontiff, who passed into rest on the 20th of August 1823. His successor was Leo XII.

Piis VIII. (Francesco Xavier Castiglioni), pope from 1829 to 1830, who came of a notable family at Cingoli near Ancona, was born on the 20th of November 1761. He studied canon law at Rome, became vicar-general at Anagni and later at Fano, and in 1800 was appointed bishop of Montalto. Because he refused the oath of allegiance to the Napoleonic king of Italy he was carried captive to France; but in 1816 his steadfastness was rewarded by his being created cardinal-priest of Sta Maria in Trastevere; and this same year he was translated from the see of Montalto to that of Cesena. In 1821 he was made cardinal-bishop of Frascati, also grand penitentiary; and later he became prefect of the Congregation of the Index. In the conclave which followed the death of Leo XII., Castiglioni, the candidate of France, was elected pope on the 31st of March 1829. He avoided nepotism, abandoned the system of espionage employed by his predecessor, and published an encyclical condemning Bible societies and secret associations. He rejoiced over Catholic emancipation in England, recognized Louis Philippe as king of the French, and exhibited a pacific spirit in dealing with the problem of mixed marriages in Germany. Born out with work, he died on the morning of the 1st of December 1830. His successor was Gregory XVI.

Piis IX. (Vigino Maria Mastai-Ferretti), pope from 1846 to 1878, was born on the 13th of May 1792 at Sinigaglia, the fourth son of Count Jerome and Countess Catherine Vollazzi; the family of Mastai was of ancient descent, and the title of count came to it in the 17th century, while later the elder branch, allied by marriage with the Ferretti family, took that name in addition. He spent some time at the College of Piarists in Volterra, and then proceeded to Rome with the intention of entering the pontifical guard as an officer. In spite of his good connexions, he was disappointed in this aim as it became known that he suffered from epilepsy. The malady, however, was successfully concealed; and in 1819 he was ordained priest. After ministering for some time in his native town, he accompanied Cardinal Muzzi to Chile (1831). On his return he was entrusted by Leo XII. with the direction of the Roman hospital of San Michele: in 1830 he received the archbishopric of Spoleto, in 1832 the bishopric of Imola, and in 1840 Gregory XVI. created him a cardinal, with the title Santi Pietro e Mareccellino.

On the death of Gregory XVI. (June 1, 1846) the College of Cardinals met in conclave on the 14th of June. But their deliberations were destined to last but a short while; for, on the 16th of June, Cardinal Mastai Ferretti had already obtained the requisite two-thirds majority, and ascended the papal chair under the title of Piis IX. In his various capacities he had gained considerable popularity: he had shown himself to be of a kindly disposition and a zealous churchman, and his reputation for piety and tact stood high; he possessed, too, a winning personality and a handsome presence.

The reign of Piis IX. began at an extremely critical time. The problem of the government of the Papal States, transmitted to him by his predecessor, stood in urgent need of solution, for the actual conditions were altogether intolerable. The irritation of the populace had risen to such a pitch that it found vent in revolts which could only be quelled by the intervention of foreign powers; and the ferment in the dominions of the Church was accentuated by the fact that the revolutionary spirit was in the ascendant in all the states of Europe. The proclamation of a papal crusade to aid all political offenders made an excellent impression on the people; and Piis at once instituted preparations for a reform of the administration, the judicature and the financial system. The regulations affecting the censorship were mitigated, and a breath of political liberalism vitalized the whole government. Piis at once acquired the reputation of a reforming pope. But the prestige so gained was not sufficient to calm the people permanently, and two demands were urged with ever increasing energy—a share in the government and a national,
Italian policy. The problem of giving the people a due share in the government was one of peculiar difficulty in the papal states. It was not simply a question of adjusting the claims of monarch and subject: it was necessary, at the same time, to oust the clergy—who, till then, had held all the more important offices in their own hands—from their dominant position, or at least to limit their privileges. That the clerical character of the administration could not be indefinitely retained was plain enough; it would seem, to any clear-thinking statesman: for, since the restoration of the papal state in 1814, the pernicious effects of this confusion of the spiritual and the secular power could no longer be denied. But Pius IX. lacked the courage and perspicacity to draw the inevitable conclusions from these premises; and the higher clergy at Rome were naturally opposed to a policy which, by laicising the administration, would have deprived them of the power and privileges they had so long enjoyed. In these circumstances it is not surprising that the pope, while making concessions to his people, did so with reservations which, so far from restoring peace, served only to aggravate the turmoil.

By a motu proprio of the 2nd of October 1847 the government of the city of Rome was reorganized and vested in a council of 120 members, not more than four of whom were to be clerics. But the pope reserved to himself the right of nominating the first members, and the new senate was only later to have the right of filling up vacancies by co-optation. The institution of a state council (consulata) was announced on the 19th of April 1847; and on the 14th of October it was called into existence by a motu proprio. It consisted of 24 councillors, who were to be selected from the list of candidates to be submitted by the provincial assemblies. A cardinal and one other prelate were to be at its head. The consulta was to be divided into four sections, dealing with (1) legislation, (2) finance, (3) internal administration, (4) the army and public works. Matters of importance were, however, to be submitted to the College of Cardinals, after being debated in the consulta. A motu proprio of the 29th of December altered the constitution of the ministerial council. Nine mutually independent ministries were formed, and the principle of the responsibility of the ministers was established: but all the positions were filled by clerics.

The agitation for constitutional government was urgent in the demand for further concessions; but they came too late. On the 12th of February a proclamation of the pope transferred three powers to the Chamber of Deputies. The executive assembly of the revolution in Paris nullified the effect. At the formation of the Antonelli ministry (March 11), only the three departments of foreign affairs, finance and education, were reserved by the clergy; while the remaining six were entrusted to laymen. On the 14th of March 1848 Pius took the last step, and published a constitution (Fundamental Statute for the Secular Government of the States of the Church). Two chambers were to be formed. The first (alto consiglio) consisted of members nominated for life by the pope; the second, of a hundred elected deputies. The laws adopted by these two chambers had first to undergo the scrutiny of the College of Cardinals, before being submitted to the pope for his assent or rejection. Ecclesiastical, or even more immediately papal, was the veto over any law passed by the Chamber. On the 28th of March, 1849, a decree of the pope gave the Chamber an equal voice with the clergy in the legislative council; but it was further required to abstain from the enactment of laws conflicting with the discipline of the Church, and from criticism of the diplomatic and religious relations of the Holy See with foreign powers.

The utility of this constitution was never tested; for the demand for an extension of popular rights was now eclipsed by a still more passionate aspiration towards the national unity of Italy. This nationalist movement at once took head against Austria. On the 18th of March the revolution broke out in Milan, and King Albert of Sardinia undertook the conduct of the war against the emperor. When news of the events at Milan reached Rome the populace was swept away in a whirlwind of enthusiasm: the Austrian embassy was mobbed; the imperial arms, surrounding the main gate of the palace, were torn down; and great troops of volunteers clamoured to be led against Austria. Pius was carried away at first on the flood-tide of excitement, and seemed, after his proclamation of the 30th of March, on the point of conferring his blessing upon the war against Austria. But the course of political events during the next few weeks damped his ardour. When, on the 29th of April, in his allocation to the cardinals, he proclaimed the papal neutrality, the Romans received his vacillation as a sign of treachery; and the storm, precluded from discharging its fury on Austria, broke over his head. When the ministry in power resigned office on the 1st of May, the Mamiani administration was formed, only one cleric being included. Mamiani himself, whose writings were on the Index, had little sympathy with the pope, and did all that was possible to complete the secularization of government in the States of the Church. He received his dismissal on the 1st of August, and was followed by Count Fabbri, then by Count de Rossi, who made the last attempt to restore order by a moderate liberal policy. On the 15th of November, as he was about to open the Chambers, he was assassinated on the staircase leading to the hall of session. A state of anarchy ensued. Armed bands gathered before the Quirinal, and attempted to storm it. To avoid further bloodshed the pope was compelled to assent to the formation of a radically democratic ministry under Galetti. The Swiss, who composed the papal guard, were disbanded; and the protection of the pontiff was transferred to the civil militia; in other words, Pius IX. was a prisoner. On the evening of the 24th of November he contrived by the aid of the French and Bavarian ambassadors—the duc d'Harcourt and Count Spaur—to leave the palace unobserved, in the dress of a common priest, and to reach Gaeta in the kingdom of Naples. From this refuge he issued a breve on the 27th of November, protesting against the sacrifice practised on himself, declaring all actions forced upon him to be null and void, and appointing the deputation to carry on the government in his absence. Since the Chamber declined to recognize this step, and the pope was equally resolute in refusing to hold any intercourse with the deputation which it despatched to him, a supreme Giunta was provisionally created by the Chamber on the 11th of December to discharge all the functions assigned to the executive power by the constitution. On the 17th of the same month Pius made a public protest; and, as soon as the elections for a national assembly were announced, he forbade any participation in them, menacing the disobedient with the penalties of the Church (Jan. 1, 1849). The elections, however, were held; and on the 9th of February the pope nominated to the Chamber of Deputies three clerics, at the election of a Roman republic. Pius answered by a protest dated the 14th of February. All the ecclesiastical property of the Roman state was now declared to be vested in the republic; convents and religious edifices were requisitioned for secular purposes; benevolent institutions were withdrawn from clerical influence; and church establishments were deprived of the right to realize their possessions. In the beginning of December Pius had already appealed to the European powers for assistance; and on the 7th of February 1849 it was resolved in the Consistory to approach officially France, Austria, Spain and Naples, with a view to their armed intervention. The French republic, under the presidency of Louis Napoleon, was the first state to throw troops into the field; and the immediate result was the fall of Gaeta before Civita Vecchia; only to be defeated at first by Garibaldi. But, after receiving reinforcements, he prosecuted the war successfully, and made his entry into Rome on the 3rd of July; while, in the early part of May an Austrian army advanced into the north of the papal states. On the 14th of July Oudinot proclaimed the restoration of the pontifical dominion; and, three days later, Pius IX. issued a manifesto entrusting the government to a commission appointed by himself. On the 12th of April 1850 Pius returned to Rome, supported by foreign arms, embittered, and hostile henceforward to every form of political liberalism or national sentiment. In Gaeta he had mentally cut himself loose from all ideas of progress, and had thrown himself into the arms of the Jesuits. His subsequent policy was stamped by reaction. Whether it might have been possible to avoid the catastrophe of 1848 is a difficult question. But there can be no question whatever that the policy which
PIUS (POPE) 689

Pius now inaugurated, of restoring the old pre-revolutionary conditions, sealed the fate of the temporal dominion of the papacy. He made no attempt to regain the estranged affections of the populace, and took no measures to liberate himself and his subjects from the incubus of the last few years. He even sought to exact vengeance for the events of that period: the state officials, who had compromised themselves, lost their offices; and all grants in aid were forfeited if the recipients were discovered by the secret commissions (consigli di censura) to have taken part in the revolutionary movement. The tribunals extorted declarations on the part of witnesses by floggings, deprivation of food, and like methods of torture. In many cases the death sentence was executed at their instance, though the guilt of the accused was never established. The system of precautionary arrest, as it was termed, rendered it possible for any man to be thrown into prison, without trial and without verdict, simply on the ground that he lay under suspicion of plotting against the government. The priests, who usurped the judicial function, displayed such cruelty on several occasions that officers of the Austrian army were compelled to record a protest. The consequence of these methods was that every victim—innocent or guilty—ranked as a martyr in the estimation of his fellow-citizens. A subsidiary result was the revival of brigandage, which found a suspicious degree of support among the people. Corruption was rampant among the officials; the police were accused of illicit bargaining with criminals; and nothing but contempt was entertained for the papal army, which was recruited from the dregs of humanity. To this was added a diestrous financial administration, under which the efficiency and credit of the country sank to appalling depths. The system of taxation was calculated with a view to relieving the Church and the clergy, and imposing the main burden upon the laity. In this department the family of Cardinal Antonelli seems to have played a fatal part. The secretary of state was born in humble circumstances: when he died he left a fortune of more than 100,000,000 lire, to which a daughter succeeded in establishing herself. His brother Felippo was president of the Roman Bank, and his brother Luigi the head of the Annona—an office created to regulate the import of grain. The pope himself had neither the will nor the power to institute searching financial reforms; possibly, also, he was ignorant of the facts.

The mismanagement which obtained in the papal dominions could not escape the observation of the other powers. As early as the Congress of Paris in 1856 the English ambassador, Lord Clarendon, had directed an annihilating criticism against the government of the pontiff; and a convincing proof of the justice of his verdict was given by Pius himself, in his treatment of the famous Mortara case. A Jewish boy of eighteen was taken from his parents in Rome and the rite of baptism performed on him without their knowledge or consent. The pope flatly refused to restore the "Christian" to his Jewish parents, and turned a deaf ear both to the protest of public opinion and the diplomatic representations of France and England. The sequel to this mode of government was that the growing embitterment of the subjects of the Church came to be sympathized with outside the bounds of Italy, and the question whether the secular authority of the papacy could be allowed to continue became a much-debated problem. Even the expression of the doubt was symptomatic. In 1859 appeared an anonymous brochure, Le Pape et le congrès, composed by Laguerremonie, the friend of Napoleon III., in which it was proposed, to ensure the pope "un reveu considérable" and the city of Rome, but to relieve him of a political task to which he was not competent. In 1861 another anonymous pamphlet, Pro causa italica ad episcopos catholicos, was published in Florence, advocating the ecclesiastico-political programme of Cavour; and the pope was horrified when he discovered that it came from the pen of Passaglia, the professor of dogmatic theology. In spite of all, the national idea gained strength in Italy, and the movement towards unity found powerful champions in King Victor Emmanuel of Sardinia and his great statesman Cavour. Free scope was given when the understanding between the two powers protecting the papal state—France and Austria—broke down. So soon as Napoleon and Cavour had come to an agreement war ensued, France and Sardinia being ranged against Austria (1859). The result was that Austria lost the greater part of her Italian possessions, while the pope also forfeited two-thirds of his dominions. By the war of 1866, in which Italy fought on the Prussian side, Victor Emmanuel gained Venice in addition; so that the States of the Church now formed the last remaining obstacle to complete national unity. In September 1864, France—who had been the protectress of these states since 1849—had concluded a treaty with Victor Emmanuel, undertaking to withdraw her garrison from Rome in two years time; while, on his part, the king agreed to abstain from any attack on the papal dominions, and to guarantee the safety of the pope and the patria potestas. The emperor Napoleon had, in point of fact, recalled his troops in 1866; but in 1867, when Garibaldi crossed the frontiers of the papal state at the head of his volunteers, he declared the treaty violated and again threw his regiments into Rome. Three years later the time came when he could employ his arms more advantageously elsewhere, and after the outbreak of the war with Germany Rome was evacuated. The news that the French Empire had fallen produced an electoral effect in Italy: the Italian parliament called on the king to occupy Rome; on the 8th of September Victor Emmanuel crossed the borders; and on the 20th of September the green-white-and-red of the tricolour floated over the Capitol. The protests of Pius IX. remained unheeded, and his attempts to secure another foreign intervention met with no success. On the 2nd of October Victor Emmanuel instituted a plebiscite in Rome and the possessions of the Church to decide the question of annexation. The result of the suffrage was that 153,681 votes were given in favour of union with Italy, and 1,027 against the proposed incorporation: that is to say only the direct dependants of the Vatican were opposed to the change. The papal state was now merged in the kingdom of Italy, which proceeded to define its diplomatic relations with the Holy See by the law of the 19th of May 1871 (see ITALY: History).

In his capacity as head of the Church, Pius IX. adhered to the principles of the Ultramontanist party, and contributed materially to the victory of that cause. The political reaction which followed the revolutionary era in most quarters of Europe offered a favourite soil for his efforts; and in several countries he found it possible to regulate the relations between Church and state from the standpoint of the curia. In 1851 he concluded a concordat with Queen Isabella II. of Spain, proclaiming Roman Catholicism the sole religion of the Spanish people, to the exclusion of every other creed (art. 1); and we find the papacy in another concordat with the South American republic of Ecuador (1862). A third concordat, negotiated with the emperor Francis Joseph I. of Austria (1855), entrusted the supervision of schools and the censorship of literature to the clergy, recognized the canon law, and repealed all secular legislation conflicting with it. France came into line with the wishes of the pope in every respect, as Napoleon needed clerical support in his political designs. Even in Germany he found no resistance; on the contrary, he was able to secure advantageous compacts from individual states (Hesse, 1854; Württemberg, 1857). In fact, the growing tendency to romanize Catholicism—to bring it, that is to say, into close connexion with Rome, and to a state of dependency on the guidance and instructions of the curia—made special progress in Germany.

Among the most important acts of Pius IX. must be counted his proclamation of the dogma of the Immaculate Conception of the Virgin Mary, by the bull Ineffabilis Deus, on the 8th of December 1854. In this bull the preservation of Mary from every stain of hereditary sin, in the first moment of her conception, was declared to be a divinely revealed truth, which consequently demanded universal acceptance (see IMMATURE CONCEPTION). By this means a view, which till then had been no more than a pious belief, was elevated into a dogma to be held de fide; though grave doubts on the subject had always been entertained, even in the midst of the Church itself. For the inner life of that
Church this solution of the controversy was of great significance, and created a desire for further dogmatic decisions on the Virgin Mary—her resurrection and ascession. But the procedure of Pius IX. proved of far-reaching importance from another point of view. True, he had taken the opinion of the bishops on the subject, and had received the assent of a large majority; none the less, the verdict was pronounced by himself alone, not by an ecumenical council. Thus by arrogating the function formerly exercised by the ecumenical council, he virtually laid claim to the infallibility which had always been regarded as inherent only in the doctrinal pronouncements of such a council: in other words, he availed himself of a privilege not accorded to him till the 18th of July 1870.

Though the Marian dogma of 1854 received, with very few exceptions, an enthusiastic welcome in Roman Catholic circles, another measure of the pope, ten years later, excited a painful sensation even among the orthodox members of the Church. As reigning sovereign of the papal states Pius IX. had passed through a "liberal period": as head of the Church, he had never been liable to attacks of liberalism. Nevertheless, his return from exile left its mark on his spiritual administration. From this period onwards he deliberately and stubbornly set his face against the influence of modernism on ecclesiastical life; showed his displeasure at and distrust of the scientific theology and philosophy which marked a modern advance (Günther, Frohschammer and Döllinger); and, entrenched in the stronghold of medieval ideals, combated the transformations of the new order of society, and the changes in the relationship between Church and state, which obtained in most countries of Europe since the French Revolution. After long and careful consultation, the adverse criticisms which he had expressed on various occasions were published on the 8th of December 1864, together with the encyclical Quanta cura, under the title Syllabus declarations praecipuas nostrae aetatis errores (see Syllabus). In this Pius claimed for the Church the control of all culture and all science, and of the whole educational system. He rejected the liberty of faith, conscience and worship enjoyed by other creeds; and bade an easy farewell to the idea of tolerance. He claimed the complete independence of the Church from state control; upheld the necessity of a continuance of the temporal power of the Roman See; and finally, in the last clause, declared that "the pontiff neither can be nor ought to be reconciled with progress, liberalism and modern civilization." The publication of this syllabus created a profound impression: for it declared war on modern society, and committed the papacy to the principles of Ultramontanism (q.v.). But, as any attempt to translate its precepts into practice would entail a disastrous conflict with the existing régime as established by the Concordat of 1817, the pope had frequently shown a tendency to belittle the significance of the manifesto and to deny that its rules are absolutely binding.

But these well-meant explanations, however comprehensible, are refuted by the unequivocal pronouncements of Pius IX., Leo XIII., and many recognized ecclesiastical authorities—e.g. Cardinal Manning, archbishop of Westminster, who described the syllabus as an emanation from the highest doctrinal authority in the Church.

The zenith of Pius's pontificate was attained on the 18th of July 1870 when the Vatican council proclaimed the infallibility of the pope and the universality of his episcopate, thus elevating him to a pinnacle which none of his predecessors had reached and at the same time fulfilling his dearest wish. That, personally, he laid great stress on the acceptance of the dogma, was a fact which he did not attempt to conceal during the long preliminary deliberations of the council; and his attitude was a not incon siderable factor in determining its final resolutions. But the loss of the papal states, immediately afterwards, was a blow from which he never recovered. Whenever he brought himself to speak of the subject—and it was not rarely—he repeated his protest in the bitterest terms, and, to the end of his days, refused to be reconciled with the "sacrosanct" king of Italy. When, in Germany, the situation created by the Vatican council led to the outbreak of the Kulturkampf, Pius IX. failed to display the tact peculiar to his successor. For, in the encyclical Quod quadam (Feb. 5, 1875), he took the rash step of declaring invalid the Prussian laws regulating the relationship between Church and state—the only result being that the feud was still further embittered.

In these later years the dark days of his "captivity" were amply compensated by the proofs of reverence displayed by Roman Catholic Christianity, which accorded him magnificent ovations as his period of jubilee began to fall due. The twenty-fifth anniversary of his pontificate was celebrated with great splendour on the 20th of June 1871; for he was the first pope who had thus reached the traditional "years of Peter." In 1872 his 80th birthday gave occasion for new demonstrations; and 1875 was a so-called "year of jubilee." Finally, in 1877, the fifty years of his priesthood were completed: an event which brought him innumerable expressions of loyalty and led to a great manifestation of devotion to the Holy See from all the Roman Catholic world. On the 7th of February 1878 Pius IX. died. His successor was Leo XIII.
under Alonzo de Ojeda, by whom he was entrusted with the charge of the unfortunate settlement at San Sebastian. He accompanied Balboa (whom he afterwards helped to bring to the block) in the discovery of the Pacific; and under Pedrarías d'Avila he received a repartimiento, and became a cattle-farmer at Panama. Here in 1522 he entered into a partnership with a priest named Hernando de Luque, and a soldier named Diego de Almagro, for purposes of exploration and conquest towards the south. Pizarro, Almagro and Luque afterwards renewed their compact in a more solemn and explicit manner, agreeing to conquer and divide equally among themselves the opulent empire they hoped to reach. Explorations were then undertaken down the west coast of South America, in which Pizarro, though left for months with but thirteen followers on a small island without ship or stores, persisted till he had coasted as far as about 9° S. and obtained distinct accounts of the Peruvian Empire. The governor of Panama showing little disposition to encourage the adventurers, Pizarro resolved to apply to the sovereign in person for help, and with this object sailed from Panama for Spain in the spring of 1528, reaching Seville in early summer. Charles V. was won over, and on the 26th of July 1529 was executed at Toledo the famous capitulation, by which Pizarro was upon certain conditions made governor and captain-general of the province of New Castile for the distance of 500 leagues along the newly discovered coast, and invested with all the authority and prerogatives of a viceroy, his associates being left in wholly secondary positions. One of the conditions of the grant was that within six months Pizarro should raise a sufficiently equipped force of two hundred and fifty men, of whom one hundred might be drawn from the colonies; as he could not make up his due complement he sailed clandestinely from San Lucar in January 1530. He was afterwards joined by his brother Hernando with the remaining vessels, and when the expedition left Panama in January of the following year it numbered three ships, one hundred and eighty men, and twenty-seven horses. The subsequent movements of Pizarro, belong to the history of Peru (p. 6). After the final effort of the Incas to recover Cuzco in 1536-37 had been defeated by Diego de Almagro, a dispute occurred between Pizarro and Almagro respecting the limits of their jurisdiction. This led to battle; Almagro was defeated (1538) and executed; but his supporters conspired, and assassinated Pizarro on the 26th of June 1541.

PIZZICATO (from Ital. picare, to pluck or twitch), a term in music for a direction to the players of stringed instruments, that the passage so marked is to be played by plucking the strings with the fingers instead of using the bow.

PIZZICATO—PLACENTA

From A. H. Young and A. Robinson, in Cunningham's Text-Book of Anatomy. Fig 1.—Diagram representing a very young human ovum almost immediately after its entrance into the decidua, and whilst the place of its entrance is still covered with a plug of fibrin. The ectoderm has already proliferated and embraced spaces which contain maternal blood and are continuous with the maternal blood-vessels.

It is the decidua basalis which is specially interesting in considering the formation of the placenta. That part which is nearest the ovum is called the "stratum compactum," but further away the uterine glands dilate and give a spongy appearance to the mucous membrane which earns this particular layer the name of "stratum spongiosum." Processes grow out from the surface of the ovum which penetrate the stratum compactum of the decidua basalis and capsularis and push their way into the enlarged maternal blood sinuses; these are the "chorionic villi." Later, the "allantoic" or "abdominal stalk" grows from the mesoderm of the hind end of the embryo into the chorionic villi which enter the decidua capsularis, and in this blood-vessels pass which push their way into the maternal blood sinuses. Eventually the original walls of these sinuses, together with the false amnion, disappear, and nothing now separates the maternal from the foetal blood except the delicate walls of the foetal vessels covered by some nucleated noncellular tissue, known as syncytiotrophoblast, derived from the chorionic epithelium, so that the embryo is able to take its supply of oxygen and materials for growth from the mother and to give up carbonic acid and excretory matters. It is the gradual enlargement of the chorionic villi in the decidua basalis together with the interstitial maternal blood sinuses that forms the placenta; the decidua capsularis and vera eventually become pressed
PLAGIARISM—PLAGIOCLASE

PLAGIARISM, an appropriation or copying from the work of another, in literature or art, and the passing off of the same as original or without acknowledgment of the real authorship or source. The Lat. plagiarius meant a kidnapper, stealer or abductor of a slave or child, though it is also used in the modern sense of a literary piller or purloiner by Martial (I. 53, 9). The word plagius is used in the Digest of the offence of kidnapping or abduction, and the ultimate source is probably to be found in plego, to lead, to trap, cognate with Gr. πληγόμενον, a hurt, a plait. The idea of plagius is very comprehensively broader and has grown up with the increasing sense of property in works of the intellect. (See COPYRIGHT.)

PLAGOCLASE, an important group of rock-forming minerals, consisting of an isomorphous series between albite, or soda-felspar and anorthite, or lime-felspar. Intermediate members are thus soda-lime-felspars, which in their crystallographical, optical and other physical characters vary progressively with the chemical composition between the two extremes albite (NaAlSi3O8) and anorthite (CaAl2Si2O8). This variation is continuous in the series, but specific names are applied to members falling between certain arbitrary limits, viz.: Albite, Ab (=NaAlSi3O8); Oligoclase, AbAn to AbAn; Andesine, AbAn to AbAn; Labradorite, AbAn to AbAn; Bytownite, AbAn to AbAn; Anorthite, An (=CaAl2Si2O8).

All these plagioclase minerals are monoclinic, or anorhonic (triclinic) system. They possess a perfect cleavage parallel to the basal pinacoid P (001) and a somewhat less pronounced cleavage parallel to the pinacoid M (010). The angle between these two cleavages varies from 86° 24' in albite to 85° 40' in anorthite. It was on account of the oblique angle between the cleavages that A. Breithaupt in 1847 gave the name plagio-clase (Gr. πλαγιός, oblique, and κλαίειν, to cleave) to these felspars, to distinguish them from the orthoclasie felspar in which the corresponding cleavage angle is a right angle. It should be noted that the potash— and potash-soda-felspars, microcline (KAlSi3O8) an anorhonic, though also anorhonic, are not included in the plagioclase series of soda-lime-felspars. Crystals are
usually tabular in habit, parallel to the plane \( M \), as shown in the accompanying figure; sometimes, however, they are flattened parallel to \( P \), this being a characteristic habit of the pegmatitic variety of albite; microlite crystals forming the ground-mass of volcanic rocks are usually elongated in the direction of the edge between \( P \) and \( M \).

Twining is an important character, which is almost invariably present and affords a ready means of distinguishing the plagioclase feldspars from other feldspars. Most frequent is the twinning according to the \( 1-10 \) law with \( M \) as twin-plane. One half of the twin is turned through 180° about the normal to this plane and the two portions are united along the same plane (for figures of twinned crystals see Albitre). The basal planes of the two portions are inclined to each other at a salient or re-entrant angle of 2° 12' in albite and 8° 20' in anorthite. This twinning is usually polysynthetic, being many times repeated, and giving rise to numerous thin lamellae, which are the cause of the fine striations on the cleavage planes \( P \) and parallel to the edge \( PM \), so characteristic of the plagioclases as seen in hand specimen. Viewed in polarized light, thin sections of twinned crystals show a very characteristic banded structure parallel to \( M \). A second twin-law is known as the "pericline-law" because of its frequent occurrence in the axis of the crystal (the crystallographic axis \( b \) ) and the plane of composition is the \( 1-10 \) rhombic section; the latter is a plane which intersects the prism faces \( T \) and \( L \) in a rhomb; it is a plane of orientation of the crystal and varies with different species. In addition to being twinned according to these two laws, plagioclase may also be twinned on the Carlsbad-, Baveno- and Manebach-laws, as in orthoclase (\( q.v. \)).

The optical characters of the plagioclases have been the subject of much study, since they are of great value in determining the constituents of rocks in thin sections under the microscope. The mean indices of refraction and the angles of extinction on the cleavages \( P \) and \( PM \) are given in the accompanying table; the differences are not very great. The meaning of the + and - directions will be seen from the figure, where the face \( P \) slopes from left to right, i.e. the angle between the normals to the faces lettered \( P \) and \( M \) is less than 90°. The extinction angles on other faces, or in sections of known orientation in the crystal, also give constants of determinative value: for example, in sections perpendicular to the plane \( M \) the extensions in crystals twinned according to the albite-law are symmetrical with respect to this plane, and the maximum value given in the table. Not only do the directions of extinction (axes of light-elasticity) vary in the different species, but also the optic axis angle, so that while albite is optically positive, anorthite is negative, and a member near andesine has an axial angle of 90°. The figures seen in convergent polarized light through the \( P \) and \( PM \) cleavages are characteristic of the different species. A detailed summary of the optical characters and their employment in determining the several members of the plagioclase group is given by H. Rosenbusch, "Ausblickspische Physiographie der Mineralien und Gesteine" (4th ed., Stuttgart, 1905).

The plagioclases occur as primary constituents of igneous rocks of almost every kind, and are also are frequent as secondary minerals in the various acid rocks. Albite and oligoclase are more characteristic of acidic rocks, while the basic members at the anorthite end of the series are characteristic of rocks containing less silica. The composition may, however, vary from the extreme end members of the plagioclase group, as shown by H. Rosenbusch, "Ausblickspische Physiographie der Mineralien und Gesteine" (4th ed., Stuttgart, 1905).

For further particulars respecting individual species and their modes of occurrence see: ALBITE; ANDESINE; ANORTHITE; BYOTTITE; LABRADORITE; OLIGOCLEAS.

PLAGUE (in Gr. λόγος; in Lat. pestis, pestilentia), in medicine, a term given to an epidemic disease causing a great mortality, and used in this sense by Galen and the ancient medical writers, but now confined to a special disease, otherwise called Oriental, Levantine, or Bubonic Plague, which may be shortly defined as a specific infectious fever, one variety being characterized by buboes (glandular swellings) and carbuncles. This definition excludes many of the celebrated pestilences recorded in history—such as the plague of Athens, described by Thucydides; that not less celebrated one which occurred in the reign of Marcus Aurelius and spread over nearly the whole of the Roman world (A.D. 165-180), which is referred to, though not fully described, by the contemporary pen of Galen; and that of the 3rd century (about 253), the symptoms of which are known from the allusions of St Cyprian (Sermo de mortalitate). There is a certain resemblance between all these, but they were very different from Oriental plague. "Plague" was formerly divided into two chief varieties: (1) mild plague, pestis minor, viral plague (Radcliffe), pestis fruste, in which the special symptoms are accompanied by hiccough or general disturbance; and (2) ordinary epidemic or severe plague, pestis major, in which the general disturbance is very severe. Cases which are rapidly fatal from the general disturbance without marked local symptoms have been distinguished as fulminant plague (pestis siderans, pestis foudroyante).

History up to 1880.—The first historical notice of the plague is contained in a fragment of the physician Rufus of Ephesus, who lived in the time of Trajan, preserved in the Collections of Oríbasius.2 Rufus speaks of the buboes called pestilential as being specially fatal, and as being found chiefly in Libya, Egypt and Syria. He refers to the testimony of a physician, Dionysius, who lived probably in the 3rd century B.C. or earlier, and to Dioscorides and Posidonius, who fully described these buboes in a work on the plague which prevailed in Libya in their time. Whatever the precise date of these physicians may have been, this passage shows the antiquity of the plague in northern Africa, which for centuries was considered as its home. The great plague referred to by Livy (lx. Epitome) and more fully by Orosius (Histor. iv. 11) was probably the same, though the symptoms are not recorded. It is reported to have destroyed a million of persons in Africa, but is not stated to have passed into Europe.

It is not till the 6th century of our era, in the reign of Justinian, that we find bubonic plague in Europe, as a part of the great cycle of pestilence, accompanied by extraordinary natural phenomena, which lasted fifty years, and is described with a singular misunderstanding of medical terms by Gibbon in his forty-third chapter. The descriptions of the contemporary writers Procopius, Evagrius and Gregory of Tours are quite unmistakable.2 The plague of Justinian began at Pelusium in Egypt in A.D. 542; it spread over Egypt, and in the same or the next year passed to Constantinople, where it carried off 10,000 persons in one day, with all the symptoms of bubonic plague. It appeared in Gaul in 546, where it is described by Gregory of Tours with the same symptoms as lues inguinaria (from the frequent seat of buboes in the groin). In Italy there was a great mortality in 545, which the most notable epidemic was in 557, which so depopulated the country as to leave it an easy prey to the Lombards. In 571 it is again recorded in Liguria, a

and in 590 a great epidemic at Rome is connected with the pontificate of Gregory the Great. But it spread in fact over the whole of Italy, as well as reaching the towns and radiating inland. In another direction it extended from Egypt along the north coast of Africa. Whether the numerous pestilences recorded in the 7th century were the plague cannot now be said; but it is possible that the pestilences in England chronicled by Bede in the years 604, 612, 679 and 683 may have been of this disease, especially in 660 pestis insignaria is again recorded in Rome. For the epidemics of the succeeding centuries we must refer to more detailed works.

It is impossible, however, to pass over the great cycle of epidemics in the 14th century known as the Black Death. Whether in all the pestilences known by that appellation one really admet of doubt, but it is clear that in some at least it was the bubonic plague. Contemporary observers agree that the disease was introduced from the East; and one eyewitness, Gabriel de Mussis, an Italian lawyer, traced, or indeed accompanied, the march of the plague from the Crimea (whither it is said to have been introduced from Tartary) to Genoa, where with a handful of survivors of a Genoese expedition he landed probably at the end of the year 1347. He narrates how the few that had themselves escaped the pest transmitted the contagion to all they met. Other accounts, especially old Russian chronicles, place the origin of the disease in the Far East; but there is an ancient Oriental theory (Lersch, from old chronicles), France and Spain, were ravaged by a plague supposed to have arisen in Asia, scarcely less destructive than the black death. England was probably seldom quite free from bubonic plague, but the mortality was less in the following years. In 1466, 40,000 persons died of plague in Paris; in 1477-1485 the cities of northern Italy were devastated, and in 1485 Brussels. In the fifteenth century of Henry VII. (1499-1500) a scourge fell in London, to which city we must refer.

The 16th century was not more free from plague than the 15th. Simultaneously with a terrible pestilence which is reported to have decimated the population of China, plague prevailed over Germany, Holland, Italy and France, and again revived at various times in the first half. In 1529 there was plague in Edinburgh; in London in 1537-1539, and again 1547-1548; and also in a search of England, though probably not absent before. Some of the epidemics of this period in Italy and Germany are known by the accounts of eminent physicians, as Vechs, Fracastorius, Mercurialis, Guglielmo Bartoli, Everhard Roon, etc. whose writings are important because the question of contagion first began to be raised, and also plague had to be distinguished from typhus fever, which began in this century to appear in Europe.

The epidemic of 1553-1564 in London and England was very severe. It spread almost simultaneously through London, Oxford, Cambridge, and York, and in the county of Kent. In London the first time plague was an everyday occurrence, of which some were less afraid than of a headache (Borgarutius). In 1570, 200,000 persons died in Moscow and the neighbourhood, in 1572, 50,000 at Lyons; in 1576, 5000 at Edinburgh, and in 1579 at Antwerp.

When, however, in 1575 a new wave of plague passed over Europe, its origin was referred to Constantinople, whence it was said to have spread by sea to Malta, Sicily and Italy, and by land through the Austrian territory to Germany. Others considered that the disease originated locally; and, indeed, considering previous history, no importation of plague would seem necessary to explain its presence in Europe. Italy suffered severely (Venice, in 1579, 90,000; North Europe dot less, though later; London in 1580-1582. In 1585 Brussels was visited by the most destructive plague known in its history. The great epidemic of 1592 in London seems to have been a part of the same epidemic, which was hardly extinguished by the end of the century, and is noted in London again in 1599. On the whole, this century shows a decrease of plague in Europe.

The second half of the 17th century was still prevalent in Europe, though considerably less so than in the middle ages. In the second half a still greater decline is observable, and by the third quarter the disease had disappeared or was disappearing from a great part of western Europe. The epidemics in England will be most conveniently considered in one series. From this time

1 See Hecker, "Epidemic plagues, especially in 1347-1349, at Venice, 1529, 1547-1548, and 1571-1572; Barbi, "Epidemics in the Middle Ages," trans., by Babington, Sydenham Soc. (London, 1834); Volksmedizin des Mittelalters, ed. Hirsch (Berlin, 1865); R. Hoevener, Der schwere Tod in Deutschland (Berlin, 1882).

The works of English physicians of this period are of little medical value; but Lodge’s "Treatise of the Plague" (London, 1603) deserves mention.
onwards we have the guidance of the "Bills of Mortality" issued in London, which, though drawn up on the evidence of ignorant persons, are doubtless roughly true. The accession of James I. in 1603 brought the great epidemic destruction in London which is known as the Plague of 1665.

In this and subsequent years the disease was widely diffused in England—for instance, Oxford, Derbyshire, Newcastle. It prevailed at the same time in Holland, and had done so some years previously in the northern Germany. In the same year (1663) one million persons are said to have died of plague in Egypt. This plague is said to have lasted eight years in London. At all events in 1665 we have the first great epidemic, with a total of 115,785. After this there is a remission till about 1670, when plague, again began to spread in northern Europe, especially Germany and Holland, and which at that time ravaged by war. In 1625 (the first great epidemic in Holland) was the third great London plague with 35,417 deaths—though the year 1624 was remarkably exempt, and 1626 nearly so. In 1630 was the great plague of Milan, described by Ripamonti. In 1632 a severe epidemic, apparently from Rotterdam, reached Derwentwater and here was the fourth great plague year in London with a mortality of 10,400, and even in the next year 3082 persons died of the same disease. The same year 7000 out of 20,000 inhabitants of Newcastle died of plague in 1635 it was at Hull. About the same time, 1633-1637, plague prevalent in Holland, and the epidemic of Nijmegen is celebrated as having been described by Diemerbroeck, whose work _Tractatus de peste, 4to, 1641-1665_ is one of the most important on the subject. The English epidemic was widely spread and lasted till 1647, in which year, the mortality amounting to 3997, we have the fifth epidemic in London. The army diseases of the Civil Wars were chiefly smallpox fever, though the latter was not so numerous among them, as at Wallingford Castle (Willis, _Of Fevers, Works_, ed. 1681, p. 131) and Dunscar Castle. From this time till 1664 little was heard of plague in England, though it did not cease on the Continent. In Ireland it is said to have been seen for the last time in 1657.

In 1665 one of the most destructive of all recorded epidemics in Europe raged in Naples; it is said to have carried off 300,000 persons in the space of five months. It passed to Rome, but there was much less fatal, making 14,000 victims only—a result attributed by some to the precautions and sanitary measures introduced by Cardinal Castaldi, whose work, a splendid folio, was published on this occasion (_Tractatus de avertendi et profugando peste politico-legalis_, Bologna, 1684) is historically one of the most important on the subject of quarantine, &c. Genoa lost 60,000 inhabitants from plague, which was introduced by tradesmen which was comparatively limited spread of this frightful epidemic in Italy at this time is a most noteworthy fact. Minorca is said to have been depopulated. Nevertheless the epidemic spread in the next few years over Spain and Germany, and a little later to Holland, where Amsterdam in 1663-1664 was again ravaged with a mortality given as 50,000, also Rotterdam and Haarlem. Hamburg suffered in 1664.

**The Great Plague of London.**—The preceding enumeration will have prepared the reader to view the great plague of 1665-66 in its true relation to others, and not as an isolated phenomenon. The preceding years had been unusually free from plague, and it was not mentioned in the bills of mortality till in 1665 the first of these isolated cases were observed in the parishes of St. Giles and St. Martin's, Westminster, and a few occurred in the following winter, which was very severe. About May 1665 the disease again became noticeable, and spread, but somewhat slowly. Boghurst, a contemporary doctor, notices that it crept down Holborn and took six months to travel from the western suburbs (St Giles) to the eastern (Stepney) through the city. The mortality rapidly rose from 45 in May to 590 in June, 6137 in July, 17,036 in August, 31,159 in September, after which it began to decline. The total number of deaths from plague in that year, according to the bills of mortality, was 68,506. In a population estimated at 460,000 this mortality of about 15 per cent. is supposed to have fled to escape the contagion. This number is likely to be rather too low than too high, since of the 6432 deaths from spotted fever many were probably really from plague, though not declared so to avoid painful restrictions. In December there was a sudden fall in the mortality which continued through the winter; but in 1666 nearly 2000 deaths were recorded.

According to some authorities, especially Boghurst, the plague was imported into London by bales of merchandise from Holland, which came originally from the Levant; according to others it was introduced by Dutch prisoners of war; but Boghurst regarded it as of local origin. It is in favour of the theory that it spread by some means from Holland that plague had been all but extinct in London for some seventeen years, and prevailed in Holland in 1663-1664. But from its past history and local conditions, London might well be deemed capable of producing such an epidemic. In the bills of mortality since 1663 there are only three years when no deaths from plague are recorded. The uncleanliness of the city was comparable to that of the cities at the present day, and, according to contemporary testimony (Garenqeiros, _Angliae flagellum_, London, 1647, p. 85), little improved since Erasmus wrote his well-known description. The spread of the disease only partially supported the doctrine of contagion, as Boghurst says: "The disease spread not altogether by contagion at first, nor began only at one place and spread further and further as an eating sore doth all over the body, but fell upon several places of city and suburbs like rain." In fact dissemination seems to have taken place, as usual, by the conversion of one house after another into a focus of infection, particularly by the fatal custom of shutting up infected houses with all their furniture and goods, so almost equivalent to a sentence of death on all therein, but caused a dangerous concentration of the poison. The well-known custom of marking such houses with a red cross and the legend "God have mercy upon us!" was no new thing: it is found in a proclamation in the possession of the present writer dated 1641; and it was probably older still. Boghurst testifies to the futility and injurious effects of these regulations. The lord mayor and magistrates not only carried out the appointed administrative measures, but looked to the cleanliness of the city and the relief of the poor, so that there was little or no actual want; and the burial arrangements appear to have been well attended to. The college of physicians, by royal command, put forth such advice and prescriptions as were thought best for the emergency. But it is clear that neither these measures nor medical treatment had any effect in checking the disease. Early in November with colder weather it began to decline; and in December there was so little fear of contagion that those who had left the city "crowded back as thick as they fell." As has often been observed in other plague epidemics, sound people could enter infected houses and even sleep in the beds of those who had died of the plague before they were even cold or cleansed from the stench of the disease (Hogdes). The sympathy of those who have had the observed need not be here considered. The disease was, as always, most destructive in squalid, dirty neighbourhoods and among the poor, so as to be called the "poor's plague." Those who lived in the town in barges or ships did not take the disease; and the houses on London Bridge were but little affected. Of those doctors who remained in the city some eight or nine died, not a large proportion. Some had the rare courage to investigate the mysterious disease by dissecting the bodies of the dead. Hogdes implies that he did so, though he left no full account of his observations. Dr. George Thomson, a chemist and a disciple of Van Helmont, followed the example, and nearly lost his life by an accident which immediately followed the operation of opening the body. The plague of 1665 was widely spread over England, and was

2. For this period see Index to Remembrancie in _Archives of City of London_ 1570-1663 (London, 1878); Richardson, _Plague and Pestilence in North of England_ (Newcastle, 1859).
PLAGUE generally regarded as having been transmitted from London, as it appeared mostly later than in the metropolis, and in many cases the importation by a particular person could be traced. Places near London were likewise affected, as French and German ships, which arrived there before August 1665, were accounted the cause of the disease. Though cases were reported in the East Indies in December 1664 and in New York in March 1665, it was not until 1667 that it reached New England, and was attributed to cleanliness and good drainage. When it finally disappeared. The disappearance of plague in London was attributed to the Great Fire, but no such cause existed in other cities. It has also been ascribed to quarantine, but no effective quarantine had been instituted that could have stopped the spread of the disease. In the absence of a cure, the cessation of plague in England must be regarded as spontaneous.

But this was no isolated fact. A similar cessation of plague was noted in other parts of western Europe. In 1660 a severe plague raged in Cologne and on the Rhine, which was pro-
longed till 1670 in the district. In the Netherlands there was plague in 1665–1666, but there are no definite notices of it after 1672. France saw the last plague epidemic in 1665, till it returned in 1720. In the years 1675–1684 a new plague epidemic appeared in North Africa, Turkey, Poland, Hungary, Austria and Germany, progressing generally northward. Malta lost 11,000 persons in 1665, and Silesia in 1683–1684, 76,000 or probably more deaths. Plague in 1681 lost 83,000 by plague. Dresden was affected in 1680, Magdeburg and Halle in 1682, and there was a mortality of 4372 out of 22,000 in 1684. Many cities suffered about the same time; but in 1683 the plague disappeared from Germany till the epidemic of 1707. In Spain it ceased about 1681; in Italy certain towns were attacked till the end of the century, but not later (Hirsch).

Plague in the 18th Century.—At the beginning of this period plague was very prevalent in Constantinople and along the Danube. In 1701 there was great destruction in the Ukraine. In 1704 it began to spread through Poland, and later to Silesia, Lithuania, Prussia and a great part of Germany and Scandinavia. In Prussia and Lithuania 298,000 persons perished; Danzig, Hamburg and other cities suffered severely. Hardly any part of Europe escaped in 1710. In Stockholm there was a mortality of 40,000. Certain places near Brunswick (10° E.) marked the western limit of the epidemic; and cholera was arrested at the same spot in later years (Hirsch).

At the same time the plague spread westward from the Danube to Transylvania and styria, and (1713) appeared in Austria and Bohemia; it caused great mortality in Vienna. There it passed to Prague and Ratisbon—to the former, possibly to the latter, almost certainly conveyed by human intercourse. This city (12° E.) was the western limit reached in this year. Hiser states that the plague passed into Bohemia and Saxony in Europe after the great hurricane of the 27th of February 1714.

In 1717 plague raged severely in Constantinople; and in 1719 it made a fresh progress westward into Transylvania, Hungary, Galicia and Poland. The epidemic lasted till after 1725. It appears that each successive invasion had a more easterly western limit, and that the gradual narrowing of the range of plague, which continued, was still going on.

This process suffered a temporary interruption by the outbreak of plague of southern France in 1720–1722. In 1720 Marseilles became affected with an epidemic plague, the origin of which was ascribed by some to contagion through the ship of a Captain Chataud which arrived on the 20th of May 1720, from Syria, where plague at that time prevailed, though not epidemically when he sailed. Six of the crew had died on the voyage to Leghorn, but the disease was declared not to be plague. Cases of plague occurred, however, on the ship, and on the 22nd of June among porters unloading the cargo. Hence, according to believers in contagion, the disease passed to families in the "old town," the poor part of the city, where they were never afterwards found. It had arrived from Syria, which were put in quarantine. According to others the plague arose in Marseilles from local causes; and recent researches show that the suspicion of contagious disease occurred in the town before the arrival of Chataud's ship.

Opinions were divided, and the evidence appears even now nearly balanced, though the believers in contagion and importation gained the day. The disease was not so severe, thousands of unburied corpses filled the streets, and in all 40,000 to 60,000 persons were carried off. In December 1721 the plague passed away, though isolated cases occurred in 1722. It passed to Provence, and was fixed in 1724–1725 in the south of France. It was not of great mortality, but in Toulon not till 1721, when it destroyed two-thirds of the population. The epidemic spread generally over Provence, but not to other parts of France, notwithstanding that, as confessed by D'Antrechau, consul of Toulon, a believer in contagion, the disease was communicated by sick persons in the hospitals. The disease was in fact, as in other cases, self-limited. In all 87,659 persons are said to have died out of a population of nearly 250,000. The great epidemic caused a panic in England which led to the introduction (under Mead's advice) of quarantine regulations, never previously enforced, and also led to the publication of many pamphlets, e., besides Mead's well-known Discourse on Pestilential Contagion, London, 1665.

Plague in Sicily in 1743.—An outbreak of plague at Messina in 1743 is important, not only for its fatality, but as one of the strang-
ests in the history of disease. A favorite city of an epidemic contagion, Messina had been free from plague since 1624, and the Sicilians considered themselves safe from the rigour of the quarantine laws which they thought to have preserved them. In May 1743 a vessel arrived from Corfu, one of the rare ships which had ever suffered some suspicious deaths. The ship and cargo were burnt, but soon after cases of a suspicious form of disease were observed in the hospital and in the poorest parts of the town; and in the summer a fearful epidemic of plague developed itself which destroyed 40,000 or 50,000 persons, and then became extinct without spreading to other parts of Sicily.

Spread of Plague from the East.—Independent of the epidemics of Marseilles and Messina, the spread of plague from the East con-
tinued, though it was less frequent. The late 18th century had a greater influence of the plague law of Limin, 1. Toulon, 1744 the disease was in the Ukraine, Hungary, the borders of Car-
niola, Moravia and Austria, extending along the Carpathians as far as the country of Galicia (20° E.), and in 1745 also as far as the Prussian frontier. It lasted till 1745, and then disappeared from those parts for fifteen years. In 1755–1757 plague prevailed in parts of European Turkey, whence it on one occasion extended into Transylvania, in the neighbour-
hood of Pecs, but did not check itself in the north (Hiser).

In 1770 a destructive plague arose in Moldavia during the Russo-
Turkish War, and shortly afterwards in Wallachia, apparently endemic in the former country at least. It affected also Trans-
ylvania and part of Hungary, and still more severely Poland, but was confined to Podolia, Volhynia, the Ukraine and east Galicia (5° E.), not even penetrating as far as Warsaw. After destroying, it is said, 300,000 persons, and without being checked by any quarantine regulations, the plague died out finally in March 1771; it being remarkable for its short duration and spontaneous limitation (Hiser).

In another direction the plague spread over Little Russia in 1770, and devastated Kieff, while in the next year it broke out in Moscow and produced one of the most destructive epidemics of modern times. More than 50,000 persons, nearly one-fourth of the popula-
tion, were destroyed.

The remaining European plague-epidemics of the 18th century were inconsiderable, but on that very account noteworthy. Tranz-
sylvania was again affected in 1783, Slavonia and Livonia (a district of eastern Germany, but still part of Poland) in 1792, and Volhynia in 1798. The disease, while recurring in the seats of the terrible earlier epidemics, was more limited in its range and of shorter duration. An epidemic in Dalmatia in 1783–1784 is noteworthy for its general constancy in the same region. In the last years of the century (1799–1800) there was a new epidemic in Syria and Egypt, where it affected the French and afterwards the English armies.

Plague in the 19th Century.—Plague appeared at Constanti-
nople in 1802–1803, about the same time in Armenia (Kars), and in 1801 in Bagdad. It had prevailed since 1798 in Georgia and the Caucasus, and in 1803–1806 began to spread from the north of the Caucasus into Russia, till in 1806 it was established at or near Astrakhan, and in 1807 reached Zareff, 200 m. higher up the Volga. These localities are interesting as being near those where plague appeared in 1827–1828. It is also said to have entered the government of Saratov, but probably no great distance. The plague remained in the Caucasus and Georgia till 1819 at least. In 1828–1831 it was in Armenia, and again in 1840–1843, since which time it has not been heard of in that country.

2. Samolowitz, Mémoire sur la peste en Russie, 1771 (Paris, 1773); Lortiin, Pest des orientis (Berlin, 1857) p. 103; Schraud, Pest in Serbien, 1705 (2 vol., 1806).

3. From the annals of the Moravian community of Serepta on the Volga, Geschichte der Brüder-Gemeinde Sarepta, by A. Gitsch (Sarepta and Berlin, 1865) and also Tholozan, Epidémies de peste du Caucausie (Paris, 1879).
In 1868 plague was at Constantinople, in 1890 at Smyrna. In 1812 was a more general epidemic affecting these places and also Egypt. An outbreak at Odessa is supposed to have been brought from Constantinople, and thence to have passed to Transylvania. In 1813 a severe plague at Bucharest is supposed to have been brought from Constantinople. About the same time plague prevailed in Bosnia, and is supposed to have passed thence to Dalmatia in 1815. In 1814-1815 it again appeared in Egypt, and once more invaded the continent of Europe in Albania and Bosnia. Two insular outbreaks, Malta in 1813 and Corfu in 1815, attracted much attention as being both thought to be cases of importation by sea-traffic, and there seems good reason for this opinion.

A panic spread through Europe in 1815 in consequence of an outbreak in Noja on the eastern coast of Italy. According to one view it was imported from the opposite coast of Dalmatia, though no definite history of contagion was established; according to others, it originated endemically in that place. It remained, however, strictly confined to a small district, perhaps in consequence of the extraordinarily rigorous measures of isolation adopted by the Italian government. In 1828 an isolated epidemic appeared in Greece in the Morea, supposed to have been brought by troops from Egypt. In 1834-1835 an outbreak took place at Tutchkof in Bessarabia; the town was strictly isolated by a military cordon and the disease did not spread. Cronstadt in Transylvania was the scene of a small outbreak in 1828, which was said to be isolated by similar measures (Lorinser). A far more serious epidemic was connected with the campaign of the Russian army against Turkey in 1828-1829. Moldavia, Wallachia and Bessarabia were widely affected; the disease broke out also in Odessa and the Crimea, and isolated cases occurred in Transylvania. The most northerly points reached by the plague were near Czernowitz on the frontier of Bessamibia and Bukowina, and its limitation was as before attributed to the Russian and Austrian military cordons.

In 1831 another epidemic occurred in Constantinople and Roumelia; in 1837 again in Roumelia and in Odessa—its last appearance in these regions, and the last on the European continent except an isolated outbreak in Dalmatia in 1840, and one in Constantinople in 1841. The plague-epidemics in Egypt between 1833 and 1845 are very important in the history of plague, since the disease was almost for the first time scientifically studied in its home by skilled European physicians, chiefly French. The disease was found to be less contagious than had been supposed by tradition, and most of the French school went so far as to deny the contagiousness of the disease altogether. The epidemic of 1834-1835 was not less destructive than many of those notorious in history; but in 1844-1845 the disease disappeared.

In 1853 plague appeared in a district of western Arabia, the Asir country in North Yemen, and it is known to have occurred in the same district in 1815, as it did afterwards in 1874 and 1879. In 1874 the disease extended within four days' march of Mecca. From the scantiness of population the mortality was not great, but it became clear that this is one of the endemic seats of plague. In June 1858 intelligence was received in Constantinople of an outbreak of disease at the small town Benghazi, in the district of Barca, province of Tripoli, North Africa, which though at first misunderstood was clearly bubonic plague. From later researches there is reason to believe that it began in 1856 or in 1855. The disease did not spread, and ceased in the autumn, to return with less violence in 1859, when it died out. In the autumn of 1873 it returned, but came again to a spontaneous termination.

After the epidemic of Benghazi in 1856-1859, plague was next heard of in the district of Makú, in the extreme north-west of Persia in November 1863. It occurred in a scattered population, and the mortality was not absolutely large.

In 1867 an outbreak of plague was reported in Mesopotamia (Irak), among the marshes of Hindieh bordering on the lower Euphrates. The epidemic began in December 1866 (or probably earlier) and ceased in June 1867. But numerous cases of a fatal mild bubonic disease (mild plague or pestis minor) occurred both before and after the epidemic, and according to Tholozan similar cases had been observed nearly every year from 1856 to 1865.

The next severe epidemic of plague in Irak began in December 1873. But facts collected by Tholozan show that pestis minor, or sporadic cases of true plague, had appeared in 1868 and subsequent years. The outbreak of 1873-1874 began about 60 m. from the origin of that of 1867. It caused a much greater mortality and extended over a much wider area than that of 1867, including the towns of Kerbela and Hillah. After a short interval it reappeared at Dinviah in December 1874, and spread over a much wider area than in the previous epidemics. This epidemic was carefully studied by Surgeon-Major Colvill. He estimated the mortality at 4,000. The epidemic ceased in July, but broke out again early in 1876, and in this year extended northwards to Bagdad and beyond. The whole area now affected extended 250 m. from north-west to south-east, and the total number of deaths was believed to be 20,000. In 1877 plague also occurred at Shuster in south-west Persia, probably conveyed by pilgrims returning from Irak, and caused great mortality.

After its customary cessation in the autumn the epidemic began again in October 1876, though sporadic cases occurred all the summer. The disease appeared in 1877 in other parts of Mesopotamia also with less severity than in 1876, but over a wider area, being now announced at Samara, a town 70 m. above Bagdad on the Tigris. The existence of plague in Bagdad or Mesopotamia was not again announced till the year 1884, when accounts again appeared in the newspapers, and in that July the usual official statement was made that the plague had been stamped out.

In 1870-1871 it appeared in a district of Muri in Persian Kurdistan to the south of Lake Urumiah (far removed from the outbreak of 1867). The epidemic appears, however, to have died out in 1871, and no further accounts of plague there were received. The district had suffered in the great epidemic of plague in Persia in 1829-1835. In the winter 1876-1877 a disease which appears to have been plague appeared in two villages in the extreme north of the province of Khorâssân, about 25 leagues from the south-east angle of the Caspian Sea. In March 1877 plague broke out in Resit, a town of 20,000 inhabitants, in the province of Ghilan, near the Caspian Sea at its south-west angle, from which there is a certain amount of trade with Astrakhan. In 1832 a very destructive plague had carried off half the inhabitants. In 1877 the plague was very fatal. From March to September 4,000 persons were calculated to have died. The disease continued till the spring of 1878. In 1877 there was a doubtful report of the same disease at Astrabad, and also in some parts near the Perso-Afghan frontier. In 1878 plague again occurred in Kurdistan in the district of So-uj-Bulak, said by Dr Tholozan to be the same as in the district of Mukri where it occurred in 1870-1871. These scattered outbreaks of plague in Persian territory are the more remarkable because that country
PLAGUE

had been generally noted for its freedom from plague (as compared with Asiatic Turkey and the Levant).

A few cases of plague occurred in January 1877 at Baku on the west shore of the Caspian, in Russian territory. An outbreak of plague on European soil in 1878–1879 on the banks of the Volga caused a panic throughout Europe. In the summer of 1877 a disease prevailed in several villages in the neighbourhood of Astrakhan and in the city itself, which was clearly a mild form of plague (pestis minor). It caused no deaths (or only one due to a complication) and died out apparently spontaneously. An official physician, Dr Kastorsky, who investigated the matter for the government, declared the disease to be identical with that prevailing in the same year at Resht in Persia; another physician, Dr Janizky, even gave it the name of pestis nostras. In October 1878 some cases appeared in the stanitsa or Cossack military settlement of Vetlanka, 130 m. from Astrakhan on the right bank of the Volga, which seem to have puzzled the physicians who first observed them, but on the 30th of November were recognized as being but the mild plague as had been observed the year before near Astrakhan by Dr Düpner, chief medical officer of the Cossacks of Astrakhan. His report on the epidemic is the only original one we know. At the end of November the disease became suddenly more severe, and most of those attacked died; and from the 21st of December it became still more malignant, death occurring in some cases in a few hours, and without any buboes being formed. No case of recovery was known in this period. At the end of the year it rapidly declined, and in the first weeks of January still more so. The last death was on the 24th of January. In the second half of December, when the disease had already lasted two months, cases of plague occurred in several neighbouring villages, all of an extremely malignant type, so that in some places all who were attacked died. In most of these cases the disease began with persons who had been at Vetlanka, though this was not universally established. The inhabitants of these villages, terrified at the accounts from Vetlanka, strictly isolated the sick, and thus probably checked the spread of the disease. But it vividly suffered a spontaneous decline. By the end of January there were no cases left in the district except at one village (Selitrennoye), where the last occurred on the 9th of February. The total number of cases in Vetlanka, out of a population of about 1700, was 417, of whom 362 died. In the other villages there were about 62 deaths from plague, and not more than two or three cases of recovery. In consequence of the alarm excited by this appearance of plague upon European soil, several European governments immediately took steps to guard against the spread of the disease. The British commissioners were Surgeon-Major Colvill and Dr J. F. Payne, who, like all the foreign commissioners, reached the spot when the epidemic was over. With respect to the origin of this epidemic, the possibility of its having originated on the spot, as in Resht and on the Euphrates in very similar situations, is not to be denied. An attempt was made to show that the contagion was brought home by Cossacks returning from the Turkish War, but on absolutely no evidence. In the opinion of Dr Payne the real beginning of the disease was in the year 1877, in the vicinity of Astrakhan, and the sudden and widespread outbreak among the peasantry of the district was no more than had been observed in other places. The Astrakhan disease may have been imported from Resht or Baku, or may have been caused concurrently with the epidemics of these places by some cause affecting the basin of the Caspian generally.

Plague in India.—It was used to be held as a maxim that plague never again appeared east of the Indus; nevertheless it was observed during the 19th century in more than one distinct centre in India. So long ago as 1815 the disease appeared in Guzerat, Kattwyar and Cutch, "after three years of severe famine."1

1 J. Netten Radcliffe, Reports; Tholozan, Histoire de la peste bubonique en Perse (Paris, 1874).
2 See, besides, De Bériol (1879–1880); Hirsch and Sommerring, Pest-Epidemie 1878–1879 in Astrachan (Berlin, 1880); Zuber, La Peste d’Astrachan en 1878–1879 (Paris, 1880); Colvill and Payne, Report to the Lord President of the Council (1879). The dates are all reduced to new style.

It reappeared early next year, in the same locality, when it extended to Sind as far as Hyderabad, and in another direction south-east as far as Ahmedabad and Dholerah. But it disappeared from these parts in 1820 or early in 1821, and was not heard of again till July 1836, when a disease broke out into violence at the town of Pali in Marwar in Rajputana. It spread from Pali to the province of Meywar, but died out spontaneously in the hot season of 1837. The origin of these two epidemics was obscure. No importation from other countries could be traced.

In 1823 (though not officially known till later) an epidemic broke out at Kedarnath in Gurwhal, a sub-district of Kumaon on the south-west of the Himalayas, on a high situation. In 1834 and 1836 other epidemics occurred, which at least attracted the attention of government. In 1849–1850, and again in 1852, the disease raged very severely and spread southward. In 1853 Dr Francis and Dr Pearson were appointed a commission to inquire into the malady. In 1857–1858 another outbreak occurred. The symptoms of this disease, called maha muree or mahamari by the natives, were precisely those of oriental plague. The feature of blood-spitting, to which much importance had been attached in later periods of the disease, is not known; the only circumstance was the death of animals (rats, and more rarely snakes) at the outbreak of an epidemic. The rats brought up blood, and the body of one examined after death by Dr Francis showed an affection of the lungs.4

Oriental plague was observed in the Chinese province of Yunnan from 1871, and also at Pakhói, a port in the Tongking Gulf, in 1882—being said to have prevailed there at least fifteen years. In both places the symptoms were the same, of undoubted bubonic plague. At Pakhói it recurs nearly every year.5

In 1858 therefore plague existed or had existed within ten years, in the following parts of the world: (1) Bengal; Africa; (2) Persian Kurdistan; (3) Irak, on the Tigris and Euphrates; (4) the Asir country, western Arabia; (5) on the lower Volga, Russia; (6) northern Persia and the shores of the Caspian; (7) Kumaon and Gurwhal, India; (8) Yunnan and Pakhói, China.

Literature.—See the following works, besides those already quoted: Kamintus, Regimen contra epidemia sive pestem, 4to, c. 1504 (many editions); Jacobus Soldsus, Opus ignis de peste, 4to (Venice, 1478); Alexius, De pestem, 4to, 16 Venice, 1503; Nicolaus Massa, De febre pestilenția, 4to (Venice, 1556, &c.); Fioravanti, Regimento della peste, 8vo, Venice, 1556; John Woodall, The Surgeon’s Mate, folio (London, 1659); Van Helmont, Tummnis pestis, 8vo (Cologne, 1644, &c.); Muratori, Trattato del governo della peste, Modena, 1714; John Howard, An Account of Laceratoes in Europe, &c., 4to (London, 1789); Patrick Kessell, A Treatise of the Plague, 4to (London, 1791); Thomas Hancock, Researches into the Laws of Pestilence, 8vo (London, 1821); Fodor, Leçons sur les Épidémies, &c., 4 vols. 8vo (Paris, 1822–1824); Segur Dupuyron, Recherches historiques, &c., sur la peste (1837); Bilard, La Peste orientale, 8vo (Paris, 1839); Griesinger, Die Infektionskrankheiten (2nd ed., 8vo, Erlangen, 1864). (J. F. P.)

History since 1850.—The most striking feature of the early history of plague summarized above is the gradual retrogression of plague from the west, after a series of exceedingly destructive outbreaks extending over several centuries, and its eventual disappearance from Europe. It appears to have come to a sudden end in one country after another, and to have been seen there no more. Those living most to the west were the first to recover.

5 See Francis, Reports of Imperial Chinese Customs, special series No. 2, for half-year ended the 31st of March 1878, 15th issue (Shanghai); Lowry, “Notes on Epidemic Disease at Pakhói” (1882), Ibid., 24th issue, p. 31.
to be freed from its presence, namely, England, Portugal and Spain. From all these it finally disappeared about 1680, at the close of a period of pandemic prevalence. Northern and central Europe became free about 1714, and the south of France in 1722. The last outbreak in northern Russia occurred in 1770. After this plague only appeared in the south-east of Europe, whereas in Turkey it had died out by the close of the 19th century. In 1845 its long reign on this continent came to an end with an isolated outbreak in Turkey. From that time until quite recently it remained extinct, except in the East. The province of Astrakhan, where a very small and limited outbreak occurred in 1878, is politically in Europe, but geographically it belongs rather to Asia. And even in the East plague was confined to more or less clearly localized epidemics; it showed no power of pandemic diffusion. In short, if we regard the history of this disease as a whole, it appears to have lost such power from the time of the Great Plague of London in 1665, which was part of a pandemic wave, until the present day. There was not merely a gradual withdrawal eastwards lasting nearly two hundred years, but the outbreaks which occurred during that period, violent as some of them were, showed a constantly diminishing power of diffusion and an increasing tendency to localization. The sudden reversal of that long process is therefore a very remarkable occurrence. Emerging from the remote endemic centres to which it had retreated, plague has once more taken its place among the zymotic diseases with which Western communities have to reckon, and that which has for more than a century been little more than a name and a tradition has become the familiar object of investigation, carried on with all the ardour and all the resources of modern science. In what follows an attempt will be made to summarize the facts and indicate the conclusions to be drawn from recent experience.

Diffusion.—At the outset it is characteristic of this subtle disorder that the present pandemic diffusion cannot be traced with certainty to a definite time or place of origin. Herein it differs notably from other exctic diseases liable to similar diffusion. For instance, the last visitation of cholera could be traced clearly and definitely to a point of origin in northern India in the spring of 1852, and could be followed thence step by step in its march westward (see Cholera). Similarly, though not with equal precision, the last wave of influenza was traced from central Asia in the spring of 1889, to have travelled through Europe from east to west, to have been carried thence across the sea to America and the Antipodes, until it eventually invaded every inhabited part of the globe (see Influenza). In both cases no doubt remains that the all-important means of dissemination is human intercourse.

The movements of plague cannot be followed in the same way. With regard to origin, several endemic centres are now recognized in Asia and Africa, namely, (1) the district of Assy in Arabia, on the eastern shore of the Red Sea; (2) parts of Mesopotamia and Persia; (3) the district of Garwal and Kumaon in the North-West Provinces of India; (4) Yunnan in China; (5) East and the Central Africa. The last was recently discovered by Dr. Koch. It includes the district of Kisiba in German East Africa, and extends into Uganda. In applying the term "endemic centres" to these localities, no very precise meaning can be attached to the word. They are for the most part so remote, and the information about them so scanty, that our knowledge is largely guesswork. What we mean is that there is evidence to show that under various names a disease identical with plague has been more or less continuously prevalent for a number of years, but how long and how continuously is not known. Whether any of them are permanent homes of plague the evidence does not enable us to say. They seem, at any rate, to have harboured it since its disappearance from Europe, and only further investigation would disclose a still wider prevalence. For instance, there are good reasons for believing that the island of Réunion has been subject, since 1840 or thereabouts, to outbreaks under the name of "lymphangite infectieuse," an elegant euphemism characteristically French. In all the countries named plague appears to behave very much as it used to do in Europe from the time of the Black Death onwards. That is to say, there are periods of quiescence, with epidemic outbreaks which attract notice at irregular intervals.

Taking up the story at the point where the earlier historical summary leaves off, we get the following list of countries in which plague is known to have been present in each year (see Local Government Board Reports): 1880, Mesopotamia; 1881, Mesopotamia, Persia and China; 1882, Persia and China; 1883, China; 1884, China and India (as mahamari); 1885, Persia; 1886, 1887, 1888, India (as mahamari); 1889, Arabia, Persia and China; 1890, Arabia, Persia and China; 1891, Arabia, China and India (as mahamari); 1892, Mesopotamia, Persia, China, Russia (in central Asia); 1893, Arabia, China, Russia and India (as mahamari); 1894, Arabia, China and India (as mahamari); 1895, Arabia and China; 1896, Arabia, Asia Minor, China, Japan, Russia and India (Bombay); 1897, Arabia, China, Japan, India, Russia and East Africa; 1898, Arabia, Persia, China, Japan, Russia, East Africa, Madagascar and Vienna; 1899, Arabia, Persia, China, Japan, Mesopotamia, East Africa, West Africa, Philippine Islands, Straits Settlements, Madagascar, Mauritius, Réunion, Egypt, European Russia, Portugal, Sandwich Islands, New Caledonia, Paraguay, Argentine, Brazil, 1900, to the foregoing should be added Turkey, Australia, California, Mexico and Glasgow; in 1901, South Africa and in 1902 Russia chiefly at Odessa.

This list is probably by no means exhaustive, but it sufficiently indicates in a summary fashion the extent of that wave of diffusion which set in during the closing years of the 19th century. It did not fully gather way till 1896, when plague appeared in Bombay, but our modern knowledge of the disease dates from 1894, when it attacked Hong Kong and first presented itself to accurate observation. From this point a more detailed account may be given. Plague was recognized at Hong Kong in May 1894, and there can be little doubt that it was imported from Canton, where a violent outbreak—said to have caused 100,000 deaths—was in progress a few months earlier, being part of an extensive wave of infection which is believed to have come originally out of the province of Yunnan, one of the recognized endemic centres, and to have invaded a large number of places in that part of China, including Pakhoi and other seaports. Hong Kong was severely affected, and has never since been entirely free from plague. In two intermediate years—1895 and 1897—very few cases were recorded, but more recently the epidemic has gathered force again. The following table gives the cases and deaths in each of the six years 1894-1899:

The excessively high rate of mortality is probably due in part to under-statement of the number of cases. Concealment is practised by the Chinese, who are closely attacked, and it is easier to conceal sickness than death. Plague appears to have been equally persistent and destructive on the mainland in southern China during the period indicated, but no accurate details are available. In 1897 the Portuguese settlements of Lappa and Macao were invaded. In addition to the provinces of Yunnan, Kwang-si and Kwang-tung in southern China, plague is reported to have been present for several years in a district in Mongolia to the north of Peking, and distant about "twelve days' ride." More recently several localities in Mongolia and Manchuria have been affected. Formosa was attacked in 1896, and suffered considerably in subsequent years; in 1899 the Japanese government officially reported 2634 cases, with
1974 deaths. Japan itself has had a certain amount of imported plague, but not on a large scale. Speaking generally, the disease has persisted and spread in the Far East since 1894, but precise information is lacking, except with regard to Hong Kong. W. J. Simpson in his Report on the Causes of the Plague in Hong Kong (1903) reports the endemicity of the plague in that colony to be maintained by (a) infection among rats often connected with infectious material in rat runs or in houses, the virus of which has not been destroyed, (b) retention of infection in houses which are rat-ridden, and (c) infected clothing of people who have been ill or died of plague. He considers the outbreaks are favoured by the seasonal heat and moisture of the spring and early summer, and the movement from place to place of infected rats or persons. He also believes that human beings may infect rats. In 310 cases of plague examined by Simpson 56% were bubonic, 40% septic and 4% pneumonic.

In 1896 plague appeared in the city of Bombay. It was certainly present in August, but was not recognized until the 23rd of September, and the diagnosis was not bacteriologically confirmed until the 13th of October. This fact should be remembered when failure to recognize the disease on its first appearance occurs elsewhere. The origin of the Bombay invasion is shrouded in obscurity. It is not even known when or in what part of the city it began (Condon, The Bombay Plague). Several theories have been put forward, and importation by sea from China is the theory which has met with most acceptance. The native form of plague, known as mahamari, is confined to the southern slopes of the Himalaya. It is described above, but that account may be supplemented by some earlier references unearthed by the Bombay Gazetteer (vol. iv.). Ibn Battuta notices two destructive pestilences in the 14th century, and Ferishta one in 1443, which he calls aw‘un, and describes as very unusual in India. At the end of the 17th century there was a pestilence following a prolonged famine, and in the 17th century two violent epidemics are recorded under the names aw‘un and wassa. In the second of these, which occurred in the Ahmedabad district of the Bombay Presidency in 1683-89, buboes are distinctly described. In the 18th century several pestilences are recorded without description. It is at least probable from these notes that even before the undoubted outbreak, which began in Cutch in 1812, India was no stranger to epidemic plague. To return to Bombay and 1896: the infection spread gradually and slowly at first, but during the first three months of 1897 not only was the town of Bombay severely affected, but district after district in the presidency was attacked, notably Poona, Karachi, Cutch Mandvi, Bhiwandi and Daman. The number of cases and deaths reported in the presidency, exclusive of the city, in each year down to the end of 1899, was as follows:

<table>

The total for the presidency, including the city, in four years was 325,632 cases with 252,549 deaths in a population of 26,660,421 (census of 1891). The population of the city is 821,764, but during the earlier plague period large numbers fled, so that the foregoing figures do not give the true plague incidence according to population. Moreover, concealment was extensively practised. The most striking fact brought out by the tables just given is the large and steady increase year by year in the presidency, in spite of all efforts to arrest the spread of infection. It has gone on since 1899, and it has not been confined to Bombay, but has extended over the whole of India. In 1897 it had already penetrated to Rajputana, the Punjab, the North West Provinces and the Central Provinces. In the following year Bengal, Madras, Haidarabad and Mysore were invaded. Not all these provinces suffered alike, but on the whole plague steadily strengthened its hold on India generally, and hardly relaxed it in any part. The most noteworthy details available are as follows, taken from the plague mortality returns published June 1908. In the Punjab from 179 deaths in 1897 the mortality reached a maximum of 334,897 in 1905, in Agra and Oudh they rose from 72 in 1897 to 383,802 in 1905, and in Madras Presidency from 1635 in 1899 to 20,125 in 1904.

The most striking figures, however, are those for Bombay and Bengal which are given below, as well as the total mortality in India:

</table>

Outside China and India plague has caused no great mortality in any of the countries in which it has appeared, with the exception perhaps of Arabia, about which very little is known. But some of the outbreaks are interesting for other reasons, and require notice. The first case is the singular occurrence of three deaths at Vienna in October 1898. The earliest victim was an attendant named Barisch, employed in the pathological laboratory of the Vienna General Hospital, and told off to look after the animals and bacteriological apparatus devoted to the investigation of plague, cultures of which had been brought from India by the medical commissioners sent by the Royal Academy of Science in 1897. Barisch was drunk and out all night on the 8th of October; on the 14th of October he fell ill. Plague was suspected, but Dr Müller, who attended the man and had studied the disease in India, would not admit the diagnosis on clinical grounds, nor was it bacteriologically established until the 19th of October. Barisch died on the 18th of October. On the 20th one of the nurses, and on the 21st Dr Müller, fell ill. Both died of pneumonic plague, from which also Barisch had unambiguously suffered. A second nurse and a sister of mercy had feverish attacks, but no further case occurred. Barisch was shown to have been careless in the performance of his duties, and to have disregarded instructions; and the inference is that he conveyed the infection to his mouth, and so to the lungs, from the bacteriological specimens or inoculated animals. The melancholy incident illustrates several points of interest: (1) the correctness of the bacterial theory of causation, and the identity of the bacillus pestis as the cause; (2) the infectious character of the pneumonic type of disease; (3) its high fatality; (4) the difficulty of diagnosis.

The next occurrence of special interest is the appearance of plague in Portugal in 1899, after an absence of more than 200 years. Its origin is shrouded in obscurity. Oporto, the seat of the outbreak, had no connexion by sea with any place known to be infected, and all attempts to trace introduction ended in speculation or assumption. The most probable theory was that soldiers returning home from infected Portuguese possessions in the East brought it with them, but this does not explain the selection of Oporto and the escape of other places. The earliest
cases, according to retrospective inquiry, occurred in June 1899; suspicions were aroused in July, but the diagnosis was not established until August. The conclusion reached, after careful investigation by Dr Jorge, the medical officer of health, that the commencement of those cases, dated from June, is confirmed by the fact that about that time the river Po, on which the city of Braga, where the affected, began to notice an illness among themselves sufficiently novel to attract their attention and that of an English shopowner, who from their description suspected plague. Through him the suspicion was conveyed to the Medical Times and Gazette, in which the suggestion of plague at Oporto was made before any public mention of it in the town itself. The outbreak never assumed large proportions. It gained ground by degrees until October, after which it declined, and eventually ceased in February 1900. No recurrence has been officially announced. The number of cases recorded in a population of 320,000 was 310, with 114 deaths, representing a case mortality of 36.7%. They were widely scattered about the town and outlying suburbs; but no further extension occurred, except some isolated cases at Braga, a town 35 m. distant, and one at Lisbon, in the person of the distinguished bacteriologist, Professor Camara Pestana, who contracted the disease in making a post-mortem at Oporto, and died in Lisbon.

The only other appearance of plague in Europe in 1899 was on the Volga. Three places were affected, namely, Kolobovka, and Krasnoyar, in the province of Astrarrenk, and Samara, higher up the river. All three outbreaks were small and limited, and no further extension took place. A commission appointed by the Russian Government pronounced the disease to be undoubtedly plague, and it appears to have been very fatal. The origin was not ascertained.

The most interesting extensions of plague in 1900 were those in Australia and Glasgow. The following towns were affected in Australia: Sydney, in New South Wales; Adelaide, in South Australia; Melbourne, in Victoria; Brisbane, Rockhampton, Townsville, Cairns and Ipswich, in Queensland; Fremantle, Perth and Coolgardie, in West Australia. In none of these, with the exception of Sydney, did plague obtain a serious hold. The total number of cases reported in Queensland was only 123, with 53 deaths. In Sydney there were 303 cases, with 103 deaths, a case mortality of 34%. The infection is supposed to have been brought from Noumea, in New Caledonia, where it was present at the end of 1899; and the medical authorities believe that the first case, which occurred on the 10th of January, was recognized. The outbreak, which hardly reached epidemic proportions, lasted about six months. That in Glasgow was on a still smaller scale. It began, so far as could be ascertained, in August 1900, and during the two months it lasted there were 34 cases and 15 deaths. Once more the disease was not at first recognized, and its origin could not be traced. In 1901 plague invaded South Africa, and obtained a distinct footing both at Cape Town and Port Elizabeth. The total number of cases down to July was 760, with 362 deaths; the number of Europeans attacked was 196, with 68 deaths, the rest being natives, Malays, Indians, Chinese and negroes. With regard to Great Britain, a few ship-borne cases have been dealt with at different ports from time to time since 1896, but except at Glasgow the disease has nowhere obtained a footing on land.

Caustion.—Plague is a specific infectious fever, caused by the bacillus pesta, which was identified in 1894 by Kitasato, and subsequently, but independently, by Yersin (see Parasitic Diseases). It is found in the buboes in ordinary cases, in the blood in the so-called "septicemic" cases, and in the sputum of pneumatic cases. It may also be present in the urine. Post mortem it is found in great abundance in the spleen and liver. Nothing is known of its natural history outside the body, but on cultivation it is apt to undergo numerous involutions forms. Its presence in a patient is regarded as positive diagnostic proof of plague; but failure to find or to identify it does not possess an equal negative value, and should not be too readily accepted, for many instances are recorded in which expert observers have only succeeded in demonstrating its presence after repeated attempts. It is clear, from the extreme variations in the severity of the illness, that the resisting power of individuals varies greatly. According to the Plague Research Committee of Bombay, the predisposing causes are "those leading to a lower state of vitality," of which insufficient food is probably the most important. There is no evidence that age, sex or race exercises a distinct predisposing influence. The largest incidence in Bombay was on young adults; but then they are more numerous and more exposed to infection, because they go about more than the younger and the older. Similarly, the comparative immunity of Europeans in the East may be explained by their different conditions of life. It is doubtful whether the distinction drawn between pestis minor and pestis major has a real actiological basis. Very mild cases occurring in the course of an outbreak of typical plague may be explained by greater power of resistance in individuals, but the epidemic prevalence of a mild illness preceding the appearance of undoubted plague suggests some difference or modification of the exciting cause.

"It is impossible," writes Sir Richard Thorne (Local Government Board Report, 1898-1899), "to read the medical history of this disease in almost every part of the world without being impressed with the frequency with which recognized plague has been preceded by ailments of such slight severity, involving some bubonic enlargement of glands and some rise in body-temperature, as to mask the real nature of the malady." Considering the great importance of arresting the spread of infection at the outset, and the implicit reliance placed upon bacteriological criteria, the aetiology of such antecedent ailments deserves more attention than has hitherto been paid to it. Of course plague does not stand alone in this respect. Epidemic outbreaks of other diseases—for instance, cholera, diphtheria and typhoid fever—are often preceded and followed by the prevalence of mild illness of an allied type; and the true significance of this fact is one of the most important problems in epidemiology. In plague, however, it is of special importance, on account of the peculiarly insidious manner in which this disease fastens itself upon a locality.

The path by which the bacillus enters the body varies. In pneumatic cases it is presumed to enter by the air-passages, and in bubonic cases by the skin. The Bombay Plague Research Committee, whose experience is unequalled, say: "In a number of instances points of inoculation were found on the extremities of patients, from which plague cultures were obtained, and in these cases buboes were found above the point of inoculation. In the majority of instances, however, no local indication could be found marking the point at which the microbe was implanted." From the fact that bacilli are hardly ever found in the blood of bubonic cases it may be inferred that they are arrested by the lymphatic glands next above the seat of inoculation, and that the fight—which is the illness—takes place largely in the bubo; in non-bubonic cases they are not so arrested, and the fight takes place in the general circulatory system, or in the lungs. As might be expected from these considerations, the bubonic type is very little infectious, while pneumatic cases are highly so, the patients no doubt carrying the surrounding atmosphere by coughing. Whether infection can be introduced through the digestive tract by infected food is doubtful. The bacillus is non-resistant and easily killed by heat and germicidal substances, particularly acids. Little is known of its toxic action; only a weak toxin has been obtained from cultures. Of the lower animals, mice, rats, guinea-pigs, rabbits, squirrels and monkeys are susceptible to the bacillus; horses, cattle, sheep, goats, pigs, dogs and cats are more or less resistant, but cats and dogs have been known to die of plague (Oporto, Daman, Cutch and Patna).

Great Plague owes the ability to carry the infection, and were killed in vast numbers. The bacillus has been demonstrated in the bodies of fleas, flies, bugs, and ants.

Clinical Characters.—One of the results of recent observation is the classification of plague cases under three heads, which have already been mentioned several times: (1) bubonic, (2) pneumatic, (3) septicemic. (The word "pesti-caemic" is
PLAGUE

also used instead of "septi-caemic," and though etymologically objectionable, it is otherwise better, as "septicaemic" already has a specific and quite different meaning.) It should be understood that this classification is a clinical one, and that the second and third varieties are just as much plague as the first. It is known that plague bacilli have been isolated from buboes by ordinary use of the word "bubonic" has given rise to the erroneous idea that true plague is necessarily bubonic, and that non-bubonic types are a different disease altogether. The word "plague"—or "pest," which is the name used in other languages—had originally a general meaning, and may have required qualifications when applied to this particular fever; but it has now become a specific label, and the prefix "bubonic" should be dropped.

The illness varies within the widest limits, and exhibits all gradations of severity, from a mere indisposition, which may pass almost unnoticed, to an extreme violence, only equalled by the most violent forms of cholera. The mild cases are always bubonic; the other varieties are invariably severe, and almost always fatal. Incubation is generally from four to six days, but it has been observed as short as thirty-six hours and as long as ten days (Bombay Research Committee). Incubation, however, is so difficult a thing to determine that it is unwise to lay down any positive limit. As a rule the onset is sudden and well marked. The symptoms may be described under the headings given above. (1) Bubonic cases usually consist of three-fourths of the whole, and the symptoms may therefore be called typical. In a well-marked case there is usually an initial rigour—in children convulsions—followed by a rise of temperature, with vomiting, headache, giddiness, intolerance to light; pain in epigastrium, back and limbs; sleeplessness, apathy or delirium. The headache is described as splitting; delirium is of the busy type, like delirium tremens. The temperature varies greatly; it is not usually high on the first day—from 101° to 103°—and may even be normal, but sometimes it rises rapidly to 104° or 105° or even 107° F.; a full of two or three degrees on the second or third day has frequently been observed. The eyes are red and injected; the tongue is somewhat swollen, and at first covered with a thin white fur, except at the tip and edges, but later it is dry, and the fur yellow or brownish. Perspiration is marked. Constipation is the rule at first, but diarrhoea may be present, and is a bad sign. A characteristic symptom in severe cases is that the patient appears dazed and stupid, is thick in speech, and staggers. The condition has often been mistaken for intoxication. There is nothing, however, in all these symptoms positively distinctive of plague, unless it is already prevalent. The really pathognomonic sign is the appearance of buboes or inflamed glands, which happens early in the illness, usually on the second day; sometimes they are present from the outset, sometimes they cannot be detected before the third day, or even later. The commonest site is the groin, and next to that the axilla; the cervical, submaxillary and femoral glands are less frequently affected. Sometimes the buboes are multiple and on both sides, but more commonly they are unilateral. The pain is described as lancinating. If left, they usually suppurate and open outwards by sloughing of the skin, but they may subside spontaneously, or remain hard and indurated. Petechiae occur over buboes or on the abdomen, but they are not very common, except in fatal cases, when they appear shortly before death. Boils and carbuncles are rare. (2) Pneumonic plague was observed and described in many of the old epidemics, and particularly by two medical men, Dr Gilder and Dr Whyte, in the outbreak in Kathiawar in 1818; but its precise significance was first recognized by Childe in Bombay. He demonstrated the presence of the bacilli in the sputum and blood, and that the inflammation in the lungs was set up by the primary plague bacilli. The primary lesion is usually lobular, the onset marked by rigors, with difficult and hurrried breathing, cough and expectation. The prostration is great and the course of the illness rapid. The breathing becomes very hurried—forty to sixty respirations in the minute—and the face dusky. The expectation soon becomes watery and profuse, with little whitish specks, which contain great quantities of bacilli. The temperature is high and irregular. The physical signs are those of broncho-pneumonia; oedema of the lungs soon supervenes, and death occurs in three or four days. (3) In septicaemic cases the symptoms are those of the bubonic type, but more severe and without buboes. Prostration and cerebral symptoms are particularly marked; the temperature rises rapidly and very high. The patient may die comatose within twenty-four hours, but more commonly death occurs on the second or third day. Recovery is very rare.

There is no reason for doubting that the disease described above is identical with the European plagues of the 14th and subsequent centuries. It does not differ from them in its clinical features more than epidemics of other diseases are apt to vary at different times, or more than can be accounted for by difference of handling. The swellings and discolorations of the skin which play so large a part in old descriptions would probably be equally striking now but for the surgical treatment of buboes. Since then, the comparatively small destructiveness of modern plague, even in India, may be explained by the improved sanitary conditions and energetic measures dictated by modern knowledge. The case mortality still remains exceedingly high. The lowest recorded is 34% in Sydney, and the highest 95% at Hong Kong in 1899. During the first few weeks in Bombay it was calculated by Dr Viegas to be as high as 90%. It is very much higher among Orientals than among Europeans. In the Bombay hospitals it was about 70% among the former, and between 30% and 40% among the latter, which was much the same as in Oporto, Sydney and Cape Town. It appears, therefore, that plague is less fatal to Europeans than cholera. The average duration of fatal cases is five or six days; in the House of Correction at Byculla, where the exact period could be well observed, it was five and a half days. Patients who survive the tenth or twelfth day have a good chance of recovery. Convalescence is usually prolonged. Second attacks are rare, but have been known to occur.

Diagnosis.—When plague is prevalent in a locality, the diagnosis is easy in fairly well-marked cases of the bubonic type, but less so in the other varieties. When it is not prevalent the diagnosis is never easy, and in pneumonic and septicaemic cases it is impossible without bacteriological assistance. The earliest cases have hardly ever been even suspected at the time in any outbreak in a fresh locality. It may be taken at first for almost any fever, particularly typhoid, or for venereal disease or lymphangitis. In plague countries the diseases with which it is most liable to be confounded are malaria, relapsing fever and typhus, or broncho-pneumonia in pneumonic cases.

Treatment.—The treatment of plague is still symptomatic. The points requiring most attention are the cerebral symptoms—headache, sleeplessness, delirium, &c.—and the state of the heart. Alcohol and cardiac stimulants may be required to prevent heart failure. Speaking generally, it is important to preserve strength and guard against collapse. Extracts of supra-natural gland have been found useful. Buboes should be treated on ordinary surgical principles. An antibiotic serum has been prepared from horses by the Institut Pasteur in France, but has not met with success. The results in India obtained by British and various foreign observers were uniformly unfavourable, and the verdict of the Research Committee (1900) was that the serum had "failed to influence favourably the mortality among those attacked." Success was somewhat noisily claimed for an improved method tried in Oporto, but the evidence is of little or no value. Of 142 cases treated, 21 died; while of 72 cases not treated, 46 died; but the former were all hospital patients, and included several convalescents and many cases of extreme mildness, whereas the non-serum cases were treated at home or in hospital, and some being only discovered when death had made further concealment impossible. Later observations have, however, established that the Yersin-Roux serum is of undoubted benefit when used early in the case, in fact during the first twenty-four hours. Very large doses, so much as 150 cc. may be injected subcutaneously or preferably intravenously, and it is stated to modify the whole course of...
the disease. Another serum has been prepared by Lustig and Galeotti.

**Morbid Anatomy.—**(1) Bubonic cases. A bubo is found to consist of a chain of enlarged glands, surrounded by a mass of engorged connective tissue, coagulated blood and serum. Nearly all the lymphatic glands in the body are a little swollen, but those which lie low down show chiefly a change of engorgement and liver are always enlarged, the former to sometimes twice or thrice its natural size. The lungs are engorged and oedematous, and often show haemorrhages. The kidneys are enlarged and congested. The serous membranes show petechiae and haemorrhages. The right side of the heart is frequently dilated, with clots in the cavities. The heart muscle is normal, or soft and friable. The substance of the brain, spinal cord and nerverunks is normal, but the membranes are engorged. (2) Pneumonic cases. The lymphatic glands are hardly affected. There is general engorgement and oedema of the lungs, with pneumonic patches varying in size and irregularly distributed. (3) Septicaemic cases. Nearly all the lymphatic glands in the body are involved, and have a characteristic appearance. They are enlarged to the size of an almond, rounded, firm and pink; there is some engorgement and oedema on section; the substance is rather soft, and can be scraped off with a knife. The surrounding tissue is not engorged or oedematous. The description of the other organs given under (1) applies also to (2) and (3).

**Dissemination.—**Given the bacillus, the questions arise, How is it disseminated? and What are the conditions that favour its propagation? That it is conveyed from person to person is an undoubted fact, proved by innumerable cases, and tacitly implied by the word "infectious," which is universally allowed. The sick are a source of danger and one means of dissemination, and, since the illness may be so slight as to pass unrecognized, an obviously insidious one. The ambulatory plague patient goes far to explain the spread of the disease without leaving any track. But there is evidence that persons may carry the infection and give it to others without being ill at all themselves. One such case occurred at Glasgow, and another at Oporto. In the Glasgow case the wife of a laundrwoman employed in handling plague linen contracted the disease. She was brought into connexion with it in no other way, and there can be no doubt that she took it from her husband, though he was not ill at all himself. The Oporto instance is still more conclusive. Two little girls had plague at Argoncilhe, a suburb some miles from Oporto, and were the only cases which occurred in that place. Their father was a riverside labourer, who lodged during the week in Oporto, but went home for Sunday. He was not ill, but several cases of plague occurred in the house in which he lodged. How the poison passes from one person to another is less clear. In pneumonic cases patients no doubt spread it around them by coughing, and others may take it up through the air-passages or the skin; but even then the range of infection is small, and such cases are comparatively rare. In the vast majority of cases the bacillus are in the lymphatic or the circulatory system, and aerial contagion, even for a short distance, seems highly improbable. This view is borne out by the experience in hospitals and with "contacts," which goes to show that with reasonable care and under fair conditions the risk of infection from ordinary plague patients is very small. When persons live crowded together in close contact, and when they are careless with regard to discharges of all kinds from patients, the risk is obviously much increased. Discharges—vomited matters, spute, urine and faeces—are possible media by which plague is spread from person to person. They also contaminate clothing, which thus becomes another means of dissemination capable of acting at a distance. This is the most probable explanation of the two cases of indirect infection related above. Failure to infect or induce plague from clothing that has been worn by plague patients proves nothing. Such clothing is not necessarily infectious; indeed, the probability is that it is not, unless contaminated by discharges. There is no evidence that merchandise and foodstuffs are means of dissemination, but a great deal of evidence against such a theory. Then we come to the lower animals. Attention has been concentrated on rats, and some observers seem disposed to lay upon them the whole blame for the propagation and spread of plague, which is held to be essentially a rat-borne disease. The susceptibility of rats has been noted from remote times and in many countries, particularly in China, but it has never attracted so much attention as during the recent pandemic of plague. The mortality among rats was reported, and the broad fact that they do die of plague is incontestable. It is therefore easily intelligible that they may play an important part in multiplying and fixing the poison on a locality. As to how they convey it from man to man the greatest probability is in favour of the flea as an intermediary. Mortality among rats is said to precede the appearance of human plague, but the evidence of this is always retrospective and of a very loose character. At Sydney a careful investigation was made; and the conclusion reached by Dr Tidswell was that "there was no ground for even a suspicion that our epidemic was being maintained by any process of direct contagion between man and man;" but that rats were the carriers. In Glasgow the experience was just the contrary. Personal connexion was traced in every case, and rats excluded; there was no mortality among them, and of 300 caught and examined none had plague (Chalmers). Similarly, at Oporto, personal connexion was traced in all the earlier cases; there was no mortality among rats, and no evidence to connect them with the outbreak (Jorge). Again, a comparison between rat-infested and rat-free districts in Bombay showed a much higher incidence of plague in the latter. A campaign against rats in Bombay by which 50,000 or 60,000 were killed in a short time had no effect in checking the disease. Plague-rats have rarely been found in ships sailing from infected ports; and though millions of these animals must have been carried backwards and forwards from quay to quay between Hong-Kong, Bombay and the great European ports, they have not brought the disease ashore.

By far the most important communication on the rôle of rats in the spread of plague is formed by the "Report on the Plague Investigations in India" (Journal of Hygiene, vol. vi. No. 4; vol. vii. No. 3, 1907). The chief conclusions arrived at in the report as the result of experiments are the following:

1. Healthy rats contracted plague from infected rats when the only apparent means of communication between the two was the rat flea (*bubo* *cheopis*).

2. In 21 experiments out of 38, 55% of healthy rats living in flea-proof cages have contracted plague after receiving fleas collected from rats either dead or dying of septicaemic plague; consequently it is proved the rat flea can transmit plague from rat to rat.

3. Close and continuous contact of plague-infected animals with healthy ones does not infect the latter if fleas are excluded.

4. Should fleas be free from epidemic plague one starts and spreads in proportion to the number of fleas present.

5. Guinea-pigs set free in plague-infected houses become infected with the rat flea and develop plague in a certain percentage.

6. Fleas caught on plague-infected rats are able to infect rats placed in flea-proof cages.

7. Guinea-pigs placed in plague-infected houses do not contract plague if they are protected from fleas; those placed in cages protected by a border of sticky paper at least six inches in radius, which the fleas cannot jump over, do not contract plague; the others not similarly protected do not.

8. Chronic plague may prevail in rats.

On this report it may, therefore, be taken that aerial infection, except, perhaps, in pneumonic cases, may be excluded, and that the chief source of infection is the flea. It was also shown that animals may become infected through the faeces of a flea which has been on a plague-infected rat. This may serve to explain the manner in which plaque-infected linen and clothing may convey the disease. The report also considers it proved that the bacillus *pestis* multiplies in the stomach of a flea and may remain a considerable time within its host.

Browning Smith says the following facts are admitted as known.

(1) Plague can be carried by fleas from an unhealthy rat. (2) A flea can retain the plague bacillus alive for seven or eight days. (3) Man is, in the majority of cases, infected through the skin, though the puncture may not be seen. (4) The rat flea, when finding no rats, will attack man and it will also attack other animals.
Very little light has been thrown on the conditions which favour the prevalence of plague. We do not know why it has developed a diffusive activity of late years, nor why it has attacked some places and consistently passed by others, such as Singapore. The words "dirt" and "insanitary conditions" are much used, but such general terms explain nothing. Singapore, where plague has seven times been introduced, but never taken hold, is probably quite as dirty and insanitary as Hong-Kong, and it is pertinently remarked by the Bombay Research Committee that *filth per se* has but little influence, inasmuch as "there occurred in the House of Correction at Byculla, where cleanliness is brought as near to perfection as is attainable, an outbreak which exceeded in severity that in any of the filthy chawls and tenements around." Again, in Oporto there is an area which combines every possible sanitary defect—dense overcrowding, great poverty, no light, no air, no drainage, no scavenging, water brought in buckets. Plague got into this quarter, but did not spread there; on the other hand, it appeared in other and vastly superior parts of the town. Yet in at least one case neither the patient nor the "contacts" were removed, but were all shut up in one room with a sentry at the door and another in the street. The seasonal variations have been well marked and extremely regular in Bombay. The disease begins to be active in late autumn or the beginning of winter, and reaches its height in February or March, dying down in the summer. Baldwin Latham made an elaborate examination of the meteorological conditions, and more particularly of the vapour tension, from which he draws the conclusion that the seasonal variations are due to exhalation from the ground. His observations are original and worth attention. A simpler explanation is that the people live more indoors, and are so more exposed to infection during the plague season. The curve shows two rises, one at the beginning of winter, and the other at the commencement of the monsoon, and at both these times the people are driven indoors. A broad survey of the epidemiological facts suggests some general conclusions. The outbreaks fall into two well-defined groups: (1) those in which the disease is destructive and persistent, (2) those in which its effects are slight and transient. In the former the poison clearly fastens on the locality, and gradually increases its hold. The disease is infected, not merely the people in it; if for they evacuate it, the disease soon ceases among them, and if they return in a short time, they are again attacked. Now the poison is contained, as we have already seen, in the discharges from patients, and in such infected localities the standing conditions and the habits of the people combine to retain the discharges on the premises. The floors, mostly of mud covered with dung, are fouled with spittle, vomit, and urine, and, being seldom or never cleaned out, foster a gradual accumulation of poison, to which infected rats and the concealment of illness contribute. These are just the conditions which prevailed in Europe in the old plague days. They do not prevail now in those "white countries" which have been invaded but have repelled the attack with comparative ease and little loss. It may be concluded, with some confidence, from experience and theory alike, that localities where they do not prevail may fail to keep plague out, but have very little to fear from it, except the disturbance of trade caused by the traditional terrors that still cling to the name.

*Prevention.*—The principles are the same as those which govern the prevention of other infectious diseases. "Sanitary cords" and the like are obsolete. International procedure is supposed to be regulated by the Venice convention of 1897 (see QUARANTINE), but that instrument contains an optional clause allowing countries to do as they please with their own frontiers. Except Great Britain and Germany, all the other European countries retain quarantine in a more or less stringent form at seaports. It is generally used as a system of local extortion imposed upon travellers and shipping. According to the Venice convention, ships are divided into (1) healthy, (2) suspected, (3) infected. (1) Healthy are those free from plague throughout the voyage; (2) suspected, those in which plague has occurred, but no fresh case within twelve days; (3) infected, those in which plague has occurred within twelve days. Great Britain relies on medical inspection, removal of sick or suspected cases, and supervision of the healthy arriving on an infected ship; infected clothing is burnt and infected ships are disinfected. The procedure is the same in the German Empire, except that the infected cholera boat was changed by the director of the Plague Office, passing through the Suez Canal are subject to similar inspection; sick persons are landed at Moses Wells, and suspected ones detained. The risk of importing plague from India has been materially lessened by medical inspection of outward-bound ships at the principal ports. This has been very thoroughly carried out at Bombay with good results. In 1897 pilgrimages from India to the Hedjaz were prohibited. By the Venice convention a number of articles of merchandise are classed as susceptible and liable to be refused admission, but the only ones which there is any reason to consider dangerous are used clothing and rags. A watch should be kept on rats at ports of arrival and on board ships from infected countries.

When plague is present in a place, the measures to be taken are the usual ones for dealing with infectious disease, with some additions. The sick and suspected should be removed in special ambulances to an isolation hospital, their soiled linen, &c., should be burnt, and the premises disinfected. Corrosive sublimate in an acid solution is the best disinfectant, but sulphuric acid, 1 in 250, is efficient and cheaper. Suspected cases should be bestowed in a special isolated building until the diagnosis is fully determined. "Contacts should be kept under observation. Rats should be exterminated as far as possible, especially by means of the Danyas virus, which spreads into human habitations through the drainage system and the communication between it and the human burrows. The greatest care should be taken in dealing with the hospital linen and discharges from patients. Hospital staffs should be kept apart. Inoculation with Haffkine's prophylactic fluid should be offered to all persons willing to avail themselves of it. It is especially desirable for hospital and ambulance staffs to be inoculated with a vaccine prepared from sterilized cultures of plague bacillus. Inoculation is harmless, and the results obtained in India justify a favourable opinion of its protective efficacy. At Hubli, where nearly the whole population was inoculated between the 11th of May and the 27th of September 1897, the system of inoculation against plague with a fluid prepared from sterilized virus of the disease was introduced in India by Professor Haffkine early in 1897. The composition of this fluid was unknown, and was a search for its formula by the Government, who procured its employment to be free from danger, and it was used on a large scale in various parts of India without producing injurious effects. In September 1902 the standard method of manufacturing this fluid was patented by the Government, and the Haffkine Institute on its own authority, with the object of expediting the process, and thus meeting the heavy demand then being made for it, took the valuable German process for the production of the fluid, and communicated with a large scheme of inoculation. The change involved the omission of a proportion of carbolic acid which had up till then been added to the original fluid as a further precaution against contamination. The new fluid, or water agar process, contained no carbolic acid, other methods being relied upon to ensure its purity. On the 6th of November 1902, nineteen persons who had been inoculated on the 30th of October in the village of Malkowal from a single bottle (containing 1 and 24 cm.) of the new fluid, had all died of tetanus, and all of them subsequently died. A commission, consisting of Sir Lawrence Jenkins, Lieut.-Colonel Bomford, M.D., principal of the Medical College, Calcutta, and Major Semple, of the Staff of the Government Medical College, Bombay was appointed by the government of India to inquire into the disaster. They found that the germ of tetanus had been introduced into the fluid before the bottle was opened at Malkowal, and they thought it probable that this might have occurred owing either to insufficient sterilization or to the process of filling the bottle from a larger flask having been performed with defective precautions. They appeared to the opinion that carbolic acid was a valuable agent in restraining tetanus bacilli, and they, therefore, thought that its omission was a grave mistake. Experiments undertaken in India by two independent inquiries appeared to confirm the view, and their conclusions, together with the data on which they were based, were submitted with the report of the commission for examination and further experiment to the Lister Institute in London. With reference to the findings of the Malkowal commission the Institute were asked to report (1) on the comparative efficacy of the standard and new fluids as a
In 1898, the mean mortality among the inoculated was 1.3%; among the uninoculated 13.3%. At Daman the mortality was—
inoculated 1.6%, uninoculated 24.6%; at Dhwarhar, inoculated 1.2%, uninoculated 5.2%. In all these cases the numbers dealt with were large and the test fair.

Simpson, in The Practitioner (Dec. 1906), gives an analysis of the results of Haffkine's serum inoculations as follows:

In Poona, out of 5593 uninoculated cases the incidence was 6.8%, while in 1300 inoculated cases it was only 0.33%. Klein also prepares a new pathogenic from the dried organs of a guinea-pig, and one of the most interesting experiments is that of Strong (Archivo für Schiffs- und tropische Hygiene, April, 1906), who uses for producing immunity in man a living virulent culture of tetanus bacilli. For this purpose the patient is bled, the pus is filtered out and with no more unpleasant results than those occurring after vaccination. Inoculation protects against attack, and greatly modifies the illness when it fails to protect. How long the protection lasts has not been determined, but it appears to be several months at least.

The main authorities for the researches into plague are in the official reports of recent years from India and elsewhere. See generally W. J. Simpson, A Treatise on Plague (1905).

Protection against plague; (2) on the comparative liability of each fluid to contamination; and (3) on the probable origin of the pathogenic virus in the Mallowal cases. Their report on these points (Dec. 1904) contained the following conclusions: (1) The Institute accepts the account from the Poonah Commission that the new prophylactic is not less efficacious than the old. (2) The Institute is of opinion that in the hands of more or less unskilled workers it is easier to ensure freedom from contamination by Haffkine's standard method of manufacturing plague vaccine than with the 'water agar process' as employed by him. (3) The Institute is in entire agreement with the committee as to the value of 5% carbolic acid in restraining tetanus growth when added to plague prophylactic, and its experiments emphasize still further the importance of this addition in preventing growth and toxic formation in a vaccine which might be liable to the possibility of contamination with spores of tetanus. (4) The tests showed that the Institute's serum killed 100% of the tetanus bacilli but that in all probability tetanus was at the time of inoculation in the fluid contained in the bottle, but that it is impossible to determine at what stage in its propagation, whether in the bottle or in the human system, it became contaminated.

The government decided, on the advice of the director, that only the standard fluid should be manufactured at the plague institute. This fluid was sterilized by methods approved by the Indian Plague Commission and contained the requisite proportion of carbolic acid. It was bottled by a new method patented by Dr E. Maynard.

The result of the inquiries by the commission and the Lister Institute led to a protracted controversy with regard to the responsibility of Mr Haffkine's laboratory, and to his subsequent treatment by the government of India; and the leading bacteriologists in England warmly took up his cause. A parliamentary Return of Papers was issued in June 1907, and in The Times of 1 June 1907, a correspondent wrote: "Mr Ronald Ross, R. T. Hewlett, A. S. Grunbaum, W. J. Simpson, R. F. C. Leith, W. R. Smith, G. Sims Woodhead, E. Klein, S. Fleiner and C. Hunter Stewart, pointing out that the evidence was so far from showing that Mr Haffkine's laboratory was to blame, made it clear to those acquainted with bacteriological work that it had nothing to do with the occurrence. They agreed that there was strong evidence to show that the contamination took place when the bottle was opened at Mallowal, owing to the abolition by the plague authorities of the technique prescribed by the Bombay laboratory, and to the consequent failure to sterilize the forces which were used in opening the bottle and which during the process were dropped on the ground; and they complained of the inadequacy of the inquiries made by the Indian government, and called for Mr Haffkine's exoneration. The result of this debate was that the laboratory had admitted that the tetanus germs had entered the fluid before the bottle was opened, and that a grave injustice had been done to Mr Haffkine. Acting on this view, in November 1907, the Indian government invited Mr Haffkine again to take up work in India.
Towards the close of the 4th century Ambrose of Milan, fearing the loss or corruption of the venerable melodies which had been preserved by means of oral tradition only, endeavoured to restore to their primitive purity, and to teach the clergy to sing them with greater precision. A still more extensive work of the same nature was undertaken, two centuries later, by Pope Gregory the Great. And thus arose two schools of ecclesiastical music, still known as the "Ambrosian" and the "Gregorian chant"—the first of which is practised only in the diocese of Milan, while the latter is universally accepted as the authorized "Roman use." In order to explain the essential differences between these two schools, we must describe in detail some of the peculiar characteristics of plain song.

The melodies which form the répertoire of plain chant are not written in modern major and minor scales, but in certain tonalities bearing names analogous to those of the early Greek "modes," though constructed on very different principles. Of these "modes," fourteen exist in theory, though twelve only in practical use. The intervals of each "mode" are derived from a fundamental sound, called its "final." The compass of each mode comprises eight sounds—that of the first, third, fifth, seventh, ninth, eleventh and thirteenth "modes" extending to the octave above the "final," and that of the second, fourth, sixth, eighth, tenth, twelfth and fourteenth extending from the fourth note below the final to the fifth note above it. Concerning the "mode" proper of the final, called the "authentic modes," occupy the lowest place in each system of sounds, and that of the second series, called the "plagal modes," the middle place—the same "final" being common to one "authentic" and one "plagal mode." The following table exhibits the entire system, expressed in the alphabetical notation peculiar to modern English music—the "final" being indicated in each case by an asterisk, and the position of the semitones, from which each mode derives its distinctive character, by brackets.

The oldest version of this melody now extant is undoubtedly to a certain extent impure; but tradition imparts to it a very high antiquity, and even our doubts as to the authorship of the new generally accepted reading extend only to one single note. A widely accepted tradition points out this melody as the tune sung to *In exitu Israel*, as part of the Great Hallel (see * Psalms*), which is generally (but hardly rightly) identified with the hymn sung by Christ and His apostles immediately after the Last Supper.

One very powerful argument in favour of the Jewish origin of the psalm-tones lies in the peculiarity of their construction. It is impossible to ignore the perfect adaptation of these venerable melodies to the laws of Hebrew poetry, as opposed to those which pervade Greek and Latin verse. The division of the tune into two distinct strains, exactly balancing each other, points assuredly to the intention of singing it to the two contrasted phrases which, inseparable from the constitution of a Hebrew verse, find no place in any later form of poetry. And it is very remarkable that this constructional peculiarity was never imitated, either in the earliest hymns or antiphons we possess or in those of the middle ages—evidently because it was found impossible to adapt it to any medieval form of verse—even to the * Te Deum*, which, though a manifest reproduction of the Hebrew psalm, was adapted by Ambrose to a melody of very different formation, and naturally so since so many of its phrases consist of one "mode" only, balanced in the following verse.

This peculiarity now passes for the most part unnoticed; and the * Te Deum* is constantly sung to a psalm-tone, very much to the detriment of both. But in the middle ages this abuse was unknown; and so it came to pass that, until the "School of the Restoration" gave birth, in England, to the single chant, avowedly built upon the lines of its Gregorian predecessor, and a somewhat later period to the double one, so constructed as to weld two verses of the psalm into one, often with utter disregard to the sense of the words, the venerable psalm-tones stood quite alone—the only melodies in existence to which the psalms could be chanted. And so intimate is the adaptation of these plain-chant melodies to the rhythm as well as to the sense of the sacred text, even after its translation into more modern languages, so strongly do they swing with the one and emphasize the other, that it is difficult to believe that the composition of the music was not coeval with that of the poetry.

Next in antiquity to the psalm-tones are the melodies adapted to the antiphons, the offertoria, the graduals and the introits, sung at High Mass. Those proper to the *Ordinarium missarum* are probably of later date. Those belonging to hymns and sequences are of all ages. Among the latest we possess—perhaps the very latest of any great importance—is that of *Lauda Sion*, a very fine modern mode, sung by Ambrose in *Lamentationes*, the celebrated sequence written by Thomas Aquinas about 1260.

To the melodies adapted to the *Lamentations* and the *Exsulcit*, as sung in the Church of Rome during Holy Week, it is absolutely impossible to assign any date at all. All we know is that they are of extreme antiquity, and beautiful beyond all description. The melody of *Exsulcit* is, indeed, very frequently cited as the finest example of plain song in existence.

To assert that melodies so old as these have been handed down to us in their original purity would be absurd. But the presence of corruption rarely passes undetected by the initiated; and vigorous efforts have been made from time to time to purify the received text by reference to the oldest and most trustworthy MSS. attainable. Such an effort was begun on a very extensive scale by the "Congregation of Rites," at the instigation of Pope Pius IX., in the year 1868; and the labours of that learned body, together with those of the monks of Solesmes and elsewhere, have done much towards the restoration of plain chant to the highest state of purity possible. In England the Plain-Song and Medieval Music Society, founded in 1888, has also done valuable work by its publications. (W. S. R.)

**PLAINTIFF**, one who brings a "plaint" (Low Lat. * plancia plangere*, beat the breast, lament), the name, in law, of the party who brings an action against another, who is called the...
PLAIT—PLANARIANS

707

"defendant." In suits for divorce the party bringing the suit is
styled the "petitioner," the party against whom it
is brought the "respondent."

PLAIT (through O. Fr. plait, from Lat. plicium, folded, hold together, fold), probably a fold, especially a fold of cloth, now
usually in the collatoral form "plait." It is now princi-
pally applied to entwined strands of ribbon, hair, straw, or fibre.

PLAN (from Lat. planus, flat), a diagram on a flat surface;
hence by analogy any deliberate scheme or design. In archi-
technique, a "plan" is a horizontal geometrical section of the
walls of a building, or indications, on a horizontal plane, of the
relative positions of the walls and partitions, with the various
openings, such as windows and doors, recesses and projections,
chimneys and chimney-breasts, columns, pilasters, &c. This
term is sometimes incorrectly used in the sense of design (g.v.).

PLANARIANS, a well-defined group of animals, characterized
externally by their ovoid or vermiform shape, their gliding
movement and their soft, unsegmented, ciliated bodies: inter-
ally by that combination of low somatic type of structure and
complex gonidial organization which is characteristic of the
Phylaemia (g.v.). Their low type of bodily structure may be
exemplified by the facts that the mouth is the only means of
ingress to and egress from the blind alimentary sac, and that no
vascular system is differentiated. Most Planarians are aquatic
and the cilia that cover the body produce by their beating a
stirring of the water. Hence the class is generally known by the
name Turbellaria.

Planarians form one of the basal groups of the animal kingdom.
They are the simplest of multicellular creeping things. In them
the gliding movement has become habitual. The lowest
Planarians are still largely free-swimming animalcules and we
can trace within the limits of the group the development of the
creeping habit and the consequences that flow from it. It has
led to the differentiation of anterior and posterior extremities;
to the formation of bilateral symmetry; and to the development
of a mucilaginous protecting the body against friction. It entails
the concentration of the scattered nervous system on the ventral
surface and at the anterior end, and it has induced the segregation
of the diffused sense-organs in the head. The Planarians occupy
a position midway between the simple planaria larva of Coel-
enterates and the segmented Annelids. They have probably
sporadically diverged from an early Coelomate stock, or represent
an independent class descended from a two-layered parentage
distant from that of the Coelenterates; a view which is adopted
in the present article.

Occurrence.—Most Turbellaria are aquatic. They abound on the
seashore and in fresh water, amongst weeds or under cover
of stones, shells and sand. Few of them are pelagic or deep-
water forms, and only some half-dozen Planarians are known
to be parasitic. A large number of land Planarians are known,
chiefly from tropical and southern temperate countries.

The majority of marine Planarians are nocturnal or cryptozoic,
hiding away during the period of low tide to avoid desiccation
of their soft spongy bodies and coming out at night or during high
tide to feed. They are mostly carnivorous, and their movements
are correlated largely with the nature of their food. The smaller,
more active species occur in companies amongst the finer sea-
weeds over which they creep or swim in pursuit of their food.
The larger marine species occur singly or in pairs on Ascidi-
cans, Nullipores or Polyzoa, from whence as the tide rises they
rise to feed. By the time the next low tide exposes them, these
Planarians have so completely digested their meal that we know
very little of its nature. The common fresh-water Planarians
form either little companies of a dozen or more, usually of a
single species, huddled together under a stone or in some cranny
(sense to fold), or societies of several species that inhabit
Sphaugnum and other fresh-water vegetation. This fresh-water
Planarian fauna is of two kinds, the fauna of permanent and that
of temporary sheets of water and both show a certain adaptation
to their environment. The latter, being subject to greater
extremes of temperature than the lacustrine Planarians, produce

1 These references are to the literature at the end of this article.

thick-shelled eggs only. The development of these eggs is rapid
in warm water, slow in cold: so that a pool after a few days of
early spring sunshine is soon populated and provision is made for
the continuance of the race should a cold snap follow. The
lacustrine Planarians exhibit a different form of adaptation.
The eggs laid by many of these animals are either thin-shelled
and sometimes hatched or thick-shelled and slowly hatched.
The lake-water, however, is in spring, even after sunshine, of a much
lower temperature than that of pool-water, but the masses of
Sphaugnum and other weeds that border lakes and marshes are
often warmer than the open water and may be as much as 15° or
15° C. higher in temperature. Here the Planarians assemble
to benefit from the warmth, and under such favourable conditions
lay thin-shelled eggs which rapidly develop; whilst in colder
surroundings or at the onset of winter thick-shelled resting
eggs are laid. In this manner we can understand the abun-
dance of Planarian life in cold meres and transitory pools in
Great Britain, Scandinavia, Finland, Denmark and North
America.

In contrast to the general habit among Turbellaria of haunting
dim or dark places, the station chosen by a few species is exposed
and strongly illuminated. The marine Convoluta and Poly-
chaerus and the fresh-water Vortex viridis may be taken as
equivalents. Convoluta paradoxus occurs among brown weeds which
receive much light during neap tides and strong direct sun
or light every fortnight. Polychaerus creeps about the New
England shore without resorting habitually to cover, and is also
strongly isolated. Vortex resembles the green Hydra of our
ponds in choosing the lightest side of its surroundings; and
finally, Convoluta roseofuscescentes paints the beach green in Brittany,
part of Normandy and Natal. In every such case the Planarian
is coloured brown or green by the presence of photosynthetically
active cells and the singular heliotropic habit of these Turbellaria
is associated with the illumination necessary for the activity of
their coloured cells.

Only one branch of the Planarians has become terrestrial, but
this has spread over almost all the whole globe. One species
(Rhynchoedemus terrestris, fig. 1, c) is fairly common in Great
Britain under stones, logs and occasionally on fungi, but the
Holarctic countries (North America, Europe and North
Asia) are extremely poor in terrestrial species. In coun-
tries and lying in the centre and in the south of the great continents
and in the south temperate continental islands and archipelagoes
these land Planarians become more abundant and varied; and
being frequently transported with earth or plants they are often
found in botanists' and botanical gardens far from their native
country. Their distribution offers some points of special
interest showing a close relationship between the South American
fauna and that of Australia and New Zealand: between the land
Planarians of Madagascar, of Ceylon and of Indo-Malaya: and
a marked contrast between Japan and the rest of the Palearctic
region (see Von Graff [1], 1895).

External Characters.—Planarians range from the minute forms
no larger than Infusoria to ovate, marine species, 6 in. in
diameter and to ribbon-like land forms 8 in. in length. The
majority are small, somewhat cylindrical organisms with a
flat creeping surface. Others, comprising the common fresh-
water and marine forms, are flattened and leaf-like, often
provided with a pair of tentacles near the front end of the
body, and in some cases the whole dorsal surface is beset with
papillae. The land forms are elongate and smooth, and their
anterior extremity is often modified into the arcuate shape
of a cheese-cutter. Their movements are usually of a gliding
character. The minuter forms perform short excursions around their
station, and in so doing recall Infusoria. The larger forms, in addition to gliding like pellicles, fold the
expanded anterior part of their body into a couple of fans,
with which they swim after the fashion of a skate. The
folded margins of other forms clasp the weeds on which they
live. Adhesion is effected by the mucous investment of the
body and frequently by some specially developed local secretion
of slime, or by a sucker. By these means, aided by their
algal-frequenting and cryptic habits, the Turbellaria, though soft-bodied, are able to withstand the violence of the waves.

The anterior end in all Turbellaria is the site of the chief sense-organs, and in some forms (Proboscidea) becomes transformed into an invaginable proboscis of highly tactile nature. Such forms lead naturally to the Nemertina (q.v.).

Coloration.—The coloration of Planarians is of interest. The flattened marine forms are often brilliantly coloured on the dorsal surface, either uniformly or with some striking marginal band; or they may exhibit longitudinal bands of contrasting tints or a mottled appearance. The significance of these colours is not fully understood, but in some cases of sympathetic coloration the derivative function of the pigments is probably to aid cryptic resemblance. The terrestrial Planarians exhibit the most striking patterns in longitudinal striping and cross-bars which appear to have no relation to the environment of these essentially nocturnal animals. The fresh-water forms are colourless or dusky, often dark-brown, possibly in relation to the retention of heat; but in a number of both fresh-water and marine Planarians a green colour is present, constantly in some species, sporadically in others.

This green effect is due to the infection of the Planarian by a minute alga which multiplies in the tissues and may profoundly affect the habits and even the structure of its "host." The planarian so affected acquires a heliotropic habit; it becomes gregarious and in extreme cases ceases to ingest solid food. In Convoluta rosscfenisi the green cells have become indispensable. They function both as the nutritive and excretory organs of the Planarian, and the young animal cannot develop until it is infected and has acquired a supply of these green cells which become incorporated into its tissues (Gamble and Keeble [7]). Brown algal cells (Zooxanthellae) are known in other species of Convoluta.

Food.—The food of Turbellarians consists, in the smaller species, of diatoms, unicellular algae, microscopic animals and other Turbellarians; in the larger ones, worms, mollusca and insects. The fine feeders capture their food chiefly at night by gulping down the minute organisms that settle or swim in their neighbourhood. The coarse feeders enclose their prey with a coating of slime and then proceed either to engulf it in their expansible mouth or to perforate it by their trumpet-like pharynx. The mouth is remarkably variable in position (fig. 2). In many flattened Planarians it is placed centrally on the ventral surface somewhat as in a jelly-fish. In the majority it is nearer the anterior end, but in a few remarkably elongate forms it occupies a position near the hinder end of the animal. In the cylindrical forms (Rhabdocoels) a similar variability in the position of the mouth is met with.

Anatomy.—The structure of the Turbellaria though greatly varied in detail, conforms to a single type of somatic organization which is transitory in the higher invertebrates. The sexual organs, on the other hand, are found on two or more types, and the astounding complications of these structures suggest that their evolution has been governed by quite other factors or combinations of factors than those that have guided the somatic evolution of the group.
respiratory organs are developed, probably in correlation with the absence of a blood-vascular system. On the other hand, the process of reproduction is elaborately organized. The Planarians are hermaphrodite and, as in so many other small animals, the body, after attaining maturity, becomes in many Planarians practically a genital sac and is soon exhausted by the repeated calls upon its reserves that are involved in the rapid production of eggs and spermatozoa. The intervals between successive clutches has been found in *Comatula roscoffensis* to be a month, thus suggesting the influence of the lunar tides upon maturation.

**Integument.** —The epidermis is ciliated and highly glandular. It consists of a single layer of cubical or oblong cells with the structure seen in Fig. 5. The glandular secretion takes various forms, such as mucous, mucinoid granular blocks, or fusiform refringent homogeneous rods. These rods or “rhabdites” are classification of the Planarian is based on them. Thus we have the *Rhabdocoelida* with straight gut and the *Tricladiida* and the *Polycladida* with triple and multiple branches to the gut. The Rhabdocoelida are further divided into three groups: the Acoela

**Fig. 4.—Portion of a transverse section of Mesostoma ehrenbergii* (X300).**

The epidermis (E) consists of cells divided into an outer and inner zone, the latter containing rhabdites (Rb). The cilia (C) are thickened about the middle of their length. Below the epidermis is the basement-membrane (BM), a layer of circular muscles (C) and of longitudinal ones (L). Below this again is the mesenchyma (M), made up of branched cells and dorso-ventral muscle-fibres (DM). The mesenchymatous glands (Rm) are producing rhabdites (Rm) which pass outwardly.

- Frequently coloured red or yellow, and are highly characteristic of the Turbellaria. Their real use is unknown. In only two genera does the epidermis produce cuticular spines (*Acanthohae, Enaniia*) on the surface, but chitinoid hooks, spines and spicules occur frequently on the lining membrane of the male and female copulatory ducts.

Below the epidermis is a firm basement membrane into which the subjacent muscles are inserted. They are divided into outer circular and inner longitudinal groups and subdivided in the larger forms by diagonal fibres, and in the most highly differentiated Planarians there are six muscular layers, two of each kind. In a number of Turbellaria the musculature is modified to form a sucker either single or double and anterior or posterior, and it undergoes further modification in connexion with the pharynx and reproductive organs.

**Fig. 6.—Main trunks of the Excretory System of Mesostoma ehrenbergii, O. Sch., opening to the exterior through the mouth: ph, Pharynx.**

With a simple syncytial gut not sharply separated from the surrounding mesenchyma; the Rhabdocoela, with a hollow gut and a perivisceral schizocoelid span; and the Allocoela with a lobate gut and reduced schizocoel. The last group leads one naturally to the Tricladida; the Polyclads being an independent group.

The pharynx varies widely in structure. In the Acoela it is a mere thickening and pitting of the integument. In the Rhabdocoela a great number of elaborate modifications are found. These are based on the type of a buccal invagination, which forms the pharyngeal sheath, and from the bottom of this there springs a muscular outwardly directed tube or fold. In the Allocoela and Tricladida the pharynx is an elongate protrusible cylinder, and in the Polyclads it may be an immensely distensible frilled organ, the folds of which have independent movement, or an elongate tube. At the base of the pharynx lie the openings of salivary glands. In the Polycladida the section of the alimentary tract into which the pharynx opens is a median stomach from which the intestinal branches radiate. The stomach in few forms is provided with digestive glands. The branches possess an independent musculature and exhibit active peristalsis. The intestines of Planarians is not closed, and digestion appears to be largely intracellular and not cavitary.

**Mesenchyma.** —The mesenchyma (Bohmg; parenchyma asept.) consists of a mass of branched vacuolated cells, imbedded in which lie gland-cells, pigment-cells and the excretory system. It envelops the genital organs, which though in the mesenchyma are not of it, and it forms an investment to the gut and to the space (schizocoel) which often occurs between the gut and the mass of the mesenchyma. The mesenchymatous gland-cells are of different kinds. (1) Single cells in which rods (rhabdites) are developed (fig. 4, Rm). Such cells in embryonic life give rise to a process which perforates the soft basement-membrane and penetrates between the epidermal cells. The process becomes hollow, and the rhabdites pass outwards along it to the surface of the animal, forming in many Turbellarians thickly set rows of rods on the head. (2) Similar cells contain nematocysts in a few Planarians (*Microstoma, Stenostoma, Anonymus viridis* and *Stylechoplana tarda*). Whether these

**Fig. 8.—The Nervous System of a Simple Planarian (Haploplastron, one of the Acoela).**

B, the brain which gives off a dorsal (DN) and a ventral ( VN) plexus and also lateral nerves (LN). The mouth (M) and the otocyst (OT) are shown. The former is ventral, the latter dorsal in position.
nematocysts develop in the Turbellarian is doubtful, and it is not impossible that they are derived from the tissues of some coelenterate animals eaten by the Planarian, as has been shown to be the case in the nematocysts of Solida. (3) Cells producing acellulate spicules, sometimes associated with a spiral thread. These structures are often associated together in batteries, notably so in the remarkable genus *Acoela*.

**Excretory System.**—The excretory system consists of protonephridia, that is, of tubes opening to the exterior by one or more apertures, and after branching extensively in the mesenchyma, end blindly in peculiar hollow cells (flame-cells) provided with a bunch of synchronously vibrating cilia. The excretory tubules of some have a markedly sinuous course and are provided with cilia. The motion of these cilia and of the flame-cells is to induce an outward current of the fluid from the canals, but the process of excretion seems to be performed chiefly by the branched mesenchymatous flame-cells. The position of the external opening varies greatly. It may be single or paired, mid-ventral or terminal, or again multiple and arranged in pairs along the dorsal surface (Triclada and probably in Polycladida). The flame-cells are arranged in pairs in Tricladida, but lie less regularly in the mesenchyma of most forms. Finally, it is noteworthy that in the Acoela no excretory system is known.

**Nervous System.**—The nervous system is present in all divisions of the order. It consists of a paired, anterior ganglion lying ventral to the gut, and from this ganglion off, right and left, dorsal, lateral and ventral fibres interconnected by a plexus. The nerve-cells are scattered throughout this plexus. The chief development of the system occurs in relation to the muscular body-wall, sense-organs and the pharynx. In these characters the nervous system of Planarians shows an interesting transition from the scattered plexus of Coelenterates to the segmental ganglia and sympathetic nervous system of Annelids.

**Sense-organs.**—These occur in the form of tactile organs, otocysts and eyes. The whole skin of many Planarians is sensitive, and amongst the ordinary locomotor cilia long stiff ones are found which it is natural to think are tactile organs. The head-end is often provided with specialized cells that appear to subserve the sense of touch and possibly of taste also. The abundance of rhabmites, of long stiff cilia, and the great mobility and sensitiveness of this region, bear out this conclusion. A further development of cephalic, sensory structures occurs in the form of a crescentic groove (Polyclada) of paired, lateral pits (*Microstoma*, fig. 10) of mobile papillae on the extreme front margin (Land Triclads) and of extensible tentacles, marginal or nuchal in most Polycladida.

The otocyst occurs commonly in the Acoela and sporadically in every other division of the group. It is with one exception a single median organ placed over the brain, and consists of a uni- or bi-cellular sac containing a calcareous concretion lying in a fluid. From what is known of these organs in higher invertebrates we may infer that they serve to increase the perception of slow wave-movement and enhance the control of the muscular sense.

Eyes are generally present in Planarians. Two types are distinguishable—eyes with a cup-shaped retina facing outwards, and those with an inverted retina facing inwards. The former occur in Triclads and Polyclads around the margin of the body often a hundred or more may be present. The latter occur in all groups except the Acoela, but are limited to the neighbourhood of the brain or bases of the nuchal tentacles. Recent investigation has shown that the essential part of the eyes has in all cases a complicated structure and is not a mere epidermal cell-group enclosed by pigment and provided with an optic nerve. On the contrary (Hesse [10]), adequately known eyes are composed of rod-cells that contain each an axial filament or bundle of fibrillae (the termination of the nerve), and the distal end of the rod-cell is converted into a stratified usually broad border where the action of light commences. A group of such specialized rod-cells is enclosed in a pigmented cup opening either outwards or inwards and pierced by an optic nerve. The whole is usually depressed beneath the epidermis, but in some Acoela and Allacoeca the eyes retain a surface-position. In the Polyclads eyes may increase by division and in Triclads may decrease in number by fusion (Carrière [11]). The marginal and often radial disposition of the scattered eyes, and the protostomal position of the paired eyes, afford interesting evidence of the intermediate position that Planarians occupy between the radiate Coelentera and the bilateral Annelids.

**Reproduction.**—All Turbellaria are hermaphrodiote, and reproduce sexually, but a few forms (Microstomidae and some Triclads)

---

**Fig. 9.**—Double Eye found on the brain of Polyclads. Each consists of a pigment cup and of four nerve-end cells (rods-cells) in which the nerves terminate.

**Fig. 10.**—Microstoma lineare, Oc, undergoing division. There are 16 individuals, 8 with mouth apertures, showing the buds of the first (m), second (m'), third (m''), and fourth (m'''') generation. The fifth generation has not yet acquired a mouth aperture. c, ciliated grooves; e, eye spots; t, intestine.

**Fig. 11.**—Plan of an Acoelous Turbellarian.

**Fig. 12.**—Plan of a Rhabdocoelous Turbellarian.
Trioclads, on the other hand, fragment, without undergoing preparatory changes.

The male and female genital ducts (gono-ducts) open to the exterior, either through a common chamber on the ventral surface (most Rhabdocoela and all Trioclads, figs. 12, 14) or by separate apertures that are also ventral. In the latter case, the male gonopore is usually in front of the female one (all Polycladida and some Rhabdocoelida). A separate opening is sometimes acquired by one or other of the accessory reproductive organs (as by the spermotheca in some Rhabdocoela in which it is dorsal).

The generative organs of the Planarians are complex. Male and female germ-cells develop in one and the same individual and reach the exterior by independent ducts. These ducts are provided with accessory glands along their course and terminate in penial or vaginal structures, often of great complexity, which are surrounded by an “atrium” or invagination of the ventral body-wall. From this invagination a special vesicle “uterus” is often developed for the reception of the fertilized egg previous to oviposition.

The Acoela present the simplest arrangement. In this group (fig. 11) the male germ-cells arise in follicles each of which is the product of a single sperm-mother-cell. From these follicles, the motile spermatozoa enter the paired sperm-duct, which opens by a single aperture near the hinder end of the animal, and is provided with a simple unarmed glandular penis. The female germ-cells or ova arise from a paired ovary, some of the cells of which appear to act as nurse-cells, supplying the young eggs with nourishment. When mature the eggs are transferred to the oviduct. At the point where the two oviducts join in order to open to the exterior they receive a conical sac (spermotheca) which contains spermatozoa. At this point the eggs are fertilized, and deposited in a småclaginous mass which is attached to algae or buried in the sand. It is characteristic of the Acoela that the testes and ovaries should not be continuous with either the sperm-duct or the oviduct respectively.

In one genus of the Acoelous Turbellaria—Polycelaerus—this primitive arrangement undergoes a development which foreshadows the complicated ovaria and vitellaria of higher forms. In Polycelaerus the eggs mature in a special roomy chamber and are here provided with yolk which is elaborated by a sterile part of the ovary. Thus we have a differentiation of germ-cells into two portions allocated to two chambers: fertile ova which open eventu-

ally into the oviduct, and sterile ova that become yolk-cells and open into the brood-pouch.

The remaining Rhabdocoelida possess separate ovaries and yolkglands. The union between the two sets of ducts takes place in the genital atrium which is provided with a spermotheca for the fertilization of the ova, but in at least one sub-family (Cylindrostominae) the spermotheca opens by a special dorsal pore. These ova, together with the yolk and spermatooza, are then transferred to another atrial diverticulum—the uterus, in which a shell is formed and from which they are deposited in the form of a cocoon. In addition, a muscular pouch, the so-called “bursa copulatrix,” is usually present. The male organs of Rhabdocoelida are no less complex. The testes are either follicular (Alloeocoelida) or compact

(Rhabdocoelida), and communicate indirectly or directly with the paired seminal ducts. The ducts unite at the base of an evaginable penis. This muscular organ is provided with glandular and chitinoid appendages of considerable complexity, and, in addition to these, a poison gland and duct are sometimes present. In certain genera (Macrocrinacea, Procrinacea) the penis is used for catching prey, perhaps exclusively so in the former genus. The opening of the atrium into the oral cavity in Cylindrostominae and of the male organ into the mouth of Procrinacea is possibly explained by this fact.

From the Alloeocoelida we pass readily to the Triclads. In both of these groups the reproductive organs are based on the same plan; but in Trioclads the separation of ovarian and vitellarian portions of the gonad is less perfectly effected. The oviduct transmits the eggs from the anteriorly placed ovary, and receives in its course the openings of numerous vitellaria (fig. 14). No distinct spermotheca is developed, but a cocoon is formed in a special chamber—
...the uterus—which may either be a dilatation of the common oviduct (vagina) or of the atrium, and may open to the exterior independently—(single in Utter, but in Symulidium). In Bdelogala the uterus is said to act as a spermatheca. In addition to these structures, accessory muscular organs are found in Dendrocoelium and developed to a high degree in Thysanozoon and certain other invertebrates, is early apparent. The ovum by unequal segmentation gives rise to megameres and micromeres, and between the two, intermediate cells form one or more of the three chief groups, and Plana, in which they form the so-called adenoschiz and adenoschizly (see von Graff, 1899).

Lastly, the Polyclads offer certain distinctive sexual characters. The ova are follicular, with additional and the ovary itself and their own yolk (fig. 15). The oviducts open into a chamber which, after receiving a voluminous shell-gland, opens by a muscular bursa to the exterior. No special uterus is developed, but from the point of union of these two organs a double duct is given off which may separate either to the exterior (Trigonoporus). The testes are equally diffused and the seminal vesicles usually form a median muscular eversible sac which opens in front of the female genital pore. In Symulidium, on the other hand, the duct from the testes may open into the ovary. Moreover, it may be paired (Thysanozoon) or multiple. Thus in Anonymus twelve or more pairs occur. In Cryptodea, two, or more rarely one, may be present, but in this genus they all lie in a common sac. In Polyplavia twenty pores occur ranged about the female pore, but the most posteriorly placed of these structures are devoid of a seminal duct. This condition supports the view that Polyclads in the penis was at first a glandular organ probably used for attracting prey and that it has become secondarily connected with reproduction. In confirmation of this conclusion we have the observations of Lang (5) that Yungia strophistoma (by origin of Pot.) never has a penis when brought into contact with them. (See Whitman [9].) The genus Laidilalia differs from all other Polyclads in possessing a dorsal genital opening.

The development of the Planarians is fairly well known. Except for one or two species of Polyclads, development is direct and without metamorphosis; but in Thysanozoon and Yungia the embryo develops eight very strongly ciliated lobes which form a circumporal larval processes. These have been compared with the girdle of Trochosphere larva and also with the eight rows of swimming plates in Ctenophores. From the name of the genus we discover these larval forms are called Müller's larvae (fig. 15). In the Rhabdocoela the eggs are usually laid in a shell which has characteristic shapes. Each capsule contains a single ovum and several yolk-cells. Segmentation of the former gives rise to the differentiated megacytes and micromeres. The latter give rise to the epidermis which is laid down in the hinder parts of the egg, the former giving rise to the parenchyma. The pharynx and the rudiment of the gonads are the first organs to appear (Breslau [13], 1505). The development of the Acoela differs in certain particulars from that of other Rhabdocoela. The ova contain yolk-granules, and develop immediately into an amoeboid stage, which can live without a shell, are in a gelatinous envelope. Each ovum segments into a two-layered embryo composed of a ciliated outer layer and a central syncytium. No trace of a gut appears and the syncytium becomes differentiated into a more fluid central portion and a thinner peripheral zone. The former, together with the wandering phagocytes, corresponds functionally to the separate gut of most Metazoa, the formation of a mesoderm and various internal organs. There is no distinction of germ-layers, and the gut is gradually formed from the mesoderm. Development depends on a single cell, and the appearance of the genital organs the ova and the seminal vesicles, but does not give rise to the parenchyma and would seem to belong to the Embryonophytae. This condition of the polycladous worms, which is very widespread in the animal kingdom, would seem to have been the case in an egg-laying ancestral form. In general the cases of Turbellaria are quite uncertain, and on present evidence it seems legitimate to hold that they are the most highly differentiated division both in embryonic and adult structure.

**Systematic Arrangement.**

Order Turbellaria. — Free-living Platyzelmia with a ciliated epidermis. No excretory organ, no protonephridial type. A single pharynx. A median or metagastic (stachys) orifices over the brain. Small, often flattened forms. All marine and freshwater, usually by small or green algal cells. One subspecies parasitic in Echinoderms.

- Tribe II. Rhabdocoeola (fig. 12). — Gut and parenchyma separate, the excretory organs form a single group of organs, Testes compact. Penes and pharynx often complex, occasionally protruded through a common opening. Marine and freshwater. Many freshwater forms infected by algal cells. Typhloplanas, Pfiigista, most of the species parasitic in Nephilis, in Gastropods and Holothurians.

- Tribe III. Allocoela. — Gut and parenchyma distinct. Intestine straight or lobate. Testes follicular. Penes and pharynx separate, but the excretory organs are a single group of organs, Testes compact. Penes and pharynx often complex, occasionally protruded through a common opening. Marine and freshwater. Many freshwater forms infected by algal cells. Allocoela, Typhloplanas, Pfiigista, most of the species parasitic in Nephilis, in Gastropods and Holothurians.

**Sub-order B. Dendrocoelida.** — Large forms with flattened body, branched intestine, follicular testes and follicular ovaries or compact ova. Marine and freshwater. Body split into two parts, each containing the ova and testes respectively. All marine except Plagiostoma lemnari (deep-water, Geneva) and the Botrophilidae.

**Sub-order C. Dendrocoelida.** — Large, flattened, branched intestine, follicular testes and follicular ovaries or compact ova. Marine and freshwater. Body split into two parts, each containing the ova and testes respectively. All marine except Plagiostoma lemnari (deep-water, Geneva) and the Botrophilidae.

**Sub-order D. Laidilalia.** — Body-leaf-like. Intestine composed of a median stomach with many branched or reticate coecon; testes and ovaries follicular; genital openings usually separate, the male generally being the more complex. All marine except Plagiostoma lemnari (deep-water, Geneva) and the Botrophilidae.

**LITERATURE.**

1. L. von Graff (Rhabdocoeola, Acoela, Trichadiada, Myxoozoon, and rest of which Lang, 1905); (3) (Rhabdocoeola, Acoela, Trichadiada, Myxoozoon, and rest of which Lang, 1905); (2) Arbeiten aus der soll. Inst. zur Graz (1904, 1905, 1906); (3) "Turbellaria," in Drinn's Klassen v. Ordnungen d. Thierreich, vol. ii.; (4) Turbellaria als Parasiten u. Wirthe (Graz, 1904); (5) A. J. Lang, "Leve Platyzelium. System and organs concentrated at the anterior end of the body, diffused elsewhere.

- Sub-order A. Rhabdocoida. — Gut syncytial or tubular. Female gonads always compact.

- Tribe II. Laidilalia. — Body-leaf-like. Intestine composed of a median stomach with many branched or reticate coecon; testes and ovaries follicular; genital openings usually separate, the male generally being the more complex. All marine except Plagiostoma lemnari (deep-water, Geneva) and the Botrophilidae.

- Tribe III. Allocoela. — Gut and parenchyma distinct. Intestine straight or lobate. Testes follicular. Penes and pharynx separate, but the excretory organs are a single group of organs, Testes compact. Penes and pharynx often complex, occasionally protruded through a common opening. Marine and freshwater. Many freshwater forms infected by algal cells. Typhloplanas, Pfiigista, most of the species parasitic in Nephilis, in Gastropods and Holothurians.

- Tribe IV. Dendrocoelida. — Large, flattened, branched intestine, follicular testes and follicular ovaries or compact ova. Marine and freshwater. Body split into two parts, each containing the ova and testes respectively. All marine except Plagiostoma lemnari (deep-water, Geneva) and the Botrophilidae.

**Appendix to the Turbellaria.**

Class Trematodoeidae. — This small class of Platyhelminthes possesses a peculiar form of the Turbellaria (and in particular the Vorticidae rhabdocoeola) with the Trematoda. At the same time the Trematodoeidae present certain peculiar structural features which entitle the class to an independent position. The Trematodoeidae is provided with the dilated tentacles which occur on the anterior or lateral margins of the body. The body measures about 5 mm. in length, and the flattened ventral surface is armed with a sucker. It presents the Gulf of Eden of the appearance of a minute cephalopod, but in Craspedia the posterior
part of the dorsal surface is raised up into three transverse fringed lamellae. These animals are epizoic, i.e., they are attached to the outer surface of other organisms, but are not ectoparasitic for they ingest Infusoria, Rotifera and Diatoms. Most of the species occur on fresh-water crayfish and crabs in Chile, Madagascar, the Malay Archipelago and Australasia. Two Brazilian forms are known, one from the pulmonary chamber of the Mollusc Amphalaria and the other from water tortoises. The genus Temnocephala is found in all the countries mentioned. The two others, Cepedella and Actinodactyella are only known from Australia.

The epidermis offers an interesting transitional structure. It is still, as in Turbellaria, cellular, or rather syncytial without cell-boundaries, but in most species has lost its cilia and developed a thick cuticle as in Trematodes, pierced by the necks of subdermal gland-cells. These cells, however, still retain the Turbellarian character of secreting rhabdites and form thickly-grouped tracts. The mouth, which is placed near the anterior end, leads into a bulbous pharynx from which a short, broad digestive sac is given off. The excretory system is peculiar. Besides the ordinary flame cells, single large canaliculated cells may form the commencement of the tubules, composed of comparatively few cells with large nuclei. They open to the exterior by a pair of contractile sacs situated dorally at the level of the mouth as in certain Trematodes. Each sac is the product of a single cell, and is said to contain several branches of "flames" or synchronously contractile cilia. The reproductive system recalls that of certain Rhabdocoela, whilst the nervous system has retained a more primitive condition. The brain, which is placed over the mouth, gives rise to six main longitudinal tracts interconnected by a subdermal network. A pair of eyes is placed above the brain.

Class and order Temnocephalidea.—Platyelmia in which the flattened body is produced into anterior or anterior and lateral tentacular processes and carries a ventral sucker. The epidermis is a syncytium covered by a thick cuticle. Cilia and rhabdites are present. Family I.: Temnocephalidae: 4-12 anterior tentacles. Family II.: Actinodactyldidae. Lateral tentacular processes.

**PLANCEER** or **PLANCHER** (O. Fr. planicer, or planicher, planking), in architecture, a term sometimes used in the same sense as a soffit, but more correctly applied to the soffit of the corona in a cornice.

**PLANCHE, JEAN BAPTISTE GUSTAVE** (1806—1857), French critic, was born in Paris on the 16th of February 1806. Introduced by Alfred de Vigny to François Buluz, he began to write for the Revue des deux mondes, and continued to do so until 1840. He resumed his connexion with the journal in 1846 and contributed to it until his death in Paris on the 26th of September 1857. Gustave Planche was an altogether honest critic and refused to accept a place from Napoleon III. for fear of compromising his freedom. He was in early life a fervent admirer of George Sand, and he lavished praise on De Vigny. But he had nothing but scorn for Victor Hugo, whose earlier dramas he characterized as odes, those following Le Roi s’amuse as anti-theses, and the later ones as nothing but spectacle. His critical papers were collected under the titles: Portraits littéraires (1830-1849); Nouveaux portraits littéraires (1854); and art criticisms, Études sur l’école française (1855).

See Ernest Montéquat, in the Revue des deux mondes (June 1858); Hatzfeld and Meunier, Les Critiques littéraires du XIXe siècle (1891).

**PLANCHE, JAMES ROBINSON** (1796—1880), English dramatic and antiquary, was born in London on the 27th of February 1796, the son of a watchmaker of Huguenot descent. In 1810 he was articled to a bookseller. In 1818 his first dramatic piece, a burlesque entitled Amorose, King of Little Britain, was produced at Drury Lane theatre. From this time onwards he made play-writing his principal work. In 1820-1821 he wrote ten pieces for the Adelphi theatre. In 1823 he designed the dresses for Charles Kemble’s revival of King John at Covent Garden, and superintended its production. This was the first time that an historical drama had been “dressed” in the costume of the period. In 1828 he began writing regularly for Covent Garden theatre, and in 1830 was manager of the Adelphi. On Mme Vestris taking the Olympic theatre in 1831, Planché entered into an agreement with her to write a series of plays. The first of these, Olympic Revels, a burlesque, was given on the opening night of the theatre, the performance being given in correct classical costume. In 1834 his Pair One with the Golden Locks was produced by Webster at the Haymarket. In 1847 Mme Vestris became manageress of the Lyceum theatre, and Planché was engaged as her leading author and designer, his principal success being the Island of Jewels (1849). Subsequently he wrote for a number of other managements, his last dramatic piece being King Christmas (1871), but he also wrote the songs for Baby and Beboy at Covent Garden (1872). In addition to his dramatic work Planché enjoyed a considerable reputation as an antiquary and heraldic student. He was a Fellow of the Society of Antiquaries, and aided in the foundation of the British Archaeological Association in 1843. In 1834 he published The History of British Costumes. In 1854 he was appointed Rouge Croix pursuivant of arms at the Heralds’ College, and in 1866 Somerset herald. In 1869, at the request of the War Office, he arranged the collection of armour at the Tower of London in chronological order. He died at Chelsea on the 30th of May 1880.

Planché’s Recollections and Reflections were published in 1872.

**PLANK, GOTTLIEB JAKOB** (1751—1833), German Protestant divine and historian, was born at Nürtingen in Württemberg, where his father was a notary, on the 15th of November 1751. Educated for the Protestant ministry at Blaubeuren, Bebenhausen and Tübingen, he became rector at Tübingen in 1774, preacher at Stuttgart in 1780, and professor of theology at Göttingen in 1784. At Tübingen he wrote Das Tagebuck eines neuen Ethnommenes. In 1781 he published anonymously the first volume of his Geschichte des protestantischen Lehrbegriffs; the second, also anonymous, appearing in 1783, and it was completed in six volumes in 1800. It was followed by an extensive Geschichte der christlich-kirchlichen Gesellschaftsverfassung in five volumes (1803-1809). Both are works of considerable importance, and are characterized by abundant learning. He died on the 31st of August 1833. His son Heinrich Ludvig Planck (1785—1831), also professor of theology at Göttingen, published Bemerkungen über den ersten Brief an den Thimothes (1868) and Abriss d. philos. Religionslehre (1821).
flowers are borne in dense pendulous heads, which contain either male or female flowers; the small one-seeded fruits are densely crowded in a ball, from which they gradually separate in drying, and are readily carried by the wind. The wood, which is hard and heavy, though not strong, is used in Persia and other countries for house construction and furniture. A variety of forms are known in cultivation, the commonest being the maple-leafed (acerifolia), the London plane, which has usually three-lobed leaves; var. lasiinata has very deeply much divided leaves, and var. variegate, variegated foliage. Platanus occidentalis, an allied species, is a native of the United States, being most abundant and growing to its largest size in the bottom lands of the basins of the lower Ohio and the Mississippi rivers. It was introduced into England early in the 17th century, and is occasionally met with in western and central Europe. Professor C. S. Sargent (Silva of North America) refers to it as the most massive if not the tallest, deciduous-leaved tree of the North American forest; it is known in America as sycamore and buttonwood. It differs from P. orientalis in its less deeply lobed, more leathery pubescent leaves and in the usually solitary balls of fruit.

2. The name of a carpenter's hand-tool, used for levelling and smoothing (Lat. planus, level) the surface of wood. The machine tool used for a similar purpose for metals is generally known as a planing-machine or planer.

PLANE. In botany, the common name of a handsome tree known botanically as *Platanus orientalis*, a native of Greece and western Asia, a favourite shade-tree of the ancient Greeks and Romans, and introduced by the latter to south-west Europe. It

**PLANE, C. K.**

**PLANCK, KARL CHRISTIAN** (1856-1880), German philosopher, was born at Stuttgart on the 17th of January 1856. He studied at Tübingen, where he became doctor of philosophy in 1870 and Privatdozent in 1874. During this period the influence of Reiff led him to oppose the dominant Hegelianism of the time. In 1870-1871 he published his great book, *Die Weltalter*, in which he developed a complete original system of philosophy, based on the realistic view that thought should proceed from nature to the highest forms of existence in the spiritual life. Not only did Planck oppose the idealism of his confrères; his views were, in another aspect, directly antagonistic to the Darwinian theory of descent, which he specifically attacked in *Wahrheit und Flachheit des Darwinismus* (Nördlingen, 1872). The natural consequence of this individuality of opinion was that his books were practically disregarded, and Planck was deeply indenased. The ill success of *Die Weltalter* served him to new efforts, and he repeated his views in *Katalepsis des Rechts* (1872), *Grundlagen einer Wissenschaft der Natur* (1861), *Secte und Geist* (1871), and numerous other books, which, however, met with no better fate. In the meantime he left Tübingen for Ulm, whence he came finally to the seminary of Maulbronon. He died on the 7th of June 1880 in an asylum after a short period of nervous prostration. After his death a summary of his work came into the hands of K. Köstlin (author of *Aesthetics*, 1869), who published it in 1881 under the title Testament eines Deutschen, Philosophie der Natur und der Menschheit. Planck's views were elaborately developed, but his method of exposition told heavily against their acceptance. He regarded himself as the Messiah of the German people.

Beside the works above quoted, he wrote *System des reinen Idealsismus* (1851); *Anthropologie und Psychologie auf naturwissenschaftlicher Grundlage* (1874); a political treatise, *Bismarck: Siedlungsdeutschland und der deutsche Nationalstaat* (1872); and *Logisches Caesalgesetz und naturliche Zweckamdrthigkeit* (1872).

See Umfrid, Karl Planck, dessen Werke und Wirken (Tübingen, 1881); and Schmidt, "Das Lebensideal Karl Christian Plancks," in Vorträge der philosophischen Gesellschaft (Berlin, 1896).

**PLANE.** 1. In botany, the common name of a handsome tree known botanically as *Platanus orientalis*, a native of Greece and western Asia, a favourite shade-tree of the ancient Greeks and Romans, and introduced by the latter to south-west Europe. It

**PLANET** (Gr. πλανήτης, a wanderer), in the ancient astronomy, one of seven heavenly bodies characterized by being in motion relative to the fixed stars, which last appeared immovable upon the celestial sphere. As thus defined the planets were the sun, the moon, Mercury, Venus, Mars, Jupiter and Saturn. In modern astronomy since Copernicus, the term is applied to any opaque body moving around the sun. Taken in its widest sense it applies to the satellites which are sometimes termed secondary planets.

Each of these moves around a planet larger than itself, which it accompanies in its revolution round the sun. A planet not revolving round another is termed a primary planet.

The primary planets are classified as major and minor. The former are eight in number and, with the sun, form the principal members of the solar system, under which head their arrangement is described. The earth on which we live is the third in the order of the major planets from the sun. With respect to the positions of their orbits relative to the earth, the other planets are distinguished as inferior and superior. The former, only two in number, comprise Mercury and Venus, which revolve between the earth and the sun. The superior planets are those whose orbits are outside that of the earth. The synodic revolution of an inferior planet is the time in which it performs a revolution relative to the line joining the earth and the sun. This is greater than its actual time of revolution. The phases or appearances presented by such a planet depend upon its configuration with respect to the earth and sun, and therefore go through their complete periods in a synodic revolution. At superior conjunction the illuminated hemisphere of the planet is presented to the earth so that it presents the form of a full moon. As it moves towards inferior conjunction, the lines from the planet to the sun and to the earth, or the angle sun-earth as seen from the planet, on which the phase depends, continually make a greater angle. At the time of greatest elongation this angle is 90°, and the planet appears one half illuminated, like the moon at first or last quarter. Then, as it approaches inferior conjunction, the visible portion of the disk assumes the crescent form, and while the circle bounding the disk continually increases owing to the approach of the planet to the earth, the crescent becomes thinner and thinner until, near inferior conjunction, the planet is no longer visible. After conjunction the phases occur in the reverse order. The brilliance of the planet as measured by the total amount of light we receive from it, goes through a similar cycle of change. The point of greatest brilliancy is between inferior conjunction and greatest elongation. In the case of Venus this phase occurs about three or four weeks before and after inferior conjunction.
The relative sizes of the planets are also given, orientated in their true axial position with regard to the ecliptic. The nearer planets (and also the Moon) are separately compared (fig. 3); and then shown (on a smaller scale) in comparison with the more distant ones (fig. 4). Finally scale diagrams of the distances of the orbits of the satellite-systems of Saturn, Uranus, Jupiter and Neptune are given (fig. 5).
The phases of a superior planet are less strongly marked, because the lines from the planet to the earth and sun never increase to a right angle. The result is that although the apparent disk of Mars is sometimes gibbous in a very marked degree, it is always more than half illuminated. In the case of the other superior planets, from Jupiter outward, no variation in phase is perceptible even to telescopic vision. The entire disk always seems fully illuminated.

The most favourable time for viewing an inferior planet is near that of greatest brilliancy. As it recedes further from the earth, although a continually increasing proportion of its disk is illuminated by the sun, this advantage is neutralized by the diminution in its size produced by the increasing distance. When a superior planet is in opposition to the sun it rises at sunset and is visible all night. This is also the time when nearest the earth, and therefore when the circumstances are most favourable for observation.

The greater the distance of a planet from the sun the less is the speed with which it moves in its orbit. The orbit being larger, the time of its revolution is greater in a yet larger degree. An approximation to the general laws of speed in different planets is that the linear speed is inversely proportional to the square root of the mean distance. From this follows Kepler's third law, that the squares of the times of revolution are proportional to the cubes of the mean distances.

Notes on the Plate showing Planetary Spectra.

Only those lines and bands are mentioned which are peculiar to the planets; the Fraunhofer lines are therefore omitted.

It was once supposed that the planets were surrounded by comparatively dense atmospheres. The question whether such an atmosphere is the case, and, if so, what is the physical constitution of the atmospheres, is a difficult one, on which there is much discussion.

The linear speed of a planet is inversely proportional to the square root of the mean distance from the sun. This follows from the general laws of motion and Kepler's third law. The linear speed is therefore inversely proportional to the square root of the mean distance.

Notes on the Plate showing Planetary Spectra.

Only those lines and bands are mentioned which are peculiar to the planets; the Fraunhofer lines are therefore omitted.

Actual observation has thus far shown no well marked deviation in the spectra of any of the inner group of planets, Mercury, Venus and Mars, from the solar spectrum as we see it. It follows that if any of these planets may have must, if transparent, be rare. The evidence in the cases of Venus and Mars is given in the articles on these planets. Taking the outer group of planets, it is found that the spectrum of Jupiter shows one or more very faint shaded bands not found in that of the sun. In Saturn these bands become more marked, and in Uranus and Neptune many more are seen. The spectra in question have been observed both optically and photographically by several observers, among whom Huggins, Vogel and Lowell have been most successful. It may be said, in a general way, that seven or eight very marked dark bands, as well as some fainter ones are observable in the spectra of the two outer planets. The general conclusion from this is that these planets are surrounded by deep and dense atmospheres, semi-transparent, of a constitution which is probably very different from that of the earth's atmosphere. But it has not, up to the present time, been found practicable to determine the chemical constitution of these appendages, except that hydrogen seems to be an important constituent. (See Plate.)

Stability of Planetary Atmospheres.

Only those lines and bands are mentioned which are peculiar to the planets; the Fraunhofer lines are therefore omitted.

From this follows Kepler's third law, that the squares of the times of revolution are proportional to the cubes of the mean distances. The stability of the planets is therefore assured.

PLATE II.

FIG. 1. ORION NEBULA.—Typical of the spectrum of the gaseous nebulae; contains bright lines of nebulum, hydrogen and helium. (The helium lines are too faint to show in this reproduction.)

FIG. 2. RIGEL.—Typical of the helium star spectrum; contains, in addition to the helium series and so-called Orion lines, dark lines of hydrogen.

FIG. 3. SIRIUS.—The hydrogen type spectrum; contains dark hydrogen lines at their greatest strength and many fine metallic lines.

FIG. 4. PROCYON.—Transition or hydrogen-to-solar type spectrum. The hydrogen lines are weaker, the metallic lines stronger than in Sirius.

FIG. 5. SUN.—Hydrogen absorption fainter, metallic lines stronger and more numerous.

FIG. 6. ARCTURUS.—Advanced solar type spectrum.

FIG. 7. BETELGEUSE.—Typical of the spectrum partaking of the nature of that of the sun and that of the long-period variable star exemplified in Fig. 8.

FIG. 8. MIRA CETI.—A spectrum typical of the long-period variable, containing bright hydrogen lines and dark bands or flutings which are sharply defined on the more refrangible edge. [Plate used in photographing this spectrum was not sensitive below λ7200, hence no light-action below that point.]
one which absorbs the same fraction of the thermal radiation falling upon it whatever the wave length of this radiation—exposed to the sun’s radiation in void space tends to assume a definite temperature, called the normal temperature, the degree of which depends upon the distance of the body from the sun. This is a result of Kirchhoff’s law of radiation.

2. An atmosphere surrounding such a body, if at rest, will tend to assume a state of thermal equilibrium, in which the temperature will be the same at all heights.

3. If the atmosphere is kept in constant motion by an interchange between its higher and lower portions, the tendency is towards adiabatic equilibrium, in which the temperature diminishes at a constant rate with the height, until it may approach the absolute zero. The rate of diminution depends upon the intensity of gravity and the physical constants of the gases composing the atmosphere.

4. In the actual case of a planet surrounded by an atmosphere and exposed to the sun’s radiation, the actual rate of diminution of temperature with height above the surface of the planet lies between the extreme limits just defined, the rate varying widely with the conditions. The general tendency will be towards a condition in which the temperature at the base of the atmosphere is higher than the normal, while in the upper regions it is lower. The temperature of the surface of the planet on which the atmosphere rests is determined partly by the sun’s radiation and partly by the temperature of the air. What we should generally expect in the absence of any selective absorption by the air is that the temperature of the lower air would be higher than that of the material surface on which it rests. But this condition might be reversed by the effect of such absorption in either the air or the material of the planet.

It would follow from these laws that the temperature of the superior planets diminishes rapidly with distance from the sun, and must therefore be far below that of the earth, unless they are shielded by atmospheres of such height and density as to be practically opaque to the rays of heat, or unless they have no solid crust.

The resemblance of the spectra of Mars, Jupiter and Saturn to that of the sun leads to the conclusion that the atmospheres of these planets are transparent down to the reflecting surface of the body. The temperature of these surfaces must therefore be determined by Kirchhoff’s law, unless they resemble the sun in being entirely liquid or gaseous, or in having only solid nuclei surrounded by liquid matter in a condition of continual movement.
end of the 18th century the conviction that such a planet existed was so strong that an association of astronomers was formed to search for it. The first discovery of the looked-for planet was not, however, made by any member of this association, but by Giuseppe Piazzi of Palermo. On the 1st of January 1801 he noted a small star in Taurus, which, two days later, had changed its place, thus showing it to be a planet. Shortly after Piazzi's discovery the body was lost in the rays of the sun, and was not again seen until near the following opposition in 1801–1802. The orbit was then computed by C. F. Gauss, who found its mean distance from the sun to correspond with Bode's law, thus giving rise to the impression that the gap in the system was filled up. The planet received the name Ceres.

On the 28th of March 1802 H. W. M. Olbers (1758–1840) discovered a second planet, which was found to move in an orbit a little larger than that of Ceres, but with a very large eccentricity and inclination. This received the name of Pallas. The existence of two planets where only one was expected led Olbers to his celebrated hypothesis that these bodies were fragments of a larger planet which had been shattered by an internal convulsion; and he proposed that search should be made near the common node of the two orbits to see whether other fragments could be found. Within the next few years two other planets, or perhaps two worlds were discovered, making four. No others were found for more than a generation; then on the 8th of December 1845 a fifth, Astrea, was discovered by K. L. Hencke of Driesen. The same observer added a sixth in 1847. Two more were found by J. R. Hind of London during the same year, and from that time discovery has gone on at an increasing rate, until the number now known is more than six hundred and is growing at the rate of thirty or more annually.

Up to 1890 discoveries of these bodies were made by skillful search with the telescope and the eye. Among the most successful observers were Johann Palisa of Vienna, C. H. F. Peters (1815–1890) of Clinton, New York, and James Craig Watson (1798–1885) of University, Michigan. The great majority of discoveries are made almost entirely by photography. When a picture of the stars is taken with a telescope moved by clockwork, so as to follow the stellar sphere in its apparent diurnal rotation, the stars appear on the plates as minute dots. But if the image of a planet is imprinted on the plate it will generally appear as a short line, owing to its motion relative to the stars. Any such body can therefore be detected on the plate by careful examination much more expeditiously than by the old method of visual search. The number now known is so great that it is a question whether they can be much longer individually followed up so as to keep the run of their movements.

Among the distinctive features of the planets of this group one is their small size. None exists which approaches either Mercury or the moon in dimensions. The two largest, Ceres and Juno, present, at opposition a visible disk about 1° in diameter, corresponding to about 400 miles. The successively discovered ones naturally have, in the general average, been smaller and smaller. Appearing only as points of light, even in the most powerful telescopes, nothing like a measure of their size is possible. It can only be inferred from their apparent magnitude that the diameters of those now known may range from fifteen or twenty miles upwards to three or four hundred, the great majority being near the lower limit. There is yet no sign of a limit to their number or minuteness. From the increasing rate at which new ones approaching the limit of visibility are being discovered, it seems probable that below this limit the number of unknown ones is simply countless; and it may well be that, could samples of the entire group be observed, they would include bodies as small as those which form the meteors which so frequently strike our atmosphere. Such being the case, the question may arise whether the total mass of the group may be so great that its action on the major planets assists of detection. The computations of the probable mass of those known, based upon their probable diameter as concluded from the light which they reflect, have led to the result that their combined action must be very minute. But it may well be a question whether the total mass of the countless unknown planets may not exceed that of the known. The best answer that can be made to this question is that, unless the smaller members of the group are almost perfectly black, a number great enough to produce any observable effect by their attraction would be visible as a faintly illuminated band in the sky. Such a band is occasionally visible to very keen eyes; but the observations on it are, up to the present time, so few and uncertain that nothing can positively be said on the subject. On the other hand, the faint "Gegenschein" opposite the sun is sometimes regarded as an intensification of this supposed band of light, due to the increased reflection of the sun's light when it would be back perpendicularly (see ZODIACAL LIGHT). But this supposed, though it may be well founded, does not seem to fit with all the facts. All that can be said is that, while it is possible that the light reflected from the entire group may reach the extreme limit of visibility, it seems scarcely possible that the mass can be such as to produce any measurable effect by its attraction.

Another feature of the group is the generally large inclinations and eccentricities of the orbits. Comparatively few of these are either nearly circular or near any common plane. Considering the conditions statistically, the best conception of the distribution of the planets of this group may be gained by considering the position of their poles on the celestial sphere. The pole of each orbit is defined as the point in which an axis perpendicular to the plane intersects the celestial sphere. When the poles are marked as points on this sphere it is found that they tend to group themselves around a certain position, not far from the pole of the invariable plane of the planetary system, which again is very near that of the orbit of Jupiter. This statistical result of observation is also inferred from theory, which shows that the pole of each orbit revolves around a point near the pole of the invariable plane with an angular motion varying with the mean distance of the body. This would result in the sky from the actual location, that of Jupiter, the latter being the centre of position of the whole group. From this it would follow that, if we referred the planes of the orbit to that of Jupiter, the nodes upon the orbit of that planet should also be uniformly scattered. Examination, however, shows a seeming tendency of the nodes to crowd into two nearly opposite regions, in longitudes of about 180° and 330°. But it is difficult to regard this as anything but the result of accident, because as the nodes move along at unequal rates they must eventually scatter, and must have been scattered in past ages. In other words it does not seem that any other than a uniform distribution can be a permanent feature of the system.

A similar law holds true of the eccentricities and the perihelia. These may both be defined by the position of the centre of the orbit relative to the sun. If $a$ be the mean distance and $e$ the eccentricity of an orbit, the geometry of the ellipse shows that the centre of the orbit is situated at the distance $ae$ from the sun, in the direction of the aps钜ion of the body. When the centres of the orbits are laid down on a diagram it is found that they are not scattered equally around the sun but around a point lying in the direction of the centre of the orbit of Jupiter. The direction of Jupiter's orbit, the line of action of the planet, that is, the line $S$ governing these may be seen from fig. 1. Here $S$ represents the position of the sun, and $J$ that of the centre of the orbit of Jupiter. The direction $JS$ produced is that of the perihelion of Jupiter, which is now near longitude 12°. As the perihelion moves through its secular variation, the line $S$ revolves around $S$. Theory then shows that for every observed body there will be a certain point $A$ near the line $S$ and moving with it. Let $C$ be the actual position of the centre of the planetoid. Theory shows that $C$ is in a straight line with $A$ and $S$, and the line of direction shown by the arrow, the linear eccentricity $ae$ being represented by the line $SC$. It follows that $e$ will be at a minimum when $AC$ passes through $S$, and at a maximum when in the opposite direction. The position of $A$ is determined in the case of different planetoids, but is generally about two-thirds of the way from $S$ to $J$. The lines $AC$ for different bodies are at any time scattered miscellaneous around the region $A$ as a centre. $AC$ may be called the constant of eccentricity of the planetoid, while $SC$ represents its actual but varying eccentricity.
Growing of the Planetoids.—A curious feature of these bodies is that when they are classified according to their distances from the sun a tendency is seen to cluster into groups. Since the mean distance and mean motion of each planet are connected by Kepler’s third law, it follows that this grouping may also be described as a tendency toward certain times of revolution or certain values of the mean motion around the sun. This feature was first noticed by D. Kirkwood in 1870, but at that time the number of planetoids known was not sufficient to bring out its true nature. The seeming fact pointed out by Kirkwood was that, when these bodies are arranged in the order of their mean motions, there are found to be gaps in the series at those points where the mean motion is commensurable with that of Jupiter; that is to say, there seem to be no mean daily motions near the values 59°, 74°, and 98°, which are respectively 2, 3, and 4 times that of Jupiter. Such mean motions are nearly commensurable with that of Jupiter, and it is shown in celestial mechanics that when they exist the perturbations of the planet by Jupiter will be very large. It was therefore supposed that if the commensurability should be exact the orbit of the planet would be unstable. But it is now known that such is not the case, and that the only effect of even an exact commensurability would be a libration of long period in the mean motion of the planetoid. The gaps cannot therefore be accounted for on what seemed to be the plausible supposition that the bodies required to fill these gaps originally existed but were thrown out of their orbits by the action of Jupiter. The fact can now be more precisely stated by saying that we have not so much a broken series as a tendency to an accumulation of orbits between the points of commensurability. The law in question can be most readily shown in a graphical form. In fig. 2 the horizontal line represents distances from the sun, increasing toward the left, of which certain equidistant numerical values are given below the line. Points on the line corresponding to each 0.01 of the distances are then taken, and at each point a perpendicular line of dots is drawn, of which the number is equal to that of the planetoids having this mean distance, no account being taken of fractions less than 0.01. The accumulations between the points of close commensurability with the mean motion of Jupiter may be seen by inspection. For example, at the point 2-59 the mean motion is three times that of Jupiter; at the point 2-81 twice the mean motion is equal to five times that of Jupiter; at 3-24 the mean motion is twice that of Jupiter. It will be seen that there is a strong tendency toward grouping near the values 2-75, and a lesser tendency toward 3-1 and 2-4. It is probable that the grouping had its origin in the original formation of these bodies and may be plausibly attributed to the formation of three or more separate rings which were broken up to form the group.

Continuing the question beyond these large collections, it will be seen that between the values 3-22 and 3-33 there are no orbits at all. Then between 3-3 and 3-5 there are nine orbits. The space between 3-5 and 3-5 is thus far a complete blank; then there are three orbits between 3-90 and 3-95, not shown in the diagram.

A group of great interest, of which only three members are yet known, was discovered during the years 1906-1907. The mean distance of each member of this group, and therefore its time of revolution, is so near that of Jupiter that the relations of the respective orbits are yet unknown. The case thus offered for study is quite unique in the solar system, but its exact nature cannot be determined until several more years of observation are available.

Several planetoids of much interest are situated without the limits of the groups shown in the figure. Eros is so near the sun, and its orbit is so eccentric, that at perihelion it is only about 0-16 outside the orbit of the earth. On those rare occasions when the earth is passing the perihelion point of the orbit at nearly the same time with Eros itself, the parallax of the latter will be nearly six times that of the sun. Measurements of parallax made at these times will therefore afford a more precise value of the solar parallax than can be obtained by any other purely geometrical measurement. An approach almost as close as the nearest geometrically possible one occurred during the winter of 1893-1894. Unfortunately the existence of the planet was then unknown, but after the actual discovery it was found that during this opposition its image imprinted itself a number of times upon the photographs of the heavens made by the Harvard Observatory. The positions thus discovered have been extremely useful in determining the elements of the orbit. The next near approach occurred in the winter of 1900-1901, when the planet approached within 0-32 of the earth. A combined effort was made by a number of observatories at this time to determine the parallaxes both by micrometric measures and by photography. Owing to the great number of stars with which the planet had to be compared, and the labour of determining their positions and reducing the observations, only summary results of this work are now available. These are mentioned in the article PARALLAX. So far as can yet be seen, no other approach so near as this will take place until January 1931.

A few of the minor planets are of such special interest that some pains will doubtless be taken to determine their orbits and continue observations upon them at every available opposition. To this class belong those of which the orbits are so eccentric that they either pass near that of Jupiter or approach near that of the earth. With most of the others little more can be done than to compute their elements with a view of subsequently identifying the object when desired. Unless followed up at several oppositions after discovery, the planet is liable to be quite lost. Of those discovered before 1890 about fifteen have not again been found, so that if discovered, as they doubtless will be, identification will be difficult.

The system of nomenclature of these bodies is not free from difficulty. When discoveries began to go on at a rapid rate, the system was introduced of assigning to each a number, in the order of its discovery, and using as its symbol its number enclosed in a circle. Thus Ceres was designated by the symbol C; Pallas by Ψ, &c., in regular order. This system has been continued to the present time. When photography was applied to the search it was frequently doubtful whether the planet of which the image was detected on the plates was or was not previously known. This led to the use of capital letters in alphabetical order as a temporary designation. When the alphabet was exhausted a second letter was added. Thus there are planetoids temporarily designated as A, B, &c., and AB, AC, &c. The practice of applying a name to be selected by the discoverer has also been continued to the present time. Originally the names were selected from those of the gods or goddesses of classical mythology, but these have been so far exhausted that the name is now left to the discretion of the person selecting it. At present it is customary to use both the number and the name, the former being necessary to the ready finding of the planetoid in a list, while the name serves for more certain identification.

(S. N.)

PLANK, a flat piece of timber, sawn and planed; it is technically distinguished from a "board" by its greater thickness, and should measure from 2 to 4 in. in thickness and from 10 to 11 in.
PLANKTON, a name invented by Professor Victor Hensen for the drifting population of the sea. This is a convenient heading under which to discuss not only plankton proper, but the benthos, or crawling population of the sea-bottom. Scientific investigation of these subjects dates from the reports of the "Challenger" expedition, which, despite its many successors, still stands out as the most important of the oceanographic expeditions, alike in the work achieved, the distance traversed, the time occupied, and the money devoted to the publication of the results. It laid the foundation of our knowledge of the physics and chemistry of ocean water, of oceanic and atmospheric currents, of the contour of the sea-bottom, and of the main features of distribution of deep-sea life. Later work has confirmed and expanded, but not revoked, the conclusions thus attained. But, in spite of this and of several subsequent expeditions, it cannot be pretended that we are in a position to formulate general canons of marine distribution other than of the most tentative character. Two fallacies underlie many attempts to define distributional oceanic areas for special groups: the assumption that such areas can be made to bear some relation to existing geographical or even national divisions; the other, that what is true for one group of the animal kingdom must hold good equally for another. It is necessary at the outset to divest oneself of these errors; oceanic conditions depend only very indirectly upon the distribution of the land, and strongly swimming or freely floating animals are not to be confined by the same factors as determine the distribution of sessile forms, whose range is governed by a variety of circumstances.

As Wyville Thomson pointed out long ago, there is but one ocean. This surrounds the southern half of the globe, and has two large gulfs, generally called the Atlantic and Pacific Oceans, which meet through narrow channels in the small Arctic Ocean, and a half gulf, the Indian Ocean. The Atlantic and Pacific exhibit a striking homology of atmospheric pressure and of prevalent wind and current; the Indian, to a great extent, resembles the southern half of a larger one, but this resemblance is modified by the neighbourhood of vast land masses. The prevalent winds, dependent on the fairly constant distribution of atmospheric pressure over the great oceans, are the most important determinant of currents. As at most points in the ocean the temperature, salinity and chemical composition of the water are mainly determined by the currents—that is, by the movement at the place whence the water came—it is obvious that a study of currents must precede any general view of the distribution of marine forms.

Regard must be had not merely to the superficial currents indicated in fig. 1, but also to the movements of the deeper layer. Ice melting at the poles, together with polar precipitation of hail, snow and rain, yields large quantities of water of low salinity and very low temperature; this water sinks under the warmer saltier surface water drifted from lower latitudes, and, creeping slowly north and south from the poles, covers the bottom of all the great open oceans at very uniformly low temperatures (in some cases as low as 30° F). Between surface and bottom the temperature gradually decreases (except where affected by local circumstances), and in the middle layers the existence of slow currents is suspected. The cold bottom water wells up to the surface in certain areas, replacing the surface water drained away by currents, notably to the westward of the great land masses. Ocean water is remarkably uniform as regards its contained salts and gases, and it does not seem likely that we can look to these to explain the facts of distribution. In its temperature, on the contrary, there is enormous variation. While the bottom water of the ocean is very cold, and the mid-water of a more or less intermediate temperature, the surface water, according as it has drifted from the equator polewards or in the reverse direction, has a mean annual temperature somewhere between 84° and 30° F, losing or gaining heat on its way. In the case of narrow or "closed" seas, and near land masses, sea-water does not exhibit that uniformity of composition which characterizes the open ocean; but even in such cases the temperature is largely influenced by adjacent currents, and, though less obviously than in the open ocean, seems to be a very important agent in distribution. The fauna of the sea is divisible into the plankton, the swimming or drifting fauna which never rests on the bottom (generally taken now to include E. Haeckel's nekton, the strong swimmers, such as fish and cephalopods), and the benthos, which is fixed to or crawls upon the bottom. These groups require a further subdivision according to depth—the more necessarily since, to some zoologists, any water over 100 fathoms is "deep" or even "abyssal." It is simplest to begin with the benthos. From

**Fig. 1.**—Diagram of the Atlantic Ocean, showing the Main Surface Currents (some are seasonal only); the corresponding Indian and Pacific currents are cited in parentheses; they are rarely so strongly marked as in the Atlantic.

1. Counterequatorial (also 1 Pacific and Indian).
2. North Equatorial (also Pacific).
3. The Equatorial (also 2 Pacific and Indian).
4. Gulf Stream proper (Japan Stream).
5. Brazil Current (Australian Current).
7. Labrador Current (Kamchatka Current).
8. Falkland Current.
10. South Atlantic Drift, ill defined (South Pacific Drift).
13. Peru Current.
14. Antarctic Circumpolar Drift, 7, its northerly branches on the west sides of Africa and South America.
distinguished as the epibenthos. As with the shallowest or tidal zone, its nature varies much more according to latitude and the character of the coast than the deeper zones. Everywhere, however, the epibenthic fauna is exposed to certain definite environmental conditions, as compared with a deeper fauna; namely, a high or fairly high temperature (except near the poles); a fairly good light, with its important consequence, a vegetable basis of food supply; tide and current to distribute the larvae to a suitable habitat, which the varied nature of the bottom near land is likely to furnish. Passing farther seawards, we find a steeper slope to about the 500-fathom line, the so-called continental slope. In this zone the environment is absolutely different. The water, no longer subject to seasonal variations of temperature, or to direct sunlight, is cold, and of a nearly uniform annual temperature (300 fathoms, ≈ 44°F.). Light has disappeared from all but the shallower part, and with it plant life; tide and current are no longer felt. To the latter fact is due, however, a great part of the food supply, which maintains in this zone an abundant fauna: a great quantity of organic matter, brought down by river action, produced by disintegrated sea-wood, and due to the death of surface organisms, together with the finer clayey materials of land waste, settles to the bottom in quiet water, near the 100-fathom contour, thus making the mud-line the richest feeding-ground in the ocean (Murray). The mud-line is the real upper limit of this zone; it typically begins at about 100 fathoms, but may begin at 5 to 20 fathoms in deep sheltered firths, or be pushed down to 300 fathoms where currents are strong. The fauna of this zone may be termed the mesobenthos; it is not so abundant, nor so sharply characterized, as the epibenthos, and yet is sufficiently distinct to deserve at any rate a provisional name. Another difference of condition between epibenthos and mesobenthos is the pressure of the water; at a depth of 500 fathoms this is, roughly speaking, half a ton to the square inch. It is very doubtful whether this enormous pressure makes the slightest difference to marine invertebrates, the tissues of which are uniformly permeated by fluids, so that the pressure is uniform in every direction; but animals with free gasses naturally require time to adjust the gas-pressure when altering their levels. As regards the penetration of light, assimilative rays useful to plant life probably do not reach beyond 150 fathoms. Photographic rays have been detected as low as 220 fathoms, and if any light penetrate beyond this depth, it will consist only of blue, violet and ultra-violet rays: it has been suggested that the red colour prevalent in many deep-sea animals may be a screen from these hurtful rays. Below the 500-fathom line the ocean bottom exhibits almost uniform conditions everywhere, varied only by the character of the bottom deposit and the amount of food supply. In this zone, which extends from about 500 fathoms to the greatest depths (which may in some cases exceed 5000 fathoms, or more than 30 m.), the temperature at any given point is uniform throughout the year, and is always very low: the mean at 2200 fathoms is 35.2°F.; at greater depths and in special circumstances less than 30°F. has been recorded. The darkness is probably absolute; for food the animals are dependent upon each other and upon the incessant rain of dead plankton from higher levels; the pressure may be anything between half a ton and five tons per square inch. To the fauna which lives in these remarkable circumstances the name hypobenthos may be applied.

That each of the three benthic groups is well characterized by a special fauna is shown by the following table, out of the total numbers of species captured by the "Challenger" at seventy stations in these three zones:

<table>
<thead>
<tr>
<th>Species confined to this Zone.</th>
<th>Species occurring in other Zones.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Epibenthos.</td>
<td>91%</td>
</tr>
<tr>
<td>Mesobenthos.</td>
<td>9%</td>
</tr>
<tr>
<td>Hypobenthos.</td>
<td>9%</td>
</tr>
</tbody>
</table>

Out of the 25% of its species which the mesobenthos shares with other zones, 59% occur also in the epibenthos, about 40% in the hypobenthos; the mesobenthos, therefore, on these figures, may be taken to consist of 74% of peculiar species, 15% shared with the epibenthos, 10% with the hypobenthos. Speaking of the benthos as a whole, it may be said that the following rule holds good: The number of individuals, the proportion of species to genera, and the number of individuals of a given species, all decrease with increasing depth. Animal life also tends to diminish with increasing distance from land; this may be partly due to the greater food supply near land, partly to the fact that population is obviously thinned on the advancing fringe of a migration. The plankton can be subdivided into at least two groups. The fauna to which light and warmth are more or less necessary, which feeds either upon plants or upon organisms nearly dependent upon plant life, may be termed the epiphytoplankton. This fauna is capable of a good deal of vertical movement upwards and downwards, the causes of which are still obscure, but most of its members seem rarely to descend lower than about 100 fathoms. Below this depth the fauna may be called the mesoplankton. In every area this appears to have its peculiar species, but the careful study by opening and closing tow-nets of the distribution of the mesoplankton is of so recent a growth that no statistics, such as we have of the benthos, are available. It is now generally admitted that the epiphytoplankton extends to the lower limit of the light (2730 to 2402 fathoms, Validinia); but the number of specimens decreases rapidly after 200 fathoms, and below 1000 fathoms very little is captured. The conditions of light, temperature, currents, &c., are practically those of the corresponding depths of the benthos; as regards the food, however, the mesoplankton can only depend upon intercepting dead organisms which are falling from higher horizons, or on capturing many particles which the plankton immediately over the bottom may prove to be sufficiently distinct to be separately classed as hypoplankton.

The main subdivisions of the marine fauna having thus been briskly sketched, it is advisable to consider them in somewhat more detail. The epibenthos is obviously that fauna "Epibenthos," to which, except in polar regions, light and warmth are necessary; and the absence of these at greater depths is
probably the chief barrier to its vertical extension; the food supply is sufficiently plentiful in, at any rate, the upper parts of the mesobenthic zone to present no obvious barrier. The chemical constitution of the water (except to animals in brackish water near river mouths) and the pressure appear to exert little or no influence; and only those species which attach themselves to clean hard substances would be repelled by the mud-line.

The chief barrier to a horizontal extension of the epibenthos is undoubtedly temperature. As an example of its distribution may be taken the Gastropod and Lamellibranch Molluscs, as groups of which the distribution has been studied for many years by specialists. The shallow-water species fall into provinces (compare Cooke, Camb. Nat. Hist. vol. "Molluscs," ch. xii.), and a comparison of figs. 1 and 3 shows at once the profound influence upon them of the great currents. Taking the Atlantic Ocean, we find the Arctic species, tempted southwards by the cold Labrador Current, repelled northwards by the warm North Atlantic Drift. The Boreal or sub-Arctic species, many of which are identical on both sides of the ocean (2 and 2', fig. 3), lie much farther southwards on the west than on the east side, from the same causes. The warm-water molluscs of West Africa (5) are cut off from those of the east side (7) by the cold water from the great easterly Antarctic Drift, which impinges on the Cape, giving it a special fauna (6). On the South American coasts the tropical and temperate fauna reach respectively to 28° S. and 45° S. on the east coast, owing to the warm Brazil Current; but the corresponding groups on the west coast only to 5° S. and 37° S., being kept back by cold upwelling and Humboldt's Current. This influence is visible in individual species as well as in the fauces of a fauna: Purpura leptilus, a temperate form, reaches on the east side of the Pacific to 24° N. and on the East Atlantic to 32° N.; but on the West Pacific only to 41° N. and the West Atlantic to 42° N., being repelled by the Japan stream (and other warm currents of the south-west monsoon) and Gulf Stream respectively.

But while some species may be confined to a bay, others to a province, others to an ocean, there are cosmopolitan species which either vertical or horizontal barriers, or both, fail to restrain. In relation to temperature the wide-ranging species are termed eurythermal, the limited, stenothermal (Moebius); the terms are useful to record a fact, but are not explanatory. It seems to be the case that to every organism is assigned a minimum temperature below which it dies, a maximum temperature above which it dies, and an optimum temperature at which it thrives best; but these have to be studied separately for every species. Similarly, in regard to depth, species have been classed as eurybathic and stenobathic, but, since increased depth practically means diminished temperature, these are probably merely expressions of the same fact in another form. That an Arctic shallow-water species should stretch to considerable depths is not surprising, but it is remarkable to find such forms as, for example, Venus mesodesma on a New Zealand beach at 55° F. and in 1000 fathoms at 37° F. off Tristan d'Acunha. The provinces of zoological distribution, like the geographical divisions of mankind, must be taken merely to indicate the fauces of a well-characterized fauna, not to imply the restriction of all its habitants to that area.

In considering the effect of temperature (and this applies to plankton as well as to benthos down to 100 fathoms), attention must be directed not only to the question of general warmth or cold as expressed by the mean annual temperature, but also to the range between the annual extremes: these ranges of variation have been carefully mapped by Sir J. Murray (Geog. Journ. xii. 113; compare ibid. xiv. 34). Still more important to the death-rate than these is the suddenness with which such variations occur: many animals are known to endure great extremes of heat and cold if exposed to them gradually, but to succumb to rapid alterations of temperature. Hence the frontier districts (Mischgebiete) between opposing currents are characterized by a heavy death-rate, and constitute marked barriers. A conspicuous instance of such a barrier in distribution is afforded at the Cape. The warm Mozambique Current, with a south-westerly direction off Natal, meets a north-east branch of the cold Antarctic Drift, and is beaten back eastwards: a result of the constant warring of these hot and cold currents is a high range of sudden temperature variation. Hence the Cape fauna

Generally termed Patagonian or Magellanic for purely epi- benthic forms, but in many cases, such as Venus mesodesma on a New Zealand beach at 55° F. and in 1000 fathoms at 37° F. off Tristan d'Acunha, the provinces of zoological distribution, like the geographical divisions of mankind, must be taken merely to indicate the fauces of a well-characterized fauna, not to imply the restriction of all its habitants to that area.

---

In considering the effect of temperature (and this applies to plankton as well as to benthos down to 100 fathoms), attention must be directed not only to the question of general warmth or cold as expressed by the mean annual temperature, but also to the range between the annual extremes: these ranges of variation have been carefully mapped by Sir J. Murray (Geog. Journ. xii. 113; compare ibid. xiv. 34). Still more important to the death-rate than these is the suddenness with which such variations occur: many animals are known to endure great extremes of heat and cold if exposed to them gradually, but to succumb to rapid alterations of temperature. Hence the frontier districts (Mischgebiete) between opposing currents are characterized by a heavy death-rate, and constitute marked barriers. A conspicuous instance of such a barrier in distribution is afforded at the Cape. The warm Mozambique Current, with a south-westerly direction off Natal, meets a north-east branch of the cold Antarctic Drift, and is beaten back eastwards; a result of the constant warring of these hot and cold currents is a high range of sudden temperature variation. Hence the Cape fauna...
PLANKTON 723

consists mainly of only such species from neighbouring provinces as can endure high sudden variations; and the distance practically impassable. For example, nineteen species of Echinoids are known from the Cape district. Of these twelve are peculiar to the Indo-Pacific province, which stretches from East Africa to the Sandwich Islands and from Japan to Australia; two species are Southern Ocean forms, all but confined to south of 40° S.; four species are peculiar to the Atlantic Ocean: of these eighteen not one gets past the Cape into the next province; the nineteen is practically a cosmopolitan (A. Agassiz, "Challenger Reports:" Echinoida); compare also C. Chum, "Aus den Tiefen des Weltmeeres," pp. 137, 150).

Among the barriers to the horizontal extension of epibenthos must be mentioned a wide deep ocean. The Indo-Pacific fauna ranges from East Africa to about 108° W., stepping from island to island over the Pacific; but this continuity is then broken by 37 degrees of longitude and more than 2000 fathoms of water, and such sessile species as are most Molluscs (cf. fig. 3) are unable to reach the American coast. This is presumably due to the fact that the planktonic larvae of epibenthic adults must settle on a suitable bottom within a certain period or die. In spite of the direct set of the currents from Florida to the British Isles, the epibenthos of the two is absolutely dissimilar; the similarity of the two Boreal provinces (2 and 2', fig. 3) is to be assigned to a former connection by way of Greenland, Iceland and Faeroe; a similar continuity, still unbroken, is exhibited by the Aleutian province on both sides of the Pacific. Though larvae cannot cross wide oceans, adults may no doubt traverse great stretches occasionally on floating timber, &c.

This barrier by distance may be instanced in another way. In the Arctic regions land masses are continuous or contiguous, and there are many circumpolar species, as, for example, Rhynchonella psittacea; towards the South Pole the southern continent is almost ice-bound, and the available land consists only of the tips of the continents and of the few oceanic islands. Hence few if any littoral species are circumpolar. For example, not a single littoral Ophiurid surrounds the South Pole, but five or six species are circumpolar in the northern hemisphere.

Taking next the mesobenthos and hypobenthos, living at depths where temperature is constant and current practically negligible, there appears theoretically to be no reason why an organism which can thrive at 500 fathoms should not have a world-wide range over the bottom of all oceans. Yet this is not often, although occasionally, known to be the case; and although perhaps, speaking generally, hypobenthic species have wider ranges than epibenthic, still they also seem to be limited. It must, however, be remembered that the ocean is large, deep hauls of trawl or dredge few, and individuals at greater depths scarcer, so that too much stress must not be laid on this point. The "Challenger" results seem to allow of at least one generalization—the deeper the fauna, the wider its range. This is shown by the following table of the "Challenger" benthos: the first column gives the number of benthos species captured at depths indicated in fathoms by the second column; the percentage of these which is known to have been captured between the tropics, as well as south and north of the tropics, is shown in the third column:

We can only guess at the causes of the apparently limited range of many deep-sea types. (a) One of these is probably the limited food supply: presumably, as with a land fauna, there are as many mouths in a given area as it will support, and an equilibrium of species is maintained which will at least hinder the extension of any one. For food the bulk of the deep-water fauna is dependent upon the rain of dead organisms falling from higher levels, these, slowly disintegrating (probably under chemical, not bacterial, action), seem to form with the bottom deposit a kind of nitrogenous ooze, through which many deep-sea organisms slowly swallow their way, as an earthworm goes through earth extracting nutrient. (b) Another hindrance to the extension of many deep-sea species is that they are holobenthic, that is, do not pass through a free-swimming larval stage; the means of dispersal is therefore regulated by the animal's own power of locomotion. Generally speaking, as might be expected, the freely-moving hypobenthos, fish and crustacea, have the widest ranges, and even these are not helped by currents, as are epibenthic or planktonic forms. The larval history of deep-water forms is, however, very obscure; (c) Lastly, extension of area of a species being at best difficult in deep water for non-swimmers, the place and date of their first migration must be taken into account; forms which have comparatively recently adopted deep-water life cannot be expected to have spread far from their original centre. As regards this point, in the first place, it is with migration, not with local evolution, that we have to deal: no classes and orders, only a few families and genera, rarely sub-orders, are peculiar to the hypobenthos; the deep members of each group consist for the most part of widely separated genera, the species do not grade into each other, but are isolated; often the case in the epibenthos; and even those genera hardly have produced these species and genera under the uniformity of their present environment. This migration downwards from the mud-line has no doubt occurred all over the world, notably in the Southern Ocean, if we may judge by the richness of the deep-water fauna there to-day; probably also largely in Arctic and sub-Arctic regions, less so in tropical and temperate zones. As to the date of migration, the following fact seems to show that it is of comparatively recent origin, and is indeed still in progress: taking the "Challenger" species from the epibenthos, from the mesobenthos, and then from zones of 500 fathoms down to 1500, each zone shares a larger percentage of species with the zone above it than with that below it (except in one case where they are nearly equal). But it is not to be supposed that all our present-day deep-water forms began their migration simultaneously, and we can say with fair certainty that migration to deep water did not begin before the close of the Mesozoic epoch. Had it begun earlier, we should find typical Mesozoic and even older forms, or their congener, at great depths: so far is this from being the case that the most venerable animals of to-day—Lingula, Amphitrite, Limulus, 75% of Crinoids, 95% of Brachiopoda, &c.—are epibenthic or mesobenthic. On the other hand, it is extremely likely that the meso- and hypobenthos are different. The hexactinellid sponges are known to have lived in quite shallow water at the date of deposition of the Inferior Oolite; to-day none occur at a less depth than 95 fathoms; and as only two genera are known from the shallow Tertiary deposits, it would seem that the migration began about Cretaceous times ("Challenger" Reports: "Hexactinellida, F. E. Schulze). In 1885 (A. Agassiz, "Challenger" Reports: "Echinoidae") 105 living genera of Echinodermata were admitted; of these 23% were known from Cretaceous but not from Tertiary deposits, 33% from Tertiary but not Cretaceous, and 40% as Recent only. The species of Cretaceous genera constituted only 29% of the epibenthic Echinoids, 44% of the mesobenthos, and no less than 55% of the hypobenthos. These species of Cretaceous genera were distributed fairly evenly over all three zones, but 73% of the species of Cretaceous genera and 55% of the Recent forms were confined to the epibenthos. As out of the twenty-five living genera known from the Cretaceous only seven are known also from Jurassic deposits, it is obvious that the close relationship is between Cretaceous and hypobenthos, rather than between any other geological and bathymetric horizons. Other instances, such as that of the Eryonidae, seem to point to similar conclusions.

Excepting the essential air-breathers, practically every phylum and class and most orders are represented in the benthos. The
epibenthos of warm seas appears to be especially wealthy in such forms as secrete heavy calcareous skeletons; but in colder water, among the epibenthos of polar or sub-polar regions, and the hypobenthos everywhere in open oceans, the predominant forms are those which exhibit little or no calcareous secretion: even the apparent exceptions, Madreporaria and Echinodermo from great depths, tend to develop slighter skeletons than their warm-water congeners. The following table will serve to illustrate this point, and to give an idea of the composition of the epibenthos of cold and warm seas and of the hypobenthos: the figures are the percentages of total species captured in each locality by H.M.S. "Challenger," the balance being made up by few specimens in scattered groups:

While the Madreporaria represent only 3% of the species at the tropical station, it must be remembered that they probably made up 65% or more of the weight.

The epibenthon is dependent either directly or proximately upon light, warmth and the presence of plant life. The wealth of minute organisms near the surface is inconceivable to those who have not seen the working of a two-net: it may be gauged by the fact that a single species is sometimes present in such quantities as to colour the sea over an appreciable area, and by the estimate that the skeletons of epibenthon from a square mile of tropical ocean a hundred fathoms deep would yield 16 tons of lime. In the tropics the wealth of species, and towards the poles the number of individuals of comparatively few species, are characteristic of the latitudes. In temperate and tropical regions there is a great difference between the epibenthon near land and that far out at sea: the former is termed neritic; it extends, roughly speaking, at least as far out as the mud-line, and is characterized by the predominance of what may be termed hemibenthic forms, that is, benthoc forms with a planktonic larval stage (Decapoda, Polyplacota, etc.), or with a planktonic phase (metageneric Medusa). The horizontal barriers to the neritic plankton are practically those mentioned as governing the epibenthon; indeed, it would seem that the distribution of hemibenthic adults is determined by that of their more delicate larvae. Special conditions of wind and current may of course carry into the neritic zone forms which are characteristic of the open sea, and vice versa. In the neritic epibenthon of polar waters the larvae of hemibenthic forms are almost absent; indeed, the development of cold-water benthos, whether shallow or abyssal, appears to be in most cases direct, this is, without a larval metamorphosis. The epibenthon of the open sea is described as oceanic; it consists almost entirely of holoplanktonic forms and their larvae. The chief barrier to horizontal distribution, here as elsewhere, is doubtless temperature. For example, through the reports of the "National" cruise (German Plankton Expedition) runs the same story; one fauna characterized their course from Shetland to Greenland and Newfoundland, another the traverse of the Gulf Stream, Sargasso Sea and the Equatorial Currents. The influence of temperature may be gauged in another way: where hot and cold currents meet, occur "frontier" districts, in which the respective organisms are intermingled, and can only exist till their maxima or minima are reached. Well-marked examples of such districts occur off New Jersey (Gulf Stream and Labrador Current), in the China Sea (warm currents of the south-west monsoon and Kamchatka Current), in the Faeroe Channel, south of the Cape (recruing of the Agulhas Current); in some of these the range of variation amounts to as much as 20° F. in the year, with the result of a collassal death-rate of the plankton, and its corollary, a rich bottom fauna, for which food is thus amply supplied. The majority of the oceanic epibenthon appears to be steno-thermal; for example, few components of the well-characterized fauna of the Gulf Stream and Sargasso Sea ever reach the British shores aside, although, if current and salinity were the determining factors and not temperature, this fauna should reach to Shetland, and even to Lofoten. It will only be possible to make satisfactory distributional areas for these oceanic forms by such systematic traverses as that of the "National" Plankton Expedition. Some members of the epibenthon are, however, extraordinarily eurythermal and eurybathic; for example, Calanus finmarchicus ranges from 70° N. to 52° S. (excepting perhaps for 12° each side of the equator), and is apparently indifferent to depth.

In the first hundred fathoms at sea the fall of temperature is gradual and slight, and forms practically no hindrance to the diurnal oscillation of the oceanic epibenthon—the alleged rise and fall of almost the entire fauna. Roughly speaking, the greatest number of animals is nearest the surface at midnight; but different species sink and rise at different times, and to or from different depths. Apart from this diurnal oscillation, unfavourable conditions at the surface send or keep the fauna down in a remarkable way: for example, in the Bay of Biscay few organisms are to be found in the first fathom in bright sunlight, but in a still, hot day the next few fathoms teem with life; yet after a few minutes' rain or rain these upper layers will be found almost deserted. This leads to the consideration of the diurnal habit of the plankton: apart from swift swimmers, the majority contents the tendency to sink either by some means of diminishing specific gravity (increasing floating power) or by increased frictional resistance. The former is generally attained (a) by increase of bulk through development of a fluid secretion of low specific gravity (vacuoles of Foraminifera, Radiolaria, etc.); (b) or of a gelatinous secretion of low specific gravity (Meduse, Chaetopoda and Echinoderm larvae, Chaetognatha, Thaliacea: the characteristic transparency of so many oceanic forms is probably attributable to this); (c) by secretion or retention of air or other gas (Physalia, Minyas, Eudone); (d) by development of oil globules (Copepoda, Cladocera, fish ova). Increased frictional resistance is obtained by flattening out the body (Physalia, Sagartia), or by its expansion into lateral processes (Teuthopterus, Glaucus), or by the development of long delicate spines or hairs (pelagic Foraminifera, many Radiolaria, many Chaetopoda and Decapod larvae). In many cases two or more of these are combined in the same organism. Notwithstanding the above adaptations, some of which are adjustable, it is difficult to understand the mechanics of the comparatively rapid oscillations of the epibenthon, of which both causes and methods are still obscure.

It will be seen from the distribution of the Thecosomatous Pteropoda—a purely oceanic group—how difficult it will prove to draw distributional areas for classes of epibenthon. P. Pelseneer recognizes in all ten such provinces ("Challenger" Reports: "Zool.," xix., xxii.) and 42 good species: of the latter 1 is confined to the Arctic, 4 to the Antarctic province, but of the remaining 37 species and eight provinces 30% occurs in all eight, 16% in seven, and only 35% have as yet been captured in a single province only.

The mesoplankton has only received serious attention during the last few years. In the "Challenger," open nets towed at various depths seemed to show the existence of a deep-water plankton, but this method gives no certain information as to the horizon of capture, the nets being open in their passage down and up. C Chun
constructed the first efficient net which could be opened and shut at known depths, using a propeller mechanism (Bibl. Zool. vol. 1); and he improved his original pattern for the "National" and "Valdivia" expeditions. The present writer has devised a net, of which the opening and closing are effected from the deck by heavy weights; this has been used successfully on the "Siboga" expedition and in cruises of the "Research" (Proc. Zool. Soc., 1898). W. Garstang has constructed an ingenious net which is useful in comparatively shallow water, but is open to criticism as being too light for depths beyond 100 fathoms; and several other types are in use. The existence of a mesoplankton, that is, of a plankton living between 100 fathoms from the surface and the bottom, has been generally considered as definitely proved by these nets. On the other hand, A. Agassiz, using the Tanner tow-nets, contends that while a mixture of surface and bottom species may occur in a closed sea near land, there is no intermediate fauna in the open ocean between about 200 fathoms from the surface and the bottom; his conclusions, based on negative evidence, have not met with general acceptance. Animals captured below the first hundred fathoms in the open sea (the Mediterranean, for special physical reasons, is on a special footing) are divisible into at least three categories: (1) those which are strictly benthonic, e.g. Calanus finmarchicus; (2) those which, so far as we know, are purely mesoplanktonic and never come to the surface, for example, the Radiolarian family Tuscariidae; (3) those which, like some Schizopoda, spend a larval period in the epiplankton, and seek deeper water when adult, rising to the surface, if at all, only at night. But until the publication of the results of expeditions provided with efficient mesoplankton nets, generalisations about this fauna had better be stated with all reserve. There is, however, a certain amount of evidence to show that the mesoplankton includes different organisms in different latitudes; that surface animals of the north and south, unable to spread into the warmer surface waters of lower latitudes, therefore sink into the cooler waters of the mesoplankton; the distributional area of such an organism will be in three dimensions bounded by isotherms (isobathytherms) and isothermoclines. As with the hypobenthos, there seems to be no theoretical reason against the universal distribution of the mesoplankton.

When a more systematic investigation of the various horizons has been carried out, many of the present cases of supposed discontinuous distribution will doubtless disappear. There are, however, undoubted cases of discontinuity where physical barriers have cut across a distributional area, an example of which may be cited here. The Isthmus of Panama was apparently only upraised about 2 m.y., or of a plankton living between an archipelago through which a great circumpolar current could pass; consequently the benthos of the Panama region shows marked alliance with the Caribbean, with which it was formerly continuous, but practically none with the Indo-Pacific. To the same case is doubtless attributable the distribution of the five Decapoda which are characteristic of the Sargasso Sea, which are circumpolar oceanic types, only occasionally littoral: three of these are known only from the Atlantic, one occurs in the Atlantic and Pacific, one in the Atlantic, Pacific and Indian Oceans. The damming of a great circumpolar current by the Isthmus of Panama is probably also responsible for the dislocation of currents which resulted in the present relations of the Gulf Stream and North Atlantic Drift to the Labrador Current, and cut the Atlantic Boreal fauna into two discontinuous districts (2 and 3', fig. 3).

Under the head of discontinuous distribution, the alleged phenomenon known as bipolarity must be mentioned. In summarising the work of the "Challenger," Sir John Murray maintained on the basis of the reports that numerous species occurred in both polar and sub-polar areas which were absent from the tropic. He regarded them as the hardy survivors of a universal fauna which had withstood that polar cooling which set in towards the close of the Mesozoic period (Murray, Trans. Roy. Soc. Edin. vol. xxxviii., 1896; G. Pfeffer, Verh. deut. Zool. Gesellschaft, ix. 1899). This view and the facts on which it was based have been acutely contested, and the question is still far from settlement (for lists of the literature see A. E. Ortmann, Am. Nat. xxxii. 583; and Miss E. M. Pratt, Mem. Manchester Soc. vol. xiv., 1901). As regards the purely epilithic and sessile fauna, there are a few undoubted instances of actual specific identity; in some classes, however, such as the Echinoderms, this does not appear to hold (Hamburger Magazinische Sammelreise; and F. Römer and F. Schaudinn's Fauna arctica); but even in these the general composition of the fauna and the presence of certain identical and peculiar genera seem to point to something more than a mere 'convergence' due to similar environment. As regards the plankton of the two polar regions and such epibenthic forms as extend also into deep water, the suggestion has been made that the Arctic and Antarctic benthos and plankton are really continuous by way of deep water in the main oceans, where the organisms can find a suitably temperate climate as an instance of this, C. Chun (Bezieh. zwischen dem arkt. und antarkt. Planton, 1897) cites Kronhia hamata, a characteristic Arctic and sub-Arctic constituent of the epibenthos and mesoplankton, known only from the mesoplankton in the tropics, but rising to 36 fathoms at 40° S. 60° E. More exact information, such as may be expected from the various Arctico-Polar expeditions, is required to settle this interesting question with its far-reaching corollaries. (G. H. FO.)

PLANQUETTE, ROBERT (1850-1933), French musical composer, was born in Paris on the 31st of July 1850, and educated at the Conservatoire. As a boy he wrote songs and operettas for café concerts, and sprang into fame as the composer of Les Cloches de Corneville (Paris, 1877; London, 1878). In this work he showed a fertile vein of melody, which won instant recognition. There is in his music a touch of pathos and romantic feeling, which, had he cared to cultivate it, would have placed him far above contemporary writers of opera bouffe. Unfortunately, he did little but "repeat tuck." In the last period of his life he brought him reputation. Le Chevauvilr Gaston was produced in 1879 with little success. In 1880 came Les Voitures de 2m. which had a long run in London in 1883 as The Old Guard, and La Continibre, which was translated into English as Naretane, though never produced. In 1882 Rip van Winkle was produced in London, being subsequently given in Paris as Rip, in both cases with remarkable success. The libretto, an adaptation by H. B. Farnie of Washington Irving's famous tale, brought out what was best in Planquette's talent. In 1884 the phenomenon of an opera by a French composer being produced in London previously to being heard in Paris was repeated in Nell Gwynne, which was tolerably successful, but failed completely when produced in Paris as La Princesse Colombine. It was followed by La Crémaillée (Paris, 1885), Surcouf (Paris, 1887; London, 1887), Captain Théodre (London, 1887), La Coarde tricolore (Paris, 1892), Le Talisman (Paris, 1892), Panurge (Paris, 1893) and Mame'squieratous (Paris, 1897).

PLANTAGENET, a surname conveniently, but unhistorically, applied to the royal line descended from the union of Geoffrey, count of Anjou, with the empress Maud, who are now styled by historians the Anjou house. It was, historically, only a personal nickname of Geoffrey, as was "Beauclerc" of his father-in-law (Henry L) and "Curtmantel" of his son (Henry II), and was derived from his wearing in his cap a sprig of the broom (genet) plant, "which in early summer makes the open country of Anjou and Maine a blaze of living gold." When the fashion of personal nicknames passed away, the members of the royal house were usually named from their birthplace, as Thomas "of Brotherton," Thomas "of Woodstock," Edmund "of Woodstock," Edmund "of Langley," Lionel "of Antwerp," and so forth. But Edward I. and his younger brother, the founder of the house of Lancaster, had still nicknames respectively, as "Crown," "Crouch," and "Cross." During the days of the dynasty the surname of Beaufort was adopted by the legitimate issue of John of Gaunt by Katherine Swynford, but that of Plantagenet was bestowed on Arthur, natural son
of Edward IV., who was created Viscount L'Isle. It appears, however, to have been adopted as a surname by Richard duke of York (father of Edward IV.) some twelve years before his death.

At the death of Geoffrey's grandson, Richard I., the succession was in doubt, John's elder brother Geoffrey having left, by the heiress of Brittany, a son and a daughter. But at that epoch the law of inheritance was in such a case unsettled, and their right was not clear. Arthur's fate is well known, and Eleanor, the daughter, was kept captive till her death in 1241. John's younger son Richard, king of the Romans, left a son Edmund, earl of Cornwall, with whom his line ended; his elder son Henry III. left two sons, of whom the younger was created earl of Lancaster and was grandfather of Henry, earl of Lancaster, whose daughter married John of Gaunt (i.e. Ghent). Edward I., the elder son, was grandfather of Edward III., the marriages of whose numerous children greatly affected English history. Edward his heir, the "Black Prince," left an only son, who succeeded his grandfather as Richard II., on whose death (1399) this line became extinct. Lionel, the next surviving brother of the Black Prince, left an only child Philippa, who married the earl of March, in whose heirs was the right to the succession. But John of Gaunt, the next brother, who had married the heiress of Lancaster and had been created duke of Lancaster in consequence, refounded the Lancastrian line, which obtained the throne in the person of his only son by her, Henry IV., on the deposition of Richard II., to the exclusion of the infant earl of March. His next brother, Edmund of Langley, who was created duke of York (1385), founded the Yorkist line, and was father, by a daughter and co-heiress of Pedro the Cruel, king of Castile, of two sons, Edward, second duke, who was slain at Agincourt, and Richard, earl of Cambridge, who by marrying the granddaughter and eventual heiress of Lionel's daughter Philippa, brought the right to the succession into the house of York.

Between their son and Henry VI. (grandson of Henry IV.) and Edward and Henry, sons and heirs of these rivals, was fought out the dynastic struggle known as "the Wars of the Roses," which proved fatal to several members of both houses. Richard, the son of Richard and Anne Mortimer, became third duke of York (1429), and was made protector of the realm 1454-1455, being finally declared heir to the throne on the triumph of his side in 1460; but he was slain at the battle of Wakefield (Dec. 31, 1460). Of his four sons, Edward, the eldest, became king as Edward IV. within three months of his death; Edmund, the second, was slain with his father at Wakefield; George, the third, duke of Clarence, was put to death in 1478; and Richard, the fourth, duke of Gloucester, became king as Richard III. in 1483 and was slain on Bosworth Field in 1485. Richard III.'s two surviving sons, Edward and Richard (the princes in the Tower), had been mysteriously put to death in 1483, so that the only male descendant of the house of York, and indeed of the whole Plantagenet race, was the duke of Clarence's son Edward, earl of Warwick (grandson of "the Kingmaker"), who was imprisoned by Richard III. (his father's younger brother) in 1483, and finally executed on Tower Hill, under Henry VII., in 1499.

Of the house of Lancaster, the only son of Henry VI. was slain after the battle of Tewkesbury (1471), while Edmund (Beaufort) duke of Somerset, a grandson of John of Gaunt, was slain at the first battle of St. Albans (1455), and all his three sons were slain or beheaded. On the death of Henry VI. and his son in 1471, so complete was the extinction of their line that its representation vested in the heirs of the two daughters of John of Gaunt by the heiress of Lancaster, viz. Philippa queen of Portugal and Elizabeth countess of Huntingdon. But by his second wife, the heiress of Castle, John had left an only daughter, wife of Henry III., king of Castile and Leon, who also left descendants, and from his third but ambiguous union sprang the house of Beaufort, whose doubtful claims to his heirship passed with his great-granddaughter Margaret, by her husband Edmund Tudor, to their son Henry VII. Although Henry was careful to claim the crown in his own right (1483), he soon fortified that claim by marrying Elizabeth, eldest daughter of Edward IV. and rightful heiress to the throne. The marriage of their eldest daughter Margaret to James IV. of Scotland in 1503 resulted in the accession of James VI. of Scotland, a century later, as next heir to the throne (see STEWART).

Although no other dynasty has reigned so long over England since the Norman Conquest, the whole legitimate male issue of Count Geoffrey Plantagenet is clearly proved to have become extinct in 1499. Of its illegitimate descendants the house of Cornwall was founded by Richard, a natural son of Richard, king of the Romans and earl of Cornwall, who was ancestor of the house of Beaufort (see above), temp. Henry VI., of the Cornwalls, "barons of Burford," and other families; but the principal house is that which was founded, at a later date, by Sir Charles Somerset, natural son of Henry (Beaufort) duke of Somerset (beheaded 1464), who was created earl of Worcester in 1513, and whose descendant Henry, marquess and earl of Worcester, obtained the dukedom of Beaufort in 1682. From him descend the ducal house, who bear the ancient arms of France and England, quarterly, within a bordure. (J. H. R.)

**PLANTAIN** (Lat. *plantago*), a name given to certain plants with broad leaves. This is the case with certain species of *Plantago, Alisma* and *Musa*, to all of which the term is popularly applied. The species of *Plantago* are mostly weeds with a dense tuft of radical leaves and scapes bearing terminal spikes of small flowers; the long spikes of *P. major*, when in seed, are used for feeding cage-birds; *P. lanceolata*, so called from its narrow lanceolate 3-6-ribbed leaves, is popularly known as ribwort; *Alisma p.* is the water-plantain, so called from the resemblance of its broad ribbed aerial leaves to those of *P. major*. The tropical fruit known as plantain belongs to the genus *Musa* (see BANANA).

**PLANTATION** (Lat. *plantare*, to plant), literally the placing of plants in the ground, hence a place planted or a collection of growing things, &c., particularly used of ground planted with young trees. The term was early applied, in a figurative sense, to the settlement of people, and particularly to the colonization of North America in the early part of the 17th century and to the settlement of Scotch and English in the forfeited lands in Ireland (see below). The practice of sending convicted criminals to serve on the plantations in the colonies became common in the 17th century (see DEPORTATION). These plantations were chiefly in the cotton, sugar and tobacco growing colonies, and the term "plantation" is thus particularly applied to estates in tropical or semi-tropical countries; the proprietors of such estates are specifically styled "planters."

The negroes on the plantations of the Southern States of North America sang their songs and hymns and danced to tunes which were traditional, and are frequently known as "Plantation Songs." It has been claimed for some of them that they represent the folk songs brought by the first slaves from Africa; but the more generally accepted view is that they were those European hymn and song tunes which the negroes picked up from the revivalist preachers or from the Europeans around them, and adapted to their own strongly marked rhythms, which are certainly of African origin. The earliest song which became familiar to those outside the Southern States was "Jim Crow," sung by Dan Rice, and introduced to England about 1836. The "Jubilee Singers," a troupe from Fisk University, Nashville, Tennessee, toured the United States and Europe in 1871; but the great popularity of the negro songs and dances, and the traditional instruments, the bones and tambourine (the banjo was not originally used by the genuine negro), was due to the so-called "negro minstrel" troupes, of which the best known in England were Christy's, whence the generic name of Christy Minstrels, and later of the Moore and Burgess troupe at St. James's Hall, London, started in 1862 and finally dissolved in 1904.

The best collection of genuine "plantation songs" and their words is *Slave Songs of the United States* (New York, 1871); see also
Plantation of Ulster.—The Irish rebellion, which had disturbed Ulster during the closing years of Elizabeth’s reign, was followed under James I by further trouble, due partly to the inability of the English government to understand the system of land ownership prevalent in Ireland. At this time the chief offenders against the authority of England were the earls of Tyrconnell and Tyrone, but in September 1607 these once powerful nobles fled from the country. The English lawyers declared that the extensive estates which they held, not in their personal capacity, but as the heads respectively of the tribes of O’Neill and O’Donnell, had become the property of the English crown; and the problem which now confronted James I and his advisers was what to do with these lands. They were not yet large enough to be cultivated properly by the scanty population living thereon. The idea of a plantation or colonization of Ulster, which was put forward as an answer to this question, is due mainly to Sir Arthur Chichester, the Irish lord deputy; its object was to secure the better cultivation of the land and to strengthen the English influence in Ulster by granting estates to English and Scottish settlers. Chichester proposed that the native inhabitants should be allowed to occupy as much land as they could cultivate, for he said, “that many of the natives in each county claim freehold in the lands they possess, and although these demands are not all made by law, yet there is land and hard and impossible to displace them.” Even if this advice were carried out on a generous scale, the deputy considered that there would be abundance of land to offer to colonists, and also to reward the class of men known as servitors, those who had served the English king in Ireland. He submitted his ideas to Sir James Ley and Sir John Davies, two of the ministers of James I; they reported to the English privy council, which signified its approval, and after the question had been illuminated by Bacon’s great intellect, a committee was appointed to make the necessary arrangements. But those responsible for the plantation made one cardinal mistake, a mistake which was to cost the country much in the future. They rejected Chichester’s idea of allotting land to the natives on a liberal scale, preferring to turn them out and to parcel out the whole of the forfeited district anew.

The forfeited lands lay in six counties, Tyrone, Donegal, Armagh, Fermanagh, Cavan and Coleraine (Londonderry), and the scheme for the plantation having been drawn up, the necessary survey began in May 1609. This was very inaccurate, but it served its purpose. The land was divided into three sections. One block was set apart for English and Scottish settlers, who were not to be allowed to have any Irish tenants; another was allotted to the women, who might have, either English or Irish tenants; and a third was reserved for the Irish. Applications were then entertained from those willing to take up the land, and under Chichester’s direction the settlement was proceeded with. The land was divided into portions of 1000, 1500 and 2000 acres, each colonist undertaking in return for his grant to build a castle or a walled enclosure, and to keep, train and arm sufficient men for its defence. Moreover he must take the oath of supremacy to James, and must not alienate his estate to an Irishman. He was given two years in which to do the necessary building; during this period he was freed from paying rent, but afterwards he must pay a quit-rent to the Crown. A scale of rents was drawn up, the native Irish paying at a rate four times as much as the English and Scottish settlers. Out of the forfeited lands provision was made for the maintenance of churches and schools, which were to be erected in conformity with the scheme.

The work progressed very slowly and much of the building was not even begun within the required time. Then in 1613 James I, who had from the first taken a lively interest in the plantation, sent Lord Carew to report on it. Carew’s inspection did not reveal a very favourable condition of affairs, and in 1615 Sir Josiah Bodley was sent to make a further report about the progress of the work. A third report and survey was made three years later by Nicholas Furnar, who found in the six counties 1574 British families, with 6215 men capable of bearing arms. He said that even on the lands occupied by the colonists the cultivation of the soil was still very much neglected. The words spoken by Bacon in 1617 with reference to the plantation had come true. “Take it from me,” he said, “that the bane of a plantation is when the undertakers or planters make such haste to a little mechanical present profit, as disturbeth the whole frame and nobleness of the work for times to come.” Another survey took place in 1622, when various changes were suggested, but no serious alterations were made. On the whole the plantation had been a failure. Very few of the settlers had carried out their undertaking. In many cases the Irish had remained on the land allotted to the colonists, living under exacted bookbinding and bothelins at Carew and having plantation, and on holding “whether the legal landlords liked it or not.” As actually carried out the plantation dealt with 514,465 acres. Two-fifths of this was assigned to British colonists, being divided about equally between Englishmen and Scotchmen. Rather more than one-fifth went to the Church and about the same amount to the servitors and the natives. The best settlers were the Scots, although their tendency to marry with the Irish was noted and condemned during the early years of the settlement.

An important part of the plantation was the settlement of Coleraine and Coleraine by the corporation of the city of London. Receiving a grant of practically the whole of the county the corporation undertook to spend £20,000, and within two years to build 200 houses in Derry and 100 in Coleraine. This was the most successful part of the settlement, and to it Londonderry owes its present name.

The expulsion of the Irish from the land in which by law and custom they had a certain proprietary and hereditary right, although not carried out on the scale originally contemplated, naturally aroused great indignation among them. Attacks on the settlers were followed by reprisals, and the plantation may fairly be regarded as one of the causes which led to the terrible massacre in Ulster in 1641. During Elizabeth’s reign a scheme for the plantation of Munster was considered, and under Charles I there was a suggestion for the plantation of Connaught, but eventually both were abandoned.

The “Orders and Conditions of Plantation” are printed in Walter Harris’s Hibernia (Dublin, 1770); and in George Hill’s Historical Account of the Plantation in Ulster, 1608-1620 (Belfast, 1877). See also R. Gardiner, History of England (1899), vol. i.; and R. Bagwell, Ireland under the Stuarts (1909), vol. i.

PLANTIN, CHRISTOPHE (1514-1589), French printer, was born in a village near Tours (probably Saint-Avertin). He was sent to Paris when very young, and, having married in that town, settled in 1549 as bookbinder in Antwerp, where he was soon known as the first in his profession. A bad wound in the arm seems to have been the cause that first led him (about 1555) to apply himself to typography. The first known book printed in his office was La Institutione di una fanciulla nata nobilmente, by J. M. Bruto, with a French translation, and this was soon followed by many other works in French and Latin, which in point of execution rivalled the best printing of his time, while the masters in the art of engraving then flourishing in the Netherlands illustrated many of his editions. In 1563 Plantin himself being absent in Paris, his workmen printed the heretical pamphlet which caused his moveables to be seized and sold. It seems, however, that he recovered a great deal of his money, and in 1563 he associated himself with some friends to carry on his business on a larger scale. Among them were two grand-nephews of Dan. Bomberg, who furnished him with the fine Hebrew types of that renowned Venetian printer. His editions of the Bible in Hebrew, Latin and Dutch, his Corpus juris, Latin and Greek classics, and many other works produced at this period are renowned for their beautiful execution and accuracy. A much greater enterprise...
was planned by him in those years—the publication of a Biblia polyglotta, which should fix the original text of Old and New Testaments on a scientific basis. In spite of clerical opposition he was supported by Philip II, king of Spain, who sent him the learned Benedictus Arias Montanus to take the leading part in the work of editorship. With his zealous help the work was finished in five years (1569-1573, 8 vols. folio). Plantin earned little profit, but received the privilege of printing all liturgical books for the states of King Philip, and the office of "prototypographe regius." Though outwardly a faithful son of the church, he was till his death the partisan of a mystical sect of heretics; and it is now proved that many of their books published without the name of a printer came from his presses together with the missals, brevliaries, &c., for the Roman Catholic Church.

Besides the polyglot Bible, Plantin published in those years many other works of note, such as editions of St Augustine and St Jerome, the botanical works of Dodonaeus, Clusius and Lobelius, the description of the Netherlands by Guicciardini, &c. In 1575 his printing-office reckoned more than twenty presses and seventy-three workmen, besides a similar number that worked for the office at home. But in November 1576 the town was plundered and in part burnt by the Spaniards, and Plantin had to pay an exorbitant ransom. He established a branch of his office in Paris; and when in 1583 the states of Holland sought a typographer for the newly erected university at Leiden, he left his much reduced business in Antwerp to his son-in-law John Moretort (Moretus) and Francis van Ravelinghen (Raphelengius), and settled there. When in 1585 Antwerp was taken by the prince of Parma and affairs became more settled, he left the office in Leiden to Raphelengius and returned to Antwerp, where he laboured till his death on the 1st of July 1589. His son-in-law, John Moretus, and his descendants continued to print many works of note in officina Plantiniana," but from the second half of the 17th century the house began to decline. It continued, however, in the possession of the Moretus family, which religiously left everything in the office untouched, and when in 1876 the town of Antwerp acquired the old buildings with all their contents, for 1,200,000 francs, the authorities were able with little trouble to create one of the most remarkable museums in existence (the Musée Plantin, opened August 19, 1877).

See Max Rooses, Christophe Plantin imprimeur anversois (Antwerp, 1882); Aug. de Backer and Ch. Ruelens, Annales de l'imprimerie Plantinienne (Brussels, 1865); Degeorge, La Maison Plantin (2nd ed., Brussels, 1878). (P. A. T.)

PLANTS.

In the most generally used sense, a plant is a member of the lower or vegetable order of living organized things; the term is also popularly applied to the smaller herbaceous plants, thus excluding trees and shrubs. The early use of the word is for a twig, shoot, cutting or sapling, which was the meaning of Lat. planta (for plancit, the root being that seen in planus, flat, &c. Gr. πλαντή, broad; planta thus meant a spreading shoot or sucker). Other meanings of "plant" are derived from the verb "to plant." Lat. plantare, to fix in position or place. It is thus used of the flax, hemp, etc., which requires for the carrying on of an industry or business, and in colloquial or slang use, of a swindle, a carefully arranged plot or trap laid or fixed to deceive; cf. also "plantation". In the following sections the botanical sense of the word is followed, the term used being generally as opposed to "animals."

CLASSIFICATION OF PLANTS

Some account of the history of plant classification and the development of a natural system in which an attempt is made to show the actual relationships of plants is given, in the article Botany. The plant world falls into two great divisions, the higher or flowering plants (Phanerogams), characterized by the formation of a seed, and the lower or flowerless plants (Cryptogams), in which no seed is formed but the plants are disseminated by means of unicellular bodies termed spores. The term Cryptogam is archaic, implying a hidden method of reproduction as compared with the obvious method represented by the flower of the Phanerogams; with the aid of a good microscope it is, however, easier to follow the process of fertilization in many Cryptogams than in the flowering plants. These two divisions are moreover of unequal value, for the Cryptogams comprise several groups differing from each other by characters as marked as those which separate some of them from the Phanerogams. The following groups or sub-kingsoms are those which are now generally recognized:

Thallophyta are the most slowly organized plants and include a great variety of forms, the vegetative portion of which consists of a single cell or a number of cells forming a more or less branched thallus. They are characterized by the absence of that differentiation of the body into root, stem and leaf which appears in the higher plants, and by the simplicity of their internal structure. Both sexual and asexual reproduction occur, but there is usually successively of sexual generation (gametophyte) and asexual generation (sporophyte) which characterizes the higher groups. The group has until recent years been regarded as comprising three classes distinguished by well-marked structural peculiarities, the Algae (including the Seaweeds) which contain chlorophyll, the Fungi which have no chlorophyll and therefore lead a saprophytic or parasitic mode of life, and the Lichens which are composite organisms consisting of a Fungi and a type of Algae; the latter are bound together by a strong chemical bond (symbiosis); the Algae were regarded as a section of Fungi. Such a system of classification, although convenient, is not the most natural one, and a sketch of the system which better expresses the relationships between the various subdivisions here given. It has however been deemed advisable to retain the older groups for purpose of treatment in this work, and articles will be found under the headings Bacteria, and Lichens. The study of phylogeny has suggested four sub-classes arranged in the following sequence: (1) Bacteria; (2) Cyanophyceae (blue-green algae); (3) Flagellatae; (4) Myxomycetes (Slime-fungi); (5) Pteridophyta, (6) Conjugatae (Mycetozoa); (7) Chlorella (Chlorophyceae (Green Algae)); (8) Heterocontae (Chlorophyceae (Red Algae)); (9) Eumycetes (Fungi); (10) Phycomycetes (Algal fungi); (11) Phycomycetes (Brown Algae). Bacteria (see BACTERIOLOGY) and Cyanophyceae (see ALGAE), which are often grouped together as Schizophyta, are from points of view of both structure and reproduction extremely simple organisms, and stand apart from the remaining groups, which are regarded as the higher organisms, indirectly or by the Flagellatae, a group of unicellular aquatic organisms combining animal and plant characteristics which may be regarded as the starting point of unicellular Thallophytes on the one hand and of the Protista on the other. Thus simple organisms, the Heterocontae, Chlorophyceae and Phaeophyceae show an obvious connexion with the Flagellatae; the Peridiceae may be regarded as the higher development of the Chlorophyceae; the Diatomaceae cannot be directly connected; the origin of the Rhodophyceae is also obscure; while the Characeae are an advanced and isolated group (see ALGAE). The Myxozooza (g.v.) or Myxomycetes are a saprophytic group without chlorophyll, of simple structure and isolated position. The algal fungi, Phycomycetes, are obviously derived from the Green Algae, while the remaining Fungi, the Eumycetes, appear to have sprung from the same stock as the Rhodophyceae (see Fungi). Owing to the similarity of structure and mode of life it is convenient to treat the Lichens (g.v.) as a distinct class, while recognizing that the component fungus and alga are representatives of their former classes.

The Thallophyta are a Phanerogam have sprung from the higher Thallophyta, and together form the larger group Archeophyta, so-called from the form of the organ (archeogenium) in which the egg was developed. The Archeophyta are characterized by a well-marked alternation of gametophyte and sporophyte generations; the former bears the sexual organs which are of characteristic structure and known as antheridia (male) and archegonia (female) respectively; the fertilization having taken place, the sporophyte generation rises to the spore-bearing generation, and the spore on germination give rise directly or indirectly to a second gametophyte.

The Mosses and Liverworts (see BRYOPHYTA) include forms with a more or less leaf-like thallus, such as those of the liverworts, and forms in which the plant shows a differentiation into a stem bearing remarkably simple leaves, as in the true mosses. They have no true roots, and their structure is purely cellular or conducting bundles of a very simple structure are present. The independence of the plant which is generally attached to the soil by hair-like structures is the sexual generation, the sporophyte is a stalked or sessile capsule
which remains always attached to the gametophyte from which it derives the whole or part of its nourishment.

In the true plants (Phanerogamae or Spermatophyta) there are on the other hand a well developed independent sporophyte which is differentiated into stem, leaf and root with highly organized interrelated structures, including true vascular bundles. In general structure they approach those of the land plant which we may collectively call the Vascular Plants as contrasted with the Cellular Plants—Thallophyta and Bryophyta. The gametophyte is a small structure which shows varying degrees of independence affording an interesting transition to the next group.

Spermatophyta are characterized by an extreme reduction of the gametophyte generation. The sporophyte is the plant which is developed from the seed, and shows a wonderful variety of form; the internal structure also shows increased complexity and variety as compared with the other group of vascular plants, the Pteridophyta. The spores, as in the heterosporous Pteridophyta, are carried in indusium—polysporangia in the microsporangia (pollen sacs) on special leaves (sporophylls) known as stamens, and macrospores (embryo-sac) borne in microsporangia (sporangia) known as carpels. The fertile leaves or sporophylls are generally aggregated on special shoots to form flowers which may contain one or both kinds. The microspores are set free from the sporangium and carried generally by wind or insect agency to the vicinity of the macrospore, which never leaves the ovule. The male gametophyte is formed by one or two cells and, except in a few primitive forms where the male cell still retains the motile character as in the Pteridophyta, it is carried passively to the macropore by a development in a reduction of the pollen grain, the pollen tube. The Spermatophyta are thus land plants par excellence and have, with the few exceptions cited, lost all trace of an aquatic ancestry. Aquatic plants occur among them, and these are adaptations of land plants to an aquatic environment. After fertilization the female cell, now called the oosperm, divides and part of it develops into the embryo (new sporophyte), which remains dormant for a time still protected by the ovule in which it grew. This is the seed. The seed is a new structure characteristic of this group, which is therefore often referred to as the Seed-plants. The seed is set free from the ovule and serves as the means of dissemination (see Flower; Pollination; Fruit, and Seed). The Spermatophyta fall into two classes, Gymnosperms (g.s.) and Angiosperms (a.s.); the former are the more primitive group, appearing earlier in geological time and the more homogenous in their development to the Pteridophyta. A recently discovered fossil group, the Psilophyta (see Palaeobotany) have characters intermediate between the Pteridophyta and the more primitive seed-plants.

In Gymnosperms—so-called because the ovules (and seeds) are borne on an open sporophyll or carpel—the macrosporophyll and macrosporangia are not as a rule associated in the same shoot and are generally arranged in cone-like structures; one or two small prophyllial cells are formed in the germination of the microspore; the male cells are in some older members of the group motile though usually passive. The ovule is not enclosed in an ovary, and the ovules are borne on naked or nakedly accrescent thalli, in the upper part of which are formed several rudimentary archegonia. The fertilized egg-cell (oospore) forms a filamentous structure, rudimentary carpel; the protophloey is present; the ovule or ovule-bearing embryo develops, on one as a rule reaching maturity. The embryo consists of an axis bearing two or more cotyledons and ending below in a radicle; it lies in a generally copious food-storing tissue (endosperm) which is the remains of the female prophylls.

The plant has a well-developed main root (tap-root) and a single or branched leafy stem which is provided with a means of secondary increase in thickness. The leaves are generally tough-skinned and last for more than one season.

The Angiosperms, which are much the larger class, derive their name from the fact that the carpel or carpels form a closed chamber, the ovary, in which the ovules are developed—associated with this is a well-developed often reproductive structure—thallus, in the upper part of which are formed several rudimentary archegonia. The fertilized egg-cell (oospore) forms a filamentous structure, rudimentary carpel; the ovule is enclosed in an ovary, and the ovule or ovule-bearing embryo develops, on one as a rule reaching maturity. The embryo consists of an axis bearing two or more cotyledons and ending below in a radicle; it lies in a generally copious food-storing tissue (endosperm) which is the remains of the female prophylls.

The plant has a well-established main root (tap-root) and a single or branched leafy stem which is provided with a means of secondary increase in thickness. The leaves are generally tough-skinned and last for more than one season.

The Angiosperms, which are much the larger class, derive their name from the fact that the carpel or carpels form a closed chamber, the ovary, in which the ovules are developed—associated with this is a well-developed often reproductive structure—thallus, in the upper part of which are formed several rudimentary archegonia. cavity as "the cell," and the contained protoplasm or other substances, if present, as cell-contents. This is in accordance with the original use of the term "cell," which was applied in the 17th century to the cavities of plant-tissues on the analogy of the cells of honeycomb. The use of the term to mean the individualized nucleated mass of living protoplasm, which, whether with or without a limiting membrane, primitively forms the proximate histological element of the body of every organism, dates from the second quarter of the 19th century. For a more detailed description of the cell see Cytoology and the section on Cytology of Plants below). In all but the very simplest forms the plant-body is built up of a number of these cells, associated in more or less definite ways. In the higher (more complicated) plants the cells differ very much among themselves, and the body is composed of definite systems of these units, each system with its own characteristic structure, depending partly on the characters of the component cells and partly of the higher plants. The term parenchyma is applied to tissues whose cells are isodiametric or cylindrical in shape, p. 4488 tissues consisting of long narrow cells, with pointed ends.

We may now proceed to a systematic account of the anatomy of the different groups of plants, beginning with the simplest, and passing to the more complicated forms.

Thalassiothyras.—The simplest members of both the Algae and the Fungi (g.v.) (the two divisions of the Thalassiothyrae, which is the lowest of the four great groups into which the plant-kingdom may be divided) have no cell-contents. In the Algae such a cell consists essentially of: (1) a nucleus, (2) a plastid, (3) an assimilating apparatus consisting of a coloured protoplasmic body, called a chromatophore, the pigment of which in the true green forms is chlorophyll, and which may then be called a chloroplast. The whole of these living structures are covered externally by the dead cell-membrane (fig. 1 A). It is from such a living and assimilating cell, performing as it does all the vital functions of a green plant, that, according to current theory, all the different cell-forms of a higher plant have been differentiated in the course of descent.

Among the Green Algae the differentiation of cells is comparatively slight. Many forms, even when multicellular, have all their cells identical in structure and function, and are often spoken of as "physiologically unicellular." The cell is commonly joined end to end in simple or branched filaments. Such differentiation as exists in the higher types mainly takes two directions. In the fixed forms the cell or cells which attach the plant to the substratum have a peculiar form, containing chlorophyll and constituting a rudimentary fixing organ or rhizoid (fig. 1 C). In certain types living on damp soil, the rhizoids penetrate the substratum, and in addition to fixing the plant absorb dissolved substances (dissolved salts) from the substratum (fig. 1 B and D).

The second type of differentiation is that between supporting axis and assimilating appendages. The cells of the axis are common, as are the tissues and cells that form chlorophyll that make the appendages (Drapanalia). This differentiation is parallel with that between stem and leaf of the higher plants. In the group of the Siphonales both these types of differentiation may exist in the same, long, branched, tube-like and multilacunar "cell" (cavatocoele), which here forms the plant-body. Protosiphonia (fig. 1 B) is an example parallel with Oedocladium; Bryopsis, with Drapanalia. In Closterium the imitation of a higher plant by the differentiation of fixing, supporting and assimilating organs (root, stem and leaf) from different branches of the single cell is strikingly complete. In the Siphonales family of Codiaceae the branches of the primitive cell become considerably interwoven and aggregated in such a way as to form a dense tissue-like structure is often produced. In this we get a further differentiation between the central tubes (branches of the primitive cell), which run in a longitudinal direction through the body of the thallus, little or no nutrition being derived from the food substances from one region to another, and the peripheral ones, which are directed perpendicularly to the surface of the body, ending blindly there, contain abundant chlorophyll, and are the assimilating organs (fig. 1 E).

None of the existing Red Seaweeds (Rhodophyceae) has a unicellular body. The thallus in all cases consists of a branchial filament of cells placed end to end, as in many of the Green Algae. Each branch grows simply by the transverse division of its apical cell. The branches may be quite free or they may be united laterally to form a solid body of more or less firm and compact consistency. This may have a radial stem-like organization, a central cell-association derived from a number of early dividing cells, from branches, which together form a cortex round the central thread, the whole structure having a cylindrical form which only branches when the thread is cut transversely. From the central thread grows out generally the surface and forms in its turn a new central thread, from whose cells arise new short branches. Or the thallus may have a leaf-like form, the branches from the central threads which form the midrib growing out mainly in one plane, from which a lamina, extended right and left of the midrib. Numerous variations and modifications of these forms exist. In all cases, while the internal threads which bear the cortical branches consist of elongated cells with a thick wall, the external threads, mainly for conduction of food substances, the superficial cells of the branches themselves are packed with chromatophores and form the chief assimilating tissue of the plant. In the brown Seaweeds the thallus is branched from the base or from the sides of the cells, and, pushing among the already-formed threads in a longitudinal direction, serve to strengthen the thallus by weaving its original threads together. The cells belonging to any given thread may be recognized at an early stage of growth, because each cell

---

Fig. 14.—Examples of the differentiation of the tissue of plants.

1. End of hydroid of the Moss Minium, showing particularly thin oblique end-wall. No pits.
2. Sister section of two adjacent leptoids of the Moss Polytrichum juniperinum. The leptoids are living and nucleated. They bulge in the neighbourhood of the very thin cross-wall. Note resemblance to II and K.
3. Optical section of cell of parenchyma in the same moss. Embedded in the protoplasrn are a number of starch grains.
4. Part of elongated stereid of a Moss. Note thick walls and oblique slit-like pits with opposite inclination on the two sides of the cell seen in surface view.
5. One side of the end of hydroid (tracheid) of a Pteridophyte (fern), with scalariform pits.
6. Optical section of two adjacent leptoids (slieve-tube segments) of Pteridophyceae, with sieve plates (s. pl.) on oblique end-wall and side-walls.
7. Part of spiral hydroid (tracheid) of Phanerogam (Flowering Plant).
8. Three segments of a "pitted" vessel of Phanerogam.
9. Optical section of leptoid (sieve-tube segment) of Phanerogam, with two protid (companion) cells, s. pl., sieve-plate.
10. Optical section of part of thick-walled stereid of Phanerogam, with almost obliterated cavity and narrow slit-like oblique pits.
11. Part of vertical section through blade of typical leaf of Phanerogam. u.e., Upper epidermal cells, with (c) cuticle. (b) Assimilating (palisade) cells, sp., Assimilating (spongy) cells with large lacunae. l.e., Lower epidermis, with st., stoma.
12. Absorbing cell, with process (root-hair) from pelliferous layer of root of Phanerogam.
13. Endodermal cell of Phanerogam, with suberized central band on radial and transverse walls.

on the method of association. Such a system is called a tissue-system, the word tissue being employed for any collection of cells with common structural, developmental, or functional characters to which it may be conveniently applied. The word is derived from the general resemblance of the texture of plant substance to that of tissue fabrics, and dates from a period when the fundamental constitution of plant substance from individual cells was not yet discovered. It is convenient here to define the two chief types of cell-form which characterize tissues
is connected with its neighbours belonging to the same thread by two depressions or pits, one at each end. The common wall separating
the pits of the two adjoining cells is pierced by strands of protoplasm.
The wall between the two pits may then naturally involve the localization of the absorption in the region, and the function of absorption (which in the simpler forms is carried out by the whole of the vegetative part of the mycelium
penetrating a solid or immersed in a liquid substratum) is subserved by the outgrowth of the hyphae of the surface-layer of that region into rhizoids, which, like those of the Algae living on soil, resemble the root-hairs of the higher plants. The internal tissue of the body of the solid higher Fungi, particularly the elongated stalks (stipe)
of the fructifications of the Agarics, consists of hyphae running in a longitudinal direction, which no doubt serve for the conduction of organic food substances, just as do the trumpet-hyphae, which, in a sculptured way, though not in origin, of the higher Brown Seaweeds. (In one genus (Lactarius) "milk-tubes," recalling the laticiferous tubes of many vascular plants, are found.) These elongated hyphae are frequently thick-walled, and in some cases form a central strand, which may serve to resist longitudinal pulling strains. This is particularly marked in certain lichens of shrubby habit. The internal tissues, either consisting of obvious hyphae
or of pseudoparenchyma, may also serve as a storehouse of plastic food substances.

Looking back over the progress of form and tissue-differentiation
in the Thallophyta, we find that, starting from the simplest unicellular forms with no external differentiation of the body, we have a complexification process which may be likened to that
where determined by the principles of the division of physiologic
labour and of the adaptation of the organism to the needs of its environment. In the first place there is a differentiation of
fixing organs, which in forms living on a soft nutrient substratum penetrate it and become absorbing organs. Secondly, in the Algæ, which build up their own food from inorganic materials, we have a differentiation of supporting axes from
assimilating appendages, and as the body increases in size and becomes a solid mass of cells or interwoven threads, a corresponding differentiation of a superficial assimilative system from the deep-lying parts. In both Algæ and Fungi the latter
process is generally associated with the formation of the laterally
bulky Brown Seaweeds, where assimilation is strongly localized, some of the deep cells are highly specialized for the latter function.
In the higher forms a storage and a mechanically-strengthening
system may also be developed, and in some fungal external protective tissue. The "hyphal" mode of growth, i.e. the formation of the thallus, whatever its external form, by branched, continuous or septe, coenocytic tubes (Sphäneae and Fungi), or by simple or branched cell-threads (Red
and many Green Algæ), in both cases growing mainly or entirely at
the apex of each branch, is almost universal in the group, the
exceptions being met with almost entirely among the aquatic forms
of the flaccid Red Seaweeds. The free surface is increased by
the segmentation of an apical cell of the whole shoot, or by cell division in some other type of meristem.

Bryophyta.—The Bryophyta [including the Liverworts (Hepaticae) and Mosses (Musci)], the first group of mainly terrestrial
plants, exhibit considerably more advanced tissue differentiation, in response to the greater complexity in the conditions of life on land. In a general way this greater complexity may be said to consist (1) in the restriction of regular absorption of water to those parts of the plant-body embedded in the soil, (2) in the evaporation of water from the parts exposed to the air (transpiration). Have these two principles not find
expression till we come, in the ascending series, to the Vascular Plants. In the Bryophytes water is still absorbed, not only from the soil but also largely from rain, dew, &c.,
through the general surface of the subaerial body (thallus), or in the more differentiated forms through the leaves. The lowest Hepaticae have an extremely simple subaerial structure, little more advanced than that found in some of the higher Green Algæ and very much simpler than in the large Red and Brown Seaweeds. The plant-body (thallus) is always small and
normally lives in very damp air, so that the demands of terres-
trial life are at a minimum. It always consists of true parenchyma, and is entirely formed by the cutting off of segments
from an apical cell.

**ANATOMY**

**PLANTS**
A sufficient description of the thallus of the liverworts will be found in the article BRYOPHYTA. We may note the universal occurrence on the lower surface of the thallus of fixing and absorbing rhizoids in accordance with the terrestrial habit of the Bryophyta. The Marchantiaceae (see article BRYOPHYTA) show considerable tissue-differentiation, possessing a distinct assimilative system of cells differentiated into inner cortical and outer periderm regions, and arising from the basal cells of large cavities in the upper part of the thallus. These cavities are completely roofed by a layer of cells; in the centre of the roof is a pore surrounded by a ring of special 'conduction' cells; a network of these 'conduction' cells is connected with the lacunae, mesophyll and stomata, which form the assimilative and transpiring (water-evaporating) apparatus in the leaves of flowering plants. The frondose (thalloid) Jornandermiales show no development of these rhizoids which are absent in an assimilative tissue in all but the Marchantiaceae. The cells of the thallus usually have more chlorophyll than the rest. In three genera — Blyttia, Symplygymna and Hymenophyllum — there are one or more strands or bundles consisting of long thick-walled fibrefibre-like (parenchymatous) cells, running longitudinally through the thick midrib. The walls of these cells are strongly lignified (i.e. consist of woody substance) and are irregularly but thickly stuffed with simple pits (see CYTOLOGY), which are usually arranged in spirals running round the cells. These are often elongated in the direction of the spiral (fig. 1, l). These cells are not living in the adult state, though they sometimes contain a small remainder of chlorophyll. As a rule they conduct water through the thallus, the assimilating parts of which are in these forms often raised above the soil and are comparatively remote from the rhizoid-bearing (water-absorbing) region. Such differentiated and conducting cells are very rarely found in the sporangium of the liverworts which is the simpler form of the sporophore and the small and peculiar group of these plants, the Anthocerotaeae, a distinct assimilating and transpiring system is found in the wall of the very long cylindrical capsule, clearly rendering the sporogonium largely independent of the supply of elaborated organic food from the thallus of the mother plant (the gametophyte). A richly chlorophyllous tissue with numerous intercellular spaces containing water and organic matter, strikingly resembles those of the vascular plants (see below). If the axis of such a sporogonium were prolonged downwards into the soil to form a fixing and absorptive root, the whole structure would become a physiological plant. The relative absence of these structures in the liverworts no means all respects the leading features of the sporophyte or ordinary vegetative and spor-bearng individual in Pteridophytes and Phanerogams. These facts, among others, have led to the theory, plausible in some respects, of the origin of this sporophyte by descent from an Anthocereus-like sporogonium (see PTERIDOPHYTA). But in the Bryophytes the sporogonium never becomes a sporophyte plant and the adult thallus remains a true gametophyte for gametophyte for its water and mineral food, and the facts give us no warrant for asserting homology (i.e. morphological identity) between the differentiated tissues of an Anthocereus sporogonium and the sporangium of the liverworts. Only the very small thalloid forms of the Marchentiales are of any value in plant biology. In these the stem bears numerous cell-filaments (rhizoids) which fix the plant to the substratum upon which it is growing.

In the Mosses the plant-body (gametophyte) is always separable into a radially organized, supporting and conducting axis (stem) and thin, flat, assimilating, and transpiring appendages (leaves). To the base of the stem are attached a number of branched cell-threads (rhizoids) which fix the plant to the soil, fixing the plant and absorbing water from soil. For the histology of the comparatively simple but in many respects aberrant B ps mosses (Sphagnum), see BRYOPHYTA. The stem of the mosses is usually one celled throughout, bears tracheids and rhizoids which form the outer cortex. This passes gradually into the thinner-walled parenchyma of the inner cortex. The whole of the cortex, stem-cor, and parenchyma alike, is commonly living, and its cells contain chlorophyll; they are not differentiated into inner cortical and outer periderm regions as in the Liverworts. The plant-body of the mosses is usually a soft spongy or cottony tissue, containing a constant amount of water, which living on soil is occupied by a strand of narrow elongated hydroids, which differ from those of the liverworts in being thin-walled, undoubtedly hydroids (fig. 1, j). The hydrom strand has in most cases no connection with the ectocortex and passes up the stem and spreads out below the sexual organs or the foot of the sporogonium. It has been shown that it conducts water with a greater degree of perfection than in the liverworts and in the sporogonium there is a similar strand, which is of course not in direct connection with the stem, but continues the conduct of water from the strand of the gametophyte axis. In the aquatic, semi-aquatic, and xerophilous types, where the whole surface of the plant absorbs water, perpendicularly in the first two cases and during rain in the last, the hydrom strand is either much reduced or altogether absent. In accordance with the general physiological plan of plants, where the whole surface of the plant absorbs water by means of its basal rhizoids that a water-conducting (hydrom) strand is developed. The leaves of the hydrobioid liverwort, and the leaves of the moss and other liverworts, consist of square or oblong assimilating (chlorophyllous) cells. In many the cells bordering the leaf are produced into teeth, and very frequently they are thick-walled so as to form a supporting rim, which if occasionally incised forms a leaflet or leaf or leaf bundle and forms an approach to leptom, though it is not so specialized as the leptom of the higher Phaeophycæae. Associated with the leaf or leaf bundle are parenchymatous leaf-trabeculae containing hydroids identical in character with those of the central strand of the stem, and no doubt serving to conduct water to or from the leaf according as the latter is acting as a transpiring or a water-absorbing organ. In a few cases the hydrom strand is continued into the cortex of the stem as a leaf-trace bundle (the anatomically demonstrable trace of the leaf in the stem). This in several cases runs vertically downwards for some distance in the outer cortex, and only a small bundle of discoidal cells is formed by the branches of the leaf-trace bundle, and here the leaf-trace bundle consists of a few strands of cells surrounding the transverse canal. Such a leaf-trace bundle is called a leaf-trace; the leaf-trace bundle is called a leaf-trace; the leaf-trace bundle is evidently formed by the conjoined bases of the leaf-trace branch of which is composed of the same three tissues. As the aerial stem is traced down into the underground rhizome portion, these three strands change their size and shape. The outermost of the three, forming the bulk of the cylinder and its elements becoming mixed with thick-walled steleides; at the same time this central hydrom steloid strand becomes three-lobed, with deep furrows between the lobes. The central strand, which supplies the outer elements of the bundle with water and receives the water from the central mass by a few starchy cells, the remains of the amyl sheath. At the periphery of the lobes are some comparatively thin-walled living cells mixed with a few thick-walled hydroids, which are the first elements of the new leaves. Outside this are three arcs of large cells showing characters typical of the endodermis in a vascular plant; these are interrupted by strands of narrow, elongated, thick-walled cells, which send branches into the little brown scales borne by the rhizome. The surface layer of the rhizome bears rhizoids, and its whole structure strikingly resembles that of the typical root of a vascular plant. In Catharinæa

732

PLANTS [ANATOMY]
the central hydrom cylinder of the aerial stem is a loose tissue,
interstices being filled up with thin-walled, starchy parenchyma. In
Davallonia superba, a large New Zealand moss, the hydroids of the
central cylinder of the aerial stem are mixed with thick-walled steroids forming a hydrom-stereom strand which
is characteristic of the Polytrichaceae.

The central hydrom strand in the stem of the sporogonium of
most mosses has already been alluded to. Besides this there is
usually a living conducting tissue, sometimes differentiated as
leptoderm, sometimes in various forms of more or less uniform
quality, usually a hydrom-stereom strand on the outer side, and
internally by a more or less well-differentiated endoderms, abutting
on an irregularly cylindrical lacuna; the latter separates the central
conducting cylinder from the cortex of the stem, which, like the
cortex of the gametophyte stem, is usually different and is throughly
an outer thick-walled stereom and an inner starchy parenchyma.

Frequently, also, a considerable differentiation of vegetative/tissue
occurs at the wall of the spore-capsule itself, and in some of the
higher forms a special assimilating and transpiring organ situated
just below the capsule at the top of the stem, with a richly lacunar
chlorophyllous parenchyma and stomata like those of the wall of the
capsule in the Anthoceracean Liverworts. Thus the histo-
logical differentiation of the sporogonium of the higher mosses is
one of considerable complexity; but there is here even less reason
to suppose that these tissues have any homology (phylogenetic
community of origin) with the similar ones met with in the higher
plants.

The features of histological structure seen in the Bryophytic
series are such as we should expect to be developed in response
to the exigencies of increasing adaptation to terrestrial life on
soil, and of increasing size of the plant-body. In the liverworts
we find fixation of the thallus by water-absorbing rhizoids; in
certain forms with a localized region of water-absorption the
development of a primitive hydrom or water-conducting system;
and in others with rather a massive type of thallus the differentia-
tion of a central assimilative and transpiring system. In the
more highly developed series, the mosses, this last division
of labour takes the form of the differentiation of special assimilative
organs, the leaves, commonly with a midrib containing
elongated cells for the ready removal of the products of assimila-
tion; and in the typical forms with a localized absorptive region,
a well-developed hydrom in the axis of the plant, as well as
similar hydrom strands in the leaf-midribs, are constantly met
with. In higher forms the conducting strands of the leaves
are continued downwards into the stem, and eventually come
into connexion with the central hydrom cylinder, forming a
complete cylindrical investment apparently distinct from the
latter, and exhibiting a differentiation into hydrom, leptoderm,
and epidermis, which, however, only parallel those found among
the true vascular plants. Similar differentiation, differing in some
details, takes place independently in the other
generation, the sporogonium. The stercor of the moss is
found mainly in the outer cortex of the stem and in the midrib
of the leaf.

Vascular Plants.—In the Vascular Plants (Pteridophytes,
I.e. ferns, horse-tails, club mosses, &c., and Phanerogams or
Flowering Plants) the main plant-body, that which we speak of
in ordinary language as 'the plant,' is called the sporophyte
because it bears the asexual reproductive cells or spores.
The gametophyte, which bears the sexual organs, is either
a free-living thallus corresponding in degree of differentiation
with the lower liverworts, or it is a mass of cells which
always remains enclosed in a spore and is parasitic upon the
sporophyte.

The body of the sporophyte in the great majority of the
vascular plants shows a considerable increase in complexity
over that found in the gametophyte of Bryophytes. The
principal new feature in the external conformation of the body
is the acquisition of true roots, the nearest approach to
which in the lower forms we saw in the 'rhizome' of Poly-
trichaceae. The primary root is a downward prolongation
of the primary axis of the plant. From this, as well as from
various parts of the shoot system, other roots may originate.
The root differs from the shoot in the characters of its surface
tissues, in the absence of the green assimilative pigment chloro-
phyll, in the arrangement of its vascular system and in the mode
of growth at the apex, all features which are in direct relation
to its normally subterranean life and its fixative and absorptive
functions. Within the limits of the sporophyte generation the
Pteridophytes and Phanerogams also differ from the Bryophytes
in possessing special assimilative and transpiring organs, the
leaves, though these organs are developed, as we have seen,
in the gametophyte of many liverworts and of all the mosses.
The leaves, again, have special histological features adapted to
the performance of their special functions.

In root, stem and leaf, we can trace a three-fold division of
tissue system, a division of which there are indications among
the lower plants, and which is the expression of the fundamental
conditions of the evolution of a bulky differ-
entiated plant-body. From the primitive uniform
mass of undifferentiated assimilating cells, which
we may conceive of as the starting-point of differentiation,
though such an undifferentiated body is only actually realized
in the thallus of the lower Algae, there is, (1) on the one hand,
a specialization of a surface layer regulating the immediate
relations of the plant with its surroundings. In the typically
submerged Algae and in submerged plants of every group this
is the absorptive and the main assimilative layer, and may also
be produced by the production of mucilage be of use in the protection
of the body in various ways. In the terrestrial plants it differs
in the subterranean and subaerial parts, being in the former
pre-eminent absorptive, and in the latter protective—provision
at the same time being made for the gaseous interchange
of oxygen and carbon dioxide necessary for respiration and feeding.
This surface layer in the typically subaerial "shoot" of the
sporophyte in Pteridophytes and Phanerogams is known as the
epidermis, though the name is restricted by some writers, on
account of developmental differences, to the surface layer of
the shoot of Angiosperms, and by others extended to the whole
surface layer of the whole plant in both these groups. On the
other hand, we have (2) an internal differentiation of conducting tissue,
the main features of which as seen in the gametophyte of Bryo-
phytes have already been fully described. In the Vascular Plants
this tissue is collectively known as the vascular system. The
remaining tissue of the plant-body, a tissue that we must regard
phylogenetically as the remnant of the undifferentiated tissue
of the primitive thallus, but which often undergoes further
differentiation of its own, the better to fulfil its characteristically
vital functions for the whole plant, is known, from its peripheral
position in relation to the primitively central conducting tissue,
as the cortex. Besides absorption, assimilation, conduction
and protection there is another very important function for
which provision has to be made in any plant-body of considerable
size, especially when raised into the air, that of support. Special
tissues (stereom) may be developed for this purpose in the cortex,
or in immediate connexion with the conducting system, according
to the varying needs of the particular type of plant-body.
The important function of aeration, by which the inner living
masses of the bulky plant-body obtain the oxygen necessary
for their respiration, is secured by the development of an extensive
system of intercellular spaces communicating with the external
air.

In relation to its characteristic function of protection, the
epidermis, which, as above defined, consists of a single layer of cells
has typically thickened and cuticularized outer walls. But it is not only
by this that the plant-body takes the first mechanical injury from without, and against the entry of smaller
parasites, such as fungi and bacteria, but also and especially to
prevent the evaporation of water from within the stem, a function
which it is given by it closely and ingeniously to perform (stomata) leading from the air outside to the system of intercellular spaces below. Each
stoma is surrounded by a pair of peculiarly modified epidermal cells, the guard-cells, which are opened and closed when air
is wanted according to the need for transpiration. The structure of the stomata of the sporophyte of vascular plants is fundamentally
the same as that of the stomata on the sporogonium of the true
mosses and of the liverwort Anthocerat. Stomata are often situated
at the bottom of pits in the surface of the leaf. This arrangement is
a method of checking transpiration by creating a still atmosphere
above the pore of the stoma, so that water vapour collects in it
and reduces the evaporation of water from its surface. This type of stomata,
which is extremely various in its details, is found especially,
as we should expect, in plants which have to economize their water
supply. The stomata serve for all gaseous interchange between the plant and the surrounding air. The guard-cells contain chlorophyll. The mesophyll is a type of parenchymatous tissue, the function of which is to store water for use. Sometimes the epidermis is considerably more developed by tangential division of its cells, forming a many-layered water-tissue. This is found especially in plants that are submerged in water. The cells of the water-tissue have lost through transpiration by the supply coming from the roots. The water stored in such a time supplies the immediate need of the transpiring cells and prevents the injury which would result from the water-vapour tension of the atmosphere.

The epidermis of a very large number of species bears hairs of various kinds. The simplest type consists simply of a single elongated cell projecting at the surface level. More elaborate hairs consist of a chain of cells; others, again, are branched in various ways; while yet others have the form of a flat plate of cells placed parallel to the leaf surface and consisting mainly of a few epidermal cells or they may simply contain air. A very common function of hairs is to diminish transpiration, by creating a still atmosphere between them, as in the case of the sphenostoma already mentioned.

Mention may be made here of a class of epidermal organs, the hydathodes, the wide distribution and variety of which have been revealed by recent research. These are special organs, sometimes occurring on the outer surface of leaves, and at other times in the water in liquid form when transpiration is diminished so that the pressure in the water-channels of the plant has come to exceed a certain critical value. They are predominantly found in aquatic plants but also abundant in certain tropical climates where active root absorption goes on while the air is nearly saturated with water vapour. In one type they may take the form of specially-modified single epidermal cells in which the epidermis hairs are without cells, and in direct connection with the vascular system. The cells concerned, like all secreting organs, have abundant protoplasm with large nuclei, and sometimes, in addition, part of the cell-wall is modified as a filter. In a second type they are situated at the ends of trachal strands and consist of a group of richly protoplasmic cells belonging to the epidermis (as in the leaves of many ferns), or to the subjacent tissue (the commonest type in flowering plants); in this last case the cells in question are differentiating into hydathodes, i.e. a network of fine intercellular spaces, which are normally filled with water and debouch on one or more intercellular cavities below the epidermis. Above each cavity is situated a so-called water-stoma, no doubt derived phylogenetically from an ordinary stoma, enclosed by guard-cells which have nearly or entirely lost the power of movement. The pores of the water-stoma are the outlets of such a stoma. The cell-body is thus the cavity surrounded by a sheath of cuticularized cells. In other cases the epidermis may be absent altogether, the trachal strand debouching directly on the lacunae of the mesophyll. This last type of hydathode is usually situated near the apex of the leaf, the epidermal hairs being modified glands, secreting the water they expel from the leaf. [Many other types of glands also exist, either in connexion with the epidermis or not, such as nectaries, digestive glands, oil, resin and mucilage glands, which are in the main co-opted for the secretion of the plant, but they are not of significance in relation to the primary vital activities, and cannot be dealt with in the limits of the present article.] The typical epidermis of the shoot of a land plant, is not very water-bearing. In some plants living in situations where they cannot depend on a regular supply from the roots (e.g. epiphytic plants and desert plants) have absorptive hairs or scales on the leaf epidermis through which rain and dew can be absorbed. Such hydathodes also are capable of absorbing as well as excreting water.

The surface layer of the root, sometimes included under the term epidermis, is particularly taken from the outside of the stem. In correspondence with its water-absorbing function it is not cuticularized, but remains usually thin-walled; the absorbing surface is increased by its cells being provided with numerous vacuoles, or macerating the tracheides to round them. They are firmly to particles of soil, thus at once fixing the root firmly in the soil, and enabling the hair to absorb readily the thin film of water ordinarily surrounding the particles (fig. 1, U). The root-hair ends hug the atmosphere, and so carry out a number of the functions of the root hairs, towards the outer surface, thus facilitating the passage of the apex as it is pushed between the particles of soil.

The cortex, as has been said, is in its origin the remains of the primitive inner tissue of the mesophyll after differentiation of the surface layer and the conducting system. It consists primitive ly of typical living parenchyma; but its differentiation may be extremely varied, since in the complex bodies of the higher plants its functions are numerous. In all green plants which have a special protective epidermis, the cortex of the leaf bears the function of the same leaf by virtue of the outer surface being limited by the epidermis. In the leafy shoot this function is mainly localized in the cortical tissue of the leaves, known as mesophyll. The mesophyll, which is essentially a parenchymatous tissue containing chloroplasts, and is penetrated by a system of intercellular spaces so that the surfaces of the assimilating cells are brought into contact with air to as large an extent as possible, in order to facilitate gaseous interchange between the assimilating cells and the atmosphere. At the same time the cells of the mesophyll are transpiring cells, i.e. the evaporation of water from the leaf goes on from them into the intercellular spaces. The only pathways for the gases which thus pass between the cells of the mesophyll and the outside air are the stomata. A land plant has nearly always to protect itself against over-transpiration, and for this reason the stomata of the typical dorsiventral leaf (fig. 2, A), which has distinct upper and lower faces, are placed mainly or exclusively on the lower side of the leaf, whereas the water vapour that escapes from them, being lighter than air, cannot pass away from the surface of the leaf, but remains in contact with it and thus tends to check further transpiration. The stomata are a more or less important part in the complex system of intercellular spaces which is found in the loosely arranged mesophyll (spongy tissue) on that side. This is the main transpiring tissue, and is protected from direct illumination and consequent too great evaporation. The main assimilating tissue, on the other hand, is under the upper epidermis, where it is well illuminated, and consists of oblong cells densely packed with chloroplasts and with their long axes perpendicu lar to the surface (palisade tissue). The intercellular spaces are here very narrow channels between the palisade cells. Leaves whose blades are normally held in a vertical position possess palisade tissue and stomata on both sides (isobilateral leaves) (fig. 2, B), since there is no difference in the illumination and other external conditions, while those which are cylindrical or of similar shape (centric leaves) have it all round. The leaves of shade plants have little or no differentiation of palisade tissue. In fleshy leaves which contain a great bulk of tissue in relation to their chlorophyll content, the central mesophyll contains little or no chlorophyll and acts as water-storage tissue. The cortex of a young stem is usually green, and plays a more or less important part in the assimilative function. It also always possesses a well-developed lacunar system communicating with the external air through stomata (in the young stem) or lenticels (see below). This lacunar system not only enables the cells of the cortex itself to respire, but also forms channels through which air can pass to the deeper-lying tissues. The cortex of the older stem of the root frequently acts as a reserve store-house for food, so that it is still growing after the shoot is dead, and is not only in providing the stets of the plant in the leaf-blade this sometimes appears as a layer of thickened subepidermal cells, the hypoderm, often also as subepidermal bundles of sclerenchymatous fibres, or as similar bundles extending right across the leaf from one epidermis to the other and thus acting as struts. Isolated cells (idioblasts), thickened in various ways, are not uncommonly found supporting the tissues of the leaf. In the larger veins of the leaf, the cortex consists entirely of parenchyma, whereas the small veins, particularly the very frequent type of mechanical tissue is collenchyma. This consists of elongated cells with cellulosic walls, which are locally thickened along the original corners of the cells, reducing the lumen of the vessels or of the tracheides to one or two cylinders, so that a number of vertical pillars of cells are connected by comparatively thin walls form the framework of the tissue. This tissue remains living and is usually formed quite early, just below the epidermis, where it provides the first peripheral support for a still growing stem or petiole. Sclerenchyma may be formed later in various positions in the cortex, according to local needs. Scattered single steroids or bundles of fibres are not uncommon in the cortex of the root.

FIG. 2.— Transverse Sections of Leaves.

The innermost layer of the cortex, abutting on the central cylinder of the bundle, is the phellogen, or pheloterm, and is often differentiated. In the leaf-blade it takes the form of special parenchymatous sheaths to the bundles. The cells of these sheaths are often distinctly differentiated in their position of the leaf-blade (the sheath of the phellogen) into a little or no chlorophyll. Occasionally, however, they are particularly rich in chloroplasts. These bundle sheaths are important in the conduction of carbohydrates away from the assimilating cells of the mesophyll to the leaves. In the leaf-blades, the pheloterm is developed as an endodermis (see below). In other cases it does not differ histologically from the parenchymatous cells of the leaf-blade (the sheath of the phellogen) but is distinguished by containing particularly abundant starch, in which case it is known as a starch sheath.

All in all, the characters common to the two highest groups of plants, the Pteridophytes and Phanerogams, is the possession of a double (hydrom-leptom) conducting system, such as we saw among the highest mosses, the charaleans, and ferns. The vascular system of the Pteridophytes has an entirely separate evolution. All the surviving forms, however, have a completely established double system with the specific characters alluded to, and since there is every reason to believe that the two systems of evolution of the primitive Pteridophytes must have been essentially similar to those of the Bryophytes, the various stages in the evolution of the conducting system of the latter (fig. 1) are useful to compare with the arrangements met with in the former.

The hydroid of a Pteridophyte or of a Phanerogam is characteristically a dead, usually elongated, cell of considerable length, which is generally and extensively thick-walled with lignified (wood) spiral (fig. 1, p.).

### Tissue Elements
- **or annular thickenings,** or thick lignified walls, in completely perforated by piths (fig. 1, q.) (usually bordered pits) of various shapes, of the pits may be separated by a network of thickening when the tracheid is reticulate or they may be transversely elongated and separated by or edges of thickening like the rungs of a ladder (scalariform thickening). When, in place of a modified septum, the tracheid is perforated by a single wide band, the same kind of wall thickening, but composed of a number of cells whose cross walls have disappeared, the resulting structure is called a vessel. Vessels are common in the Angiospermous group of Flowering Plants (fig. 1, t.).

During the development of a xylem cylinder, the secondary thickenings of the primary phloem are clearly shown in the figure, 1, q.) (fig. 1, q.) (usually bordered pits) of various shapes, of the pits may be separated by a network of thickening when the tracheid is reticulate or they may be transversely elongated and separated by or edges of thickening like the rungs of a ladder (scalariform thickening). When, in place of a modified septum, the tracheid is perforated by a single wide band, the same kind of wall thickening, but composed of a number of cells whose cross walls have disappeared, the resulting structure is called a vessel. Vessels are common in the Angiospermous group of Flowering Plants (fig. 1, t.).

The tracheid of a Pteridophyte (fig. 1, o.) is also an elongated cell, with a thin lining of protoplasm, but destitute of a nucleus, and always in communication with the next cell of the leaf-blade by either thin-walled with lignified (wood) spiral (fig. 1, p.).

### Evolution of the Stele in Pteridophytes
- **Evolution of the Stele in Pteridophytes**

As the primitive stelar of a Pteridophyte is traced upwards to the primary stele, the protoxylem elements become continuous round the xylem. At the same time the stele becomes more bulky, all its elements increasing in number (fig. 4). Soon a bundle goes off to one lateral side of the shoot, and then a segment of xylem-vessel, or protoxylem, and usually an arc of endodermis, which closes round the bundle as it detaches itself from the stele. As the stelar is traced farther upwards it is found that various pairs of protoxylem elements are joined together to form a continuous stele loop. In many Pteridophytes the solid haustellate is maintained throughout the axis. In others a central parenchyma or primary phloem appears as a new region of the primitive stelar conjunctive tissue, in parallel with the protoxylem. Sometimes this condition,
that of the *amphiphloic haplostele*, is maintained throughout the adult stem (Lindsay). In the majority of ferns, at a higher level, after the stele has increased greatly in diameter, a large-celled true pith or medulla, resembling the cortex in its characters, and quite distinct from conjunctive, from which it is separated by an internal endodermis, appears in the centre. These successive new tissues, appearing in the centre of the stele, as the stem of a higher fern is traced upwards from its first formed parts, are all in continuity with the respective corresponding external tissues at the point of origin of each leaf trace (see below). Where internal phloem is present this is separated from the internal endodermis by an endocycle or "internal pericycle," as it is sometimes called, and from the xylem by an *internal mesocycle*—these two layers, together with the outer mesocycle and pericycle, constituting the conjunctive tissue of the now hollow cylindrical stele. (The conjunctive frequently forms a connected whole with bands of axis. The type of siphonostele characteristic of many ferns, in which are found internal phloem, and an internal endodermis separating the vascular conjunctive from the pith, is known as a *solenostele*. The solenostele of the ferns is broken by the departure of each leaf-bundle, the outer and inner endodermis joining so that the stele becomes horseshoe-shaped and the cortex continuous with the pith (fig. 6). Such a break is known as a *leaf-gap*. A little above the departure of the leaf-bundle the stele again closes up, only to be again broken by the departure of the next leaf-bundle. Where the leaves are crowded, a given leaf-gap is not closed before the next ones appear, and the solenostele thus becomes split up into a number of segments, sometimes band-shaped or semilunar, sometimes isodiametric in cross-section (fig. 7). In the latter case each segment of the solenostele frequently resembles a *haplostele*, the segments of inner endodermis, pericycle, phloem and

---

[Diagrams and text explaining the anatomy of various ferns' steles, with labels identifying parts such as cortex, medulla, pith, xylem, phloem, and endodermis.]
In some sphenostelic ferns, and in many dicytostelic ones additional vascular strands are produced in the form of a hollow cylinder to fill the gap between the leaf-trace and the inner wall of the vascular tube. They usually run freely in the pith and join the primary tube in the neighborhood of the leaf-gaps. Settling in the complete internal vascular cylinder, having the same structure and relations toward the cambium as in the protoxylem, in some cases, a small strand or a whole part of the secondary cylinder is formed.

Dicyclic.

The vascular supply of the leaf (leaf-trace) consists of a single strand only in the sphenostelic and some of the more primitive dicyclic ferns. In the "microphyllous" groups of Pteridophytes (Lycopodiales and Equisetales) in which the leaves are large relative to the stem, the primary system is thus connected with the stem, the single bundle destined for each leaf is split up into a number of strands whose departure causes no disturbance in the cauline stele. In the "megaphyllous" forms, on the other hand, (Ferns) whose leaves are large relatively to the stem, the departure of the corresponding strand causes a gap (leaf-gap) in the vascular cylinder, as already described. In the haptostelic ferns the leaf-trace appears as a single strand with a tendency to assume the shape of a horse-shoe on cross-section, and this type is also found in the more primitive sphenostelic types. In the highly developed forms, as already indicated, the leaf-trace is split up into a number of strands which leave the base and sides of the leaf-gap independently. In these cases, the cambium is divided into two parts, and though usually reducible to the outline of the primitive "horse-shoe" or more elaborated, they may in some of the complex families (Marchantiales) be arranged in several concentric circles, thus initiating the arrangement of strands formed in the stem. The evolution of the vascular structure of the petiole in the higher ferns is strikingly parallel with that of the stem, except in some few special cases where water-storage which can be drawn upon when the water supply from the root is deficient.

Parallel of Ontogeny with Differentiation of the Phloem: The "Stele" of Gymnosperms and Dicotyledons (9).

In ferns the secondary cylinder is developed independently from the primary cylinder and in dicytostelic forms. In the formation of the stem of any fern characterized in the adult condition by one of the more advanced types of vascular structure all stages of increase in complexity from the haptostele of the first-formed stem to the particular condition characteristic of the adult stem are gradually passed through by a series of changes exactly parallel with those which have already been described for the xylem. These changes are in all cases due to the development of an additional order of vascular bundles, and though usually reducible to the outline of the primitive "horse-shoe," or more elaborated, they may in some of the complex families (Marchantiales) be arranged in several concentric circles, thus initiating the arrangement of strands formed in the stem. The evolution of the vascular structure of the petiole in the higher ferns is strikingly parallel with that of the stem, except in some few special cases where water-storage which can be drawn upon when the water supply from the root is deficient.

Stem "Stems of Pteridophytes" (S. spinosa), exarch-diaich in several (fig. 10). In other species, however, a peculiar type of polyphyllus is met with, in which the segments of the leaf are derived from the leaf-bases of some of the phloem bundles, which contain abundant starch. Some regions of it, particularly the whole or part of the pericycle, but sometimes also the endoderm, are typically converted into thick-walled cells (sclerarchic endodermis), which is important in strengthening the stem, particularly in enabling it to resist bending strains. The relative peripheral position in the stem of the pericycle is important in this respect. Various secondary meristems (see p. 741) arise in the external conjunctive.

Anatomy of Gymnosperms and Dicotyledons (10).
Most of the collateral bundles of this siphonostele are leaf-trace bundles, which can be traced up from any given point till they are found to pass out of the cylinder, travel through the cortex of the stem and enter a leaf. The remaining bundles (compensation bundles) which go to make up the cylinder are such as have been described as the collateral bundles of the leaves. The leaf trace of any given leaf rarely consists of a single bundle only (unisascular); the number of bundles of any given trace is always odd; they may either be situated all together before the leaf or they may be distributed at intervals in the flowering parts of the plant. The median bundles of the trace are typically the largest, and at any given level of the stem the bundles destined for the next leaf above are as a whole larger than those which are destined to supply higher leaves. Leaf-trace bundles are formed in essentially the same way as the leaves, but when in the case of a plurisascular trace the bundles are distributed at intervals round the cylinder it is usual that the gaps so occur in the intervals between the adjacent bundles.

In some cases this individualization is carried further, the cortex and pith becoming continuous between the bundles which appear as isolated strands embedded in a general ground-tissue. Each bundle has its own investment of tissue corresponding to its external conjunctive, and now called peridsim. The bundles sometimes keep their arrangement in correspondence with the stele, though the continuous cylinder no longer exists (species of Ranunculus). This condition is known as asept. In some aseptic stems (Nymphaeaceae) the number of bundles is greatly increased and they are scattered throughout the ground tissue. A "polystelic" condition arises in some members of this order by the association of collateral bundles round a common conductive. A similar phenomenon is seen in two widely separated genera of flowering plants: Primula & Ascida and Pinnata elongata (Sachs.).

The monocotyledons, one of the primary divisions of angiosperms, is typically divided into large leaves with broad sheathing bases containing a very great number of bundles. This rule is more accurately true in the monocotyledons (type of composite leaf). In the second species of angio sperm, the bundles are arranged in a ring, with accompanying com- mon peridsim. In the asep. a adventitious bundles of the pith are also developed, the inner side of the bundle.

is often fibrous (fig. 16). It is possible to suppose that this condition is derived from the asep., but the evidence on the whole leads to the conclusion that it has arisen by an increase in the number of the bundles within the stele, and that the leaf-trace bundles are long before they escape from the original bundle-ring of the primitive cylinder.

In the stems of many water-plants various stages of reduction of the vascular system, especially of the xylem, are met with, and very often this reduction leads to the formation of a compact stele in which the individuality of the separate bundles may be suppressed, so that no bundle is left which is wholly unaltered. The xylem is generally unaltered, and there is normally a well-marked endodermis (fig. 17).

**Aberrant Types of Stele in Angiospermae.**

**Reduced Haplollstele Type.**

**Fig. 17.**—Transverse section of the stele of a water-plant (Naias):—

| l, Interzellular section representing xylem; pb, phloem; e, endodermis. |

In other cases the reduction goes much further, till the endodermis eventually comes to surround nothing but an intercellular channel formed in place of the stele tissue.

In the blade of a typical leaf of a vascular plant—essentially a tissue-forming organ—of a leaf is a phenomenon of adventitious tissue—the vascular system takes the form of a number of separate, usually branching and anastomosing strands. These, with their associated xylem and phloem, form a kind of framework which is of great importance in supporting the leaf itself. Some plants, e.g. Verbena, have a single strand of xylem and a single strand of phloem, while others, e.g. Paullinia, provide a number of channels, penetrating every part of the leaf, along which water and dissolved substances are conveyed to, and elaborated from, the mesophyll cells. The bundle-system is of course continuous with that of the petiole and stem. The leaf-bundles are always collateral (the phloem being turned downwards and the xylem upwards), even in Ferns, where the petiolar strands are concentric, and they have the ordinary mesophyll and peridsim of the collateral bundle. The latter is often selerized, especially opposite the phloem, and to a less extent opposite the xylem, in the stem. As a bundle is traced towards its base, it is frequently found that several xylem and phloem are reduced, and there is normally a well-marked endodermis (fig. 17).

**Stem Tissue of Leaf and Root.**

**Fig. 18.**—Vertical section of a Palm-stem, showing the vascular bundles, 74, curved inwards and then outwards.
Laticiferous Tissue.

The body of a vascular plant is developed in the first place by repeated division of the fertilized egg and the growth of the products of division. The body thus formed is called the *embryo*, and this develops into the adult plant, not by continued growth of all its parts as in an animal, but by localization of the regions of cell-division and growth, such a localized region being called a *growing-point*. This localization takes place first at the two free ends of the primary axis, the descending part of which is the primary root, and the ascending the primary shoot. Later, the axis branches by the formation of new growing-points, and in this way the complex system of axes forming the body of the ordinary vascular plant is built up. In the flowering plants the embryo, after developing up to a certain point, stops growing and rests, enclosed within the *seed*. It is only on "germination" of the latter that the development of the embryo into the free plant is begun. In the Pteridophytes, on the other hand, development from the egg is continuous.

The triple division of tissues is laid down in most cases at a very early period of development—in the flowering plants usually before the resting stage is reached. In many Pteridophytes the first leaf is formed very early, and arising from it, is developed at its base, usually becoming continuous with the cylinder of the root; the strand of the second leaf is formed in a similar way and runs down to join that of the first, so that the stem is formed by the joined bases of the leaf-traces. In other cases, however, a continuous primitive stele is developed, extending from the primary stem to the primary root, the leaf-traces arising later. This is correlated with the comparatively late formation and small development of the first leaves. The evidence scarcely admits of a decision as to which of these methods is to be regarded as primitive in descent.

In the seed-forming plants (Phanerogams) one or more primary leaves (cotyledons) are already formed in the resting embryo. In cases where the development of the embryo is advanced at the resting period, traces run from the cotyledons and determine the symmetry of the stele of the primitive axis, the upper part of which often shows stem-structure, in some respects at least, and is called the hypocotyledonary stem or *hypocotyl*, while the lower part is the primary root.
from the outer sides of these initial cells. In most of the Phanerogams the apical (or primary) meristem, instead of consisting of a single apical cell or a group of initials, is stratified—i.e., it is

the differentiation of leaf-bundles, which typically begins at the base of the leaf and extends upwards into the leaf and downwards into the petiole, is the first development of vascular tissue, and is seen at a higher level than the formation of a stele.

The latter is produced (except in cases of complete atrophy where a cylinder is never formed) after a number of leaf-traces have appeared on the basal sides of the stem so as to form a circle or annulus. In the transverse section, the spaces intervening between adjacent bundles become bridged by small-celled tissue closing the cylinder. In this tissue fresh bundles may become differentiated, and what remains of it becomes the rays of the fully-differentiated leaf-trace.

In many cases exist which are intermediate between the two extreme types described. In these the stele becomes obvious in transverse portion at the same level as that at which the first leaf-traces are developed. Where a large-celled pith is produced, this often becomes obvious very early, and in some cases it appears to have separate initials situated below those of the hollow vascular cylinder.

In some cases there is a primary layer of perimeter at the apex, this is really the young pith, the distinction between the stelar and cortical initials, if it exists, being, as is so often the case, impossible to make out. The young tissue of the stelar cylinder, in the case of the modified siphonostele characteristic of the dicotyledonous stem, differs from the adjoining pith and cortex in its narrow elongated cells, a difference produced by the stopping of transverse and the increased frequency of longitudinal divisions. This separation is quite distinct in the young vascular bundles of the medus (desmogen strands). The protosteum and protophloem are developed in a few cells from the inner and outer margins, respectively, of the desmogen strand, the desmogenic tissue left over giving rise to the outer and inner elements of the bundle. Differentiation of the xylem progresses outward, of the phloem inwards, but the two tissues never meet in the centre. Sometimes development stops altogether, and a layer of undifferentiated parenchyma (the mesoderm) is left between them; or it may continue indefinitely, the central cells keeping pace by their tangential division with the differentiation of tissue on each side. In this case the formation of the primary bundle passes straight over into the formation of secondary tissue by a cumbium, and no line can be drawn between the two processes. The differentiation of the stelar steleum, which usually takes the form of a sclerified pericycle, and may extend to the endodermis and pericycle, takes place about a generation later than the formation of the primary vascular strand. In the very frequent cases where the bundles have considerable individuality, the fibrous 'pericyclic' cap very clearly has a common origin from the radial initials of the vascular cambium.

In such cases it is part of the periderm or sheath of elongated narrow-celled tissue surrounding the individual bundle.

The separation of layers in the apical meristem of the root is usually very much more obvious than in that of the stem. The outermost is the cambyum, which gives rise to the root-cap, and in Dicotyledons to the piliferous layer as well. The periblem, one cell thick at the apex, produces the cortex, to which the piliferous layer belongs, in Monocotyledons; and the periblem is in the Monocotyledons the very outermost layer of the root-cap. In a few cases the boundaries of the different layers are not traceable. The protosteum and the phloem strands are developed alternately, just within the outer limit of the young cylinder. The differentiation of metaxylem follows according to the type of root-stele, and, finally, any stercor there may be is developed. Differentiation is very much more rapid—new layers of tissues are completely formed much nearer to the apex, than is the case in the stem. This is owing to the elongating region (in which protostele and protophloem alone are differentiated) being very much shorter than in the stem. The root-hairs grow out from the cells of the piliferous layer immediately behind the elongating region.

The branches of the stem arise by multiplication of the cells of the epidermis and cortex at a given spot, giving rise to a secondary branch, at the end of which an apical meristem is established. The vascular system is connected in various ways with that of the parent axis by the differentiation of bundle-connexions across the connecting cylinders of the latter. This is known as exogenous branch-formation. In the root, on the other hand, the origin of branches is endogenous. The cells of the pericycle, usually opposite a protostele strand, divide tangentially and give rise to a new growing-point. The new root thus laid down burrows through the cortex of the mother-root and finally emerges into the soil. The connexions of its stelle with that of the parent are made across the pericycle of the latter. In most of the existing Pteridophytes, in the Monocotyledons, and in annual plants among the Dicotyledons, there is no further growth of much structural importance in the tissues after differentiation from the primary meristems. But in nearly all perennial Dicotyledons, in all dicotyledonous and gymnospermous trees and shrubs,

and in fossil Pteridophytes belonging to all the great groups, certain layers of cells remain meristematic among the permanent tissues, or after passing through a resting stage reacquire meristematic properties, and give rise to secondary tissues. Such meristematic layers are called secondary meristems. There are two types of secondary meristem, the cambium and the phellogen.

The formation of secondary tissues is characteristic of all woody plants, to whatever class they belong. Every great group or phylum of vascular plants, when it has become dominant in the vegetation of the world, has produced members with the tree habit arising by the formation of a thick woody trunk, in most cases by the activity of a cambium.

The cambium in the typical case, which is by far the most frequent, continues the primary differentiation of xylem and phloem in the desmognan strand (see above), or arises in the resting stage of a secondary type of tissue, i.e. xylem and phloem to the primary tissues. New tangential walls arise in the cells which are the seat of cambial activity, and an initial layer of cells is established which cuts off tissue mother-cells on the inside and outside, alternately contributing to the xylem and to the phloem. A tissue mother-cell of the xylem may, in the most advanced types of Dicotyledons, give rise to—(1) a tracheid; (2) a segment of a vessel; (3) a xylem-fibre; or (4) a vertical file of xylem-parenchyma cells. In the latter case the mother-cell is divided by a number of horizontal walls. A tissue mother-cell of the phloem may give rise to (1) a segment of a sieve-tube with its companion cells or cells; (2) a phloem-fibre; (3) a single phloem-parenchyma (cambiform) cell, or a vertical file of phloem parenchyma cells. In certain points of the cambium it does not give rise to xylem and phloem elements, but cuts off cells on both sides which elongate radially and divide by horizontal walls; these thus form a given initial cell of the cambium and has once begun to produce cells of this sort it continues the process, so that a radially plate of parenchyma cells is formed stretching in one plane through the xylem and phloem. Such a cell-plate is called a medullary ray.

It is essentially a living tissue, and serves to place all the living cells of the secondary vascular tissues in communication. It conducts plastic substances inwards from the cortex, and its cells are frequently full of starch, which they store in winter. They are accompanied by intercellular channels, or vessels, and by ordinary fibres, which, in the most recent forms of secondary tissue, remain as the last cells, which sometimes replace them altogether. The parenchyma is often arranged in tangential bands between the layers of sieve-tubes and tracheal elements. The xylem parenchyma is often found in strands associated with the tracheal elements. These strands are not isolated, but form a connected network through the wood. The xylem parenchyma cells are connected, and are the mother-cells of the tracheal and other secondary elements. They are always elongated, some one-sided, with pits—i.e. pits with a border on the tracheal element side, and simple on the parenchyma cell side. The fibres are frequently found in tangential bands between similar bands of tracheae or sieve-tubes. These bands are rarely, if ever, found to run parallel, but grow in thickness. The fibres belong to the same morphological category as the parenchyma, various transitions being found between them; thus there may be thin-walled cells of the shape of fibres, and ordinary fibres may be divided into a number of simple cells. These intermediate cells, like the ordinary parenchyma, frequently store starch, and the fibres themselves, though usually dead, sometimes retain their protoplasm, and in that case may also be the seat of starch accumulations. The vessels and tracheae are very various in size, shape and structure in different plants. They are nearly always aggregated in strands, which, like those of the parenchyma, are not isolated, but are connected with one another. In contrast with the tracheae, the vessels are divided by reduced cavities, functioning as mechanical rather than as waterconducting elements. All transections are found between such forms and the vessels. The vessels are connected by intercellular channels, or vessels, forming a transition on superficial view with the true wood-fibres belonging to the parenchymatous system; but their pits are always bordered, though in the extreme type they are reduced to mere slits in the wall. The secondary phloem, like the secondary phloem of tracheal elements, have end-walls bearing a row of sieve-plates; plates also occur on the radial side-walls.

The tissue-elements just described are found only in the more complex plants, and are not always present in the most recent types. A considerable evolution in complexity can be traced in passing from the simplest forms of xylem and phloem found in the primary vascular tissues both among Pteridophytes and Phanerogams to the most complex types. In some cases the xylem has either already become a simple, consisting of tracheids which act as stereos as well as hydrom, and a little amyloidal; while the phloem-parenchyma sometimes undergoes a differentiation, part being developed as amyloidal, part as phloidal cells. In other cases the phloidal cells of the secondary phloem do not form part of the phloem-parenchyma, but occupy the top and bottom cells of the secondary xylem by large bordered pits. These primary vascular tissues of Angiosperms are likewise nearly always simple, consisting merely of tracheae and sieve-tubes often associated with amyloidal. A characteristic peculiarity, both

in the primary and secondary tissue, is that the protoxyl cells of the phloem are here always sister-cells of the leptolots and are known as companion-cells. In the secondary tissues of Dicotyledons we may have, as already described, considerably more differentiation of the cells, all the varieties being referable, however, on the one hand to the tracheal or sieve-tube type, on the other to the parenchymatous type. The main feature is the development of special vascular stelae and storage tissues. In some cases special secretory tissues, resin ducts, oil glands, laticiferous tissue, crystal sacs, may be developed among the ordinary secondary vascular elements.

The limit of each year's increment of secondary wood, in those plants whose yearly activity is interrupted by a regular winter dormancy period, is marked by a more or less distinct line, which is produced by the sharp contrast between the wood formed in the late summer of one year (characterized by the sparseness or small diameter of the tracheal elements, or by the preponderance of fibres, or by a combination of these characters, giving a semitenue to the wood) and the loose spring wood of the next year, with its absence of fibres, or its numerous large tracheae. The abundance of water-conducting channels is in relation to the need for a large and rapid supply of water to the unfolding leaves in the spring and early summer. In Gymnosperms, where vessels and fibres are absent, the late summer wood is composed of radially narrow thick-walled tracheids, the wood of the succeeding spring being wide-walled and thin-walled, so that the limit of the year's growth is very well marked. The older wood of a large tree forming a cylinder in the centre of a trunk frequently of the second middle, or the outer middle. The living elements die, and the walls of all the cells often become hardened, owing to the deposit in them of special substances. Wood thus altered is known as heart-wood, or duramen, as distinguished from the heartwood of the young trunks, or alburnum, which, forming a cylinder next the cambium, remains alive and carries on the active functions of the xylem, particularly the conduction of water. The heart-wood ceases to be of any use to the tree except as a support, but owing to its dryness and hardness it is of much use for industrial purposes. The great hardness of teak is due to the silica deposited in the heart-wood, and the special colouring matters of various woods, such as satinwood, ebony, &c., are confined to the heartwood of the young trunks and not in the outer middle. The living elements die, and the walls of all the cells often become hardened, owing to the deposit in them of special substances. Wood thus altered is known as heart-wood, or duramen, as distinguished from the heartwood of the young trunks, or alburnum, which, forming a cylinder next the cambium, remains alive and carries on the active functions of the xylem, particularly the conduction of water.
In many annual plants no cambium is formed at all, and the same is true of most perennial Pteridophytes and Monocotyledons. This may be due to the fact that the vascular tissue of such plants is an extensive, though not entire, cambial tissue. The bundles of plants which form cambium are, on the contrary, called open. In stems with open bundles the formation of cambium and secondary tissue may be confined to the primary bundles, and the formation of cambium and secondary tissue is said to be entirely fascicular. In this case either very little secondary tissue is formed, as in the gourds, some Ranunculaceae, &c., or a considerable amount may be produced (clematis, barberry, ivy). In the latter event the cells of the primary rays are either merely stretched radially, or they divide to keep pace with the growth of the bundles. If this division occurs by means of a localized secondary meristem connecting the cambial layers of adjacent bundles, an interfascicular cambium is formed, as in the fascicular cambium. The interfascicular cambium may form nothing but parenchymatous tissue, producing merely continuations of the primary rays. Such rays are usually broader and more prominent than the secondary rays formed within the wedges of wood opposite the primary bundles, and are distinguished as principal rays from these narrower subordinate or fascicular rays (fig. 24). This is the typical case in most trees where the primary bundles are close together. Where the primary bundles are farther apart, so that the primary rays are wider, the interfascicular cambium may form several fairly broad (principal) secondary rays in continuation of certain radial bands of the primary ray, and between these, wedges of secondary xylem and phloem; or, finally, secondary xylem and phloem may be formed by the whole circumference of the cambium, fascicular and interfascicular alike, interrupted only by narrow secondary rays, which have no relation to the primary ones.

In a good many cases, sometimes in isolated genera or species, sometimes characteristic of whole families, so-called anomalous cambial layers are formed in the stem, either as an extension of, or addition to, the original cambial cylinder. These are frequently associated with irregularities in the activity of the original cambium. Irregularity of cambium occurs in various families of woody dicotyledonous plants, mostly among the woody climbers, known as lianes, characteristic of tropical and sub-tropical forests. In the simplest cases the cambium produces xylem more freely along certain tracts of the circumference than along others, so that the stem loses its original cylindrical form and becomes elliptical or lobed near the ground. In other cases a secondary cambium ceases to be active around these bays and joins across the outside of the bay, where it resumes its normal activity, thus isolating a phloem strand, or, as it is sometimes called, a phloem island, in the midst of the xylem. The significance of these phenomena, which present many minor modifications in different cases, is not fully understood, but one purpose of the formation of phloem monontories and islands seems to be the protection of the sieve-tubes from crushing by the often considerable peripheral pressure that is exercised on the stems of these lianes. Sometimes the original cambial ring is broken into several arcs, each of which is completed into an independent cambium, so that a number of secondary cambial rings are formed. The formation of additional cambial cylinders or bands occurs in the most various families of Dicotyledons and in some Gymnosperms. They may arise in the pericycle or endocycle in the cortex of the stem or root, either on the cambial layer of the secondary xylem or phloem. The activity of the new cambium is often associated with the stoppage of the original one. Sometimes the activity of the new cambium begins in a single meristem and is followed by the formation of concentric rings or arcs of secondary xylem and phloem. In other cases a most intricate arrangement of secondary tissue masses is produced, quite impossible to interpret unless all stages of the development have been clearly observed. In some cases the whole stem breaks up into separate woody strands, often twisted like the strands of a rope, and running into one another at intervals. An ordinary cambium is scarcely ever found in the Monocotyledons, though a number of varieties in non-tropical woods resemble the primary bundles, and gives rise externally to a little secondary cortex, and internally to a secondary parenchyma in which are developed numerous zones of additional bundles, usually of concentric structure, with phloem surrounded by xylem.

The cambium in the root, which is found generally in those plants which possess a cambium in the stem, always begins in the conjunctive tissue external to the primary phloem, and Cambium (138) cambium in contact with the primary, and secondary xylem internally. In roots which thicken but slightly, whose cambium usually appears late, and where modification or development beyond this is not far the case, cambium begins on both sides, making a broad, secondary (principal) ray, which interrupts the vascular ring and is divided at its inner extremity by the islet of primary xylem; or (b) forms secondary xylem and phloem in the interior of the ray, continuing along the ray, when these, narrow, secondary rays are formed at intervals, just as in the stem. Thus the structure of an old thickened root approximates to that of an old thickened stem, and is similarly as the vascular tissue is formed the primary xylem. Owing to the resistance offered by the hard first-formed secondary xylem, the bays are pushed outwards as growth proceeds, and the wide line becomes a circle. Opposite the primary xylems, the cambium appears on either side of the ray, and on both sides of the secondary (principal), and cambium is formed by the whole circumference of the cambium, fascicular and interfascicular alike, interrupted only by narrow secondary rays, which have no relation to the primary ones.

In nearly all plants which produce secondary vascular tissues, bundles of a cambium are formed along the cambial cylinder, arising externally to, but in quite the same fashion as, the cambium, and producing like the latter an external and an internal secondary tissue. This is the phellogen, and the whole of the tissue it gives rise to is termed the phellem. The phellogen derives its name from the fact that its external product is the characteristic tissue known as cork. This consists typically of close-fitting layers of cells with thickly suberized walls, intended to replace the external protective layer of the plant when the latter, incapable as it is of further growth after its original formation, is broken and cast off by the increase in thickness of the stem through the activity of the cambium. Cork is also formed similarly in the root after the latter has passed through its primary stage as an absorptive organ, and its structure is becoming assimilated to that of the stem. The internal tissue formed by the phellogen is known as phelloderm, and consists usually of ordinary parenchyma. The phellogen may arise, in the first place, in any tissue of the axis external to the actual vascular tissues—i.e. in the epidermis itself (rarely), in any layer of the protoderm, or in the cortex or in the ground tissue, or in the external layer of the cortex immediately below the epidermis; in the root, the pericycle. All the tissues external to the cork are cast off by the plant. The extent of development of the phelloderm is dependent upon whether the phellogen has a superficial or a deep-seated origin. In the former case the formation of phelloderm is trivial in amount; in the latter, considerable, since this tissue has to replace the cast-off cortex, as a metabolic and protective tissue.
PLANTS

The phellogens are replaced by successive new phellogenic layers of deeper and deeper origin, each forming its own layer of cork. Eventually the new phellogen is at the level of the secondary phloem, and are formed in the parenchyma of the latter, keeping pace in their inward march with the formation of fresh secondary phloem by the cambium. The complex system of dead and dying tissues cut off by these successive phellogen, together with the latter themselves—in fact, everything outside the innermost phellogen, constitutes what is often known botanically as the bark of the tree. Rhytidome is, however, a preferable term, as the word bark has long been established in popular usage to mean all the tissue that can easily be peeled off—i.e., everything down to the wood of the tree. The rough surface of the bark of many trees is due to the successive phellogen not arising in regular concentric zones, but forming in arcs which throughout the year and from the root to the top of the tree, special “wound-cork” is also often formed round accidental injuries so as to prevent the rotting of the tissues by the soaking in of rain and the entrance of fungal spores and bacteria. A peculiar modification of periderm is formed by the phellogen in the submerged organs (roots or stems) of many aquatic or marsh-loving plants. This may take various forms and may cover the whole of the organ or be localized in special regions; but its cells are always living and are separated by very large intercellular spaces containing air. This tissue is called pneumatodens, on the roots of certain trees living in marshy places, which rise above the soil in order to obtain air.

History and Bibliography.—The study of plant anatomy was begun in the middle of the seventeenth century as a direct result of the construction of microscopes, with which a clear view of the structure of plant tissues could be obtained. The Englishman Sweere and the Italian Malpighi almost simultaneously published illustrated works on the subject, in which they described, for the most part very accurately, what they saw with the new instruments. The subject was practically dormant for nearly a century and a half, largely owing to the dominance of classifieric botany under the influence of Linnaeus. It was revived by several German workers, prominent among whom were Treviranus and Link, and later Moldenhawer, as well as by the Frenchmen Mirbel, at the beginning of the 19th century. The new work largely centred round a discussion of the nature and origin of vessels, conspicuous features in young plant tissues which thus acquired an importance in the contemporary literature out of proportion to their real significance in the construction of the vascular plant. The whole of the writings of this time are dominated by a preoccupation with the functions of the different tissues, in itself an excellent standpoint for investigation, but frequently leading in the case of these early investigators to one-sided and distorted views of the facts of structure. The pioneer of modern plant anatomy was Hugo von Mohl (fl. 1830), who carefully investigated and described the facts of anatomical structure without attempting to fit them into preconceived views of their meaning. He produced a solid body of accurately described facts which has formed the secure groundwork of subsequent advance. From Mohl down to the eighth decade of the century the study of anatomy was entirely in the hands of a group of German investigators, prominent among whom were several of the most eminent founders of modern scientific botany—such, for instance, as Nigeli, Ranke and De Bary. To the first we owe the secure foundation of our knowledge of the structure and course of the vascular strands of the higher plants ("Ueber den Bau und die Anordnung der Gefässbündel bei den Stamm und Wurzel der Phanerogamen," Beiträge zur wissenschaftlichen Botanik, Heft i., Leipzig, 1859); to the second the establishment of the sound morphological doctrine of the central cylinder of the axis as the starting-point for the consideration of the general arrangement of the tissues, and the first clear distinction between primary and secondary tissues (Botanische Zeitung, 1861 and 1863); to the last the putting together of the facts of plant anatomy known up to the middle of the eighth decade of the century into that great encyclopaedia of plant anatomy, the Vergleichende Anatomie der Pflanzen (Stuttgart, 1876; Eng. trans., Comparative Anatomy of the Vegetative Organs of the Phanerogams and Ferns, Oxford, 1882). In 1870-1871 Van Tieghem published his great work, "Sur la Racine," Ann. sci. nat. bot. (Paris). This was not only in itself an important contribution to plant anatomy, but served as the starting-point of a series of researches by Van Tieghem and his pupils, which has considerably advanced our knowledge of the details of histology, and also culminated in the foundation of the doctrine of the stele (Van Tieghem and Douliot, "Sur la polystélie," Ann. sci. nat. bot., 1881). Van Tieghem, Traité de botanique (and ed. Paris, 1880-1881). This has had a most important effect on the development in recent years of morphological anatomy.

In the progress of the last three decades, since the publication of De Bary's great work, five or six main lines of advance can be distinguished. First, the knowledge of the details of histology has of course advanced greatly in the direction through the ceaseless activity of very numerous, mainly German, workers, though no fundamentally new types of tissue have been discovered. Secondly, the histology of fossil plants, particularly woody plants of the Carboniferous period, has been placed on a sound basis, assimilated with general histological doctrine, and has considerably enlarged our conceptions of plant anatomy as a whole, though again without revealing any entirely new types of structure. This branch of the subject, founded by Corda, Göppert, Stenzel and others in Germany, was enormously advanced by Williamson's work on the Coal Measures plants, recorded in the magnificent series of memoirs, "Researches on the Organization of Fossil Plants of the Coal Measures" (Phil. Trans. Roy. Soc., vols. i.-xix., 1871-1903). The work of Solms-Laubach in Germany, Renault and Bertrand in France, and in recent years of Zeller in France, and Scott, Seward and others in England, has greatly enlarged our conceptions of the anatomy of fossil plants in an important degree. While convincing us that the plants of past ages in the earth's history were exposed to very similar conditions of life, and made very much the same adaptive responses as their modern representatives, one of the main results of this line of work has been to reveal important data enabling us to fill various gaps in our morphological knowledge and to obtain a more complete picture of the evolution of tissues in the vascular plants. One of the most striking incidents in the progress has been the recognition within the last few years of the existence of an extinct group of plants lying on the borderland between Filicales and Gymnophylla and known as the Cycadofilicales, a group in which, curiously enough, the reproductive organs remained undiscovered for some time after the anatomy of the vegetative organs was sufficiently well known to afford clear evidence of their true affinities. Thirdly, we have to record very considerable
progress in our knowledge of distinctively morphological anatomy, i.e. the study of tissues from the standpoint of evolution. The Russian plant-anatomist, Russow, may be said to have founded the consideration of plant tissues from the point of view of descent (Vergleichende Untersuchungen über die Leitungsbahnen der Pflanzen, St Petersburg, 1872; and Betrachtungen über Leitungsbündel und Grundgewebe, Dorpat, 1873). He was ably followed by Strasburger (Über den Bau und die Leitungsbahnen der Pflanzen, Jena, 1891), Haberlandt and others. The explicit adoption of this point of view has had the effect of clearing up and rendering definite the older morphological doctrines, which for the most part had no fixed criterion by which they could be tested.

Since about 1893 this branch has been most actively pursued in England, where the work of Boodle and of Gwynne-Vaughan (especially on Ferns) has been the most important, leading to a coherent theory of the evolution of the vascular system in these plants (Tansey, Evolution of the Ptilicinaceae Vascular System, Cambridge, 1908); and in America, where Jeffrey has published important papers on the morphology of the vascular tissues of the various groups of Pteridophytes and Phanerogams and has sought to express his conclusions in a general morphological theory with appropriate terminology. As a result of this activity Van Tieghem's so-called "Stellar theory" has been revised and modified in the light of more extended and detailed anatomical and developmental knowledge. Schoute's Die Stelár-Theorie (Grüningen, 1902), gives an important critical account of this subject.

Fourthly, attention must be called to the great development of what is called "Systematic Anatomy," i.e. the study of the anatomical features characteristic of the smaller groups of flowering plants, i.e. the orders, families, genera and species. Radlkoffer (1883) was the first to call attention to the great importance of this method in systematic botany; as providing fresh characters on which to base a natural classification. Solereder's great work, Systematische Anatomie der Dicotyledonen (Stuttgart, 1898-1908; Eng. trans., Systematic Anatomy of Dicotyledons, Oxford, 1908), brings together so many of the facts as are at present known in an orderly arrangement. Theoretically this branch of the subject should connect with and form the completion of "morphological anatomy," but the field has not yet been sufficiently explored to allow of the necessary synthesis. The true relation of "systematic" to "ecological" anatomy (see below) also awaits proper elucidation.

Fifthly, we have to record the foundation of the modern study of "physiological anatomy" (i.e. the study of the specific functions of the various tissues) by Schwendener (Das mechanische Prinzip in den Monocotylen, 1874, and other works), followed by numerous pupils and others, among whom Haberlandt (Physiologische Pflanzen-Anatomie, Leipzig, 1st ed., 1884, 4th ed., 1909, and other works) is pre-eminent. The pursuit of this study has not only thrown valuable light on the economy of the plant as a whole, but forms an indispensable condition of the advance of morphological anatomy. A great deal of work still remains to be done in this department, which at the present time affords one of the most promising fields of anatomical investigation.

Finally we may mention "ecological anatomy," i.e. the study of anatomical features directly related to the habitat. A very considerable body of knowledge relating to this subject already exists, but further work on experimental lines is urgently required to enable us to understand the actual economy of plants growing under different conditions of life and the true relation of the hereditary anatomical characters which form the subject matter of "systematic anatomy" to those which vary according to the conditions in which the individual plant is placed. On these lines the future of anatomical study presents almost inexhaustible possibilities. (A. G. T.)

**Physiology of Plants**

The so-called vegetable physiology of a generation ago was in arrear of animal, and particularly of human, physiology, the study of the latter being followed by many more observers, and from its relative degree of advancement being the more capable of rapid development. It was fully recognized by its followers that the dominating influence in the structure and working of the body was the protoplasm, and the division of labour which it exhibited, with the accompanying or resulting differentiation into various tissues, was the special subject of investigation. Many who followed the study of vegetable structure did not at that time give an equal prominence to this view. The early histological researches of botanists led them to the recognition of the vegetable cell, and the leading writers in the middle of the 19th century pointed out the probable identity of Von Mohl's "protoplasm" with the "sarcodé" of zoologists. They laid great stress on the nitrogenous nature of protoplasm, and noted that it preceded the formation of the cell-membrane. But by the ordinary student of thirty years later their work was to some extent overlooked, and the cell-wall assumed a prominence to which it was not entitled. The study of the differentiation of protoplasm was at that time seldom undertaken, and no particular attention was paid either to fixing it, to enable staining methods to be accurately applied to it, or to studying the action of chemical reagents upon it. It is only comparatively recently that the anatomical study of this investigation used by animal physiologists have been carefully and systematically applied to the study of the vegetable organisms. They have, however, been attended with wonderful results, and have revolutionized the whole study of vegetable structure. They have emphasized the statements of Von Mohl, Cohn, and other writers alluded to, that the protoplasm is here also the dominant factor of the body, and that all the peculiarities of the cell-wall can only be interpreted in the light of the needs of the living substance.

The Nature of the Organisation of the Plant, and the Relations of the Cell-Membrane and the Protoplasm.—This view of the study of the plant as that which possesses it, it is the nature of investigation lead us to a greatly modified conception of its organization, and afford more completely an explanation of the peculiarities of form found in the vegetable kingdom.

The study of simple organisms, many of which consist of nothing but a little mass of protoplasm, exhibiting a very rudimentary degree of differentiation, so far as our methods enable us to determine any at all, shows that the duties of existence can be discharged in the absence of any cell-wall. Those organisms which possess the latter are a little higher in the scale of life than those which remain uncoated by it, but a comparison of the behaviour of the two quickly enables us to say that the membrane is of but secondary importance, and that for those which possess it, it is not at all an exec-utive covering for the living substance. Its physical properties, permeability by water, extensibility and elasticity, receive their interpretation in the needs of the latter. We come, accordingly, to regard it as practically an exoskeleton, and its functions as distinctly subordinate to those of the protoplasm which it clothes. If we pass a little higher up the scale of life we meet with forms consisting of two or more cells, each of which contains a similar minute mass of living substance. A study of them shows that each is practically independent of the others; in fact, the connexion between them is so slight that they can separate and each become free without the slightest disadvantage to another. So long as they are connected together mechanically they have apparently the power of influencing one another in various ways, and of passing liquid or gaseous materials from one to another. The conjoined organism is, in fact, a colony or association of the protoplasmic units, though each unit retains its independence. When we pass, again, from these to examine more bulky, and consequently more complex, plants, we find that the differences which can be observed between them and the simple lowly forms are capable of being referred to the increased number of the protoplasmic units and the consequent enlarged bulk of the mass or colony. Every plant is thus found to be composed of a number of these protoplasmic units, or, as they may preferably be termed,
protoplasts, all of which are at first exactly alike in appearance and in properties. This is evident in the case of such plants as have a body consisting of filaments or plates of cells, and is little less conspicuous in those whose mass is but small, though the cells are evidently capable of computation in three dimensions. It does not appear to be the same with the bulkier plants, such as the ordinary green weeds, for although they can be dissected, but a study of their earlier development indicates that they do not at the outset differ in any way from the simple undifferentiated forms. Each commences its existence as a simple naked protoplast, in the embryo-sac or the archegonium, as the case may be. After the furious fusion with another similar protoplast, which constitutes what we call fertilization, the next stage in complexity already noted may be observed, the protoplasm becoming clothed by a cell-membrane. Very soon the single cell gives rise to a chain of cells, and this in turn to a cell mass, the individual units of which are at first quite uniform. With increase of number, however, and consequently enlargement of bulk in the colony, differentiation becomes compulsory. The requirements of the several protoplasts must be met by supplies from without, and, as many of them are deep seated, varieties of need arise, so that various members of the colony are set apart for special duties, masses of them being devoted to the discharge of one function, others to that of another, and so on. Such limitations of the powers and properties of the individuals have for their object the well-being of the community of which those individuals are constituents.

**Physiological and Morphological Differentiation.**—The first indication of this differentiation in the vegetative body of the plant can be seen not only in the terrestrial green plants which have been particularly referred to, but also in the bulkier seaweeds. It is an extension of the first differentiation which was observable in the simple protoplasts first discussed, the formation, that is, of a protective covering. *Fucus* and its allies, which form conspicuous members of the larger Algae, have their external cells much smaller, more closely put together, and generally much denser than the rest of their tissue. In the lowly as well as the higher green plants we have evidence of specialization of the external protoplasts for the same purpose, which takes various shapes and shows different degrees of completeness, culminating in the elaborate barks which clothe our forest trees.

The second prominent differentiation which presents itself takes the form of a provision to supply the living substance with water. This is a primal necessity of the protoplast, and every cell gives evidence of its need by adopting one of the various ways in which such need is supplied. What little differentiation can be found to exist in the protoplasm of the simple unicellular organism shows the importance of an adequate water-supply, and indeed, the dependence of life upon it. The naked cells which have been alluded to live in water, and call therefore for no differentiation in connexion with this necessity; but those which are surrounded by a cell-wall always develop within themselves a vacuole or cavity which occupies the greater part of their interior, and the hydrostatic pressure of whose contents keeps the protoplasm in contact with the membrane, setting up a condition of turgidity.

The need for a constant supply of water is partly based upon the constitution of protoplasm, so far as we know it. The apparently structureless substance is saturated with it; and if once a cell is completely dried, even at a low temperature, in the enormous majority of cases its life is gone and the restoration of water fails to enable it to recover. Besides this intimate relationship, however, we can point to other features of the necessity for a constantly renewed water supply. The protoplasm derives its food from substances in solution in the water; the various waste products which are incident to its life are excreted into it, and so removed from the sphere of its activity. The raw materials from which the food is constructed are absorbed from the exterior in solution in water, and the latter is the medium through which the gaseous constituents necessary for life reach the protoplasm. Moreover, growth is essentially dependent upon water-supply. There is little wonder, then, that in a colony of protoplasts such as constitute a large plant a considerable degree of differentiation is evident, bearing upon the question of water supply. Certain cells of the exterior are set apart for absorption of water from the soil, this being the source from which supplies are derived. Others are devoted to the purpose of conveying it to the protoplasts situated in the interior and at the extremities of the plant, a conducting system of considerable complexity being the result.

Other collections of cells are in many cases set apart for giving rigidity and strength to the mass of the plant. It is evident that as the latter increases in bulk, more and more attention must be paid to the dangers of uprooting by winds and storms. Various mechanisms have been adopted in different cases, some connected with the subterranean and others with the sub-aerial portions of the plant. Another kind of differentiation in such a cell-mass as we are dealing with is the setting apart of particular groups of cells for various metabolic purposes. We have already the formation of numerous mechanisms which have arisen in connexion with the question of food supply, which may not only involve particular cells, but also lead to differentiation in the protoplasm of those cells, as in the development of the chloroplastids of the leaves and other green parts.

The inter-relations of the members of a large colony of protoplasts such as constitute a tree, demand much adjustment. Relations with the exterior are continually changing, and the needs of different regions of the interior are continually varying, from time to time. Two features which are essentially protoplasmic assume a great importance when we consider these relations. They are the power of receiving impressions or stimuli from the exterior, and of communicating with each other, with the view of co-ordinating a suitable response. We have nothing structural which corresponds to the former of these. In this matter, differentiation has proceeded very differently in animals and plants respectively, no nerves or sense organs being structurally recognizable. Communication between the various protoplasts of the colony is, however, carried on by means of fine protoplasmic threads, which are continuous through the cell-walls.

All the peculiarities of structure which we encounter consequently support the view with which we started, that the protoplast itself is the dominant factor in vegetable structure, and that there need be but one subject of physiology, which must embrace the behaviour of protoplasm wherever found. There can be no doubt that there is no fundamental difference between the living substance of animals and plants, for many forms exist which cannot be referred with certainty to either kingdom. Free-swimming organisms without cell-membranes exist in both, and from them series of forms can be traced in both directions. Cellulose, the material of which vegetable cell-walls are almost universally composed, at any rate in their early condition, is known to occur, though only seldom, among animal organisms. Such forms as *Volvox* and the group of the *Myxomycetes* have been continually referred to both kingdoms, and their true systematic position is still a subject of controversy. All physiology, consequently, must be based upon the identity of the protoplasm of all living beings.

This method of study has to a large extent modified our ideas of the relative importance of the parts of such an organism as a large tree. The interest with which we regard the latter no longer turns upon the details of the structure of its trunk, limbs and roots, to which the living substance of the more superficial parts was subordinated. Instead of regarding these as only ministering to the construction of the bulky portions, the living protoplasts are taken as the essential portion of the tree, and all the other features are important mainly as ministering to their individual well-being and to their multiplication. The latter feature is the growth of the tree, the well-being of the protoplasts is its *life* and *health*. The interest passes from the bulky dense interior, with the elaborate features of its cell-walls, to the superficial parts, where its life is in evidence. We see herein the reason for the great subdivision of the body, with its
PLANTS

Physiology

Finely cut twigs and their ultimate expansions, the leaves, and we recognize that this subdivision is only an expression of the need to place the living substance in direct relationship with the environment. The formation and gradually increasing thickness of its bark are explained by the continually increasing need of adequate protection to the living cortex, under the strain of the increasing frame by which the enormous multiplication of its living protoplasts demands, and the development of which leads to continual rupture of the exterior. The increasing development of the wood as the tree grows older is largely due to the demands for the conduction of water and mineral matters dissolved in it, which are made by the increased number of leaves which from year to year it bears, and which must each be put into communication with the central mass by the formation of new vascular bundles. Similar considerations apply to the peculiar features of the root-system. All these points of structure can only be correctly interpreted after a consideration of the needs of the individual protoplasts, and of the large colony of which they are members.

Gaseous Interchanges and their Mechanism.—Another feature of the construction of the plant has in recent years come into greater prominence than was formerly the case. The organism is largely dependent for its vital processes upon gaseous interchanges. It must receive a large constituent of what ultimately becomes its food from the air which surrounds it, and it must also take in from the same source the oxygen of its respiratory processes. On the other hand, the aerial environment presents considerable danger to the young and tender parts, where the protoplasts are most exposed to extremes of heat, cold, wet, &c. These must in some way be harmonized. No doubt the primary object of the cell-wall of even the humblest protoplasm is protection, and this too is the meaning of the coarser tegumentary structures of a bulkier plant. These vary considerably in completeness with its age; in its younger parts the outer cells wall undergoes the change known as cuticularisation, the material being changed both in chemical composition and in physical properties. The corky layers which take so prominent a share in the formation of the bark are similarly modified and subserve the same purpose. But these protective layers are in the main impermeable by gases and by either liquid or vapour, and prevent the access of either to the protoplasts which need them. Investigations carried out by Brown and Escombe, and by Brown and Boussingault, have shown clearly that the view put forward by Boussingault, that such absorption of gases takes place through the cuticular covering of the younger parts of the plant, is erroneous and can no longer be supported. The difficulty is solved by the provision of a complete system of minute intercellular spaces which form a continuous series of delicate canals between the cells, extending throughout the whole substance of the plant. Every protoplasm, except in the very young regions, has part of its surface abutting on these, so that its wall is accessible to the gases necessary for its vital processes. There is no need for cuticularization here, as the external dangerous influences do not reach the interior, and the processes of absorption which Boussingault attributed to the external cuticularized cells can take place freely through the delicate cell-walls of the interior, saturated as these are with water. This system of channels is in communication with the outer atmosphere through numerous small apertures, known as stomata, which are abundant upon the leaves and young twigs, and gaseous interchange between the plant and the air is by their assistance rendered constant and safe. This system of intercellular spaces, extending throughout the plant, constitutes a reservoir, charged with an atmosphere of different composition from that of the external air. Its gaseous constituents varying from time to time and from place to place, in consequence of the interchanges between itself and the protoplasts. It constitutes practically the external environment of the protoplasts, though it is ramifying through the interior of the plant.

The importance of this provision in the case of aquatic vascular plants of sturdy bulk is even greater than in that of terrestrial organisms, as their environment offers considerable obstacles to the renewal of the air in their interior. They are without stomata on their submerged portions, and the entry of gases can only take place by diffusion from the water through their external cells, which are not cuticularized. Those which are only partially submerged bear stomata on their exposed portions, so that their environment approximates towards that of a terrestrial plant, but the access to the water being less easy and complete, so that they need a much larger reservoir of air in their interior. This is secured by the development of much larger intercellular spaces, amounting to lacunae or passages of very considerable size, which are found ramifying in different ways in their interior.

Transpiration.—In the case of terrestrial plants, the continual renewal of the water contained in the vacuoles of the protoplasts demands a copious and continuous evaporation. This serves a double purpose, bringing up from the soil continually a supply of the soluble mineral matters necessary for their metabolic processes, which only enter the plant in solutions of extreme dilution, and at the same time keeping the plant cool by the process of evaporation. The latter function has been found to be of extreme importance in the case of plants exposed to the direct access of the sun's rays, the heat of which would rapidly cause the death of the protoplasts were it not employed in the evaporation of the water. Brown and Escombe have shown that the amount of solar energy taken up by a green leaf may often be fifty times as much as it can utilize in the constructive processes of which it is the seat. If the heat were allowed to accumulate in the leaf unchecked, they have computed that its temperature would rise during bright sunshine at the rate of more than 10° C. per minute, with of course very rapid fatal results. What is not used in the constructive processes is employed in the evaporation of the water, the leaf being thus kept cool. Whether the leaf is brightly or only moderately illuminated, the same relative proportions of the total energy absorbed are devoted to the purposes of composition and construction respectively. This large evaporation, which constitutes the so-called transpiration of plants, takes place not into the external air but into this same intercellular space system, being possible only through the delicate cell-walls upon which it abuts, as the external coating, whether bark, cork or cuticle, is impermeable by watery vapour. The latter ultimately reaches the external air by diffusion. Hence the rate of transpiration varies in proportion as the amount of water in the epidermal cells becomes greater or less.

Mechanism and Function of Stomata.—It is not quite exact to speak of either the gaseous interchanges or the transpiration as taking place through the stomata. The entry of gases into, and exit from, the cells, as well as the actual exhalation of watery vapour from the latter, take place in the intercellular space system of which the stomata are the outlets. The opening and closing of the stomata is the result of variation in the turgidity of their guard cells, which is immediately affected by the condition of turgidity of the cells of the epidermis contiguous to them. The amount of watery vapour in the air passing through a stoma has no effect upon it, as the surfaces of the guard cells abutting on the air chamber are strongly cuticularized, and therefore impermeable. The only way in which their turgidity is modified is by the entry of water into them from the contiguous cells of the general epidermis and its subsequent withdrawal through the same channel. This opening and closing of the stomata must be looked upon as having a direct bearing only on the emission of watery vapour. There is a distinct advantage in the regulation of this escape, and the mechanism is directly connected with the greater or smaller quantity of water in the epidermal cells. The opening of these apertures by gases entering the internal reservoirs is not disadvantageous to the gaseous interchanges—indeed it may be directly the reverse. It may lead to an incipient asphyxiation, as the supply of oxygen may be greatly interfered with and the escape of carbon dioxide may be almost stopped. It may at other times lead to great difficulties in the supply of the gaseous constituents which are used in the
manufacture of food. The importance of transpiration, is, however, so great, that these risks must be run.

The Ascend of Water in Trees.—The supply of water to the peripheral protoplasts of a tree is consequently of the first importance. The means by which water is supplied is that by means of a system of ducts, known as the stele, running in the stele of the root, the vessels of the wood of which are sometimes filled with water, but at other times contain air, and this often under a pressure less than the ordinary atmospheric pressure. This pressure of the turgid cortex on the central stele is known as root pressure, and is of considerable amount. This pressure leads to the filling of the vessels of the wood of both root and stem in the earl part of the year, before the leaves have expanded, and gives rise to the exudation of fluid known as bleeding when young stems are cut in early spring.

Root pressure is one of the forces co-operating in the forcing of the water upwards. The evaporation which is associated with transpiration is another, and perhaps the most insistent of the forces. It is insufficient to explain the process of lifting water to the top of tall trees. There is at present also a want of agreement among botanists as to the path which the water takes in the structural elements of the tree, two views being held. The older is that the water travels in the woody cell-walls of the vascular bundles, mainly under the action of the forces of root pressure and transpiration, and that the cavities of the vessels contain only air. The other is that the vessels are not empty, but that the water travels in their cavities, which contain columns of water in the course of which are large bubbles of air. On this view the water flows upwards under the influence of variations of pressure and tension in the vessels. These forces however fail to furnish a complete explanation of the ascent of the current, and others have been thought to supplement them, which have more or less weight. Westermaier and Godlewski put forward the view that the living cells of the medullary rays of the wood, by a species of osmosis, act as a kind of pumping apparatus, by the aid of which the water is lifted to the top of the tree, a series of pumping-stations being formed. Though this at first met with some acceptance, Strasburger showed that the action goes on in great lengths of stem the cells of which have been killed by poison or by the action of heat. More recently, Dixon and Joly in Dublin and Askenasy in Germany have suggested the action of another force. They have shown that columns of water of very small diameter resist tensile strain that they can be lifted bodily instead of flowing along the channel. They suggest that the forces causing the movement are complex, and draw particular attention to the pull upwards in consequence of disturbances in the leaves. In these we have (1) the evaporation from the damp delicate cell-walls into the intercellular spaces; (2) the imbition by the cell-wall of water from the vacuole; (3) osmotic action, consequent upon the subsequent increased concentration of the cell sap, drawing water from the wood cells or vessels which abut upon the leaf parenchyma. They do not, of course, deny the co-operation of the other forces which have been suggested, except so far as these are incompetent to explain what is seen in the separate columns rather than a flowing stream. This view requires the existence of certain anatomical arrangements to secure the existence of these columns, and cannot be said to be fully established.

Nature of the Food of Plants.—The recognition of the fundamental identity of the living substance in animals and plants has directed attention to the manner in which plants are nourished, and especially to the exact nature of their food. The idea was till recently currently accepted, that anything which plants absorbed from without, and which went to build up their organic substance, or to supply them with materials for excreta, or to enable them to live, was food. The theory known as assimilation, which, in its classical form, was brought forward by Strasburger, was that all the carbon, which these plants absorbed in the form of carbon dioxide, but draw elaborated products from the bodies of their hosts. Those Fungi which are saprophytic can only live upon organic substances which they obtain by breaking them down. They derive from decomposing animal or vegetable matter. Even in the higher flowering plants, in which the processes of the absorption of substances from the environment has been most fully studied, it is found that the substance in the stem and root is, in the main, very closely to those of the group last mentioned. When the young sporophyte first begins its independent life,—when, that is, it exists in the form of the embryo in the seed,—its living substance has no power of utilizing the simple inorganic compounds of carbon dioxide, but it does the same by breaking them down. The nutritive palbum is supplied to it in the shape of certain complex organic substances which have been stored in some part or other of the parent plant from which it springs. When the tuber of a potato begins to germinate the shoots which it puts out derive their food from the accumulated store of nutritive material which has beed laid up in the tubers in the young plant. When the tuber is cut in two, and a young root or twig, we find that the cells in the which the substances, the protoplasm, of the plant is being formed and increased, are not supplied with carbon dioxide and mineral matter, but with substances elaborated material as sugar and proteid substances, or others closely allied to them.

Identity of the Food of Animals and Plants.—It is evidently to the acid tastes of consumption of food, and of consequent nutrition and increase of living matter, that we, when thinking of the problem, must inquire what are the nutrient material of plants. If we go back to the first instance cited, the embryo in the seed and its development, we find what is necessary for its nutrition by inquiring what are the materials which are deposited in the seed, and which become exhausted by consumption as growth and development proceed. We find them to consist of representatives of the three chief classes of food, the animal, vegetable, and mineral, and whose presence renders seeds such valuable material food for animal consumption. They are mainly carbohydrates such as starch and sugar, proteid in the form of globulins or albumins, and in many cases, oils, which latter substances the other bodies of similar nutritive value are less widely distributed.

The differences between the nutritive processes of the animal and the plant are not therefore fundamental, as the are properly held to be. The general vegetable protoplasm has not the capacity of being nourished by inorganic substances which are denied to the living substance of the animal world. Differences connected with the supply of nutritive material of food between the protoplasm of the animal and plant are not correlated with the structure of the organisms, which makes the method of absorption different. The cell-walls of plants render the entry of solid material into the organism impossible. The food which they contain, as soluble foodstuffs, and which are stationary habit of plants, and the almost total absence of locomotion, makes it impossible for them to seek their food.

The Special Apparatus of Plants for constructing Food.—The essence of the difference of the two classes of organisms is very simple. Plants are furnished with a constructive mechanism by which they are enabled to fabricate the food on which they live from the inorganic, gaseous and liquid matters which they absorb. The fact that such absorption does not render these substances food; they are taken in as food, but as raw materials to be subjected to the action of this constructive mechanism, and by it to be converted into substances that can nourish protoplasm, both vegetable and animal. It is sometimes forgotten, when discussing questions of animal nutrition, that all the food materials of all living organisms are prepared originally from inorganic substances in exactly the same way as it is prepared by the plant. It is the chlorophyll apparatus of the vegetable kingdom. A consideration of these facts emphasizes still more fully the view with which we set out, that all living substance is fundamentally the same, though differentiated both anatomically and physiologically in many directions and in different degrees. All is nourished alike on materials originally prepared by a mechanism attached to the higher vegetable kingdom, and dissolved from the products of the photosynthesis of the leaves of the flower, and of the cortex of the young twigs and petioles. Usually
they are absent from the cells of the epidermis, though in some of the lower plants they are met with there also. The plastids are not rich in starch; the chloroplasts consist of two distinct layers, the outer one being a more or less homogeneous layer of gelatinous pigment, leaving the plastid colourless. Chlorophyll is not soluble in water, nor in acids or alkalies without decomposition.

Physiology of plants is of the necessity of manufacturing carbohydrates from the carbon dioxide which the air contains, and which is absorbed from it after it has entered the intercellular passages and has reached the cells containing the plastids. This process is only carried out under the influence of light, preferably moderate sunlight. The reason for the distribution of the chloroplasts described above is consequently seen. The relation of the chlorophyll to light has been studied by many observers. If a solution of chlorophyll is placed in the path of beam of light which is then allowed to fall on a prism, the resulting spectrum will be found to be modified. Instead of presenting the appearance of a continuous band in which all the colours are represented, it is interrupted by seven vertical dark spaces. The pigments which are absent from the solution of chlorophyll would have occupied those spaces have no power to pass through it, or in other words chlorophyll absorbs those particular rays of light which are missing.

The absorption of these rays implies that the pigment absorbs radiant energy from the sun, and gives us some explanation of its power of constructing the carbohydrates which has been mentioned and which is the apparent function of photosynthesis. It is still not completely understood at present, nor can we say exactly what is the part played by the pigment and what is the role of the protoplasm of the plastid. It is not certain either whether the action of the chlorophyll apparatus is the conversion of carbon dioxide into carbohydrates or whether it is concerned, and if so how far, with the construction of proteids also.

As the action of the chlorophyll apparatus is directly dependent upon light, the chief result of its activity is the building up of complex compounds, it has become usual to speak of the processes it sets up under the name of photosynthesis.

The presence of light and when the plant is subjected to a suitable temperature, photosynthesis commences provided that the plant has access to air containing its normal amount of carbon dioxide, about 3 parts, or rather less, in 10,000. The plant and the inter-action of the two is immediately obvious, also, the necessity of chlorophyll. It has been suggested that the course of events is as follows: the carbon dioxide is decomposed into carbon monoxide and water, while water is simultaneously split up into hydrogen and oxygen; the hydrogen and carbon monoxide then unite to form formaldehyde and the oxygen is exhaled. This explanation is unsatisfactory from many points of view, but till quite recently no acceptable alternative has been advanced. Recent evidence that in the presence of sunlight, carbohydrate is produced, indeed there are strong reasons for disbelieving in its occurrence. The formation of formaldehyde has till recently not been satisfactorily proved, though it has been obtained from certain low plants under certain conditions, and certainly it is not required as one of the ingredients of forming nutritive carbohydrates in darkness, when supplied with a compound of this body with sodium-hydrogen-sulphite. But it is certain that it can only be present in a cell in very small amount at certain moment, for an extremely dilute solution acts as a poison to protoplasm. If formed, as it probably is, it is immediately changed into some more complex combination, and so rendered incapable of exerting its poisonous action.

Bayer's hypothesis was entertained by botanists partly because it explained the gaseous interchanges accompanying photosynthesis. These show that a definite intake of carbon dioxide is always accompanied by an evolution of oxygen.

Recent investigations have confirmed Bayer's view of the formation of formaldehyde, but a different explanation has been recently advanced. The first chemical change suggested is an interaction between the carbonised water and chlorophyll, which leads to the simultaneous formation of formaldehyde and hydrogen peroxide. These reactions are not immediately obvious, for the formaldehyde at once undergoes a process of condensation or polymerization by the proto- plasm, and combines with the hydrogen peroxide to form water and free oxygen by another agency in the cell, of the nature of one of the enzymes of which we shall speak later on.

Polymerization of the aldehyde was also a feature of Bayer's hypothesis, so that this view does not very materially differ from those he advanced. More emphasis is, however, now laid on the action of the protoplasm in the polymerization, while the initial stages are still not definitely explained.

The steps which lead from the appearance of formaldehyde to that of the first well-defined carbohydrate are again matters of speculation. Some empirical law of polymerization, while the simpler composition than a sugar has so far been detected. Nor is the nature of the first formed sugar certain; the general opinion has been that it is a simple hexose such as glucose or fructose, but recent research, especially that of Baeyer and of Karrer, has led to the view that sugar is a polysaccharide. If this is true, then the first carbohydrate synthesized, and that the hexose found in the plant result from the decomposition of a more complex carbohydrate which is not only existing in the plant—therelations and several functions—requires renewed investigation.

The first visible carbohydrate formed, one which appears so rapidly in the plant, is the cellulose. This carbohydrate is a part of the cell-wall, and which cellulose is regarded as the first evidence of the setting up of the process, is starch. This is met with in the form of small granular specks in the substance of the chloroplast, specks which assume a blue colour under the influence of iodine. The carbohydrates as a whole are known as starch, as soon as the apparatus became active, led to the opinion formerly held, that the work of the latter was complete only when the starch was formed. We have seen that the starch is preceded by the formation of sugar, and it seems that the sugars are not the product of surplus manufacture. As much sugar as is produced in excess of the immediate requirements of the cell is converted into the carbohydrate, the cellulose, which is the chief constituent of the chlorophyll apparatus, and is so withdrawn from the sphere of action, thereby enabling the construction of further quantities of sugar to take place. The presence of too much sugar in solution in the sap of the cell inhibits the activity of the chloroplasts; hence the necessity for its removal. Starch, indeed, wherever it appears in the plant seems to be a reserve store of carbohydrate material, deposited where it is found for longer or shorter periods till it is needed for consumption. The energy of the plant is so frequently associated with its conversion into sugar fits it especially to be a reserve or stored material.

Proteid Formation.—We have seen that it has been suggested that the chlorophyll apparatus may perhaps be concerned in the manufacture of proteids. But it is very questionable if this is the case, or if the nitrogen is taken up by the green plant in independence of the two is suggested by the fact that fungi can live on a vegetable medium which contain carbohydrates together with certain salts of ammonia, but which are free from proteids. It is certain that certain proteids cannot be nourished by organic compounds of nitrogen, any more than that of animals. We must therefore surmise that possession of a mechanism which can construct proteids, if supplied with these compounds of nitrogen together with sugar.

The mechanism which has been associated with the green plants in the leaves—at any rate there is a certain body of evidence pointing in this direction. It may be, however, that there is no special mechanism, but that this power is a particular differentiation of a physiological kind, existing in all green plants, and that nitrogen, not being alone, but in association with carbohydrates is absorbed by certain cells. The idea of an identity of protoplasm does not involve a denial of special powers developed in it in different situations, and the possession of such a power by the vegetable tends to prove the identity and unity of the protoplasmic organisation and thought in the protoplasm of cells of the human brain.

While we do not feel that we are completely in the dark also as to what are the particular proteids which are first constructed.

The nitrogen which is assimilated to the conditions under which proteids are formed. There is a certain amount of evidence that at any rate in some cases light is necessary, and that the violet rays of the spectrum are chiefly concerned. But the subject requires further investigation.

The normal green plant is seen thus to be in possession of a complete machinery for the manufacture of its own food. The method of which such food when manufactured is incorporated into, and stored in the chloroplast, and whether it could not be used for other purposes. This is, however, also the case with the nutrition of animal protoplasm.

The building up and nutrition of the living substance by the foods manufactured or absorbed is properly spoken of as the assimilation of such food. To up to very recently the original absorption and subsequent treatment of the carbon dioxide and the compounds with nitrogen has been called by the same term. We frequently find the expression used, the 'assimilation' of carbon dioxide, or of
nitetum." As this is not the incorporation of either into the living substance, but is only its manufacture into the complex substances which we find in the plant, it seems preferable to limit the term "assimilation" to the processes by which foods are actually taken into the plant proper.

Symbiosis.—Though green plants thus possess a very complete mechanism for the manufacture of their different foodstuffs, it is not always exercised to the fullest extent. Many of them are known that have not the power of assimilating at all, and are thus compelled to obtain the food they need in a fully prepared condition from their environment. It may be that they procure it from decomposing organic matter in the soil, or they may get it by absorption from other plants to which they attach themselves, or they may in any ease obtain it by preying upon insect life. The power of green plants, not even specialized in any of these directions, to absorb certain carbon compounds from the air, is a topic of remarkable importance in the history of botany, as shown by Acton in 1889. Similar observations have been made in the case of various compounds of nitrogen, though these have not been so complex as the proteids. It was formerly the custom to regard all substances thus entering the plant as being entirely taken up at one time or another supplying the necessities of the other. Such a relationship is known as symbiosis, and the large majority of the cases of so-called parasitism among green plants can be referred to it. This hypothesis probably was that there was a substance, of the cases of such plants as the rattle (Rhizophora), the eye-bright (Eupharia), and other members of the Natural Orders, Scrophulariaceae and Santalaceae, which effect a union between their roots and the soil, and thus furnishing growing points for them. The plants place underground, while the bulk of both partners in the symbiosis rises into the air, renders the association a little difficult to see, but there is no doubt that the plants in question do afford each other assistance, so intimate a partnership was never, in the case of the pronounced case of parasitism, that of Cuscuta, the dodder, which infects particularly clover fields, appears to differ only in degree from this. The plants, one of them being normally parasitic, remains a little chlorophyll. The advantages it can offer to its host are, however, infinitesimal when compared with the injury it does it. Many other cases of symbiosis have been investigated with some success, for they are attracted to the neighbourhood of the mycelium. The two classes are recognized. The first, which are called ectotrophic, the fungal filaments form a thick felt or sheath round the root, either completely enclosing it or leaving the apex free. They seldom penetrate the living tissues, but live so in a part of the host, and form a connection between masses of the hyphae of the Fungus. This type of mycorhiza is found among the Poplars, Oaks and Fir trees. The other type is called endotrophic. The fungal filaments penetrate the root, or fine rootlets from the stem and ramify in the interior. Some make their way through the cells of the outer part of the cortex towards the root-tip, and form a mycelium or hyphal mat, which generally penetrates into the interior of the cells. From this branches pass into the middle region of the cortex and ramify through the interior half of its cells. They often cause a considerable hypertrophy of the tissue. From the outer cortical mycorhiza, which are not found in all trees, a very fine network runs almost through the entire cortex in the soil. In such cases the roots of the plants are usually found spreading in soils which contain a large amount of humus, or decaying vegetable matter. The organic compounds of the latter are thus taken up by the fungi, and this forms a principle place of root-hairs, the tree ceasing to develop the latter. The food so absorbed passes to the outer cortical mycorhiza, and from this to the inner hyphae, which appear to be the organs of the interchange of substances between the two partners. The connection of the nuclei of the cells, which they enter, and in which they form aggregations of interwoven filaments. The prothalli of the Petrod.
This peculiar relationship suggests at once a symbiosis, the Fungus gaining its nutrition mainly or entirely from the green plant, while the latter in some way or other is able to utilize the free nitrogen of the air. Whether the fixation of the nitrogen was brought about by their structure or by the action of the mycelium which is affected remains undecided. Two views are still receiving certain support, though the second of them appears the more probable. These are: (1) That the green plant is so stimulated by the symbiosis that it can more clearly than usual fix nitrogen or cause it to be fixed. (2) That the fixation of the gas is carried out by the fungal organism either in the soil or in the plant, and the nitrogenous substance so produced is transferred and utilized by the symbiotic organism, as is the case by the green plant. Certain evidence which supports this view will be referred to later.

Whatever opinion is held on this point, there seems no room for doubt that the fixation of the nitrogen is concerned only with the root, and that the green leaves take no part in it. The nodules, in particular, appear to play the important part in the process. Martin, who has worked out this view, gives the following details which bear out this view. They are supplied with a regular system of conducting vascular bundles communicating with those of the roots. Their cells during the period of incubation of the symbiotic organism are abundantly supplied with starch. The cells in which the fungoid organism is vigorously flourishing are exceedingly active, showing large size, brilliant nuclei, protoplasm and vacuole, all of which give signs of intense metabolic activity. The sap in these and similar cells is clear, in which the starch granules have already disappeared. In accordance with Low's suggestion that the living protoplasm in presence of an alkali and free nitrogen can build up ammonium nitrate, or some similar body. It is, however, at present undecided whether the substances formed are at first at the expense of the atmospheric nitrogen.

The idea that the atmospheric nitrogen is gradually being made use of by the green plant has been growing steadily. Besides the phenomena of the symbiosis just discussed, certain experiments tend to show that we have a constant fixation of this gas in the soil by various Bacteria. Resembling Kossowsitch, we find that Bacteria, like Nitrobacter, Nitroso bacter, and even some of the Algae, are capable of fixing nitrogen. A number of experiments, by André, Laurent and Schlessing, and more recently by Kossowsitch, seem to establish the fact, though the details of the process remain undiscovered. Berthelot imputes it to the action of several species of bacteria, including Nitrobacter. Kossowsitch claims that aluminose, when the latter is cultivated free from its ordinary host. Laurent and Schlessing affirm that the free nitrogen of the air can be fixed by a number of humble green plants, principally those belonging to the genera Nitella, Nitrocladium, Nitrososphaeria, Nitrosonema, and Nitroso bacter. The Algae are supplied with nitrogen by the bacteria, and in turn construct carbohydrate material, part of which goes to the microorganisms. This is supported by the fact that when the mixed culture is isolated and kept in pure air, the green plants do not grow when it is left in darkness. If there is a plentiful supply of carbon dioxide, more nitrogen is fixed.

Nitrification and Denitrification in the Soil.—Another aspect of the nitrogen cycle has been the subject of much investigation and controversy since 1877. The round changes which various organic matter undergoes in the soil, and how it is ultimately made use of by plants, presents some curious features. We have seen that when nitrogenous matter is present in the condition of humus, some plants can absorb it by their roots or by the aid of mycorhizas. But the changes in it in the usual course of nature are much more profound than these. It becomes in the soil the prey of various microorganisms. Ammonia appears immediately as a product of the disruption of the nitrogen-containing organic molecule. Later, oxidation processes take place, and the ammonia gives rise to nitrites and nitrates, the reactions being carried on successively rather than simultaneously, so that it is only towards the end of the decomposition of the organic matter that nitrification of the ammonia which is formed is set up. In this process of nitrification we can distinguish two phases, first the formation of nitrites, and secondly their oxidation to nitrates. The researches of Warington in England and Winogradsky on the Continent have satisfied us that nitrification is a specifically bacterial process, and that probably more than one species of each exists. One of them comprising the genera Nitrosomonas and Nitrosooccus, has the power of oxidizing salts of ammonium to the condition of compounds of nitrogen, but cannot recover it in other forms. A second group has no further oxidation takes place. The oxidation of the nitrites into nitrates is effected by another organism, much smaller than the first. The name Nitrobacter has been given to this genus, most of our knowledge of which is derived from the researches of Kossowsitch.

The two kinds of organism are usually both present in the same soil, those of the second type immediately oxidizing the nitrites which those of the first form from ammonium salts. The Nitro-
not appear to be concerned with digestion so directly as the others is probably that which forms vegetable jelly from pectic substances occurring in the cell-wall.

The enzymes which act upon glucosides are many; the best known are emulsin and myrosin, which split respectively amygdalin, the so-called prussic acid of plants, and sinigrin, which has a wide distribution among those of the Cruciferae. Of less frequent occurrence are erithrozym, rhamnose, and gaultheria.

The proteolytic enzymes, or those which digest proteids, are usually divided into two groups, one which breaks down ordinary proteins into diffusible bodies, known as peptones, which are themselves the characteristic products of this group. The other group splits proteins into their component amino-acids, which have been spoken of before. This group is represented by the erepsins of the protoplasm of other organs. A third enzyme, the trypsin of the glycophytes, possesses the power of both the above and enzyme, relationships existing between these enzymes are still the subjects of experiment, and we cannot regard them as exhaustively examined. It has been observed in a large number of cases that, in the leaves, many trypsin have been discovered, and one form of erepsin, at least, is very widespread. Among the trypsin the we have the papain of the Papaw fruit (Carica Papaya), the bromelin of the Pine-apple, and the enzymes present in many germinating seeds, in the seedlings of several plants, and in other parts. Another enzyme, rennet, which in the animal body is proteolytic, is frequently met with in plants, but its action has not been ascertained.

The digestion of fats or oil has not been adequately investigated, but its decomposition in germinating seeds has been found to be due to an enzyme, which has been called lipase. It splits it into a fatty acid and glycerol, and the same seems to have been discovered in other action. The details of the further transformations have not yet been specified.

Oxidases.—Another class of enzymes has been discovered in both animals and plants, and they do not appear to take any part in digestion. They are processes in which they attack, and have consequently been named oxidases. Very little is known about them.

In many cases the digestion of reserve food materials is effected by enzymes specifically directed to the destruction of the particular type of compound. The proteins are split into proteids, the proteids into amino-acids, the carbo-hydrates into sugar, and the fats into glycerol and fatty acids, each enzyme or group of enzymes taking care of one particular process. This property of living substance can be proved in the case of the cells of the higher plants, but it is especially prominent in many of the more lowly organisms, such as the Bacteria. The presence of such an enzyme would seem to be an essential condition of the existence of life, and we may infer that it is possessed by all the living organisms of the vegetable kingdom, and that this power is an of such a power in the vegetable organisms. At the same time it must be remembered that the secretion of enzymes by Bacteria is often suppressed.

Supply and Distribution of Energy in Plants.—It is well known that one of the conditions of life is the maintenance of the process which is known as respiration. It is marked by the constant and continuous liberation of a certain volume of carbon dioxide and water vapour. There is no direct connexion between the two, the oxygen is absorbed almost immediately by the protoplasm, and appears to enter into some kind of physiological operation. The carbon dioxide on the other hand is an instability and is continually breaking down to a certain extent, giving rise to various substances of different degrees of complexity, some of which are again built up by it into its own substances, and others are separated from it by the composition of protoplasm, water and carbon dioxide are the most prominent. These respiratory processes are associated with the liberation of energy by the protoplasm, energy which it applies to various purposes. The assimilation of complex foods commonly may be regarded as supplying the protoplasm with a potential store of energy, as well as building up its substance. Whenever complex bodies are built up from simple ones we have an absorption of energy in the form of its potential energy. When decomposition of complex bodies into simpler ones takes place we have the liberation of some or all of the energy that was used in their construction.

Such questions as these have not been directed to the question of the supply, distribution and expenditure of energy in the vegetable kingdom. This is an extremely important question, since the supply of energy to the animal world has been found to depend ultimately on the vegetable kingdom. The flow of energy through the several protoplasts which make up the body of a plant is as necessary as is the transport to them of the food they need; indeed, the two things are inseparably connected. The source of energy which is the only one accessible to the ordinary plant as a whole is the radiant energy of the rays of the sun, and its absorption is mainly due to the properties of chlorophyll. This colouring matter, as shown by its absorption spectrum, picks out of the ordinary beam of light the rays of the sun which is rich in red and blue light of the green and yellow. This energy is obtained especially by the chloroplastids, and it is at once devoted to the construction of green matter, the prussic acid, being thus turned from an energy-depleting substance to a source of energy. The distribution of this potential charge is carried out by processes which depend partly upon the oxidation of the carbohydrates so formed, and therefore upon an expenditure of part of the energy, also mark the storage of energy in the potential form. Indeed, the destruction of protoplasm itself is the same thing. Even in these constructive processes there occurs a constant passage of energy backwards and forwards from the kinetic to the potential condition and versa. The energy in question, however, is the fixation of a certain part of the radiant energy absorbed by the chlorophyll. The rays of the visible spectrum do not supply all the energy which the plant obtains. It has been suggested by several botanists, with considerations which are both visual or chemical can be absorbed and utilized by the protoplasm without the intervention of any pigment such as chlorophyll. There is some evidence pointing to the existence of this power in the cells of the higher plants. If we have a group of plants to allow themselves of the heat rays. There is, no doubt, a direct interchange of heat between the plant and the air, which in many cases takes place in the form of heat, by which the air. Indeed, the tendency to absorb heat in this way, either from the air directly from the sunlight, has already been pointed out as a danger which needs to be averted by transpiration.

The question of the distribution of this stored energy to the separate protoplasts of the plant can be seen to be the same problem as the distribution of the food. The material and the energy go together, the decomposition of one substance toward the other, which is used at one in the vital processes of the cell, being in fact largely employed in constructing protoplasm or storing various products. The actual liberation in any cell is only gradual, and generally takes the form of heat. The metabolic changes in the cells, however, concern other decompositions side by side with those which involve the building up of protoplasm from the metabolic processes of simple substances. So far as we know, the protoplasm is the seat of transformations which are continually proceeding, being partially decomposed and again constructed, the new feed being incorporated into it. The changes involve a continual liberation of the energy which is used, which by the respiratory process is set up in a new and more active form.

The supply of oxygen to a plant is thus seen to be as directly connected with the process of energy transformation as the supply of food concerned in its nutrition. If the access of oxygen to a protoplasm is interfered with its normal respiration soon ceases, but frequently other changes supervene. The partial asphyxiation of a protoplasm is attended by a process by which the protoplasm is compelled to set up a supplementary series of decompositions, which result in the liberation of energy just as those of the respiratory process. One of the constant features of respiration—the exhalation of carbon dioxide—can still be observed. This comes in almost all such cases from the decomposition of sugar, which is split up by the protoplasm into alcohol and carbon dioxide. Such decompositions are now generally, for the most part, broken down and oxidized under the influence of a series of enzymes, the complex molecule of the sugar liberates a constant amount of energy, as can be seen from the study of the fermentation set up by yeast, which is a process of this kind, in that it is intensively studied by the presence of the carbon dioxide and alcohol which, as a result of heat, raises the temperature of the fermenting wort. It has been ascertained that in many cases this decomposition is effected by the secretion of an enzyme, which has been termed zyme. This body has been prepared from active yeast, and from several other parts which have been kept for some time in the absence of oxygen. The protoplasm appears to be able also to bring about the change without secreting any enzyme.

The content of energy in the plant is, as we have seen, derived originally from the kinetic radiant energy of the sun. In such cells as are capable of absorbing it, by virtue of their chlorophyll apparatus, the greater part of the radiant energy of oxygen and carbon dioxide is converted from cell to cell of the compounds constructed every part of the plant is put into possession of the energy it needs. The store of energy thus accumulated has to be distributed to all parts of the plant. A certain part of it is devoted to the maintenance of

PHYSIOLOGY

PLANTS
the framework of the fabric of the cell, and the construction of a continuously increasing skeleton; part is used in maintaining the normal temperature of the plant, part in constructing various substances, and part in growth in which the interplay of all purposes in the working of the vital mechanism. A great part again is utilized in that increase of the body of the plant which we call growth.

Growth, as usually spoken of, includes two essentially different processes. The first of these, which may be regarded as growth proper, is the manufacture of additional quantities of living substance. The second, which is usually included in the term, is the increase in size of the plant-body, and the increase of the volume of its parts. This is a process of building up from simple or relatively simple materials; the construction of its cellulose framework and supporting substance is done by the living substance after its own formation is completed, and is attended by a partial decomposition of such living substance.

Growth is always going on in plants while they are alive. Even the oldest trees put out continually new leaves and twigs. It does not, of course, follow that increase of bulk is always conspicuous; in large trees death is present side by side with life, and the counterbalances the other. As, however, we can easily see that the constructive processes are much greater than those which lead to the disappearance of material from the plant-body, there is generally to be expected a considerable increase in size. This is, in nearly all cases, attended by a permanent change in form. This is not perhaps so evident in the case of axial organs as it is in the case of shoots; but modifications, but even in them it can be detected to a certain extent.

In the lowest plants growth may be co-extensive with the plant-body; in all plants of any considerable size, however, it is localized in certain regions of the plant, and there growth takes place by the addition of new protoplasts or cells. These regions have been called growing points. In such stems and roots as increase in thickness there are other growing regions, which consist of cylindrical sheaths known as cambium. By the growth of these regions, the protoplasts in these merismatic areas the substance of the plant is increased. In other words, as these growing regions consist of cells, the growth of the entire organ or plant will depend upon the birth of new cells or protoplasts of which the merismatic tissues are composed.

The growth of a cell will be found to depend mainly upon three factors. Growth is essential to nutritive activity; materials, at the expense of which the increase of its living substance can take place, and which supply the needed potential energy. (2) There must be a supply of water to such an extent as to set up a certain hydrostatic pressure in the cell, for only turgid cells can grow. (3) The supply of water must be associated with the formation of osmotic substances in the cell, or it cannot be made to enter it.

The cell must have a certain temperature, for the activity of a protoplast is markedly affected by changes in the temperature within which it is placed. (5) There must be a supply of oxygen to the growing cell, for the protoplast is dependent upon this gas for the performance of its vital functions, and particularly for the liberation of energy. If the oxygen does not supply the protoplast with sufficient energy, the protoplast is dependent upon the oxygen in the atmosphere for the supply of energy to be available for the construction of the protoplast. This is evident from the consideration that the growth of the cells is attended by the growth in surface of the cell wall, and as the latter is the protoplast which is responsible for the formation of wall, no protoplast can function without oxygen being admitted to it.

When these conditions are present, the course of the growth of the plant appears to be the following: The young cell, immediately it is cut off from its fellow, absorbs water, in consequence of the presence in it of osmotically active substances. With the water it takes in the various nutritive substances which the former contains in solution. There is set up at once a certain hydrostatic pressure, due to the turgidity which ensues upon such absorption, and the extension of the cell wall stretches, at first in all directions. The growth or increase of the protoplasm at the expense of the nutritive matter for a time keeps pace with the increased size of the cell, but by and by it becomes greater than the extension and the cell wall starts to interior. Eventually the protoplasm usually forms only a lining to the cell wall, and a large vacuole filled with cell sap occupies the greater part of the cell. The cell wall, although at first rigidity is therefore not commensurate with the increase in the size of the cell. The stretching of the cell wall by the hydrostatic pressure is fixed by a secretion of new particles and their deposition upon the older protoplasm. This is a process, and while it is concomitant with the formation of new substance upon the old. When the limit of extensibility is reached the cell wall increases in thickness from the continuation of the latter of the two processes, and varies slightly throughout its course; it begins slowly, increases to a maximum, and then becomes slower till it stops. The time during which these regular changes in the rate can be observed is generally spoken of as the grand period of growth.

If we consider the behaviour of a growing organ such as a root, we find that, like a cell, it shows a grand period of growth. Just behind its apex the cells are found to be all in process of active division, and a great apical apex of cells is seen. This is a region which is associated more particularly with the formation of the vacuoles, consequent upon the establishment of considerable hydrostatic pressure in them, thus causing the bulk of the cells to be greatly enlarged. Here it is that the actual extension in length of the root takes place, and the cells reach the maximum point of the grand period. They then gradually lose the power of growth, the oldest walls thicken, the protoplasm, from the apex partitioning with it, and they pass gradually over into the condition of the permanent tissues.

The same order of events may be ascertained to take place in the stem; but in this region it is complicated by the occurrence of nodes and internodes, growth in length being confined to the apical region, which may be growing simultaneously. The region of growth in the stem is, as a rule, much longer than that of the root. The growth of the leaf is at first apical, but this is not very prolonged, and the permanent enlargement is due to an intercalary growing region near the base.

The turgidity in the cells of a growing member is not uniform, but shows a fairly rhythmic variation in its different parts. If the member is one which shows the effects of turgidity, such as a leaf, the two sides frequently show a difference of degree of turgidity, and consequently of rate of growth. If we consider a leaf in the region of its apex we find that as the leaf, or at least a side of the leaf, is closely rolled up, the upper or ventral surface being quite concave. As it gets older it gradually unfolds and expands into the adult form. This is due to the fact that while young the turgidity of the upper surface of the leaf is relatively large, but as the leaf becomes rolled up as it develops the maximum turgidity and growth change to its upper side, and so it becomes unfolded or expanded. These two conditions are generally described under the names of hypostrophy and exostrophy respectively.

Cylindrical organs may exhibit similar phenomena. One side of a stem may be more turgid than the opposite one, and the maximum turgidity, with its consequent growth, may alternate between two opposite sides. The stem is then said to be dichotomously or spiral-phylled, and the results are very obvious. This elongating all the time, pointing to all points of the compass in succession. This continuous change of position has been called circumvolution, and is held to be universal in all growing cylindrical organs. The passage of the maximum turgidity round the stem may vary in rapidity in different places, causing the circle to be replaced by an ellipse. The bending to sides alternately, described above as circumvolution, may be regarded as only an extreme instance of the latter.

Nervous System of Plants.—So far we have considered the plant almost exclusively as an individual organism, carrying out its own vital processes, and unaffected by its surroundings except so far as these supply it with the materials for its well-being. When we pass from the shoots to the roots and other structures in those surroundings and the consequent changes a plant must encounter, it appears obvious that interaction and adjustment between the plant and its environment must be constant and well balanced. That such adjustment shall take place postulates on the part of the plant a kind of perception or appreciation of the changing conditions which affect it.

Careful examination soon shows an observer that such perceptions exist, and that they are followed by certain purposeful changes in the plant, sometimes mechanical, sometimes chemical, the object being evidently to secure some advantage for the plant, to ward off some danger, or to extricate it from some difficulty. We may speak, indeed, of the plant as possessed of a rudimentary nervous system, by the aid of which adjustments are brought about. The most constantly occurring changes that beset a plant are connected with illumination, temperature, moisture, and contact with foreign bodies. Setting aside other susceptibilities, we have evidence that most plants are sensitive to all these.

If a growing stem receives stronger illumination on one side than another, its apex slowly turns from the vertical in the direction of the light source, continuing its change of position until it is in a direct line with the incident rays. If a root is similarly illuminated, a similar change of direction of growth follows, but
in this case the organ grows away from the light. These movements are spoken of as heliotropic and aplethiotropic curvatures. The purpose of the movement bears out the assumption that the plant is trying to adjust itself to its environment. The stem, by pointing directly to the light source, secures the best illumination possible for all of its leaves, the latter being distributed symmetrically around it. The root is made to press its way into the darker cracks and cannies of the soil, so bringing its root-hairs into better contact with the particles round which the hygroscopic water hangs. Leaves respond in another way to the same influence, placing themselves across the path of the beam of light.

Similar sensitiveness can be demonstrated in other cases. When a root comes in contact at its tip with some hard body, such as a metalimp, it grows inwards, and the tip is bent away from the obstacle. The young roots grow vertically downwards, the young stems vertically upwards. Any attempt to interfere with these directions, by placing the seedlings in abnormal positions, is frustrated by the seedlings themselves, which change their direction of growth by bringing about curves of the different parts of their axes, so that the root soon grows vertically downward again and the stem in the opposite direction. Other and older plants give evidence of the same perception, though they do not respond all in the same way. Speaking generally, stems grow upwards and roots downwards. But some stems grow parallel to the surface of the soil, while the branches both of stems and roots tend to grow at a definite angle to the main axis from which they come. These movements are spoken of as different kinds of geotropic curvatures. This power of perception and response is not by any means confined to the growing organs, though in these it is especially striking, and plays a very evident part in the disposition of the growing organs in advantageous positions. It can, however, be seen in adult organs, though instances are less numerous.

When the pinnate leaf of a Mimosa pudica, the so-called sensitive plant, is pinched or struck, the leaf droops rapidly and the leaflets become approximated together, so that their upper surfaces come into contact. The extent to which the disturbance spreads depends on the violence of the stimulation—it may be confined to a few leaflets or it may extend to all the leaves of the plant.

The leaves and leaflets of many plants, e.g., the telegraph plant, Desmodium gyrans, behave in a similar way under the stimulus of approaching darkness.

A peculiar sensitiveness is manifested by the leaves of the so-called insectivorous plants. In the case of Dionaea muscipula we find a two-lobed lamina, the two lobes being connected by a midrib, which can play the part of a kind of hinge. Six sensitive hairs spring from the upper surface of the lobes, three from each; when one of these is touched the two lobes rapidly close, bringing their upper surfaces into contact and imprisoning anything which for the moment is between them. The mechanism is applied to the capture of insects alighting on the leaf.

Drosophila, another of this insectivorous group, has leaves which are furnished with long glandular tentacles. When these are excited by the settling of an insect on the leaf they slowly bend over and imprison the intruder, which is detained there meanwhile by a sticky excretion poured out by the glands.

In both these cases the stimulation is followed, not only by movement, but by the secretion of an acid liquid containing a digestive juice, by virtue of which the insect is digested after being killed.

The purposeful character of all these movements or changes of position indicates that they are of nervous origin. We have in them evidence of two factors, a perception of some features of the environment and following this, after a longer or shorter interval, a response calculated to secure some advantage to the responding organ. We find further evidence that these two conditions are traceable to different parts of the organs concerned. The perception of the changes, or, in other words, the reception of the stimulus, is associated for example, with the tips of roots and the apices of stems. The first recognition of a specially receptive part was made by Charles Darwin, who identified the perception of stimulation with the tip of the young growing root. Amputation of this part involved the cessation of the response, even when the conditions normally causing the stimulus were still maintained. It is later demonstrated that the tips of the plumes of grasses were sensitive parts. The responding part is situated some little distance farther back, being in fact the region where growth is active. This bending part has been proved to be insensitive to the stimulus. There is consequently a transmission of the stimulus from the sensitive organ to a kind of motor mechanism situated some little way off. We find thus three factors of a nervous mechanism present, a receptive, a conducting, and a responding part. The differentiation of the plant's substance so indicated is, however, perhaps the most clear the physiological difference between the cells of these regions that can be associated with the special properties they possess. Even the root tip, which shows a certain differentiation into root cap and root apex, cannot be said to be a definite sense organ in the same way as the sense organs of an animal. The root is continually growing and so the sensitive part is continually changing its composition, cells being formed, growing and becoming permanent tissue. The cells of the tip at any given moment may be sensitive, but in a few days the power of receiving the stimulus has passed to other and younger cells which then constitute the tip. The power of appreciating the environment is therefore to be associated with the protoplasm of the particular stage of its development and is transitory in its character.

What the nature of the stimulation is we are not able to say. The protoplasm is sensitive to particular influences, perhaps of vibration, or of contact or of chemical action. We can imagine though perhaps only vaguely, the way in which light, temperature, moisture, contact, &c., can affect it. The perception of direction or the influence of gravity presents greater difficulty, as we have no clear idea of the form which the force of gravity takes. Recently some investigations by Haberlandt, Noll, and other investigators have suggested an explanation which has much to recommend it. The sensitive cells must clearly be influenced in some way by weight—not the weight of external organs but of some weight within them. This may possibly be the cell sap in their interior, which must exercise a slightly different hydrostatic pressure on the basal and the lateral walls of the cells. Or more probably it may be the weight of definite particulate structures in their vacuoles. Many experiments point to certain small grains of starch which are capable of displacement as the position of the cell is altered. Such small granules have been observed in the sensitive cells, and there is an evident correlation between these and the power of receiving the physical stimulus. It has been shown that if the organ containing them is shaken for some time, so that the contact between them and the protoplasm of the cells is emphasized, the stimulus becomes more efficient in producing movement. This reduces the stimulus to one of contact, which is in harmony with the observations made upon roots similarly stimulated from the exterior. The stimulating particles, whether starch grains in all cases, or other particles as well, have been termed statoliths.

We have spoken of the absence of structural differentiation in the sense organs. There is a similar difficulty in tracing the pathways by which the impulses are transmitted to the growing and curving regions. The conduction of such stimulation to parts removed some distance from the sense organ suggests paths of transmission comparable to those which transmit nervous
impulses in animals. Again, the degree of differentiation is very slight anatomically, but delicate protoplasmic threads have been shown to extend through all cell-walls, connecting together all the protoplasts of a plant. These may well serve as conductors of nervous impulses. The nervous mechanism thus formed is very rudimentary, but in an organism the conditions of whose life render locomotion impossible great elaboration would seem superfluous. There is, however, very great delicacy of perception or appreciation on the part of the sense organs, stimuli being responded to which are quite incapable of impressing themselves upon the most highly differentiated animal.

The power of response is seen most easily in the case of young growing organs, and the parts which show the motor mechanism are mainly the young growing cells. We do not find their behaviour like that of the motor mechanism of an animal. The active contraction of muscular tissue has no counterpart in the plant. The peculiarity of the protoplasm in almost every cell is that it is especially active in the regulation of its permeability by water. Under different conditions it can retain it more strongly or allow it to escape more freely. This regulation of turgor is as characteristic of vegetable protoplasm as contraction is of muscle. The response to the stimulus takes the form of increasing the permeability of particular cells of the growing structures, and so modifying the degree of the turgidity that is the precursor of growth in them. The extent of the area affected and of the variation in the turgor depends upon many circumstances, but we have no doubt that in the process of modifying its own permeability by some molecular change we have the counterpart of muscular contractility.

The response made by the adult parts of plants, to which reference has been made, is brought about by a mechanism similar in nature though rather differently applied. If the leaf of Mimosa or Desmodium be examined, it will be seen that at the base of each leaflet and each leaf, just at the junction with the respective axes, is a swelling known as a pulvinus. This has a relatively large development of succulent parenchyma on its upper and lower sides. In the erect position of the leaf the lower side has its cells extremely turgid, and the pulvinus thus forms a cushion, holding up the petiole. On stimulation these cells part with their water, the lower side of the organ becomes flaccid, and the weight of the leaf causes it to fall. The small pulvini of the leaflets, by similar changes of the distribution of turgidity, take up their respective positions after receiving the stimulus. In some cases the two sides of the pulvinus vary their turgidity in turns; in others only the lower side becomes modified.

Similar turgescence changes, taking place with similar rapidity in the midrib of the leaf of Dionaea, explain the closing of the lobes upon their hinge. More slowly, but yet in the same way, we may note the change in turgidity of certain cells of the Drosera tentacles, as they close over the imprisoned insect.

Organic Rhythm.—It is a remarkable fact that during the process of growth we meet with rhythmic variation of such turgidity. The existence of rhythm of this kind has been observed and studied with some completeness. It is the immediate cause of the phenomena of circumnutation, each cell of the circumnutating organ showing a rhythmic enlargement and decrease of its dimensions, due to the admission of more and less water into its interior. The restraint of the protoplasm changes gradually and rhythmically. The sequence of the phases of the rhythm of the various cells are co-ordinated to produce the movement. Nor is it only in growing organs that the rhythm can be observed, for many plants exhibit it during a much longer period than that of growth. It is easy to realize how such a rhythm is produced by the action of a periodic stimulus, and can consequently serve as the basis for the movement of the stimulated organ. This rhythmic affection of vegetable protoplasm can be observed in very many of its functions. What have been described as “periodicities,” such as the daily variations of root-pressure, afford familiar instances of it. It reminds us of a similar property of animal protoplasm which finds its expression in the rhythmic beat of the heart and other phenomena.

**PATHOLOGY**

**Phytopathology** or plant pathology (Gr. φυτά, plant), comprises our knowledge of the symptoms, course, causes and remedies of the maladies which threaten the life of plants, or which result in abnormalities of structure that are regarded, whether due directly to injury or not, to life, as unsightly or undesirable. In its systematized form, as a branch of botanical study, it is of recent date, and, as now understood, the subject first received special attention about 1850, when the nature of parasitism began to be intelligible; but many disjointed references to diseased conditions of plants had appeared long before this. The existence of blights and mildews of cereals had been observed and recorded in very ancient times, as witness the Bible, where half a dozen references to such scourges occur in the Old Testament alone. The epidemic nature of wheat-rust was known to Aristotle about 350 B.C., and the Greeks and Romans knew these epidemics well, their philosophers having shrewd speculations as to causes, while the people held characteristic superstitions regarding its origin. In the medication of special festivals and deities to the pests. Plant knowledge that flies emerge from galls. The few records during the middle ages are borne out by what is known of famines and pestilence. Shakespeare’s reference in King Lear (Act iii, sc. iv.) may be quoted as evincing acquaintance with mildew in the 17th century, as also the interesting Rouen law of loverdo (1660). Malpighi in 1679 gave excellent figures and accounts of leaf-rolling and gall insects, and grew in 1882 equally good descriptions of a leafmining caterpillar. During the 18th century more academic treatment of the subject began to replace the scattered notes. Hales (1727-1733) discussed the rotting of wounds, cankers, &c., but much had to be done with the microscope before any real progress was possible, and it is easily intelligible that until the theory of nutrition of the higher plants had been founded by the work of Ingenhousz, Priestley and De Saussure, the way was not even prepared for accurate knowledge of cryptogamie parasites and the diseases they induce. It was not till De Bary (1866) made known the true nature of parasitic fungi, based on his researches between 1853-1863, that the vast domain of epidemic diseases of plants was opened up to fruitful investigation, and such modern treatises as those of Frank (1880 and 1895), Sorauer (1886), Kirchner (1890), were gradually made possible. Plant pathology embraces several branches of study, and may be conveniently divided as follows:—

1. The observation and accurate description of symptoms (Diagnosis).
2. The study of causes or agencies inducing disease (Aetiology).
3. The practise of preventive and remedial measures (Therapeutics).

In plants, however, the symptoms of disease are apt to exhibit themselves in a very general manner. Our perceptions differentiate but imperfectly symptoms which are due to very different causes and reactions, probably because the organization of the plant is so much less highly specialized than that of higher animals. The yellowing and subsequent casting of leaves, for instance, is a very general symptom of disease in plants, and may be induced by drought, extremes of temperature, insufficient or excessive illumination, excess of water at the roots, the action of parasites, Fungi, insects, worms, &c., or of poisonous gases, and so forth; and extreme caution is necessary in dealing with such descriptions of such symptoms, especially when the untrained eye has taken no cognisance of, or has only vaguely observed, the numerous collateral circumstances of the case.

The causes of disease may be provisionally classified somewhat as follows, but it may be remarked at the outset that no one of
these proximal causes, or agents, is ever solely responsible; and it is very easy to err in attributing a diseased condition to any of them, unless the relative importance of primary and subordinate agencies is discernible. For instance, a Fungus epidemic is impossible unless the climatic conditions are such as to favour the dispersal and germination of the spores; and when the plant is killed off owing to the supersaturation of the soil with water, it is by no means obvious whether the excess of water and dissolved materials, or the exclusion of oxygen from the root-hairs, or the lowering of the temperature, or the accumulation of foul products of decomposition should be put into the foreground. In every case there are chains of causation concerned, and the same factors will be differently grouped in different cases.

Bearing in mind these precautions, we may classify the proximal causal agents of disease as—

I.—External agencies.

A. Non-living.
   a. Material.
      1. Physical—Soil.
         Water. 
      a. Atmosphere.
         2. Chemical—Fertilizer.
      b. Plants.
      a. Atmosphere.

B. Living.
   a. Animals.
   b. Internal.

II.—Internal agencies.

While such a classification may serve its purpose as a sort of index, it must be confessed that the limits of its usefulness are soon reached. In the first place, the so-called “internal causes” of disease is probably a mere phrase covering our ignorance of the factors at work, and although a certain convenience attaches to the distinction between those cases where tender breeders of plants apparently exhibit internal predisposition to suffer more readily from others parasites, low temperatures, excessive growth, etc.—as is the case with some grafted plants, cultivated hybrids, etc.—the mystery involved in the phrase “internal causes” only exists until we find what action of the living or non-living environment of the essential mechanism of the plant has upset its equilibrium.

I.—Passing to the recognized external agencies, the physical condition of the soil is a fruitful source of disease. If too closely packed, the soil particles present mechanical obstacles to growth; if too retentive of moisture, the root-hairs suffer as already hinted; if too open or waterlogged, the plant suffers losses in the same way. Those properties of soil known as texture, porosity, depth, inclination to the horizon, &c., are concerned here. Many maladies of plants are traceable to the chemical composition of soils—e.g. deficiency in lime, nitrate of soda, nitrates, etc. These results, especially nitrates and the presence of poisonous salts of iron, copper, &c., or (in the soil about the roots of trees in towns) of coal-gas and so forth. But it is worthy of special attention that the mere chemical composition of the soil is not sufficient to cause the disease, as it is usual to speak of an invasion of a plant by some parasitic fungi or animals, as though the disease were due to an invasion and not to a predisposition of the soil. The Vertebrata come within the scope of our subject, chiefly as destructive agents which cause wounds or devour young shoots before they are formed; &c., and with these are to be contrasted the animals injure roots, sires, and birds nip off buds, horned cattle trample young shoots, &c., and so forth. It is among the Invertebrata that epidemics of destruction are referred to, though these are of far more general occurrence, and in speaking of an epidemic of elephants or of rabbits, though we use the term when speaking of blight insects; there is little consistency in the matter, as it is usual to speak of an invasion or scourge of locusts or of blight, etc. When the soil of the land is infested with grazing animals, as by rabbits, the soil is no longer susceptible of adequate drainage, and all the usual injurious effects of waterlogged soils may result. The soil, therefore, should be treated as a subject of consideration in all questions of agricultural economy.

Animals and plants as agents of disease or injury form part of the subject of this subject for it is obvious that every species of organism, as is recognized even by those who do not so readily apprehend that diseased conditions in general are always signs of defeat in the struggle for existence between the suffering organism and the environment that is the reason why we call it disease.

The Vertebrata come within the scope of our subject, chiefly as destructive agents which cause wounds or devour young shoots before they are formed; &c., and with these are to be contrasted the animals injure roots, sires, and birds nip off buds, horned cattle trample young shoots, &c., and with these are to be contrasted the animals injure roots, sires, and birds nip off buds, horned cattle trample young shoots, &c., and so forth. The soil, therefore, should be treated as a subject of consideration in all questions of agricultural economy.

Turning to the non-material external agents, probably no factors are more responsible for ill-health in plants than temperature and light. Every plant is constrained to carry out its functions of growth, nutrition, reproduction, &c., between certain limits of temperature, and somewhere between these limits each function finds an optimum temperature at which the working of the living machinery is at its best, and other things being equal, the greater the ground area of the plant the more critical are the temperature conditions; and many disasters are due to the failure to provide such suitable temperatures—e.g. in greenhouses where plants require very different optimum temperatures and illumination conditions. Every organism is probably subject to some particular change which involves temperature in themselves not excessive but in wrong sequence; how many more useful plants could be grown in the British Kingdom if the deceptively mild springs were not so often followed by sharp falls of temperature? The indirect effects of temperature are also important. Trees, of which the young buds are "nipped" by frost, will frequently become evident in the material itself. It is not, however, to serve as points of entry for Fungi; and numerous cases are known where even high temperatures can be endured on rich, deep, retentive soils by plants which at once succumb to drought on shallow or non-retentive soil.

All chlorophyll plants require light, but in very different degrees, as exemplified even in the United Kingdom by the shade-bearing beech and the light-demanding larch and birch; and as with temperature so with light, every plant and even every organ has its optimum of illumination. The "drawn" or etiolated condition of over-shaded plants is a case in point, though here the soft, waxy leaves are not so much the result of injury as they serve as points of entry for Fungi; and numerous cases are known where high temperatures can be endured on rich, deep, retentive soils by plants which at once succumb to drought on shallow or non-retentive soil.

we do not look on their depredations as diseases, though the gradual deterioration of hay under the exhausting effects of rotting caterpillaries like Rhamusia, and the onslaught of rusty fungi when unduly abundant, should teach us how unimportant to the definition the question of size may be.

But there is, among the fungi that we find the most disastrous and elusive agents of disease. Parasitic Fungi may be, as regards their direct action, purely local — e.g. Schizium, which forms gall-like tumours of roots and stipules, and the exudation of fluid and exsiccation on juniper stems; numerous leaf Fungi such as Puccinia, Austinia, Septoria, &c., causing yellow, brown or black spots on leaves; or Ustilago in the anthers of certain flowers. In such cases the immediate damage done may be slight, but the effects of prolonged action and the summation of numerous attacks at a number of points are often enormous, certain of these leaf-diseases costing millions sterling annually to some planting and agricultural interests. In other cases the fungus may be more rampant, and, instead of a local effect, exerts a general destructive action throughout the plant — e.g. Pythium, which causes the damping off of seedlings, reducing them to a putrid mass in a few hours, and hence the destruction of vast quantities of seedlings. Many Fungi, in themselves not very aggressive, slowly bring about important and far-reaching secondary effects. Thus, many Hymenomycetes (Agaric, Polypore, &c.) live on the wood of these trees. Their growth depends on the slow conversion of the wood into available nutritive substances. As these work gradually invades the vessels occupied with the transmission of water up the trunk, cuts off the current, and so kills the tree; in other cases, it blocks the respiratory ventilation of the tissues by interference with the diffusion of oxygen, resulting in "fouling." Numerous Fungi, though conspicuous as parasites, cannot be said to do much individual injury to the host. The extraordinary malformations known as "wound fevers" are brought about by the attack of Fungi on the immediate neighborhood of wounds in which the mycelium of Eosoaecus (on birch) or Austinia (on silver fir) are living, may be borne in considerable numbers for years without any very extensive apparent injury to the tree. Again, the curious distortions on the stems of netles attacked by the Austinia form of the heteroecious Puccinia Caries (see Fungi for Heteroecism), or on maize stems and leaves attacked by Ustilago Maydis, or on the inflorescence of crucifers infected with Cystopus, &c., are due, in most cases, to the indirect effects of numerous attacks or of extensive epidemics which eventually tell. Some very curious details are observable in these cases of malformation. For instance, the Austinia is encountered in two quite different stages of development, duration and arrangement, and even shape of foliage leaves from the normal; and the shoots of Uromyces infected with the aecidia of Uromyces Pisi develop a number of normal stems which may be found, and where both have been taken for different species. Similarly with Anemone infected with Puccinia and Vasscinum with Calyptostoma, and many other cases of deformations due to hypertrophy or atrophy. In these cases of injury, the terms tolerance and parthenogenesis, where the host plant seems to accommodate itself very well to the presence of the fungus, paying the tax it exacts and notwithstanding its pernicious effect on the organism. The more the matter has been studied, the more evident has become the association between host and fungus, which in many cases is many times repeated in various species of plants — e.g. an alga infected with a Chytridium — indeed, matters can hardly be otherwise. But the case is obviously different when a plant dies because some essential organ or tissue tract has been destroyed, and other parts have suffered because supplies are cut off — e.g. when the upper parts of a tree die off owing to destruction of the roots, or to the ringing of the stem lower down, and such destruction is not limited to a single part of the plant. In a large number of cases, however, the disease is purely local, and does not extend far into the organ or tissue affected.

If a mass of living plant-tissue is cut, the first obvious change noted is one of colour: the white "flush" of a potato or an apple turned brown as the air enters, and closer examination shows that cell walls and contents are alike affected. The cut cells die, and oxidized products are concerned in the change of colour, the brown juices escaping and the cells falling and disorganizing. The cell walls, however, are still uninjured below. Such healing by cork formation is accompanied by a rise of temperature: the active growth of the dividing cells increases, and in some cases a high degree of temperature is maintained, until a state of "wound fever" supervenes until the healing is completed. The phenomena described occur in all cases of cicatrization of wounds in nature — e.g. leaf-tissue, young stems, roots, &c., when cut, and the repeated breaking up of the rigid cell-walls, the contraction in the occlusion of broken twigs and of falling leaves, and it is from the actively growing "callus" developed at the surface of the wounded tissues of cuttings, budgings, pruning, &c., that the healing and renewal of tissues occur of which advantage is taken in the practice of what might well be termed plant surgery. A further phenomenon in connexion with the increase of the flow and accumulation of plastic materials at the seat of injury. The enhanced metabolism creates a current of drainage on the supply of available food-stuffs around. The phenomenon of a wound "callus" extends to all injury of animals and plants, and, as a parasitic organism gains access to a cell — e.g. Plectrochelis causes the invaded Pilaebus to swell up, and changes the whole course of its cell metabolism, and similarly with Plasmodiophora in the potato.

Irritation and hypertrophy of cells are common signs of the presence of parasites, as evidenced by the numerous malformations, galls, witches'-brooms, &c., on diseased plants. The well-known fact of the death of unoccupied leaves on young trees, where the fungus is endophytie, the tissues of the branches are invaded, and the plant brought to living protoplasm, and that respiratory activity and growth may be accelerated by chloroform, ether and even powerful mineral poisons, such as mercuric chloride, in minimal doses, offers some explanation of these phenomena; the ingestion of the Fungus, &c., and other responses to the presence of irritating agents.

Still further insight is afforded by our increasing knowledge of the enzymes, and it is to be remarked that both plants and enzymes are very common in just such parasitic fungi as induce discolorations, hypertrophies and the death of cells— e.g. Botrytis, Ergot, &c. Now it is clear that if an organism gains access to all parts of a plant, it may induce hypertrophy, by stimulating the reproduction of tissues, and the division of cell walls. It may even internalize the cell, so to speak. Thus, the fungus may have the latter behaving abnormally — i.e. it may be diseased throughout; and such actually occurs in the case of Euphorbia pervaded with Uromyces Pisi, the presence of which alters the whole aspect of the plant, and causes branchlets and leaves to be destroyed. Further, every host may be killed and the plant forthwith destroyed— e.g. Phytophthora in potatoes. If, on the other hand, the irritating agent is local in its action, causing only a few cells to react, we have the various pimplles, exsiccations, outgrowths, &c., exhibited, such as Ulstilago Maydis on the maize, various galls, witches'-brooms, &c.

It must not be overlooked that the living cells of the plant react against the parasite as well as to all external agencies, and the picture of disease becomes intelligible only if we bear in mind that it consists in this altered metabolism —deflected physiology — as here interpreted. The root is an organ of absorption, the shoot an organ of respiration and photosynthesis we may even say that the root is the leaf of the lower parts of the plant, or the shoot the leaf of the upper parts. If, on the contrary, the gradual cooling is met by a corresponding depletion of the cells of water, even intense cold may be sustained without injury.

Or, take another case. If the attack of a parasite is met by the formation of some substance in the protoplasm which is chemotactively repulsive to the invader, it may be totally incapable of penetrating the cell, even though equipped with a whole armory of enzymes. The enzymes, while far more potent than many body-attackers, are not so selective, and easily overcome the more passive resistances offered by mere cell-walls and cell-contents of other plants, the protoplasm of which forms bodies chemotactically attractive to the Fungi.

The enemica of the species is not so much dependent on the foregoing. In order that a Fungus may enter a plant, it must be able to overcome not merely the resistance of cell-walls, but that of the living protoplasm; if it cannot do this, it must remain harmless — e.g. Fungi, Herbacium wound low, &c., and, at most, vegetate in the intercellular spaces and anchor itself to the cell-walls, e.g. Trichosporia. The inability to enter the cells is generally due to the lack of chemotactie bodies, to incapacity to form cellulose-dissolving enzymes, to the existence in the host- cells of antagonistic bodies which neutralise or destroy the acids, enzymes or poisons formed by the hyphae, or even to the formation of an impenetrable barrier to the protoplasm. The Fungus may, however, when inside it does not follow that the Fungus can kill the cell, and many cases are known where the Fungus can break through the cell's first line of defence (cell-wall and protoplasmic lining). It must, however, struggle through a curious osmotic condition, and hypertrophy, accumulation of plastic bodies or secretions, discolorations, &c., indicate the suffering of the still living cell. Finally, cases occur where the invaded cell so adapts itself to the presence of the invader — e.g. Erysipheae, Pyrenomycetes, &c., — that the Fungus is no longer recognisable.

The dissemination of plant parasites is favoured by many circumstances not always obvious, whence an air of mystery regarding epidemics was easily created in earlier times. The spores of Rust and other parasites are very light and of considerable quantity, and are capable of being conveyed by birds, bees, ants, flies, worms etc. to plant by snails; those of tree-killing polypore, &c., by mice, rabbits, rats, &c., which rub their fur against the hymenophores. Bird-droppings are often the means of spreading the spores of the billberries, and flies convey the conidia of ergot from fungous plants. Insects, indeed, are largely concerned in disseminating Fungi, either on their bodies or via the alimentary canal. Worms bring spores of the surface of soil, ducks and other birds convey them on their feet, and, as is well known, wind and other physical
PLANTS

PATHOLOGY

agencies are very efficient in dissemination. The part played by man also counts for much. Gardeners and farm laborers convey spores from one bed to another; carted soil, manure, &c., may abound in spores of Smuts, Fusarium, Polyporei and in sclerotia; and animal life, particularly birds and pests, also help to disperse and infect different parts of different spores. Every time a carpenter saws fresh timber with a saw recently put through wood attacked with dry-rot, he risks infecting it with the Fungus; and similarly in pruning, in propagating by cuttings, or grafting.

The annual losses due to epidemical plant diseases attain proportions not easily estimated. As regards money value alone the following figures are in illustration. In 1882 the United States was calculated to have lost at least $5,000,000 from disease, and in 1897 alone which Prussia suffered from tobacco blight was estimated at $5,000,000.

The terrible losses sustained by whole communities of farmers, planters, foresters, &c., from plant diseases have naturally stimulated the search for remedies, but even now the search is too often conducted in the spirit of the believer in quack medicines, although the agricultural world is awakening to the fact that before any measures likely to be successful can be attempted, the whole chain of causation of the disease must be investigated. Experience with epidemics, dearly bought in the past, has shown that one cause in the laying open to the inroads of some Fungus or insect, hitherto leading a quiet endemic life in the fields and forests, large tracts is at one with food, along which it may range rampant without check to its dispersal, nutrition and dissemination. Wild hypotheses as to changes in the constitution of the host-plant, leading to supposed vulnerability previously non-existent, would point only in the right direction, and that nature is acting. But truth has been grasped that an epidemic results when the external factors favor a parasite somewhat more than they do the host. It may be that in particular cases particular modes of cultivation determine the prevalence of a disease; or on the other hand, overwhelming evidence exists to show that the principal causes of epidemics reside in circumstances which favour the spread, nutrition and reproduction of the pest, and the lesson to be learnt is that preventive measures must be established, and that the cause of the calamity is in the circumstances, and not in the pest, and that must be sought. Nevertheless, epidemics occur, and practical measures are devised to meet the various cases and to check the ravages of the pests. The preventive consists in most cases in spraying the affected plants with poison, in infections on the ground, or in dusting them with fungicidal or insecticidal powders, or applying the fumes of lethal gases. For the composition of the numerous fungicides and insecticidal preparations, reference should be made to the following principles generally applied. The poison must not be strong enough to injure the roots, leaves, &c., of the host-plant, or allowed to act long enough to bring about such injury. Care and intelligence are especially needful with certain unctuous or poisonous gases, or the operators may suffer. It is worse than useless to apply drastic remedies if the main facts of the life-history of the pest are not known; e.g., the application of ordinary antiseptics is useless with the decaying pseudostems of Stiltage, or Ustilago, is growing can only result in failure, and similarly if tobacco fumes, for instance, are applied when the insects concerned congregate in the green bottoms. Similar applications at the moment when spores are dispersed on the surface, say to Peronospora, or to the young mycelia of ephemeral parasites, e.g. Erysiphe, or the steeping in hot water of thoroughly ripe hard grains to stop insect invasion, or the slitting of bean plants in pots, with hydrocyanic acid gas when young insects are commencing their ravages, e.g. Red-spider—all these and similar procedures timed to catch the pest at a vulnerable stage are intelligent and predictable prophylactic measures, as has been repeatedly shown.

Numerous special methods of preventing the spread of Fungi, or the migrations of insects, or of trapping various animals; of leaving infested ground fallow, or of growing another crop useless to the pests; of inclosing and sealing off ground thoroughly; or of producing indirect methods, such as the grafting of less resistant scions on more vigorous stocks, of raising special late or early varieties by crossing or selection, and so on, have also met with success; but it is not to such methods as such that the future means of control means that some peculiarity of quick growth, early ripening or other life-feature in the plant is for the time being taken advantage of. A steady constant interest in fresh means of stopping or removing against epidemic pests is that of introducing other epidemics among the pests themselves—e.g. the infection of rats and mice with disease bacilli, or of locusts with insect-killing Fungi, and similar methods. That the encouragement of insectivorous birds has been profitable is well established, and it is equally well-known that their destruction may lead to disastrous insect plagues.

Symptoms.—The symptoms of plant diseases are, as already said, apt to be very general in their nature, and are sometimes so vaguely defined that little can be learned from them as to the causes at work. We may often distinguish between primary symptoms and secondary or subordinate symptoms, but for the purposes of classification in an article of this scope we shall only attempt to group the various cases under the more obvious signs of disease exhibited.

Diseases are among the commonest of all signs that a plant is "sickly." The progression of the disease is often marked by the presence of one symptom while another is still in a secondary stage. Discolorations, in particular, are often a consequence of many other conditions. Over-transpiration (Etiolation), as seen in geraniums kept in too warm a situation, and is then accompanied by soft tissues, elongation of internodes, leaves usually reduced in size, &c. The laying of a dead leaf on the ground will sometimes cause young leaves to follow a temperature, often seen in young wheat in cold springs. Cases of pallor due to too intense illumination and destruction of the chlorophyll may also be distinguished. Chlorosis is a form of pallor where the leaves steadily turn yellow in patches, and are often found to contain iron, and can be cured by adding ferrous salts. Lack of other ingredients may also induce chlorotic conditions. Yellowing is a symptom of a great variety of causes. If accompanied by wilting may be due to drought. Over-transpiration in bright wintry weather, when the roots are not absorbing, often results in yellowing. In other cases the presence of insects, Fungi or poisons at various points, may be looked for. Albinism, with which variegated foliage may be considered, concerns a different set of causes, still obscure, and usually regarded as internal, though experiments go to show that some variegations are infections.

Albinism, with which variegated foliage may be considered, concerns a different set of causes, still obscure, and usually regarded as internal, though experiments go to show that some variegations are infections.

Diseases and Symptoms.—The symptoms of plant diseases are, as already said, apt to be very general in their nature, and are sometimes so vaguely defined that little can be learned from them as to the causes at work. We may often distinguish between primary symptoms and secondary or subordinate symptoms, but for the purposes of classification in an article of this scope we shall only attempt to group the various cases under the more obvious signs of disease exhibited.
wounds due to plants which entwine, pierce or otherwise materially injure trees, &c., on a large scale.

Excrescences, more or less abnormal in character, are frequent signs of diseased organs. They are due to hyper-
trophy of young tissues, which may undergo profound alterations subsequently, and occur on all parts of the plants. The injury which initiates their formation is often abrupt, puncture or Fungus infection—but the minute wound or other disturbance, instead of healing over normally, is frequently maintained as a permanent irritation of the cells by fungi. These fungi, which are found on the woody stem, branches, &c., and themselves sometimes woody, of which Burs of various kinds afford common illustrations. Among the simplest examples of the former are the hairs which follow the irritation of the cells by mites. These hairs, which often occur in tufts, and are so coloured and arranged that they were long taken for fungi and placed in the "genus" Erineum. Cecidia or galls arise by the hypertrophy of the subepidermal cells of a leaf, cortex, &c., which has been pierced by the ovipositor of an insect, and in which the egg is deposited. The irritation set up by the hatching egg and its resulting larva appears to be the stimulus to development, and not a poison or enzyme injected by the insect. The extraordinary forms, colours and textures of the true galls have always formed some of the most interesting of biological questions, for not only is there definite co-operation between the gall and the insect, but the gall may show signs that the same insect may induce galls of different kinds on different plants or organs, while different insects induce different galls on the same plant—e.g. the numerous galls on the oak—but the gall itself may be divided into the outer or external galls, nourishment to its particular larva, and often appears to be borne without injury to the plant. This latter fact is no doubt due to the production of an excess of plastic materials over and above which is the usual condition by the gall-maker himself; in other cases,—technically Cecidia—are not always due to insects. The nodules on the roots of leguminous plants are induced by the presence of a minute organism now known to be an injury to the plant. Those on turpials and other Cruciferae are due to the infection of Plasmodiophora, a dangerously parasitic Myxomycete. Nodules due to "cel-worms" (Nematodes) are produced on numerous plants; but in general there is a variety of galls on tomatoes, cucumbers, &c., and the only too well known Phyloxera, which cost France and other vine-growing countries many millions of dollars, is another case in point. Fungus-galls on leaves and stems are commonly pockets, formed by the fungus, as in the black blistering swellings of Ustilago Maydis, the yellow swellings on nettles due to Acidanthera, &c.

In many cases the swellings on leaves in minute, and may be termed disease growths induced by the use of Agrophyrum, Protheca, Cyanospora, many Ustilagineae, &c. These cases are not easily distinguished superficially from the pustular outgrowth of actual mycelia and spores (stromata) of such fungi as Nectria, Puccinia, &c. The cytoplasm of the cells in some cases due to Ckev-, Ustilago-, Pyrenopeziza, &c., is also been here, and the tyro may easily confound with these the layers and cushions of eggs laid on similar organs by some other forms. The occurrence of gall-like swellings in plants, which no external cause has as yet been determined, and which are therefore often ascribed to internal causes of disease. Such are the cork-warts on elms, maples, &c., and the class of outgrowths known as Intumescences. Recent research points to definite external conditions of moisture, affecting the processes of respiration and transpiration and, &c., as being responsible for some of these. The "scar" of potatoes is another case in point. Frost blisters are particular swellings due to the upgrowth of callus-tissue into cavities caused by the uprising of the superficial cortex under the action of intense cold.

Turning now to outgrowths of a woody nature, the well-known fusco, common on elms and other trees are cases in point. They are due to some injury—e.g. bruising by a cart-wheel, insects—having started a callus on which adventitious buds arise. From the point of bases of buds thus formed, of food-material being accumulated at the injured place, other buds arise at the base of or around the injured one. If matters be propitious to the development of these buds, then a tuft of twigs will appear; but it is often arrested at an early stage, new buds are again formed, and in larger numbers than before, and the continued repetition of these processes leads to a sort of conglomerate woody mass of fused bud-bases, not connected with the living cambium. The outward growth is crowded portion of woody material as it slowly grows. There are many varieties of burs, though most woody outgrowths of old trees are not to be confounded with them, e.g. the knot of Taxodiaceae, the burls of American chestnut, and the "witches'-brooms", with all the twigs astray to extremely short outgrowths. Witches' burls are the tufted bunches of twigs found on silver fir, banches and other trees, and often present reminiscences to birds' nests or clumps of wiselike. It only seen from a distance.

They are branches in which a perennial Fungus (Aecidium, Esoa, &c.) has obtained a hold. This Fungus stimulates the main twig to grow, and after the death of the main twig, new twigs arise each year. The burl is simply made of each incipient twig and stimulates it to a repetition of the process, and so in the course of years large brolm-like tufts result, often many miles in diameter. But undoubtedly the most interesting of the woody excrescences on trees are cankers. A canker is the result of repeated frustrated attempts on the part of the callus to heal up a wound. If a clean wound is made in the wood, and the cambium and the insect is killed, the callus is able to cover over it, and in this callus—regenerative tissue—new wood, &c., soon forms, and if the wound was a small one, no trace is visible after a few years. But the oculating callus is a mass of delicate islets of living protoplasm, and the Fungus is able to work into this callus and make it the source of other &c., and the new tissues as they are formed, results in irregular growths; the still uninjured cambium area goes on thickening the branch, and in some cases, remain unthickened, and the portion in which the Fungus is at work may for the time being grow rapidly. Such cankers often commence in mere insect punctures, frosted buds, cracks in the cortex, &c., into which a germinating spore enters. The seriousness of the damage done is illustrated by the ravages of the larch disease, apple canker.

Exudations and Rotting. The outward symptoms of many diseases consist in excessive discharges of moisture, often accompanying the presence of a disease. Leaking ducts, such as a disease, fill both the tissue and the ducts, and the liquid in the ducts is thus unable to reach the remainder of the plant, and the condition is termed "leaking." The commonest examples of leakage of this kind are the exudations of algae and bacteria from wounds, as e.g. Aphides—and may be easily penetrated by certain Fungi such as Pescas, Nectria; and when thus attacked, the repeated conflicts between the cambium and the callus, on the one hand, trying to heal over the wound, and the infecting Fungus by mitotic or spore formation, results in irregular growths; the still uninjured cambium area goes on thickening the branch, and the cambium is finally occluded, resulting in the death of the branch, and in some cases, remain unthickened, and the portion in which the Fungus is at work may for the time being grow rapidly. Such cankers often commence in mere insect punctures, frosted buds, cracks in the cortex, &c., into which a germinating spore enters. The seriousness of the damage done is illustrated by the ravages of the larch disease, apple canker.

Honey-dew. The sticky condition of leaves of trees—especially lime—hot weather is owing to exudations of sugar. In many cases the flow of honey-dew is known as the cycle of Cocks, and is of immense importance for such exudations, and at least one instance is known where a Fungus—Claviceps—causes it. But it also appears that honey-dew may be excreted by ordinary processes of over-turgescence precipitating the sugar as a liquid at the usual points. Eriophyes, or Calendula, and Calendula, &c., that these exudations on leaves should afterwards serve as pabulum for Fungi—e.g. Pumago, Antennaria—so not surprising, and the leaves of limes are often black with them.

Flux.—A common event in the exudation of turbid, frothing liquids from wounds in the bark of trees, and the odour of putrefaction, and even alcohocal fermentation in these are sufficiently explained by the coexistence of albuminous and saccharine matters with fungi, yeasts and bacteria in such fluids. It is clear that in these cases the obvious summer—the flux—not is the primary cause. Some wound in the succulent tissues has become infected by the organisms referred to, and their continued action prevents healing. At certain seasons the wound "bleeds," and the organisms—some of which, by the way, are remarkable and interesting forms—are rapidly disposed of. The flux is not like the subsiding of a tumour, in fact, very like that of the fermentation of palm wine and pulque, where the juices are obtained from artificial cuts. Comparably with these cases is that of Cuckoo-spl, due to the juices sucked out by Aphrophora on herbaceous plants of all kinds. Outflow of resin—Resinos—also come under this general heading; but although some resin-fluxes are traced to the destructive action of a particular fungus, and others, or still, to the conditions as well as certain forms of Gummosis, are still in need of explanation.

BACTERIOSIS.—Many of the plant diseases involving rot have been ascribed to the action of bacteria, and in some cases—e.g. cabbage—rot, a disease of hairy roots, each conidiophore of another, &c., that bacteria are causally connected with the disease. It is not sufficient to find bacteria in the rotting tissues, however, nor even to be successful in infecting the plant through an artificial wound, though such special species of bacteria as occur in the alleged cases of bacteriosis the saprophytic bacteria in the tissues are to be regarded as merely secondary agents.

6. NERosis.—A number of diseases the obvious symptoms of which are the local drying up and death of tissues, in many cases
with secondary results on organs or parts of organs, may be brought together under this heading. No sharp line can be drawn between these diseases and some of the inauspicious, inasmuch as it often depends on the internal conditions whether necrosis is a dry-rot, or a wet-rot, in the sense I employ the term dry-rot, when it would come under the preceding category. The "dying back" of the twigs of trees and shrubs is a frequent case. The cortical tissues gradually shrink and dry out, turning brown and black in patches or all over, and when at length the whole stem rots and may tissues dry up the whole twig dies off. This may be due to frost, especially in "thin-barked" trees, and often occurs in beeches, peach trees, or it may result from the erosion by wind and hailstones, gun-shot wounds in covers, &c., the latter of course less frequent. It is the common result of fires passing along too rapidly to burn the trees; and "thin-barked" trees—hornbeam, beech, firs, &c. —may be burned in this manner. Sometimes the cortical tissues die back to the south-west after the removal of shelter. The effects of frost and of sunburn are frequently quite local. The usual necrosis of the cortex occurs—drying up, shrivelling, and consequent stretching and cracking of the dead cortex on the wood beneath. Such frost-cracks, sun-cracks, &c., may then be slowly healed over by callus, but if the conditions for necrosis recur the crack may be again opened, or if Fungi, &c., interfere with occlusion, the healing is prevented; in such cases the local necrosis may give rise to cankers. The dying back of twigs may be brought about by many causes. General attacks of leaf-diseases invariably lead to starvation, and the fructifications of Fungi, parasitic caterpillars, and other insects. Drought and consequent defoliation result in the same, and these considerations help us to understand how old-established trees in parks, &c., apparently in good general health, may become attacked with "dying back." Such attacks may involve the twigs and smaller branches: the roots have here been penetrated into subsoil or other unsuitable medium, or some drainage scheme has deprived them of water, &c., and a dry summer just turns the scale. Such phenomena are by no means uncommon, when we consider their roots under pavement or other impervious covering do well for a time, but suddenly fail to supply the crown sufficiently with water during a dry summer.

Monstrosities.—A large class of cases of departure from the normal form, depending on different and often obscure causes, may be grouped together under this heading; most of them are of the vegetable kingdom, and it is an impertinent matter to decide how far they should be regarded as pathological if we insist that a disease threatens the existence of the plant, since many of these malformations—e.g., double flowers, phylloidy of floral parts, contortions and fascinations, dwarfishness, &c., may be transmitted in cultivation, but occur in nature without evident injury to the variety. In many cases, however, monstrosities of flowers have been shown to be due to the irritating action of minute insects or Fungi, and others are known which, although induced by causes unknown to us, and regarded as internal, would not be likely to survive in the wild condition. This subject brings the domain of pathology, however, into touch with that of variation, and we may expect the systematic naturalist to make complete investigations of the causes and conditions which would decide in any given case how far a variation in form would be prejudicial or otherwise to the continued existence of a species. Under the head of malformations we place cases of abnormal development, e.g., dwarfing. The question of the origin of Fungi or minute insects, the presence of unsuitable food-materials and so on, as well as cases of transformation of stamens into petals, conversion of broad leaves into narrow ones, &c., may be considered in the same manner. The damage done by the eating or otherwise distorted by mechanical obstacles; stems by excess of food in rich soils, the attacks of minute parasites, oversight by climbing plants, &c. Leaves are especially apt to vary, and although the formation of crests, pitchers, puckers, &c., must be put down to the results of abnormal development, it is often difficult to draw the line between teratological and merely varietal phenomena. For instance, the difference between the long-stalked and short-stalked varieties of plants is a mere matter of degree; and it is impossible to draw the line between the more or less submergent leaves of many Umbelliferae or the submerged and floating leaves of an aquatic Ranunculus or Cabomba. When we come to phenomena such as proliferations, vivipary, the development of "Lammas flowers," adventitious buds, epicormic branches, and to those malformations of flowers known as peloria, phylloidy, virescence, &c., while assured that definite, and in many cases recognizable, physiological disturbances are at work, we find ourselves on the borderland between the strictly physiological and the pathological, and what we are doing must be examined with due regard to all the circumstances, and no generalization seems possible beyond what has been sketched. The subject of monstrosities, especially the phenomena of apogamy, is exposed in the light of recent researches into the effects of external conditions on reproduction.

This sketch of an enormous subject shows us that the pathology of plants is a special department of the study of variations which threaten injury to the plant, and passes imperceptibly into the study of variations in general. Moreover, we have good reasons for inferring that different constellations of external causes may determine whether the internal pathological disturbances induced by them will lead to pathological and dangerous variations, or to changes which may be harmless or even advantageous to the plant concerned.

subdivided plant geography into floristic plant geography and ecological plant geography. The former is concerned with the division of the earth's surface into major districts characterized by floristics—taxonomic ecography. The subdivision of plants—the geographic distribution (both past and present) of the various taxonomic units, such as species, genera, and families. On the other hand, ecological plant geography seeks to ascertain the distribution of plant communities, such as associations and formations, and enquires into the nature of the factors of the habitat which are related to the distribution of plants—plant forms, species, and communities. In a general way, floristic plant geography is concerned with species, ecological plant geography with vegetation. The study of the distribution of species dates back to the time of the early systematists, the study of vegetation to the time of the early botanical travellers. Humboldt, for example, described his view of the scope of plant geography as follows: "C'est cette science qui considère les vegetaux sous les rapports de leur association locale dans les differents climats" (1807: 14).

The Habitat.—The term habitat, in its widest sense, includes all the factors of the environment which affect a plant or a plant community, though the term is frequently used to signify only some of these factors. The factors of the habitat may be grouped as follows: geographical, physical, and biological.

Geographical Factors.—Geographical position determines the particular species of plants which grow in a given locality. This matter is bound up with the centres of origin and with the past migrations of species; and such questions are usually treated as a part of floristic plant geography. Here, therefore, floristics and geography are closely connected. Schimper, in defining the term habitat, appears to exclude all geographical factors. They state that "the term habitat is understood to include everything relating to the factors operating in a geographically defined locality, so far as these factors are concerned with plants (1910: 24) but the exclusion of geographical and historical factors from the concept of the habitat does not appear to be either desirable or logical.

Edaphic factors are frequently classified as edaphic or soil factors and climatic factors; but there is no sharp line of demarcation between them. Edaphic factors include all those relating to the soil. The water content of the soil, its mineral content, its humus content, its temperature, and its physical characteristics, such as its depth and the size of its component particles are all edaphic factors. Climatic factors include all those relating to atmospheric temperature, rainfall, atmospheric humidity, and the like. The action of wind is also a climatic attitude. Excess exposure to winds are also climatic: such are often spoken of as physiological factors. The difficulty of sharply delimiting edaphic and climatic factors is seen in the case of temperature. Soil temperature is dependent on direct radiation, which is partly on the colour and constitution of the soil, and partly on the water content of the soil. Again, the temperature of the air is affected by radiation from the soil; and radiation differs in various soils.

Biological Factors.—These include the rections of plants and animals on the habitat. Here again, no sharp boundary-line can be drawn. In one sense, the accumulation of humus and peat is a biological factor, as it is related to the work of organisms in the soil; but the occurrence or otherwise of these organisms in the soil is probably related to definite edaphic and climatic conditions. Again, the well-known action of earthworms may be said to be a biological work; but the resulting aeration of the soil causes edaphic differences; and earthworms are absent from certain soils, such as peat. Again, the pollination of flowers and the dispersal of seeds by various animals are biological factors, but their pollination and dispersal by the wind cannot be so regarded. The influence of man on plants and vegetation is also a biological factor, which is frequently ignored, and treated as such, if it were a thing apart.

When the nature and effect of ecological factors have become more fully understood, it will be possible to dispense with the above artificial classification of factors, and to frame one depending on the nature of the factors involved. Such a classification is not possible in the present state of knowledge.

Ecology and Physiology.—Whilst our knowledge of the nature and effect of habitat is still in a very rudimentary condition, much progress has been made in recent years in the study of plant communities; but even here the questions involved in relating the facts of the distribution of plant communities to the factors of the habitat are very imperfectly understood. This is due to a lack of precise knowledge of the various habitat factors and of the facts of responses made by plants to these factors. Until much more advance has been made by ecologists in the investigation of the nature of habitat factors, and until the effect of the factors on the plants has been more closely investigated by physiologists, it will remain impossible to place ecology on a physiological basis: all that is possible at present is to give a physiological bias to certain aspects of ecological research. Obviously no more than this is possible until physiologists are able to state much more precisely than at present what is the influence of common salt on the plants of salt-marshes, of the action of calcium carbonate on plants of calcareous soils, and of the action of humous compounds on plants of fens and peat mires.

Ecological Classes.—Many attempts have been made to divide plants and plant communities into classes depending on habitat factors. One of the best known classifications on these lines is that by Warming. Warming recognized and defined four ecological classes as follows:

Hydrophytes.—These live in a watery or wet substratum, with at least 80% of water. Warming included plants of peat-bogs among his hydrophytes.

Xerophytes.—These plants which live in very dry places, where the substratum has less than 10% of water.

Halophytes.—These are plants living in situations where the substratum contains a high proportion of sodium chloride.

Mesophytes.—These plants which live in localities which are neither specially dry nor specially wet nor specially salty.

Such terms as hydrophytes, xerophytes, and halophytes had been used by plant geographers before Warming's time e.g., by Schouw, and the terms evidently supply a want felt by botanists as they have come into general use. However, the terms are incapable of exact definition, and are only useful when used in a very general way. The above classification by Warming, although it was without doubt the best ecological classification which had, at the time, been put forward, has not escaped criticism. The criticisms were directed chiefly to the inclusion of sand dune plants among halophytes, to the exclusion of halophytes from xerophytes, to the inclusion of "bog xerophytes" among hydrophytes, to the inclusion of all conifers among xerophytes and of all deciduous trees among mesophytes, and to the group of mesophytes in general.

Schimper made a distinct advance when he distinguished between physical and physiological dryness or wetness of the soil. A soil may be physically wet; but if the plants absorb the water only with difficulty, as in a salt marsh, then the soil is, as regards plants, physiologically dry. All soils which are physically dry are also physiologically dry; and hence only the physiological dryness or wetness of soils need be considered in ecology.

Schimper used the term xerophytes to include plants which live in soils which are physiologically wet or damp. Schimper recognized that the two classes are connected by transitional forms, and that it is useless to attempt to give the matter a statistical basis. It is only in a general sense like Schimper's that such ecological terms as xerophytes have any value; and it is not possible, at least at present, to frame ecological classes, which shall have a high scientific value, on a basis of this nature. Whilst Schimper objected to the constitution of a special category, such as mesophytes, to include all plants which are neither pronounced xerophytes nor pronounced hydrophytes, he recognized the necessity of a third class in which to place those

1 Humboldt and Bömmel, Essai sur la géographie des plantes (Paris, 1807).
2 Flahaut and Schröter (op. cit.).
plants which, like deciduous trees and bulbous plants, are hydrophytes during one season of the year and xerophytes during another season of the year. Such plants, which may be termed phanerophytes, occupy a greater mass of the flora than any other group—indeed the majority of the species of the central European flora, Schimper termed tropophytes.

Recently, Warming (1909: 136), assisted by Vahl, has modified his earlier classification, and adopted the following:

A. The soil (in the widest sense) is very wet, and the abundant water is available to the plant (at least in hydrophytes).

1. **Hydrophytes.**—These include plants of the plankton, or microphytes, that float free in water, or the epiphytes, or microphytes, which float on or are suspended in water, and of the benhos, or all aquatic plants which are fixed to the substratum.

2. **Nepophytes.**—These are more or less terrestrial plants which normally have their roots in soil but whose branches and foliage are more or less aerial. Warming admits there is no sharp limit between marsh plants and land plants; and it seems equally obvious that there is no sharp line between some of his helophytes and some of his hydrophytes. For example, the difference between aquatic plants with floating leaves, such as the yellow-water-lily (Nymphaea lutea) and those with erect leaves, such as Typha angustifolia, is probably more apparent than real. Among helophytes, Warming places reed plants of the reed swamp, and includes such trees as the elder (Alinus rutundifolius), willows (e.g. Salix alba, S. fragilis, S. cinera, S. caprea, and pine), when these grow in marshy places.

3. The soil is probably hydrophytologically.

3. **Oxylphytes.**—These plants, sometimes spoken of as "bog xerophytes," grow in soils which contain an abundance of free humus compounds, and include plants which grow on fens and moors.

4. **Psychrophytes.**—These include the plants which grow on the cold soils of subarctic and polar districts.

5. **Halophytes.**—These are plants which grow on saline soils.

6. **Lithophytes.**—These are plants which grow on the rocks, or free from soil on cliffs and mountains.

7. **Psammophytes.**—These are plants that grow on sand and gravel, and may be associated with halophytes in saline areas.

8. **Xerophytes.**—Here are placed certain "xerophytic perennial herbs" which occur on "particular dry kinds of soil, such as limestone rocks, stiff clay, and so forth" (Warming, 1909: 286).

9. The climate is very dry, and the properties of the soil are determined by clay or earth.

10. **Eremophytes.**—Under this term, are placed plants of deserts and steppes.

11. **Psilophytes.**—Here are placed plants found in "sandy vegetation," viz., (i.) "thorny sand vegetation," including: (a) orchard-scrub, (b) thorn-bushland and thorn-forest; (ii.) true savannah: tropical and sub-tropical savannah; (iii.) savannah-forest, including birch-forest in Africa and ' campos serrados ' in Brazil" (Warming, 1909: 287 et seq.).

12. **Sclerophyta formations.** e.g., garigue, maquis, and forests of evergreen oaks (Q. Ilex, Q. Ballota, Q. Suber), and of Eucalyptus spp.

E. The soil is physically or physiologically dry.

1. **Coniferous forest formations.** e.g., of Pinus sylvestris, Picea excelsa, Abies pectinata, Larix sibirica, L. decidua.

F. "Soil and climate favour the development of mesophytic formations.

16. **Mesoophytes.**—Warming defines mesophytes as "plants that show a preference for soil and air of moderate humidity, and avoid soil with standing water or containing a great abundance of salts" (1909: 317). Under mesophytes, Warming places plants occurring in "Arctic and Alpine mat-grassland and mat-herbage," in "mat-vegetation of the Alps," in meadows, in pasture on cultivated soil, in "mesophytic bushland," in deciduous dicotyledonous forests, and in evergreen dicotyledonous forests.

This new system of Warming's, whilst probably too involved ever to come into general use, must be taken as superseding his older one; and perhaps the best course open to botanists is to select such terms as appear to be helpful, and to use the selected terms in a general kind of way and without demanding any precise definitions of them: it must also be borne in mind that the various classes are neither mutually exclusive nor of equivalent rank. From this point of view, the following terms will perhaps be useful:

Hydrophytes (submerged aquatic plants).—Plants whose vegetative organs live wholly in water; e.g., most Algae, many mosses, such as Fontinalis spp., and liverworts, such as Juncaginaria spp.; a few Pteridophytes, such as Pilularia spp., Isoles spp.; several flowering plants, such as Sparganium, Ceratophyllum spp., Halotonia palustris, Utricularia spp., Littorella lacustris.

Hemi-hydrophytes (swamp plants, marsh plants, &c.).—Plants which are more or less submerged or partly submerged and partly aerial; Vaucheria terrestris, Philonotis fontana, Scapania undulata, Mar silia spp., Sabina nitens, Azolla spp., Equisetum limosum, Typha angustifolia, Phragmites communis, Scirpus lacustris, Nymphaea alba.

Hygrophytes.—Plants which are sub-evergreen or evergreen but not sclerophyllous, and which live in moist soils; e.g., Lastraea Fistula, Pera prostrata, Carex ovata, Pilularia lanceolata, and Adiantum Filifolium.

Xerophytes.—Plants which grow in very dry soils; e.g., most lichens, Ammophila (Psama) arenaria, Elymus arenarius, An abasis artemioides, Zolla media, Sedum acre, Butelium spinosum, Artemisia herbacea, Zostiloba arborescens.

Halophytes.—Plants which grow in very saline soils; e.g., Triglochin maritimum, Salicornia spp., Zygophyllum corymbosum, Aster tri lepis, Artemisia maritima; it should be mentioned here, however, that "a halophyte, in fact, is one form of xerophyte" (Warming, 1909: 219).

Sclerophytes.—These are plants with evergreen leathery leaves, typical of tropics, sub-tropics, and Mediterranean regions; e.g., Quercus Suber, Ilex Aquifolium, Hedera Helix, Eucalyptus Globulus, Rosmarinus officinalis. Sclerophyllous leaves are usually characterised by either sub- or sub-margin, a thick cuticle, small stomata, which are rarely present on the lower side of the leaf, close-set palisade tissue and a feeble system of air-spaces.

Hydro-xerophytes ("bog xerophytes").—Plants which live in wet, peaty soils, and which possess aerenchyma and xerophy lous leaves; e.g., Cladium Mariscus, Erophorum angustifolium, Rubus Chamaemorus, and Vaccinium Viitis-Idaeae. The term "xoxylo phyte" is open to the objection that some peaty waters are alkaline, and not xerophytic as the term implies. Many plants of peaty soils are sclerophyllous.

Tropophytes.—Plants which are hydrophytes during some favourable part of the year and xerophytes during the rest of the year; e.g., various tropical trees and shrubs, deciduous herbaceous plants with underground perennating organs, and annuals and ephemerals.

Plant Communities.—The study of plant communities (Formation dehors or synecology) has made much progress in recent years. Even here, however, general agreement has not been reached; and the questions involved in relating the facts of the distribution of plant communities to the factors of the habitat are very imperfectly understood. Plant communities may be classified as follows:

A **Plant association** is a community of definite floristic composition: it may be characterized by a single dominant species; or, on the other hand, it may be characterized by a number of partners of different species; or is associated with an undergrowth, which, whilst elsewhere two or more species may share dominance. The former are pure associations, and are well illustrated by a heather moor, where Calluna vulgaris is the dominant plant. The latter are mixed associations, such as fens, where different facies are produced by the varying abundance of characteristic plants, such as Cladium Mariscus, Phragmites communis, Molinia coerulea, Calamagrostis lanceolata, and Juncus effusus. The different facies are possibly related to slight differences in a generally uniform habitat: it is unscientific to regard them as due to chance; still, in the majority of cases, the causes of the different facies have not been demonstrated. A local aggregation of a species other than the dominant one in an association brings about a plant society; for example, societies of Erica Tetralis, of Scirpus caspia, of Molinia coerulea, of Carex curta, of Narthecium ossifragum, and others may occur within an association of Calluna vulgaris. The plant societies are also doubtless due to slight variations of the habitat.

The plant association is sometimes referred to in technical language; the termination -etum is added to the stem of the generic name, and the specific name is put in the genitive. Thus

1 Warming (1909, op. cit.).
2 Ibid. (1904, op. cit.).
A plant formation is a group of associations occupying habitats which are in essentials identical with each other. Thus, associations of Agropyrum (Trisetum) juncetum, of Carex arenaria, of Ammophila (Pamano) arenaria, and of other plants occur on sand dunes: the associations are related by the general identity of the habitat conditions, namely, the physiological dryness and the loose soil; but they are separated by differences in floristic composition, especially by different dominant species, and by minor differences of the common habitat. The whole set of associations on the sand dunes constitutes a plant formation.

The plant formation may be designated in technical language by the termination -ion added to a stem denoting the habitat. Thus, a sand dune formation may be termed Anarenion. The associational term, in the genitive, may be added to the formational term to indicate the relationship of the formation and the association; thus, a plant association of Ammophila arenaria belonging to the plant formation of the sand dunes may be designated an Anarenion Ammophiliæ-arenariae (cf. Moss, op. cit. 1910: 43).

The question of universal names for vegetation units is bound up with that of the universality or otherwise of particular formations. Remote regions which are floristically distinct may have same presence of physically almost identical and not be covered by different formations” (Clements, 1905: 205). For example, the sand dunes of North America and those of western Europe are widely separated in geographical position and therefore in floristic composition, yet they are related by common physical factors. This relationship may be indicated by the addition of some prefix to the formational name. For example, an Anarenion in one climatic or geographical region might be termed an α-Anarenion and one in a different region a β-Anarenion, and so on (Moss, loc. cit.).

It is, however, frequently desirable to consider such allied formations as forming a single group. Such a group of formations may be designated a plan federation: and this term may be defined as a group of formations, which are characterized by common edaphic factors of the habitat, and which occur in any geographical region. Thus, different geographical or climatic regions are characterized by salt marshes. The latter all agree in their edaphic characteristics; but they differ climatically and in floristic composition. The salt marshes of a given region constitute a single plant formation: the salt marsh formations of the whole world constitute a plant federation.

Again, it is possible to arrange plant associations into groups related by a common plant term. Thus woodland associations may be classified as deciduous, coniferous, or evergreen forests, savannas, prairies, wetlands, grasslands, and so on. These, in a general way, are the formations of Warming, and (in part) the climatic formations of Schimper. Thus the various reed-swamps of the whole world constitute a “formation” in Warming’s sense (1900: 187).

There is much difference of opinion among ecologists and plant geographers as to which of these points of view is the most fundamental. Among British authorities, it is now customary to adopt the position of Clements, who states (1905: 292) that “the connexion between formation and habitat is so close that any application of the term to a division greater or smaller than the habitat is both illogical and unfortunate,” and that (1905: 18) “habitats are inseparable from the formations which they bear” (cf. Moss, 1910).

From the standpoint of plant communities, it is convenient to divide the earth’s surface into (1) tropical districts; (2) subtropical and warm temperate districts; (3) temperate districts; (4) cold temperate and frigid districts.

Tropical Districts. Tropical districts have been subdivided by Schimper (1903: 260, et seq.) as follows:—
(i) Tropical woodland: (a) rain forest, (b) monsoon forest, (c) savana forest, (d) thorn forest. (ii) Tropical grassland: (a) steppes and steppic desert: (b) scrub, (c) succulent plants, (d) perennial herbs.

Schimper regards the minor divisions as groups of “climatic formations” and distinguishes certain tropical “edaphic formations,” such as mangrove swamp, dunes, and rain forests and high monsoon forests in the tropics occur when the average rainfall is 70 in. (178 cm.) per annum, and that tropical forest may prevail when the mean annual rainfall is below 35 in.

A tropical rain forest exhibits great variety both of species of plant and of plant forms. There is great diversity in the trees and bushes of tangled lianas, and a wealth of flowers in the leafy forest crown. Humboldt 2 points out that whilst temperate forests frequently furnish pure associations, such uniformity of association is usually absent from the tropics. Some tropical forests exhibit dense foliage from the forest floor to the topmost leafy layer; and the traveller finds the mass of foliage almost impenetrable. Other tropical forests afford a free passage and a clear outlook. It is obvious that tropical forests will eventually be subdivided into plant associations; but the difficulties in determining the relative abundance of the species of plants in the upper layers of tropical rain and monsoon forests are very great. One reason is the great struggle for light which takes place in tropical forests is the number of epiphytic plants which grow on the high branches of the trees.

The leaves of the trees are frequently leathery consistency, very long usually, and closely packed, and thus they agree closely with the leaves of sclerophyllous forest generally.

Monsoon forests are characterized by localities with a seasonal rainfall. The trees keep their foliage during the dry season and renew it during the monsoon rains. With a less abundant rainfall, savana forest and thorn forest occur. Less precipitation induces tropical grassland, which, according to Schimper (1903: 279), is found in the savana region, and in the montane and alpine regions all grassland in the tropics is artificial. Still greater drought induces desert vegetation; but, as deserts are characteristic of the drier districts, they are described later on.

Mangrove swamps, or tropical tidal forests, occur in saline or brackish swamps on flat, muddy shores in the tropics; and, being almost independent of atmospheric precipitations, Schimper regards them as “edaphic formations.” However, they are climatic communities in the sense that they occur only in hot districts. Cases such as this illustrate the difficulty of regarding the distinction between "climatic formations" and "edaphic formations." The plant association of mangrove swamps, and many of the fruits and seeds of the mangrove trees and shrubs are provided with devices to enable them to float and with curious pneumatophores or prop roots. The latter serve as supports and aids to the plant in means of floating air to the parts below water. The seedlings of characteristic species of Rhizophoraceae germinate on the trees, and probably perform some assimilative work by means of their hypocotyl.

Other tropical "edaphic formations" occur on sandy shores, where the creeping Ipomoea biloba (Pes-caprae) and trees of Barringtonia form characteristic plant associations.

The succession of associations on new soils of a tropical shore has recently been described by Ernst. 3

2. Warm Temperate and Subtropical Districts.—In subtropical and warm temperate districts, characterized by mild and rainy winters and hot and dry summers, we find two types of forests. First, there are forests of evergreen trees, with thick, leathery leaves. Such forests are known as sclerophyllous forests, and they occur in the Mediterranean region, in south-west Africa, in south California, in certain parts of Chile, and in eastern South America. In the Mediterranean district, forests of this type are sometimes dominated by the Cork Oak (Quercus Suber), sometimes by the Holm Oak (Q. Iliae). When these forests become degenerate, maquis and garigues respectively are produced. Maquis and garigues are characterized by the abundance of shrubs and under-shrubs, especially by shrubby Leguminous plants, and by species of dry savannas. Secondly, there are forests of deciduous trees. In the Mediterranean region, even comparatively low altitudes, forests occur of the maritime pine (Pinus maritima) and of the Aleppo pine (P. halpensis); and these forests are also widespread in Russia and Asia, and in the districts bordering on the evergreen oaks. The occurrence of forests of this type in the Mediterranean and in Arctic regions, whose dominant species belong to the same genus (Pinus) and to the same plant form, renders it probable that the association or plant community is determined by conditions of climate, rather than by the race of the dominant species of tree.

difficult to regard "coniferous forests" as a natural ecological group. At much higher altitudes, in the south-west of the Mediterranean region, there occur a number of coniferous species such as Cedrus atlantica. These occur from about 4000 ft. (1219 m.) to about 8000 ft. (2438 m.) on the Atlas Mountains. Some sclerophyllous forests of the eastern Atlantic Mountains are, owing to a comparatively high rainfall, characterized by a deciduous, often large-leaved vegetation such as Quercus phylla, Ulmus campestris (auct. alg.), Alnus rotundifolia, Salix pendiculata, Prunus avium, &c.; and thus they have some elements in common with the deciduous forests of central Europe.

These Mediterranean montane regions are situated near the sea or in mountainous regions, and (as already stated) are characterized by winter rains. In inland localities, where the rainfall is much lower, steppe occurs. For example, in southern Algeria, a region of steppe is situated on a flat plain about 3000 ft. (914 metres) high, between the southern slopes of the Tell Atlas and the northern slopes of the Saharan Atlas. The rainfall is so low that it is chiefly in the winter, and averages only about 10 in. (254 mm.) per annum. Here we find the plant associations of Halfa or Esparto Grass (Stipa tenacissima) alternating with steppes of Chil (Artemisia herba-alba); and each plant association extends for several miles of parallel strip. In the hollows of this steppe region, salt water lakes occur, known as Chotts; and on the saline soils surrounding the Chotts, a salt marsh formation occurs, with species of Salicornia, some of which are undershrubs.

Just as in the Mediterranean region, the occurrence of steppe occurs. At Khordia, in south-eastern Algeria, the mean annual rainfall, from 1887 to 1892, was about 41 in. (114 mm.). In 1890, it fell as low as 2 in. (53 mm.) (Schimper, 1903: 666). At Beji Ouled and Colomb Boudjemil, in south-western Algeria, 147 mm. was recorded. If all this rain had been there for about three years. Here the gravelly desert is characterized by "cushion plants," such as Anabasis arenaria, and by "cushion herbs," such as Draba retama, and by spiny plants, such as Zizyphus lotus and Zilla macrospinosa; whereas succulent plants are rare. Both in the steppe and in the desert, small ephemeral species occur on the bare ground away from the large plants and especially in the wadis. Steppe and desert formations are of the open type.

3. Temperate Districts.—The temperate districts are characterized by forests of deciduous trees and of coniferous trees, the latter being of different species from those of the warm temperate districts, but frequently of the same plant form. The identity of plant form of many of the conifers of both temperate and of warm temperate districts is probably a matter of phylogenetic and not of ecological import.

Britain is fairly typical of the west European district. In these islands, we find forests of oak or woods of oak (Quercus Robur and Q. sessiliflora), of birch (Betula lenta), of ash (Fraxinus excelsior), and of beech (Fagus sylvatica). In central Scotland, forests occur of Pinus sylvestris; and, in south-eastern England, extensive plantations and self-sown woods occur of the same species.

4. Oriental Districts and Frigid Districts.—In the coldest portion of the northern temperate zone, forests of dwarfed trees occur, and these occasionally spread into the Arctic region itself (Schimper, 1904: 688). Schimper distinguishes moss tundra, Polytrichum tundra, Pinus tundra, and the lichens and the spiny sub-Arctic (Cadaonia tundra, Flatysma tundra, and Aeletoria heart. Where the climate is most rigorous, rock tundra occurs (p. 685).

The types of vegetation (tropical forests, sclerophyllous forest, temperate forests, tundra, &c.) thus briefly outlined are groups of Schimper's "climatic formations." Such groups are interesting in that they are vegetation units whose physiognomy is, in a broad sense, related more to climatic than to edaphic conditions. For example, Schimper, after describing the sclerophyllous woodland of the Atlas district and of the Cape district, says: "The scrub of the West and South Africa in its ecological aspect resembles so completely the other sclerophyllous formations that a description of it must seem a repetition." This resemblance, however, only has reference to the general aspect or physiognomy of the vegetation and to the plant forms; the floristic composition of the various sclerophyllous—and other physiognomically allied—associations in the various geographical districts is very different; and indeed it is true that, just as the general physiognomy of plant associations is related to climate, so their floristic composition is related to geographical position. Hence, in any cosmopolitan treatment of vegetation, it is necessary to make the necessary from the standpoint of the climatic or geographical district in which they occur; and this

*As very little experimental work has been done with regard to physiological dryness in physically wet habitats, any classification such as the above must be of a tentative nature. 

1 See Moss, Rankin, and Tansley, "British Woodlands." Botany School (Cambridge, 1910.

Indeed is consistently done by Schimper. Finally, within any district of constant or fairly constant climatic conditions, it is possible to distinguish plant communities which are related chiefly to edaphic or soil conditions; and the vegetation units of these definite edaphic areas are the plant formations of some writers, and, in part, the "edaphic formations" of Schimper.

When a district like England is divided into edaphic areas, a general classification such as the following may be obtained:—

1. Physically and physiologically wet habitats, with the accompanying plant communities of large, free-swamp, and marshes.

2. Physically wet but physiologically dry habitats, with the accompanying plant communities of fens, moors, and salt marshes.

3. Physically and physiologically dry habitats, with the accompanying plant communities of sand dunes and sandy heaths with little humus in the soil.

4. Habitats of medium wetness, with the accompanying plant communities of fens and grasslands. This class may be subdivided as follows:

a. Habitats poor in mineral salts, especially calcium carbonate, often rich in acid humus compounds, and characterized by oak and birch woods, silicious pasture, and heaths with much acid humus in the sandy soil.

b. Habitats rich in mineral salts, especially calcium carbonate, poor in acid humus compounds, and characterized by ash wood, beech woods, and calcareous pasture.

Ecological Adaptations.—It is now possible to consider the ways in which the inhabitants of various plant communities show in a given geographical district such as modern Europe, of which England of course forms a part. In the present state of knowledge, however, this can only be done in a very meagre fashion; as the effect of habitat factors on plants is but little understood as yet either by physiologists or ecologists.

Hydrophytes and hemi-hydrophytes (aquatic plants).—Of marine hydrophytes, there are, in this country, only the grass-wracks (Zostera marina and Z. nana) among the higher plants. Even these species are sometimes left stranded by low spring tides, though the mud in which they are rooted remains saturated with sea-water. Although many plants typical of fresh water are able to grow also in brackish water, there are, of course, few species which are capable of the quite different type of adaptation. Such species perhaps include Ruppia maritima, R. spiralis, Zannichellia palustris, Z. polycarpa, Potamogeton interruptus (= P. flabelatus), and Najas marina.

In freshwater lakes and ponds, especially if the water is stagnant, aquatic plants are abundant. Aquatic vegetation may be conveniently classified as follows:

B. Aquatic plants with floating leaves: Glyceria fluitans, Nymphaea alba, N. coerulea, N. candida, (Nuphar) lutea, Calla trichocarpig, Potamogeton polygigynus.

C. Aquatic plants with floating leaves: Lemna spp., Hydrocharis Morsus-ranae, Casalia (Nymphoides) alba.

D. Aquatic plants with erect leaves or stems: Sagittaria sagittifolia, Scirpus lacustris, Hippuris vulgaris, Sium latifolium.

E. Aquatic plants with erect leaves or stems (reed swamp plants): Equisetum palustre, Phragmites communis, Glyceria aquatica, Carex riparia, Iris pseudacorus, Rumex Hydrolythophyllum, Oenanthe fistulosa, Bidens spp.

F. Marsh plants: Alopecurus geniculatus, Carex disticha, Juncus spp., Caltha palustris, Nasturtium palustre.

In many aquatic plants, the endosphere of the seed is absent or very scanty. The root-system is usually small. Root-hairs are frequently much reduced, or the roots are airless. In broad hollow. Strengthening tissue of all kinds (and sometimes even the phloem) is more or less rudimentary. The stems are frequently characterized by aeration channels, which connect the aerial parts with the submerged parts which are buried in practically airless mud or silt. Submerged leaves are usually filamentous or narrowly ribbon-shaped, thus exposing a large amount of surface to the water, some of them involving gases which they must absorb, and into which they must also excrete certain gases. Stomata are often absent. Absorption and excretion of gases in solution being carried out through the epidermal layer. Chloroplasts are frequently present in the epidermis as in some submerged plants. Many few aquatic plants are pollinated under water, but this is well known to occur in species of Zosteria and of Najas. In such plants, the pollen grains are sometimes filiform and not spherical in shape. The case of aquatic plants with aerial flowers is. Observe...
the ordinary laws of pollination. Heterophyll is rather common among aquatic plants, and is well seen in several aquatic species of Ranunculus, many species of Potamogeton, Sagittaria sagittifolia, Scirpus lacustris, Castalia (Nymphaea) alba, Hipposiphon vulgatus, and the like. Insectivorous species occur among aquatic plants; e.g. Utricularia spp., which are locally abundant in peaty waters, are insectivorous. Xerophytes. — These plants have devices (a) for procuring water, (b) for processing the water, or (c) for escaping from it. These adaptations are obviously related to the physically or physiologically dry habitats in which the plants live. Plants of physically dry habitats, such as deserts and the like, are frequently long tap-roots which double in some cases, reach down to a subterranean water supply. The same plants have sometimes a superficial root system and are able to utilize interstitial waters in raings. In species of Lapidaria, as Volkmann's maintains, the root-hairs of Salicornia possess this property. There has been, however, performed upon halophytes very little phylogenetically experimental work which commands general acceptance. Some xerophytes live in habitats which are physically wet, but which are said to be physiologically dry. Related to the physiological drought, such plants possess some xerophytic characters, relatively slight, but must be that these plants possess the aeration channels which characterize many hydrophytes and semi-hydrophytes. The occurrence of xerophytic characters in plants of this type has given rise to much difference of opinion. It is sometimes maintained, for example, by Schimpfer, that their xerophytic characters are related to the physiological dryness of the habitat: this, however, is denied by others who maintain (Clements, 1905: 127) that the xerophytism is due to the persistence of ancestral characters. It is possible, of course, that explanation is correct in particular cases, as the views are by no means mutually exclusive. With regard to the occurrence of plants, such as Juncus effusus, which possess xerophytic characters though they grow in water, it is possible, as mentioned above, that physiological dryness, it should be remembered that such habitats are liable to occasional physical drought; and a plant must eventually succumb if it is not adapted to the extreme conditions of its habitat. The xerophytic characters of these species are the same as those of many marsh plants, such as Juncus effusus and Iris pseudacorus, are able to survive in dry situations, such as banks and even garden rockeries.

Tropophytes. — These plants are characterized by being xerophytic during the unfavourable season. For example, deciduous trees shed their leaves in winter: geophytes go through a period of dormancy. Many of them, after shedding the leaves, may become permanent in the soil, and have no need for the maintenance of the plant tissues during the winter months. This may be a temporary state, but it is certainlyption that xerophytes are able to maintain themselves in dry conditions and are thus in a better position to survive the dry season than the more succulent forms. The xerophytes are characterized by their ability to survive in dry conditions and to make use of the available moisture in the soil. They are able to conserve water and to make use of the available moisture in the soil. They are able to survive in dry conditions and to make use of the available moisture in the soil. They are able to survive in dry conditions and to make use of the available moisture in the soil. They are able to survive in dry conditions and to make use of the available moisture in the soil.
PLANTS

scoparius, Polentilla procmanciae, Galium hercynicum (=G. saxatile), Gnaophila subtilicrum, Digitalis purpurea. Other plants occur indifferent both on calcareous and on non-calcareous soils.

Schimper said that lime acts as a poison on some plants and not on others, and sometimes that it is the physiological dryness of calcareous soils that is the important factor. In relation to this, it is pointed out that some markedly calcicole species occur on sand dunes; but this may be due to the lime which is frequently present in dune sand as well as to the physical dryness of the soil. Further, no theory of calcicole and calcifugous plants can be regarded as satisfactory which fails to accommodate the fact that both kinds of plants occur among aquatic as well as among terrestrial plants. Schimper (1903: 102) thinks that in the case of aquatic plants, the difference must depend on the amount of lime in the water, for the physical nature of the substratum is the same in each case. Again, acidic humus does not form in calcareous soils; and hence one does not expect to find plants characteristic of calcicolous peat or humus on calcareous soils. Some such species are Blechnum, Adiantum, Flexia, Calluna vulgaris, Vaccinium, Myrtillus, Rubus, Chamaenerion, Empetrum nigrum, Drejera spp. Some, at least, of these species possess mycohiza in their roots, and are perhaps unable to live in soils where such organisms are absent.

In England, the number of calcicoles species is greater than the number of silicicole species. It would therefore be curious if it were true (Neritine, 1904, F. R. H. on plants as a poison, 1874-1895) said that some plants may be calcicole in one geographical district and not in another. However, until now, there is no exact chemical composition of natural material. In contrast, the chemical composition of the water and the effects of lime in the water makes it impossible to decide the vexed question of the relationship between calcicole and calcifugous plants to the presence or absence of calcium carbonate in the soil. From such points of view, Schimper stated, "that ecology is only in its infancy."

CYTOLOGY

The elementary unit of plant structure, as of animal structure, is the cell. Within it or its modifications all the vital phenomena of which living organisms are capable have their origin. Upon observing the structure and phenomena of the cell, a study of its physiological activities, depends the ultimate solution of all the important problems of nutrition and growth, reception and conduction of stimuli, heredity, variation, sex and reproduction.

The Cell Theory.—For a general and historical account of the cell theory see CYTOLOGY. It is sufficient to note here that cells were first of all discovered in various vegetable tissues by Robert Hooke in 1663. Later on, Schleiden and Schwann in 1838, D. C. van Leeuwenhoek in 1674-1832, and Robert Brown in 1831, but its existence had already been discovered by some observers and it had been seen by Fontana in some animal cells as early as 1781. The cell theory so far as it relates to plants was established by Schleiden in 1838. He showed that all the organs of plants are built up of cells, that the plant embryo originates from a single cell, and that the physiological activities of the plant are dependent upon the individual activities of these vital units. This conception of the plant as an aggregate or colony of independent vital units governing the nutrition, growth and reproduction of the whole cannot, however, be maintained. It is true that in the cellular plants all the vital activities are excited by chemical influences, but in the cellular plants there is a more or less highly developed differentiation of physiological activity giving rise to different tissues or groups of cells, each with a special function. The cell in such a differentiation is no longer therefore regarded as an independent unit. It is an integral part of an individual organization and as such the exercise of its functions must be governed by the organism as a whole.

General Structure and Differentiation of the Vegetable Cell.—The simplest cell forms are found in embryonic tissues, in reproductive cells and in the parenchymatous cells, found in various parts of the plant. The epidermal, conducting and strengthening tissues show on the other hand considerable modifications both in form and structure.

The protoplast, the living part of the cell consists of a semifluid granular substance, called the cytoplasm, one or more nuclei, and sometimes centrosomes and plastids. Cells from different parts of a plant differ very much in their cell-contents. Young cells are full of cytoplasm, old cells generally contain a large vacuole or vacuoles, containing cell-sap, and with only a thin, almost invisible layer of cytoplasm on their walls. Chlorophyll grains, chromatophores, starch-grains and oil-globules, all of which can be distinguished either by their appearance or by chemical reagents, may also be present. Very little is known of the finer structure of the cytoplasm of a vegetable cell. It is sometimes differentiated into a clearer outer layer, of hyaloplasm, commonly called the ektoplam, and an inner granular endoplasm. In some cases it shows, when submitted to a careful examination under the highest powers of the microscope, and especially when treated with reagents of various kinds, traces of a more or less definite structure in the form of a meshwork consisting of a clear homogeneous substance containing numerous minute bodies known as microsomes, the spaces being filled by a more fluid ground-substance. This structure, which is visible both in living cells and in cells treated by reagents, has been interpreted by many observers as a network of threads embedded in a homogeneous ground-substance. Bütschli, on the other hand, interprets it as a finely vacuolated foam-structure or emulsion, comparable to that which is observed when small drops of a mixture of finely powdered potash and oil are placed in water, the vacuoles or alveoli being spaces filled with liquid, the more solid portion representing the mesh-work in which the microsomes are placed. Evidence is not wanting, however, that the cytoplasm must be regarded as, fundamentally, a semifluid homogeneous substance in which by its own activity, granules, vacuoles, fibrils, &c., can be formed as secondary structures.

The cytoplasm is largely concerned in the formation of spindle fibres and centrosomes, and such structures as the cell membrane, cilia, or flagella, the coenocentrum, nematoasts or eibriods and phycodes are also products of its activity.

Protoplasmic Movements.—In the cells of many plants the cytoplasm frequently exhibits movements of circulation or rotation. The cells of the staminal hairs of Tradescantia virginica contain a large sap-cavity across which run, in all directions, numerous protoplasmic threads or bridges. In these, under favourable conditions, streaming movements of the cytoplasm in various directions can be observed. In other forms such as Elodea, Nitella, Chara, &c., where the cytoplasm is mainly restricted to the periphery of the sap vacuole and lining the cell wall, the streaming movement is exhibited in one direction only. In some cases both the nucleus and the chromatophores may be carried along in the rotating stream, but in others, such as Nitella, the chromatophores may be completely suspended, while one layer of the cytoplasm in direct contact with the cell wall.

1 Ewart. On the Physics and Physiology of Protoplasmic Streaming in Plants. (Oxford, 1903), gives an excellent account of the phenomena of protoplasmic streaming with a full discussion of the probable causes to which it is due.
in the Cyanophyceae. These substances can, however, be dissolved out in water, and the green colouring matter of the chloroplast then becomes visible. The chloroplast consists of two parts, a colourless ground substance, and a green colouring matter, which is contained either in the form of fibrils, or in more or less regular spherical masses, in the colourless ground-mass. The chloroplasts increase in number by division, which takes place in higher plants when they have attained a certain size, independent of the division of the cell. In Spirogyra and allied forms the chloroplast grows as the cell grows, and only divides when this divides. The division in all cases takes place by constriction, or by a simultaneous splitting up into an equal number of equatorial planes. Chloroplasts are very sensitive to light and are capable in some plants of changing their position in the cell under the stimulus of a variation in the intensity of the light rays which fall upon them. In the chromatophores of many Algae and in the Liverwort Anthoceros there are present homogeneous, highly refractive, crystal-like bodies, called pyrenoids or starch-centres, which are composed of proted substances and surrounded by an envelope of starch-grains. In Spirogyra the pyrenoids are distinctly connected by cytoplasmic strands to the central mass of cytoplasm, which surrounds the nucleus, and according to some observers, the pyrenoids are visible only by division, followed by a similar division of the cytoplasmic strands (Wakker). These pyrenoids, which remain colourless, and serve simply as starch-formers in parts of the plant not exposed to the light, are called leucoplasts or amyloplasts. They are composed of a homogeneous proteid substance, and often contain albuminoid or proteid crystals of the same kind as those which form the pyrenoid. If exposed to light they may become converted into chloroplasts. The formation of starch may take place in any part of the leucoplast. When formed inside it, the starch-grains exhibit a concentric stratification; when formed externally in the outer layers, the stratification is excrctic, and the hilum occurs on that side farthest removed from the plastid. As the starch-grains grow, the leucoplasts gradually disappear.

Chromoplasts are the yellow, orange or red colour-bodies found in some flowers and fruits. They arise either from the leucoplasts or chloroplasts. The fundamental substance or stroma is colourless and homogeneous. The colour is due to the presence of xanthophyll, or caroten or both. The colouring matters are not dissolved in the stroma of the chromoplast, but exist as amorphous granules, with or without the presence of a protein crystal, or in the form of fine imperfectly crystalline needle-like crystals. The different green-coloured forms of Tamus communis, Asparagus, Lonicera, berries of Solanum, flowers of Calla lilies, Paeonia, Tropaeolum, bracts of Silene, &c., and in the root of the carrot. In some cases the plastid disappears and the chromoplast may last for a long time. The colour of these crystals is very varied. The red plastids of Raphanus and Vicia. These crystals consist of rod-like, thin plates, flat ribbons or spirals. Starch grains may often be seen in contact with the pigment crystals. The crystalline form appears to be due entirely to the caroten, which can be artificially crystallized from an alcohol or ether solution. In addition to the plastids, there are found in some plant-cells, e.g., in the epithelial cells of the leaf of species of Vanilla (Walker), and in the epidermis of different parts of the flower of Punica, Orinchehiopsis, &c. (Zimmermann), highly refractive bodies of globular form, elodiplasts, which consist of a granular protein ground-substance containing drops of oil. They are stained deep red in dilute solutions of alcian blue in the Proteoplasms.—Starch may be found in the chlorophyll bodies in the form of minute granules as the first visible product of the assimilation of carbon dioxide, and it occurs in large quantities as a reserve food material in the cells of various parts of plants. It is highly probable that starch is only produced as the result of the activity of chromatophores, either in connexion with chloroplasts, chloroplasts or leucoplasts. Starch exists, in the majority of cases, in the form of grains, which are composed of stratified layers arranged around a nucleus or hilum. The stratification, which may be centric or excentric, appears to be due to a difference in density of the various layers. The density of the outermost layer, the density decreasing more or less uniformly from the outside layer to the centre of hilum. The outermost, newly formed layer is composed of a more homogeneous, denser substance than the inner one, and can be distinguished in all starch-grains that are in process of development. The separate layers of the starch-grain are deposited on it by the activity of the chromatophore, and according to Meyer the grain is always surrounded by a thin layer of the chromatophore which completely separates it from the cytoplasm. The layers appear to be made up of elements which are arranged radially. These, according to Meyer, acicular crystals, which he calls trichides. The starch grain may thus be regarded as a crystalline structure of the nature of a sphere-crystal, as has been suggested by many observers.

The form of the starch grain is in some cases a secretion from the plastid (Meyer, 1895) or to a direct transformation of the protoplasm of the plastid (Timberlake, 1901) has not been definitely established. Aleurone.—Aleurone is a proteid substance which occurs in seeds especially those containing oil, in the form of minute granules or large grains. It may be in the form of an albumen crystal sometimes associated with a more or less spherical body—globoid—composed of a combination of an organic substance with a double phos- phate of magnesium and calcium. Albumen crystals are also to be found in the cytoplasm, in leucoplasts and rarely in the nucleus. Glycogen, a substance related to starch and sugar, is found in the Fungi and Cyanophyceae as a food reserve. It gives a characteristic red-brown reaction with iodine solution. In the yeast cell it serves as a reserve store of carbohydrate and is sometimes used as a reserve of nutrition and is sometimes so abundant as to fill the cell almost entirely (Errera, 1882, 1895; Wagner and Peniston, 1910). The glycogen occurs in the amyloplasts of various Fungi, Bacteria, Cyanophyceae, diatoms, &c., in the form of thick long wisps, and has a characteristic reaction towards methylene blue (Meyer). It appears to have some of the characteristics of nucleic acid, and according to Meyer may be a combination of nucleic acid with an unknown organic base.

Numerous other substances are also found in the cytoplasm, such as tannin, fats and oil, resins, mucilage, cutin, tuc, percha, sulphur and calcium oxalate crystals. The cell sap contains various substances in solution such as sugars, inulin, alkaloids, glucosides, organic acids and various inorganic salts. The colours of flowers are due to colouring matters contained in the sap of which the chief is anthocyanin.

Reference must also be made here to the enzymes or unorganized ferment which occur so largely in the cytoplasm. It is probable that most, if not all, the metabolic changes which take place in a cell, such as the transformation of starch, proteids, sugar, cellulose, and the decomposition of numerous other organic substances which would otherwise require a high temperature or powerful reagents is also due to their activity. Their mode of action is similar to that of ordinary mechanical catalytic agents, such as finely divided platinum (see Bayliss, The Nature of Enzyme Action, and J. R. Green, The Soluble Ferments).

The Nucleus.—The nucleus has been demonstrated in all plants with the exception of the Cyanophyceae and Bacteria, and the construction of the nucleus appears to be given in some of their characteristics. The nucleus is regarded as a controlling mass of cell-activity, upon which the growth and development of the cell in large measure depends, and as the agent by which the transmission of specific qualities from one generation to another is brought about. If it is absent, the cell loses its power of assimilation and growth, and soon dies. Haberlandt has shown that in plant cells, when any new formation of membrane is to take place in a given spot, the nucleus is found in its immediate vicinity; and the nucleus found that only that portion of the protoplasm of a cell which contains the nucleus is capable of forming a cell-wall; whilst Townsend has further shown that if the mucilaginous material of the protoplasm to the nucleated mass, either of the same cell or of a neighbouring cell, it retains the power of forming a cell-membrane.

The Structure of the Nucleus.—In the living condition the resting nucleus appears to consist of a homogeneous ground substance containing a large number of small chromatins granules and one or more large spherical granules—nucleol—the whole being surrounded by a limiting membrane which separates it from the cytoplasm. When fixed and stained this granular mass is resolved into a more or less distinct granular network which consists of a substance called Linin, only slightly stained by the ordinary nuclear stains, and embedded in it, a more deeply stained substance: Chromatins. The latter is considered to form a part of the Linin network, but has usually also a strong affinity for nuclear stains. The staining reactions of the various
parts of the nucleus depend to some extent upon their chemical constitution. The chromatin is practically identical with nuclein. This has a strong attraction for basic aniline dyes, and can usually be distinguished from other parts of the cell which are more easily coloured by acid anilines. But the staining reactions of nuclei may vary at different stages of their development; and it is probable that there is no method of staining which differentiates with certainty the various morphological constituents of the nucleus.

Our knowledge of the chemical constitution of the nucleus is due to the pioneer researches of Sir Lauder Brunton, Ploss, Miescher, Kossel and a host of more recent investigators. Nuclein is a complex albuminoid substance containing phosphorus and iron in organic combination (Macallum). It appears to be a combination of a protein with nucleic acid. Recent researches have shown that the nucleic acid can be broken up by chemical means into a number of different compounds or bases. The results at first obtained were very confusing and seemed to show that nucleic acid is very variable in constitution, but thanks to the work of Schlesinger and Stendel (Germany), Ivar Bang (Sweden) and Walter Jones and Levene (America), the confusion has been reduced to some sort of order, and it now seems probable that all ordinary nucleic acids yield two parine bases, adenine and guanine; two pyrimidine bases, cytosine and thymine and a hexose carbohydrate, the identity of which is uncertain.

The Nucleolus.—In the majority of plant-nuclei, both in the higher and lower plants, there is found, in addition to the chromatin network, a deeply stained spherical or slightly irregular body (sometimes more than one) called the nucleolus (fig. 2, A to D). It is often vacuolar, sometimes granular, and in other cases it is a homogeneous body with no visible structure or differentiation. The special function of this organ has been a source of controversy during the past few years, and much uncertainty still exists as to its true nature. It forms a part of the linin or plastin network of the nucleus and may become impregnated with varying quantities of chromatin stored up for use in the formation of the chromosomes and other nuclear actions. The relation of the nucleolus to the chromosomes is clearly seen in the reconstruction of the daughter nuclei after division in the cells of the root-apex of Phaseolus (fig. 1, A to F). The chromosomes (fig. 1, A) unite to form an irregular mass (fig. 1, B) out of which is evolved the nucleolus and nuclear network (figs. 1, E, F) by a fusion of the chromosomes (fig. 1, C, D).

Centrosome.—The centrosome is a minute homogeneous granule found in the cytoplasm of some cells in the neighbourhood of the nucleus. It is generally surrounded by a granular or radiating cytoplasmic substance. In plant cells its presence has been demonstrated in the Thalliphytes and Bryophytes. In the higher plants the structures which have been often described as centrosomes are too indefinite in their constitution to allow of this interpretation being placed upon them, and many of them are probably nothing more than granules of the fragmented nucleolus. The centrosomes in plants do not appear to be permanent organs of the cell. They are prominent during cell-division, but may disappear in the resting stage. They are more easily seen, when the nucleus is about to undergo mitosis, at the ends of the spindle, where they form the centres towards which the radiating fibres in the cytoplasm converge (see fig. 7, E G). The centrosome or centrosphere is usually regarded as the dynamic centre of the cell and a special organ of division; but its absence in many groups of plants does not lend support to this view so far as plant-cells are concerned.

Nuclear Division.—The formation of new cells is, in the case of uninucleate cells, preceded by or accompanied by the division of the nucleus. In multinucleate cells the division of the nucleus is independent of the division of the cell. Nuclear division may be direct or indirect, that is to say it may either be accompanied by a series of complicated changes in the nuclear structures called mitosis or karyokinesis (fig. 2), or it may take place by simple direct division, amitosis, or fragmentation. Direct division is a much less common phenomenon than was formerly supposed to be the case. It occurs most frequently in old cells, or in cells which are placed under abnormal conditions.

**FIG. 1.—Reconstruction of the daughter nuclei of Phaseolus.**

**Tradescantia**; and in various other cells which have lost their power of division. It has been shown that, in cells of Spirogyra placed under special conditions, amitotic division can be induced, and that normal mitosis is resumed when they are placed again under normal conditions. Amitosis is probably connected by a series of intermediate gradations with karyokinesis.

**Mitosis.**—In indirect nuclear division the nucleus undergoes a series of complicated changes, which result in an equal division of the chromatic substance between the two daughter nuclei. Four stages can be recognized. (1) Prophase.—The nucleus increases in size; the network disappears, and a much convoluted thread takes its place (fig. 2, B). The chromatin substance increases in amount; the thread stains more deeply, and in most cases presents a homogeneous appearance. This is commonly called the spirem-figure. The chromatin thread next becomes shorter and thicker, the nucleioli begin to disappear, and the thread breaks up into a number of segments—chromosomes—which vary in number in different species, but are fairly constant in the same species (fig. 2, C, D). Coincident with these changes the nuclear membrane disappears and a spindle-shaped or barrel-shaped group of threads makes its appearance in the midst of the chromosomes, the longitudinal axis of which is at right angles to the plane of the division (fig. 2, F). At each pole of this spindle figure there often occur fibres radiating in all directions into the cytoplasm, and sometimes a minute granular body, the centrosome, is also found there. (2) Metaphase.—The chromosomes pass to the equator of the spindle and become attached to the
spindle-fibres in such a way that they form a radiating star-shaped figure—*Aster*—when seen from the pole of the spindle. This is called the nuclear plate (fig. 2, E, F, G, H). As they pass into this position they undergo a longitudinal splitting by which the chromatin in each chromosome becomes divided into equal halves. (3) *Anaphase.*—The longitudinal division of the chromosomes is completed by the time they have taken up their position in the nuclear plate, and the halves of the chromosomes then begin to move along the spindle-fibres to opposite poles of the spindle (fig. 2, I, J). Many observers hold the view that the chromosomes are pulled apart by the contraction of the fibres to which they are attached. (4) *Telephase.*—When they reach the poles the chromosomes group themselves again in the form of stars—*Diaster*—with spindle-fibres extending between them (fig. 2, K). The chromosomes then fuse together again to form a single thread (fig. 2, L), a nucelolus appears, a nuclear membrane is formed, and daughter nuclei are thus constituted which possess the same structure and staining reactions as the mother nucleus.

The spindle figure is probably the expression of forces which are set up in the cell for the purpose of causing the separation of the daughter chromosomes. Hartog has endeavoured to show that it can only be formed by a dual force, analogous to that of magnetism, the forces being comparable to the lines of force in a magnetic field and possibly due to electrical differences in the cell. The spindle arises partly from the cytoplasm, partly from the nucleus, or it may be derived entirely from the nucleus—intranuclear spindle—as occurs in the majority of the lower plants (Fungi, &c.). The formation of the spindle begins in the prophase of division. A layer of delicate filamentous cytoplasm—knephoplasm—may collect around the nucleus, or at its poles, out of which the spindle is formed. As division proceeds, the filamentous nature of this cytoplasm becomes more prominent and the threads begin either to converge towards the poles of the nucleus, to form a bipolar spindle, or may converge towards, or radiate from, several different points, to form a multipolar spindle. The wall of the nucleus breaks down, and the cytoplasmic spindle-fibres become mixed with those derived from the nuclear network. The formation of the spindle differs in details in different plants.

The significance of this complex series of changes is very largely hypothetical. It is clear, however, that an equal quantitative division and distribution of the chromatin to the daughter cells is brought about; and if, as has been suggested, the chromatin consists of minute particles or units which are the carriers of the hereditary characteristics, the nuclear division also probably results in the equal division and distribution of one half of each of these units to each daughter cell.

*Reduction Divisions* (Melosis).—The divisions which take place leading to the formation of the sexual cells show a reduction in the number of chromosomes to one-half. This is a necessary consequence of the fusion of two nuclei in fertilization, unless the chromosomes are to be doubled at each generation. In the vascular cryptogams and phanerogams it takes place in the spore mother cells and the reduced number is found in all the cells of the gametophyte, the full number in those of the sporophyte. We know very little of the details of reduction in the lower plants, but it probably occurs at some stage in the life history of all plants in which sexual nuclear fusion takes place. The reduction is brought about simply by the segmentation of the spireme thread into half the number of segments instead of the normal number. In order to effect this the individual chromosomes must become associated in some way, for there is no diminution in the actual amount of nuclear substance, and this leads to certain modifications in the division which are not seen in the vegetative nuclei. The two divisions of the spore mother cell in which the reduction takes place, follow each other very rapidly and are known as *Heterotype* and *Homotype* (Flemming), or according to the terminology of Farmer and Moore (1905) as the *meiotic phase.*

In the heterotype division the spireme thread is divided longitudinally before the segmentation occurs (fig. 2, B), and this is preceded by a peculiar contraction of the thread around the nucleolus which has been termed *synapsis* (fig. 1, A). A second contraction may take place later, immediately preceding the segmentation of the thread. It has been suggested that synapsis may be connected with the early longitudinal splitting of the thread, or with the pairing of the chromosomes, but it is possible that it may be connected with the transference of nucleolar substance to the nuclear thread. The segments of each chromosome are usually twisted upon each other and may be much contorted (fig. 2, C, D), and appearances are observed which suggest a second longitudinal division, but which are more probably due to a folding of the segment by which the two halves come to lie more or less parallel to each other, and form variously shaped figures of greater or less regularity (fig. 2, E). The chromosomes now become attached to the spindle-fibres (fig. 2, F, G) and as the daughter chromosomes become pulled asunder they often appear more or less V-shaped so that each pair appears as a closed ring of irregular shape, the ends of the V's being in contact thus—<>. (fig. 2, H, I, J, K). This V has been variously interpreted. Some observers consider that it represents a longitudinal half of the original segment of the spireme, others that it is a half of the segment produced by transverse division by means of which a true qualitative separation of the chromatin is brought about. The problem is a very difficult one and cannot be regarded as definitely settled, but it is difficult to understand why all this additional complexity in the division of the nucleus should be necessary if the final result is only a quantitative separation of the chromatin. It seems to be fairly well established that in the meiotic phase there is a true qualitative division brought about by the pairing of the chromosomes during synapsis, and the subsequent separation of whole
chromosomes to the daughter nuclei. The method by which this is brought about is, however, the subject of much controversy. There are two main theories: (1) that the chromosomes which finally separate are at first paired side by side (Allen, Grégoire, Berghs, Strasburger and others), and (2) that they are joined together or paired end to end (Farmer and Moore, Gregory, Mottier and others). Good cytological evidence has been ad-
duced in favour of both theories, but further investigation is necessary before any definite conclusion can be arrived at. The second or homotypic division which immediately follows reverts to the normal type except that the already split chromosomes at once separate to form the daughter nuclei without the inter-
vention of a resting stage.

Cell Division.—With the exception of a few plants among the Thallophytae, which consist of a single multinucleate cell, Caulerpa, Vauclercia, &c., the division of the nucleus is followed by the division of the cell either at once, in uninucleate cells, or after a certain number of nuclear divisions, in multinucleate cells. This may take place in various ways. In the higher plants, after the separation of the daughter nuclei, minute granular swellings appear, in the equatorial region, on the connecting fibres which still persist between the two nuclei, to form what is called the cell-plate. These fuse together to form a membrane (fig. 1, G, D) which splits into two layers between which the new cell-wall is laid down. In the Thallophytae the cytoplasm may be segmented by constriction, due to the inward growth of a new cell wall from the old one, as in Spirogyra and Cladophora, or by the formation of cleavage furrows in which the new cell-wall is secreted, as occurs in the formation of the spores in many Algae and Fungi. Cell budding takes place in yeast and in the formation of the conidia of Fungi.

In a few cases both among the higher and the lower plants, of which the formation of spores in the ascus is a typical example, new cells are formed by the aggregation of portions of the cytoplasm around the nucleus which become delimited from the rest of the cell contents by a membrane. This is known as free cell formation.

In Fucus and allied forms the spindle-fibres between the daughter nuclei disappear early and the new cell-wall is formed in the cytoplasm.

Cell Membrane.—The membrane which surrounds the pro-
toplasm in the majority of plants is typically composed of cellulose, together with a number of other substances which are known as pectic compounds. Some of these have a neutral reaction, others react as feeble acids. They can be distinguished by their insolubility in cuprammonia, which dissolves cellulose, and by their behaviour towards stains, some of which stain pectic substances but not cellulose. Cellulose has an affinity for acid stains, pectic substances for basic stains. The cell-membrane may become modified by the process of lignification, suberization, cuticularization or gelatinization. In the Fungi it is usually composed of a modified form of cellulose known as fungus cellulose, which, according to Mangin, consists of callose in combination either with cellulose or pectic compounds. The growth of the cell-wall takes place by the addition of new layers to those already formed. These layers are secreted by the protoplasm by the direct apposition of substances on those already in existence; and they may go on increasing in thickness, both by apposition and by the intussusception of particles probably carried in through the protoplasmic fibres, which penetrate the cell-wall as long as the cell lives. The growth of the cell-wall is very rarely uniform. It is thickened more in some places than in others, and thus are formed the spiral, annular, and other markings, as well as the pits which occur on various cells and vessels. Besides the internal or centripetal growth, some cell-walls are thickened on the outside, such as pollen grains, oospores of Fungi, cells of Peridinaceae, &c. This centrifugal growth must apparently take place by the activity of protoplasm external to the cell. The outer protective walls of the oospores of some Fungi are formed out of protoplasm containing numerous nuclei, which is at an early stage separated from the protoplasm of the oospore. In the Peridinaceae, Diatoms and Desmids, according to recent researches, the thick-

enings on the outer walls of the cells are due to the passage of protoplasm from the interior of the cell to the outside, through pores which are found perforating the wall on all sides.

Cell-walls may be modified by the impregnation of various substances. Woody or lignified cell-walls appear to contain sub-
stances called conferrins and vanillin, in addition to various other compounds which are imperfectly known. Lignified tissues are coloured yellow by aniline sulphate or aniline chloride, violet with chlor-iodide and hydrochloric acid, and characteristic reactions are also given by mixtures containing phenol, indol, skatol, thallin, sulphate, &c. (see Zimmermann’s Microtechnique). Staining reagents can also be used to differentiate lignified cell-walls. Cuticularized or suberized cell-walls occur especially in those cells which per-
form a protective function. They are impervious to water and gases. Both cuticularized and suberized membranes are insoluble in cuprammonia, and are coloured yellow or brown in a solution of chlor-iodide of zinc. It is probable that the corky or suberized cells do not contain any cellulose (Gilson, Wisselins); whilst cuti-

cularized cells are only modified in their outer layer, cellulose inner layers may be still recognizable. The suberized and cuticularized cell-walls appear to contain a fatty body called suberin, and such cell-walls can be stained red by a solution of alcain, the lignified and cellulose membranes remaining unstained.

Fertilization.—The formation of the zygote or egg-cell takes place usually by the fusion of the contents of two cells, and always includes, as an essential feature, the fusion of two germ nuclei. In many of the lower plants the fusing cells are gametes which are precisely similar so far as size and general appearance are concerned; and the whole contents of the two cells fuse together, cytoplasm with cytoplasm, nucleus with nucleus, nucleolus with nucleolus and plastid with plastid. The gametes may be motile (some Al-
gae) or non-motile, as in Spirogyra, Macor, Bas-
idiobolus, &c. In many of the lower plants and in all higher plants there is a difference in size in the fusing cells, the male cell being the smaller. The reduction in size is due to the absence of cytoplasm, which is in some cases so small in amount that the cell consists mainly of a nucleus. In all cases of complete sexual differenti-
ation the egg-cell is quies-
cent; the male cell may be motile or non-motile. In many of the Fungi the non-motile male cell or nucleus is carried by means of a fertilizing tube actually into the interior of the egg-cell, and is extruded through the apex in close proximity to the egg nucleus. In the Florideae, Lichens and Laboulbeniaceae the male cell is a non-motile spermatium, which is carried to the female organ by movements in the water. In Monoblepharis, one of the lower Fungi, in some Algae, in the vascular Cryptogams, in Cycads (Zamia and Cycas), and in Ginkgo, an isolated genus of Gymnosperms, the male cell is a motile spermatozoid with two or more cilia. In the Algae, such as Fucus, Volvos, Oedogonium, Bulbochaete, and in the Fungus Monoblepharis, the spermatozoid is a small oval or elongate cell containing nucleus, cytoplasm and sometimes plastids. In the Characeae, the Vascular Cryptogams, in Zamia and Cycas, and in Ginkgo, the spermatozoids are more or less highly modified cells with two or more cilia, and resemble in many respects, both in their
structure and mode of formation, the spermatozoids of animals. In Characeae and Muscineae they are of elongate spiral form, and consist of an elongate dense nucleus and a small quantity of cytoplasm. At the anterior end are attached two cilia or flagella. In the Vascular Cryptogams the structure is much the same, but a more or less spherical mass of cytoplasm remains attached to the posterior spirals, and a large number of cilia are grouped along the cytoplasmic anterior portion of the spiral. In Zamia (fig. 4, A), Cycas and Ginkgo they consist of large spherical or oval cells with a coiled band of cilia at one end, and a large nucleus which nearly fills the cell. They are carried by the pollen tube to the apex of the prothallus, where they are extruded, and by means of their cilia swim through a small quantity of liquid, contained in a slight depression to the oosphere. In the other Phanerogams the male cell, which is non-motile, is carried to the oosphere by means of a pollen tube. In the spermatozoids of Chara, Vascular Cryptogams, and in those of Cycas, Zamia and Ginkgo, the cilia arise from a centroosome-like body which is found on one side of the nucleus of the spermatozoid mother-cell. This body has been called a blepharoplast, and in the Pteridophytes, Cycads and Ginkgo it gives rise to the spiral band on which the cilia are formed. Belajeff regards it as a true centrosome; but this is doubtful, for while in some cases it appears to be connected with the division of the cell, in others it is independent of it. The egg-cell or oosphere is a large cell containing a single large nucleus, and in the green plants the rudiments of plastids. In plants with multinucleate cells, such as Albigo, Peronospora and Vacheria, it is usually a unicellular clump differentiated by separation of the nuclei from a multinucleate cell, but in Albigo bili it is multinucleate, and in Sphaeroplea it may contain more than one nucleus. In some cases the region where the penetration of the male organ takes place is indicated on the oosphere by a hyaline receptive spot (Oedogonium, Vacheria, &c.), or by a receptive papilla consisting of hyaline cytoplasm (Peronospora). Fertilization is effected by the union of two nuclei in all those cases which have been carefully investigated. Even in the multinucleate oosphere of Albigo bili the nuclei fuse in pairs; and in the oospheres of Sphaeroplea, which may contain more than one nucleus, the egg nucleus is formed by the fusion of one only of these with the spermatozoid nucleus (Klebs). In the higher Fungi nuclear fusions take place in basidia or asci which involve the union of two (fig. 7, A) nuclei, which may be regarded as physiologically equivalent to a sexual fusion. The union of the germ nuclei has now been observed in all the main groups of Angiosperms, Gymnosperms, Ferns, Mosses, Algae and Fungi, and presents a striking resemblance in all. In nearly all cases the nuclei appear to fuse in the resting stage (fig. 3, C). In many Gymnosperms the male nucleus penetrates the female nucleus before fusing with it (Blackman, Ikene). In other cases the two nuclei place themselves side by side, the nuclear membrane between them disappears, and the contents fuse together—nuclear thread with nuclear thread, and nucleus with nucleus—so completely that the separate constituents of the nuclei are not visible. It was at one time thought that the centrosomes played an important part in the fertilization of plants, but recent researches seem to indicate that this is not so. Even in those cases where the cilia band, which is the product of the centrosome-like body or blepharoplast, enters the oovum, as in Zamia (c in fig. 4, B, C, D), it appears to take no part in the fertilization phenomena, nor in the subsequent division of the nucleus. During the process of fertilization in the Angiosperms it has been shown by the researches of Nawaschin and Guignard that in Lilium and Fritillaria both generative nuclei enter the embryo sac, one fusing with the oosphere nucleus, the other with the polar nuclei (fig. 3, A, B). A double fertilization thus takes place. Both nuclei are elongated vermiform structures, and as they enter the embryo sac present a twisted appearance like a spermatozoid without cilia (fig. 3, A, B). It has since been shown by other observers that this double fertilization occurs in many other Angiosperms, both Dioryctyles and Monocotyledons, so that it is probably of general occurrence throughout the group (see Angiospermes).

The Nucleus in Relation to Heredity.—There is a certain amount of cytological evidence to show that the nucleus is largely concerned with the transmission of hereditary characters. Whether this is entirely confined to the nucleus is, however, not certain. The strongest direct evidence seems to be that the nuclear substances are the only parts of the cells which are always equivalent in quantity, and that in the higher plants and animals the male organ or spermatozoid is composed almost entirely of the nucleus, and that the male nucleus is carried into the female cell without a particle of cytoplasm.

Since, however, the nucleus of the female cell is always accompanied by a larger or smaller quantity of cytoplasm, and that in a large majority of the power plants and animals the male cell also contains cytoplasm, it cannot yet be definitely stated that the cytoplasm does not play some part in the process. On the other hand, the complex structure of the nucleus with its separate units, the chromosomes, and possibly even smaller units represented by the chromatin granules, and the means taken through the complex phenomena of mitosis to ensure that an exact and equal division of the chromosomes shall take place, emphasizes the importance of the nucleus in heredity. Further, it is only in the nucleus and in its chromosomes that we have any visible evidence to account for the Mendelian segregation of characters in hybrids which are known to occur. Visible differences in the chromosomes have even been observed, especially in insects, which are due apparently to an unequal division by which an additional or accessory chromosome is produced, or in some cases one or two extra chromosomes which differ in size from the others. These differences indicate a separation of different elements in the formation of the chromosomes and have been definitely associated with the determination of sex. It is possible, however, that the segregation of characters in the gametes may depend upon something far more subtle and elusive than the chromosomes or even of possible combinations of units within the chromosomes, but so far as we can see at present these are the only structures in the cell which can be satisfactorily associated. Bovery in fact has put forward the view that the chromosomes are elementary units which maintain an organic continuity and independent existence in the cell. The cytological evidence for this appears to be made stronger for animal than for plant cells. From numerous investigations which have been made to trace the chromosomes through the various stages of the nuclear ontogeny of plant cells, it appears that the individuality and continuity of the chromosomes can only be conceived as possible if we assume the existence of something like chromosome centres in the resting nucleus around which the chromosomes become organized for purposes of division. Rosenberg (1909) adduces evidence for 1.

1 Stransburger (1909) states very definitely that he has observed the entrance of the male nucleus into the egg without a trace of cytoplasm.
the existence of chromosomes or "prochromosomes" in resting nuclei in a large number of plants, but most observers consider that the chromosomes during the resting stage become completely resolved into a nuclear network in which no trace of the original chromosomes can be seen.

Special Cell-Modifications for the Reception of Stimuli.—In studying the physiology of movement in plants certain modifications of cell-structure have been observed which appear to have been developed for the reception of the stimuli by which the response to light, gravity, and contact are brought about. Our knowledge of these structures is due mainly to Haberlandt.

Organs which respond to the mechanical stimulus of contact are found to possess special contrivances in certain of their cells—(1) sensitive spots, consisting of places here and there on the epidermal cells where the wall is thin and in close contact with protoplasmic projections. These occur on the tips of tendrils and on the tentacles of Drosera; (2) sensitive papillae found on the irritable filaments of certain stamens; and (3) sensitive hairs or bristles on the leaves of Dionaea muscipula and Mimosa pudica—all of which are so constructed that any pressure exerted on them at once reacts on the protoplasm.

Response to the action of gravity appears to be associated with the movements of starch grains in certain cells—statothecial cells—by which pressure is exerted on the cytoplasm and a stimulus set up which results in the geotropic response.

The response to the action of light in diatropic leaves is, according to Haberlandt, due to the presence of epidermal cells which are shaped like a lens, or with lens-shaped thickenings of the cuticle, through which convergence of the light rays takes place and causes a differential illumination of the lining layer of protoplasm on the basal walls of the epidermal cells, by which the stimulus resulting in the orientation of the leaf is brought about. Fig. 5, A, shows the convergence of the light to a bright spot on the basal walls of the epidermal cells of Saxifraga hirsutum, and fig. 5, B, shows a photograph taken from life through the epidermal cells of Tradescantia fluminensis. Notwithstanding the fact, however, that these cells are capable of acting as very efficient lenses the explanation given by Haberlandt has not been widely accepted and evidence both morphological and physiological has been brought forward against it.

The presence of an eye-spot in many motile unicellular Algae and swarm spores is also probably concerned with the active response to light exhibited by these organisms. In Euglena viridis, which has been most carefully studied in this respect, the flagellum which brings about the movement bears near its base a minute spherical or oval refractive granule or swelling which is located just in the hollow of the red pigment-spot (fig. 6); and it has been suggested that the association of these two is analogous to the association of the rods and cones of the animal eye with their pigment layer, the light absorbed by the red pigment-spot setting up changes which react upon the refractive granule and being transmitted to the flagellum bring about those modifications in its vibrations by which the direction of movement of the organism is regulated.

The Nuclei of the Lower Plants.—It is only in comparatively recent times that it has been possible to determine with any degree of certainty that the minute deeply staining bodies described more especially by Schmitz (1879) in many Algae and Fungi could be regarded as true nuclei. The researches of the last twenty years have shown that the structure of the nucleus and the phenomena of nuclear division in these lower forms conforms in all essential details to those in the higher plants. Thus in the Basidiomycetes (fig. 7) the nuclei possess all the structures found in the higher plants, nuclear membrane, chromatin network and nucleolus (fig. 7, B), and in the process of division, chromosomes, nuclear spindle and centrosomes are to be seen (fig. 7, C-G). The investigations of Dangeard, Harper, Blackman, Miss Fraser and many others have also

In the Cyanophyceae the contents of the cell are differentiated into a central colourless region, and a peripheral layer containing the chlorophyll and other colouring matters together with granules of a reserve substance called cyanophycin. Chromatin is contained in the central part together with granules known as volutin, the function of which is unknown. The central body probably plays the part of a nucleus and some observers consider that it has the characters of a typical nucleus with mitotic division. But this is very doubtful. The central body seems to consist merely of a spongy mass of slightly stainable substance, more or less impregnated with chromatin, which divides by constriction. At a certain stage in the division figures are produced resembling a mitotic phase (fig. 8, i), which are not, in walls are pitted, and protoplasmic connexions between the laticiferous tubes and neighbouring parenchyma-cells have been seen. There are two types of laticiferous tissue—non-articulate and articulate. The non-articulate tissue which occurs in Euphorbiaceae, Asclepiadaceae, consists of long tubes, equivalent to single multinucleate cells, which ramify in all directions throughout the plant. Laticiferous vessels arise by the coalescence of two similar cells. The distal ends of the cells do not only fuse together in longitudinal and transverse rows, but put out transverse projections, which fuse with others of a similar nature, and thus form an anastomosing network of tubes which extends to all parts of the plant. They are known in the Compositae (Gelberia), Campanulaceae, Papaveraceae, Lobelieae, Papayaceae, in some Aroidiace and Musaceae, and in Euphorbiaceae (Manihot, Heva). The nuclei of the original cells persist in the protoplasmic membrane. The reticulum which forms the laticiferous vessels may be distinguished in many cases in the young embryo while still in the dry seed (Scott), but the latex vessels in process of formation are more easily seen when germination has begun. In the process of cell-wall formation the cell-walls degenerate gradually at some one point. The opening, which is at first very small, increases in size, and before the cross-wall has entirely disappeared the contents of the two cells become continuous (Scott). The absorption of the cell-walls takes place very early in the germinating seedling.

**Sieve Tubes.**—The sieve tubes consist of partially fused rows of cells, the transverse or lateral walls being perforated by minute openings, through which the contents of the cells are connected with each other, and which after a certain time become closed by the formation of callus on the sieve plates. The sieve tubes contain a thin reserve layer of protoplasm on their walls, but no nuclei, and the cell sap contains albuminous substances which are coagulable by heat. Starch grains are sometimes present. In close contact with the segments of the sieve tubes are companion cells which communicate with the sieve tubes by delicate protoplasmic strands; they can be distinguished from ordinary parenchymatous cells by their small size and dense protoplasm. Companion cells are not found in the Pteridophyta and Gymnosperms. In the latter their place is taken by certain cells of the medullary rays and bres parenchyma. The companion cells are cut off from the same cells as those which unite to form the sieve tube. The mode of formation of the sieve plate is not certainly known; but from the fact that delicate connecting tubes are still found between the cells from their first development it is probable that it is a special case of the normal protoplasmic continuity, the sieve pores being produced by a secondary arrangement of the contents through which these delicate strands pass. According to Lecomte, the young walls consist partly of cellulose and partly of a substance which is not cellulose, the latter existing in the form of slight depressions, which mark the position of the future pores. As the sieve plate grows these non-cellulosic regions swell and gradually become converted into the same kind of mucous substance as that contained in the tube; the two cells are thus placed in open communication. If this is correct it is easy to see that the changes which take place may be initiated by the original delicate protoplasmic strands which pass through the cell-wall. (For further information regarding tissues, see the section on Anatomy above.)

**Protoplasmic Continuity.**—Except in the unicellular plants the cell is not an independent unit. Apart from their dependence in various ways upon neighbouring cells, the protoplasts of all plants are probably connected together by fine strands of protoplasm which pass through the cell-wall (tang, Russow, Gardiner, Kientz-Gerloff and others) (fig. 9). In *Pinus* the presence of connecting threads has recently been demonstrated throughout all the tissues of the plant. These protoplasmic strands are, except in the case of sieve tubes, so delicate that special methods have to be employed to make them visible. The basis of these methods consists in causing a part of the cell to become coagulated by sulphuric acid or zinc chloride, and subsequent staining with Hoffmann's blue or other aniline dyes. The results so far obtained show that the connecting threads may be either "pit-threads" which traverse the closing membrane of the pits in the cell-walls (fig. 9, B), or "wall-threads" which are present in the wall of the cell (fig. 9, A). Both

**Fig. 8.—Cell Structure of the Cyanophyceae.** (From Proc. Roy. Soc., vol. ixii.)

**Fig. 9.—Continuity of protoplasm of cells of *Tamus communis* (A) and endodermis of *Lilium Martagon* (B).**
pit-threads and wall-threads may occur in the same cell, but more often the threads are limited to the pits. The pit-threads are larger and stain more readily than the wall-threads. The threads vary in shape and arrangement in different parts of the plant. They are very thick in *Viscum album*, and are well seen in *Platycodon muliflorus* and *Lilium Martagon*. They are present from the beginning of the development of the cell-wall, and arise from the spindle fibres, all of which may be continued as connecting threads (endospore of *Tamus communis*), or part of them may be overlaid by cellulose lamellae (endospore of *Lilium Martagon*), or they may be all overlaid in pollen mother-cells and pollen grains of *Helleborus foetidus*. The presence of these threads between all the cells of the plant shows that the plant body must be regarded as a connected whole; the threads themselves probably play an important part in the growth of the cell-wall, the conduction of food and water, the process of secretion and the transmission of impulses.

**Morphology of Plants**

The term *morphology*, which was introduced into science by Goethe (1817), designates, in the first place, the study of the form and composition of the body and of the parts of which the body may consist; secondly, the relations of the parts of the same body; thirdly, the comparison of the bodies or parts of the bodies of plants of different kinds; fourthly, the study of the development of the body itself; fifthly, the study of the processes by which the plant reproduces itself; sixthly, the investigation of the historical origin and descent of the body and its parts (phylology); and, lastly, the consideration of the relation of the parts of the body to their various functions, a study that is known as *organography*.

It is a last department of morphology that was the first to be pursued. The earliest scientific result of the study of plants was the recognition of the fact that the various parts of the body are associated with the performance of different kinds of physiological work; that they are, in fact, organs discharging special functions. The origin of the organography of the present day may be traced back to Aristotle, who described the parts of plants as "organs, though very simple ones." He tried to explain them until many centuries had passed that the parts began to be regarded from the point of view of their essential nature and of their mutual relations; that is, morphologically instead of organographically. Joachim Jung, in his *Isagoge phytosophica* (1678), recognized that the plant-body consists of certain definite members, root, stem and leaf, and defined them by their different form and by their mutual relations. This point of view was further developed in the following century by Caspar Friedrich Wolff (*Theoria generationis*, 1759), who first followed the development of the members at the growing-point of the stem. He observed that the "appendicular organs," as he called the leaves, are developed in the same way, whether they be foliage-leaves, or parts of the flower, and stated his conclusions thus: "In the entire plant, whose parts we wonder at as being, at the first glance, so extraordinarily diverse, I finally perceive and recognize nothing beyond leaves and stem (for the root may be regarded as a stem). Consequently all parts of the plant, except the stem, are modified leaves." Similar views were arrived at by Goethe, though by the deductive rather than the inductive method, and were propounded in his famous pamphlet, *Versuch die Metamorphose der Pflanzen zu erklären* (1790), from which the following is quoted: "The underlying relationship between the various external parts of the plant, such as the leaves, the calyx, the corolla, the stamens, which develop one after the other and, as it were, out of one another, has long been generally recognized by investigators, and has in fact been specially studied; and the operation by which one and the same organ presents itself to us in various forms has been termed *Metamorphosis of Plants*."

"Pure Morphology.—Thus it became apparent that the many
and various organs of plants are, for the most part, different forms of a small number of members of the body, which have been distinguished as follows, without any reference to function. The thallus (thallome) is a plant-body which is not differentiated into the members root, stem and leaf; it is the morphologically simplest body, such as is of common occurrence in the lower plants (e.g. Thallophyta). In a differentiated body the stem (caulome) is an axis capable of bearing leaves and (directly or indirectly) the proper reproductive organs. The leaf (phyllome) is an appendicular member only borne by a stem, but differing from it more or less obviously in form and development, though co-ordinate with it in complexity of structure. The root is an axis which never bears either leaves or the proper reproductive organs (whether sexual or asexual) of the plant. The hair (trichome) is a superficial appendage of simple structure, which may be borne by any of the other members. The emergence is also an appendicular member of more complex structure than the hair (e.g. the prickles of the rose). Further, it has been found convenient to designate the leaf-bearing stem as a whole by the term shoot, so that the body may, as Sachs suggested, be primarily analysed into shoot and root.

At the present time some objection is being taken to this purely morphological conception of the body and its parts as being too abstract. It is urged that the various parts are, as a matter of fact, organs; and that it is therefore inadmissible to ignore their functions, as is done in the foregoing definitions. To this it may be replied that pure morphology and organography are not alternatives, but are two complementary and equally necessary modes of considering the composition of the plant-body. Moreover, the abstract terms “stem,” “leaf,” “root,” etc., are absolutely indispensable; and are continually used in this sense by the most ardent organographers. It has not yet been suggested that they should be replaced by organographical terms; were this accomplished, descriptive botany would become impossible.

It is also urged against these definitions that they are not of universal applicability; that there are exceptional structures which cannot be brought within the limits of any one of them. But admitting the validity of this criticism, and even going so far as to question the possibility of ever devising absolutely inclusive and, at the same time, exclusive definitions, no sufficient reason is adduced for giving up all attempt at morphological analysis.

Homology.—All members belonging to the same morphological category are said to be homologous, however diverse their functions. Thus, in a phanerogam, the sepal, petals, stamens and foliage-leaves all come under the category leaf, though some are parts of the perianth, others are spore-bearing organs (sporophylls), and others carry nutritive processes. The homology of members was, in the first instance, upon similarity of development and upon similar relations to the other parts of the body, that is, upon ontogeny. But since the general adoption of the theory of evolution, similarity of descent, that is of phylogeny, has come to form an essential part of this conception; in other words, in order that their homology may be established the parts compared must be proved to be homologous.

The introduction of the phylogenetic factor has very much increased the difficulty of determining homologies; for the data necessary for tracing phylogeny can only be obtained by the study of a series of allied, presumably ancestral, forms. One of the chief difficulties met with in this line of research, which is one of the more striking developments of modern morphology, is that of distinguishing between organs which are “reduced,” and those which are really “primitive.” The object of the phylogenetic study of any organ is to trace it back to its primitive form. But, as will be pointed out later, organs are often found to have undergone “degeneration” or “reduction,” and such reduced or degenerate structures may easily be mistaken for primitive structures, and so the investigator may be misled.

The effect of the phylogenetic factor in homology may be illustrated in the following cases. The leaves of the true mosses and those of the club-mosses (Lycopodium, Selaginella) being somewhat alike in general appearance and in ontogeny, might be, and indeed have been, regarded as homologous on that ground. However, they belong respectively to two different forms in the life-history of the plants; the leaves of the mosses are borne by the gametophyte, those of the club-mosses by the sporophyte. In accordance with the prevalent antithetic view of the alternation of generations in these plants (see PLANTS, REPRODUCTION OF), the forms distinguished as sporophyte and gametophyte are not homogenic; consequently their leaves are not homologous, but are only functionally similar (homoplastic; see infra).

Another effect is that different degrees of homology have to be recognized, just as there are different degrees of relationship or affinity between individual plants. When two organs can be traced along the same line of descent to one primitive form, that is when they are found to be monophyletic, their homology is complete; when, however, they are traceable to two primitive forms, though these forms belong to the same morphological series, they are polyphyletic and therefore only incompletely homologous. For instance, all the leaves of the Bryophyta are generally homologous inasmuch as they are all developments of the gametophyte. But there is reason to believe that they have been differentiated quite independently in various groups, such as the Marchantiaceae, the Jungermanniaceae, and the mosses proper; consequently their phylogeny is not the same, they are polyphyletic, and therefore they are not completely homologous, but are parallel developments.

Analogy.—Considering the parts of the body in relation to their functions, that is as organs, they are found to present peculiarities of form and structure which are correlated with the functions that they have to discharge; in other words, the organ shows adaptation to its functions. All organs performing the same function and showing similar adaptations are said to be homologous or homoplastic, whatever their morphological nature may be; hence organs are sometimes both homologous and analogous, sometimes only analogous. The tendrils of a vetch and of a cucumber are analogous, and also homologous because they both belong to the category leaf; but they are only analogous to the tendrils of the vine and of the passionflower, which belong to the category stem.

Metamorphosis.—It has already been pointed out that each kind of member of the body may present a variety of forms. For example, a stem may be a tree-trunk, or a twining stem, or a tendril, or a thorn, or a creeping rhizome, or a tuber; a leaf may be a green foliage-leaf, or a scale protecting a bud, or a tendril, or a pitcher, or a floral leaf, either sepal, petal, stamen or carpel (sporophyll); a root may be a fibrous root, or a swollen tap-root like that of the beet or the turnip. All these various forms are organs discharging some special function, and are examples of what Wolff called “modification,” and Goethe “metamorphosis.” It may be inquired what meaning is to be attached to these expressions, and what are the conditions and the nature of the changes assumed by them. The leaf of the higher plants will be taken as the illustrative case because it is the most “plastic” of the members, the one that is, which presents the greatest variety of adaptations, and because it has been most thoroughly studied.

In this, as in all morphological inquiries, two lines of investigation have to be followed, the phylogenetic and the ontogenetic. Beginning with its phylogeny, it appears, so far as present knowledge goes, that the differentiation of the shoot of the sporophyte into stem and leaf first occurred in the Pteridophyta; and, in accordance with the views of Bower (Origin of a Land-Flora), the primitive leaf was a reproductive leaf, a sporophyll, from which the foliage-leaf was derived by progressive sterilization. From the nature of the case, this view is not, and could not be, based upon actual observation; this view is therefore not generally accepted; however, it seems to correspond more closely than any other to the facts of comparative morphology. It was formerly assumed, and the view is still held, that the foliage-leaf was the primitive form from which all others were derived, mainly on
the ground that, in ontology, the foliage-leaf generally precedes the sporophyll. The phylogeny of the various floral leaves, for instance, was generally traced as follows: foliage-leaf, bract, sepal, petal, stamen and carpel (sporophyll)—in accordance with what Goethe termed "ascending metamorphosis." Recent researches, however, and especially those of Celakovsky, tend to prove that the perianth-leaves have not been derived from the stamens (i.e. from sporophylls); that is, they are the result of "descending metamorphosis." Moreover there is the fact that the flowers of nearly all the primitive phanerogams, such as the Gymnosperms, consist solely of sporophylls, having no perianth. There is thus a considerable body of evidence to support Bower's view of the primitive nature of the sporophyll.

Accepting this view of the phylogeny of the leaf, the perianth-leaves (sepals and petals) and the foliage-leaves may be regarded as modified or metamorphosed "sporophylls; that is, as leaves which are adapted to functions other than the bearing of spores. The sepals are generally organs for the protection of the flower-bud; the petals, for attracting insects by their conspicuous form and colour; the foliage-leaves, for the assimilation of carbon dioxide and other associated functions. But this phyllogenetic differentiation of the organs was not what Wolff and Goethe had in mind; what they contemplated was an ontogenetic change, and there is abundant evidence that such changes actually occur. Taking first the conversion of members of one morphological category into those of another, this has been actually observed, though rarely. Goebel (Organographie) gives several instances of the conversion of the root into a shoot in ferns, and a few in phanerogams (Listeria osea, Neottia nidus-avis, Anthurium longifolium). Much more common is the conversion of one form of a member into another form. The most varied changes of this kind have been described, and are generally familiar as "monstrosities"; the study of them constitutes, under the name of teratology, a distinct department of biology. A simple case is that of "double" flowers, in which the number of the petals is increased by the "metamorphosis" of stamens; or again the conversion of floral leaves into green leaves, a change known as "chloranthy". These changes may be brought about by external causes, such as the attacks of insects or of fungi, alterations in external conditions, &c., or by some unexplained internal disturbance of the morphological equilibrium. They can also be effected experimentally. Goebel has shown that if the developing foliage-leaves of the fern Onoclea struthiopteris be removed as they are formed, the subsequently developed sporophylls assume more or less completely the habit of foliage-leaves, and may be sterile. Similarly bud-scales can be caused to develop into foliage-leaves, if the buds to which they belong are caused to grow out in the year of their formation by the removal of the existing foliage-leaves.

Useful and suggestive as they often are, teratological facts played, at one time, too large a part in the framing of morphological theories; for it was thought that the "monstrosus" form gave a clue to the essential nature of the organ assuming it. There is, however, no sufficient reason for regarding the monstrous form as necessarily primitive or ancestral, nor even as a stage in the ontology of the organ. For when the older morphologists spoke of a stamen as a "metamorphosed" leaf, it was implied that it originated as a foliage-leaf and subsequently became a stamen. As a matter of fact, a stamen is a stamen and nothing else, from the very beginning. The development of the organ is already determined at its first appearance upon the growing-point; though, as already explained, the normal course of its ontogeny may be interfered with by some abnormal external or internal condition. The word "metamorphosis" cannot, in fact, be used any longer in its original sense, for the change which it implied does not normally occur in ontogeny, and in phylogeny the idea is more accurately expressed by the term "differentiation." However, it may still be useful in describing "monstrosities," and perhaps also those cases in which an organ serves first one purpose and then another, as when a leafy shoot eventually becomes a thorn, or the base of a foliage-leaf becomes a bud-scale.

Differentiation.—Any account of the general morphology of living organisms is incomplete if it does not include some attempt at an explanation of its causation; though such an attempt cannot be carried far at the present time. A survey of the vegetable kingdom indicates that evolution has proceeded, on the whole, from the simple to the complex; at the same time, as has been already mentioned, evidence of reduction or degeneration is common. Thus in the series Bryophyta, Pteridophyta, Phanerogamia, whilst the sporophyte presents progressive development, the gametophyte presents continuous reduction.

Evolution means the gradual development of "highly organized" from "lowly organized" forms; that is, of forms in which the "physiological division of labour" is more complete, from those in which it is less complete; of forms possessing a variety of organs, from forms possessing but few. Differentiation means the development and the specialization as organs of various parts of the body. It presents itself in two aspects: there is morphological differentiation, which can be traced in the distinction of the members of the body, root, stem, leaf, &c.; there is physiological differentiation, which can be traced in the adaptation of these members to various functions. But, in actual operation, these two processes are simultaneous; every member is developed as an organ for the performance of some special function.

Factors in Evolution.—Evolution in the race involves progressive differentiation in the individual; hence the causes of evolution and of differentiation must be the same. The evolution of higher from lower plants, it is generally assumed, has proceeded by various paths. With regard to the causation of variation Darwin says (Origin of Species, ch. v.): "In all cases there are two factors, the nature of the organism, which is much the most important of the two, and the nature of the conditions. The direct action of changed conditions leads to definite or indefinite results. In the latter case the organization seems to become plastic, and we have much fluctuating variability. In the former case the nature of the organism is such that it yields readily, when subjected to certain conditions, and all or nearly all the individuals become modified in the same way."

In spite of the statement that the "nature of the organism" is the most important factor in variation, the tendency amongst evolutionists has been to take much more account of the influence of external conditions. Exceptions to this attitude are Lamarck, who speaks with regard to animals (but not to plants) of "la composition croisante de l'organisation" (Philosophie zoologique, t. i.), and Nägeli, who attributes variation to causes inherent in the "idiolasm," and has elaborately worked out the view in his Abstammungslehre.

The position assumed in this article is in agreement with the views of Lamarck and of Nägeli. All but the lowest plants visibly tend towards or actually achieve in various degrees the differentiation of the body, whether sporophyte or gametophyte, into stem, leaf, root, &c., that is, the differentiation of parts not previously present. It is inconceivable that external conditions can impart to an organism the capacity to develop something that it does not already possess: can impart to it, that is, the capacity for variation in the direction of higher complexity. The alternative, which is here accepted, is that differentiation is essentially the expression of a developmental tendency inherent in the protoplasm of plants. Just as every crystallizable chemical substance assumes a definite and constant crystalline form which cannot be accounted for otherwise than by regarding it as one of the properties of the substance, so every living organism assumes a characteristic form which is the outcome of the properties of its protoplasm. But just as the crystalline form of a chemical substance is stable and fixed, the organized form of a living organism is unstable and subject to change.

Influence of External Conditions.—This position does not, however, exclude the influence of external conditions; that influence is undeniable. Darwin's expression "the nature of the organism" has been interpreted in the preceding paragraph to mean an inherent tendency towards higher organization; that interpretation may now be completed by adding that the
