ADVERTISEMENT.

THIS work, though formed on the basis of the Dictionary in two volumes quarto, published several years since, by the same Author, is in effect AN ENTIRELY NEW WORK; the articles being either considerably enlarged, or entirely re-written, and in every instance being adapted to the present improved state of Chemical Science.

A
DICTIONARY
OF
CHEMISTRY.

ABSORBENT. The more soluble earths, more especially the porous friable specimens, were formerly distinguished by the name of absorbent earths. This division comprehended clay, lime, and magnesia; but modern chemists have justly rejected the denomination as vague and indefinite.

Absorption. By this term chemists understand the conversion of a gaseous fluid into a liquid or solid on being united with some other substance. It differs from condensation in this being the effect of mechanical pressure, or the abstraction of caloric. Thus, if muriatic acid gas be introduced into water, it is absorbed, and muriatic acid is formed; if carbonic acid gas and ammoniacal gas be brought into contact, absorption takes place, and solid carbonate of ammonia is produced by the union of their ponderable bases.

There is a case of condensation, which has sometimes no doubt been mistaken for absorption, though none has taken place. When an inverted jar containing a gas confined by quicksilver is removed into a trough of water, the quicksilver runs out, and is replaced by water. But, as the specific gravity of water is so much inferior to that of quicksilver, the column of water in the jar resists the atmospheric pressure only with 1-14th the power of the quicksilver, so that the gas occupies less room from being condensed by the superior pressure, not from absorption.

Abstraction. In the process of distillation, the volatile products which come over, and are condensed in the receivers, are sometimes said to be abstracted from the more fixed part which remains behind. This term is chiefly used when an acid or other fluid is repeatedly poured upon any substance in a retort, and distilled off, with a view to change the state or composition of either. See Distillation.

Acescent. A substance which becomes sour or acid by spontaneous decomposition is said to be acescent. This word is sometimes used, but less properly, instead of acidulous, or subacid, to denote a substance slightly acid.

Acetats. The salts formed by the combination of the acetic acid with alkalis, earths, and metals. Of these little is yet known.

Acetits. The salts formed by the combination of the acetous acid with alkalis, earths, and metals. For the alkaline and earthy salts, see Acid (Acetous); and for the metallic, the respective metals.

Acetous. Of or belonging to vinegar, or the acetous acid. See Acid (Acetous).

Achromatic. Telescopes formed of a combination of lenses, which in a great measure correct the optical aberration arising from the various colours of light, are called achromatic telescopes. Some of these have been made wonderfully perfect, and their excellence appears to be limited only by the imperfections of the art of glass-making. The artifice of this capital invention of Dollond consists in selecting, by trial, two such pieces of glass, to form the object lenses, as separate the variously coloured rays of light to equal angles of divergence, at different angles of refraction of the mean ray; in which case it is evident, that, if they be made to refract towards contrary parts, the whole ray may be caused to deviate from its course without being separated into colours. The difficulty of the glass-maker is in a great measure confined to the problem of making that kind of glass which shall cause a great divergence of the coloured rays with respect to each other, while the mean refraction is small. See Glass; also Aplanatic.

Acid. In the infancy of any science, when the attention of its cultivators is chiefly employed upon substances that differ from each other by great and obvious variations, it is easy to establish criterions, by which the classification of bodies may be effected: but when any particular branch is carried to a considerable degree of perfection, there will always be found a variety of articles, which form a connection between one class and another, and render it difficult to draw the line of discrimination. Acids were formerly distinguished by the popular criterion of the taste which is peculiar to them, and is denoted by the word sourness. Modern discoveries have, however, exhibited acids, in which the leading properties are too obscure to be of any great utility in determining their nature when unknown; and it is only from the general assemblage of properties, that they can be distinguished. These properties are,

1. Their taste is sour, and, unless diluted with water, corrosive. 2. They change blue vegetable colours to red. 3. Most of them unite with water in all proportions; and many have so strong an attraction to that fluid, as not to be exhibited in the solid state. 4. At a moderate temperature, or in the humid way, they combine with alkalis so strongly, as to take them from all other substances. 5. They combine with most bodies, and form combinations attended with many interesting phænomena; upon the due explanation of which great part of the science of chemistry depends.

There are a considerable number of instances in which combustible substances are converted into acids by being burned. Thus sulphur, by combustion, affords sulphuric acid; azotic air, repeatedly ignited by electricity, affords nitrous acid; and phosphorus, by burning, is converted into phosphoric acid. The analogy of other facts appears to justify the general position, that acids consist each of a peculiar basis, altered by combustion; and, as it is now generally admitted that the vital or truly respirable part of the atmosphere, that is oxigen, is absorbed during combustion, it will follow that an acid consists of a combustible substance united with oxigen.

This is indeed the simplest way of stating the result. But it is of the greatest importance, in scientific pursuits, to be cautious in simplifying our deductions. General hypotheses are most commonly constructed, by overlooking such concomitant circumstances in natural events as are least striking; but which, nevertheless, cannot be reasoned out of the course of the actual processes. When this expedient is used to obtain a delusive show of simplicity, the business of inquiring into the phænomena which are exhibited around us degenerates into a war of words, and the facts are no longer impartially displayed; such facts being always esteemed of greatest value as seem most effectual in supporting the favourite system. It must be confessed, however, on the other hand, that all useful investigation must necessarily tend to the discovery of general truths, and the developement of the simple laws of nature; that systems, formed in the less perfect state of any science, will of course be founded on fewer facts, and will, by successive emendation, become more and more complicated; and, consequently, that the real improvement of any theory will almost always consist in the rejection of principles formerly held to be essential to the science.

Oxigen, however, does not always form acids, and acids may be formed without the presence of oxigen. And if we suppose oxigen to be neutralized in the former case, as when hidrogen by its combination with it forms water, in which no acidity can be discovered; how is it that this same hidrogen, when combined with sulphur, possesses the properties of an acid? Hence Berthollet infers, that the principle of acidity must be something different from oxigen; and he is inclined to revive an old doctrine, that it is the matter of fire.

Several ingenious attempts have been made to ascertain the strength of acids, and the real quantity of saline matter contained in such as cannot, by any means hitherto devised, be deprived of water. Both these objects are very difficult to be obtained, and the latter, more especially, does not seem to be determinable by any other process, than such as shall actually leave the acid in a pure state, without the presence of water or any other substance. The prospect of this appears to be so unpromising, as almost effectually to discourage any attempts at performing it. The former inquiry seems to be within our power, provided the determination of the strength of acids be understood to imply nothing more than to deduce a method of ascertaining the quantity of acid, of a given density, which may be contained in any given measure of the same acid, more or less diluted with water. Experiments carefully made, by adding certain regulated quantities of water to equal portions, of the densest acids, will exhibit a series of densities or specific gravities, which, being tabulated, will serve to indicate the quantities of the densest acid which may be contained in any other portions of the same acid examined at the temperature of the original experiments, or with a due allowance for any variation between the temperatures. The utility of such tables has long been admitted in the mixtures of water and alcohol. See ALCOHOL.

A very usual method of ascertaining the comparative strengths of different acids, consists in saturating them with alkaline salt; that acid being supposed the strongest which requires the greatest quantity of alkali to cause the total disappearance of its acid properties: concerning which, however, see ATTRACTION. Against this, it is an insurmountable objection, that the acids do not differ from each other merely in strength, as estimated by this criterion, but are principally distinguished from each other by their several attractions to other substances, which follow no constant law deducible from experiments made with alkalis. So that the acid, which requires the greatest quantity of alkali for its saturation, will not maintain the same precedence when applied to earths, metals, or combustible bodies. As the method of examination by alkalis may nevertheless have its uses, especially in acids of the same kind, it is proper to observe, that the best mode of using the alkali is in a solution of a determinate specific gravity, as the real quantity of alkali may thus be ascertained with more accuracy, than if it were in a dry form. Distilled water must be used, and the specific gravity of this should be previously determined. The alkali too should be perfectly freed from carbonic acid, by boiling with quicklime, as directed under the article POTASH. By this test the proportional strength of different specimens of the same acid may be accurately known.

The acids hitherto discovered have been usually distributed into classes, accordingly as their radicals are derived from the mineral, vegetable, or animal kingdom. A more scientific mode has lately been attempted, that of classing them by the number of their radicals: but in the present state of our knowledge this mode is very imperfect, as some of the acids have never yet been decomposed, so as to ascertain whether they have in fact one or more radicals. Thus far therefore it is defective: and the difference at the same time is rather nominal than real; for the acids derived from the mineral kingdom are all considered in this arrangement as being compounds, while those from the other two are confounded together, as consisting of three or more ingredients; two only, the prussic and lithic, having four.

We are at present acquainted with 31. Of these, 16 are obtained from the mineral kingdom. 1. The sulphuric acid. 2. The sulphurous. 3. The nitric. 4. The muriatic. 5. The oxigenated muriatic. 6. The hyperoxigenated muriatic. 7. The carbonic. 8. The phosphoric. 9. The phosphorous. 10. The boracic. 11. The fluoric. 12. The arsenic. 13. The arsenious. 14. The molybdic 15. The molybdenous. 16. The chromic.

The vegetable kingdom furnishes us with 12. 1. The acetous. 2. The acetic. 3. The oxalic. 4. The malic. 5. The citric. 6. The tartarous. 7. The mucous. 8. The gallic. 9. The benzoic. 10. The succinic. 11. The camphoric. 12. The suberic.

From the animal kingdom 3 are obtained. 1. The prussic. 2. The lithic. 3. The sebacic

Besides these, there are 6 doubtful. 1. The melitic, from the mineral kingdom. 2. The moroxylic, from the vegetable 3. The amniotic. 4. The bombic. 5. The laccic. 6. The rosacic; all from the animal kingdom.

ACID (ACETIC). Radical vinegar, as this acid was formerly called, after having been considered as the acetous acid simply in a concentrated state, was long presumed to differ from it in being more oxigenised; whence it was distinguished, according to the principles of the new nomenclature, by the termination in *ic*.

From some late experiments of Mr. Pérès, however, and more recently of Chaptal, it appears to differ from the acetous acid by an abstraction of part of one of the ingredients of its compound base, the carbon, while the proportions between the oxigen and hidrogen remain the same in both.

The following is one of the experiments by which this conclusion is supported:

A hundred parts of each of the acids, the acetous and acetic, being saturated with pure potash, and the solutions evaporated, each affords a white, foliated deliquescent salt. Equal parts of each of these salts being put into two retorts, and exposed to an equal, graduated, and violent heat, two or three drops of a fetid and acrid water, without any acidity perceptible to the taste, passed over from the acetate; while the acetite gave out only some fumes, diffusing a similar smell. Both the salts melted and grew black; and as the heat was augmented, the retorts and receivers were covered within with a white vapour, which ultimately disappeared. A black residuum was left in each retort, and being washed by repeated affusions of boiling distilled water, the remainder, when dry, exhibited all the characters of oxide of carbon. The quantity of this oxide of carbon obtained from the acetate was 1-17th of its weight; that from the acetite 1-13th.

Thus, as all the vegetable acids yet known consist of a binary radical, compounded of hidrogen and carbon, which are combined with oxigen, and differ only in their relative proportions, this has perhaps as fair a claim to be considered as a different acid, as at least some of the others; though, while it is classed as a modification of the acetous, its termination is appropriate, as it virtually contains more oxygen, if it be not formed by an addition of this principle to the acetous acid itself.

Indeed it would appear probable, from some experiments since made by Mr. Dabit of Nantes, that there is an actual addition of oxigen. On distilling a mixture of acetite of potash and sulphuric acid, the product was acetic acid: on substituting muriatic acid for the sulphuric, acetous acid was obtained; but when he added black oxide of manganese to the latter mixture, acetic acid was formed. In none of these cases was any carbonic acid emitted, till toward the end of the distillation.

This acid has been generally obtained by distilling the crystallized acetit of copper. This being reduced to powder, and put into a glass or earthen retort, a fluid possessing little acidity first rises, which is soon succeeded by a very powerful acid. The receiver is then changed to obtain the latter separate. This acid has a greenish hue, from a small portion of oxide of copper coming over with it, and requires to be rectified by distillation with a gentle heat. It may thus be obtained perfectly colourless, if the fire be not urged too much toward the end of the operation, and the portion of oxide of copper left in the retort be not distilled too dry. The residuum of the first distillation is a brown copper-coloured powder, frequently exhibiting a metallic appearance on the sides of the retort: it is a powerful pyrophorus, contains but little oxide, and a little carbon.

This process requires some care, that the acid may be perfectly divested of the deleterious principles of the copper. Mr. Badollier, an apothecary of Chartres, recommends, as an easier method, the distillation of a mixture of equal parts of acetite of lead and sulphat of copper, by a moderate heat; when he says the acid will come over perfectly pure: but this has not succeeded in the hands of some other chemists, who always found the product contaminated with sulphurous acid. All danger of impregnation with copper, however, may be avoided, by obtaining the acid from acetit of soda, distilled with half its weight of sulphuric acid. Indeed Pérès, who has been already quoted, affirms, that he obtains a large quantity of acetic acid, as colourless and pungent as the radical vinegar of the shops, by distilling two parts of good white wine vinegar with one of sulphuric acid, and bringing the mixture suddenly to ebullition.

Acetic acid is transparent and colourless like water. Its smell is extremely pungent and acrid. When applied to the skin, it reddens and corrodes it in a very short time. It is exceedingly volatile, wholly evaporating on exposure to the air; and when heated in the open air takes fire readily. At 50° below 0 it freezes. It unites with water in any proportion, and on mixture with it heat is evolved. It forms salts termed acetates with earths, alkalis, and metals, which differ from the acetites, though their nature has not yet been much examined. It acts with more energy than the acetous on metals. It dissolves camphor, and the essential oils, as was observed by the elder Mr. Henry of Manchester; and a preparation of this kind, first made by him, is sold by the name of *aromatic vinegar*.

It is used for smelling to in cases of faintness, little crystals of sulphat of potash being put into a bottle, and moistened with it for this purpose. This mixture is commonly called *volatile salt of vinegar*. A few drops of sulphuric acid, added to a phial of the acetite of potash, make a strong smelling bottle by the evolution of the acetic acid.

This acid is sometimes contaminated with sulphurous acid, which may be known by the vapour occasioning an unpleasant sensation in the lungs; with sulphuric, which may be detected by muriate of barytes; with copper, which supersaturation with pure ammonia will show; with lead, the test of which is sulphuret of ammonia. Its specific gravity should be at least 1·060. —*Lagrange.* — *Thomson.* — *Fourcroy.* — *Parkinson.* — *Henry.* — *An. de Chimie.*

Acid (Acetous). This acid is produced by a peculiar fermentation from vinous liquors. See Fermentation (Acetous). Its qualities depend much on the method of exciting and of conducting that fermentation. The wine which in France is generally converted into vinegar, and which for its cheapness is generally employed for this purpose, is such as has become already sour; although the better and the more spirituous the wine is, and also the more of the vinous spirit that can be retained in the vinegar, the better and stronger this will be. Becher says in his Physica Subterranea, that having digested wine in order to convert it into vinegar in a bottle hermetically sealed, he found, that although a longer than the ordinary was required, the vinegar produced was much stronger than when free air is admitted. Cartheuser also affirms, that the strength of vinegar may be much increased, by adding some ardent spirit to the wine before it is exposed to the acetous fermentation.

Different methods are practised by manufacturers for making vinegar, who are generally believed to be possessed of some secret for this purpose. Nevertheless, no more seems requisite in the preparation of good vinegar, than to employ wine, and to conduct the fermentation in the most advantageous method; in the same manner as good wine can only be made from good must, and by a well conducted fermentation. The principal part of these operations is performed by nature.

The method of making vinegar consists in mixing the wine to be fermented with its dregs and its tartar, and in exposing this liquor to a heat of about seventy or eighty degrees. This fermentation seems to require more heat than the spirituous. It also excites more heat and tumult; and although it ought to be allowed to proceed briskly, yet it is necessary from time to time to check it.

Boerhaave describes, in his Elements of Chemistry, the following process, which seems to be well contrived for the making of vinegar.

Take two large oaken vats, or hogsheads, and in each of these place a wooden grate or hurdle at the distance of a foot from the bottom. Set the vessel upright, and on the grate place a moderately close layer of green twigs, or fresh cuttings of the vine. Then fill up the vessel with the footstalks of grapes, commonly called the cape, to the top of the vessel, which must be left quite open.

Having thus prepared the two vessels, pour into them the wine to be converted into vinegar, so as to fill one of them quite up, and the other but half full. Leave them thus for twenty-four hours, and then fill up the half-filled vessel with liquor from that which is quite full, and which will now in its turn only be left half full. Four-and-twenty hours afterwards repeat the same operation, and thus go on, keeping the vessels alternately full and half full during twenty-four hours till the vinegar be made. On the second or third day there will arise in the half-filled vessel, a fermentative motion, accompanied with a sensible heat, which will gradually increase from day to day. On the contrary, the fermenting motion is almost imperceptible in the full vessel; and as the two vessels are alternately full and half full, the fermentation is by this means in some measure interrupted, and is only renewed every other day in each vessel.

When this motion appears to have entirely ceased, even in the half-filled vessel, it is a sign that the fermentation is finished; and therefore the vinegar is then to be put into casks close stopped, and kept in a cool place.

A greater or less degree of warmth accelerates or checks this, as well as the spirituous fermentation. In France it is finished in about fifteen days, during the summer; but if the heat of the air be very great, and exceed the twenty-fifth degree of Reaumur's thermometer, (88½° Fah.,) the half-filled vessel must be filled up every twelve hours; because, if the fermentation be not so checked in that time, it will become violent, and the liquor will be so heated that many of the spirituous parts, on which the strength of the vinegar depends, will be dissipated, so that nothing will remain after the fermentation but a vapid liquor, sour indeed, but effete. The better to prevent the dissipation of the spirituous parts, it is a proper and usual precaution to close the mouth of the half-filled vessel, in which the liquor ferments, with a cover made of oak wood. As to the full vessel, it is always left open, that the air may act freely on the liquor it contains; for it is not liable to the same inconveniencies, because it ferments but very slowly.

In the Dictionnaire Portatif des Arts et Métiers, another method is described, by which a very good vinegar is commonly made at Paris from the lees of wine. For this purpose all the wine contained in the lees is pressed out and put into large casks, the bung-holes of which are left open. These casks are put into a hot place, and if the fermentation proceeds too fast, it must be checked by adding more fresh wine. The process is very similar to the foregoing.

In this country wine of course is not used, but other matters susceptible of undergoing the vinous fermentation; as an infusion of malt, cider, melasses, the refuse raisins left after making raisin wine. Many persons make a good vinegar for domestic purposes by exposing coarse sugar or melasses, mixed with water, to the heat of the sun in summer, in a vessel not closely stopped.

The appearances which accompany the acetous fermentation, resemble much those that occur in the spirituous fermentation. In both fermentations an intestine motion, a swelling, a hissing noise, and an ebullition may be perceived. There are, nevertheless, essential differences between them. Besides that the products of the vinous and acetous fermentations differ exceedingly, the heat produced by the former is scarcely sensible, while that produced by the latter is considerable. Again, there is reason to believe that the vapour which exhales from vinegar during fermentation is not noxious, as the vapour of fermenting wine is; at least, it has not been observed to produce such bad effects. On the contrary, as the acid of vinegar more and more disengages or unfolds itself, it seems to acquire more power to retain the basis of carbonic acid, which is the truly dangerous part of the vapours of fermentation. Lastly, vinegar does not deposit tartar as wine does, even although it has been made with wine that had not deposited its tartar. But the sediment of vinegar is a viscid, oily, and very putrescent matter. The grape-stalks used in the making of vinegar, to promote and increase the fermentation, are covered over with this matter during the operation. They are generally washed clean, and carefully preserved, to promote the fermentation of more vinegar, because the acid with which they are soaked acts powerfully as a leven or ferment. The casks also which have been used for the preparation of vinegar are to be cleansed from the abovementioned viscid matter, and kept for the same use, as they are rendered fitter than new casks for the preparation of vinegar. The concrete mucous sediment produced from the slow decomposition of vinegar, and called mother, is likewise an acetous ferment, and is used for this purpose by the country people in France.

It appears that the strength of vinegar is impaired by too speedy fermentation in vessels not at all stopped, most probably from the escape of alcohol, which certainly contributes to its fermentation. Hence small casks or vessels imperfectly closed, are best suited to this process. In England the vinegar makers use several hundreds of casks disposed in the open air, with the bung-hole upwards, and covered each with a tile to exclude the rain. Beer is brewed of a proper strength from malt for this express purpose. The addition of hops is not here used.

Milk also affords vinegar by fermentation. This fluid does not afford ardent spirit enough to favour the operation, which therefore requires either the addition of a small portion of spirit, or a considerable heat, such as that of a warm oven for two or three days.

Much ingenious reasoning has been offered by philosophers on the effects of the acetous fermentation, and the component parts of vinegar. The leading and established facts are, that mucilage is necessary for the production of this acid by fermentation, and that oxygen is absorbed in the process. From the order of convertibility of vegetable acids into each other, it appeared highly probable, that these had one common basis, and differed only in the greater or less degree of acidification. And in fact it is now known, that they have all the same radical, consisting of hidrogen and carbon; but, these differ in their proportion to each other, as well as in the relative proportion of oxigen.

Vinegar thus prepared, however, is not pure acetous acid, as it contains likewise mucilage, tartar, colouring matter, and frequently the malic and citric acids. In this state it is very subject to decomposition; but Scheele discovered, that if it be made to boil for a few moments, it may be kept afterwards a long time without alteration. When distilled at a temperature not exceeding that of boiling water, till about two-thirds of it have passed over, all these impurities are left behind, and the product, commonly known by the name of distilled vinegar, is pure acetous acid. If it be not distilled gently, or too much be drawn off, it acquires an empyreuma.

Glass vessels are preferable for the distillation of vinegar; as well as for most other chemical operations, where their size and the required heat will permit. Earthen or stone ware vessels may also be used. For larger quantities a copper alembic with a glass head and worm pipe of pure tin is recommended. Some direct that the inside should be tinned, and others that it should be smeared with grease. This last contrivance does not seem to promise much advantage, and may vitiate the acid, since Rozier remarks, that fat oils and vinegar have some action on each other in distillation. There is probably nothing to fear from the bare copper, if the vinegar be poured in hot. For the confectioners have long since remarked, that hot vinegar does not corrode or receive any impregnation from the copper vessels, though there is much danger in suffering it to remain in them cold. This has been explained, not from the difference of temperature, but the exclusion of the external air by the vapo of the hot fluid, which in neither case act on the copper, unless oxigen be pres to be absorbed.

Though the acetous acid is commonly product of the acetous fermentation, ve may be obtained by other means. The insip saccharine, mucilaginous, and extractive m ters of vegetables may be converted i this acid by various processes. The sp taneous action of the sulphuric acid up them always changes them in part i acetous acid. Fourcroy remarks, that t mere tendency of concentrated sulphu acid to saturate itself with water is a ve active cause of the alteration it occasions vegetable substances. This alteration co sists in three different though simultaneo effects: on one hand it unites a portion their hidrogen with a portion of their ox gen to form the water with which it sat rates itself: on the other, carbon is sep rated, which imparts to the mixture a brow and even black colour, and soon precip tates to the bottom of the acid; at th same time a third portion of these matte passes to the state of acetous acid, whic remains mixed with the sulphuric, and ma be separated from it by distillation; so tha there is no vegetable substance, whic treated in the cold way with this poten acid, does not yield more or less acetou acid, on being afterward subjected to th action of fire.

Nitric acid, which has such a powerfu tendency to destroy vegetable compounds always forms from them a little aceto acid, at the same time with the mucous an oxalic, and perhaps even malic acid. Crel showed long ago, that alcohol itsel was partly converted into acetous acid when treated with the nitric. Even the muriatic acid, though much less powerful than the sulphuric or nitric, effectuates a similar conversion, when allowed to stand a considerable time on vegetable substances. But above all the oxigenated muriatic acid, notwithstanding its little solubility, being received in the state of gas into vegetable juices, or solutions of vegetable substances, has the property of converting part of them into acetous acid. Thus, on treating alcohol by this agent it is converted much more into acetous acid than into ether; and for this reason the muriatic ether is always acid, and but little in quantity.

It has been supposed, that all the other vegetable acids were capable of passing to the state of acetous acid, and that this was the common term of their acidification; but it has by no means been fully proved. If in fact the tartarous acid, as well as the malic, appear to be susceptible of this conversion; and if the tartarous acidule may be considered, from its constant presence in wine, as the ferment that induces its acetification, and as affording a matter itself that becomes acetous acid: the same cannot be said of the oxalic acid, the strongest and most unalterable of all the vegetable acids, and one that resists all spontaneous alteration, in the same circumstances under which the tartarous acid and tartrits are decomposed and destroyed.

Neither does the acetous fermentation absolutely require to be preceded by the vinous, as was formerly supposed, and too implicitly believed on the authority of Boerhaave. In reality, says Fourcroy, all vegetables are capable of undergoing the acid or acetous fermentation, without having experienced the vinous. This is the case with leaves and roots; with cabbages soured in water, to make sour crout; starch or farina in starch-makers' sour waters; and dough itself, which, if it be suffered to ferment a little too violently, becomes acid, and gives a very perceptible sour taste to the bread made of it. In the instances just given it was imagined, that an imperceptible vinous fermentation first took place: but we cannot admit a vinous fermentation, of which we have no proof and no appearance, in the sap of trees at the moment of its extraction, and in extracts speedily prepared, all which contain acetous acid. The urine too of man, and of some animals, certainly does not undergo the vinous fermentation, yet it readily affords this acid by an intestine movement of its own component parts. We must conclude, therefore, that there is an acetous fermentation independent of the vinous, as well as a formation of acetous acid in matters not in the state of wine.

The acetous acid is perfectly limpid, of a tolerably pleasant smell, a pungent acid taste, and of a specific gravity not exceeding 10·005. It is more volatile than decomposable, and exposed alone to the fire evaporates entirely. It has no action on hidrogen, carbon, phosphorus, or sulphur. With the mode in which it is affected by the potent acids, we are not yet fully acquainted; though it is known that, concentrated sulphuric acid being poured on 2 parts of acetite of potash, in a tubulated retort, and exposed to a gentle heat, sulphurous acid and acetic acid will be given out with great effervescence; and nitric acid decomposes it into water and carbonic acid. It weakly dissolves the boracic acid, and absorbs the carbonic. Charcoal, according to the discovery of M. Lowitz, has the property, when powdered and mixed with the acetous acid, of retaining the acid part, and allowing the watery to evaporate, at the heat of 212°. If the charcoal be afterward exposed to a strong heat, the acetous acid is driven off; and thus Lowitz obtained it in a very highly concentrated state.

The acetous acid unites with all the alkalis and most of the earths, and with these bases it forms compounds, some of which are crystallizable, and others have not yet been reduced to a regularity of figure. The salts it forms are distinguished by their great solubility; their decomposition by fire, which carbonizes them; the spontaneous alteration of their solution; and their decomposition by a great number of acids, which extricate from them the acetous acid in a concentrated state. It unites likewise with most of the metals.

With barytes the saline mass formed by the acetous acid does not crystallize; but, when evaporated to dryness, it deliquesces by exposure to air. This mass is not decomposed by acid of arsenic. By spontaneous evaporation, however, it will crystallize in fine transparent prismatic needles, of a bitterish acid taste, which do not deliquesce when exposed to the air, but rather effloresce.

With potash this acid unites, and forms a deliquescent salt scarcely crystallizable, called formerly foliated earth of tartar, and regenerated tartar. The solution of this salt, even in closely stopped vessels, is spontaneously decomposed: it deposits a thick, mucous, flocculent sediment, at first gray, and at length black; till at the end of a few months nothing remains in the liquor but carbonate of potash, rendered impure by a little coaly oil.

With soda it forms a crystallizable salt, which does not deliquesce. To this salt no name has been generally given, though it has very improperly been called mineral foliated earth. According to the new nomenclature it is acetite of soda.

The salt formed by dissolving chalk or other calcareous earth in distilled vinegar, formerly called salt of chalk, or fixed vegetable sal ammoniac, and by Bergman calx acetata, has a sharp bitter taste, appears in the form of crystals resembling somewhat ears of corn, which remain dry when exposed to the air, unless the acid has been superabundant, in which case they deliquesce. By distilling without addition, the acid is separated from the earth, and appears in the form of a white, acid, and inflammable vapour, which smells like acetous ether, somewhat empyreumatic, and which condenses into a reddish brown liquor.

This liquor, being rectified, is very volatile and inflammable: upon adding water it acquires a milky appearance, and drops of oil seem to swim upon the surface. After the rectification, a reddish brown liquor remains behind in the retort, together with a black thick oil. When this earthy salt is mixed with a solution of sulphate of soda, the calcareous earth is precipitated along with the sulphuric acid, the acetous acid uniting with the soda, makes a crystallizable salt, by the calcination of which to whiteness, the soda may be obtained. This acetous calcareous salt is not soluble in spirit of wine.

Of the acetite of strontian little is known, but that it has a sweet taste, is very soluble, and is easily decomposed by a strong heat.

The salt formed by uniting vinegar with ammonia, called by the various names of spirit of Mindererus, liquid sal ammoniac, acetous sal ammoniac, and by Bergman alkali volatile acetatum, is generally in a liquid state, and is commonly believed not to be crystallizable, as in distillation it passes entirely over into the receiver. It nevertheless may be reduced into the form of small needle-shaped crystals, when this liquor is evaporated to the consistence of a syrup.

Westendorf, by adding his concentrated vinegar to carbonate of ammonia, obtained a pellucid liquid, which did not crystallize, and which by distillation was totally expelled from the retort, leaving only a white spot. In the receiver under the clear fluid a transparent saline mass appeared, which being separated from the fluid, and exposed to gentle warmth, melted, and threw out abundance of white vapours, and in a few minutes shot into sharp crystals resembling those of nitre. These crystals remain unchanged while cold, but they melt at 120° and evaporate at about 250°. Their taste at first is sharp and then sweet, and they possess the general properties of neutral salts.

With magnesia the acetous acid unites, and, after a perfect saturation, forms a viscid saline mass, like a solution of gum arabic, which does not shoot into crystals, but remains deliquescent, has a taste sweetish at first, and afterward bitter, and is soluble in spirit of wine. The acid of this saline mass may be separated by distillation without addition.

Glucine is readily dissolved by acetous acid. This solution, as Vauquelin informs us, does not crystallize; but is reduced by evaporation to a gummy substance, which slowly becomes dry and brittle; retaining a kind of ductility for a long time. It has a saccharine and pretty strongly astringent taste, in which that of vinegar however is distinguishable.

Yttria dissolves readily in acetous acid, and the solution yields by evaporation crystals of acetite of yttria. These have commonly the form of thick six-sided plates, and are not altered by exposure to the air.

Alumine, obtained by boiling alum with alkali, and edulcorated by digesting in an alkaline lixivium, is dissolved by distilled vinegar in a very inconsiderable quantity. A considerable quantity of the earth of alum, precipitated by alkali, and edulcorated by hot water in Margraaf's manner, is soluble in vinegar, and a whitish saline mass is then obtained, which is not crystallizable. From this mass a concentrated acetous acid may be obtained by distillation. Or to a boiling solution of alum in water gradually add a solution of acetate of lead till no further precipitate ensues. The sulphate of lead having subsided, decant the supernatant liquor, evaporate, and the acetat of alum may be obtained in small needle-shaped crystals, having a strong styptic and acetous taste. This salt is of great use in dyeing and calico-printing. The alumine must be recently precipitated, and 240 parts of the acid dissolve only 20 5-7ths.

Acetit of zircone may be formed by pouring acetous acid on newly precipitated zircone. It has an astringent taste. It does not crystallize; but, when evaporated to dryness, forms a powder, which does not attract moisture from the air. It is very soluble both in water and alcohol; and is not so easily decomposed by heat as nitrat of zircone.

The acetous acid has no action upon siliceous earth; for the needle-shaped crystals observed by Durande in a mixture of vinegar with the earth precipitated from a liquor of flints, do not prove the solubility of siliceous earth, as Leonhardi observes.

Concerning the action of vinegar on alcohol, see ETHER. This acid has no effect upon fat oils, except that when distilled together, some kind of mixture takes place, as the Abbé Rozier observes. Neither does distilled vinegar act upon essential oils; but Westendorf's concentrated acid dissolved about a sixth part of oil of rosemary, or one half its weight of camphor; which latter solution was inflammable; and the camphor was precipitated from it by adding water.

Vinegar dissolves the true gums, and partly the gum resins, by means of digestion.

Boerhaave observes, that vinegar by long boiling dissolves the flesh, cartilages, bones, and ligaments of animals.

The Count de Lauraguais obtained a highly concentrated acid from verdigrise, in an icy form. This form has hitherto been entirely ascribed to the cupreous particles combined with, or at least acting upon it; but M. Lowitz has shown, that the acetous acid itself possesses the property of assuming a crystallized form.

This chemist prepared a concentrated acetous acid (alkohol aceti) by congelation in the following manner:—He froze a whole barrel of vinegar as much as possible, then distilled the remaining unfrozen vinegar in a water bath; by which means he at first especially collected the spirituous ethereal parts; the vinegar, which next comes over, he froze again as much as possible, and afterward purified it, by distilling it again with three or four pounds of charcoal powder. By this means he never failed to procure a very pure, sweet-smelling, highly concentrated acid; the agreeable odour of which, however, may be still further improved by the addition of a proper quantity of the ethereal liquor collected at the beginning of the first distillation, but which must be previously dephlegmated by two or three rectifications.

After the distillation on the water-bath was over, that no acid might be lost, he removed the retort, with the charcoal powder which remained in it, to a sand-bath; and thus he obtained, by means of a strong fire, a few ounces more of a remarkably concentrated acid, which was of a yellow colour.

Having collected about ten ounces of this concentrated acid, he exposed it to a cold equal to 195 of de Lisle's thermometer; in which situation it shot into crystals from every part. He let what remained fluid drop away from the crystals into a basin placed underneath, first in the cold air, and afterward at the window within doors. There remained in the bottle snow-white finely foliated crystals, closely accumulated upon each other, which at first he took to be nothing but ice: on placing them upon the warm stove, they dissolved into a fluid which was perfectly as limpid as water, had an uncommonly strong highly pungent, and almost suffocating acetous smell, and, in the temperature of 145 of de Lisle's scale, immediately congealed into a solid white crystallized mass, resembling camphor.

The quantity of this glacial acid amounted to two ounces; and the following are the most remarkable properties which it exhibits in this uncommonly beautiful crystallized state:

1. In a temperature of 145 degrees, the previously liquefied glacial acid begins to shoot into beautiful arborescent and plumous figures, exactly in the same manner as water that undergoes a gradual congelation. There is at this time a considerable extrication of air-bubbles, and at length the vinegar congeals into a crystallized and completely solid mass.

2. This crystallized glacial acid requires a temperature of at least 126, in order to become fluid again.

3. The crystallization of the fluid glacial acid is soonest effected by placing it in water mixed with snow or ice.

4. If only a part of the crystallized glacial acid be melted, by the application of the warm hand an appearance of very fine crystallizations is afforded, provided the warmth of the room is not greater than 130 degrees. This may be repeatedly produced. If it be suffered to remain undisturbed in this temperature, large spicular crystals are seen to shoot up along the sides of the bottle, considerably above the fluid, and frequently to bend over to the opposite side, in the form of an arch, till they dip into the liquid acid again.

5. One of the most remarkable phænomena is this, that, by exposure to an increasing cold, a great variety of excessively delicate vegetations, resembling a sublimation, take place in the empty part of the bottle. Although they stretch out very far, and hang as it were floating in the empty part of the bottle, they only adhere by a very small point. They are so extremely thin and transparent, as not to be discernible in certain directions; and they frequently exhibit all the various colours of the rainbow.

6. By placing the glacial acid in snow, the four following equally pleasing appearances may be produced:

If, as exactly as possible, the smallest degree of cold in which the glacial acid is capable of beginning to freeze, be applied, there are immediately formed, on opening the bottle and shaking it a little, an immense number of extremely thin floating crystals, which are in the form of equilateral triangles, quadrangular planes, &c., and exhibit, especially in clear weather, the finest variety of colours.

On increasing the cold, and afterwards opening and shaking the bottle as before, beautiful, shining, thin crystals, of a quadrangular, pentangular, hexangular, radiated form, fall to the bottom, and exactly resemble flakes of snow.

In a still greater degree of cold, little radiated balls, or globular lumps, fall down to the bottom, increasing very quickly in size during their descent.

Lastly, if the refrigeration be carried to its highest pitch, and the bottle be opened and shaken before the crystallization has spontaneously begun, the acid congeals throughout, with an extraordinary quickness, into a compact snow-white, striated mass.

For the production of these appearances, it is necessary that the glacial acid be previously brought into a perfectly liquid state.

7. The internal surface of the bottle, in which the glacial acid is kept, is frequently covered over with the finest delineated figures, some of which are crisped, after the manner of the frost on windows; others, on the contrary, are of an angular, jagged, or rectilinear form, amongst which are also sometimes to be seen, quite distinct from the other figures, equilateral triangles.

8. When the glacial acid begins to crystallize in a quiet place, the surface of the still fluid acid is covered over, as soon as some spicular and arborescent crystals shoot from the bottom upwards, with a crust as shining and smooth as a mirror; underneath which, however, a large concavity is immediately afterwards formed by the air, which is extricated in great abundance, and mounts upwards.

9. Glacial acetous acid in its solid or crystallized state, notwithstanding the great quantity of air-bubbles that are entangled in its whole mass, occupies much less space than it did in its fluid state.

After M. Lowitz had attended to these striking properties, and had observed that the acetous acid in this state is of such an extraordinary strength and purity as to be in its highest degree of perfection, he took all possible pains to find out a method of obtaining in the glacial form all the acetous acid contained in vinegar.

The strength of each sort of vinegar, which it was necessary for him to know in his experiments, by degrees he ascertained in the following manner: viz. To one drachm of vinegar he added, drop by drop, a clear solution of equal parts of salt of tartar and water, till all at once a cloudiness or precipitation appeared. Although, on the appearance of this sign, the acid is already supersaturated with the alkali, yet it seems to be a more accurate test for ascertaining its strength, than the cessation of effervescence; for, as the point of saturation approaches, the effervescence becomes so imperceptible, that it is almost impossible to determine with precision when it is really at an end. Every five drops of the alkaline solution, which he finds it necessary to add to the vinegar, till the precipitation takes place, he reckons as one degree. Thus, for example, if a determinate quantity of vinegar requires 25 drops for this effect, he denotes its strength by five degrees. This is about the strength of good distilled vinegar.

That vinegar, which in consequence of its concentration is capable of crystallizing in a great degree of cold, he calls crystallizable vinegar; the crystals separated, after the crystallization is completed, from the remaining fluid portion, he calls glacial vinegar; and lastly, to the fluid residuum he gives the name of mother ley of vinegar.

From a great number of experiments he found, that vinegar must have at least twenty-four degrees of concentration, before it can be brought to crystallize by exposure to the most intense cold. Vinegar must be of the strength of 42 degrees at least, in order to become glacial vinegar; viz. in this state of concentration it has the property of crystallizing in a degree of cold not exceeding that in which water begins to freeze.

He found that charcoal, on being distilled with vinegar in a water-bath, possesses the singular, and hitherto unknown property, of imbibing a certain quantity of the acetous acid in a very concentrated state, and of retaining it so strongly, that the acid cannot be separated from it again, but by the application of a considerably greater degree of heat than that of boiling water. Upon this circumstance is founded the new method which he discovered of concentrating vinegar, so as to obtain all its acid in the purest state, viz. that of a glacial vinegar.

Let a barrel of vinegar be concentrated by freezing in the manner before described, and let the concentrated vinegar thus obtained, free from all inflammable or spirituous parts, be put into two retorts: add to each of them five pounds of good charcoal reduced to a fine powder, and subject them to distillation in a water-bath. When no more drops of acid come over, put the distilled liquor into two fresh retorts; and after adding five pounds of charcoal powder to each, proceed as before to distillation in a water-bath. In the mean time, the two first retorts are to be placed in a sand-bath, that, by means of a brisk fire, the crystallizable acid which is retained in the apparently dry charcoal powder may be expelled from it. The heat must be strong enough to make the drops follow one another every two seconds; and when, in this degree of heat, 20 seconds intervene between each drop, the acid which has been collected must be removed; for what follows is hardly any thing else but mere water. In this manner about six ounces and a half of crystallizable acid, which is generally of the strength of between 36 and 40 degrees, may be collected from each retort. As soon as the distillation by the water-bath in the two other retorts is over, the distilled liquor is to be poured back again into the first retorts, upon the charcoal powder, which remains in them, and which has been already used; and from each of these retorts the remaining crystallizable acid (which generally amounts to as much as the first quantity) is to be abstracted by distillation in a sand-bath. These operations may be alternately repeated, till all the acid of the vinegar which had been concentrated by freezing, is converted into crystallizable acid; or until the distilled liquor, constantly becoming weaker and weaker at every repetition of the distillation, comes over at length in the state of mere water; which, with the above-mentioned quantity of charcoal powder, generally happens at the fourth or fifth distillation. Now, in order to obtain the greatest part of the pure acid contained in the crystallizable vinegar, in the form of glacial acid, it must be set to crystallize in a great degree of cold; and the mother ley must be afterwards thoroughly drained from the glacial acid, by letting it drop from the crystals, first in the cold, and then in the room before the window. The mother ley may be rendered further crystallizable, by distilling it with a little charcoal powder; the weaker part which comes over first being put aside. But if a person wish to keep the crystallizable acid (which far exceeds Mr. Westendorf's in point of strength) for other purposes, and without separating any glacial acid from it, he must distil the whole of it again with charcoal powder in a sand-bath.

M. Lowitz found by accurate experiments, that by means of this curious process ten pounds of vinegar concentrated by freezing to the nineteenth degree, may be made to yield 38 ounces of crystallizable vinegar, from which 20 ounces of glacial acid may be obtained.

What constitutes the excellence of this

method is, that the concentration and purification are effected by one and the same medium, viz. the charcoal powder; in consequence of which, both intentions are fulfilled at the same time.

The crystallization of the acid is, at the same time, the means by which it acquires its highest degree of concentration, and its greatest purity; for the extraneous matter, which cannot otherwise be parted, even with the assistance of the charcoal, from the genuine acid, is thus separated from the pure acetous crystals, and left behind in the mother ley.

It was this extraneous matter, which cannot well be separated from the pure acetous acid by any other means but by crystallization, that led Dr. Amburger, agreeably to the results of his experiments, to draw conclusions contrary to Mr. Westrumb's theory, respecting the convertibility of the acetous acid into the acid of sugar.

M. Lowitz, in the course of his experiments relative to this process, for concentrating and purifying vinegar by charcoal powder and crystallization, made the following observations:

1. With one pound of charcoal powder very little more than ten drachms of crystallizable acid is obtained; and this is the case, whether the vinegar, which is to be distilled over it, be strong or weak, in a large or in a small quantity. It is taken for granted, however, that the vinegar shall contain at least as much acid as the charcoal powder is capable of imbibing and retaining in the distillation by the water-bath.

2. The quantity of crystallizable acid which is obtained, is in a direct ratio to the quantity of charcoal powder employed.

3. The least cold in which crystallizable acid, prepared by means of charcoal powder, shoots into crystals, is that of 175 degrees.

4. In the first distillation a yellow crystallizable acid comes over: but in the subsequent distillations by which the acid is purified from all its colouring or inflammable matter, it is always obtained perfectly limpid like water.

5. Crystallizable acid of the strength of 38 degrees, yielded glacial acid of 54 degrees of concentration, whilst the strength of the mother-ley amounted only to 28 degrees.

6. All glacial acetous acid is not of an equal strength.

7. M. Lowitz thinks he has observed that glacial acetous acid is stronger, in proportion to the intenseness of the cold by which it has been produced.

8. In a cold of 183 degrees, he obtained glacial acetous acid of the strength of 54°, which he finds to be the highest degree of concentration that the acetous acid is capable of obtaining.

9. As the water-bath, though it insures success, is often inconvenient, and takes up a great deal of time, it may be dispensed with by a skilful management of the fire; which, however, requires very great attention.

M. Lowitz, in the further prosecution of the experiments which concentrated glacial acetous acid, observed many other curious phænomena, which are as follow:

If vinegar concentrated by freezing be distilled very slowly, and without any addition, there comes over, at last, a small quantity of crystallizable acid, from which, by means of a great degree of cold, a little glacial acetous acid may be procured. This method, however, is not only very tedious, but the acid thus obtained is highly impure and empyreumatic.

By abstracting a large quantity of common distilled vinegar, over charcoal powder, first in a water-bath and afterwards in a sand-bath, crystallizable acetous acid may in like manner be obtained; but, on account of the great proportion of water in distilled vinegar, this method is extremely tedious.

Reflecting on this property of glacial acetous acid, viz. that it requires for its liquefaction a degree of warmth considerably greater than that in which the completely liquefied glacial acid is capable of crystallizing, M. Lowitz was led to discover a method by which crystallizable acid may be made to crystallize in a cold 15 degrees less than that which was before required, viz. Into some previously liquefied glacial acid he dipped a thin cotton wick, crystallized the acid by placing it in snow, and then in a cold of 158 degrees applied the same wick, with the crystals adhering to it, to the surface of some crystallizable acid of the strength of 38 degrees; there immediately formed round the end of the wick a number of needle-shaped crystals, which visibly increased in size; the surface of the acid became covered over with an icy crust; a great number of radiated crystals, exactly resembling flakes of snow, gradually sunk to the bottom of the bottle, where they continued to accumulate; and at length the acid, throughout, shot into fine large crystals. By this mode of treatment, it is rendered unnecessary to wait for a cold of 175 degrees; so that we have it in our power, at all times, to obtain acetous acid in the state of very beautiful transparent crystals, of a regular prismatic shape, and several inches in length.

From two pounds three ounces of perfectly dry acetate of soda, and a pound and a half of highly concentrated sulphuric acid, M. Lowitz prepared, according to Mr Westendorf's method, 13 ounces of an alcohol aceti, of the strength of 32 degrees. By exposing it in the night-time to a cold of 174 degrees, and by applying to its surface some crystals of glacial acetous acid, adhering to a cotton-wick, he immediately brought it to crystallize; and the next morning, in a cold of 182 degrees, he found it formed into beautiful prismatic crystals, which were three inches in length. After the mother-ley was poured off, these crystals weighed three ounces two drachms and a half. He distilled this mother-ley, the strength of which still amounted to 24 degrees, with two pounds of charcoal powder, in a water-bath: the acid which came over into the receiver had a very sweet smell, and was now only of the strength of 16 degrees. From the residuous powder he afterwards obtained, by distillation in a sand-bath, two ounces six drachms and a half of a smoking crystallisable acid, of the strength of 36 degrees.

The properties of this glacial acid, prepared from Mr. Westendorf's vinegar, are precisely the same as those of the glacial acid which is obtained by means of charcoal powder alone; whence it follows, that the acid is not altered by its combination with a foreign body (viz. the alkali), and its subsequent separation from it; or that the charcoal produces the same effect as the alkali.

After much reflection, M. Lowitz was so happy as to find out another very effectual method of separating the acetous acid from the other substances combined with it, so as to obtain it at once in the state of a glacial acid of the greatest possible strength. The separating medium which he thought of, is a sulphate of potash supersaturated with sulphuric acid, a salt, in which, conformably to his purpose, the sulphuric acid exists in a perfectly dry and dephlegmated state:

His first business was to contrive an easy method of preparing this salt, the properties of which have been hitherto but little examined; and after various trials, he hit upon the following successful process;

Mix together in a tall matrass seven parts of water with an equal quantity of sulphuric acid, and to the very hot mixture add, as quickly as the effervescence will permit, four parts of salt of tartar or levigated pot-ashes. As soon as the mixture becomes cool, the supersaturated sulphate of potash shoots into fine large crystals. After the whole is become quite cold, and the cystallization is at an end, the liquor (which may serve again for a fresh mixture of the same kind) is to be poured off, and the salt which remains in the matrass is to be shaken together, and to be well rinsed as quickly as possible with cold water, in order to cleanse it from all the sulphuric acid which adheres to its surfaces, and which would otherwise be prejudicial to the dry acid. The crystals are afterwards to be dried by exposure to the fire, and to be triturated to a very fine powder, which, just before it is used, must be again thoroughly exsiccated.

By means of this salt, a highly concentrated glacial acetous acid may be obtained in the following manner:

Let three parts of acetate of soda, prepared with vinegar distilled over charcoal, and evaporated to perfect dryness, be melted in a strong heat; then pour it out, and rub it to a very fine powder. Mix this powder very accurately with eight parts of supersaturated sulphate of potash, that has been previously well dried, and in like manner reduced to a fine powder; put the whole into a retort, and distil it with a gentle heat, in such a manner, that along with the drops some vapours also may be perceived to come out of the neck of the retort; but by no means so that the receiver shall be filled with these vapours. Notwithstanding the moderate heat, the acetous acid comes over very fast; and the quantity of glacial acid, of the strength of 54 degrees, which is thus obtained, amounts to nearly two parts, and possesses all the characters which have been before described.

By this process, seven pounds of glacial acetous acid may be obtained from 300 pounds of common vinegar; and from five pounds of distilled vinegar, of the strength of five degrees, two ounces of glacial acid may be procured in the space of six hours.

This glacial acid generally acquires an unpleasant smell, from which, however, it may be completely freed by distillation with charcoal powder, in the proportion of at least five or six parts of the latter to one part of the acid: or, to three ounces of this acid add about a drachm of perfectly dry and finely pulverized acetate of lime; shake them well and repeatedly together, and let the mixture remain exposed to the sunshine till the disagreeable smell is entirely gone; then redistil the vinegar in a gentle heat.

In its purification, whatever be the way in which it is effected, this glacial acid is unavoidably lowered some degrees in strength.

The melting of the acetated soda only serves for the expulsion of all the watery parts from the salt; but a glacial acid of the strength of between 46 and 50 degrees may be procured from a merely exsiccated acetate of soda.

For the production of glacial acetous acid, by means of the supersaturated sulphate of potash, not only the acetated soda, but also well dried acetate of lime may be employed.

How much preferable this last process, with sulphate of potash saturated with an excess of acid, is to the other, in which glacial acetous acid is prepared from Mr. Westendorf's vinegar, will appear from a comparative statement of the following particulars:

1. In the direct separation by means of sulphuric acid, we are restrained from adding to the acetated salt as much of the sulphuric acid as is necessary for the expulsion of all

the vinegar contained in the acetated soda, lest the required acetous acid should be too much debased by sulphuric or sulphureous acid: whereas, in the separation by means of the supersaturated sulphate of potash, no harm at all can arise from adding an excess of the sulphate, for the purpose of dislodging the whole of the acetous acid contained in the acetated soda; for the superfluous portion of sulphuric acid, combined with the alkali, adheres to it too strongly, and is too fixed in the fire, to be disengaged, and raised up, by that gentle degree of heat which is sufficient for the separation of the acetous acid.

2. In the affusion of a very concentrated sulphuric acid upon the thoroughly dried acetate, we are far from being able to make the sulphuric acid penetrate the salt in an equal manner; which, however, is a matter of great consequence: whereas, in the trituration of the acetate with the supersaturated sulphate of Mr. Lowitz, the most equal commixture of both salts is readily effected.

3. During the affusion (though it be performed with the greatest caution) of highly concentrated sulphuric acid, a great heat is excited, whereby some of the acetous acid is instantly consumed, a volatile sulphurous acid is produced, and part of the acetous acid is dissipated and lost in the form of vapour. But nothing of this kind takes place in M. Lowitz's last invented method; for there the salts do not begin to act reciprocally upon each other till the fire is applied.

4. The acid prepared according to Mr. Westendorf's method, always contains an admixture of the sulphuric; which, however, for the reason already assigned, is by no means the case with the glacial acetous acid of M. Lowitz, provided the management of the fire is properly attended to.

5. Twenty-four ounces of acetated soda, treated with sulphuric acid, give only 12 ounces of a barely crystallizable acid, of the strength of 32 degrees, from which, at most, only six ounces of glacial acid can be procured. On the other hand, the same quantity of acetated soda (previously fused) treated with the supersaturated sulphate of potash, yields nearly 16 ounces of glacial acetous acid, of the strength of 54 degrees.

6. Glacial acetous acid cannot be obtained from M. Westendorf's vinegar, except in winter, and by exposure to a very intense cold: but in the last described method of Mr. Lowitz, an exceedingly strong glacial acid may be immediately prepared at any time.

7. The supersaturated sulphate of potash may be prepared from various pharmaceutical residua; for instance, from the sulphate of potash which remains after the purification of pot-ashes, and the residuum from the liquor anodynus; and even the residuum, after the preparation of glacial acetous acid by means of supersaturated sulphate of potash, may, when the sulphate of soda which is produced is separated from it, be made to serve again, on the addition of fresh sulphuric acid, for another similar process.

A weak glacial-acetous acid may be concentrated in the following easy and at the same time entertaining manner:

Place the bottle containing the fluid glacial acetous acid, which is to be concentrated, up to its neck in a vessel full of ice and water: in another quantity of previously concentrated glacial acetous acid, surrounded in like manner with ice, dip a thin cotton-twist or wick; as soon as some crystals are perceived to have attached themselves to the wick, apply the same to the surface of the glacial acid, which is to be concentrated, and it will be seen to shoot into considerably large crystals. In the course of an hour or two, let the weaker part, which still remains fluid, be poured off, into another bottle, from the concentrated and crystallized glacial acid.

In winter this concentration of the glacial acetous acid may be effected in the following still more simple manner:

Pour the glacial acid, which is to be concentrated, into a glass bottle or jar with four sides; crystallize the acid by placing it in snow, or by exposure, in any other way, to cold; and then place it in a warm room, before the window (where, however, the rays of the sun are prevented from entering), in such a manner that one side of the bottle may come into close contact with the cold pane of the window. In the course of ten or twelve hours, the strongest part of the acid will arrange itself, in clusters of crystals, all along that side of the bottle which touches the pane of the window, whilst on the other side of the bottle which faces the room, the much weaker portion of the vinegar is found in a perfectly fluid state: so that all that remains to be done, is to pour off this fluid part into another bottle.

From the weaker portion that is separated in the concentration of the glacial acetous acid, more glacial acid may yet be obtained, by exposure to cold, and more especially by means of the before-described process with the cotton wick: and even the still weaker mother-ley, which remains at last, may very easily be brought to crystallize afresh, by the help of a gentle distillation.

Decisive experiments, and those frequently repeated, convinced M. Lowitz, that the 54th degree is the highest pitch of concentration to which glacial acetous acid is capable of being brought. Notwithstanding all the pains he took, he never was able, either by distillation, or by any of the other concentrating methods already mentioned, to push the concentration of glacial acetous acid even a single degree further; on the contrary, the acid was rendered weaker by some degrees in all such attempts.

The reason of this seems to be, that the acetous acid, like some of the mineral acids, when still further dephlegmated, or deprived of its watery parts, is no longer capable of remaining in a condensed state, but probably assumes an aërial or gaseous form; otherwise, in the further abstraction of its watery parts, how could there be such a constant diminution of its strength, evidently owing to a loss of acid?

Upon this principle we can easily account for the extraordinary quantity of air-bubbles, which are produced as often as the glacial acetous acid passes from the fluid to the solid crystallized state. The white appearance of the crystals depends on the same cause.

Hence, too, we see the impossibility of having a glacial acetous acid which shall retain its solid crystallized form during summer, unless it be kept in a place where the warmth never exceeds, at most, 126 degrees. Thus, for example, in a cellar the temperature of which remains constantly at 131 degrees, summer and winter, a strong glacial acetous acid would never become fluid; but if the same acid should be brought into this cellar in a perfectly liquefied state, it would never crystallize there, on account of the difference between the temperature required for the crystallization, and that which is necessary for the liquefaction of glacial acetous acid.

By very accurate experiments M. Lowitz found, that the least cold which suffices, without the application of ice or snow, for the crystallization of a perfectly fluid glacial acetous acid of the strength of 54 degrees, is that of 132 degrees. All that is needful is, after letting the glacial acid stand some time in water of the abovementioned temperature, to open the bottle, and shake it a little, so that the external air may enter and have free access to the acid.

Lastly, we may at all times obtain glacial acetous acid in a crystallized form by means of an artificial cold; viz. Pour the acid into a thin slender bottle, wrap round this some rag moistened with a little rectified sulphuric ether, and whirl it about briskly in the air.

It is a circumstance worthy of notice, that the weakest glacial acetous acid, in respect to the quantity of alkali necessary to its saturation, is stronger than the strongest nitrous acid. On this test, however, see ATTRACTION.—*Bergman.*—*Margraaf.*—*Wenzel.*—*Crell's Annals.*—*Thomson.*—*Journ. de Phys.*—*An. de Chim.*—*Poerner.*

ACID (AMNIOTIC). On evaporating the liquor amnii of the cow to one-fourth, Vauquelin and Buniva found, that crystals form in it by cooling. These are contaminated by a portion of extractive matter, from which they may be freed by washing with a very small quantity of water. These crystals are white and shining, slightly acid to the taste, redden litmus paper, and are a little more soluble in hot than cold water. They are likewise soluble in alcohol. On ignited coals they swell, turn black, give out ammonia and prussic acid, and leave a bulky coal. With the alkalis this acid forms very soluble salts, but it does not decompose the carbonate without the assistance of heat. It does not precipitate the earthy salts, or the nitrats of mercury, lead, or silver. The acids precipitate it from its combinations with alkalis in a white crystalline powder. Whether it exist in the amniotic liquor of any other animal is not known.

The title of this compound to be considered as a distinct acid however is disputed, as it is said to be only a prussiat of ammonia.—*An. de Chime.*

ACID (ARSENIC). The earlier chemists were embarrassed in the determination of the nature of the white sublimate which is obtained during the roasting of cobalt and other metallic ores, known in commerce by the name of arsenic: its solubility in water, its power of combining with metals in their simple state, together with other apparently heterogeneous properties, rendered it difficult to determine whether it ought to be classed with metals or salts. Subsequent discoveries have shown the relation it bears to both: when treated with combustible matter, in close vessels, it sublimes in the metallic form (see ARSENIC); combustion, or any analogous process, converts it into an oxide; and when the combustion is carried still further, the arsenical basis becomes itself converted into an acid.

We are indebted to the illustrious Scheele for the discovery of this acid, though Macquer had before noticed its combinations. It may be obtained by various methods. If six parts of nitric acid be poured on one of the concrete arsenious acid, or white arsenic of the shops, in the pneumato-chemical apparatus, and heat be applied, nitrous gas will be evolved, and a white concrete substance, differing in its properties from the arsenious acid, will remain in the retort. This is the arsenic acid. It may equally be procured by means of the oxigenated muriatic acid; or by heating concentrated nitric acid with twice its weight of the solution of the arsenious acid in muriatic acid. And Landirani informs us that the arsenious acid may be converted into the arsenic by repeated sublimations, the air being renewed every time; for thus the arsenious acid imbibes the requisite quantity of oxigen from the atmospheric air present in the operation. In either case an acid is obtained, that does not crystallize, but attracts the moisture of the air, has a sharp caustic taste, reddens blue vegetable colours, is fixed in the fire, and of the specific gravity of 3·391. Fourcroy says it contains at least a sixth part of its weight of oxigen; but Berthollet estimated it at not more than a tenth.

If the arsenic acid be exposed to a red heat in a glass retort, it melts and becomes transparent, but assumes a milky hue on cooling. If the heat be increased, so that the retort begins to melt, the acid boils, and sublimes into the neck of the retort. If a covered crucible be used instead of the glass retort, and a violent heat applied, the acid boils strongly, and in a quarter of an hour begins to emit fumes. These, on being received in a glass bell, are found to be arsecious acid; and a small quantity of a transparent glass, difficult to fuse, will be found lining the sides of the crucible. This is arseniate of alumine.

Combustible substances decompose this acid. If two parts of arsenic acid be mixed with about one of charcoal, the mixture introduced into a glass retort, coated, and a matrass adapted to it; and the retort then gradually heated in a reverberatory furnace, till the bottom is red; the mass will be inflamed violently, and the acid reduced, and rise to the neck of the retort in the metallic state mixed with a little oxide and charcoal powder. A few drops of water devoid of acidity will be found in the receiver.

With sulphur the phænomena are different. If a mixture of six parts of arsenic acid and one of powdered sulphur be digested together, no change will take place; but on evaporating to dryness, and distilling in a glass retort, fitted with a receiver, a violent combination will ensue, as soon as the mixture is sufficiently heated to melt the sulphur. The whole mass rises almost at once, forming a red sublimate, and sulphurous acid passes over into the receiver.

If pure arsenic acid be diluted with a small quantity of water, and hidrogen gas, as it is evolved by the action of sulphuric acid on iron, be received into this transparent solution, the liquor grows turbid, and a blackish precipitate is formed, which, being well washed with distilled water, exhibits all the phænomena of arsenic. Sometimes too a blackish gray oxide of arsenic is found in this process.

If sulphurated hidrogen gas be employed, instead of simple hidrogen gas, water and a sulphuret of arsenic are obtained.

With phosphorus phosphoric acid is obtained, and a phosphuret of arsenic, which sublimes.

The arsenic acid is much more soluble than the arsenious: according to Lagrange, two parts of water are sufficient for this purpose. It cannot be crystallized by any means; but on evaporation assumes a thick honey-like consistence.

No acid has any action upon it: if some of them dissolve it by means of the water that renders them fluid, they do not produce any alteration in it. The boracic and phosphoric are vitrifiable with it by means of heat, but without any material alteration in their natures. If phosphorous acid be heated upon it for some time, it saturates itself with oxygen, and becomes phosphoric acid.

The arsenic acid combines with all the earthy and alkaline bases, and forms salts very different from those furnished by the arsenious acid.

All these arseniates are decomposable by charcoal, which separates arsenic from them by means of heat.

The arseniat of barytes is insoluble, uncrystallizable, soluble in an excess of its acid, and decomposable by sulphuric acid, which precipitates a sulphate of barytes.

Of the arseniat of strontian nothing is known, but no doubt it resembles that of barytes.

With lime-water this acid forms a precipitate of arseniat of lime, soluble in an excess of its base, or in an excess of its acid, though insoluble alone. The acidulous arseniat of lime affords on evaporation little crystals, decomposable by sulphuric acid. The same salt may be formed by adding carbonat of lime to the solution of arsenic acid. This acid does not decompose the nitrat or muriat of lime; but the saturated alkaline arseniats decompose them by double affinity, precipitating the insoluble calcareous arseniat.

If arsenic acid be saturated with magnesia, a thick substance is formed near the point of saturation. This arseniat of magnesia is soluble in an excess of acid: and on being evaporated takes the form of a jelly, without crystallizing. Neither the sulphat, nitrat, nor muriat of magnesia is decomposed by arsenic acid, though they are by the saturated alkaline arseniats.

Arsenic acid saturated with potash does not crystallize. This arseniat, being evaporated to dryness, attracts the humidity of the air, and turns the sirup of violets green, without altering the solution of litmus. It fuses into a white glass, and with a strong fire is converted into an acidule, part of the alkali being abstracted by the silex and alumine of the crucible. If exposed to a red heat with charcoal in close vessels it swells up very much, and arsenic is sublimed. It is decomposed by sulphuric acid; but in the humid way the decomposition is not obvious, as the arsenic acid remains in solution. On evaporation, however, this acid and sulphat of potash are obtained.

If arsenic acid be added to the preceding salt, till it ceases to have any effect on the sirup of violets, it will redden the solution of litmus; and in this state it affords very regular and very transparent crystals, of the figure of quadrangular prisms, terminated by two tetraëdral pyramids, the angles of which answer to those of the prisms. These crystals are the arsenical neutral salt of Macquer. As this salt differs from the preceding arseniat by its crystallizability, its reddening solution of litmus, its not decomposing the calcareous and magnesian salts like it, and its capability of absorbing an additional portion of potash, so as to become neutral, it ought to be distinguished from it by the term of acidulous arseniat of potash.

With soda in sufficient quantity to saturate it arsenic acid forms a salt crystallizable like the acidulous arseniat of potash. Pelletier says, that the crystals are hexaëdral prisms terminated by planes perpendicular to their axis. This neutral arseniat of soda, however, while it differs completely from that of potash in this respect, and in becoming deliquescent instead of crystallizable on the addition of a surplus portion of arsenic acid, resembles the arseniat of potash in its decomposition by charcoal, by acids, and by the earths.

Combined with ammonia, arsenic acid forms a salt affording rhomboidal crystals analogous to those of the nitrat of soda. The arseniat of ammonia, which is produced likewise in the decomposition of nitrat of ammonia by arsenious acid, is decomposable in two ways by the action of heat. If it be gently heated, the ammonia is evolved, and the arsenic acid is left pure. If it be exposed to a violent and rapid heat, part of the ammonia and part of the acid reciprocally decompose each other; water is formed; azotic gas is given out; and the arsenic sublimes in a shining metallic form. Magnesia partly decomposes the arseniat of ammonia, and forms a triple salt with a portion of it.

Arsenic acid saturated with alumine forms a thick solution, which, being evaporated to dryness, yields a salt insoluble in water, and decomposable by the sulphuric, nitric and muriatic acids, as well as by all the other earthy and alkaline bases. The arsenic acid readily dissolves the alumine of the crucibles in which it is reduced to a state of fusion; and thus it attacks silex also, on which it has no effect in the humid way.

We know nothing of the combination of this acid with zircone.

By the assistance of a strong fire, as Fourcroy affects, arsenic acid decomposes the alkaline and earthy sulphates, even that of barytes; the sulphuric acid flying off in vapour, and the arseniat remaining in the retort. It acts in the same manner on the nitrat, from which it expels the pure acid. It likewise decomposes the muriats at a high temperature, the muriatic acid being evolved in the form of gas, and the arsenic acid combining with their bases, which it saturates; while the arsenious acid is too volatile to have this effect. It acts in the same manner on the fluats, and still more easily on the carbonats, with which, by the assistance of heat, it excites a brisk effervescence. Lagrange, however, denies that it acts on any of the neutral salts, except the sulphate of potash and soda, the nitrat of potash, and the muriats of soda and ammonia, and this by means of heat. It does not act on the phosphats; but precipitates the boracic acid from solutions of borats when heated.

Arsenic acid does not act on gold or platina; neither does it on mercury or silver without the aid of a strong heat: but it oxides copper, iron, lead, tin, zinc, bismuth, antimony, cobalt, nickel, manganese, and arsenic.

This acid is not used in the arts, at least directly, through indirectly it forms a part of some compositions used in dyeing. It is likewise one of the mineralizing acids combined by nature with some of the metallic oxides.—*Fourcroy.*—*Lagrange.*—*Thomson.*

Acid (Arsenious). Fourcroy was the first who distinguished by this name the white arsenic of the shops, which Scheele had proved to be a compound of the metal arsenic with oxigen, and which the authors of the new chemical nomenclature had consequently termed oxide of arsenic. As, however, it manifestly exhibits the properties of an acid, though in a slight degree, it has a fair claim to the title; for oxides and acids are perfectly similar in this, that both consist of a base united with oxigen, and the only difference between them is, that the compound in which the acid properties are manifest is termed an acid, and that in which they are not is called an oxide.

This acid, which is one of the most virulent poisons known, frequently occurs in a native state, if not very abundantly; and it is obtained in roasting several ores, particularly those of cobalt. In the chimneys of the furnaces where this operation is conducted, it generally condenses in thick semitransparent masses; though sometimes it assumes the form of a powder, or of little needles, in which state it was formerly called flowers of arsenic.

The arsenious acid reddens the most sensible blue vegetable colours, though it turns the sirup of violets green. On exposure to the air it becomes opake, and covered with a slight efflorescence. Thrown on burning coals, or a hot iron, it evaporates in white fumes, with a strong smell of garlic. In close vessels it is volatilized; and, if the heat be strong, vitrified. The result of this vitrification is a transparent glass, capable of crystallizing in tetraëdra, the angles of which are truncated. It is easily altered by hidrogen and carbon, which deprive it of its oxigen at a red heat, and reduce the metal, the one forming water, the other carbonic acid, with the oxigen taken from it: as it is by phosphorus, and by sulphur, which are in part converted into acids by its oxigen, and in part form an arsenical phosphuret or sulphuret with the arsenic reduced to the metallic state. Hence Margraaf and Pelletier, who particularly examined the phosphurets of metals, have asserted they might be formed with arsenious acid. Its specific gravity is from 4·000 to 5·000; and according to Berthollet it appears to consist of 93 parts arsenic, and 7 parts oxigen.

It is soluble in fifteen times its weight of boiling water, but requires eighty times its weight of cold. The solution crystallizes, and the acid assumes the form of regular tetraëdrons according to Fourcroy; but, according to Lagrange, of octaëdrons, and these frequently varying in figure by different laws of decrement. It crystallizes much better by slow evaporation, than by simple cooling. The solution is very acrid, reddens blue colours, unites with the earthy bases, decomposes the alkaline sulphurets, and forms with them a yellow precipitate, in which the arsenic approaches the metallic state. There are even some metals, which act upon the solution, and have a tendency to decompose the acid, so as to form a blackish precipitate, in which the arsenic is very slightly oxided.

The action of the other acids upon the arsenious is very different from that which they exert on the metal arsenic. By boiling sulphuric acid dissolves a small portion of it, which is precipitated as the solution cools. The nitric acid does not dissolve it, but by the help of heat converts it into arsenic acid. Neither the phosphoric nor the carbonic acid acts upon it; yet it enters into a vitreous combination with the phosphoric and boracic acids. The muriatic acid dissolves it by means of heat, and forms with it a volatile compound, which water precipitates: and the oxigenated muriatic acid acidifies it completely, so as to convert it into arsenic acid.

The arsenious acid combines with the earthy and alkaline bases. The earthy arsenites possess little solubility, and hence the solutions of barytes, strontian, and lime, form precipitates with that of arsenious acid.

This acid enters into another kind of combination with the earths, that formed by vitrification. Though a part of this volatile acid sublimes before the glass enters into fusion, part remains fixed in the vitrified substance, to which it imparts transparency, a homogeneous density, and considerable gravity. The arsenical glasses appear to contain a kind of triple salt, since the sand and alkalis enter into an intimate combination at the instant of fusion, and remain afterward perfectly mixed. All of them have the inconvenience of quickly growing dull by exposure to the air.

With the fixed alkalis the arsenious acid forms thick arsenites, which do not crystallize; which are decomposable by fire, the arsenious acid being volatilized by the heat; and from which all the other acids precipitate this in powder. These saline compounds were formerly termed livers, because they were supposed to be analogous to the combinations of sulphur with the alkalis.

With ammonia it forms a salt capable of crystallization. If this be heated a little, the ammonia is decomposed, the azote is evolved, while the hidrogen, uniting with part of the oxigen of the acid, forms water.

Neither the earthy nor alkaline arsenites have yet been much examined; what is known of them being only sufficient to distinguish them from the arseniats.

If we except the nitrats and oxigenated muriats, the other salts have but little action on the arsenious acid. It has no action on the sulphats, muriats, or fluats; except that, if muriat of soda be heated with the arsenious acid, a portion of the muriatic acid it contains is given out. Assisted by heat it expels the acid of carbonats with effervescence, and unites with their bases. It precipitates the acid from borats with difficulty.

But the nitrats, and the superoxigenated muriat of potash, act on the arsenious acid in a very remarkable manner. On treating the nitrats and arsenious acid together, the nitrous acid, or nitrous vapour, is extricated in a state very difficult to be confined, as Kunckel long ago observed; part of its oxigen is absorbed by the arsenious acid; it is thus converted into arsenic acid, and an arseniat is left in the retort. The same phænomena take place on detonating nitrats with arsenious acid; for it is still sufficiently combustible to produce a detonation, in which no sparks are seen, it is true, but with commotion and effervescence; and a true arseniat remains at the bottom of the crucible. It was in this way chemists formerly prepared their fixed arsenic, which was the acidulous arseniat of potash mentioned in the preceding article. The nitrat of ammonia exhibits different phænomena in its decomposition by arsenious acid, and requires considerable precaution. Pelletier, having mixed equal quantities, introduced the mixture into a large retort of coated glass, placed in a reverberatory furnace, with a globular receiver. He began with a very slight fire; for the decomposition is so rapid, and the nitrous vapours issue with such force, that a portion of the arsenious acid is carried off undecomposed unless you proceed very gently. If due care be taken, that the decomposition proceeds more slowly, nitrous acid first comes over: if the fire be continued, or increased, ammonia is next evolved: and lastly, if the fire be urged, a portion of oxide of arsenic sublimes in the form of a white powder, and a vitreous mass remains in the retort, which powerfully attacks and corrodes it. This is arsenic acid. The superoxigenated muriat of potash, too, by completely oxiding the arsenious acid converts it into arsenic acid, which by the assistance of heat is capable of decomposing the muriat of potash that remains.

The arsenious acid is used in numerous instances in the arts, under the name of white arsenic, or of arsenic simply. In many cases it is reduced, and acts in its metallic state.

Some attempts have been made to introduce it into medicine; but, as it is known to be one of the most violent poisons, it is probable that the fear of its bad effects may long deprive society of the advantages it might afford in this way. An arsenite of potash was extensively used by the late Dr. Fowler of York, who published a treatise on it, in intermittent and remittent fevers. He likewise assured the writer, that he had found it extremely efficacious in periodical headach, and as a tonic in nervous and other disorders: and that he never saw the least ill effect from its use, due precaution being employed in preparing and administering it. Externally it has been employed as a caustic to extirpate cancer, combined with sulphur, with bole, with antimony, and with the leaves of crowfoot; but it always gives great pain, and is not unattended with danger. Febure's remedy was water one pint, extract of hemlock ℥j, Gouland's extract ℥iij, tincture of opium ʒj, arsenious acid, gr. x. With this the cancer was wetted morning and evening; and at the same time a small quantity of a weak solution was administered internally. A still milder application of this kind has been made from a solution of one grain in a quart of water, formed into a poultice with crumb of bread.

In cases of persons poisoned by arsenious acid it has been usual to administer oils, milk, and similar remedies. But these, at the moment, are said to be frequently more dangerous than useful; and in their stead alkaline sulphurets dissolved in water, or water highly impregnated with sulphurated hidrogen gas, are strongly recommended.

As it is an object of considerable importance, when a person is suspected of having been poisoned by arsenic, to ascertain the truth of the fact, we insert the following directions from Mr. Henry's excellent Epitome of Chemistry: Let the stomach be removed entirely from the body, a ligature being previously made at each orifice, and its whole contents washed out into an earthen or glass vessel. The arsenic, on account of its specific gravity, will settle to the bottom, and may be obtained separate by washing off the other substances by repeated affusions of cold water. These washings should not be thrown away, till the presence of arsenic has been clearly ascertained. It may be expected at the bottom of the vessel in the form of a white powder, which must be carefully collected, dried on a filter, and submitted to the following trials.

Boil a small portion of the powder with a few ounces of distilled water, in a clean Florence flask, and filter the solution. To part of the solution add a portion of water saturated with sulphurated hidrogen gas; and if arsenic be present a golden-yellow sediment will fall down, which will appear sooner, if a few drops of acetic acid be added. A similar effect will be produced by sulphuret of ammonia. To another part of the solution add a single drop of a weak solution of carbonat of potash, and afterward a few drops of a solution of sulphat of copper; and the presence of arsenic will be manifested by a yellowish green precipitate. Or a portion of the suspected powder may be boiled with a dilute solution of pure potash, and with this precipitate a solution of sulphat of copper, when a similar appearance will ensue still more remarkably, if arsenic be present. The colour of this precipitate is perfectly characteristic: it is that of the pigment called Scheele's green. Similar experiments may be made at the same time with actual arsenic, as standards of comparison, to identify the presence of the supposed arsenic with greater certainty. Any of the sediments produced by the foregoing experiments may be collected, dried, and laid on red hot charcoal; when a smell of sulphur will arise, and be followed by that of garlic.

But the most decisive test is by reducing the arsenic to a metallic state, in which its characters are less equivocal. For this purpose, let a portion of the white sediment collected from the contents of the stomach be mixed with three times its weight of black flux, or with two parts of very dry carbonat of potash, and one of powdered charcoal. Procure a tube of thin glass, eight or nine inches long, and one sixth of an inch in diameter, sealed hermetically at one end. Coat the closed end with clay for about an inch, and let the coating dry. Then put into the tube the mixture of the powder and flux, and if any should adhere to the inner surface, let it be wiped off by a feather, so that the inner surface of the upper part of the tube may be quite clean and dry. Stop the end of the tube loosely with a little paper, and heat the coated end only on a chafing-dish of red hot coals, taking care to avoid breathing the fumes. The arsenic, if any be present, will rise to the upper part of the tube, on the inner surface of which it will form a thin brilliant coating. Having broken the tube, and scraped off the reduced metal, a little of this may be laid on heated iron, when, if it be arsenic, a dense smoke and garlic smell will be perceived: you may likewise put a small quantity between two polished plates of copper, surround it by powdered charcoal to prevent its escape, bind the plates tightly together with iron wire, and expose them to a low red heat. If the included substance were arsenic, a white stain will be left on the copper.

It is to be observed, that neither the stain on copper, nor the garlic smell, will be produced by the white oxide, or arsenious acid, if heated without the addition of some inflammable ingredient.—*Fourcroy*.—*Lagrange*.—*Thomson*.—*Henry*.

Acid (Benzoic). This acid was first described in 1608, by Blaise de Vigenere, in his Treatise on Fire and Salt, and has been generally known since by the name of flowers of benjamin, or benzoin, because it was obtained by sublimation from the resin of this name. As it is still most commonly procured from this substance, it has preserved the epithet of benzoic, though known to be a peculiar acid, obtainable not from benzoin alone, but from different vegetable balsams, vanello, cinnamon, ambergris, the urine of children, frequently that of adults, and always, according to Fourcroy and Vauquelin, though Giese denies this, that of quadrupeds living on grass and hay, particularly the camel, the horse, and the cow. There is reason to conjecture, that many vegetables, and among them some of the grasses, contain it; and that it passes from them into the urine. Fourcroy and Vauquelin found it combined with potash and lime in the liquor of dunghills, as well as in the urine of the quadrupeds above mentioned; and they strongly suspect it to exist in the anthoxanthum odoratum, or sweet-scented vernal-grass, from which hay principally derives its fragrant smell. Giese, however, could find none either in this grass or in oats.

The usual method of obtaining it affords a very elegant and pleasing example of the chemical process of sublimation. For this purpose a thin stratum of powdered benzoin is spread over the bottom of a glazed earthen pot, to which a tall conical paper covering is fitted: gentle heat is then to be applied to the bottom of the pot, which fuses the benzoin, and fills the apartment with a fragrant smell, arising from a portion of essential oil and acid of benzoin, which are dissipated into the air; at the same time the acid itself rises very suddenly in the paper head, which may be occasionally inspected at the top, though with some little care, because the fumes will excite coughing. This saline sublimate is condensed in the form of long needles, or straight filaments of a white colour, crossing each other in all directions, When the acid ceases to rise, the cover may be changed, a new one applied, and the heat raised: more flowers of a yellowish colour will then rise, which require a second sublimation to deprive them of the empyreumatic oil they contain.

The sublimation of the acid of benzoin may be conveniently performed by substituting an inverted earthen pan instead of the paper cone. In this case the two pans should be made to fit, by grinding on a stone with sand, and they must be luted together with paper dipped in paste. This method seems preferable to the other, where the presence of the operator is required elsewhere; but the paper head can be more easily inspected and changed. The heat applied must be very gentle, and the vessels ought not to be separated till they have become cool.

The quantity of acid obtained in these methods differs according to the management, and probably also from difference of purity, and in other respects of the resin itself. It usually amounts to no more than about one eighth part of the whole weight. Indeed Scheele says, not more than a tenth or twelfth. The whole acid of benzoin is obtained with greater certainty in the humid process of Scheele: this consists in boiling the powdered resin with lime-water, and afterwards separating the lime by the addition of muriatic acid. Twelve ounces of water are to be poured upon four ounces of slaked lime; and, after the ebullition is over, eight pounds, or ninety-six ounces, more of water are to be added: a pound of finely-powdered benzoin being then put into a tin vessel, six ounces of the lime-water are to be added, and mixed well with the powder; and afterwards the whole of the lime-water in the same gradual manner, because the benzoin would coagulate into a mass, if the whole were added at once. This mixture must be gently boiled for half an hour with constant agitation, and afterwards suffered to cool and subside during an hour. The supernatant liquor must be decanted, and the residuum boiled with eight pounds more of lime-water; after which the same process is to be once more repeated: the remaining powder must be edulcorated on the filter by affusions of hot water. Lastly, all the decoctions, being mixed together, must be evaporated to two pounds, and strained into a glass vessel.

This fluid consists of the acid of benzoin combined with lime. After it is become cold, a quantity of muriatic acid must be added, with constant stirring, until the fluid tastes a little sourish. During this time the last-mentioned acid unites with the lime, and forms a soluble salt, which remains suspended, while the less soluble acid of benzoin, being disengaged, falls to the bottom in powder. By repeated affusions of cold water upon the filter, it may be deprived of the muriat of lime and muriatic acid, with which it may happen to be mixed. If it be required to have a shining appearance, it may be dissolved in a small quantity of boiling water, from which it will separate in silky filaments by cooling. By this process the benzoic acid may be procured from other substances, in which it exists.

As an œconomical mode of obtaining this acid, Fourcroy recommends the extraction of it from the water that drains from dunghills, cowhouses, and stables, by means of the muriatic acid, which decomposes the benzoat of lime contained in them, and separates the benzoic acid, as in Scheele's process. He confesses the smell of the acid thus obtained differs a little from that of the acid extracted from benzoin: but this, he says, may be remedied, by dissolving the acid in boiling water, filtering the solution, letting it cool, and thus suffering the acid to crystallize, and repeating this operation a second time.

Mr. Accum found the benzoic acid which he obtained from vanello pods contaminated with a yellow colouring matter, from which it could not be freed by repeated solutions and crystallizations; but by boiling with charcoal powder, the acid was rendered perfectly pure.

The acid of benzoin is so inflammable that it burns with a clear yellow flame without the assistance of a wick. The sublimed flowers in their purest state, as white as ordinary writing-paper, were fused into a clear transparent yellowish fluid, at the two hundred-and-thirtieth degree of Fahrenheit's thermometer, and at the same time began to rise in sublimation. It is probable that a heat somewhat greater than this may be required to separate it from the resin. It is strongly disposed to take the crystalline form in cooling The concentrated sulphuric and nitric acids dissolve this concrete acid, and it is again separated, without alteration, by adding water. Other acids dissolve it by the assistance of heat, from which it separates by cooling, unchanged. It is plentifully soluble in ardent spirit, from which it may likewise be separated by diluting the spirit with water. It readily dissolves in oils, and in melted tallow. If it be added in a small proportion to this last fluid, part of the tallow congeals before the rest, in the form of white opake clouds. If the quantity of acid be more considerable, it separates in part by cooling, in the form of needles or feathers. It did not communicate any considerable degree of hardness to the tallow, which was the object of this experiment. When the tallow was heated nearly to ebullition, it emitted fumes which affected the respiration, like those of the acid of benzoin, but did not possess the peculiar and agreeable smell of that substance, being probably the sebacic acid. A stratum of this tallow, about one-twentieth of an inch thick, was fused upon a plate of brass, together with other fat substances, with a view to determine its relative disposition to acquire and retain the solid state. After it had cooled it was left upon the plate, and in the course of some weeks it gradually became tinged throughout of a blueish green colour If this circumstance be not supposed to have arisen from a solution of the copper during the fusion, it seems a remarkable instance of the mutual action of two bodies in the solid state, contrary to that axiom of chemistry which affirms, that bodies do not act on each other unless one or more of them be in the fluid state. Tallow itself however has the same effect.

Pure benzoic acid is in the form of a light powder, evidently crystallized in fine needles, the figure of which is difficult to be determined from their smallness. It has a white and shining appearance; but when contaminated by a portion of volatile oil, is yellow or brownish. It is not brittle as might be expected from its appearance, but has rather a kind of ductility and elasticity, and on rubbing in a mortar becomes a sort of paste. Its taste is acrid, hot, acidulous, and bitter. It reddens the infusion of litmus, but not sirup of violets. It has a peculiar aromatic smell, but not strong unless heated. This, however, appears not to belong to the acid; for Mr. Giese informs us, that on dissolving the benzoic acid in as little alcohol as possible, filtering the solution, and precipitating by water, the acid will be obtained pure, and void of smell, the odorous oil remaining dissolved in the spirit. Its specific gravity is 0·667. It is not perceptibly altered by the air, and has been kept in an open vessel twenty years without losing any of its weight. None of the combustible substances have any effect on it: but it may be refined by mixing it with charcoal powder and subliming, being thus rendered much whiter and better crystallized. It is not very soluble in water. Wenzel and Lichtenstein say four hundred parts of cold water dissolve but one, though the same quantity of boiling water dissolves twenty parts, nineteen of which separate on cooling.

The benzoic acid unites without much difficulty with the earthy and alkaline bases.

The benzoat of barytes is soluble, crystallizes tolerably well, is not affected by exposure to the air, but is decomposable by fire, and by the stronger acids. That of lime is very soluble in water, though much less in cold than in hot; and crystallizes on cooling. It is in like manner decomposable by the acids, and by barytes. The benzoat of magnesia is soluble, crystallizable, a little deliquescent, and more decomposable than the former. That of alumine is very soluble; crystallizes in dendrites; is deliquescent; has an acerb and bitter taste; and is decomposable by fire, and even by most of the vegetable acids. The benzoat of potash crystallizes on cooling in little compacted needles. All the acids decompose it, and the solution of barytes and lime form with it a precipitate. The benzoat of soda is very crystallizable, very soluble, and not deliquescent like that of potash: but it is decomposable by the same means. It is sometimes found native in the urine of graminivorous quadrupeds; but by no means so abundantly as that of lime. The benzoat of ammonia is volatile, and decomposable by all the acids and all the bases. The solutions of all the benzoats, when drying on the sides of a vessel wetted with them, form dendritical crystallizations.

Trommsdorf found in his experiments,

that benzoic acid did not act upon metals, but united with their oxides.

From the chemical properties of this acid, it appears to differ from the other vegetable acids in the nature and properties of the principles that constitute its radical. Its odour, volatility, combustibility, great solubility in alcohol, and little solubility in water, formerly occasioned it to be considered as an oily acid; and have led modern chemists to conceive, that it contains a large quantity of hidrogen in its composition, and that it is in the superabundance of this combustible principle its difference from the other vegetable acids consists. Its solubility in the powerful acids, and its subsequent separation, indicate that its principles are not easily separable from each other. Attempts have been made to decompose it by repeated abstraction of nitric acid: the nitric acid rises first, scarcely altered except toward the end of the process, when nitrous gas comes over; and the acid of benzoin is afterwards sublimed with little alteration. By repeating the process, however, it is said to become more fixed, and at length to afford a few drops of an acid resembling the oxalic in its properties.

The benzoic acid is occasionally used in medicine, but not so much as formerly; and enters into the composition of the camphorated tincture of opium of the London college, heretofore called paregoric elixir.—*Fourcroy.*—*Thomson.*—*Scherer's Allg. Journ. der Chemie.*

ACID (BOMBIC). Mr. Boissier de Sauvages observed, that the juices of the silkworm, in a certain diseased state, contained an acid. Chaussier found, that in the moth state it emits an acid liquor; and this he found to be deposited, when it spins its cocoon, in a reservoir near the anus. By bruising the animal, and infusing it in alcohol, he obtained a solution of the acid; which on evaporating the alcohol was found to be a pungent yellow fluid, capable of reddening vegetable blues, and uniting with alkalis and some of the earths. He supposed it to be a peculiar acid; but it has not yet been farther investigated, and from analogy it is probable, that like the formic acid, and some others, it is merely a compound of the acetous.

ACID (BORACIC). The neutral salt composed of this acid and soda, had long been used both in medicine and the arts under the name of borax, when Homberg first obtained the acid separate in 1702, by distilling a mixture of borax and sulphat of iron. He supposed, however, that it was a product of the latter; and gave it the name of *volatile narcotic salt of vitriol*, or *sedative salt*. Lemery the younger soon after discovered, that it could be obtained from borax equally by means of the nitric or muriatic acid; Geoffroy detected soda in borax; and at length Baron proved by a number of experiments, that borax is a compound of soda and a peculiar acid. Cadet has disputed this; but he has merely shown, that the borax of the shops is frequently contaminated with copper: and Struve and Exchaquet have endeavoured to prove that the boracic and phosphoric acids are the same; yet their experiments only show, that they resemble each other in certain respects, not in all.

To procure the acid, dissolve borax in hot water; and filter the solution: then add sulphuric acid by little and little, till the liquid has a sensibly acid taste. Lay it aside to cool, and a great number of small shining laminated crystals will form. These are the boracic acid. They are to be washed with cold water, and drained upon brown paper.

Boracic acid thus procured is in the form of thin irregular hexagonal scales, of a silvery whiteness, having some resemblance to spermaceti, and the same kind of greasy feel. It has a sourish taste at first, then makes a bitterish cooling impression, and at last leaves an agreeable sweetness. Pressed between the teeth, it is not brittle but ductile. It has no smell; but, when sulphuric acid is poured on it, a transient odour of musk is produced. Its specific gravity in the form of scales is 1·479; after it has been fused, 1·803. It is not altered by light. Exposed to the fire it swells up, from losing its water of crystallization, and in this state is called calcined boracic acid. It melts a little before it is red-hot, without perceptibly losing any water, but it does not flow freely till it is red, and then less than the borat of soda. After this fusion it is a hard transparent glass, becoming a little opake on exposure to the air, without abstracting moisture from it, and unaltered in its properties, for on being dissolved in boiling water it crystallizes as before. This glass is used in the composition of false gems.

Boiling water scarcely dissolves one fiftieth part, and cold water much less. When this solution is distilled in close vessels, part of the acid rises with the water, and crystallizes in the receiver. It is more soluble in alcohol, and alcohol containing it burns with a green flame, as does paper dipped in a solution of boracic acid.

Neither oxigen gas, nor the simple combustibles, nor the metals, produce any change upon boracic acid, as far as is at present known. If mixed with finely powdered charcoal it is nevertheless capable of vitrification; and with soot it melts into a black bitumen-like mass, which however is soluble in water, and cannot easily be burned to ashes, but sublimes in part. With the assistance of a distilling heat it dissolves in oils, especially mineral oils; and with these it yields fluid and solid products, which impart a green colour to spirit of wine. When rubbed with phosphorus it does not prevent its inflammation, but an earthy yellow matter is left behind. It is hardly capable of oxiding or dissolving any of the metals except iron and zinc, and perhaps copper; but it combines with most of the metallic oxides, as it does with the alkalis, and probably with all the earths, though the greater part of its combinations have hitherto been little or not at all examined. It is of great use in analysing stones that contain a fixed alkali.

The boracic acid has a more powerful attraction for lime, than for any other of the bases, though it does not readily form borat of lime by adding a solution of it to lime-water, or decomposing by lime-water the soluble alkaline borats. In either case an insipid white powder, nearly insoluble, which is the borat of lime, is however precipitated. The borat of barytes is likewise an insoluble, tasteless, white powder.

Bergman has observed, that magnesia, thrown by little and little into a solution of boracic acid, dissolved slowly, and the liquor on evaporation afforded granulated crystals without any regular form: that these crystals were fusible in the fire without being decomposed: but that alcohol was sufficient to separate the boracic acid from the magnesia. If however some of the soluble magnesian salts be decomposed by alkaline borats in a state of solution, an insipid and insoluble borat of magnesia is thrown down. It is probable, therefore, that Bergman's salt was a borat of magnesia dissolved in an excess of boracic acid; which acid being taken up by the alcohol, the true borat of magnesia was precipitated in a white powder, and mistaken by him for magnesia.

One of the best known combinations of this acid is the native magnesio-calcareous borat of Kalkberg, near Lunenburg: the *wurfelstein* of the Germans, *cubic quartz* of various mineralogists, and *boracite* of Kirwan. It is of a grayish white colour, sometimes passing into the greenish white, or purplish. Its figure is that of a cube, incomplete on its twelve edges, and at four of its solid angles, the complete and incomplete angles being diametrically opposite to each other. The surfaces generally appear corroded. It strikes fire with steel, and scratches glass. Its specific gravity is 2·566, as determined by M. Westrumb, who found it to be composed of boracic acid 0·68, magnesia 0·1305, lime 0·11; with alumine 0·01, silex 0·02, and oxide of iron 0·0075, all of which he considers as casual. Its most remarkable property, discovered by Haüy, is, that like the tourmalin it becomes electric by heat, though little so by friction: and it has four electric poles, the perfect angles always exhibiting negative electricity, and the truncated angles positive.

Since the component parts of this native salt have been known, attempts have been made to imitate it by art; but no chemist has been able, by mixing lime, magnesia, and boracic acid, to produce any thing but a pulverulent salt, incapable of being dissolved, or exhibited in the crystallized form, and with the hardness of the borat of Kalkberg.

It has lately been denied, however, that this compound is really a triple salt. Vauquelin, examining this substance with Mr. Smith, who had a considerable quantity, found the powder to effervesce with acids; and therefore concluded the lime to be no essential part of the compound. They attempted, by using weak acids much diluted, to separate the carbonat from the borat; but they did not succeed, because the acid attacked the borat likewise, though feebly. M. Stromager having afterwards supplied Vauquelin with some transparent crystals, which did not effervesce with acids, he mixed this powder with muriatic acid, and, when the solution was effected by means of heat, evaporated to dryness to expel the excess of acid. By solution in a small quantity of cold distilled water he separated most of the boracic acid; and, having diluted the solution, added a certain quantity of oxalat of ammonia, but no sign of the existence of lime appeared. To ascertain that the precipitation of the lime was not prevented by the presence of the small quantity of boracic acid, he mixed with the solution a very small portion of muriat of lime, and a cloudiness immediately ensued through the whole. Hence he infers, that the opacity of the magnesian borat is occasioned by carbonat of lime interposed between its particles, and that the borat in transparent crystals contains none.

The borat of potash is but little known, though it is said to be capable of supplying the place of that of soda in the arts; but more direct experiments are required to establish this effect. Like that, it is capable of existing in two states, neutral and with excess of base, but it is not so crystallizable, and assumes the form of parallelopipeds.

With soda the boracic acid forms two different salts. One, in which the alkali is more than treble the quantity necessary to saturate the acid, is of considerable use in the arts, and has long been known by the name of borax; under which its history and an account of its properties will be given. The other is a neutral salt, not changing the sirup of violets green like the borat with excess of base; differing from it in taste and solubility; crystallizing neither so readily, nor in the same manner; not efflorescent like it; but like it fusible into a glass, and capable of being employed for the same purposes. This salt may be formed, by saturating the superabundant soda in borax with some other acid, and then separating the two salts: but it is obviously more eligible, to saturate the excess of soda with an additional portion of the boracic acid itself.

Borat of ammonia forms in small rhomboidal crystals, easily decomposed by fire; or in scales, of a pungent urinous taste, which lose the crystalline form, and grow brown on exposure to the air.

It is very difficult to combine the boracic acid with alumine, at least in the direct way. It has been recommended, for this purpose, to add a solution of borax to a solution of sulphat of alumine: but for this process the neutral borat of soda is preferable, since, if borax be employed, the soda that is in excess may throw down a precipitate of alumine, which might be mistaken for an earthy borat.

The boracic acid unites with silex by fusion, and forms with it a solid and permanent vitreous compound. This borat of silex, however, is neither sapid, nor soluble, nor perceptibly alterable in the air; and cannot be formed without the assistance of a violent heat. In the same manner triple compounds may be formed with silex and borats already saturated with other bases.

The boracic acid has been found in a disengaged state in several lakes of hot mineral waters near Monte Rotondo, Berchiaio, and Castellonuovo in Tuscany, in the proportion of nearly nine grains in a hundred of water, by M. Hoeffer. M. Mascagni also found it adhering to schistus, on the borders of lakes, of an obscure white, yellow, or greenish colour, and crystallized in the form of needles. He has likewise found it in combination with ammonia.

Dr. Fabroni, an able natural philosopher of Florence, informed Fourcroy, that, from particular experiments he had made, which however are not published, he considered the boracic acid as a modification of the muriatic; that it could be completely fabricated from that acid; and that the boracic acid in the Tuscan lakes, as he conceived, was probably formed in this way.

A very curious set of experiments have been lately made on it by Crell. By digesting oxigenated muriatic acid on it for a very long time, he succeeded in decomposing it, and obtained from it a substance exactly resembling charcoal; and a volatile acid resembling the muriatic in the greater number of its properties, but differing from it in not precipitating lead from its solution. Crell considers this volatile acid as very similar to the sebacic. Its fixity in the fire too is deemed an argument in favour of its being a compound; for it has been remarked, that simple substances in general are more volatile.—*Kirwan.*—*Fourcroy.*—*Lagrange.*—*Reuss.*—*Hassenfratz.*—*Kerr.*—*Thomson.*—*Ann. de Chimie.*

Acid (Camphoric). M. Kosegarten found some years ago, that an acid with peculiar properties was obtained by distilling nitric acid eight times following from camphor. Bouillon Lagrange has since repeated his experiments, and the following is the account he gives of its preparation and properties.

One part of camphor being introduced into a glass retort, four parts of nitric acid of the strength of 36 degrees are to be poured on it, a receiver adapted to the retort, and all the joints well luted. The retort is then to be placed on a sand-heat, and gradually heated. During the process a considerable quantity of nitrous gas, and of carbonic acid gas, is evolved; and part of the camphor is volatilized, while another part seizes the oxygen of the nitric acid. When no more vapours are extricated, the vessels are to be separated, and the sublimed camphor added to the acid that remains in the retort. A like quantity of nitric acid is again to be poured on this, and the distillation repeated. This operation must be reiterated till the camphor is completely acidified. Twenty parts of nitric acid at 36 are sufficient to acidify one of camphor.

When the whole of the camphor is acidified, it crystallizes in the remaining liquor. The whole is then to be poured out upon a filter, and washed with distilled water, to carry off the nitric acid it may have retained. The most certain indication of the acidification of the camphor is its crystallizing on the cooling of the liquor remaining in the retort.

To purify this acid it must be dissolved in hot distilled water, and the solution, after being filtered, evaporated nearly to half, or till a slight pellicle forms; when the camphoric acid will be obtained in crystals on cooling.

This experiment being too long to be exhibited by the chemical lecturer, its place may be supplied by the following.

A jar is to be filled over mercury with oxigen gas from the super-oxigenated muriat of potash, and a little water passed into it. On the other hand a bit of camphor and an atom of phosphorus are to be placed in a little cupel: and then one end of a curved tube is to be conveyed under the jar, and the other end under a jar filled with water in the pneumato-chemical apparatus. The apparatus being thus arranged, the phosphorus is to be kindled by means of a red-hot iron. The phosphorus inflames, and afterwards the camphor. The flame produced by the camphor is very vivid; much heat is given out; and the jar is lined with a black substance, which gradually falls down, and covers the water standing on the quicksilver in the jar. This is oxide of carbon. At the same time a gas is collected, that has all the characters of carbonic acid. The water contained in the jar is very fragrant, and contains camphoric acid in solution.

The camphoric acid has a slightly acid,

bitter taste, and reddens infusion of litmus.

It crystallizes; and the crystals upon the whole resemble those of muriat of ammonia. [Kosegarten says they are parallelopipeds of a snowy whiteness.] It effloresces on exposure to the atmosphere: is not very soluble in cold water: when placed on burning coals, gives out a thick aromatic smoke, and is entirely dissipated: and with a gentle heat melts, and is sublimed. The mineral acids dissolve it entirely. It decomposes the sulphat and muriat of iron. The fixed and volatile oils dissolve it. It is likewise soluble in alcohol, and is not precipitated from it by water; a property that distinguishes it from the benzoic acid. It unites easily with the earths and alkalis.

To prepare the camphorats of lime, magnesia, and alumine, these earths must be diffused in water, and crystallized camphoric acid added. The mixture must then be boiled, filtered while hot, and the solution concentrated by evaporation.

The camphorat of barytes is prepared by dissolving the pure earth in water, and then adding crystallized camphoric acid.

Those of potash, soda, and ammonia, should be prepared with their carbonats dissolved in water: these solutions are to be saturated with crystallized camphoric acid, heated, filtered, evaporated, and cooled, by which means the camphorats will be obtained.

If the camphoric acid be very pure, they have no smell: if it be not, they have always a slight smell of camphor.

The camphorats of alumine and barytes leave a little acidity on the tongue; the rest have a slightly bitterish taste.

They are all decomposed by heat: the acid being separated and sublimed, and the base remaining pure; that of ammonia excepted, which is entirely volatilized.

If they be exposed to the blow-pipe, the acid burns with a blue flame: that of ammonia gives first a blue flame; but toward the end it becomes red.

The camphorats of lime and magnesia are little soluble, the others dissolve more easily.

The mineral acids decompose them all. The alkalis and earths act in the order of their affinity for the camphoric acid: which is, lime, potash, soda, barytes, ammonia, alumine, magnesia.

Several metallic solutions, and several neutral salts, decompose the camphorats: such as the nitrat of barytes, most of the calcareous salts, &c.

The camphorats of lime, magnesia, and barytes, part with their acid to alcohol.—*Lagrange's Manuel d'un Cours de Chimie.*

Acid (Carbonic). This acid, being a compound of carbon and oxigen, may be formed by burning charcoal; but as it exists in great abundance ready formed, it is not necessary to have recourse to this expedient. All that is necessary is to pour sulphuric acid, diluted with five or six times its weight of water, on common chalk, which is a compound of carbonic acid and lime. An effervescence ensues, carbonic acid is evolved in the state of gas, and may be received in the usual manner.

As the rapid progress of chemistry during the latter part of the 18th century, was in a great measure owing to the discovery of this acid, it may be worth while to trace the history of it somewhat particularly.

Paracelsus and Van Helmont were acquainted with the fact, that air is extricated from solid bodies during certain processes, and the latter gave to air thus produced the name of gas Boyle called these kinds of air artificial airs, and suspected that they might be different from the air of the atmosphere. Hales ascertained the quantity of air that could be extricated from a great variety of bodies, and showed that it formed an essential part of their composition. Dr. Black proved, that the substances then called lime, magnesia, and alkalis, were compounds, consisting of a peculiar species of air, and pure lime, magnesia, and alkali. To this species of air he gave the name of fixed air, because it existed in these bodies in a fixed state. This air or gas was afterward investigated, and a great number of its properties ascertained, by Dr. Priestley. From these properties Mr. Keir first concluded that it was an acid; and this opinion was soon confirmed by the experiments of Bergman, Fontana, and others. Dr. Priestley at first suspected that this acid entered as an element into the composition of atmospherical air; and Bergman, adopting the same opinion, gave it the name of aërial acid. Mr. Bewley called it mephitic acid, because it could not be respired without occasioning death; and this name was also adopted by Morveau. Mr. Keir called it calcareous acid: and at last M. Lavoisier, after discovering its composition, gave it the name of carbonic acid gas.

The opinions of chemists concerning the composition of carbonic acid have undergone as many revolutions as its name. Dr. Priestley and Bergman seem at first to have considered it as an element; and several celebrated chemists maintained that it was the acidifying principle. Afterward it was discovered to be a compound, and that oxigen gas was one of its component parts. Upon this discovery the prevalent opinion of chemists was, that it consisted of oxigen and phlogiston; and when hidrogen and phlogiston came, according to Mr. Kirwan's theory, to signify the same thing, it was of course maintained that carbonic acid was composed of oxigen and hidrogen: and though M. Lavoisier demonstrated that it was formed by the combination of carbon and oxigen, this did not prevent the old theory from being maintained; because carbon was itself considered as a compound, into which a very great quantity of hidrogen entered. But after M. Lavoisier had demonstrated, that the weight of the carbonic acid produced was precisely equal to the charcoal and oxigen employed; after Mr. Cavendish had discovered, that oxigen and hidrogen when combined did not form carbonic acid but water; it was no longer possible to doubt that this acid was composed of carbon and oxigen. Accordingly all farther dispute about it seems now at an end.

If any thing were still wanting, to put this conclusion beyond the reach of doubt, it was to decompose carbonic acid, and thus to exhibit its component parts by analysis as well as synthesis. This has been actually done by Mr. Tennant. Into a tube of glass he introduced a bit of phosphorus and some carbonat of lime. He then sealed the tube hermetically, and applied heat. Phosphat of lime was formed, and a quantity of charcoal deposited. Now phosphat of lime is composed of phosphoric acid and lime; and phosphoric acid is composed of phosphorus and oxigen. The substances introduced into the tube were phosphorus, lime, and carbonic acid; and the substances found in it were phosphorus, lime, oxigen, and charcoal. The carbonic acid, therefore, must have been decomposed, and it must have consisted of oxigen and charcoal. This experiment was repeated by Dr. Pearson, who ascertained, that the weight of the oxigen and charcoal together was equal to that of the carbonic acid which had been introduced: and in order to show that it was the carbonic acid which had been decomposed, he introduced pure lime and phosphorus; and, instead of phosphat of lime and carbon, he got nothing but phosphuret of lime. These experiments were also confirmed by Fourcroy, Vauquelin, Sylvestre, and Brongniart. Count Mussin-Puschkin too boiled a solution of carbonat of potash on purified phosphorus, and obtained charcoal. This he considered as an instance of the decomposition of carbonic acid, and as a confirmation of the experiments above related.

Carbonic acid abounds in great quantities in nature, and appears to be produced in a variety of circumstances. It composes about one third of the weight of lime-stone, marble, calcareous spar, and other natural specimens of calcareous earth; from which it may be extricated either by the simple application of heat, or by the superior affinity of some other acid; most acids having a stronger action on bodies than this. This last process does not require heat, because fixed air is strongly disposed to assume the elastic state. Water, under the common pressure of the atmosphere, and at a low temperature, absorbs somewhat more than its bulk of fixed air, and then constitutes a weak acid. If the pressure be greater, the absorption is augmented. It is to be observed likewise, that more gas than water will absorb should be present. Heated water absorbs less; and if water impregnated with this acid be exposed on a brisk fire, the rapid escape of the aërial bubbles affords an appearance as if the water were at the point of boiling, when the heat is not greater than the hand can bear. Congelation separates it readily and completely from water; but no degree of cold or pressure has yet exhibited this acid in a dense or concentrated state of fluidity.

Carbonic acid gas is nearly twice as heavy as common air, and for this reason occupies the lower parts of such mines or caverns as contain materials which afford it by decomposition. The miners call it choke damp. The Grotto del Cano, in the kingdom of Naples, has been famous for ages on account of the effects of a stratum of fixed air, which covers its bottom. It is a cave or hole in the side of a mountain, near the lake Agnano, measuring not more than eighteen feet from its entrance to the inner extremity; where if a dog or other animal that holds down its head be thrust, it is immediately killed by inhaling this noxious fluid.

Carbonic acid gas is emitted in large quantities by bodies in the state of the vinous fermentation (see FERMENTATION), and on account of its great weight it occupies the apparently empty space or upper part of the vessels in which the fermenting process is going on. A variety of striking experiments may be made in this stratum of elastic fluid. Lighted paper, or a candle dipped into it, is immediately extinguished; and the smoke remaining in the carbonic acid gas renders its surface visible, which may be thrown into waves by agitation like water. If a dish of water be immersed in this gas, and briskly agitated, it soon becomes impregnated, and obtains the vivid taste of Pyrmont water. In consequence of the weight of the carbonic acid gas, it may be dipped out in a pitcher, or bottle, which, if well corked, may be used to convey it to great distances: or it may be drawn out of a vessel by a cock like a liquid. The effects produced by pouring this invisible fluid from one vessel to another have a very singular appearance; if a candle or small animal be placed in a deep vessel, the former becomes extinct, and the latter expires in a few seconds, after the carbonic acid gas is poured upon them, though the eye is incapable of distinguishing any thing that is poured. If, however, it be poured into a vessel full of air, in the sunshine, its density being so much greater than that of the air, renders it slightly visible by the undulations and streaks it forms in this fluid, as it descends through it.

Carbonic acid reddens infusion of litmus;

but the redness vanishes by exposure to the air, as the acid flies off. It has a peculiar sharp taste, which may be perceived over vats in which wine or beer is fermenting; as also in sparkling Champaign, and the brisker kinds of cider. Light passing through it is refracted by it, but does not effect any sensible alteration in it; though it appears from experiment, that it favours the separation of its principles by other substance. It will not unite with an overdose of oxigen, of which it contains 72 parts in 100, the other 28 being pure carbon. It not only destroys life, but the heart and muscle of animals killed by it lose all their irritability, so as to be insensible to the stimulus of galvanism.

Carbonic acid is dilated by heat, but not otherwise altered by it. It is not acted upon by oxigen, or any of the simple combustibles. Charcoal absorbs it, but gives it out again unchanged. Phosphorus is insoluble in carbonic acid gas; but, as already observed, is capable of decomposing it by compound affinity, when assisted by sufficient heat: and Priestley and Cruickshank have shown, that iron, zinc, and several other metals, are capable of producing the same effect. If carbonic acid be mixed with sulphurated, phosphorated, or carbonated gas, it renders them less combustible, or destroys their combustibility entirely, but produces no other sensible change. Such mixtures occur in various analyses, and particularly in the products of the decomposition of vegetable and animal substances. The inflammable air of marshes is frequently carbonated hidrogen intimately mixed with carbonic acid gas; and the sulphurated hidrogen gas obtained from mineral waters is very often mixed with it.

Carbonic acid appears from various experiments of Ingenhousz to be of considerable utility in promoting vegetation. It is probably decomposed by the organs of plants, its base furnishing part at least of the carbon, that is so abundant in the vegetable kingdom, and its oxigen contributing to replenish the atmosphere with that necessary support of life, which is continually diminished by the respiration of animals and other causes.

In point of affinity for the earths and alkalis, carbonic acid stands at the bottom of the scale. Before its true nature was known, its compounds with them were not considered as salts, but as the earths and alkalis themselves, only distinguished by the names of *mild*, or *effervescent*, from their qualities of effervescing with acids, and wanting causticity.

The carbonat of barytes was formed artificially by Bergman and Scheele in 1776: but Dr. Withering first found it native at Moor Alston in Cumberland in 1783. From this circumstance it has been termed Witherite by Werner. It has been likewise called *aërated heavy spar*, *aërated baroselenite*, *aërated heavy earth* or barytes, *barolite*, &c. Its crystals have been observed to assume four different forms; double six-sided, and double four-sided pyramids; six-sided columns terminated by a pyramid with the same number of faces; and small radiated crystals, half an inch in length, and very thin, appearing to be hexagonal prisms, rounded toward the point. The hexaëdrial prism is presumed to be its primitive form. Its specific gravity, when native, is 4·331; when prepared artificially it scarcely exceeds 3·763.

It may be prepared by exposing a solution of pure barytes to the atmosphere, when it will be covered with a pellicle of this salt by absorbing carbonic acid; or carbonic acid may be received into this solution, in which it will immediately form a copious precipitate: or a solution of nitrat or muriat of barytes may be precipitated by a solution of the carbonat of potash, soda, or ammonia. The precipitate in either of these cases, being well washed, will be found to be very pure carbonat of barytes. It may likewise be procured by decomposing the native sulphat of barytes by the carbonat of potash, or of soda, in the dry way, with the assistance of fire; but in this way the sulphat of barytes is never completely decomposed, and some of it remains mixed with the carbonat.

The carbonat of barytes is soluble only in 4304 times its weight of cold water, and 2304 of boiling water, and this requires a long time; but water saturated with carbonic acid dissolves 1-830th. It is not altered by exposure to the air; but is decomposed by the application of a very violent heat either in a black lead crucible, or when formed into a paste with charcoal powder. Sulphuric acid, in a concentrated state, or diluted with three or four parts of water, does not separate the carbonic acid with effervescence, unless assisted by heat. Muriatic acid does not act upon it likewise, unless diluted with water, or assisted by heat. And nitric acid does not act upon it at all, unless diluted. It has no sensible taste; yet it is extremely poisonous.

As this salt has lately been found, in large quantities, near Murton in Cumberland, and some other places in the vicinity, it might probably be introduced into manufactures with advantage, as for extracting the bases of several salts.

Carbonat of strontian was first pointed out as distinct from the preceding species by Dr. Crawford in 1790, but Dr. Hope gave the first accurate account of it in the Edinburgh Transactions. It has been found native in Scotland, at Strontian in Argyleshire, and at Leadhills. It is usually in fine striated needles, or prisms, that appear to be hexaëdral, semitransparent, and of a white colour slightly tinged with green. It is insipid; requires 1536 parts of boiling water to dissolve it; is not altered by exposure to the air; but when strongly heated in a crucible loses part of its acid; and this decomposition is facilitated by making it into a paste with charcoal powder. When the fire is strongly urged, it attacks the crucible, and melts into a glass, resembling the colour of chrysolite, or pyramidal phosphat of lime. If thrown in powder on well kindled coals, or the flame of a candle, it exhibits red sparks. The same phænomenon occurs, if it be treated with the blow pipe, which fuses it into an opaque vitreous globule, that falls to powder in the open air. Its specific gravity is only 3·66, in which it differs strikingly from the carbonat of barytes; as it does in not being poisonous, according to the experiments made by Pelletier on various animals.

Carbonat of lime exists in great abundance in nature, variously mixed with other bodies, under the name of *marble, chalk, limestone, stalactites*, &c., in which it is of more important and extensive use than any other of the salts, except perhaps the muriat of soda. It is often found crystallized, and perfectly transparent. The primitive form of its crystals is the rhomboidal prism, with angles of 101½ and 78½. Its integrant particles have the same form. Beside this, however, forty-two varieties of its crystals have been discovered and described by mineralogists. The specific gravity of the marbles is from 2·65 to 2·85; of the crystallized carbonats, about 2·7; of the stalactites, from 2·32 to 2·47; of the limestones, from 1·39 to 2·72.

It has scarcely any taste: is insoluble in pure water, but water saturated with carbonic acid takes up 1-1500th, though as the acid flies off this is precipitated. It suffers little or no alteration on exposure to the air. When heated it decrepitates, its water flies off, and lastly its acid; but this requires a pretty strong heat. By this process it is burned into lime.

The carbonat or rather subcarbonat of potash was long known by the name of *vegetable alkali*. It was also called *fixed nitre, salt of tartar, salt of wormwood*, &c., according to the different modes in which it was procured; and was supposed to retain something of the virtues of the substance from which it was extracted. This error has been some time exploded, but the knowledge of its true nature is of more recent date.

As water at the usual temperature of the air dissolves rather more than its weight of this salt, we have thus a ready mode of detecting its adulterations in general; and as it is often of consequence in manufactures, to know how much alkali a particular specimen contains, this may be ascertained by the quantity of sulphuric acid it will saturate.

This salt is deliquescent.

The carbonat of potash crystallizes, according to Fourcroy, in square prisms, the apexes of which are quadrangular pyramids. According to Pelletier they are tetraëdral rhomboidal prisms, with diëdral summits. The complete crystal has eight faces, two hexagons, two rectangles, and four rhombs. It has a urinous but not caustic taste: changes the sirup of violets green: boiling water dissolves five-sixths of its weight, and cold water one-fourth: alcohol, even when hot, will not dissolve more than 1-1200th. Its specific gravity is 2·012.

When it is very pure and well crystallized it effloresces on exposure to a dry atmosphere, though it was formerly considered as deliquescent. The fact is, that the common salt of tartar of the shops is a compound of this carbonat and pure potash; the latter of which, being very deliquescent, attracts the moisture of the air till the whole is dissolved. From its smooth feel, and the manner in which it was prepared, the old chemists called this solution *oil of tartar per deliquium*.

The carbonat of potash melts with a gentle heat, loses its water of crystallization, amounting to 0·15, or ·17, and gives out a portion of its carbonic acid; though no degree of heat will expel the whole of the acid. Thus, as the carbonat of potash is always prepared by incineration of vegetable substances, and lixiviation, it must be in the intermediate state; or that of a carbonat with sulphur of alkali: and to obtain the true carbonat we must saturate this salt with carbonic acid, which is best done by passing the acid in the state of gas through a solution of the salt in twice its weight of water; or, if we want the potash pure, we must have recourse to lime, to separate that portion of acid which fire will not expel.

Another mode, recommended by Berthollet, and which may be of use on some occasions, is to add solid carbonat of ammonia to a solution of potash not saturated, and distil the mixture: when the ammonia may be obtained in the form of gas, or caustic liquor, while the carbonat crystallizes in the retort.

The carbonat of soda has likewise been long known, and distinguished from the preceding by the name of *mineral alkali*. In commerce it is usually called *barilla*, or *soda*; in which state, however, it always contains a mixture of earthy bodies, and usually common salt. It may be purified by dissolving it in a small portion of water, filtering the solution, evaporating at a low heat, and skimming off the crystals of muriat of soda as they form on its surface. When these cease to form, the solution may be suffered to cool, and the carbonat of soda will crystallize. To obtain this salt perfectly pure Klaproth dissolves common carbonat of soda in water, and saturates this solution with nitric acid, taking care that the acid is a little in excess. He then separates the sulphuric acid by nitrat of barytes, and the muriatic acid by nitrat of silver. The fluid thus purified he evaporates to dryness, fuses the nitrat of soda obtained, and decomposes it by detonation with charcoal. He then elixiviates the residue, and crystallizes the carbonat of soda. If it be adulterated with potash, tartarous acid will form a precipitate in a pretty strong solution of it.

It is found abundantly in nature. In Egypt, where it is collected from the surface of the earth, particularly after the desiccation of temporary lakes, it has been known from time immemorial by the name of *nitrum*, *natron*, or *natrum*. This it has been proposed to retain: and accordingly the London college has adopted the term *natron*. Dr. Bostock of Liverpool lately found, that the efflorescence, which copiously covered the decaying parts of the plaster of the salt-water baths in that town, consisted of carbonat of soda. A carbonat of soda exported from Tripoli, which is called *Trona* from the name of the place where it is found, and analysed by Klaproth, contained of soda 37 parts, carbonic acid 38, water of crystallization 22·5, sulphat of soda, 2. This does not effloresce. A great deal is prepared in Spain by incinerating the maritime plant salsola; and it is manufactured in this country, as well as in France, from different species of sea-weeds. It is likewise found in mineral waters; and also in some animal fluids.

It crystallizes in irregular or rhomboidal decaëdrons, formed by two quadrangular pyramids, truncated very near their bases. Frequently it exhibits only rhomboidal laminæ. Its specific gravity is 1·3591. Its taste is urinous, and slightly acrid, without being caustic. It changes blue vegetable colours to a green. It is soluble in less than its weight of boiling water, and twice its weight of cold. It is one of the most efflorescent salts known, falling completely to powder in no long time. On the application of heat it is soon rendered fluid from the great quantity of its water of crystallization; but is dried by a continuance of the heat, and then melts. It is somewhat more fusible than the carbonat of potash, promotes the fusion of earths in a greater degree, and forms a glass of better quality. Like that, it is very tenacious of a certain portion of its carbonic acid. See the article SODA.

The carbonat of magnesia, in a state of imperfect saturation with the acid, has been used in medicine for some time under the simple name of magnesia. It is prepared by precipitation from the sulphat of magnesia by means of carbonat of potash. Equal parts of sulphat of magnesia and carbonat of potash, each dissolved in its own weight of boiling water, are filtered and mixed together hot; the sulphat of potash is separated by copious washing with water; and the carbonat of magnesia is then left to drain, and afterward spread thin on paper, and carried to the drying stove. When once dried it will be in friable white cakes, or a fine powder.

Another mode of preparing it in the great will be found under the article AMMONIA.

To obtain carbonat of magnesia saturated with acid, a solution of sulphat of magnesia may be mixed cold with a solution of carbonat of potash; and at the expiration of a few hours, as the superfluous carbonic acid, that held it in solution, flies off, the carbonat of magnesia will crystallize in very regular transparent prisms of six equal sides. It may be equally obtained by dissolving magnesia in water impregnated with carbonic acid, and exposing the solution to the open air. Dr. Thomson says, the most regular crystals will be obtained by mixing together 125 parts of sulphat of magnesia and 136 parts of carbonat of soda, both dissolved in water, filtering the solution, and then setting it aside for two or three days.

These crystals soon lose their transparency, and become covered with a white powder. Exposed to the fire in a crucible they decrepitate slightly, lose their water and acid, fall to powder, and are reduced to one-fourth of the original weight. When the common carbonat is calcined in the great, it appears as if boiling, from the extrication of carbonic acid; a small portion ascends like a vapour, and is deposited in a white powder on the cold bodies with which it comes into contact; and in a dark place, toward the end of the operation, it shines with a blueish phosphoric light. It thus loses half its weight, and the magnesia is left quite pure.

As the magnesia of the shops is sometimes adulterated with chalk, this may be detected by the addition of a little sulphuric acid diluted with 8 or 10 times its weight of water, as this will form with the magnesia a very soluble salt, while the sulphat of lime will remain undissolved. Calcined magnesia should dissolve in this dilute acid without any effervescence.

The crystallized carbonat dissolves in forty-eight times its weight of cold water; the common carbonat requires at least ten times as much, and first forms a paste with a small quantity of the fluid.

Guyton Morveau has lately found the carbonat of magnesia native, near Castella-Monte, in a stone considered there as a clay very rich in alumine. It is amorphous, as white as ceruse, and as compact as the hardest chalk; does not sensibly adhere to the tongue; and has no argillaceous smell. Its specific gravity, when all the bubbles of air it contains have escaped, is 2·612. In the fire it lost 0·585 of its weight, and became sufficiently hard to scratch Bohemian glass slightly. On analysis it was found to contain: magnesia 26·3, silex 14·2, carbonic acid 46, water 12, iron an inappreciable quantity.

The carbonat of ammonia, once vulgarly known by the name of *volatile sal ammoniac*, and abroad by that of *English volatile salt*, because it was first prepared in this country, was commonly called *mild volatile alkali*, before its true nature was known.

When very pure it is in a crystalline form, but seldom very regular. Its crystals are so small, that it is difficult to determine their figure. Bergman describes them as acute octaëdrons, the four angles of which are truncated. Romé de Lisle had compressed *tetraëdral* prisms, terminated by a diëdral summit. Bergman obtained his by saturating warm water with the salt, stopping the bottle closely, and exposing it to great cold. The crystals commonly produced by sublimation are little bundles of needles, or very slender prisms, so arranged as to represent herborizations, fern leaves, or feathers. The taste and smell of this salt are the same with those of pure ammonia, but much weaker. It turns the colour of violets green, and that of turmeric brown. Its specific gravity is 0·966. It is soluble in rather less than twice its weight of cold water, and in its own weight of hot water; but a boiling heat volatilizes it. When pure, and thoroughly saturated, it is not perceptibly alterable in the air; but when it has an excess of ammonia, it softens and grows moist. It cannot be doubted, however, that it is soluble in air; for if left in an open vessel, it gradually diminishes in weight, and its peculiar smell is diffused to a certain distance. Heat readily sublimes, but does not decompose it.

It has been prepared by the destructive distillation of animal substances and some others, in large iron pots, with a fire increased by degrees to a strong red heat, the aqueous liquor, that first comes over, being removed, that the salt might not be dissolved in it. Thus we had the *salt of hartshorn*, *salt of soot*, *essential salt of vipers*, &c. If the salt were dissolved in the water, it was called *spirit* of the substance from which it was obtained. Thus, however, it was much contaminated by a fetid animal oil, from which it required to be subsequently purified, and is much better fabricated by mixing one part of muriat of ammonia and two of carbonat of lime, both as dry as possible, and subliming in an earthen retort.

Mr. Davy has shown, that its component parts vary exceedingly, according to the manner of preparing it. The lower the temperature at which it is formed, the greater the proportion of acid and water. Thus, if formed at the temperature of 300°, it contains more than fifty per cent. of alkali; if at 60°, not more than twenty per cent.

It is well known as a stimulant usually put into smelling-bottles, frequently with the addition of some odoriferous oil.

Fourcroy has found, that an ammoniaco-magnesian carbonat is formed on some occasions. Thus, if carbonat of ammonia be decomposed by magnesia in the moist way, leaving these two substances in contact with each other in a bottle closely stopped, a complete decomposition will not take place, but a portion of this trisall will be formed. The same will take place, if a solution of carbonat of magnesia in water impregnated with carbonic acid be precipitated by pure ammonia; or if ammoniacomagnesian sulphat, nitrat, or muriat, be precipitated by carbonat of potash or of soda.

The properties of this trisall are not yet known; but it crystallizes differently from the carbonat of either of its bases, and has its own laws of solubility and decomposition.

The carbonat of glucine has only been examined by Vauquelin, though it is among the salts of that earth of which he has most accurately ascertained the properties. It is in a white, dull, clotty, powder, never dry, but greasy and soft to the feel. It is not sweet, like the other salts of glucine, but insipid. It is very light, insoluble in water, perfectly unalterable by the air, but very readily decomposed by fire.

A saturated solution of carbonat of ammonia takes up a certain portion of this carbonat, and forms with it a triple salt. This property enabled Vauquelin to separate glucine from alumine, and was one of the means of his distinguishing that earth.

Carbonic acid does not appear to be much disposed to unite with argillaceous earth. Most clays, however, afford a small quantity of this acid by heat; and Fourcroy says, that the fat clays effervesce with acids. The snowy white substance resembling chalk, and known by the name of *lac lunæ*, is found to consist almost wholly of alumine saturated with carbonic acid. A saline substance consisting of two six-sided pyramids joined at one common base, weighing five or six grains, and of a taste somewhat resembling alum, was produced by leaving an ounce phial of water impregnated with carbonic acid, and a redundancy of alumine exposed to spontaneous evaporation for some months.

Vauquelin has found, that carbonat of zircone may be formed by evaporating muriat of zircone, redissolving it in water, and precipitating by the alkaline carbonat. He also adds, that it very readily combines so as to form a triple salt with either of the three alkaline carbonats.—*Priestley.—Keir.—Bergman.—Black.—Fourcroy.—Thomson.—Kirwan.*

Acid (Chromic). This acid is but lately known, and has only been examined in small quantities by Vauquelin, who first discovered it, and by count Mussin Puschkin; yet we are better acquainted with it, than with the metal that forms its basis. However, as the chromat of iron has lately been found in abundance in the department of Var, in France, we may expect its properties to be more amply investigated, and applied with advantage in the arts, as the chromats of lead and iron are of excellent use in painting and enamelling.

It was extracted from the red lead ore of Siberia, by treating this ore with carbonat of potash, and separating the alkali by means of a more powerful acid. In this state it is a red or orange-coloured powder, of a peculiar rough metallic taste, which is more sensible in it than in any other metallic acid. If this powder be exposed to the action of light and heat, it loses its acidity, and is converted into green oxide of chrome, giving out pure oxigen gas. The chromic acid is the first that has been found to deacidify itself easily by the action of heat, and afford oxigen gas by this simple operation. It appears that several of its properties are owing to the weak adhesion of a part at least of its oxigen. The green oxide of chrome cannot be brought back to the state of an acid, unless its oxigen be restored by treating it with some other acid.

The chromic acid is soluble in water, and crystallizes, by cooling and evaporation, in longish prisms of a ruby red.

Its action on combustible substances is little known. If it be strongly heated with charcoal, it grows black, and passes to the metallic state, without melting.

Of the acids, the action of the muriatic on it is the most remarkable. If this be distilled with the chromic acid, by a gentle heat, it is readily converted into oxigenated muriatic acid. It likewise imparts to it by mixture the property of dissolving gold; in which the chromic resembles the nitric acid. This is owing to the weak adhesion of its oxigen, and it is the only one of the metallic acids that possesses this property.

It readily unites with alkalis, and is the only acid that has the property of colouring its salts, whence the name of chromic has been given it. If two parts of the red lead ore of Siberia in fine powder be boiled with one of an alkali saturated with carbonic acid, in forty parts of water, a carbonat of lead will be precipitated, and the chromat remain dissolved. The solutions are of a lemon colour, and afford crystals of a somewhat deeper hue. Those of chromat of ammonia are in yellow laminæ, having the metallic lustre of gold.

The chromat of barytes is very little soluble, and that of lime still less. They are both of a pale yellow, and when heated give out oxigen gas, as do the alkaline chromats.

If the chromic acid be mixed with filings of tin and the muriatic acid, it becomes at first yellowish brown, and afterward assumes a blueish green colour, which preserves the same shade after desiccation. Ether alone gives it the same dark colour. With a solution of nitrat of mercury it gives a precipitate of a dark cinnabar colour. With a solution of nitrat of silver it gives a precipitate, which, the moment it is formed, appears of a beautiful carmine colour, but becomes purple by exposure to the light. This combination, exposed to the heat of the blowpipe, melts before the charcoal is inflamed, and assumes a blackish and metallic appearance. If it be then pulverised, the powder is still purple; but after the blue flame of the lamp is brought into contact with this powder, it assumes a green colour, and the silver appears in globules disseminated through its substance.

With nitrat of copper it gives a chesnut red precipitate. With the solution of sulphat of zinc, muriat of bismuth, muriat of antimony, nitrat of nickel and muriat of platina, it produces yellowish precipitates, when the solutions do not contain an excess of acid. With muriat of gold it produces a greenish precipitate.

When melted with borax, or glass, or acid of phosphorus, it communicates to it a beautiful emerald green colour.

If paper be impregnated with it, and exposed to the sun a few days, it acquires a green colour, which remains permanent in the dark.

A slip of iron, or tin, put into its solution, imparts to it the same colour.

The aqueous solution of tannin produces a flocculent precipitate of a brown fawn colour.

Sulphuric acid, when cold, produces no effect on it; but when warmed it makes it assume a blueish green colour.—*Fourcroy.*—*Lagrange.*—*Thomson.*

Acid (Citric). The juice of lemons, or limes, has all the characters of an acid of considerable strength: but on account of the mucilaginous matter with which it is mixed, it is very soon altered by spontaneous decomposition. Various methods have been contrived to prevent this effect from taking place, in order that this wholesome and agreeable acid might be preserved for use in long voyages, or other domestic occasions. The juice may be kept in bottles under a thin stratum of oil, which indeed prevents, or greatly retards, its total decomposition; though the original fresh taste soon gives place to one which is much less grateful. In the East Indies it is evaporated to the consistence of a thick extract. If this operation be carefully performed by a very gentle heat, it is found to be very effectual. When the juice is thus heated the mucilage thickens, and separates in the form of flocks, part of which subsides, and part rises to the surface: these must be taken out. The vapours which arise are not acid. If the evaporation be not carried so far as to deprive the liquid of its fluidity, it may be long preserved in well closed bottles; in which, after some weeks standing, a farther portion of mucilage is separated without any perceptible change in the acid.

Of all the methods of preserving lemon-juice, that of concentrating it by frost appears to be the best, though in the warmer climates it cannot conveniently be practised. Lemon-juice, exposed to the air, in a temperature between 50° and 60°, deposits in a few hours a white semitransparent mucilaginous matter, which leaves the fluid, after decantation and filtration, much less alterable than before. This mucilage is not of a gummy nature, but resembles the gluten of wheat in its properties: it is not soluble in water when dried. More mucilage is separated from lemon-juice by standing in closed vessels. If this depurated lemon-juice be exposed to a degree of cold of about seven or eight degrees below the freezing point, the aqueous part will freeze, and the ice may be taken away as it forms; and if the process be continued until the ice begins to exhibit signs of acidity, the remaining acid will be found to be reduced to about one-eighth of its original quantity, at the same time that its acidity will be eight times as intense, as is proved by its requiring eight times the quantity of alkali to saturate an equal portion of it. This concentrated acid may be kept for use, or, if preferred, it may be made into a dry lemonade, by adding six times its weight of fine loaf sugar in powder.

The above processes may be used when the acid of lemons is wanted for domestic purposes, because they leave it in possession of the oils, or other principles, on which its flavour peculiarly depends; but in chemical researches, where the acid itself is required to be had in the utmost purity, a more elaborate process must be used. Boiling lemon-juice is to be saturated with powdered chalk, the weight of which is to be noted, and the powder must be stirred up from the bottom, or the vessel shaken from time to time. The neutral saline compound is scarcely more soluble in water than selenite; it therefore falls to the bottom, while the mucilage remains suspended in the watery fluid, which must be decanted off; the remaining precipitate must then be washed with warm water until it comes off clear. To the powder thus edulcorated, a quantity of sulphuric acid, sufficient to saturate the lime, and diluted with ten parts of water, must be added, and the mixture boiled a few minutes. The sulphuric acid combines with the earth, and forms sulphat of lime, which remains behind when the cold liquor is filtered, while the disengaged acid of lemons remains dissolved in the fluid. This last must be evaporated to the consistence of a thin sirup, and sulphuric acid must be then added in small portions, to precipitate the lime, if any should still remain in combination with the citric acid. When no more precipitate is afforded by the addition of sulphuric acid, a farther evaporation separates the pure citric acid in little needle-like crystals. It is necessary that the sulphuric acid last added should be rather in excess, because the presence of a small quantity of lime will prevent the crystallization. This excess will be found in the mother water.

M. Dize, a skilful apothecary at Paris, who has repeated this process of Scheele on a very extensive scale, asserts, that an excess of sulphuric acid is necessary, not only to obtain the citric acid pure, but to destroy the whole of the mucilage, part of which would otherwise remain, and occasion its spoiling. It is not certain, however, but the sulphuric acid may act on the citric itself, and by decomposing it produce the charcoal, that M. Dize ascribes to the decomposition of mucilage: and if so, the smaller the excess of sulphuric acid the better. He also adds, that to have it perfectly pure it must be repeatedly crystallized, and thus it forms very large and accurately defined crystals, in rhomboidal prisms, the sides of which are inclined in angles of 60° and 120°, terminated at each end by tetraëdral summits, which intercept the solid angles. These, however, will not be obtained when operating on small quantities.

Its taste is extremely sharp, so as to appear caustic. Distilled in a retort, part rises without being decomposed; it appears to give out a portion of vinegar; it then evolves carbonic acid gas, and a little carbonated hidrogen; and a light coal remains. It is among the vegetable acids that must powerfully resist decomposition by fire.

In a dry and warm air it seems to effloresce; but it absorbs moisture, when the air is damp, and at length loses its crystalline form. A hundred parts of this acid are soluble in seventy-five of water at 60° according to Vauquelin. Though it is less alterable than most other solutions of vegetable acids, it will undergo decomposition when long kept. Fourcroy thinks it probable, that it is converted into acetous acid before its final decomposition.

It is not altered by any combustible substance; charcoal alone appears to be capable of whitening it. The most powerful acids decompose it less easily than they do other vegetable acids: but the sulphuric evidently converts it into acetous acid. The nitric acid likewise, according to Fourcroy and Vauquelin, if employed in large quantity, and heated on it a long time, converts the greater part of it into acetous acid, and a small portion into oxalic. Scheele indeed could not effect this: but Westrumb supposes, that it was owing to his having used too much nitric acid; for on treating 60 grains of citric acid with 200 of nitric he obtained 30 grains of oxalic acid, with 300 grains of nitric acid he got 15, and with 600 grains no vestige of oxalic acid appeared.

If a solution of barytes be added gradually to a solution of citric acid, a flocculent precipitate is formed, soluble by agitation, till the whole of the acid is saturated. This salt at first falls down in powder, and then collects in silky tufts, and a kind of very beautiful and shining silvery bushes. It requires a large quantity of water to dissolve it.

The citrat of lime has been mentioned already, in treating of the mode of purifying the acid.

The citrat of potash is very soluble and deliquescent.

The citrat of soda has a dull saline taste; dissolves in less than twice its weight of water; crystallizes in six-sided prisms with flat summits; effloresces slightly, but does not fall to powder; boils up, swells, and is reduced to a coal on the fire. Lime-water decomposes it, but does not render the solution turbid, notwithstanding the little solubility of citrat of lime.

Citrat of ammonia is very soluble; does not crystallize unless its solution be greatly concentrated; and forms elongated prisms.

Citrat of magnesia does not crystallize. When its solution had been boiled down, and it had stood some days, on being slightly shaken it fixed in one white opake mass, which remained soft, separating from the sides of the vessel, contracting its dimensions, and rising in the middle like a kind of mushroom.

Its combination with the other earths has not yet been examined . and its action upon metals has been little studied. Scheele however found, that it did not precipitate the nitric solutions of white metals, as the malic acid does.

All the citrats are decomposed by the powerful acids, which do not form a precipitate with them, as with the oxalats and tartrits. The oxalic and tartarous acids decompose them, and form crystallized or insoluble precipitates in their solutions. All afford traces of acetous acid, or a product of the same nature, on being exposed to distillation: this character exists particularly in the metallic citrats. Placed on burning coals they melt, swell up, emit an empyreumatic smell of acetous acid, and leave a light coal. All of them, if dissolved in water, and left to stand for a time, undergo decomposition, depose a flocculent mucus which grows black, and leave their bases combined with carbonic acid, one of the products of the decomposition. Before they are completely decomposed, they appear to pass to the state of acetits.

The affinities of the citric acid are arranged by Vauquelin in the following order: barytes, lime, potash, soda, strontian, magnesia, ammonia, alumine. These for zircone, glucine, and the metallic oxides, are not ascertained.

The citric acid is found in many fruits united with the malic acid; which see for the process of separating them in this case.

Acid (Fluoric). The fusible spar, which is generally distinguished by the name of Derbyshire spar, consists of calcareous earth in combination with the acid at present under our consideration. If the pure fluor, or spar, be placed in a retort of lead, with a receiver of the same metal adapted, and half its weight of sulphuric acid be then poured upon it, the fluoric acid will be disengaged in the aërial form by the application of a moderate heat. This acid gas readily combines with water; for which purpose it is necessary that the receiver should previously be half filled with that fluid When experiments are required to be made with the acid in the elastic state, it must be received over mercury.

Mr. Accum, however, has found, by mingling the acid thus obtained with water impregnated with sulphurated hidrogen gas, that it always contains lead. Tin it acts upon less, and silver not at all: but to obtain the acid pure he recommends the following process. One part of fluor spar in fine powder is to be mixed with two of sulphuric acid, and one of water. The mixture is then to be introduced into a glass retort, to which a glass receiver has been previously luted containing two ounces of water. Heat being then applied, the distillation is to be carried on slowly. After the decomposition of the fluat of lime is effected, which may be known by the disappearance of the whitish vapours in the retort, the contents of the receiver must be filtered, and distilled water added to the filtered fluid, till, on a new admixture of water, no farther cloudiness appears. The acid thus obtained contains no silex; it is absolutely pure, and may be kept in glass bottles covered within with wax, or, in preference, with a hard varnish.

The distinguishing and most remarkable property of this acid is its power of combining with and volatilizing siliceous earth, which remains suspended with it in the permanently elastic form. The first experiments with fluor spar were made in glass vessels, and were attended with the singular phænomenon of an earthy matter being deposited at the instant that the acid air came into contact with the water in the recipient. Upon examination it was found to consist of siliceous earth; and subsequent experiments proved, that it was obtained by corrosion of the glass retort, and deposited in consequence of the acid possessing a less power of suspending siliceous earth when combined with water, than when in the elastic state.

Fluoric acid in the state of gas is as invisible as the air: yet if it come into contact with the least moisture, it becomes more or less cloudy. It has a pungent, acrid smell, pretty analogous to that of the muriatic acid, yet not exactly the same. It is much heavier than common air, but its specific gravity is not accurately determined, perhaps because we never have it pure. It extinguishes a candle, first rendering the flame green; kills animals; and reddens vegetable blues. Light is refracted by it in proportion to its density. Heat dilates it, but does not appear to alter its nature, since it retains all its properties after passing through a red-hot tube of porcelain. When placed in contact with oxigen gas, atmospheric air, or azot, it does not alter or absorb it, and remains unaltered by it. If, however, either of these gases contain water, a thick white vapour is formed, not merely from the condensation of the gas, but from the precipitation of part of the earth it contained.

From its being unaffected by any of the combustible substances, its base is unknown: but it is presumed from analogy to consist of some base united with oxigen, and having too powerful an attraction for it to yield it to any known combustible.

Mr. Henry infers, from some phænomena that occurred in his endeavours to decompose it, that it is capable of being further oxigenised like the muriatic, and, in this state of acting on mercury.

Water, either fluid or frozen, readily absorbs this acid; which melts the ice, lowering its temperature as it liquefies it, or heats the water as it condenses in it.

Most of the metallic oxides absorb this acid in the state of gas but slowly; when it is dissolved in water, it acts on them more readily, and forms peculiar metallic salts.

From the remarkable property this acid possesses of corroding glass, it has been employed for etching on it, both in the gaseous state and combined with water; and an ingenious apparatus for this purpose is given by Mr. Richard Knight in the Philosophical Magazine, vol. xvii. p. 357.

M. Kortum, of Warsaw, having found that some pieces of glass were more easily acted upon by it than others, tried its effect on various stones. Rock crystal, ruby, sapphire, lux sapphire, emerald, oriental garnet, amethyst, chrysolite, aventurine, girasol, a Saxon topaz, a Brazilian topaz burnt, and an opal, being exposed to the fluoric gas at a temperature of 122° F., were not acted upon. Diamond exposed to the vapour on a common German stove for four days was unaffected. Of polished granite neither the quartz nor mica appeared to be attacked, but the feldt-spar was rendered opake and muddy, and covered with a white powder. Chrysoprase, an opal from Hungary, onyx, a carnelian from Persia, agate, chalcedony, green Siberian jasper, and common flint, were etched by it in twenty-four hours; the chrysoprase near half a line deep, the onyx pretty deeply, the opal with the finest and most regular strokes, and all the rest more or less irregularly. The uncovered part of the brown flint had become white, but was still compact: water, alcohol, and other liquids, rendered the whiteness invisible, but as soon as the flint became dry it appeared again. The same effect was produced on carnelian, and on a dark brown jasper, if the operation of the acid were stopped as soon as it had whitened the part exposed without destroying its texture. A piece of black flint, with efflorescent white spots, and partly covered with the common white crust, being exposed five days to the gas at a heat of about 68° F., was reduced from 103 grains to 91, and rendered white throughout. Some parts of it were rendered friable. White Carara marble in twenty-four hours, at 77°, lost 1-30th of its weight, but the shining surface of its crystallized texture was distinguishable. Black marble was not affected either in weight or colour, and agate was not attacked. Transparent foliated gypsum fell into white powder on its surface in a few hours; but this powder was not soluble in dilute nitric acid,—so that the fluoric acid had not destroyed the combination of its principles, but deprived it of its water of crystallization. A striated zeolite, weighing 102 grains, was rendered friable on its surface in forty-eight hours, and weighed only 85½ grains. On being immersed in water, and then dried, it gained 2½ grains, but did not recover its lustre. Barytes of a fibrous texture remained unchanged. A thin plate of Venetian talc, weighing 124 grains, was reduced to 81 grains in forty-eight hours, and had fallen into a soft powder, which floated on water. M. Kortum poured water on the residuum in the apparatus, and the next day the sides were incrusted with small crystalline glittering flakes, adhering in detached masses, which could not be washed off with dilute nitrous acid.

Of the combination of this acid with most of the bases little is known.

The native fluat of lime, the fluor spar already mentioned, is the most common. It is rendered phosphorescent by heat, but this property gradually goes off, and cannot be produced a second time. With a strong heat it decrepitates. At a heat of 130° of Wedgwood it enters into fusion in a clay crucible. It is not acted upon by the air, and is insoluble in water. Concentrated sulphuric acid deprives it of the fluoric acid with effervescence, at the common temperature, but heat promotes its action. Besides its use for obtaining this acid, it is much employed in chimney ornaments, and as a flux for some ores and stones.

The fluoric acid takes barytes from the nitric and muriatic, and forms a salt very little soluble, that effloresces in the air.

With magnesia it precipitates, according to Scheele, in a gelatinous mass. But Bergman says, that a part remains in solution, and by spontaneous evaporation shoots on the sides of the vessel into crystalline threads resembling a transparent mass. The bottom of the vessel affords also crystals in hexagonal prisms, ending in a low pyramid of three rhombs. He adds, that no acid decomposes it in the moist way, and that it is unalterable by the most violent fire.

The fluat of potash is not crystallizable; and if it be evaporated to dryness it soon deliquesces. Its taste is somewhat acrid and saline. It melts with a strong heat, is afterward caustic, and attracts moisture.

This fluat, as well as those of soda and ammonia, are commonly obtained, as Fourcroy conceives, in the state of triple salts, being combined with siliceous earth.

The fluat of soda affords small crystals in cubes and parallelograms, of a bitterish and astringent taste, decrepitating on burning coals, and melting into semitransparent globules with the blowpipe without losing their acid. It is not deliquescent, and difficultly soluble. The concentrated acids disengage its acid with effervescence.

The fluat of ammonia may be prepared by adding carbonat of ammonia to diluted fluoric acid in a leaden vessel, observing, that there is a small excess of acid. This is a very delicate test of lime.

Fourcroy informs us, that ammonia and magnesia form a triple salt with the fluoric acid.

Scheele observed, that the fluor acid united with alumine into a salt, that could not be crystallized, but assumed a gelatinous form. Fourcroy adds, that the solution is always acid, astringent, decomposable and precipitable by all the earthy and alkaline bases, but capable of uniting with silex and the alkalis into various triple salts. A native combination of alumine and soda with fluoric acid has been found lately in a semitransparent stone from Greenland. See Cryolite.

The affinity of the fluoric acid for silex has already appeared. If the acid solution of fluat of silex, obtained by keeping the solution of the acid in glass vessels, be evaporated to dryness, the fluoric acid may be disengaged from the solid salt remaining, as Fourcroy informs us, either by the powerful acids, or by a strong heat: and if the solution be kept in a vessel that admits of a slow evaporation, small brilliant crystals, transparent, hard, and apparently of a rhomboidal figure, will form on the bottom of the vessel, as Bergman found in the course of two years' standing.

Beside the fluor spar and cryolite, in which it is abundant, fluoric acid has been detected in the topaz; in wavellite, in which, however, it is not rendered sensible by sulphuric acid; and in fossil teeth and fossil ivory, though it is not found in either of these in their natural state.—*Scheele.*—*Bergman.*—*Fourcroy.*—*Henry.*—*Phil. Journal.*—*Voigt's Mag. der Naturkunde.*

Acid (Formic). It has long been known, that ants contain a strong acid, which they occasionally emit; and which may be obtained from the ants, either by simple distillation, or by infusion of them in boiling water, and subsequent distillation of as much of the water as can be brought over without burning the residue. After this it may be purified by repeated rectifications, or by boiling to separate the impurities; or after rectification it may be concentrated by frost.

This has now lost its rank as a separate acid, as it has been shown by Fourcroy and Vauquelin to be a compound of the malic and acetic.

We have been informed, that it has been employed among quacks as a wonderful remedy for the toothach, by applying it to the tooth with the points of the forefinger and thumb.

Acid (Gallic). This acid is found in different vegetable substances possessing astringent properties, but most abundantly in the excrescences termed galls, or nutgalls, whence it derives its name. It may be obtained by macerating galls in water, filtering, and suffering the liquor to stand exposed to the air. It will grow mouldy, be covered with a thick glutinous pellicle, abundance of glutinous flocks will fall down, and in the course of two or three months the sides of the vessel will appear covered with small yellowish crystals, abundance of which will likewise be found on the under surface of the supernatant pellicle. These crystals may be purified by solution in alcohol, and evaporation to dryness.

Or muriat of tin may be added to the infusion of galls till no more precipitate falls down; the excess of oxide of tin remaining in the solution may then be precipitated by sulphurated hidrogen gas: and the liquor will yield crystals of gallic acid by evaporation.

A more simple process, however, is that of M. Fiedler. Boil an ounce of powdered galls in sixteen ounces of water to eight, and strain. Dissolve two ounces of alum in water, precipitate the alumine by carbonat of potash, and, after edulcorating it completely by repeated ablutions, add it to the decoction, frequently stirring the mixture with a glass rod. The next day filter the mixture; wash the precipitate with warm water, till this will no longer blacken sulphat of iron; mix the washings with the filtered liquor, evaporate, and the gallic acid will be obtained in fine needled crystals.

These crystals obtained in any of these ways, however, according to Mr. Davy, are contaminated with a small portion of extractive matter; and to purify them they may be placed in a glass capsule in a sand heat, and sublimed into another capsule, inverted over this and kept cool. M. Deyeux indeed recommends to procure the acid by sublimation in the first instance; putting the powdered galls into a glass retort, and applying heat slowly and cautiously; when the acid will rise, and be condensed in the neck of the retort. This process requires great care, as, if the heat be carried so far as to disengage the oil, the crystals will be dissolved immediately. The crystals thus obtained are pretty large, laminated, and brilliant.

The gallic acid, placed on a red-hot iron, burns with flame, and emits an aromatic smell not unlike that of benzoic acid. It is soluble in 24 parts of cold water, and in 3 parts at a boiling heat. It is more soluble in alcohol, which takes up an equal weight if heated, and one-fourth of its weight cold.

Concentrated sulphuric acid decomposes and carbonizes it; and the nitric acid converts it into malic and oxalic acids.

United with barytes, strontian, lime, and magnesia, it forms salts of a dull yellow colour, which are little soluble, but more so if their base be in excess. With alkalis we only know it forms salts that are not very soluble in general, and precipitate metallic solutions in coloured gallats.

Its most distinguishing characteristic is its great affinity for metallic oxides, so as to take them in general from the most powerful acids. The more readily the metallic oxides are to part with their oxigen, the more they are alterable by the gallic acid. To a solution of gold it imparts a green hue; and a brown precipitate is formed, which readily passes to the metallic state, and covers the solution with a shining golden pellicle. With nitric solution of silver it produces a similar effect. Mercury it precipitates of an orange yellow; copper, brown; bismuth, of a lemon colour; lead, white; iron, black. Platina, zinc, tin, cobalt, and manganese, are not precipitated by it.

The gallic acid is of extensive use in the art of dyeing, as it constitutes one of the principal ingredients in all the shades of black, and is employed to fix or improve several other colours. It is well known as an ingredient in ink. See GALLS, DYEING, and INK.

ACID (HYDROTHIAN). Some of the German chemists distinguish sulphuretted hidrogen by this name, on account of its properties resembling those of an acid.

ACID (LACCIC). About the year 1786, Dr. Anderson of Madras was made acquainted with a substance formed as a kind of nidus by the female of an insect of the genus coccus, of which the natives are very fond. This substance, which has a considerable resemblance to bees wax, he named white lac. In 1789 a small quantity of it was sent to Europe; and in 1793 it was analysed by Dr. Pearson, at the request of sir Joseph Banks. It is of a gray colour, opaque, rough, and in roundish pieces, weighing from three to fifteen grains, and fusible at 145°. On pressing it between the fingers, particularly when fresh gathered, a reddish fluid is squeezed out.

Two thousand grains of the white lac being exposed to a heat just sufficient to melt it, 550 grains of a reddish watery liquid, like that pressed out by the fingers, oozed out of the mass. To this Dr. Pearson gives the name of laccic acid.

This fluid reddens blue litmus paper; after being filtered has a slightly saltish taste, with bitterness, but is not at all sour; when heated smells like bread just baked; and on standing deposits a small quantity of sediment. Its specific gravity at 60° is 1·025. Having been evaporated till it grew very turbid, it afforded on standing small needle-shaped crystals in mucilaginous matter.

Two hundred and fifty grains being put into a retort, the liquor distilled over very fast at the temperature of 200°, and left a small quantity of extractive matter behind. The distilled liquor was transparent and yellowish. A strip of litmus paper, which had been put into the receiver, was not reddened, and another, previously immersed in a solution of sulphat of iron, was turned blue by solution of potash.

A hundred grains of the distilled liquor being evaporated till it grew turbid, and set by for a night, afforded a group of acicular crystals, not amounting to a quarter of a grain. These tasted only bitterish.

A similar quantity evaporated to dryness in a low temperature left a blackish residuum, which was not entirely dissipated by heating the spoon very hot in the naked fire.

Carbonat of lime dissolved in the distilled liquor with effervescence; and on adding carbonat of potash a copious precipitation ensued. A little of this mixture being evaporated to dryness, and the residuum heated red-hot, nothing remained but carbonat of lime and carbonat of potash.

This liquid did not render nitrat of lime turbid; but it did both nitrat and muriat of barytes.

The reddish liquor obtained by melting the lac excited effervescence with carbonat of soda, three grains of which were sufficient to neutralise five hundred of the liquor. A quantity of mucilaginous matter, with a little carbonat of lime, was precipitated. The saturated solution being filtered, and duly evaporated, afforded on standing deliquescent crystals, which on exposure to fire left a residuum of carbonat of soda.

Lime-water produced a light purple turbid appearance in the reddish liquor, and on standing clouds were just perceptible. Sulphat of lime occasioned a white precipitate, but no smell of sulphurated hidrogen gas was perceived. Tincture of galls gave a green precipitation. Sulphat of iron produced a purplish colour, but no precipitation: neither was any formed on adding to the mixture first a little vinegar, and then a little potash. Acetit of lead threw down a reddish precipitate, which the addition of a little nitric acid redissolved. Nitrat of mercury produced a whitish turbid mixture. Oxalic acid immediately threw down some white needly crystals. Tartrit of potash occasioned a precipitate not unlike what takes place with tartarous acid, but it did not redissolve on adding potash.

It appears, therefore, that this is either a new acid, or an acid disguised by circumstances not yet developed.—*Phil. Trans. for 1794, part ii.*

Acid (Lactic). By evaporating sour whey to one-eighth, filtering, precipitating with lime-water, and separating the lime by oxalic acid, Scheele obtained an aqueous solution of what he supposed to be a peculiar acid, which has accordingly been termed the *lactic*. To procure it separate, he evaporated the solution to the consistence of honey, poured on it alcohol, filtered this solution, and evaporated the alcohol. The residuum was an acid of a yellow colour, incapable of being crystallized, attracting the humidity of the air, and forming deliquescent salts with the earths and alkalis.

Bouillon Lagrange has since examined it more narrowly; and from a series of experiments concludes, that it consists of acetic acid, muriat of potash, a small portion of iron probably dissolved in the acetic acid, and an animal matter.—*Ann. de Chimie.*

Acid (Lithic). This was discovered about the year 1776 by Scheele, in analysing human calculi, of many of which it constitutes the greater part, and of some, particularly that which resembles wood in appearance, it forms almost the whole. It is likewise present in human urine, and in that of the camel; and Dr. Pearson found it in those arthritic concretions commonly called chalkstones, which Mr. Tennant has since confirmed.

The following are the results of Scheele's experiments on calculi, which were found to consist almost wholly of this acid:

1. Dilute sulphuric acid produced no effect on the calculus, but concentrated dissolved it; and the solution distilled to dryness left a black coal, giving off sulphurous acid fumes. 2. The muriatic acid, either diluted or concentrated, had no effect on it even with ebullition. 3. Dilute nitric acid attacked it cold; and with the assistance of heat produced an effervescence and red vapour, carbonic acid was evolved, and the calculus was entirely dissolved. The solution was acid, even when saturated with the calculus, and gave a beautiful red colour to the skin in half an hour after it was applied; when evaporated it became of a blood red, but the colour was destroyed by adding a drop of acid: it did not precipitate muriat of barytes, or metallic solutions, even with the addition of an alkali: alkalis rendered it more yellow, and, if superabundant, changed it by a strong digesting heat to a rose colour; and this mixture imparts a similar colour to the skin, and is capable of precipitating sulphat of iron black, sulphat of copper green, nitrat of silver gray, superoxigenated muriat of mercury, and solutions of lead and zinc, white. Lime-water produced in the nitric solution a white precipitate, which dissolved in the nitric and muriatic acids without effervescence, and without destroying their acidity. Oxalic acid did not precipitate it. 4. Carbonat of potash did not dissolve it, either cold or hot, but a solution of perfectly pure potash dissolved it even cold. The solution was yellow; sweetish to the taste; precipitated by all the acids, even the carbonic; did not render lime-water turbid; decomposed and precipitated solution of iron brown, of copper gray, of silver black, of zinc, mercury, and lead, white; and exhaled a smell of ammonia. 5. About 200 parts of lime-water dissolved the calculus by digestion, and lost its acrid taste. The solution was partly precipitated by acids. 6. Pure water dissolved it entirely, but it was necessary to boil for some time 360 parts with one of the calculus in powder. This solution reddened tincture of litmus, did not render lime-water turbid, and on cooling deposited in small crystals almost the whole of what it had taken up. 7. Seventy-two grains distilled in a small glass retort over an open fire, and gradually brought to a red heat, produced water of ammonia mixed with a little animal oil, and a brown sublimate weighing 28 grains, and 12 grains of coal remained, which preserved its black colour on red hot iron in the open air. The brown sublimate was rendered white by a second sublimation; was destitute of smell, even when moistened by an alkali; was acid to the taste; dissolved in boiling water, and also in alcohol, but in less quantity; did not precipitate lime-water; and appeared to resemble succinic acid.

Fourcroy has found, that this acid is almost entirely soluble in 2000 times its weight of cold water, when the powder is repeatedly treated with it. From his experiments he infers, that it contains azot, with a considerable portion of carbon, and but little hidrogen, and little oxigen.

Of its combinations with the bases we know but little. The lithiat of lime is more soluble than the acid itself; but on exposure to the air it is soon decomposed, the carbonic acid in the atmosphere combining with the lime, and precipitating both the lithic acid and new formed carbonat of lime separate from each other. The lithiat of soda appears from the analysis of Mr. Tennant to constitute the chief part of the concretions formed in the joints of gouty persons. The lithiat of potash is obtained by digesting calculi in caustic lixivium; and Fourcroy recommends the precipitation of the lithic acid from this solution by acetous acid, as a good process for obtaining the acid pure in small, white, shining, and almost pulverulent needles.—*Scheele.—Bergman.—Phil. Trans.—Ann. de Chimie.*

Acid (Malic). This acid is thus called because it was found by Scheele chiefly in the juice of apples, though few are met with in a greater variety of productions, as it has been discovered in almost all fruits, in different parts of vegetables, and in various insects, particularly the ant. Indeed all vegetable and even animal substances, that are capable of being converted into oxalic acid by the action of the nitric, appear first to acquire the properties of the malic acid; and it may perhaps be considered as the first stage of acidification, in all the natural and artificial processes, in which carbon and hidrogen are combined with oxigen to form an acid; as it contains a larger proportion of these radicals than any of its kindred acids, and retains more of the nature of the animal or vegetable substance from which it was formed. The oxigenated muriatic acid converts insipid vegetable substances into the malic acid still more readily than the nitric does, and the malic acid obtained is more permanent, not so readily passing to the state of oxalic acid. To convert gum into malic acid nothing more is requisite than to powder it, put it into oxigenated muriatic acid, and shake them together a little while.

As it is most pure and abundant in unripe apples, it may be obtained by saturating their juice with carbonat of potash, and precipitating with acetat of lead. When no more falls down, the precipitate is to be washed with water, and then decomposed by adding dilute sulphuric acid, till the supernatant fluid acquires a sour taste unmixed with any sweetness. If there be an excess of sulphuric acid, this may be remedied by the addition of a little of the malat of lead. The sulphat of lead being then separated by filtration, the liquid may be evaporated till it becomes of a thickish consistence, and a dark red colour, but it will not yield crystals.

In a great many fruits it is mixed with citric acid, as in the juice of gooseberries in particular, and the following mode may be employed to separate them. The juice being boiled down to the consistence of honey, pour on it alcohol, which dissolves both the acids, and leaves behind a large quantity of mucilage. Saturate the two acids in the alcoholic solution with carbonat of lime, and wash the precipitate with boiling water, which will take up the malat of lime, and leave the citrat. The malat of lime may then be decomposed by sulphuric acid.

The malic acid will not crystallize, but after having been boiled down to a thick consistence will desiccate in layers like a shining varnish by being exposed to a dry air. It is easily decomposed by fire, and gives out an acid liquor, a great deal of carbonic acid gas, and a little carbonated hidrogen, and leaves behind a light spongy coal. Its empyreumatic acid appears to resemble that which has been termed pyromucous. Kept in bottles, it undergoes a slow spontaneous decomposition, ferments perceptibly, becomes at first slightly vinous, and deposits a mucous, filamentous, flocculent sediment, which is ultimately carbonized. It is alterable by all the powerful acids, the sulphuric carbonizing it, and the nitric converting it into oxalic acid.

The malat of barytes is capable of solution and crystallization. That of lime affords small irregular crystals, that are not very soluble in boiling water, though they are in an excess of their own acid, or in vinegar, as is likewise the malat of barytes. The malat of lime, thus dissolved in its own acid, grows thick in the air, and forms a solid shining substance resembling varnish. This malat has been found by Vauquelin in various plants, and he observes, that, if the juice of a plant afford a copious precipitate with oxalat of ammonia, and with acetat of lead a light flocculent precipitate, easily soluble in vinegar, we may be certain it contains malat of lime. The malat of alumine is very little soluble: those of magnesia and the three alkalis are deliquescent.

The malic acid precipitates the nitrats of mercury, lead, and silver, in which it differs from the citric acid.

Acid (Mellitic). M. Klaproth has lately discovered in the melilite, or honeystone, what he conceives to be a peculiar acid of the vegetable kind combined with alumine. This acid is easily obtained by reducing the stone to powder, and boiling it in about seventy times its weight of water; when the acid will dissolve, and may be separated from the alumine by filtration. By evaporating the solution it may be obtained in the form of crystals. The following are its characters:

It crystallizes in fine needles or globules by the union of these, or small prisms. It does not seem however at first to possess this property, but gradually acquires it on exposure to the air, perhaps by absorbing oxigen. Its taste is at first a sweetish sour, which leaves a bitterness behind. On a plate of hot metal it is readily decomposed, and dissipated in copious gray fumes, which affect not the smell; leaving behind a small quantity of ashes, that do not change either red or blue tincture of litmus. Neutralized by potash it crystallizes in groups of long prisms: by soda, in cubes, or triangular laminæ, sometimes in groups, sometimes single: and by ammonia, in beautiful prisms with six planes, which soon lose their transparency, and acquire a silvery white hue. If the melitic acid be dissolved in lime-water, and a solution of calcined strontian or barytes be dropped into it, a white precipitate is thrown down, which is redissolved on adding muriatic acid. With a solution of acetit of barytes, it produces likewise a white precipitate, which nitric acid redissolves. With solution of muriat of barytes it produces no precipitate, or even cloud; but, after standing some time, fine transparent needly crystals are deposited. The melitic acid produces no change in a solution of nitrat of silver. From a solution of nitrat of mercury, either hot or cold, it throws down a copious white precipitate, which an addition of nitric acid immediately redissolves. With nitrat of iron it gives an abundant precipitate of a dun yellow colour, which may be redissolved by muriatic acid. With a solution of acetit of lead it produces an abundant precipitate, immediately redissolved on adding nitric acid. With acetit of copper it gives a grayish green precipitate; but it does not affect a solution of muriat of copper. Lime-water precipitated by it is immediately redissolved on adding nitric acid.

M. Klaproth was never able to convert this acid into the oxalic by means of nitric acid, which only changed its brownish colour to a pale yellow.

Acid (Molybdenous). Molybdena is susceptible of four different stages of oxigenation: at the lowest it is in the state of a black oxide; its next is a blue oxide; with an additional portion of oxigen it becomes green, and, beginning to assume acid properties, is termed *molybdenous acid*; and when it is saturated with as much oxigen as it can take up, it is of a yellowish white colour, and is the *molybdic acid*, an account of which is given in the succeeding article.

Acid (Molybdic). The ore of molybdena is a substance that greatly resembles plumbago or black lead; but its texture is scaly, and it is not easily pulverised, on account of a degree of flexibility which its laminæ possess. It may, however, be reduced to powder by grinding it in a mortar with some sulphat of potash; the hardness and angular figure of the particles of this salt tending greatly to facilitate the division. The salt may afterward be washed off by three or four affusions and decantations of hot water.

None of the known acids have any effect upon molybdena, except the sulphuric, arsenic, and nitric. The ore of molybdena is not attacked by the arsenic acid till the water is evaporated. If then the heat be increased a little, arsenic rises into the neck of the retort, and toward the end of the operation sulphuret of arsenic is sublimed. Sulphurous acid goes over into the receiver. The molybdic acid remains in the retort, contaminated, however, with arsenic and its sulphuret.

The concentrated nitric acid being poured upon powdered ore of molybdena in the proportion of two parts of the former to one of the latter; the mixture is scarcely warmed in the retort, before the whole mass passes over into the receiver with great heat. Scheele considers this mixture as in danger of taking fire, when the quantity is large, and therefore uses the diluted nitric acid.

Six ounces of diluted nitric acid being added to one ounce and a half of the powdered ore of molybdena in a retort, no effect takes place during the digestion; but as soon as the mixture begins to boil, red vapours are extricated with great intumescence, so that it is necessary to use a large retort. The distillation should be continued to dryness; after which the same quantity of nitric acid being again poured on the residuum, it will be distilled off with the same appearances as before. This process being again and again repeated until the fourth or fifth time, the residual powder becomes less and less in quantity, until at last it consists of six drachms and a half of white pulverulent matter resembling chalk. This substance, by edulcoration with hot water, being freed from some sulphuric acid and a small quantity of iron, is the acid of molybdena.

The ore, or sulphuret of molybdena may likewise be converted into the acid state by detonation in a red-hot crucible with three or four times its weight of purified nitre. The reddish alkaline mass which remains is to be dissolved in water, and affords both sulphat and nitrat of potash by evaporation. The remaining lixivium appears to consist of a combination of the molybdic acid with a portion of the alkali. This acid falls down, upon the addition of diluted sulphuric acid; which, however, must be cautiously added, because an excess will suspend the precipitate; and if the solution be hot, no precipitate whatever ensues. It is not easy to deprive this precipitate of the last portions of alkali.

The molybdic acid may also be obtained by powdering sulphuret of molybdena, and torrefying it in an inclined crucible, to separate the sulphur, and oxigenate the metal. The heat must be raised immediately to a very high degree; and when the molybdena has lost its brilliancy, and become gray, the process is to be finished with a more moderate heat, to prevent fusion, stirring the matter with an iron spatula continually. The acid is then to be separated, by digesting it repeatedly in a solution of ammonia, having first reduced it to a fine powder; and the ammonia is to be expelled by distillation in a glass retort, and ultimately heating the residuum to a white heat. This mode has lately been recommended by M. Bucholz; but he observes, that the ammonia must be expelled from the acid without delay, as by keeping it a little while a decomposition takes place.

The molybdic acid requires about five hundred times its weight of water to dissolve it. The solution is sour and austere to the taste, reddens litmus, coagulates solutions of soap, and precipitates alkaline sulphurets. The addition of potash forms a salt, which is much more soluble in water than the pure acid itself, and affords crystals by evaporation. This neutral salt does not rise by the action of heat, like the pure acid itself. With ammonia it forms a neutral salt, which parts with its alkali in a gentle heat. The solution of the acid expels the carbonic from chalk or magnesia, and effervesces with alumine, forming salts of difficult solution with these earths. It precipitates barytes from its nitrous or muriatic solutions, and forms a neutral compound very sparingly soluble in cold water; but it does not precipitate the solutions of other earths. It precipitates silver, mercury, and lead from the nitrous acid, and also lead from the muriatic acid. These precipitates are reducible by the blow-pipe upon charcoal. The other metals are not precipitated. The neutral alkaline molybdats precipitate all metallic solutions. Gold, muriat of mercury, zinc, and manganese are precipitated in the form of a white powder; iron and tin from their solutions in muriatic acid; of a brown colour; cobalt, of a rose colour; copper, blue; and the solutions of alum and quick lime, white. If a dilute solution of recent muriat of tin be precipitated by a dilute solution of molybdat of potash, a beautiful blue powder is obtained.

The concentrated sulphuric acid dissolves a considerable quantity of the molybdic acid, the solution becoming of a fine blue colour as it cools, at the same time that it thickens: the colour disappears again on the application of heat, but returns again by cooling. A strong heat expels the sulphuric acid. The nitric acid has no effect on it; but the muriatic dissolves it in considerable quantity, and leaves a dark blue residuum when distilled. With a strong heat it expels a portion of sulphuric acid from sulphat of potash. It also disengages the acid from nitre and common salt by distillation. It has some action upon the filings of the metals in the moist way.

The molybdic acid has not yet been employed in the arts, though experiments have lately been made for the purpose of ascertaining its useful properties. Mr. Hermbstaedt has found, that it throws down a dark violet precipitate from tincture of cochineal; and that a piece of kerseymere, boiled in a solution of the acid, acquired a colour approaching to bright green, which was converted into a bluish gray by drying in the sun. The cloth impregnated with this mordant was dyed of an agreeable violet by immersion in a hot bath of cochineal. Mr. Jaeger carried these experiments still further. He used the supermolybdat of potash. A solution of this salt being mixed with a saturated solution of tin was boiled for half an hour in a retort, and then set by for eight or ten days. The supernatant liquor, which by this time had acquired a deep blue colour, gave a bright blue colour to muslin, and a deeper blue to woollen. Mixed with infusion of quercitron bark it gave a good Saxon green. He tried it likewise with other colours, and found the results in general very satisfactory, many of the colours being extremely fixed, and unalterable by the sun, air, or acids. In particular, he obtained a black much more durable than the common by a composition of molybdat of potash, acetit of alumine, and logwood. He likewise found, that the blue tincture above mentioned, if evaporated by a gentle heat, afforded a fine blue, soluble in water, and capable of being employed either for writing or painting. Richter had long before obtained a fine blue precipitate from molybdat of potash and muriat of tin.—*Fourcroy.—Phil. Trans.—Scherer's Chem. Journ.*

ACID (MOROXYLIC). In the botanic garden at Palermo, Mr. Thompson found an uncommon saline substance on the trunk of a white mulberry-tree. It appeared as a coating on the surface of the bark in little granulous drops of a yellowish and blackish brown colour, and had likewise penetrated its substance. M. Klaproth, who analysed it, found that its taste was somewhat like that of succinic acid; on burning coals it swelled up a little, emitted a pungent vapour scarcely visible to the eye, and left a slight earthy residuum. Six hundred grains of the bark loaded with it were lixiviated with water, and afforded 320 grains of a light salt, resembling in colour a light wood, and composed of short needles united in radii. It was not deliquescent; and though the crystals did not form till the solution was greatly condensed by evaporation it is not very soluble, since 1000 parts of water dissolve but 35 with heat, and 15 cold.

This salt was found to be a compound of lime and a peculiar vegetable acid, with some extractive matter.

To obtain the acid separate, M. Klaproth decomposed the calcareous salt by acetit of lead, and separated the lead by sulphuric acid. He likewise decomposed it directly by sulphuric acid. The product was still more like succinic acid in taste; was not deliquescent; easily dissolved both in water and alcohol; and did not precipitate the metallic solutions, as it did in combination with lime. Twenty grains being slightly heated in a small glass retort, a confile of drops of an acid liquor first came over; next a concrete salt arose, that adhered flat against the top and part of the neck of the retort in the form of prismatic crystals, colourless and transparent; and a coaly residuum remained. The acid was then washed out, and crystallized by spontaneous evaporation. Thus sublimation appears to be the best mode of purifying the salt, but it adhered too strongly to the lime to be separated from it directly by heat without being decomposed.

Not having a sufficient quantity to determine its specific characters, though he conceives it to be a peculiar acid, coming nearest to the succinic both in taste and other qualities, Mr. Klaproth has provisionally given it the name of moroxylic, and the calcareous salt containing it that of moroxylat of lime.—*Scherer's Allg. Journ. der Chemie.*

Acid (Mucous). This acid has been generally known by the name of *saccholactic*, because it was first obtained from sugar of milk; but as all the gums appear to afford it, and the principal acid in sugar of milk is the oxalic, the French chemists in general now distinguish it by the name of *mucous* acid. Hermbstaedt indeed supposes, that it is merely an oxalat of lime combined with a fatty matter; but experiments seem to show the contrary.

It was discovered by Scheele. Having poured twelve ounces of diluted nitric acid on four ounces of powdered sugar of milk in a glass retort on a sand bath, the mixture became gradually hot, and at length effervesced violently, and continued to do so for a considerable time after the retort was taken from the fire. It is necessary therefore to use a large retort, and not to lute the receiver too tight. The effervescence having nearly subsided, the retort was again placed on the sand heat, and the nitric acid distilled off, till the mass had acquired a yellowish colour. This exhibiting no crystals, eight ounces more of the same acid were added, and the distillation repeated, till the yellow colour of the fluid disappeared. As the fluid was inspissated by cooling, it was redissolved in eight ounces of water, and filtered. The filtered liquor held oxalic acid in solution, and seven drams and a half of a white powder remained on the filter. This powder was the acid under consideration.

If one part of gum be heated gently with two of nitric acid, till a small quantity of nitrous gas and of carbonic acid is disengaged, the dissolved mass will deposit on cooling the mucous acid. According to Fourcroy and Vauquelin, different gums yield from 14 to 26 hundredths of this acid.

This pulverulent acid is soluble in about 60 parts of hot water, and by cooling a fourth part separates in small shining scales, that grow white in the air. It decomposes the muriat of barytes, and both the nitrat and muriat of lime. It acts very little on the metals, but forms with their oxides salts scarcely soluble. It precipitates the nitrats of silver, lead, and mercury. With potash it forms a salt soluble in eight parts of boiling water, and crystallizable by cooling. The mucit of soda requires but five parts of water, and is equally crystallizable. Both these salts are still more soluble when the acid is in excess. The mucit of ammonia is deprived of its base by heat. The mucits of barytes, lime, and magnesia, are nearly insoluble.—*Scheele's Essays.—Fourcroy.*

Acid (Muriatic), known in commerce by the name of spirit of salt. As common salt consists of this peculiar acid united with soda by so strong an affinity that both substances may be driven up by heat, instead of any separation taking place, the acid itself cannot be obtained alone, but by means of processes in which a third substance is presented to combine with the alkali. Various methods were formerly used, in which the common salt was ground with earthy substances, and then exposed to distillation. These methods have been discontinued in England since the sulphuric acid has been obtained at an easy rate. In the antient method, common salt was previously decrepitated, then ground with dried clay, and kneaded or wrought with water to a moderately stiff consistence, after which it was divided into balls of the size of a pigeon's egg: these balls, being previously well dried, were put into a retort, so as to fill the vessel two-thirds full; distillation being then proceeded upon, the muriatic acid came over when the heat was raised to ignition. In this process eight or ten parts of clay to one of salt are to be used. The retort must be of stone-ware well coated, and the furnace must be of that kind called reverberatory.

It was formerly thought, that the salt was merely divided in this operation by the clay, and on this account more readily gave out its acid: but there can be little doubt, that the effect is produced by the siliceous earth, which abounds in large proportions in all natural clays, and detains the alkali of the salt by combining with it.

The extrication of muriatic acid from common salt by means of the sulphuric is much the most elegant and effectual. The English manufacturers use iron stills for this distillation, with earthen heads: the philosophical chemist will doubtless prefer glass. One part, by weight, of strong sulphuric acid is to be added to three of decrepitated sea salt, in a retort, the upper part of which is furnished with a tube or neck, through which the acid is to be poured upon the salt. The aperture of this tube must be closed with a ground stopper immediately after the pouring. The sulphuric acid immediately combines with the alkali, and expels the muriatic acid in the form of a peculiar air, which is rapidly absorbed by water, but may be confined by mercury. As this combination and disengagement take place without the application of heat, and the aërial fluid escapes very readily, it is necessary to arrange and lute the vessels together before the vitriolic acid is added, and not to make any fire in the furnace until the disengagement begins to slacken; at which time it must be very gradually raised. Before the modern improvements in chemistry were made, a great part of the acid escaped for want of water to combine with; but by the use of Woulfe's apparatus (See LABORATORY), the acid air is made to pass through water, in which it is condensed, and forms muriatic acid of double the weight of the water, though the bulk of this fluid is increased one half only. The acid condensed in the first receiver, which contains no water, is of a yellow colour, arising from the impurities of the salt.

The marine acid in commerce has a straw colour: but this is owing to accidental impurity; for it does not obtain in the acid produced by the impregnation of water with the aëriform acid.

The base of the muriatic acid has never yet been ascertained. Some years ago Dr. Girtanner peremptorily announced that it was a compound of hidrogen and oxigen, because he conceived it to have been decomposed in some experiments in which hidrogen was produced. In all of these, however, water was present; for Girtanner was so unacquainted with the nature of this acid, as to conceive what he used in a fluid state to be free from water: and in several experiments, both analytical and synthetical, made by Van Mons with a view to ascertain this point, he could obtain nothing decisive, either to confirm or refute this hypothesis; for though hidrogen was sometimes produced, it could never be unequivocally ascertained to have proceeded from the muriatic acid, and in all his attempts at synthesis he was unsuccessful. Of the experiments of Tassaert, and of those of Mr. Henry, both of whom pursued the investigation, the same may be said. Berthollet has inferred, chiefly from a fact observed by Humboldt, that a portion of muriat of iron was formed by exposing sulphat of iron to the action of oxide of nitrogen; and from those of Cavendish, who observed, that nitric acid formed from oxigen and nitrogen by the electric spark precipitated nitrat of silver, and that nitrat of potash, from which part of its oxigen was expelled by heat, did the same; that the muriatic acid is a compound of both hidrogen and nitrogen with oxigen. The discovery of galvanism has opened a new field of inquiry. Professor Pacchioni of Pisa, and Mr. Peele of Cambridge, both profess to have found muriatic acid formed in water by its agency; and Mr. Henry obtained a similar result, though he was not perfectly satisfied that no source of fallacy was present. The experiment was attempted by the Galvanic Society at Paris without success: but more lately Mr. Sylvester has tried it with great care, and found that muriatic acid is generally formed; though sometimes the acid produced is found to be the nitric, with little or none of the muriatic. But in all these instances the quantity produced was so very small, that nothing conclusive can be affirmed, at least with respect to the base. We must not omit to mention here too the experiments of Mr. Lambe, who found, that when pure iron filings were subjected to the action of a solution of sulphurated hidrogen, a muriat of iron was obtained; and those of M. Biot, who infers, from his curious researches on refraction, that muriatic acid can neither be an oxide of hidrogen with less oxigen than water, as some have supposed, nor have nitrogen for its base.

Whatever this base may be, it appears to be capable of existing in three different states of combination distinguished by the terms *muriatic*, *oxigenised*, and *hyperoxigenised muriatic* acid. Mr. Chenevix indeed has suggested, that the first is the radical, and the other two might be termed *muriatous* and *muriatic* acids: but his radical is possessed of the characters of an acid in too decisive and potent a manner to be easily dismissed from its rank.

The muriatic acid is one of those longest known, and some of its compounds are among those salts with which we are most familiar. They are all soluble in water.

The muriat of barytes crystallizes in tables bevelled at the edges, or in octaëdral pyramids applied base to base. It is soluble in five parts of water at 60°, in still less at a boiling heat, and also in alcohol. It is not altered in the air, and but partially decomposable by heat. The sulphuric acid separates its base; and the alkaline carbonats and sulphats decompose it by double affinity. It is best prepared by dissolving the carbonat in dilute muriatic acid: and if contaminated with iron or lead, which occasionally happens, these may be separated by the addition of a small quantity of liquid ammonia, or by boiling and stirring the solution with a little lime. Mr. Goettling recommends to prepare it from the sulphat of barytes: eight parts of which in fine powder are to be mixed with two of muriat of soda, and one of charcoal powder. This is to be pressed hard into a Hessian crucible, and exposed for an hour and a half to a red heat in a wind furnace. The cold mass, being powdered, is to be boiled a minute or two in sixteen parts of water, and then filtered. To this liquor muriatic acid is to be added by little and little, till sulphurated hidrogen ceases to be evolved; it is then to be filtered, a little hot water to be poured on the residuum, the liquor evaporated to a pellicle, filtered again, and then set to crystallize. As the muriat of soda is much more soluble than the muriat of barytes, and does not separate by cooling, the muriat of barytes will crystallize into a perfectly white salt, and leave the muriat of soda in the mother water, which may be evaporated repeatedly till no more muriat of barytes is obtained. This salt was first employed in medicine by Dr. Crawford, chiefly in scrofulous complaints and cancer, beginning with doses of a few drops of the saturated solution twice a day, and increasing it gradually, as far as forty or fifty drops in some instances. In large doses it excites nausea, and has deleterious effects. Fourcroy says it has been found very successful in scrofula in France. It has likewise been recommended as a vermifuge; and we have given it with much apparent advantage, even to very young children, where the usual symptoms of worms occurred, though none were ascertained to be present. As a test of sulphuric acid it is of great use.

The muriat of potash, formerly known by the names of *febrifuge salt of Sylvius*, *digestive salt*, and *regenerated sea salt*, crystallizes in regular cubes, or in rectangular parallelopipedons; decrepitating on the fire, without losing much of their acid, and acquiring a little moisture from damp air, and giving it out again in dry. Their taste is saline and bitter. They are soluble in thrice their weight of cold water, and in but little less of boiling water, so as to require spontaneous evaporation for crystallizing. Fourcroy recommends, to cover the vessel with gauze, and suspend hairs in it, for the purpose of obtaining regular crystals.

It is sometimes prepared in decomposing sea salt by common potash for the purpose of obtaining soda; and may be formed by the direct combination of its constituent parts.

It is decomposable by the sulphuric and nitric acids, and in the dry way by the phosphoric. Barytes decomposes it, though not completely. And both silex and alumine decompose it partially in the dry way. It decomposes the earthy nitrats, so that it might be used in saltpetre manufactories to decompose the nitrat of lime.

Muriat of soda, or *common salt*, is of considerable use in the arts, as well as a necessary ingredient in our food. It crystallizes in cubes, which are sometimes grouped together in various ways, and not unfrequently form hollow quadrangular pyramids. In the fire it decrepitates, melts, and is at length volatilized. When pure, it is not deliquescent. One part is soluble in 2½ of cold water, and in little less of hot, so that it cannot be crystallized but by evaporation. According to M. Chenevix it is soluble in alcohol also, particularly when it is mixed with the hyperoxymuriat.

Common salt is found in large masses, or in rocks under the earth, in England and elsewhere. In the solid form it is called *sal gem* or *rock salt*. If it be pure and transparent, it may be immediately used in the state in which it is found; but if it contain any impure earthy particles, it should be previously freed from them. In some countries it is found in incredible quantities, and dug up like metals from the bowels of the earth. In this manner has this salt been dug out of the celebrated salt mines near Bochnia and Wieliczka, in Poland, ever since the middle of the 13th century, consequently above these 500 years, in such amazing quantities, that sometimes there have been 20000 tons ready for sale. In these mines, which are said to reach to the depth of several hundred fathoms, 500 men are constantly employed. The pure and transparent salt needs no other preparation than to be beaten to small pieces, or ground in a mill. But that which is more impure must be elutriated, purified, and boiled. That which is quite impure, and full of small stones, is sold under the name of rock salt, and is applied to ordinary uses; it may likewise be used for strengthening weak and poor brine-springs.

Though the salt mines of Wieliczka, near Cracow in Poland, have long astonished the philosopher and traveller, yet it deserves to be remarked, that the quantity of rock salt obtained from the mines of Northwich is greatly superior to that obtained at Cracow. The bishop of Llandaff affirms, that a single pit, into which he descended, yielded at a medium 4000 tons of salt in a year, which alone is about two-thirds of that raised in the Polish mines. This rock salt is never used on our tables in its crude state, as the Polish rock salt is; and though the pure transparent salt might be used with our food, without any danger, yet it is prohibited under a penalty of 40s. for every pound of rock salt so applied. It is partly purified in water, and a great part of it is sent coastwise to Liverpool and other places, where it is used either for strengthening brine-springs or sea-water.

Beside the salt mines here mentioned, where the common salt is found in a concrete state, under the name of rock salt, there is at Cordova, in the province of Catalonia in Spain, a remarkable solid mountain of rock salt: this mountain is between four and five hundred feet in height, and a league in circuit; its depth below the surface of the earth is not known. This mountain contains the rock salt without the least admixture of any other matter.

The waters of the ocean every where abound with common salt, though in different proportions. The water of the Baltic sea is said to contain one sixty-fourth of its weight of salt; that of the sea between England and Flanders contains one thirty-second part; that on the coasts of Spain, one sixteenth part; and between the tropics it is said, perhaps erroneously, to contain from an eleventh to an eighth part.

The water of the sea contains, beside the common salt, a considerable proportion of muriat of magnesia, and some sulphat of lime. The former is the chief ingredient of the remaining liquid which is left after the extraction of the common salt, and is called the mother water. Sea-water, if taken up near the surface, contains also the putrid remains of animal substances, which render it nauseous, and in a long continued calm cause the sea to stink.

The whole art of extracting salt from waters which contain it consists in evaporating the water in the cheapest and most convenient manner. In England, a brine composed of sea water, with the addition of rock salt, is evaporated in large shallow iron boilers; and the crystals of salt are taken out in baskets. In Russia, and probably in other northern countries, the sea water is exposed to freeze; and the ice, which is almost entirely fresh, being taken out, the remaining brine is much stronger, and is evaporated by boiling. In the southern parts of Europe the salt-makers take advantage of spontaneous evaporation. A flat piece of ground near the sea is chosen, and banked round, to prevent its being overflowed at high water. The space within the banks is divided by low walls into several compartments, which successively communicate with each other. At flood tide, the first of these is filled with sea water; which, by remaining a certain time, deposits its impurities, and loses part of its aqueous fluid. The residue is then suffered to run into the next compartment; and the former is again filled as before. From the second compartment, after a due time, the water is transferred into a third, which is lined with clay well rammed and levelled. At this period the evaporation is usually brought to that degree, that a crust of salt is formed on the surface of the water, which the workmen break, and it immediately falls to the bottom. They continue to do this, until the quantity is sufficient to be raked out, and dried in heaps. This is called *bay salt.*

In some parts of France, and also on the coasts of China, they wash the dried sands of the sea with a small proportion of water, and evaporate this brine in leaden boilers.

There is no difference between this salt and the lake salt extracted from different lakes, excepting such as may be occasioned by the casual intervention of some substances. In this respect the Jeltonic salt-water lake, in the Russian dominions near Saratow and Dmitrewsk, deserves our attention. In the year 1748, when the Russians first fetched salt thence, the lake was almost solid with salt; and that to such a degree, that they drove their heavy waggons over it, as over a frozen river, and broke up the salt. But since the year 1757 the water has increased so much, that at this time it is nothing more than a lake very strongly impregnated with salt. The Jeltonic lake salt contains at the same time alum and sulphat of magnesia.

At several places in Germany, and at Montmarot in France, the waters of salt springs are pumped up to a large reservoir at the top of a building or shed; from which it drops or trickles through small apertures upon boards covered with brushwood. The large surface of the water thus exposed to the air causes a very considerable evaporation; and the brine is afterward conveyed to the boilers for the perfect separation of the salt.

To free common salt from those mixtures, that render it deliquescent and less fit for the purposes to which it is applied, it may be put into a conical vessel with a small aperture at the point, and a saturated solution of the muriat of soda boiling hot be poured on it. This solution will dissolve and carry off any other salts mixed with the soda, and leave it quite pure by repeating the process three or four times.

From this salt, as already observed, the muriatic acid is extracted; and of late years to obtain its base separate, in the most œconomical mode, for the purposes of the arts, has been an object of research. The process of Scheele, which consists in mixing the muriat of soda with red oxide of lead, making this into a soft paste with water, and allowing it to stand thus for some time, moistening it with water as it gets dry, and then separating the soda from the muriat of lead by lixiviation, has been resorted to in this country. A Mr. Turner some years ago had a patent for it; converting the muriat of lead into a pigment, which was termed *mineral* or *patent yellow,* by heating it to fusion. The oxide of lead should be at least twice the weight of the salt. This would have answered extremely well, had there been an adequate and regular demand for the pigment. At present, we understand, the greater part of the carbonat of soda in the market is furnished by decomposing the sulphat of soda, left after the muriatic acid is expelled in the usual way of manufacturing it from common salt. Various processes for this purpose were tried in France and made public by the French government, all depending on the principle of decomposing the acid of the sulphat by charcoal, and at the same time adding some other material to prevent the soda from forming a sulphuret. What they consider as the best, is to mix the sulphat of soda with an equal weight of chalk and rather more than half its weight of charcoal powder, and to expose the mixture in a reverberatory furnace to a heat sufficient to bring them to a state of imperfect liquefaction. Much of the sulphur formed will be expelled in vapour and burned, the mixture being frequently stirred to promote this; and this is continued till the mass on cooling assumes a fine grain. It is then left exposed to a humid atmosphere, and the carbonat of soda may be extracted by lixiviation, the sulphur not consumed having united with the lime. Tinmen's shreds, or old iron, may be employed instead of chalk, in the proportion of 65 parts to 200 of sulphat of soda and 62 of charcoal; or chalk and iron may be used at the same time in different proportions. The muriat of soda might be decomposed in the first instance by the sulphat of iron, instead of the sulphuric acid. The carbonat of soda thus prepared, however, is not free from sulphur, and Dizé recommends the abstraction of it by adding litharge to the lixivium in a state of ebullition, which will render the alkali pure. Oxide of manganese was substituted in the same way with equal success; and this may be used repeatedly, merely by calcining it after each time to expel the sulphur.

Mr. Accum gives us the following method, as having answered extremely well in a soda manufactory, in which he was employed:—Five hundred pounds of sulphat of soda, procured from the bleachers who make a large quantity in preparing their muriatic acid from common salt, were put into an iron boiler with a sufficient quantity of soft water. Into another boiler were put 560lbs. of good American potash, or 570 if the potash were indifferent, dissolved in about 30 pails of water, or as little as possible. When both were brought to boil, the solution of potash was ladled into that of sulphat of soda, agitating the mixture, and raising the fire as quickly as possible. When the whole boiled it was ladled into a wooden gutter, that conveyed it to a wooden cistern lined with lead near half an inch thick, in a cool place. Sticks were placed across the cistern, from which slips of sheet lead two or three inches wide hung down into the fluid about four inches distant from each other. When the whole was cold, which in winter was in about three days, the fluid was drawn off, the crystallized salt was detached from the slips of lead, and the rock of salt fixed to the bottom was separated by a chisel and mallet. The salt being washed in the same cistern, to free it from impurities, was then returned to the boiler, dissolved in clear water, and evaporated till a strong pellicle formed. Letting it cool till the hand could be dipped into it, it was kept at this temperature as long as pellicles would form over the whole surface and fall to the bottom. When no more pellicles appeared without blowing on the surface, the fire was put out, and the solution returned into the cistern to crystallize. If the solution be suffered to cool pretty low, very little sulphat of potash will be found mixed with the soda; but the rocky masses met with in the market generally contain a pretty large quantity. In the process above described the produce of the mixed salt from 100lbs. of sulphat of soda was in general from 136 to 139lbs.

Beside its use in seasoning our food, and preserving meat both for domestic consumption and during the longest voyages; and in furnishing us with the muriatic acid and soda; salt forms a glaze for coarse pottery by being thrown into the oven, where it is baked; it improves the whiteness and clearness of glass; it gives greater hardness to soap; in melting metals it preserves their surface from calcination by defending them from the air, and is employed with advantage in some assays; it is used as a mordant, and for improving certain colours; and enters more or less into many other processes of the arts.

The muriat of strontian has not long been known. M. Klaproth first distinguished it from muriat of barytes. It crystallizes in very slender hexagonal prisms; has a cool pungent taste, without the austerity of the muriat of barytes, or the bitterness of the muriat of lime; is soluble in 0·75 of water at 60°, and to almost any amount in boiling water; is likewise soluble in alcohol, and gives a blood red colour to its flame.

It has never been found in nature, but may be prepared in the same way as the muriat of barytes.

The muriat of lime has been known by the names of *marine selenite*, *calcareous marine salt*, *muria*, and *fixed sal ammoniac*. It crystallizes in hexaëdral prisms terminated by acute pyramids; but if the solution be greatly concentrated, and exposed to a low temperature, it is condensed in confused bundles of needly crystals. Its taste is acrid, bitter, and very disagreeable. It is soluble in half its weight of cold water, and by heat in its own water of crystallization. It is one of the most deliquescent salts known, and when deliquesced has been called *oil of lime*. It exists in nature, but neither very abundantly nor very pure. It is formed in chemical laboratories in the decomposition of muriat of ammonia; and Homberg found, that, if it were urged by a violent heat till it condensed on cooling into a vitreous mass, it emitted a phosphoric light upon being struck by any hard body, in which state it was called *Homberg's phosphorus*.

Hitherto it has been little used except for frigorific mixtures; and with snow it produces a very great degree of cold. Fourcroy, indeed, says he has found it of great utility in obstructions of the lymphatics, and in scrofulous affections; but we do not know that any trial of it has been made in this country.

The muriat of ammonia has long been known by the name of *sal ammonia* or *ammoniac*. It is found native in the neighbourhood of volcanoes, where it is sublimed sometimes nearly pure; and in different parts of Asia and Africa. A great deal is carried annually to Russia and Siberia from Bucharian Tartary; and we formerly imported large quantities from Egypt, but now manufacture it at home. See AMMONIA.

This salt is usually in the form of cakes, with a convex surface on one side, and concave on the other, from being sublimed into large globular vessels; but by solution it may be obtained in regular quadrangular crystals. It is remarkable for possessing a certain degree of ductility, so that it is not easily pulverable. It is soluble in 3½ parts of water at 60°, and in little more than its own weight of boiling water. Its taste is cool, acrid, and bitterish. Its specific gravity is 1·42. It attracts moisture from the air but very slightly.

Muriat of ammonia has been more employed in medicine than it is at present. It is sometimes useful as an auxiliary to the bark in intermittents: in gargles it is beneficial; and externally it is a good discutient. In dyeing it improves or heightens different colours. In tinning and soldering it is employed to preserve the surface of the metals from oxidation. In assaying it discovers iron, and separates it from some of its combinations.

The muriat of magnesia is extremely deliquescent, soluble in an equal weight of water, and difficultly crystallizable. It dissolves also in five parts of alcohol. It is decomposable by heat, which expels its acid. Its taste is intensely bitter.

With ammonia this muriat forms a triple salt, crystallizable in little polyedrons, which separate quickly from the water, but are not very regularly formed. Its taste partakes of that of both the preceding salts. The best mode of preparing it is by mixing a solution of 27 parts of muriat of ammonia with a solution of 73 of muriat of magnesia; but it may be formed by a semidecomposition of either of these muriats by the base of the other. It is decomposable by heat, and requires six or seven times its weight of water to dissolve it.

Of the muriat of glucine we know but little. It appears to crystallize in very small crystals; to be decomposable by heat; and, dissolved in alcohol and diluted with water, to form a pleasant saccharine liquor.

Muriat of alumine is scarcely crystallizable, as on evaporation it assumes the state of a thick jelly. It has an acid, styptic, acrid taste. It is extremely soluble in water, and deliquescent. Fire decomposes it. It may be prepared by directly combining the muriatic acid with alumine, but the acid always remains in excess.

The muriat of zircon crystallizes in small needles, which are very soluble, attract moisture, and lose their transparency in the air. It has an austere taste, with somewhat of acrimony. It is decomposable by heat. The gallic acid precipitates from its solution, if it be free from iron, a white powder. Carbonat of ammonia, if added in excess, redissolves the precipitate it had before thrown down.

Muriat of yttria does not crystallize when evaporated, but forms a jelly: it dries with difficulty, and deliquesces.

Fourcroy observes, that when siliceous stones, previously fused with potash, are treated with muriatic acid, a limpid solution is formed, which may be reduced to a transparent jelly by slow evaporation. But a boiling heat decomposes the siliceous muriat, and the earth is deposited. The solution is always acid.—*Murray.—Fourcroy.—Henry.—Watson.—Klaproth.—Kirwan.—Phil. Trans.—Mem. de l'Instit. Nat.—Ann. de Chim.—Philos. Journal.—Phil. Mag.—Hist. Nat. de l'Espagne.*

ACID (MURIATIC, OXIGENISED). This acid, to which some of the moderns give the name of *oxi-muriatic*, and termed *dephlogisticated* by its discoverer Scheele, conformably to the theory of that time, consists of 84 parts of the preceding acid united with 16 of oxigen. It may be made by adding two parts of muriatic acid to one of finely powdered manganese, in a retort connected with Woulfe's apparatus, and applying a gentle heat to it, while the receivers are surrounded by water as near as possible to the freezing point; or by mixing eight parts of muriat of soda with three of powdered manganese, putting them into a retort, pouring on them four parts of sulphuric acid, previously diluted with an equal weight of water, and proceeding as above. The operator should be very careful, that none of the acid escapes into the air in the state of gas, as it is very injurious when respired, occasioning all the symptoms of violent catarrh by coming into contact with the membrane that lines the nostrils, and severe stricture and oppression of the chest if it enter the lungs. The best preventative of its mischievous effects, when it does thus escape, is the vapour of volatile alkali, for which it has a powerful affinity.

When the water in the receivers is kept at a temperature below 40°, the water not only saturates itself with the gas, but crystals, of a shining greenish white, form in hexaëdral scales on the surface, and round the sides, enclosing the fluid, till the whole assumes a gelatinous appearance. A very moderate heat melts the concrete matter, and even converts it into a gas, that rises in bubbles through the saturated fluid, and floats on its surface. By increasing the heat, the whole of the gas may be expelled with very little alteration; but light decomposes it, and reduces it to the state of common muriatic acid, by liberating the oxigen.

It is a singular circumstance, that one of the powerful mineral acids should be deprived of what are considered as characteristic properties of an acid by the addition of oxigen, which is deemed the acidifying principle. Its taste, instead of being sour, is harsh and styptic; and instead of reddening blue vegetable colours it destroys them, as it does most others, yellow excepted. From this property, it is of use for removing stains and discolorations from old books and prints; though it is destructive to manuscripts, as it discharges writing ink; and it is very extensively employed in bleaching, as will be seen more at large under that article. In medicine too it has been tried. Van Deiman recommends it in a dilute state against the itch and scald-head, and as a wash for the gums when scorbutic: Fourcroy mentions it as a powerful tonic: and Mr. Brathwaite of Lancaster extols it highly in doses of 10 or 15 drops against scarlet fever. But we are not inclined to give it credit for any decided superiority over other acids, that can be obtained and administered more commodiously.

Another singularity attending this acid is, that when an alkaline or earthy base is added to it, for the purpose of forming an oxi-muriat, the acid is decomposed, and two different salts are formed, one the simple muriat and the other a hyperoxi-muriat. It appears, however, that oximuriats are actually formed, though not obtainable separate by crystallization; since a solution of alkali into which oxigenised muriatic acid gas has been passed, is capable of destroying vegetable colours, and is decomposable by light alone, which neither the simple nor hyperoxigenized muriat is.

Acid (Muriatic, Hyperoxigenised). This acid, which, just the reverse of the preceding, has been obtained only in combination with some base, and never separate, appears to consist of 65 parts of oxigen to 35 of muriatic acid. To its compounds therefore we shall proceed, first premising, that we are indebted to M. Chenevix for an accurate knowledge of it, though it was discovered by Berthollet.

Hyperoximuriat of potash may be procured by receiving the oximuriatic acid, as it is formed, into a solution of potash. When the solution is saturated, it may be evaporated gently, and the first crystals produced will be the salt desired, this crystallizing before the simple muriat, which is produced at the same time with it. Its crystals are in shining hexaëdral laminæ or rhomboidal plates. It is soluble in 17 parts of cold water; and, but very sparingly, in alcohol. It is not decomposed by the direct rays of the sun. Subjected to distillation in a coated retort it first fuses, and on increasing the heat gives out oxigen gas. A hundred grains yield 75 cubic inches of this gas with about two only of azote. It is incapable of discharging vegetable colours; but the addition of a little sulphuric acid develops this property, by setting at liberty oxigenised muriatic acid. So likewise a few grains of it added to an ounce of muriatic acid give it this property. It is decomposed by the sulphuric and nitric acid. If a few grains be dropped into strong sulphuric acid, an offensive smell is produced, resembling that of a brick-kiln mixed with that of nitrous gas; and if the quantity be large enough an explosion will ensue. If the vessel be deep, it will be filled with a thick, heavy vapour, of a greenish yellow colour, but not producing the symptoms of catarrh, at least in so violent a degree as the fumes of oxigenised muriatic acid. Underneath this vapour is a bright orange-coloured fluid. This vapour inflames alcohol, oil of turpentine, camphor, resin, tallow, elastic gum, and some other inflammable substances, if thrown into it. If the sulphuric acid be poured upon the salt, a violent decrepitation takes place, sometimes, though rarely, accompanied by a flash. M. Chenevix attempted to disengage the hyperoxigenised acid from this muriat by adding sulphuric acid to it in a retort; but almost as soon as the fire was kindled an explosion took place, by which a French gentleman present was severely wounded, and narrowly escaped the loss of an eye.

The effects of this hyperoximuriat on inflammable bodies are very powerful. Rub two grains into powder in a mortar, add a grain of sulphur, mix them well by gentle trituration, then collect the powder into a heap, and press upon it suddenly and forcibly with the pestle, a loud detonation will ensue. If the mixture be wrapped in strong paper, and struck with a hammer, the report will be still louder. Five grains of the salt mixed in the same manner with two and a half of charcoal, will be inflamed by strong trituration, especially if a grain or two of sulphur be added, but without much noise. If a little sugar be mixed with half its weight of the muriat, and a little strong sulphuric acid poured on it, a sudden and vehement inflammation will ensue: but this experiment requires caution, as well as the following. To one grain of the powdered salt in a mortar add half a grain of phosphorus, it will detonate, with a loud report, on the gentlest trituration. In this experiment the hand should be defended by a glove, and great care should be taken, that none of the phosphorus get into the eyes. Phosphorus may be inflamed by it under water, putting into a wine-glass one part of phosphorus and two of the muriat, nearly filling the glass with water, and then pouring in through a glass tube reaching to the bottom three or four parts of sulphuric acid. This experiment too is very hazardous to the eyes. If olive or linseed oil be taken instead of phosphorus, it may be inflamed by similar means on the surface of the water. This salt should not be kept mixed with sulphur, or perhaps any inflammable substance, as in this state it has been known to detonate spontaneously. As it is the common effect of mixtures of this salt with inflammable substances of every kind to take fire on being projected into the stronger acids, M. Chenevix tried the experiment with it mixed with diamond powder in various proportions, but without success.

Hyperoximuriat of soda may be prepared in the same manner as the preceding, by substituting soda for potash; but it is not easy to obtain it separate, as it is nearly as soluble as the muriat of soda, requiring only 3 parts of cold water. Neither is the solubility of this salt in alcohol sufficient to separate it from the common muriat, since this also, according to M. Chenevix, is soluble in alcohol, and more especially so when accompanied by the hyperoximuriat. This gentleman, however, succeeded in obtaining a little pure hyperoximuriat of soda, by sending a current of oxigenised muriatic acid through a solution of carbonat of soda, and repeatedly crystallizing in alcohol a large quantity of the mixed salt thus formed. It crystallizes in cubes, or rhomboids little different from cubes; produces a sensation of cold in the mouth and a saline taste; is slightly deliquescent; and in its other properties resembles the hyperoximuriat of potash.

Barytes appears to be the next base in order of affinity for this acid, though its force of attraction for it is greatly inferior. The best method of forming it is to pour hot water on a large quantity of this earth, and to pass a current of oxigenised muriatic acid gas through the liquid kept warm, so that a fresh portion of barytes may be taken up as the former is saturated. This salt is soluble in about four parts of cold water, and less of warm; and crystallizes like the simple muriat. It may be obtained, however, by the agency of double affinity; for phosphat of silver boiled in the solution will decompose the simple muriat, and the muriat of silver and phosphat of barytes, being insoluble, will both fall down and leave the hyperoximuriat in solution alone. The phosphat of silver employed in this process must be perfectly pure, and not the least contaminated with copper.

The hyperoximuriat of strontian may be obtained in the same manner. It is deliquescent, melts immediately in the mouth and produces cold, is more soluble in alcohol than the simple muriat, and crystallizes in needles.

The hyperoximuriat of lime, obtained in a similar way, is extremely deliquescent; liquefies at a low heat; is very soluble in alcohol; produces much cold in solution; and has a sharp bitter taste. This salt, when perfectly saturated, possesses bleaching properties, producing whiteness in the unbleached part of printed goods, without injuring their colours; for which purpose it is made by passing the oxigenated muriatic acid gas into water, through which lime is diffused by agitation.

As the oxigenised muriatic acid decomposes ammonia, it might be supposed, that a hyperoximuriat of this base could not exist: but though for this reason it cannot be formed as the preceding salts, it may by double affinity, the carbonat of ammonia decomposing the earthy salts of this genus, giving up its carbonic acid to their base, and combining with their acid into hyperoximuriat of ammonia, which may be obtained by evaporation. It is very soluble both in water and alcohol, and decomposed by a moderate heat.

The hyperoximuriat of magnesia much resembles that of lime.

To obtain hyperoximuriat of alumine, M. Chenevix put some alumine, precipitated from the muriat, and well washed but still moist, into a Woulfe's apparatus, and treated it as the other earths. The alumine shortly disappeared; and on pouring sulphuric acid into the liquor a strong smell of hyperoxigenised muriatic acid was perceivable: but on attempting to obtain the salt pure by means of phosphat of silver, the whole was decomposed, and nothing but hyperoximuriat of silver was found in the solution. M. Chenevix adds, however, that the aluminous salt appears to be very deliquescent, and soluble in alcohol.—*Phil. Trans.*—*Henry.*—*Davy.*

ACID (MURIATIC, SULPHURETTED). By this name Dr. T. Thomson of Edinburgh has distinguished a compound of muriatic acid and oxide of sulphur, which he discovered, and which will be more fully noticed under the article SULPHUR.

ACID (NITRIC). The two principal constituent parts of our atmosphere, when in certain proportions, are capable, under particular circumstances, of combining chemically into one of the most powerful acids, the nitric, which consists, according to Mr. Davy, of 70·5 of oxigen, and 29·5 of azot, or nitrogen. If these gases be mixed in this proportion in a glass tube about a line in diameter over mercury, and a series of electric shocks be passed through them for some hours, they will form nitric acid; or, if a solution of potash be present with them, nitrat of potash will be obtained. The constitution of this acid may be further proved, analytically, by driving it through a redhot porcelain tube, as thus it will be decomposed into oxigen and nitrogen gases. For all practical purposes, however, the nitric acid is obtained from nitrat of potash, from which it is expelled by sulphuric acid.

Four parts of pure nitrat of potash coarsely powdered are to be put into a glass retort, and three parts of concentrated sulphuric acid cautiously added, taking care to avoid the fumes that arise, which is best done by standing in a current of air to convey them up the chimney. Join to the retort a tubulated receiver of large capacity, with an adopter interposed, and lute the junctures with a mixture of pipeclay, sifted sand, and cut tow. In the tubulure fix with fat lute a glass tube terminating in another large receiver, in which is a small quantity of water; and, if you wish to collect the gaseous products, let a bent glass tube from this receiver communicate with a pneumatic trough. Apply heat to the receiver by means of a sand bath. The first product that passes into the receiver is generally red and fuming; but the appearances gradually diminish, till the acid comes over pale, and even colourless, if the materials used were clean. After this it again becomes more and more red and fuming, till the end of the operation; and the whole mingled together will be of a yellow or orange colour.

In the large way, and for the purposes of the arts, extremely thick cast iron or earthen retorts are usually employed, to which an earthen head is adapted, and connected with a range of proper condensers. The strength of the acid too is varied, by putting more or less water in the receivers. The nitric acid thus made generally contains sulphuric acid, and also muriatic from the impurity of the nitrat employed. If the former, a solution of nitrat of barytes will occasion a white precipitate; if the latter, nitrat of silver will render it milky. The sulphuric acid may be separated by a second distillation from very pure nitre, equal in weight to an eighth of that originally employed; or by precipitating with nitrat of barytes, decanting the clear liquid, and distilling it. The muriatic acid may be separated by proceeding in the same way with nitrat of siver, or with litharge, decanting the clear liquor, and redistilling it; leaving an eighth or tenth part in the retort. The acid for the last process should be condensed as much as possible, and the redistillation conducted very slowly; and if it be stopped when half is come over, beautiful crystals of muriat of lead will be obtained on cooling the remainder, if litharge be used, as M. Steinacher informs us; who also adds, that the vessels should be made to fit tight by grinding, as any lute is liable to contaminate the product.

As this acid still holds in solution more or less nitrous gas, it is not in fact nitric acid, but a kind of nitrous: it is therefore necessary, to put it into a retort to which a receiver is added, the two vessels not being luted, but merely joined by paper; and to apply a very gentle heat for several hours, changing the receiver as soon as it is filled with red vapours. The nitrous gas will thus be expelled, and the nitric acid will remain in the retort as limpid and colourless as water. It should be kept in a bottle secluded from the light, otherwise it will lose part of its oxigen.

According to Lagrange, a hundred parts of the nitrat of potash afford but 43 of acid by this process; but Mr. Henry informs us that it yields above 50. He adds too, that a part is decomposed by the heat employed, and a large quantity of oxigen gas evolved, that may easily be collected. What remains in the retort is a supersulphat of potash, from which the superfluous acid may be expelled by a pretty strong heat, and the residuum, being dissolved and crystallized, will be sulphat of potash.

As nitric acid in a fluid state is always mixed with water, different attempts have been made to ascertain its strength, or the quantity of real acid contained in it. Mr. Kirwan supposed, that the nitrat of soda contained the pure acid undiluted with water, and thus calculated its strength from the quantity requisite to saturate a given portion of soda. Mr. Davy has more recently taken the acid in the form of gas as the standard, and found how much of this is contained in an acid of a given specific gravity in the liquid state. We shall merely annex to Mr. Davy's table those numbers of Mr. Kirwan's, which is much more extensive, that relate to nearly similar gravities.

NITRIC ACID OF SPECIFIC GRAVITY.		CONTAINS.		
KIRWAN.	DAVY.	OF REAL ACID, KIRWAN.	DAVY.	
			OF REAL ACID.	OF WATER.
1·5070	1·5040	·6839	·9155	·0845
1·4471	1·4475	·5809	·8039	·1961
1·4275	1·4285	·5515	·7165	·2835
1·3925	1·3906	·5000	·6296	·3704
1·3571	1·3551	·4486 +	·5688	·4312
1·3160	1·3186	·3897	·5203	·4797
1·3056	1·3042	·3750	·4904	·5096
1·2812	1·2831	·3530 +	·4603	·5397
1·2033	1·2090	·2574 +	·4527	·5473

The strongest acid that Mr. Kirwan could procure at 60° was 1·5543, which by his calculation contained ·7354 of real acid; but Rouelle professes to have obtained it of 1·583. It is observable, that, on comparing the tables of Kirwan and Davy, the aëriform acid appears to contain a considerable portion of water more than that which is combined with soda to form the nitrat.

Nitric acid should be of the specific gravity of 1·5, or a little more, and colourless. It boils at 248°, and may be distilled without any essential alteration. Exposed to the air it absorbs moisture. If two parts be suddenly diluted with one of water, the temperature will rise to about 112°; but the addition of more water to this diluted acid will lower its temperature. It retains its oxigen with little force, so that it is decomposed by all combustible bodies. Brought into contact with hidrogen gas at a high temperature, a violent detonation ensues, so that this must not be done without great caution. It inflames essential oils, as those of turpentine and cloves, when suddenly poured on them: but, to perform this experiment with safety, the acid must be poured out of a bottle tied to the end of a long stick, otherwise the operator's face and eyes will be greatly endangered. If it be poured on perfectly dry charcoal powder, it excites combustion, with the emission of copious fumes. By boiling it with sulphur it is decomposed, and its oxigen, uniting with the sulphur, forms sulphuric acid. Chemists in general agree, that it acts very powerfully on almost all the metals: but Baumé has asserted, that it will not dissolve tin; and Dr. Woodhouse of Pennsylvania affirms, that in a highly concentrated and pure state it acts not at all on silver, copper, or tin, though with the addition of a little water its action on them is very powerful. He does not mention the specific gravity of this acid: he only says, that it was prepared by first expelling the water of crystallization from nitre by heat, and then decomposing this nitre by means of strong sulphuric acid.

It has already been observed, that the nitric acid when first distilled over holds in solution a portion of nitric oxide, which is greater in proportion as the heat has been urged toward the end, and much increased by even a small portion of inflammable matter, should any have been present. The colour of the acid too is affected by the quantity of nitric oxide it holds, and Mr. Davy has given us the following table of proportions answering to its different hues.

COLOUR.	REAL ACID.	NITRIC OXIDE.	WATER.
Pale yellow	90·5	1·2	8·3
Bright yellow	88·94	2·96	8·10
Dark orange	86·84	5·56	7·6
Light olive	86·0	6·45	7·55
Dark olive	85·4	7·1	7·5
Bright green	84·8	7·76	7·44
Blue green	84·6	8·	7·4

But these colours are not exact indications of the state of the acid, for an addition of water will change the colour into one lower in the scale, so that a considerable portion of water will change the dark orange to a blue green.

The nitric acid is of considerable use in the arts. It is employed for etching on copper; as a solvent of tin to form with that metal a mordant for some of the finest dyes; in metallurgy and assaying; in various chemical processes, on account of the facility with which it parts with oxigen and dissolves metals; in medicine as a tonic, and as a substitute for mercurial preparations in siphylis and affections of the liver; as also in the form of vapour to destroy contagion. For the purposes of the arts it is commonly used in a diluted state, and contaminated with the sulphuric and muriatic acids, by the name of *aqua fortis*. This is generally prepared by mixing common nitre with an equal weight of sulphat of iron, and half its weight of the same sulphat calcined, and distilling the mixture: or by mixing nitre with twice its weight of dry powdered clay, and distilling in a reverberatory furnace. Two kinds are found in the shops, one called *double aqua fortis*, which is about half the strength of nitric acid; the other simply *aqua fortis*, which is half the strength of the double.

A compound made by mixing two parts of the nitric acid with one of muriatic, known formerly by the name of *aqua regia*, and now by that of *nitro-muriatic acid*, has the property of dissolving gold and platina. On mixing the two acids heat is given out, an effervescence takes place, oxigenated muriatic acid gas is evolved, and the mixture acquires an orange colour. This is likewise made by adding gradually to an ounce of powdered muriat of ammonia, four ounces of double aqua fortis, and keeping the mixture in a sand-heat till the salt is dissolved; taking care to avoid the fumes, as the vessel must be left open: or by distilling nitric acid with an equal weight, or rather more, of common salt.

With the different bases the nitric acid forms nitrats.

The nitrat of barytes, when perfectly pure, is in regular octaëdral crystals, though it is sometimes obtained in small shining scales. It may be prepared by uniting barytes directly with nitric acid, or by decomposing the carbonat of sulphuret of barytes with this acid. Exposed to heat it decrepitates, and at length gives out its acid, which is decomposed; but if the heat be urged too far the barytes is apt to vitrify with the earth of the crucible. It is soluble in 12 parts of cold, and 3 or 4 of boiling water. It is said to exist in some mineral waters.

The nitrat of potash is the salt well known by the name of *nitre*, or *saltpetre*. It is found ready formed in the East Indies, in Spain, in the kingdom of Naples, and elsewhere, in considerable quantities; but nitrat of lime is still more abundant. Far the greater part of the nitrat made use of is produced by a combination of circumstances which tend to compose and condense nitric acid. This acid appears to be produced in all situations, where animal matters are completely decomposed with access of air, and of proper substances with which it can readily combine. Grounds frequently trodden by cattle and impregnated with their excrements, or the walls of inhabited places where putrid animal vapours abound, such as slaughter-houses, drains, or the like, afford nitre by long exposure to the air. Artificial nitre beds are made by an attention to the circumstances in which this salt is produced by nature. Dry ditches are dug, and covered with sheds, open at the sides, to keep off the rain: these are filled with animal substances—such as dung, or other excrements, with the remains of vegetables, and old mortar, or other loose calcareous earth; this substance being found to be the best and most convenient receptacle for the acid to combine with. Occasional watering, and turning up from time to time, are necessary, to accelerate the process, and increase the surfaces to which the air may apply; but too much moisture is hurtful. When a certain portion of nitrat is formed, the process appears to go on more quickly: but a certain quantity stops it altogether, and after this cessation the materials will go on to furnish more, if what is formed be extracted by lixiviation. After a succession of many months, more or less, according to the management of the operation, in which the action of a regular current of fresh air is of the greatest importance, nitre is found in the mass. If the beds contained much vegetable matter, a considerable portion of the nitrous salt will be common saltpetre; but, if otherwise, the acid will, for the most part, be combined with the calcareous earth.

To extract the saltpetre from the mass of earthy matter, a number of large casks are prepared, with a cock at the bottom of each, and a quantity of straw within, to prevent its being stopped up. Into these the matter is put, together with wood-ashes, either strewed at top, or added during the filling. Boiling water is then poured on, and suffered to stand for some time; after which it is drawn off, and other water added in the same manner, as long as any saline matter can be thus extracted. The weak brine is heated, and passed through other tubs, until it becomes of considerable strength. It is then carried to the boiler, and contains nitre and other salts; the chief of which is common culinary salt, and sometimes muriat of magnesia. It is the property of nitre to be much more soluble in hot than cold water; but common salt is very nearly as soluble in cold as in hot water. Whenever, therefore, the evaporation is carried by boiling to a certain point, much of the common salt will fall to the bottom, for want of water to hold it in solution, though the nitre will remain suspended by virtue of the heat. The common salt thus separated is taken out with a perforated ladle, and a small quantity of the fluid is cooled, from time to time, that its concentration may be known by the nitre which crystallizes in it. When the fluid is sufficiently evaporated, it is taken out and cooled, and great part of the nitre separates in crystals; while the remaining common salt continues dissolved, because equally soluble in cold and in hot water. Subsequent evaporation of the residue will separate more nitre in the same manner.

This nitre, which is called nitre of the first boiling, contains some common salt; from which it may be purified by solution in a small quantity of water, and subsequent evaporation: for the crystals thus obtained are much less contaminated with common salt than before: because the proportion of water is so much larger, with respect to the small quantity contained by the nitre, that very little of it will crystallize. For nice purposes, the solution and crystallization of nitre are repeated four times. The crystals of nitre are usually of the form of six-sided flattened prisms, with diedral summits. Its taste is penetrating; but the cold produced by placing the salt to dissolve in the mouth is such as to predominate over the real taste at first. Seven parts of water dissolve two of nitre, at the temperature of sixty degrees: but boiling water dissolves its own weight. 100 parts of alcohol, at a heat of 176°, dissolve only 2·9.

On being exposed to a gentle heat nitre fuses; and in this state being poured into moulds, so as to form little round cakes, or balls, it is called *sal prunella*, or *crystal mineral*. This at least is the way in which this salt is now usually prepared, conformably to the directions of Boerhaave; though in most dispensatories a twenty-fourth part of sulphur was directed to be deflagrated on the nitre, before it was poured out. This salt should not be left on the fire after it has entered into fusion, otherwise it will be converted into a *nitrit* of potash. If the heat be increased to redness, the acid itself is decomposed, and a considerable quantity of tolerably pure oxigen gas is evolved, succeeded by nitrogen.

This salt powerfully promotes the combustion of inflammable substances. Two or three parts mixed with one of charcoal, and set on fire, burn rapidly; azot and carbonic acid gas are given out, and a small portion of the latter is retained by the alkaline residuum, which was formerly called *clyssus of nitre*. Three parts of nitre, two of subcarbonat of potash, and one of sulphur, mixed together in a warm mortar, form the *fulminating powder*; a small quantity of which, laid on a fire-shovel, and held over the fire till it begins to melt, explodes with a loud sharp noise. Mixed with sulphur and charcoal it forms *gunpowder*. See GUNPOWDER.

Three parts of nitre, one of sulphur, and one of fine sawdust, well mixed, constitute what is called the powder of fusion. If a bit of base copper be folded up and covered with this powder in a walnut shell, and the powder be set on fire with a lighted paper, it will detonate rapidly, and fuse the metal into a globule of sulphuret, without burning the shell.

If nitrat of potash be heated in a retort with half its weight of solid phosphoric or boracic acid, as soon as this acid begins to enter into fusion it combines with the potash, and the nitric acid is expelled, accompanied with a small portion of oxigen gas and nitric oxide.

Silex, alumine, and barytes, decompose this salt in a high temperature by uniting with its base, as was observed when speaking of aqua fortis. The alumine will effect this even after it has been made into pottery.

The uses of nitre are various. Beside those already indicated, it enters into the composition of fluxes, and is extensively employed in metallurgy; it serves to promote the combustion of sulphur in fabricating its acid; it is used in the art of dyeing; it is added to common salt for preserving meat, to which it gives a red hue; it is an ingredient in some frigorific mixtures; and it is prescribed in medicine, as cooling, febrifuge, and diuretic, and some have recommended it mixed with vinegar as a very powerful remedy for the sea scurvy.

Nitrat of soda, formerly called *cubic* or *quadrangular nitre*, approaches in its properties the nitrat of potash; but differs from it in being somewhat more soluble in cold water, though less in hot, which takes up little more than its own weight; in being inclined to attract moisture from the atmosphere;* and in crystallizing in rhombs, or rhomboidal prisms. It may be prepared by saturating soda with the nitric acid, by precipitating nitric solutions of the metals, or of the earths, except barytes, by soda: by lixiviating and crystallizing the residuum of common salt distilled with three-fourths its weight of nitric acid; or by saturating the mother waters of nitre with soda instead of potash.

This salt has been considered as useless; but professor Proust says, that five parts of it, with one of charcoal and one of sulphur, will burn three times as long as common powder, so as to form an œconomical composition for fire-works.

Nitrat of strontian may be obtained in the same manner as that of barytes, with which it agrees in the shape of its crystals, and most of its properties. It is much more soluble, however, requiring but four or five parts of water according to Vauquelin, and only an equal weight according to Mr. Henry. Boiling water dissolves nearly twice as much as cold. Applied to the wick of a candle, or added to burning alcohol, it gives a deep red colour to the flame. On this account it might be useful, perhaps, in the art of pyrotechny.

Nitrat of lime, the *calcareous nitre* of older writers, abounds in the mortar of old buildings, particularly those that have been much exposed to animal effluvia, or processes in which azot is set free. Hence it abounds in nitre beds, as was observed when treating of the nitrat of potash. It may also be prepared artificially by pouring dilute nitric acid on carbonat of lime. If the solution be boiled down to a sirupy consistence, and exposed in a cool place, it crystallizes in long prisms, resembling bundles of needles diverging from a centre. These are soluble, according to Henry, in an equal weight of boiling water, and twice their weight of cold; soon deliquesce on exposure to the air; and are decomposed at a red heat. Fourcroy says, that cold water dissolves four times its weight, and that its own water of crystallization is sufficient to dissolve it at a boiling heat. It is likewise soluble in less than its weight of alcohol. By evaporating the aqueous solution to dryness, continuing the heat till the nitrat fuses, keeping it in this state five or ten minutes, and then pouring it into an iron pot previously heated, we obtain *Baldwin's phosphorus*. This, which is perhaps more properly *nitrit of lime*, being broken to pieces, and kept in a phial closely stopped, will emit a beautiful white light in the dark, after having been exposed some time to the rays of the sun. At present no use is made of this salt, except for drying some of the gases by attracting their moisture; but it might be employed instead of the nitrat of potash for manufacturing aqua fortis.

The nitrat of ammonia possesses the property of exploding, and being totally decomposed, at the temperature of 600°; whence it acquired the name of *nitrum flammans*. The readiest mode of preparing it is by adding carbonat of ammonia to dilute nitric acid till saturation takes place.

If this solution be evaporated in a heat between 70° and 100°, and the evaporation not carried too far, it crystallizes in hexaëdral prisms terminating in very acute pyramids: if the heat rise to 212°, it will afford, on cooling long fibrous silky crystals: if the evaporation be carried so far as for the salt to concrete immediately on a glass rod by cooling, it will form a compact mass. According to Mr. Davy, these differ but little from each other, except in the water they contain, their component parts being as follows:

	contains of acid	ammonia	water
Prismatic	69·5	18·4	12·1
Fibrous	72·5	19·3	8·2
Compact	74·5	19·8	5·7

All these are completely deliquescent, but they differ a little in solubility. Alcohol at 176° dissolves nearly 90·9 of its own weight.

The chief use of this salt is for affording nitrous oxide on being decomposed by heat. See Gas, Nitrous Oxide.

Nitrat of magnesia, *magnesian nitre*, crystallizes in four-sided rhomboidal prisms, with oblique or truncated summits, and sometimes in bundles of small needles. Its taste is bitter, and very similar to that of nitrat of lime, but less pungent. It is fusible, and decomposable by heat, giving out first a little oxigen gas, then nitrous oxide, and lastly nitric acid. It deliquesces slowly. It is soluble in an equal weight of cold water, and in but little more hot, so that it is scarcely crystallizable but by spontaneous evaporation.

The two preceding species are capable of combining into a triple salt, an ammoniaco-magnesian nitrat, either by uniting the two in solution, or by a partial decomposition of either by means of the base of the other. This is slightly inflammable when suddenly heated: and by a lower heat is decomposed, giving out oxigen, azot, more water than it contained, nitrous oxide, and nitric acid. The residuum is pure magnesia. It is disposed to attract moisture from the air, but is much less deliquescent than either of the salts that compose it; and requires eleven parts of water at 60° to dissolve it. Boiling water takes up more, so that it will crystallize by cooling. It consists of 78 parts of nitrat of magnesia, and 22 of nitrat of ammonia.

From the activity of the nitric acid as a solvent of earths in analyzation the nitrat of glucine is better known than any other of the salts of this new earth. Its form is either pulverulent, or a tenacious or ductile mass. Its taste is at first saccharine, and afterward astringent. It grows soft by exposure to heat, soon melts, its acid is decomposed into oxigen and azot, and its base alone is left behind. It is very soluble and very deliquescent.

Nitrat, or rather supernitrat, of alumine crystallizes, though with difficulty, in thin, soft, pliable flakes. It is of an austere and acid taste, and reddens blue vegetable colours. It may be formed by dissolving in diluted nitric acid, with the assistance of heat, fresh precipitated alumine, well washed but not dried. It is deliquescent, and soluble in a very small portion of water. Alcohol dissolves its own weight. It is easily decomposed by heat.

Nitrat of zircone was first discovered by Klaproth, and has since been examined by Guyton-Morveau and Vauquelin. Its crystals are small, capillary, silky needles. Its taste is astringent. It is easily decomposed by fire, very soluble in water, and deliquescent. It may be prepared by dissolving zircone in strong nitric acid; but, like the preceding species, the acid is always in excess.

Nitrat of yttria may be prepared in a similar manner. Its taste is sweetish, and astringent. It is scarcely to be obtained in crystals; and if it be evaporated by too strong a heat, the salt becomes soft like honey, and on cooling concretes into a stony mass. Exposed to the air it deliquesces.—*Fourcroy.*—*Henry.*—*Murray.*—*Davy.*—*Van Mons's Journal.*—*Journ. de Phys.*—*Philos. Trans.*

Acid (Nitrous). It has already been observed, that there is no such thing, properly speaking, as *nitrous* acid, or the nitric base acidified with a minimum dose of oxigen; but that the nitric acid is capable of absorbing various portions of nitric oxide, with which it parts very readily, so that when in considerable quantity it gives it out in the ordinary state of the air, on mixing with which it assumes the appearance of a very red vapour. Hence it was formerly called *fuming nitrous acid.* It appears, however, to be capable of combining with some at least of the salifiable bases, so as to form a distinct genus of salts, that may be termed *nitrits.* But these cannot be formed by a direct union of their component parts; being obtainable only by exposing a nitrat to a high temperature, which expels a portion of its oxigen in the state of gas, and leaves the remainder in the state of a nitrit, if the heat be not urged so far, or continued so long, as to effect a complete decomposition of the salt. In this way the nitrits of potash and soda may be obtained, and perhaps those of barytes, strontian, lime, and magnesia. The nitrits are particularly characterized by being decomposable by all the acids except the carbonic, even by the nitric acid itself, all of which expel from it nitrous acid. We are little acquainted with any one except that of potash, which attracts moisture from the air, changes blue vegetable colours to green, is somewhat acrid to the taste, and when powdered emits a smell of nitric oxide.

Acid (Oxalic). This acid, which abounds in wood sorrel, and which, combined with a small portion of potash as it exists in that plant, has been sold under the name of *salt of lemons,* to be used as a substitute for the juice of that fruit, particularly for discharging ink spots and iron-moulds, was long supposed to be analogous to that of tartar. In the year 1776, however, Bergman discovered, that a powerful acid might be extracted from sugar by means of the *nitric*; and a few years afterward Scheele found this to be identical with the acid existing naturally in sorrel. Hence the acid began to be distinguished by the name of *saccharine,* but has since been known in the new nomenclature by that of oxalic.

Scheele extracted this acid from the salt of sorrel, or acidulous oxalat of potash as it exists in the juice of that plant, by saturating it with ammonia, when it becomes a very soluble triple salt, and adding to the solution nitrat of barytes dissolved in water. Having well washed the oxalat of barytes, which is precipitated, he dissolved it in boiling water, and precipitated its base by sulphuric acid. To ascertain that no sulphuric acid remained in the supernatant liquor, he added a little of a boiling solution of oxalat of barytes till no precipitate took place, and then filtered the liquor, which contained nothing but pure oxalic acid, which he crystallized by evaporation and cooling.

It may be obtained, however, much more readily and œconomically from sugar in the following way: To six ounces of nitric acid in a stoppered retort, to which a large receiver is luted, add by degrees one ounce of lump sugar coarsely powdered. A gentle heat may be applied during the solution, and nitric oxide will be evolved in abundance. When the whole of the sugar is dissolved, distil off a part of the acid, till what remains in the retort has a sirupy consistence, and this will form regular crystals, amounting to 58 parts from 100 of sugar. These crystals must be dissolved in water, recrystallized, and dried on blotting paper.

A variety of other substances afford the oxalic acid when treated by distillation with the nitric. Bergman procured it from honey, gum arabic, alcohol, and the calculous concretions in the kidneys and bladders of animals; Scheele and Hermbstadt from sugar of milk. Scheele from a sweet matter contained in fat oils, and also from the uncrystallizable part of the juice of lemons. Hermbstadt from the acid of cherries, and the acid of tartar. Goetling from beech wood. Kohl from the residuum in the distillation of ardent spirits. Westrumb not only from the crystallized acids of currants, cherries, citrons, raspberries, but also from the saccharine matter of these fruits, and from the uncrystallizable parts of the acid juices. Hoffmann from the juice of the barberry; and Berthollet from silk, hair, tendons, wool; also from other animal substances, especially from the coagulum of blood, whites of eggs, and likewise from the amylaceous and glutinous parts of flour. M. Berthollet observes, that the quantity of the oxalic acid obtained by treating wool with nitric acid was very considerable, being above half the weight of the wool employed. He mentions a difference which he observed between animal and vegetable substances thus treated with nitric acid, namely, that the former yielded, beside ammonia, a large quantity of an oil which the nitric acid could not decompose; whereas the oily parts of vegetables were totally destroyed by the action of this acid: and he remarks, that in this instance the glutinous part of flour resembled animal substances, whereas the amylaceous part of the flour retained its vegetable properties. He further remarks, that the quantity of oxalic acid furnished by vegetable matters, thus treated is proportionable to their nutritive quality, and particularly that from cotton he could not obtain any sensible quantity. Deyeux, having cut with scissars the hairs of the chick pea, found they gave out an acid liquor, which on examination proved to be an aqueous solution of pure oxalic acid. Proust and other chemists had before observed, that the shoes of persons walking through a field of chick pease were corroded.

Oxalic acid crystallizes in quadrilateral prisms, the sides of which are alternately broad and narrow, and summits diëdral; or, if crystallized rapidly, in small irregular needles. They are efflorescent in dry air, but attract a little humidity if it be damp; are soluble in one part of hot and two of cold water; and are decomposable by a red heat, leaving a small quantity of coaly residuum.—100 parts of alcohol take up near 56 at a boiling heat, but not above 40 cold. Their acidity is so great, that when dissolved in 3600 times their weight of water the solution reddens litmus paper, and is perceptibly acid to the taste.

The oxalic acid is a good test for detecting lime, which it separates from all the other acids, unless they are present in excess. It has likewise a greater affinity for lime than for any other of the bases, and forms with it a pulverulent, insoluble salt, not decomposable except by fire, and turning sirup of violets green.

With barytes it forms an insoluble salt; but this salt will dissolve in water acidulated with oxalic acid, and afford angular crystals. If, however, we attempt to dissolve these crystals in boiling water, the excess of acid will unite with the water, and leave the oxalat, which will be precipitated.

The oxalat of strontian too is a nearly insoluble compound.

Oxalat of magnesia too is insoluble, unless the acid be in excess.

The oxalat of potash exists in two states, that of a neutral salt, and that of an acidule. The latter is generally obtained from the juice of the leaves of the *oxalis acetosella*, wood sorrel, or *rumex acetosa*, common sorrel. The expressed juice, being diluted with water, should be set by for a few days, till the feculent parts have subsided, and the supernatant fluid is become clear; or it may be clarified, when expressed, with the whites of eggs. It is then to be strained off, evaporated to a pellicle, and set in a cool place to crystallize. The first product of crystals being taken out, the liquor may be further evaporated, and crystallized; and the same process repeated till no more can be obtained. In this way Schlereth informs us about nine drachms of crystals may be obtained from two pounds of juice, which are generally afforded by ten pounds of wood sorrel. Savary, however, says, that ten parts of wood sorrel in full vegetation yield five parts of juice, which give little more than a two-hundredth of tolerably pure salt. He boiled down the juice, however, in the first instance without clarifying it; and was obliged repeatedly to dissolve and recrystallize the salt to obtain it white.

This salt is in small, white, needly, or lamellar crystals, not alterable in the air. It unites with barytes, magnesia, soda, ammonia, and most of the metallic oxides, into triple salts. Yet its solution precipitates the nitric solutions of mercury and silver in the state of insoluble oxalats of these metals, the nitric acid in this case combining with the potash. It attacks iron, lead, tin, zinc, and antimony.

This salt, beside its use in taking out ink spots, and as a test of lime, forms with sugar and water a pleasant cooling beverage: and according to Berthollet it possesses considerable powers as an antiseptic.

The neutral oxalat of potash is very soluble, and assumes a gelatinous form, but may be brought to crystallize in hexaëdral prisms with diëdral summits, by adding more potash to the liquor than is sufficient to saturate the acid.

Oxalat of soda likewise exists in two different states, those of an acidulous and a neutral salt, which in their properties are analogous to those of potash.

The acidulous oxalat of ammonia is crystallizable, not very soluble, and capable like the preceding acidules of combining with other bases, so as to form triple salts. But if the acid be saturated with ammonia we obtain a neutral oxalat, which on evaporation yields very fine crystals in tetraëdral prisms with diëdral summits, one of the planes of which cuts off three sides of the prism. This salt is decomposable by fire, which raises from it carbonat of ammonia, and leaves only some slight traces of a coaly residuum. Lime, barytes, and strontian unite with its acid, and the ammonia flies off in the form of gas.

The oxalic acid readily dissolves alumine, and the solution gives on evaporation a yellowish transparent mass, sweet and a little astringent to the taste, deliquescent, and reddening tincture of litmus, but not sirup of violets. This salt swells up in the fire, loses its acid, and leaves the alumine a little coloured.—*Bergman.—Scheele.—Fourcroy.—Henry.—Murray.*

Acid (Perlate). This name was given by Bergman to the acidulous phosphat of soda, Haupt having called the phosphat of soda *sal mirabile perlatum.*

Acid (Phosphoric). The base of this acid, or the acid itself, abounds in the mineral, vegetable, and animal kingdoms. In the mineral kingdom it is found in combination with lead, in the green lead ore; with iron, in the bog ores which afford cold short iron; and more especially with calcareous earth in several kinds of stone. Whole mountains in the province of Estramadura in Spain are composed of this combination of phosphoric acid and lime. Mr. Bowles affirms, that the stone is whitish, and tasteless, and affords a blue flame without smell when thrown upon burning coals. Mr. Proust describes it as a dense stone, not hard enough to strike fire with steel; and says that it is found in strata, which always lie horizontally upon quartz, and which are intersected with veins of quartz. When this stone is scattered upon burning coals, it does not decrepitate, but burns with a beautiful green light, which lasts a considerable time. It melts into a white enamel by the blowpipe; is soluble with heat, and some effervescence in the nitric acid, and forms sulphat of lime with the sulphuric acid, while the phosphoric acid is set at liberty in the fluid.

The vegetable kingdom abounds with phosphorus, or its acid. It is principally found in plants that grow in marshy places, in turf, and several species of the white woods. Various seeds, potatoes, agaric, soot, and charcoal afford phosphoric acid*, by abstracting the nitric acid from them, and lixiviating the residue. The lixivium contains the phosphoric acid, which may either be saturated with lime by the addition of lime water, in which case it forms a solid compound, or it may be tried by examination of its leading properties by other chemical methods.

---

* To this prof. Bartholdi ascribes two accidents at the powder-mills at Elsone, where spontaneous combustion appeared to have taken place in one instance in the charcoal store-room, in the other in the box into which the charcoal was sifted; as well as three successive explosions at the powder-mills of Vosges. This certainly merits the attention of gunpowder manufacturers.

In the animal kingdom it is found in almost every part of the bodies of animals which are not considerably volatile. There is not, in all probability, any part of these organised beings which is free from it. It has been obtained from blood, flesh, both of land and water animals; from cheese; and it exists in large quantities in bones, combined with calcareous earth. Urine contains it, not only in a disengaged state, but also combined with ammonia, soda, and lime. It was by the evaporation and distillation of this excrementitious fluid with charcoal that phosphorus was first made; the charcoal decomposing the disengaged acid, and the ammoniacal salt. See PHOSPHORUS. But it is more cheaply obtained by the process of Scheele, from bones, by the application of an acid to their earthy residue after calcination.

In this process the sulphuric acid appears to be the most convenient, because it forms a nearly insoluble compound with the lime of the bones. Bones of beef, mutton, or veal, being calcined to whiteness in an open fire, lose almost half of their weight. This must be pounded, and sifted, or the trouble may be spared by buying the powder that is sold to make cupels for the assayers, and is, in fact, the powder of burned bones ready sifted. To three pounds of the powder there may be added about two pounds of concentrated sulphuric acid. Four or five pounds of water must be afterward added to assist the action of the acid; and during the whole process the operator must remember to place himself and his vessels so that the fumes may be blown from him. The whole may be then left on a gentle sand bath for twelve hours or more, taking care to supply the loss of water which happens by evaporation. The next day a large quantity of water must be added, the whole strained through a sieve, and the residual matter, which is sulphat of lime, must be edulcorated by repeated affusions of hot water, till it passes tasteless. The waters contain phosphoric acid nearly free from lime, and by evaporation, first in glazed earthen, and then in glass vessels, or rather in vessels of platina or silver, for the hot acid acts upon glass, afford the acid in a concentrated state, which, by the force of a strong heat in a crucible, may be made to acquire the form of a transparent consistent glass, though indeed it is usually of a milky, opake appearance.

For making phosphorus, it is not necessary to evaporate the water further than to bring it to the consistence of sirup; and the small portion of lime it contains is not an impediment worth the trouble of removing, as it affects the produce very little. But when the acid is required in a purer state, it is proper to add a quantity of carbonat of ammonia, which, by double elective attraction, precipitates the lime that was held in solution by the phosphoric acid. The fluid being then evaporated, affords a crystallized ammoniacal salt, which may be melted in a silver vessel, as the acid acts upon glass or earthen vessels. The ammonia is driven off by the heat, and the acid acquires the form of a compact glass as transparent as rock crystal, acid to the taste, soluble in water, and deliquescent in the air.

This acid is commonly pure, but nevertheless may contain a small quantity of soda, originally existing in the bones, and not capable of being taken away by this process, ingenious as it is. The only unequivocal method of obtaining a pure acid appears to consist in first converting it into phosphorus by distillation of the materials with charcoal, and then converting it again into acid by rapid combustion, at a high temperature, either in oxigen or atmospheric air, or some other equivalent process.

Phosphorus may also be converted into the acid state by treating it with nitric acid. In this operation, a tubulated retort with a ground stopper, must be half filled with nitric acid, and a gentle heat applied. A small piece of phosphorus being then introduced through the tube will be dissolved with effervescence, produced by the escape of a large quantity of nitric oxide. The addition of phosphorus must be continued until the last piece remains undissolved. The fire being then raised to drive over the remainder of the nitric acid, the phosphoric acid will be found in the retort, partly in the concrete and partly in the liquid form.

Sulphuric acid produces nearly the same effect as the nitric; a large quantity of sulphurous acid flying off. But as it requires a stronger heat to drive off the last portions of this acid, it is not so well adapted to the purpose. The liquid oximuriatic acid likewise acidifies it: and if phosphorus be put into this acid in a state of gas, it takes fire spontaneously, and burns vehemently.

When phosphorus is burned by a strong heat, sufficient to cause it to flame rapidly, it is almost perfectly converted into dry acid, some of which is thrown up by the force of the combustion, and the rest remains upon the supporter.

This substance has also been acidified by the direct application of oxigen gas passed through hot water, in which the phosphorus was liquefied or fused.

The general characters of phosphoric acid, are: 1. It is soluble in water in all proportions, producing a specific gravity, which increases as the quantity of acid is greater, but does not exceed 2·687, which is that of the glacial acid. 2. It produces heat when mixed with water, though not very considerable. 3. It has no smell when pure, and its taste is sour, but not corrosive. 4. When perfectly dry, it sublimes in close vessels; but loses this property by the addition of water; in which circumstance it greatly differs from the boracic acid, which is fixed when dry, but rises by the help of water. 5. When considerably diluted with water, and evaporated, the aqueous vapour carries up a small portion of the acid. 6. With charcoal or inflammable matter, in a strong heat, it loses its oxigen, and becomes converted into phosphorus.

It has been supposed that the phosphoric acid was incapable of crystallizing. Goettling, however, found sharp-pointed crystals of this acid on the sides of a glass vessel in a cellar, in which phosphorus had stood three months covered with carbonic acid gas. Mr. Guezsen of Kiel having kept some of the specific gravity of 2·1 for a few weeks in a temperature between 30° and 36° perceived that it shot into feathery crystals: on being exposed several days to a temperature varying from 28° to 14°, it curdled into an opake mass like tallow, without crystallization. This mass being rendered fluid by heat, and then exposed in a small glass tube in a freezing mixture to 49° below 0 of F. for fifteen minutes, continued fluid; though it again congealed on being kept some days at 27½°. By rest even in a temperature ranging from 54° to 68° it will crystallize when of this strength; but if diluted with more water it only curdles into an irregular mass. M. Steinacher of Paris, and M. Vitalis of Rouen, likewise confirm its crystallization; but the latter says, that the crystals become deliquescent in a heat from 77° to 88°, though Guersen found no alteration in his in the hottest days of summer.

Though the phosphoric acid is scarcely corrosive, yet, when concentrated, it acts upon oils, which it discolours, and at length blackens, producing heat, and a strong smell like that of ether and oil of turpentine; but does not form a true acid soap. It has most effect on essential oils, less on drying oils, and least of all on fat oils. Spirit of wine and phosphoric acid have a weak action on each other. Some heat is excited by this mixture, and the product which comes over in distillation of the mixture is strongly acid, of a pungent arsenical smell, inflammable with smoke, miscible in all proportions with water, precipitating silver and mercury from their solutions, but not gold; and although not an ether, yet it seems to be an approximation to that kind of combination.

Phosphoric acid united with barytes produces an insoluble salt, in the form of a heavy white powder, fusible at a high temperature into a gray enamel. The best mode of preparing it is by adding an alkaline phosphat to the nitrat or muriat of barytes.

The phosphat of strontian differs from the preceding in being soluble in an excess of its acid.

Phosphat of lime is very abundant in the native state. At Marmarosch in Hungary, it is found in a pulverulent form mixed with fluat of lime: in the province of Estramadura in Spain, it is in such large masses that walls of enclosures and even houses are built with it; and it is frequently crystallized, as in the apatite of Werner, when it assumes different tints of gray, brown, purple, blue, olive, and green. In the latter state it has been confounded with the chrysolite, and sometimes with the beryl and aqua marine, as in the stone called the Saxon beryl. It likewise constitutes the chief part of the bones of all animals.

The phosphat of lime is very difficult to fuse, but in a glasshouse furnace it softens, and acquires the semitransparency and grain of porcelain. It is insoluble in water, but when well calcined forms a kind of paste with it, as in making cupels. Beside this use of it, it is employed for polishing gems and metals, for absorbing grease from cloth, linen, or paper, and for preparing phosphorus. In medicine it has been strongly recommended against the rickets by Dr. Bonhomme of Avignon, either alone or combined with phosphat of soda. The *burnt hartshorn* of the shops is a phosphat of lime.

An acidulous phosphat of lime is found in human urine, and may be crystallized in small silky filaments, or shining scales, which unite together into something like the consistence of honey, and have a perceptibly acid taste. It may be prepared by partially decomposing the calcareous phosphat of bones by the sulphuric, nitric, or muriatic acid, or by dissolving that phosphat in phosphoric acid. It is soluble in water, and crystallizable. Exposed to the action of heat it softens, liquefies, swells up, becomes dry, and may be fused into a transparent glass, which is insipid, insoluble, and unalterable in the air. In these characters it differs from the glacial acid of phosphorus. It is partly decomposable by charcoal, so as to afford phosphorus. According to Fourcroy and Vauquelin this salt contains 54 parts of acid, and 46 of lime, while the neutral phosphat contains but 41 of acid to 59 of lime.

The phosphat of potash is very deliquescent, and not crystallizable, but condensing into a kind of jelly. Like the preceding species it first undergoes the aqueous fusion, swells, dries, and may be fused into a glass; but this glass deliquesces. It has a sweetish saline taste.

The phosphat of soda was first discovered combined with ammonia in urine by Schockwitz; and was called *fusible* or *microcosmic salt*. Margraff obtained it alone by lixiviating the residuum left after preparing phosphorus from this triple salt and charcoal. Haupt, who first discriminated the two, gave the phosphat of soda the name of *sal mirabile perlatum*. Rouelle very properly announced it to be a compound of soda and phosphoric acid. Bergman considered it, or rather the acidulous phosphat, as a peculiar acid, and gave it the name of *perlate acid*: Guyton-Morveau did the same, but distinguished it by the name of *ouretic*: at length Klaproth ascertained its real nature to be as Rouelle had affirmed.

This phosphat is now commonly prepared by adding to the acidulous phosphat of lime as much carbonat of soda in solution as will fully saturate the acid. The carbonat of lime, which precipitates, being separated by filtration, the liquid is duly evaporated so as to crystallize the phosphat of soda; but if there be not a slight excess of alkali, the crystals will not be large and regular. M. Funcke, of Linz, recommends, as a more economical and expeditious mode, to saturate the excess of lime in calcined bones by dilute sulphuric acid, and dissolve the phosphat of lime that remains in nitric acid. To this solution he adds an equal quantity of sulphat of soda, and recovers the nitric acid by distillation. He then separates the phosphat of soda from the sulphat of lime by elutriation and crystallization as usual. The crystals are rhomboidal prisms of different shapes; efflorescent; soluble in 3 parts of cold and 1½ of hot water. They are capable of being fused into an opake white glass, which may be again dissolved and crystallized. It may be converted into an acidulous phosphat by an addition of acid, or by either of the strong acids, which partially, but not wholly, decompose it. As its taste is simply saline, without any thing disagreeable, it is much used as a purgative, chiefly in broth, in which it is not distinguishable from common salt. For this elegant addition to our pharmaceutical preparations we are indebted to Dr. Pearson. In assays with the blowpipe it is of great utility; and it has been used instead of borax for soldering.

The phosphat of ammonia crystallizes in prisms with four regular sides terminating in pyramids, and sometimes in bundles of small needles. Its taste is cool, saline, pungent, and urinous. On the fire it comports itself like the preceding species, except that the whole of its base may be driven off by a continuance of the heat, leaving only the acid behind. It is the only phosphoric salt decomposable by charcoal, so as to afford phosphorus. It is but little more soluble in hot water than in cold, which takes up a fourth of its weight. It is pretty abundant in human urine, particularly after it is become putrid. It is an excellent flux both for assays with the blowpipe, and in the fabrication of coloured glass and artificial gems.

Phosphat of magnesia crystallizes in irregular hexaëdral prisms, obliquely truncated; but is commonly pulverulent, as it effloresces very quickly. It requires fifty parts of water to dissolve it. Its taste is cool and sweetish. This salt too is found in urine. Fourcroy and Vauquelin have discovered it likewise in small quantity in the bones of various animals, though not in those of man. The best way of preparing it is by mixing equal parts of the solutions of phosphat of soda and sulphat of magnesia, and leaving them some time at rest, when the phosphat of magnesia will crystallize, and leave the sulphat of soda dissolved.

An ammoniaco-magnesian phosphat has been discovered in an intestinal calculus of a horse by Fourcroy, and since by Bartholdi; and likewise by the former in some human urinary calculi. Notwithstanding the solubility of the phosphat of ammonia, this triple salt is far less soluble than the phosphat of magnesia. It is partially decomposable into phosphorus by charcoal, in consequence of its ammonia.

The phosphat of glucine has been examined by Vauquelin, who informs us, that it is a white powder, or mucilaginous mass, without any perceptible taste; fusible, but not decomposable by heat; unalterable in the air; and insoluble unless in an excess of its acid.

It has been observed, that the phosphoric acid aided by heat acts upon silex; and we may add, that it enters into many artificial gems in the state of a siliceous phosphat.—*Scheele.—Bergman.—Fourcroy.—An. de Chim.—Journ. de Med.—Chimie de Dijon.—Scherer's Journ.*

Acid (Phosphorous). This acid is prepared by the slow combustion of phosphorus, for which Pelletier gives the following instructions: Place sticks of phosphorus upright in a glass funnel, keeping them separate by putting each into a glass tube open at both ends and large enough for the phosphorus to lie loose in it. This is necessary, as they would be in danger of taking fire, and burning rapidly, if in contact. Let the pipe of the funnel be inserted into the neck of an empty bottle standing on a dish in which there is a little water. Cover the bottle and funnel with a glass jar, in the sides of which are two small tubulures, that may be left open to admit air, or stopped with a cork whenever the combustion is going on too rapidly. The acid thus obtained, which will be about three times the weight of the phosphorus employed, is a white fluid of a sirupy consistence, and slightly fetid smell. It refracts light more powerfully than phosphoric acid of equal density. On exposure to heat in a glass retort, it first loses part of its water, and at length bubbles are formed at the bottom of the vessel, which give out a dense white vapour as they burst on the surface, or take fire if there be a sufficient quantity of air present. These bubbles continue to form a long time, but at length the acid will be reduced to the state of phosphoric.

As the antient chemists had not distinguished the different states of the acid of phosphorus, the salts they had formed with it were commonly phosphites, but their properties were not known with any precision, till they were examined by Fourcroy and Vauquelin. They differ from the phosphats both in figure and taste, emit a smell of phosphorus, yield a phosphorescent light when exposed to heat, and with the oxymuriat of potash detonate by mere percussion. The affinities of the phosphorous acid for the bases differ too in their order from those of the phosphoric.

The phosphit of lime, which is incapable of being decomposed by any of the bases, is a white, insipid powder, insoluble in water, but capable of being dissolved even in acids that do not decompose it.

The acidulous phosphit of lime is a little soluble, and crystallizes in small prisms or needles of no determinate figure.

The phosphit of barytes is likewise an insipid white powder, a little soluble in water, however, and like the preceding somewhat more soluble, and crystallizing in a similar manner, when supersaturated with acid. The light it emits when fused by the blowpipe is so bright as to dazzle the eyes.

The phosphit of magnesia has no perceptible taste, is often in a soft flocculent form, but sometimes crystallized; effloresces in the air; and is soluble in 400 parts of water.

The phosphit of potash forms quadrilateral prismatic crystals with diëdral summits. It has a pungent saline taste; decrepitates in the fire; and is soluble in three parts of cold, and less of hot water.

The phosphat of soda has a cool, sweet taste. It crystallizes in elongated rhomboids, square plates, or a feathery form. It is efflorescent, but much less so than phosphat of soda, and requires only two parts of cold water to dissolve it. Hot water dissolves very little more.

The phosphit of ammonia has a very pungent taste, crystallizes frequently in very slender needles, but sometimes in quadrilateral prisms terminated by tetraëdral pyramids. If subjected to distillation in a retort it is decomposed; and the ammonia is volatilized, partly in a liquid state, partly in that of gas holding phosphorus in solution, without however taking fire spontaneously in the air. This gas emits a phosphoric light when mixed with oxigen gas. What remains in the retort is glacial phosphoric acid. If this phosphit be heated on charcoal with the blowpipe, it boils in its water of crystallization; a beautiful phosphoric light is diffused over its surface; and presently bubbles of gas burst from the middle of the vitrifying salt, which burn in the air with a bright flame, and form in the ring of white vapour of phosphoric acid. The vitreous globule left is pure phosphoric acid. Phosphit of ammonia is slightly deliquescent, soluble in two parts of water at 50°, and its solubility increases with the temperature.

A triple salt may be formed by the union of phosphorous acid with ammonia and magnesia at the same time.

The phosphit of alumine has a styptic taste, easily dissolves in water, but is not crystallizable.

Acid (Prussic). The combination of this acid with iron was long known and used as a pigment by the name of Prussian blue, before its nature was understood. Macquer first found, that alkalis would decompose Prussian blue by separating the iron from the principle with which it was combined in it, and which he supposed to be phlogiston. In consequence the prussiat of potash was long called *phlogisticated alkali*. Bergman, however, from a more scientific consideration of its properties, ranked it among the acids; and as early as 1772 Sage announced, that this animal acid, as he called it, formed with the alkalis neutral salts, that with potash forming octaëdral crystals, and that with soda rhomboids or hexagonal laminæ. About the same time Scheele instituted a series of sagacious experiments, not only to obtain the acid separate, which he effected, but also to ascertain its constituent principles. These, according to him, are ammonia and carbon; and Berthollet has only added, that its triple base consists of hidrogen and azot, nearly if not precisely in the proportions that form ammonia and carbon. Berthollet could find no oxigen in any of his experiments for decomposing this acid, as chemists are still agreed to call it; and hence he thinks himself authorised to conclude, that it contains no acidifying principle. He likewise mentions another anomaly it possesses, which is, that it cannot alone take away from other acids the metallic oxides dissolved in them, though none of them can dispossess it of an oxide with which it is united. This Berthollet ascribes to its specific heat, and tendency to assume the gaseous form. Fourcroy however infers, that it does contain oxigen, because Vauquelin obtained six times as much prussic acid in decomposing muriat of ammonia mixed with charcoal by oxide of lead, as he did when using lime instead of this oxide. Fourcroy found too, that on treating the coagulated serum of blood by nitric acid, in order to obtain oxalic acid, a vaporous product was disengaged, which being collected proved to be pure prussic acid: but azotic gas was previously evolved; whence he infers, that the prussic acid contains less azot than ammonia, as in the formation of ammonia this does not take place. Carbonic acid gas too was formed in this process. Another fact corroborates the opinion that prussic acid contains less azot than ammonia. When prussic acid is decomposed by fire, a portion of carbonated hidrogen gas is evolved during the formation of the carbonat of ammonia which is produced.

Curaudau has since attempted to establish a new theory on this head. According to him, what has been called prussic acid is merely its base, which is converted into an acid by acquiring oxigen from a metallic oxide. The calcination of the animal matter produces only two of the elements of the basis, forming with the alkali a carbonated azot of potash; and this combination has the property of decomposing water instantly, so as to form the prussic radical, by the addition of hidrogen, from it. Its attraction for the hidrogen of the water however is so great, that, if its action on the water be allowed to continue after the prussic radical is formed, it will absorb sufficient to convert the azot gradually into ammonia, which will fly off. This loss, however, he adds, may be prevented, by never moistening the calcined materials for making prussiat of potash but with a solution of sulphat of iron at the maximum of oxidation. Agreeably to this theory, Curaudau would distinguish by the name of *prussire* what is commonly called the prussic acid; the combinations of this with alkalis he would call *prussirrets*; and to those in which it has been acidified by the oxigen of some oxide, he would confine the name of prussiats.

The prussic acid is usually obtained by Scheele's method, which is this: Mix four ounces of Prussian blue with two of red oxide of mercury prepared by nitric acid, and boil them in twelve ounces by weight of water, till the whole becomes colourless; filter the liquor, and add to it one ounce of clean iron filings, and six or seven drams of sulphuric acid. Draw off by distillation about a fourth of the liquor, which will be prussic acid; though, as it is liable to be contaminated with a portion of sulphuric, to render it pure it may be rectified by redistilling it from carbonat of lime. Dr. Schaub of Cassel recommends a shorter way, which is, to pour on two parts of Prussian blue one part of sulphuric acid, diluted with an equal quantity of water, and then to distil off the prussic acid.

The prussic acid has a strong smell of peach blossoms, or bitter almonds: its taste is at first sweetish, then acrid, hot, and virulent, and excites coughing; it has a strong tendency to assume the form of gas: it has been decomposed in a high temperature, and by the contact of light, into carbonic acid, ammonia, and carbonated hidrogen: it does not readily unite with the earths and alkalis, does not destroy their alkaline properties, and is displaced even by the carbonic acid: it has no action upon metals, but unites with their oxides, and forms salts for the most part insoluble: it likewise unites into triple salts with these oxides and alkalis: the oxigenated muriatic acid decomposes it.

The peculiar smell of the prussic acid could scarcely fail to suggest its affinity with the deleterious principle that rises in the distillation of the leaves of the lauro-cerasus, bitter kernels of fruits, and some other vegetable productions; and M. Schrader of Berlin has ascertained the fact, that these vegetable substances do contain a principle capable of forming a blue precipitate with iron; and that with lime they afford a test of the presence of iron equal to the prussiat of that earth. Dr Bucholtz of Weimar, and Mr. Roloff of Magdeburg, confirm this fact. The prussic acid appears to come over in the distilled oil.

Prussiat of barytes may be formed by adding Prussian blue to a boiling solution of pure barytes, till its colour ceases to be extracted, and then filtering. The filtered liquor sometimes becomes turbid by cooling, and deposits a little oxide of iron. Being again filtered, after the expiration of some hours small yellowish crystals will form, which are prussiat of barytes. More may be obtained after this by evaporation.

The most important of the prussiats however, for its use in making Prussian blue, and as a test, is the prussiat of potash. This is commonly prepared by calcining dried bullock's blood with the common subcarbonat of potash, and lixiviating. Equal parts are very commonly used; but Dr. Bucholtz recommends two parts of blood to one of potash, as equally affording the largest possible quantity, and being less apt to act upon the oxide of iron in the blood, as well as on the crucible. These should be gradually heated to ignition, in a covered crucible with a hole in the lid: but the heat must neither be applied too suddenly, nor raised too high; and must be discontinued as soon as the small blue flame ceases. The matter should be lixiviated with as little water as possible, and without heat. This alkali is employed for making Prussian blue (see IRON, PRUSSIAT OF); but it is not sufficiently pure to be used as a test. To obtain this the following process is recommended by Mr. Henry. To a solution of potash, deprived of its carbonic acid by quicklime, and heated nearly to the boiling point, add by degrees powdered Prussian blue till its colour ceases to be discharged. Filter the liquor, wash the sediment with water till it ceases to extract any thing, mix the washings together, and pour the mixture into an earthen dish in a sand-heat. When the solution has become hot, add a little dilute sulphuric acid, and continue the heat about an hour. A copious precipitate of Prussian blue will be formed, which must be separated by filtration, and assay a small quantity of the filtered liquor in a wine glass with a little dilute sulphuric acid. If an abundant production of Prussian blue still take place, the whole liquor must be again exposed

exposed to heat with a little dilute sulphuric acid, and this must be repeated as often as necessary. Into the liquor thus far purified pour a solution of sulphat of copper in four or six times its weight of warm water, as long as a reddish brown precipitate continues to appear. Wash this precipitate, which is a prussiat of copper, with repeated affusions of warm water; and when these come off colourless lay the precipitate on a linen filter to drain, after which it may be dried on a chalk stone. When the precipitate is dry, powder it, and add it by degrees to a solution of pure potash, which will take the prussic acid from the oxide of copper. This prussiat of potash, however, will be contaminated by some portion of sulphat of potash, from part of which it may be freed by gentle evaporation, as the sulphat crystallizes first. To the remaining liquor add a solution of barytes in warm water, as long as a white precipitate ensues, observing not to add more after its cessation. The solution of prussiat of potash will now be freed in a great measure from iron, and entirely from sulphats, and by gentle evaporation will form on cooling beautiful crystals. These dissolved in cold water afford the purest prussiat of potash that can be prepared. If pure barytes be not at hand, acetat of barytes may be used instead; as the acetat of potash formed, not being crystallizable, will remain in the mother-water.

Prussiats of soda and of ammonia may be prepared in a similar manner.

The prussiat of lime too has been recommended as a test by Scheele and some other chemists.—*Mem. of the Ac. of Berlin and Stockholm.—Journ. de Phys.—Hermbstaedt's Allg.—Journ. der Chem.—Ann. de Chim.—Nicholson's Journal.*

Acid (Pyroligneous). In the destructive distillation of any kind of wood an acid is obtained, which was formerly called *acid spirit of wood*, and since pyroligneous acid. In distilling cork, however, it appeared to Fourcroy and Vauquelin, that the acid obtained resembled the acetous; and on pursuing the investigation they ascertained, both analytically and synthetically, that the pyroligneous acid is nothing more than the acetous contaminated with an empyreumatic oil produced from the wood.

Acid (Pyromucous). This acid, like the pyroligneous, was proved by the same chemists to be merely the acetous, impregnated with an aromatic oil. It was formerly distinguished by the names *spirit of honey, of sugar, of manna, of gum*, &c., according to the substance from which it was obtained. In the chemical dictionary of the French Encyclopædia it was named by Guyton-Morveau *sirupous acid*, being generally procured from sugar. But as mucilage appeared to be the substance that afforded it, it was lastly called *pyromucous*.

Acid (Pyrotartarous). This acid, obtained in a similar manner from the supertartrit of potash, proves, like the two preceding, to be acetous acid united with an empyreumatic oil.

Acid (Rosacic). The sediment known to physicians by the name of *lateritious*, that is deposited from the urine of persons labouring under febrile diseases, when these diseases take a favourable turn, has long been known to consist chiefly of an acid. According to Scheele it is the uric, which is much more abundant in this critical urine as it is called, than in urine in the ordinary state. Professor Proust, however, says that it differs from the uric in being very soluble in hot water, in having little tendency to crystallize, and in precipitating muriat of gold of a violet colour. Accordingly he distinguishes it by the name of rosacic, but it remains to be determined whether it must retain its separate rank.

Acid (Saccharine). See Acid (Oxalic).

Acid (Saccholactic). See Acid (Mucous).

Acid (Sebacic). The fat of animals is a substance nearly of the same nature as those oils called fat oils in the vegetable kingdom. It affords an acid by distillation, which may be rendered purer by rectifying. But the most elegant method of obtaining this acid consists in mixing a quantity of melted suet with quicklime, suffering the mixture to cool, and afterward boiling it with a large quantity of water. After filtration and evaporation the calcareous salt, formed by the combination of the sebacic acid with the earth, is obtained of a brown colour. A slight calcination renders it purer by the destruction of a portion of inflammable matter; and by solution, filtration, and the addition of a certain quantity of carbonic acid, to precipitate the superfluous lime, a clear solution of the sebat of lime is obtained. Evaporation of the fluid affords the pure white salt; and this, when distilled with the addition of one third of its weight of sulphuric acid, diluted with water, affords the sebacic acid, which comes over into the receiver, while the sulphat of lime remains in the retort.

The sebacic acid is liquid, fuming, and of a penetrating odour; decomposable by heat, which turns it yellow, and reduces it to a coal, after having evolved carbonic acid and carbonated hidrogen gas. Blue colours are strongly reddened by it: water dissolves it in all proportions. With lime, and also with the fixed alkalis, it forms crystallizable salts, which are not decomposed in a moderate heat. With magnesia it forms an uncrystallizable saline mass, which may be reduced to a gummy consistence. With clay, or pure argillaceous earth, it unites with difficulty, forming an astringent uncrystallizable mass. Siliceous earth is thought to be corroded by this acid, probably from its action on glass, in which it may act on the alkali and not on the earth, for it has no action upon siliceous earth precipitated from liquor of flints. Mixed with nitric acid it dissolves gold.

The acid of fat produces an ether by distillation in the usual method with alcohol: it expels the acid from the alkaline sulphats, and the nitrat and acetat of potash, and is itself decomposed by distillation. It likewise precipitates supertartrit of potash from a solution of the neutral tartrit.

When nitrous acid is abstracted from tallow, there is a production of oxalic acid, and not the sebacic. Hence it has been concluded, that this acid is nearly of the same nature as the other acids obtained from organized substances. M. Thenard has lately asserted, that the acid hitherto obtained from fat has been commonly the acetous, perhaps contaminated with the sulphurous; and sometimes, when the common potash of commerce, which is mixed with more or less muriat of soda, was used, as in Crell's process, instead of the quicklime recommended above, the muriatic. He adds, however, that he has obtained a peculiar acid, which is the true sebacic, by distilling fat, washing the product repeatedly with hot water, and filtering, evaporating, and crystallizing the liquor; or precipitating the liquor with acetit of lead, and heating the precipitate, first dried in a retort with sulphuric acid. In the latter case no acid came over into the receiver, but a melted substance like fat floated on the matter in the retort, which M. Thenard first washed well, and then dissolved in boiling water, from which it separated in small crystalline needles on cooling. These crystals were slightly acid to the taste; totally void of smell; melted like fat; were very soluble in boiling water, so as to congeal with it into a mass on cooling; dissolved freely in alcohol; precipitated the nitrats of lead, silver, and mercury, and acetits of mercury and lead; formed soluble salts with the alkalis; were precipitated from their union with potash, without being decomposed, by the sulphuric, nitric, and muriatic acid. *Crell.—Journ. de Phys.—Ann. de Chim.*

Acid (Suberic). This acid was discovered by Brugnatelli in cork, and afterward more fully examined by Bouillon la Grange. To obtain it, pour on cork grated to powder six times its weight of nitric acid, of the specific gravity of 1·26, in a tubulated retort; and distil the mixture with a gentle heat, as long as any red fumes arise. As the distillation advances, a yellow matter, like wax, appears on the surface of the liquid in the retort. While its contents continue hot, pour them into a glass vessel, placed on a sand-heat, and keep them continually stirring with a glass rod; by which means the liquid will gradually grow thick. As soon as white penetrating vapours appear, let it be removed from the sand-heat, and kept stirring till cold. Thus an orange-coloured mass will be obtained, of the consistence of honey, of a strong sharp smell while hot, and a peculiar aromatic smell when cold. On this pour twice its weight of boiling water, apply heat till it liquefies, and filter. As the filtered liquor cools it deposits a powdery sediment, and acquires a thin pellicle. Separate the sediment by filtration, and evaporate the fluid nearly to dryness. The mass thus obtained is the suberic acid; which may be purified by saturating with an alkali, and precipitating by an acid, or by boiling it with charcoal powder.

Suberic acid has a rough acerb taste, and when dissolved in boiling water excites coughing: it reddens vegetable blues, and turns the blue solution of indigo in sulphuric acid green: it is soluble in two parts of boiling water, and in about one hundred and fifty of cold: it attracts moisture from the air, and is turned brown by the action of light: it sublimes in a moderate heat without being decomposed. Its base is presumed to consist of carbon and hidrogen, though Mr. Jameson would reject the hidrogen, because he obtained it by treating charcoal with nitric acid; but this is not a sufficient proof. He likewise observes, that the acid existing ready formed in peat has the properties of the suberic. Brugnatelli has obtained a large quantity of suberic acid, mixed with oxalic, from paper.

Most of the alkaline and earthy suberats have an excess of acid, and are decomposed by heat. Those of potash and ammonia are the only ones that crystallize. The alkaline are very soluble, the earthy dissolve but sparingly.—*Crell's Annals.—Ann. de Chim.—Gehlen's Journal.—Jameson's Min. of Shetland.*

Acid (Succinic). It has long been known that amber, when exposed to distillation, affords a crystallized substance, which sublimes into the upper part of the vessel. Before its nature was understood it was called *salt of amber*, a name not yet banished from our Pharmacopœias; but it is now known to be a peculiar acid, as Boyle first discovered. The crystals are at first contaminated with a little oil, which gives them a brownish colour; but they may be purified by solution and crystallization, repeated as often as necessary; when they will become transparent and shining. Pott recommends to put on the filter, through which the solution is passed, a little cotton previously wetted with oil of amber. Their figure is that of a triangular prism. Their taste is acid, and they redden the blue colour of litmus, but not that of violets. They are soluble in less than two parts of boiling alcohol, in two parts of boiling water, and in twenty-five of cold water.

M. Planche, of Paris, observes, that a considerable quantity might be collected in making amber varnish, as it sublimes while the amber is melting for this purpose, and is wasted.

It has been prescribed in nervous and catarrhal complaints, and as a diuretic.

With barytes and lime the succinic acid forms salts but little soluble; and with magnesia it unites into a thick gummy substance. The succinats of potash and ammonia are crystallizable, and deliquescent; that of soda does not attract moisture. The succinat of ammonia is useful in analysis to separate oxide of iron.

Acid (Sulphuric). When sulphur is heated to 180° or 190° in an open vessel, it melts, and soon afterward emits a blueish flame, visible in the dark, but which, in open day-light, has the appearance of a white fume. This flame has a suffocating smell, and has so little heat that it will not set fire to flax, or even gunpowder, so that in this way the sulphur may be entirely consumed out of it. If the heat be still augmented, the sulphur boils, and suddenly bursts into a much more luminous flame, the same suffocating vapour still continuing to be emitted.

The suffocating vapour of sulphur is imbibed by water, with which it forms the fluid formerly called *volatile vitriolic*, now sulphurous acid. If this fluid be exposed for a time to the air, it loses the sulphureous smell it had at first, and the acid becomes more fixed. It is then the fluid which was formerly called the *spirit of vitriol*. Much of the water may be driven off by heat, and the dense acid which remains is the sulphuric acid, commonly called *oil of vitriol*; a name which was probably given to it from the little noise it makes when poured out, and the unctuous feel it has when rubbed between the fingers, produced by its corroding and destroying the skin, with which it forms a soapy compound.

The stone or mineral called martial pyrites, which consists for the most part of sulphur and iron, is found to be converted into the salt vulgarly called *green vitriol*, but more properly sulphat of iron, by exposure to air and moisture. In this natural process the pyrites breaks and falls in pieces; and if the change take place rapidly, a considerable increase of temperature follows, which is sometimes sufficient to set the mass on fire. By conducting this operation in an accurate way, it is found that oxigen is absorbed. The sulphat is obtained by solution in water, and subsequent evaporation; by which the crystals of the salt are separated from the earthy impurities, which were not suspended in the water.

The sulphuric acid was formerly obtained in this country by distillation from sulphat of iron, as it still is in many parts abroad: the common green vitriol is made use of for this purpose, as it is to be met with at a low price, and the acid is more easily to be extracted from it. With respect to the operation itself, the following particulars should be attended to: First, the vitriol must be calcined in an iron or earthen vessel, till it appears of a yellowish red colour: by this operation it will lose half its weight. This is done in order to deprive it of the greater part of the water which it has attracted into its crystals during the crystallization, and which would otherwise in the ensuing distillation greatly weaken the acid. As soon as the calcination is finished, the vitriol is to be put immediately, while it is warm, into a coated earthen retort, which is to be filled two thirds with it, so that the ingredients may have sufficient room upon being distended by the heat, and thus the bursting of the retort be prevented. It will be most advisable to have the retort immediately enclosed in brick-work in a reverberatory furnace, and to stop up the neck of it till the distillation begins, in order to prevent the materials from attracting fresh humidity from the air. At the beginning of the distillation the retort must be opened, and a moderate fire is to be applied to it, in order to expel from the vitriol all that part of the phlegm which does not taste strongly of the acid, and which may be received in an open vessel placed under the retort. But as soon as there appear any acid drops, a receiver is to be added, into which has been previously poured a quantity of the acidulous fluid which has come over, in the proportion of half a pound of it to twelve pounds of the calcined vitriol; when the receiver is to be secured with a proper luting. The fire is now to be raised by little and little to the most intense degree of heat, and the receiver carefully covered with wet cloths, and, in winter time, with snow or ice, as the acid rises in the form of a thick white vapour, which toward the end of the operation becomes hot, and heats the receiver to a great degree. The fire must be continued at this high pitch for several days, till no vapour issues from the retort, nor any drops are seen trickling down its sides. In the case of a great quantity of vitriol being distilled, M. Bernhardt has observed it to continue emitting vapours in this manner for the space of ten days. When the vessels are quite cold, the receiver must be opened carefully, so that none of the luting may fall into it; after which the fluid contained in it is to be poured into a bottle, and the air carefully excluded. The fluid that is thus obtained is the ordinary sulphuric acid, of which Bernhardt got sixty-four pounds from six hundred weight of vitriol; and on the other hand, when no water had been previously poured into the receiver, fifty-two pounds only of a dry concrete acid. This acid was formerly called *glacial oil of vitriol*, and its consistence is owing to a mixture of sulphurous acid, which occasions it to become solid at a moderate temperature.

The sulphuric acid made in these kingdoms is produced by the combustion of sulphur. There are three conditions requisite in this operation. Oxigen must be present to maintain the combustion; the vessel must be close, to prevent the escape of the volatile matter which rises; and water must be present to imbibe it. For these purposes, a mixture of eight parts of sulphur with one of nitre is placed in a proper vessel, enclosed within a chamber of considerable size, lined on all sides with lead, and covered at bottom with a shallow stratum of water. The mixture being set on fire, and shut up, will burn for a considerable time, by virtue of the supply of oxigen which nitre gives out when heated; and the water imbibing the sulphureous vapours, becomes gradually more and more acid after repeated combustions, and the acid is afterward concentrated by distillation. The common sulphuric acid of the shops, if diluted with an equal weight of water, frequently deposits a white sediment, consisting of various impurities; and the clear fluid poured off, and then concentrated by evaporation, will be a much purer acid. To have it as pure as possible, however, it should be rectified by distillation, which is a difficult process, requiring considerable skill and experience. For this purpose a glass retort, very carefully annealed, must be taken, and coated all over the body, and as much of the neck as is exposed to the fire, with clay and sand. This being dry, it is to be half filled with the acid, and placed on a sand-bath in a reverberatory furnace, which has an opening in the side for the neck of the retort. A receiver being applied without luting, the fire must be kindled, and raised with extreme caution. The first portion that comes over, about a sixth of the whole, may be rejected, as it is chiefly water. The concentrated acid now rises, and great care must be taken to regulate the fire, so that several seconds may elapse between the fall of the drops, as at this period the neck of the retort is very liable to be broken. The process may be continued as long as any acid is condensed.

The sulphuric acid is considerably denser than any other acid or transparent fluid, and in general its affinities are stronger. It strongly attracts water, which it takes from the atmosphere very rapidly, and in larger quantities, if suffered to remain in an open vessel, imbibing one third of its weight in twenty-four hours, and more than six times its weight in a twelvemonth. If four parts by weight be mixed with one of water at 50° they produce an instantaneous heat of 300° F.; and four parts raise one of ice to 212°; on the contrary, four parts of ice mixed with one of acid sink the thermometer to 4° below 0. When pure it is colourless, and emits no fumes. If it be heated, it becomes more and more concentrated by the loss of a portion of water, which rises before the acid itself. Its specific gravity ought to be 1·85, at which it is taken by the London college; but it may be brought, by evaporation in a sand-heat, to 2 or upward. At this strength it requires a great degree of cold to freeze it; and if diluted with half a part or more of water, unless the dilution be carried very far, it becomes more and more difficult to congeal: yet at the specific gravity of 1·78, or a few hundredths above or below this, it may be frozen by surrounding it with melting snow. Its congelation forms regular prismatic crystals with six sides. Its boiling point, according to Bergman, is 540°; according to Dalton, 590°.

Attempts have been made to ascertain the proportions of the constituent principles in this acid, but chemists have differed considerably on this head. Tromsdorf carries the sulphur as high as 70 per cent., and Berthollet even to 72; while Klaproth, Richter, and Bucholz make it little more than 42. Lately Mr. Chenevix has made some very careful experiments on the subject, which give 51·5 for the proportion of sulphur, and their accuracy is strengthened by others made by Dr. Thomson of Edinburgh; and it is probable the other chemists may have erred from mistaken calculations of the component parts of the salts employed in the analysis.

The sulphuric acid is of very extensive use in the art of chemistry, as well as in metallurgy, bleaching, and some of the processes for dyeing: in medicine it is given as a tonic, stimulant, and lithontriptic, and sometimes used externally as a caustic.

The combinations of this acid with the various bases are called sulphats, and most of them have long been known by various names. With barytes it is found native and nearly pure in various forms, in coarse powder, rounded masses, stalactites, and regular crystallizations, which are in some lamellar, in others needly, in others prismatic or pyramidal. The cawks of our country and the *Bolognian stone* (which see) are native sulphats of barytes. Their colour varies considerably as well as their figure, but their specific gravity is great, that of a very impure kind being 3·89, and the pure sorts varying from 4 to 4·865; hence it has been distinguished by the names of *marmor metallicum* and *ponderous spar*. The native sulphat of barytes according to Bergman consists of 84 barytes with 16 sulphuric acid and water, the water of crystallization being 3. According to Klaproth, however, the earth is to the acid as 2 to 1 only: and Dr. Withering, who has analysed different specimens with great care, gives nearly similar proportions, or 67·2 to 33·8: and some white rhomboidal lamellar crystals, from Kilpatrick hills near Glasgow, afforded him these proportions without any foreign admixture. The artificial sulphat has generally been estimated to contain also about 67 to 33 after having been ignited; but Mr. Chenevix, who has lately made many experiments on it with a view to ascertain the proportion of sulphur in sulphuric acid, calculates the acid in artificial sulphat of barytes to be only 23·5 or 24 per cent. This salt, though deleterious, is less so than the carbonat of barytes, and therefore perhaps preferable for preparing the muriat for medicinal purposes. It requires 43000 parts of water to dissolve it at 60°.

Sulphat of strontian has a considerable resemblance to that of barytes in its properties. It is found native in considerable quantities at Aust Passage and other places in the neighbourhood of Bristol. It requires 3840 parts of boiling water to dissolve it.

The sulphat of potash, *vitriolated kali* of the London college, formerly *vitriolated tartar*, *sal de duobus*, and *arcanum duplicatum*, crystallizes in hexaëdral prisms, terminated by hexagonal pyramids, but susceptible of several variations. Its crystallization by cooling is confused. Its taste is bitter, acrid, and a little saline. It is soluble in 5 parts of boiling water, and 16 parts at 60°. In the fire it decrepitates, and is fusible by a strong heat. It is decomposable by charcoal at a high temperature. It may be prepared by direct mixture of its component parts; but the usual and cheapest mode is to neutralize the acidulous sulphat left after distilling nitric acid, the *sal enixus* of the old chemists, by the addition of carbonat of potash. The *sal polychrest* of old dispensatories, made by deflagrating sulphur and nitre in a crucible, was a compound of the sulphat and sulphit of potash. The acidulous sulphat is sometimes employed as a flux, and likewise in the manufacture of alum. In medicine the neutral salt is sometimes used as a deobstruent, and in large doses as a mild cathartic: dissolved in a considerable portion of water, and taken daily in such quantity as to be gently aperient, it has been found serviceable in cutaneous affections, and is sold in London for this purpose as a nostrum; and certainly it deserves to be distinguished from the generality of quack medicines, very few indeed of which can be taken without imminent hazard.

The sulphat of soda is the *vitriolated natron* of the college, the well known *Glauber's salt*, or *sal mirabile*. It is commonly prepared from the residuum left after distilling muriatic acid, the superfluous acid of which may be saturated by the addition of soda, or precipitated by lime; and is likewise obtained in the manufacture of the muriat of ammonia. (See AMMONIA.) Schefer mentions another mode by Mr. Funcke, which is, making 8 parts of calcined sulphat of lime, 6 of clay, and 5 of common salt, into a paste with water; burning this in a kiln; and then powdering, lixiviating, and crystallizing. It exists in large quantities under the surface of the earth in some countries, as Persia, Bohemia, and Switzerland; is found mixed with other substances in mineral springs and sea water; and sometimes effloresces on walls. Sulphat of soda is bitter and saline to the taste: is soluble in 2·85 parts of cold water, and 0·8 at a boiling heat: it crystallizes in hexagonal prisms bevelled at the extremities, sometimes grooved longitudinally, and of very large size, when the quantity is great: these effloresce completely into a white powder, if exposed to a dry air, or even if kept wrapped up in paper in a dry place, yet they retain sufficient water of crystallization to undergo the aqueous fusion on exposure to heat, but by urging the fire melt. Barytes and strontian take its acid from it entirely, and potash partially: the nitric and muriatic acids, though they have a weaker affinity for its base, combine with a part of it when digested on it. Heated with charcoal its acid is decomposed. As a purgative its use is very general: and it has been employed to furnish soda. Pajot des Charmes has made some experiments on it in fabricating glass: with sand alone it would not succeed, but equal parts of carbonat of lime, sand, and dried sulphat of soda, produced a clear, solid, pale yellow glass.

Sulphat of soda and sulphat of ammonia form together a triple salt.

Sulphat of lime, *selenite*, *gypsum*, *plaster of Paris*, and sometimes *alabaster*, form extensive strata in various mountains. The *specular gypsum*, or *glacies Mariæ*, is a species of this salt, and affirmed by some French travellers to be employed in Russia, where it abounds, as a substitute for glass in windows. Its specific gravity is from 1·872 to 2·311. It requires 500 parts of cold water, and 450 of hot, to dissolve it. When calcined it decrepitates, becomes very friable and white, and heats a little with water, with which it forms a solid mass. In this process it loses its water of crystallization, which, according to Fourcroy, is 22 per cent. In this state it is found native in Tyrol, crystallized in rectangular parallelopipeds, or octaëdral or hexaëdral prisms, and is called *anhydrous* sulphat of lime. Both the natural and artificial anhydrous sulphat consists of 56·3 lime and 43·6 acid, according to Mr. Chenevix. The calcined sulphat is much employed for making casts of anatomical and ornamental figures; as one of the bases of stucco; as a fine cement for making close and strong joints between stone, and joining rims or tops of metal to glass; for making moulds for the Staffordshire potteries; for cornices, mouldings, and other ornaments in building. For these purposes, and for being wrought into columns, chimney-pieces, and various ornaments, about eight hundred tons are raised annually in Derbyshire, where it is called alabaster. In America it is laid on grass land as a manure.

Sulphat of magnesia, the *vitriolated magnesia* of the present, and *sal catharticus amarus* of former London Pharmacopœias, is commonly known by the name of *Epsom salt*, as it was furnished in considerable quantity by the mineral water at that place, mixed however with a considerable portion of sulphat of soda. It is afforded however in greater abundance and more pure from the bittern left after the extraction of salt from sea water. It has likewise been found efflorescing on brick walls, both old and recently erected, and in small quantity in the ashes of coals. The capillary salt of Idria, found in silvery crystals mixed withthe aluminous schist in the mines of that place, and hitherto considered as a feathery alum, has been ascertained by Klaproth to consist of sulphat of magnesia, mixed with a small portion of sulphat of iron. When pure it crystallizes in small quadrangular prisms terminated by quadrangular pyramids or diedral summits. Its taste is cool and bitter. It is very soluble, requiring only an equal weight of cold water, and three-fourths its weight of hot. It effloresces in the air, though but slowly. If it attract moisture, it contains muriat of magnesia or of lime. Exposed to heat it dissolves in its own water of crystallization, and dries but is not decomposed, nor fused but with extreme difficulty. It consists, according to Bergman, of 33 acid, 19 magnesia, 48 water. A very pure sulphat is said to be prepared in the neighbourhood of Genoa by roasting a pyrites found there; exposing it to the air in a covered place for six months, watering it occasionally; and then lixiviating. The lixivium contains the sulphats of iron, copper, and magnesia. If that of copper be abundant, it is first precipitated by iron; and the remainder of the metallic sulphats is separated by adding lime diffused in water in the proportion of about one per cent. of the ore. This lime, however, contains about 16 per cent. of magnesia. On comparing this sulphat with others, 100 parts of it were found to yield 46 of carbonat of magnesia, while French sulphat of magnesia gave but 22, Spanish 37, and English 38. This is the best mode of ascertaining its purity. Sulphat of magnesia is one of our most valuable purgatives; for which purpose only it is used, and for furnishing the carbonat of magnesia. See Acid (Carbonic).

Sulphat of ammonia crystallizes in slender, flattened, hexaëdral prisms, terminated by hexagonal pyramids: it attracts a little moisture from very damp air, particularly if the acid be in excess: it dissolves in two parts of cold and one of boiling water. It is not used, though Glauber, who called it his *secret ammoniacal salt*, vaunted its excellence in assaying.

If sulphat of ammonia and sulphat of magnesia be added together in solution, they combine into a triple salt, of an octaedral figure, but varying much; less soluble than either of its component parts; unalterable in the air; undergoing on the fire the watery fusion; after which it is decomposed, part of the ammonia flying off, and the remainder subliming with an excess of acid. It contains according to Fourcroy 68 sulphat of magnesia, and 32 sulphat of ammonia.

Sulphat of glucine crystallizes with difficulty, its solution readily acquiring and retaining a sirupy consistence; its taste is sweet, and slightly astringent; it is not alterable in the air; a strong heat expels its acid, and leaves the earth pure; heated with charcoal it forms a sulphuret; infusion of galls forms a yellowish white precipitate with its solution.

Yttria is readily dissolved by sulphuric acid; and as the solution goes on the sulphat crystallizes in small brilliant grains, which have a sweetish taste, but less so than sulphat of glucine, and are of a light amethyst red colour. They require 30 parts of cold water to dissolve them, and give up their acid when exposed to a high temperature. They are decomposed by oxalic acid, prussiat of potash, infusion of galls, and phosphat of soda.

Sulphat of alumine in its pure state is but recently known, and it was first attentively examined by Vauquelin. It may be made by dissolving pure alumine in pure sulphuric acid, heating them for some time, evaporating the solution to dryness, drying the residuum with a pretty strong heat, redissolving it, and crystallizing. Its crystals are soft, foliaceous, shining, and pearly; but these are not easily obtained without cautious evaporation and refrigeration. They have an astringent taste; are little alterable in the air; are pretty soluble, particularly in hot water; give out their acid on exposure to a high temperature; are decomposable by combustible substances, though not readily, and do not form a pyrophorus like alum.

If the evaporation and desiccation directed above be omitted, the alumine will remain supersaturated with acid, as may be known by its taste, and by its reddening vegetable blue. This is still more difficult to crystallize than the neutral salt, and frequently thickens into a gelatinous mass.

A compound of acidulous sulphat of alumine with potash or ammonia has long been known by the name of Alum; which see.

If this acidulous sulphat, or alum, be dissolved in water, and boiled with pure alumine, the alumine will become saturated with its base, and fall down an insipid white powder. This salt is completely insoluble, and is not deprived of its acid by heat but at a very high temperature. It may be decomposed by long boiling with the alkaline or earth bases; and several acids convert it into common alum, but slowly.

Sulphat of zircon may be prepared by adding sulphuric acid to the earth recently precipitated, and not yet dry. It is sometimes in small needles, but commonly pulverulent; very friable; insipid; insoluble in water, unless it contain some acid; and easily decomposed by heat.

M. Giobert imagined, that sulphuric acid was capable of absorbing an additional dose of oxigen, so that there existed an *oxisulphuric* acid; but Vauquelin has refuted this, and Chenevix found the experiments of Giobert inaccurate.

On the other hand, Mr. Dabit supposes that there is an intermediate state of acidity between the sulphuric and sulphurous, producing what he calls the oxigenated sulphurous acid. His opinion is founded on the salts produced by saturating the residuum of ether diluted in water with different bases, as according to him they differ both from the sulphats and sulphits: but this requires confirmation.—*Phil. Trans.—Irish Trans.—Journ. de Phys.—Scherer's Journ.—Mem. de l'Instit. Nat.—Nicholson's Journ.—Klaproth's Analyses.—Ann. de Chim.—Henry's Chem.*

Acid (Sulphurous). It has already been observed, that sulphur burned at a low temperature absorbs less oxigen than it does when exposed to greater heat, and is consequently acidified in a slighter degree, so as to form sulphurous acid. This in the ordinary state of the atmosphere is a gas; but on reducing its temperature very low by artificial cold, and exposing it to strong compression, it becomes a liquid. To obtain it in the liquid state, however, for practical purposes, it is received into water, by which it is absorbed.

As the acid obtained by burning sulphur in this way is commonly mixed with more or less sulphuric acid, when sulphurous acid is wanted it is commonly made by abstracting part of the oxigen from sulphuric acid by means of some combustible substance. Mercury or tin is usually preferred. For the purposes of manufactures, however, chopped straw or sawdust may be employed. If one part of mercury and two of concentrated sulphuric acid be put into a glass retort with a long neck, and heat applied till an effervescence is produced, the sulphurous acid will arise in the form of gas, and may be collected over quicksilver, or received into water, which at the temperature of 61° will absorb 33 times its bulk, or nearly an eleventh of its weight.

Water thus saturated is intensely acid to the taste, and has the smell of sulphur burning slowly. It destroys most vegetable colours, but the blues are reddened by it previous to their being discharged. A pleasing instance of its effect on colours may be exhibited by holding a red rose over the blue flame of a common match, by which the colour will be discharged wherever the sulphurous acid comes into contact with it, so as to render it beautifully variegated, or entirely white. If it be then dipped into water, the redness after a time will be restored. According to Dr. Thomson, sulphurous acid consists of 68 parts sulphur and 32 oxigen.

Sulphurous acid is used in bleaching, particularly for silks. It likewise discharges vegetable stains, and ironmoulds from linen.

In combination with the salifiable bases it forms sulphits, which differ from the sulphats in their properties. The alkaline sulphits are more soluble than the sulphats, the earthy less. They are converted into sulphats by an addition of oxigen, which they acquire even by exposure to the air. The sulphit of lime is the slowest to undergo this change. A strong heat either expels their acid entirely, or converts them into sulphats. They have all a sharp, disagreeable, sulphurous taste. The best mode of obtaining them is by receiving the sulphurous acid gas into water holding the base, or its carbonat, in solution, or diffused in it in fine powder. None of them have yet been applied to any use.

Acid (Tartarous). The casks in which some kinds of wine are kept become incrusted with a hard substance, tinged with the colouring matter of the wine, and otherwise impure, which has long been known by the name of *argal*, or tartar, and distinguished into red and white according to its colour. This being purified by solution, filtration, and crystallization, was termed *cream* or *crystals of tartar*. It was afterward discovered, that it consisted of a peculiar acid combined with potash: and the supposition that it was formed during the fermentation of the wine, was disproved by Boerhaave, Neumann and others, who showed that it existed ready formed in the juice of the grape. It has likewise been found in other fruits, particularly before they are too ripe; and in the tamarisk, sumac, balm, carduus benedictus, and the roots of rest-harrow, germander, and sage. The separation of tartarous acid from this acidulous salt, is the first discovery of Scheele that is known. He saturated the superfluous acid by adding chalk to a solution of the supertartrit in boiling water as long as any effervescence ensued, and expelled the acid from the precipitated tartrit of lime by means of the sulphuric. Fourcroy observes, that by using lime instead of its carbonat, the whole of the tartarous acid may be obtained; and the supernatant liquor will then contain pure potash, instead of the neutral tartrit of potash, which it holds in solution when chalk is used. Or four parts of tartar may be boiled in twenty or twenty-four of water, and one part of sulphuric acid added gradually. By continuing the boiling the sulphat of potash will fall down. When the liquor is reduced to one half, it is to be filtered, and if any more sulphat be deposited by continuing the boiling, the filtering must be repeated. When no more is thrown down, the liquor is to be evaporated to the consistence of a sirup, and thus crystals of tartarous acid equal to half the weight of the tartar employed will be obtained.

The tartarous acid may be procured in needly or laminated crystals by evaporating a solution of it. Its taste is very acid and agreeable, so that it may supply the place of lemon-juice. It is very soluble in water. Burnt in an open fire it leaves a coaly residuum generally containing a little lime; in close vessels it gives out carbonic acid and hidrogen gas, so that its base is a compound of hidrogen and carbon. By distilling nitric acid off the crystals they may be converted into oxalic acid, and the nitric acid passes to the state of nitrous.

The tartrits of lime and barytes are white, pulverulent, and insoluble, unless in an excess of their acid.

Tartrit of strontian, formed by the double decomposition of muriat of strontian and tartrit of potash, according to Vauquelin is soluble, crystallizable, and consists of 52·88 strontian and 47·12 acid.

That of magnesia forms a gelatinous or gummy mass.

Tartrit of potash, the *tartarised kali* of the London college, and *vegetable salt* of some, formerly called *soluble tartar*, because much more so than the supertartrit, crystallizes in oblong squares, bevelled at the extremities. It has a bitterish taste, and is decomposed by heat, as its solution is even by standing some time. It is used as a mild purgative.

The supertartrit of potash, already mentioned at the beginning of this article, is much used as a cooling and gently opening medicine, as well as in several chemical and pharmaceutical preparations. Dissolved in water, with the addition of a little sugar and a slice or two of lemon peel, it forms an agreeable cooling drink by the name of *imperial*; and if an infusion of green balm be used instead of water, it makes one of the pleasantest liquors of the kind with which we are acquainted. Mixed with an equal weight of nitre, and projected into a red-hot crucible, it detonates, and forms the *white flux*; treated in the same way with half its weight of nitre, it forms the *black flux*; and simply mixed with nitre in various proportions it is called *raw flux*. It is likewise used in dyeing, in hat-making, in gilding, and in other arts.

By saturating the superfluous acid in this supertartrit with soda a triple salt is formed, which crystallizes in large regular prisms of eight nearly equal sides, of a bitter taste, efflorescent, and soluble in about five parts of water. It consists according to Vauquelin of 54 parts tartrit of potash and 46 tartrit of soda; and was once in much repute as a purgative, by the name of *Rochelle salt*, or *sel de Seignette*.

The tartrit of soda is much less soluble than this triple salt, and crystallizes in slender needles or thin plates.

The tartrit of ammonia is a very soluble, bitter salt, and crystallizes easily. Its solution is spontaneously decomposable.

This too forms with tartrit of potash a triple salt, the solution of which yields by cooling fine pyramidal or prismatic efflorescent crystals. Though both the neutral salts that compose it are bitter, this is not, but has a cool taste.

Acid (Tungstic). What has been thus called appears to be only an oxide of Tungsten; which see.

Acid (Uric). The same with Lithic acid; which see.

Acid (Zoonic). In the liquid procured by distillation from animal substances, which had been supposed to contain only carbonat of ammonia and an oil, Berthollet imagined he had discovered a peculiar acid, to which he gave the name of zoonic. Thenard, however, has demonstrated that it is merely acetous acid combined with an animal matter.

Acidifiable. Capable of being converted into an acid by the acidifying principle. (See Acid.) Substances possessing this property are called *radicals*, or *acidifiable bases*.

Acidule. A term applied by the French chemists to those salts, in which the base is combined with such an excess of acid, that they manifestly exhibit acid properties; such as the supertartrit of potash.

Adamant. See Diamond.

Adamantine Spar. This stone, which comes to us from the peninsula of hither India, and also from China, has not engaged the attention of the chemical world till within a few years past. It is remarkable for its extreme hardness, which approaches to that of the diamond, and by virtue of which property it is used for polishing gems.

Two varieties of this stone are known in Europe. The first comes from China. It is crystallized, in six-sided prisms, without pyramids, the length of which varies from half an inch to an inch, and their thickness is about three quarters of an inch. Its colour is gray of different shades. The larger pieces are opake; but thin pieces and the edges of the prisms are transparent. Its fracture is brilliant, and its texture spathose; which causes its surface to appear lightly striated. Its crystals are covered with a very fine and strongly adherent crust of plates of silvery mica mixed with particles of red felt-spar. A yellow superficial covering of sulphate of iron was observed upon one specimen.

This stone is so hard that it not only cuts glass as easily as a diamond, but likewise marks rock crystal and several other hard stones. Its specific gravity is 3710.

Small crystalline grains of magnetical ferruginous calx are occasionally found in the adamantine spar of China, which may be separated by the magnet when the stone is pulverized.

The second variety, which comes from India, is called Corundum by the inhabitants of Bombay. It differs from the former by a white colour, a texture more evidently spathose, and lastly, because the grains of magnetical iron are smaller than in the former specimens, and are not interspersed through its substance, but only at its surface.

From its hardness it is extremely difficult to analyse. Mr. Chenevix, by repeatedly heating it red-hot, and then plunging it into cold water, caused it to appear fissured in every direction. He then put it into a steel mortar, about three quarters of an inch in diameter, and three inches deep, to which a steel pestle was closely fitted. A few blows on the pestle caused it to crumble, and the fragments were then easily reduced to an impalpable powder by an agate pestle and mortar. This powder was fused in a crucible of platina with twice its weight of calcined borax, and the glass was dissolved by boiling in muriatic acid about twelve hours. The precipitates from this solution being examined, a specimen from China was found to give from 100 parts 86·50 of alumine, 5·25 of silex, 6·50 of iron: one from Ava, alumine 87, silex 6·5, iron 4·5: one from Malabar, alumine 86·5, silex 7, iron 4: one from the Carnatic, alumine 91, silex 5, iron 1·5.

The rev Mr. W. Gregor analysed a specimen from Thibet, in the collection of Mr. Rashleigh, which gave him alumine 81·75, silex 12·125, oxide of titanium 4, water 0·937, but no iron.

This stone has been said to have been found in different parts of Europe, and near Philadelphia in America; but most, if not all of the specimens have proved not to be the adamantine spar. Lately, however, prof. Pini has discovered a stone in Italy, the characters of which, as given by him, certainly agree with those of the adamantine spar, and of their identity he has no doubt.

Adipocere. The attention of chemists has been much excited by the spontaneous conversion of animal matter into a substance considerably resembling spermaceti. The fact has long been well known, and is said to have been mentioned in the works of Lord Bacon, though I have not seen the passage. On the occasion of the removal of a very great number of human bodies from the ancient burying-place des Innocens at Paris, facts of this nature were observed in the most striking manner. Fourcroy may be called the scientific discoverer of this peculiar matter, as well as the saponaceous ammoniacal substance contained in bodies abandoned to spontaneous destruction in large masses. This chemist read a memoir on the subject in the year 1789 to the Royal Academy of Sciences, from which I shall abstract the general contents.

At the time of clearing the before mentioned burying-place, certain philosophers were specially charged to direct the precautions requisite for securing the health of the workmen. A new and singular object of research presented itself, which had been necessarily unknown to preceding chemists. It was impossible to foretel what might be the contents of a soil overloaded for successive ages with bodies resigned to the putrefactive process. This spot differed from common burying-grounds, where each individual object is surrounded by a portion of the soil. It was the burying-ground of a large district, wherein successive generations of the inhabitants had been deposited for upwards of three centuries. It could not be foreseen that the entire decomposition might be retarded for more than forty years; neither was there any reason to suspect that any remarkable difference would arise from the singularity of situation.

The remains of the human bodies immersed in this mass of putrescence were found in three different states, according to the time they had been buried, the place they occupied, and their relative situations with regard to each other. The most ancient were simply portions of bones, irregularly dispersed in the soil, which had been frequently disturbed. A second state, in certain bodies which had always been insulated, exhibited the skin, the muscles, tendons, and aponeuroses, dry, brittle, hard, more or less gray, and similar to what are called mummies in certain caverns where this change has been observed, as in the catacombs at Rome, and the vault of the Cordeliers at Toulouse.

The third and most singular state of these soft parts was observed in the bodies which fill the common graves or repositories. By this appellation are understood cavities of thirty feet in depth and twenty on each side, which were dug in the burying-ground of the Innocents, and were appropriated to contain the bodies of the poor; which were placed in very close rows, each in its proper wooden bier. The necessity for disposing a great number obliged the men charged with this employment to arrange them so near each other, that these cavities might be considered when filled as an entire mass of human bodies, separated only by two planks of about half an inch thick. Each cavity contained between one thousand and fifteen hundred. When one common grave of this magnitude was filled, a covering of about one foot deep of earth was laid upon it, and another excavation of the same sort was made at some distance. Each grave remained open about three years, which was the time required to fill it. According to the urgency of circumstances, the graves were again made on the same spot after an interval of time not less than fifteen years, nor more than thirty. Experience had taught the workmen, that this time was not sufficient for the entire destruction of the bodies, and had shown them the progressive changes which form the object of Mr. Fourcroy's memoir.

The first of these large graves opened in the presence of this chemist had been closed for fifteen years. The coffins were in good preservation, but a little settled, and the wood (I suppose deal) had a yellow tinge. When the covers of several were taken off, the bodies were observed at the bottom, leaving a considerable distance between their surface and the cover, and flattened as if they had suffered a strong compression. The linen which had covered them was slightly adherent to the bodies; and, with the form of the different regions, exhibited on removing the linen nothing but irregular masses of a soft ductile matter of a gray white colour. These masses environed the bones on all sides, which had no solidity, but broke by any sudden pressure. The appearance of this matter, its obvious composition and its softness, resembled common white cheese; and the resemblance was more striking from the print which the threads of the linen had made upon its surface. This white substance yielded to the touch, and became soft when rubbed for a time between the fingers.

No very offensive smell was emitted from these bodies. The novelty and singularity of the spectacle, and the example of the grave-diggers, dispelled every idea either of disgust or apprehension. These men asserted that they never found this matter, by them called *gras* (fat), in bodies interred alone; but that the accumulated bodies of the common graves only were subject to this change. On a very attentive examination of a number of bodies passed to this state, Mr. Fourcroy remarked, that the conversion appeared in different stages of advancement, so that, in various bodies, the fibrous texture and colour, more or less red, were discernible within the fatty matter; that the masses covering the bones were entirely of the same nature, offering indistinctly in all the regions a gray substance for the most part soft and ductile, sometimes dry, always easy to be separated in porous fragments, penetrated with cavities, and no longer exhibiting any traces of membranes, muscles, tendons, vessels, or nerves. On the first inspection of these white masses, it might have been concluded that they were simply the cellular tissue, the compartments and vesicles of which they very well represented.

By examining this substance in the different regions of the body, it was found that the skin is particularly disposed to this remarkable alteration. It was afterwards perceived that the ligaments and tendons no longer existed, or at least had lost their tenacity; so that the bones were entirely unsupported, and left to the action of their own weight. Whence their relative places were preserved in a certain degree by mere juxta-position; the least effort being sufficient to separate them. The grave-diggers availed themselves of this circumstance in the removal of the bodies. For they rolled them up from head to feet, and by that means separated from each other the extremities of the bones which had formerly been articulated. In all these bodies which were changed into the fatty matter the abdominal cavity had disappeared. The teguments and muscles of this region being converted into the white matter like the other soft parts, had subsided upon the vertebral column, and were so flattened as to leave no place for the viscera, and accordingly there was scarcely ever any trace observed in the almost obliterated cavity. This observation was for a long time matter of astonishment to the investigators. In vain did they seek in the greater number of bodies the place and substance of the stomach, the intestines, the bladder, and even the liver, the spleen, the kidneys, and the matrix in females. All these viscera were confounded together, and for the most part no traces of them were left. Sometimes only certain irregular masses were found, of the same nature as the white matter, of different bulks, from that of a nut to two or three inches in diameter, in the regions of the liver or of the spleen.

The thorax likewise offered an assemblage of facts no less singular and interesting. The external part of this cavity was flattened and compressed like the rest of the organs; the ribs, spontaneously luxated in their articulations with the vertebræ, were settled upon the dorsal column; their arched part left only a small space on each side between them and the vertebræ. The pleura, the mediastines, the large vessels, the aspera arteria, and even the lungs and the heart, were no longer distinguishable; but for the most part had entirely disappeared, and in their place nothing was seen but some parcels of the fatty substance. In this case, the matter which was the product of decomposition of the viscera, charged with blood and various humours, differs from that of the surface of the body, and the long bones, in the red or brown colour possessed by the former. Sometimes the observers found in the thorax a mass irregularly rounded of the same nature as the latter, which appeared to them to have arisen from the fat and fibrous substance of the heart. They supposed that this mass, not constantly found in all the subjects, owed its existence to a superabundance of fat in this viscus, where it was found. For the general observation presented itself, that in similar circumstances, the fat parts undergo this conversion more evidently than the others, and afford a larger quantity of the white matter.

The external region in females exhibited the glandular and adipose mass of the breasts converted into the fatty matter very white and very homogeneous.

The head was, as has already been remarked, environed with the fatty matter; the face was no longer distinguishable in the greatest number of subjects; the mouth disorganized exhibited neither tongue nor palate; and the jaws, luxated and more or less displaced, were environed with irregular layers of the white matter. Some pieces of the same matter usually occupied the place of the parts situated in the mouth; the cartilages of the nose participated in the general alteration of the skin; the orbits instead of eyes contained white masses; the ears were equally disorganized; and the hairy scalp, having undergone a similar alteration to that of the other organs, still retained the hair. Mr. Fourcroy remarks incidentally, that the hair appears to resist every alteration much longer than any other part of the body. The cranium constantly contained the brain contracted in bulk; blackish at the surface, and absolutely changed like the other organs. In a great number of subjects which were examined this viscus was never found wanting, and it was always in the above-mentioned state; which proves that the substance of the brain is greatly disposed to be converted into the fat matter.

Such was the state of the bodies found in the burial-ground des Innocens. Its modifications were also various. Its consistence in bodies lately changed, that is to say, from three to five years, was soft and very ductile; containing a great quantity of water. In other subjects converted into this matter for a long time, such as those which occupied the cavities which had been closed thirty or forty years, this matter is drier, more brittle, and in denser flakes. In several which were deposited in dry earth, various portions of the fatty matter had become semi-transparent. The aspect, the granulated texture, and brittleness of this dried matter bore a considerable resemblance to wax.

The period of the formation of this substance had likewise an influence on its properties. In general, all that which had been formed for a long time was white, uniform, and contained no foreign substance, or fibrous remains; such, in particular, was that afforded by the skin of the extremities. On the contrary, in bodies recently changed, the fatty matter was neither so uniform nor so pure as in the former; but it was still found to contain portions of muscles, tendons, and ligaments, the texture of which, though already altered and changed in its colour, was still distinguishable. Accordingly, as the conversion was more or less advanced, these fibrous remains were more or less penetrated with the fatty matter, interposed as it were between the interstices of the fibres. This observation shows, that it is not merely the fat which is thus changed, as was natural enough to think at first sight. Other facts confirm this assertion. The skin, as has been remarked, becomes easily converted into very pure white matter, as does likewise the brain, neither of which has been considered by anatomists to be fat. It is true, nevertheless, that the unguinous parts, and bodies charged with fat, appear more easily and speedily to pass to the state under consideration. This was seen in the marrow, which occupied the cavities of the longer bones. And again, it is not to be supposed, but that the greater part of these bodies had been emaciated by the illness which terminated their lives; notwithstanding which they were all absolutely turned into this fatty substance.

An experiment made by Mr. Poulletier de la Salle, and Fourcroy likewise, evinced that a conversion does not take place in the fat alone. Mr. Poulletier had suspended in his laboratory a small piece of the human liver, to observe what would arise to it by the contact of the air. It partly putrefied, without however emitting any very noisome smell. Larvæ of the dermestes and bruchus attacked and penetrated it in various directions; at last it became dry, and after more than ten years suspension, it was converted into a white friable substance resembling dried agaric, which might have been taken for an earthy substance. In this state it had no perceptible smell. Mr. Poulletier was desirous of knowing the state of this animal matter, and experiment soon convinced him and Mr. F., that it was very far from being in the state of an earth. It melted by heat, and exhaled in the form of vapour, which had the smell of a very fetid fat; spirit of wine separated a concrescible oil, which appeared to possess all the properties of spermaceti. Each of the three alkalis converted it into soap, and in a word it exhibited all the properties of the fatty matter of the burial-ground of the Innocents exposed for several months to the air. Here then was a glandular organ, which in the midst of the atmosphere had undergone a change similar to that of the bodies in the burying-place; and this fact sufficiently shows, that an animal substance which is very far from being of the nature of grease may be totally converted into this fatty substance.

Among the modifications of this femarkable substance in the burying-ground before mentioned, it was observed that the dry, friable, and brittle matter was most commonly found near the surface of the earth, and the soft ductile matter at a greater depth. Mr. Fourcroy remarks, that this dry matter did not differ from the other merely in containing less water, but likewise by the volatilization of one of its principles.

The grave diggers assert, that near three years are required to convert a body into this fatty substance. But Dr. Gibbes of Oxford found, that lean beef secured in a running stream was converted into this fatty matter at the end of a month. He judges from facts, that running water is most favourable to this process. He took three lean pieces of mutton, and poured on each a quantity of the three ancient mineral acids. At the end of three days, each was much changed: that in the nitric acid was very soft, and converted into the fatty matter; that in the muriatic acid was not in that time so much altered; the sulphuric acid had turned the other black. Mr. Lavoisier thinks that this process may hereafter prove of great use in society. It is not easy to point out what animal substance, or what situation, might be the best adapted for an undertaking of this kind. Mr. L. points out fecal matters; but I have not heard of any conversion having taken place in these animal remains, similar to that of the foregoing.

The result of Mr. Fourcroy's inquiries into the ordinary changes of bodies recently deposited in the earth was not very extensive. The grave-diggers informed him, that these bodies interred do not perceptibly change colour for the first seven or eight days; that the putrid process disengages elastic fluid, which inflates the abdomen, and at length bursts it; that this event instantly causes vertigo, faintness, and nausea in such persons as unfortunately are within a certain distance of the scene where it takes place; but that when the object of its action is nearer, a sudden privation of sense, and frequently death, is the consequence. These men are taught by experience, that no immediate danger is to be feared from the disgusting business they are engaged in, excepting at this period, which they regard with the utmost terror. They resisted every inducement and persuasion, which these philosophers made use of, to prevail on them to assist their researches into the nature of this active and pernicious vapour. Mr. Fourcroy takes occasion from these facts, as well as from the pallid and unwholesome appearance of the grave-diggers, to reprobate burials in great towns or their vicinity.

Such bodies as are interred alone in the midst of a great quantity of humid earth are totally destroyed by passing through the successive degrees of the ordinary putrefaction; and this destruction is more speedy, the warmer the temperature. But if these insulated bodies be dry and emaciated; if the place of deposition be likewise dry, and the locality and other circumstances such, that the earth, so far from receiving moisture from the atmosphere, becomes still more effectually parched by the solar rays;—the animal juices are volatilized and absorbed, the solids contract and harden, and a peculiar species of mummy is produced. But every circumstance is very different in the common burying-grounds. Heaped together almost in contact, the influence of external bodies affects them scarcely at all, and they become abandoned to a peculiar disorganization which destroys their texture, and produces the new and most permanent state of combination here described. From various observations which I do not here abridge, it was found, that this fatty matter was capable of enduring in these burying-places for thirty or forty years, and is at length corroded and carried off by the aqueous putrid humidity which there abounds.

Among other interesting facts afforded by the chemical examination of this substance, are the following from experiments by Mr. Fourcroy:

1. This substance is fused at a less degree of heat than that of boiling water, and may be purified by pressure through a cloth, which disengages a portion of fibrous and bony matter. 2. The process of destructive distillation by a very graduated heat was begun, but not completed on account of its tediousness, and the little promise of advantage it afforded. The products which came over were water charged with volatile alkali, a fat oil, concrete volatile alkali, and no elastic fluid during the time the operation was continued. 3. Fragments of the fatty matter exposed to the air during the hot and dry summer of 1786 became dry, brittle, and almost pulverulent at the surface. On a careful examination, certain portions were observed to be semi-transparent and more brittle than the rest. These possessed all the apparent properties of wax, and did not afford volatile alkali by distillation. 4. With water this fatty matter exhibited all the appearances of soap, and afforded a strong lather. The dried substance did not form the saponaceous combination with the same facility or perfection as that which was recent. About two thirds of this dried matter separated from the water by cooling, and proved to be the semi-transparent substance resembling wax. This was taken from the surface of the soapy liquor, which being then passed through the filter left a white soft shining matter, which was fusible and combustible. 5. Attempts were made to ascertain the quantity of volatile alkali in

this substance by the application of lime, and of the fixed alkalis, but without success. For it was difficult to collect and appretiate the first portions which escaped, and likewise to disengage the last portions. The caustic volatile alkali, with the assistance of a gentle heat, dissolved the fatty matter, and the solution became perfectly clear and transparent at the boiling temperature of the mixture, which was at 18 .° F. 6. Sulphuric acid, of the specific gravity of 2·0, was poured upon six times its weight of the fatty matter, and mixed by agitation. Heat was produced, and a gas or effluvium of the most insupportable putrescence was emitted, which infected the air of an extensive laboratory for several days. Mr. Fourcroy says that the smell cannot be described, but that it is one of the most horrid and repulsive that can be imagined. It did not, however, produce any indisposition either in himself or his assistants. By dilution with water, and the ordinary processes of evaporation and cooling properly repeated, the sulphats of ammonia and of lime were obtained. A substance was separated from the liquor, which appeared to be the waxy matter somewhat altered by the action of the acid. 7. The nitrous and muriatic acids were also applied, and afforded phænomena worthy of remark, but which for the sake of conciseness are here omitted. 8. Alcohol does not act on this matter at the ordinary temperature of the air. But by boiling it dissolves one third of its own weight, which is almost totally separable by cooling as low as 55°. The alcohol, after this process, affords by evaporation a portion of that waxy matter which is separable by acids, and is therefore the only portion soluble in cold alcohol. The quantity of fatty matter operated on, was four ounces, or 2304 grains, of which the boiling spirit took up the whole except 26 grains, which proved to be a mixture of 20 grains of ammoniacal soap, and six or eight grains of the phosphats of soda and of lime. From this experiment, which was three times repeated with similar results, it appears that alcohol is well suited to afford an analysis of the fatty matter. It does not dissolve the neutral salts; when cold it dissolves that portion of concrete animal oil from which the volatile alkali had flown off, and when heated it dissolves the whole of the truly saponaceous matter, which is afterwards completely separated by cooling. And accordingly it was found, that a thin plate of the fatty matter, which had lost nearly the whole of its volatile alkali, by exposure to the air for three years, was almost totally dissolved by the cold alcohol.

The concrete oily or waxy substance obtained in these experiments constitutes the leading object of research, as being the peculiar substance with which the other well known matters are combined. It separates spontaneously by the action of the air, as well as by that of acids. These last separate it in a state of greater purity, the less disposed the acid may be to operate in the way of combustion. It is requisite, therefore, for this purpose, that the fatty matter should be previously diffused in 12 times its weight of hot water; and the muriatic or acetous acid is preferable to the sulphuric or the nitrous. The colour of the waxy matter is grayish; and though exposure to the air, and also the action of the oxigenated muriatic acid did produce an apparent whiteness, it nevertheless disappeared by subsequent fusion. No method was discovered by which it could be permanently bleached.

The nature of this wax or fat is different from that of any other known substance of the like kind. When slowly cooled after fusion, its texture appears crystalline or shivery, like spermaceti; but a speedy cooling gives it a semitransparency resembling wax. Upon the whole, nevertheless, it seems to approach more nearly to the former than to the latter of these bodies. It has less smell than spermaceti, and melts at 127° F.; Dr. Bostock says 92°. Spermaceti requires 6° more of heat to fuse it (according to Dr. Bostock 20°). The spermaceti did not so speedily become brittle by cooling as the adipocere. One ounce of alcohol of the strength between 39 and 40 degrees of Baumé's areometer, dissolved when boiling hot 12 gros of this substance, but the same quantity in like circumstances dissolved only 30 or 36 grains of spermaceti. The separation of these matters was also remarkably different, the spermaceti being more speedily deposited, and in a much more regular and crystalline form. Ammonia dissolves with singular facility, and even in the cold, this concrete oil separated from the fatty matter; and by heat it forms a transparent solution, which is a true soap. But no excess of ammonia can produce such an effect with spermaceti.

Mr. Fourcroy concludes his memoir with some speculations on this change to which animal substances in peculiar circumstances are subject. In the modern chemistry, soft animal matters are considered as a composition of the oxides of hidrogen and carbonated azot, more complicated than those of vegetable matters, and therefore more incessantly tending to alteration. If then the carbon be conceived to unite with the oxigen, either of the water which is present, or of the other animal matters, and thus escape in large quantities in the form of carbonic acid gas, we shall perceive the reason why this conversion is attended with so great a loss of weight, namely, about nine tenths of the whole. The azot, a principle so abundant in animal matters, will form ammonia by combining with the hidrogen; part of this will escape in the vaporous form, and the rest will remain fixed in the fatty matter. The residue of the animal matters deprived of a great part of their carbon, of their oxigen, and the whole of their azot, will consist of a much greater proportion of hidrogen, together with carbon and a minute quantity of oxigen. This, according to the theory of Mr. Fourcroy, constitutes the waxy matter, or adipocere, which in combination with ammonia forms the animal soap, into which the dead bodies are thus converted.

Muscular fibre macerated in dilute nitric acid, and afterward well washed in warm water, affords pure adipocere, of a light yellow colour, nearly of the consistence of tallow, of a homogeneous texture, and of course free from ammonia. This is the mode in which it is now commonly procured for chemical experiment.

Ambergris appears to contain adipocere in large quantity, rather more than half of it being of this substance.—*Annales de Chimie.*—*Phil. Trans.*—*Journ. of Nat. Phil. Chem. and the Arts.*

Adopter. A vessel with two necks placed between a retort and a receiver, and serving to increase the length of the neck of the former. See Laboratory.

Ætites, or **Eagle Stone**, is a name that has been given to a kind of hollow geodes of oxide of iron, often mixed with a larger or smaller quantity of silex and alumine, containing in their cavity some concretions, which rattle on shaking the stone. It is of a dull pale colour, composed of concentric layers of various magnitudes, of an oval or polygonal form, and often polished. Eagles were said to carry them to their nests, whence their name; and superstition formerly ascribed wonderful virtues to them.

Affinity (Chemical). See Attraction (Elective).

Agaricus. The mushroom, a genus of the order Fungi. Mushrooms appear to approach nearer to the nature of animal matter, than any other productions of the vegetable kingdom, as, beside hidrogen, oxigen, and carbon, they contain a considerable portion of nitrogen, and yield ammonia by distillation. Prof. Proust has likewise discovered in them the benzoic acid, and phosphat of lime.

A few of the species are eaten in this country, but many are recorded to have produced poisonous effects; though in some foreign countries, particularly by Russia, few if any are rejected. Perhaps it is of importance, that they should be fresh, thoroughly dressed, and not of a coriaceous texture. The Russians, however, are very fond of the *A. piperatus*, which we deem poisonous, preserved with salt throughout the winter: and our *ketchup* is made by sprinkling mushrooms with salt, and letting them stand till great part is resolved into a brown liquor, which is then boiled up with spices. The *A. piperatus* has been recommended in France to consumptive people. The *A. muscarius* has been prescribed in doses of a few grains in cases of epilepsy and palsy, subsequent to the drying up of eruptions.

In pharmacy two species of *Boletus* have formerly been used under the name of agaric. The *B. pini laricis*, or *male agaric* of the shops, was given as a purgative, either in substance, or in an extract made with vinegar, wine, or an alkaline solution: and the *B. igniarius*, spunk, or touchwood, called female agaric, was applied externally as a styptic, even after amputations. For this purpose the soft inner substance was taken, and beaten with a hammer to render it still softer. That of the oak was preferred. The Germans boil this in lye, dry it, and boil it again in a solution of nitrat of potash, to use as tinder.

Agaricus Mineralis, the *mountain milk*, or *mountain meal*, of the Germans, is one of the purest of the native carbonats of lime, found chiefly in the clefts of rocks, and at the bottom of some lakes, in a loose or semi-indurated form. It has been used internally in hæmorrhages, strangury, gravel, and dysenteries; and externally as an application to old ulcers, and weak and watery eyes.

Mr. Fabroni calls by the name of *mineral agaric*, or *fossil meal*, a stone of a loose consistence found in Tuscany in considerable abundance, of which bricks may be made, either with or without the addition of a twentieth part of argil, so light as to float in water; and which he supposes the ancients used for making their floating bricks. This, however, is very different from the preceding, not being even of the calcareous genus, since it appears on analysis to consist of silex 55 parts, magnesia 15, water 14, argil 12, lime 3, iron 1. Kirwan calls it *argillo-murite*.

Agate. The oriental agate is almost transparent, and of a vitreous appearance. The occidental is of various colours, and often veined with quartz or jasper. It is mostly found in small pieces covered with a crust, and often running in veins through rocks like flint and petrosilex, from which it does not seem to differ greatly. When agates contain arborisations they are called mocha stone. These are considerably valued when the internal figure nearly resembles some animal or plant.

Aggregate. When bodies of the same kind are united, the only consequence is, that one larger body is produced. In this case, the united mass is called an aggregate, and does not differ in its chemical properties from the bodies from which it was originally made. Elementary writers call the smallest parts into which an aggregate can be divided without destroying its chemical properties, integrant parts. Thus the integrant parts of common salt are the smallest parts which can be conceived to remain without change; and beyond these, any further subdivision cannot be made without developing the component parts, namely, the alkali and the acid; which are still further resolvable into their constituent principles.

Air was till lately used as the generic name for such invisible and exceedingly rare fluids as possess a very high degree of elasticity, and are not condensable into the liquid state by any degree of cold hitherto produced: but as this term is commonly employed to signify that compound of aëriform fluids which constitutes our atmosphere, it has been deemed advisable to restrict it to this signification, and to employ as the generic term the word Gas, (which see,) for the different kinds of air, except what relates to our atmospheric compound.

Air (Atmospherical, or Common). The immense mass of permanently elastic fluid, which surrounds the globe we inhabit, must consist of a general assemblage of every kind of air which can be formed by the various bodies that compose its surface. Most of these, however, are absorbed by water; a number of them are decomposed by combination with each other; and some of them are seldom disengaged in considerable quantities by the processes of nature. Hence it is that the lower atmosphere consists chiefly of oxigen and nitrogen, together with moisture and the occasional vapours or exhalations of bodies. The upper atmosphere seems to be composed of a large proportion of hidrogen, a fluid of so much less specific gravity than any other, that it must naturally ascend to the highest place, where being occasionally set on fire by electricity, it appears to be the cause of the aurora borealis and fire-balls. It may easily be understood, that this will only happen on the confines of the respective masses of common atmospherical air, and of the inflammable air; that the combustion will extend progressively, though rapidly, in flashings from the place where it commences; and that when by any means a stream of inflammable air, in its progress toward the upper atmosphere, is set on fire at one end, its ignition may be much more rapid than what happens higher up, where oxigen is wanting, and at the same time more definite in its figure and progression, so as to form the appearance of a fire-ball.

That the air of the atmosphere is so transparent as to be invisible, except by the blue colour it reflects when in very large masses, as is seen in the sky or region above us, or in viewing extensive landscapes; that it is without smell, except that of electricity, which it sometimes very manifestly exhibits; altogether without taste, and impalpable; not condensable by any degree of cold into the dense fluid state, though easily changing its dimensions with its temperature; that it gravitates and is highly elastic, are among the numerous observations and discoveries, which do honour to the sagacity of the philosophers of the seventeenth century. They likewise knew that this fluid is indispensably necessary to combustion: but no one, except the great, though neglected, John Mayow, appears to have formed any proper notion of its manner of acting in that process.

The air of the atmosphere, like other fluids, appears to be capable of holding bodies in solution. It takes up water in considerable quantities, with a diminution of its own specific gravity; from which circumstance, as well as from the consideration that water rises very plentifully in the vaporous state in vacuo, it seems probable, that the air suspends vapour, not so much by a real solution, as by keeping its particles asunder, and preventing their condensation. Water likewise dissolves or absorbs air.

Mere heating or cooling does not affect the chemical properties of atmospherical air; but actual combustion, or any process of the same nature, destroys its oxigen, and leaves its nitrogen separate. Whenever a process of this kind is carried on in a vessel containing atmospherical air, which is enclosed either by inverting the vessel over mercury, or by stopping its aperture in a proper manner, it is found that the process ceases after a certain time; and that the remaining air, which is about three-fourths of the whole bulk, is of such a nature as to be incapable of maintaining any combustion for a second time, or of supporting the life of animals. From these experiments it is clear, that one of the following deductions must be true: 1. The combustible body has emitted some principle, which, by combining with the air, has rendered it unfit for the purpose of further combustion: or, 2. It has absorbed part of the air which was fit for that purpose, and has left a residue of a different nature: or, 3. Both events have happened; namely, that the pure part of the air has been absorbed, and a principle has been emitted, which has changed the original properties of the remainder.

The facts must clear up these theories. The first induction cannot be true, because the residual air is not only of less bulk, but of less specific gravity, than before. The air cannot therefore have received so much as it has lost. The second is the doctrine of the philosophers, who deny the existence of phlogiston, or a principle of inflammability: and the third must be adopted by those who maintain that such a principle escapes from bodies during combustion. This residue was called phlogisticated air in consequence of such an opinion.

In the opinion that inflammable air is the phlogiston, it is not necessary to reject the second inference, that the air has been no otherwise changed than by the mere subtraction of one of its principles: for the pure or vital part of the air may unite with inflammable air supposed to exist in a fixed state in the combustible body; and if the product of this union still continues fixed, it is evident, that the residue of the air after combustion will be the same as it would have been, if the vital part had been absorbed by any other fixed body. Or, if the vital air be absorbed, while inflammable air or phlogiston is disengaged, and unites with the aëriform residue, this residue will not be heavier than before, unless the inflammable air it has gained exceeds in weight the vital air it has lost; and if the inflammable air falls short of that weight, the residue will be lighter.

These theories it was necessary to mention; but it has been sufficiently proved by various experiments, that combustible bodies take oxigen from the atmosphere, and leave nitrogen; and that when these two fluids are again mixed, in due proportions, they compose a mixture not differing from atmospherical air.

The respiration of animals produces the same effect on atmospherical air as combustion does, and their constant heat appears to be an effect of the same nature. When an animal is included in a limited quantity of atmospherical air, it dies as soon as the oxigen is consumed; and no other air will maintain animal life but that which maintains combustion; that is to say oxigen, or a mixture which contains it. Pure oxigen maintains the life of animals much longer than atmospherical air.

There are many provisions in nature by which the proportion of oxigen in the atmosphere, which is continually absorbed in respiration and combustion, is again restored to that fluid In fact there appears, as far as an estimate can be formed of the great and general operations of nature, to be at least as great an absorption of the nitrogen and emission of oxigen, as is sufficient to keep the general mass of the atmosphere at the same degree of purity. Thus, in volcanic eruptions there seems to be at least as much oxigen emitted or extricated by fire from various minerals, as is sufficient to maintain the combustion, and perhaps even to meliorate the atmosphere. And in the bodies of plants and animals, which appear in a great measure to derive their sustenance and augmentation from the atmosphere and its contents, it is found that a large proportion of nitrogen exists. Most plants emit oxigen in the sunshine, from which it is highly probable that they imbibe and decompose the air of the atmosphere, retaining its noxious part, and emitting the vital part. Lastly, if to this we add the decomposition of water, there will be numerous occasions in which this fluid will supply us with disengaged oxigen; while by a very rational supposition its hidrogen may be considered as having entered into the bodies of plants for the formation of oils, sugars, mucilages, &c., from which it may be again extricated.

To determine the respirability or purity of air, it is evident that recourse must be had to its comparative efficacy in maintaining combustion, or some other equivalent process. This subject will be considered under the article EUDIOMETER.

From the latest and most accurate experiments, the proportion of oxigen in atmospheric air is by measure about 21·5 per cent.; and it appears to be very nearly the same, whether it be in this country or on the coast of Guinea, on low plains or lofty mountains, or even at the height of 7250 yards above the level of the sea, as ascertained by Gay-Lussac in his aërial voyage in September 1805. The remainder of the air is nitrogen; with a small portion of aqueous vapour, amounting to about 1·4 per cent in the driest weather; and a still less portion of carbonic acid, not exceeding a thousandth part of the whole.

As oxigen and nitrogen differ in specific gravity in the proportion of 135 to 121, according to Kirwan, and of 139 to 120 according to Davy, it has been presumed, that the oxigen would be more abundant in the lower regions, and the nitrogen in the higher, if they constituted a mere mechanical mixture; which appears contrary to the fact. On the other hand it has been urged, that they cannot be in the state of chemical combination, because they both retain their distinct properties unaltered, and no change of temperature or density takes place on their union. But perhaps it may be said, that, as they have no repugnance to mix with each other, as oil and water have, the continual agitation, to which the atmosphere is exposed, may be sufficient to prevent two fluids, differing not more than oxigen and nitrogen in gravity from separating by subsidence, though simply mixed. On the contrary it may be argued, that to say chemical combination cannot take place, without producing new properties, which did not exist before in the component parts, is merely begging the question: for though this generally appears to be the case, and often in a very striking manner, yet combination does not always produce a change of properties; as appears in Mr. Biot's experiments with various substances, of which we may instance water, the refraction of which is precisely the mean of the oxigen and hidrogen, which are indisputably combined in it.

To get rid of the difficulty, Mr. Dalton of Manchester framed an ingenious hypothesis, that the particles of different gasses neither attract nor repel each other; so that one gas expands by the repulsion of its own particles, without any more interruption from the presence of another gas, than if it were in a vacuum. This would account for the state of atmospheric air, it is true; but it does not agree with certain facts. In the case of the carbonic acid gas in the Grotto del Cano, and over the surface of brewers' vats, why does not this gas expand itself freely upward, if the superincumbent gasses do not press upon it? Mr. Dalton himself too instances as an argument for his hypothesis, that oxigen and hidrogen gasses, when mixed by agitation, do not separate on standing: but why should either oxigen or hidrogen require agitation, to diffuse it through a vacuum, in which according to Mr. Dalton it is placed?—*C.*

The theory of Berthollet, which is also that of Mr. Murray, appears consistent with all the facts, and sufficient to account for the phænomenon. If two bodies be capable of chemical combination, their particles must have a mutual attraction for each other. This attraction, however, may be so opposed by concomitant circumstances, that it may be diminished in any degree. Thus we know, that the affinity of aggregation may occasion a body to combine slowly with a substance for which it has a powerful affinity, or even entirely prevent its combining with it: the presence of a third substance may equally prevent the combination: and so may the absence of a certain quantity of caloric. But in all these cases the attraction of the particles must subsist, though diminished or counteracted by opposing circumstances. Now we know that oxigen and nitrogen are capable of combination; their particles, therefore, must attract each other: but in the circumstances in which they are placed in our atmosphere, that attraction is prevented from exerting itself to such a degree as to form them into a chemical compound, though it operates with sufficient force to prevent their separating by their difference of specific gravity. Thus the state of the atmosphere is accounted for, and every difficulty obviated, without any new hypothesis.

Alabaster. Among the stones which are known by the name of marble, and have been distinguished by a considerable variety of denominations by statuaries, and others whose attention is more directed to their external characters and appearance than their component parts, alabasters are those which have a greater or less degree of imperfect transparency, a granular texture, are softer, take a duller polish than marble, and are usually of a white colour. Some stones, however, of a veined and coloured appearance, have been considered as alabasters, from their possessing the first mentioned criterion; and some transparent and yellow sparry stones have also received this appellation.

Chemists are at present agreed in applying this name only to such opake, consistent and semitransparent stones, as are composed of lime united with the sulphuric acid. But the term is much more frequent among masons and statuaries than chemists. Chemists in general confound the alabasters among the selenites, gypsums, or plaster of Paris, more especially when they allude only to the component parts, without having occasion to consider the external appearance, in which only these several compounds differ from each other.

As the semiopake appearance and granular texture arise merely from a disturbed or successive crystallization, which would else have formed transparent spars, it is accordingly found, that the calcareous stalactites, or drop-stones, formed by the transition of water through the roofs of caverns in a calcareous soil, do not differ in appearance from the alabaster, most of which is also formed in this manner. But the calcareous stalactites here spoken of consist of calcareous earth and carbonic acid; while the alabaster of the chemists is formed of the same earth and sulphuric acid, as has already been remarked.

Album Græcum. Innumerable are the instances of fanciful speculation, and absurd credulity, in the invention and application of subjects in the more ancient materia medica. The white and solid excrement of dogs, which subsist chiefly on bones, has been received as a remedy in the medical art, under the name of Album Græcum. It consists, for the most part, of the earth of bones, or lime in combination with phosphoric acid.

Albumen. This substance, which derives its name from the Latin for the white of an egg, in which it exists abundantly and in its purest natural state, is one of the chief constituent principles of all the animal solids. Beside the white of egg it abounds in the serum of blood, the vitreous and crystalline humours of the eye, and the fluid of dropsy. Fourcroy claims to himself the honour of having discovered it in the green feculæ of plants in general, particularly in those of the cruciform order, in very young ones, and in the fresh shoots of trees: though Rouelle appears to have detected it there long before. Vauquelin says it exists also in the mineral water of Plombieres.

Mr. Seguin has found it in remarkable quantity in such vegetables as ferment without yeast, and afford a vinous liquor; and from a series of experiments he infers, that albumen is the true principle of fermentation, and that its action is more powerful in proportion to its solubility, three different degrees of which he found it to possess.

The chief characteristic of albumen is its coagulability by the action of heat. If the white of an egg be exposed to a heat of about 134° F. white fibres begin to appear in it, and at 160° it coagulates into a solid mass. In a heat not exceeding 212° it dries, shrinks, and assumes the appearance of horn. It is soluble in cold water, before it has been coagulated, but not after; and when diluted with a very large portion it does not coagulate easily. Pure alkalies dissolve it, even after coagulation. Alcohol occasions an imperfect coagulation of it, leaving it still soluble in cold water. It is precipitated by muriat of mercury, nitro-muriat of tin, acetat of lead, nitrat of silver, muriat of gold, infusion of galls, and tannin. The acids and metallic oxides coagulate albumen. On the addition of concentrated sulphuric acid, it becomes black and exhales a nauseous smell. Strong muriatic acid gives a violet tinge to the coagulum, and at length becomes saturated with ammonia. Nitric acid, at 70° F., disengages from it abundance of azotic gas; and if the heat be increased prussic acid is formed, after which carbonic acid and carbonated hidrogen are evolved, and the residue consists of water containing a little oxalic acid, and covered with a lemon-coloured fat oil. If dry potash or soda be triturated with albumen, either liquid or solid, ammoniacal gas is evolved, and the calcination of the residuum yields an alkaline prussiat.

On exposure to the atmosphere in a moist state albumen passes at once to the state of putrefaction.

From its coagulability albumen is of great use in clarifying liquids. See CLARIFICATION.

It is likewise remarkable for the property of rendering leather supple, for which purpose a solution of whites of eggs in water is used by leather-dressers; and hence Dr. Lobb, of Yeovil in Somersetshire, was induced to employ this solution in cases of contraction and rigidity of the tendons, and derived from it the desired success.

Whites of eggs beaten in a basin with a lump of alum, till they coagulate, form the *alum curd* of Riverius, or *alum cataplasm* of the London Pharmacopœia, used to remove inflammations of the eyes.—*Fourcroy.*—*Ann. de Chim.*—*Mem. de l'Instit. Nation.*—*Journ. de Physique.*

ALCHEMY. The practice of chemistry, comprehending every operation which is not mechanical, must of course have been among the earliest consequences of those efforts of the human mind, which supply our wants, and distinguish civilized nations from the uncultivated. The various arts dependent upon this science were practised for ages, before the systematic reasoning and inferences of philosophers had traced its dependencies, and formed the science itself. Immediate profit is the object of pursuit in those who practise the arts; and while the several branches of chemical operation continued to be mere arts, their professors or practisers had in general no other views. It could not but happen, however, that men of abilities would be found among these professors, who would reason well or ill upon what they saw; and as all reasoning with regard to natural appearances consists chiefly in the classing of similar phænomena, and deducing other events from them by analogy, it would follow of course, that these men would discover rules, and establish general observations, by means of which their operations would be facilitated and extended. The spirit of trade would nevertheless intermix itself with their speculations, and lead them to consider their discoveries as lucrative secrets, not to be communicated but to others of the same profession, whose successful researches had enabled them to afford other secrets in return. Thus it was that philosophical chemistry had its birth: in its infancy it was alchemy, a science whose professors were tradesmen dazzled at the fruitful and extensive consequences to which their researches seemed to lead; looking down upon and despising the common operator, who possessed no clew to lead him beyond the ordinary course of his business; and extolling their own knowledge, which, from vanity as well as motives of profit, they either kept to themselves, or communicated in mysterious and enigmatical writings. The earliest philosophical writers on chemistry were alchemists, and distinguished themselves from common chemists by this appellation. As the true methods of philosophizing became better known, and liberality of sentiment increased, chemistry became a science in the hands of men of better taste and more enlightened judgment. The writings of the alchemists and their elevated professions continued notwithstanding to have their effects upon many persons, and are not entirely without their influence at the present instant. The efficacy of chemical preparations for medical use proved sufficient for a long time to enforce a certain degree of credit in favour of a panacea, or universal medicine, powerful to cure all diseases; and a number of facts ill understood, and taken as the ground of extensive and plausible inferences, have induced numbers to believe, that metals might be transmuted into each other. This last operation was chiefly aimed at the transmutation of metals of inferior price into gold. The pretence is still used by artful persons to impose on the ignorant, and in some instances, perhaps, by the ignorant, who impose on themselves.

ALCOHOL. This term is applied in strictness only to the pure spirit obtainable by distillation and subsequent rectification from all liquids in a state of vinous fermentation, and from none but such as are susceptible of it. But it is commonly used to signify this spirit more or less imperfectly freed from water in the state in which it is usually met with in the shops; and in which, as it was first obtained from the juice of the grape, it was long distinguished by the name of spirit of wine. At present it is extracted chiefly from grain or melasses in Europe, and from the juice of the sugar-cane in the West Indies; and in the diluted state in which it commonly occurs in trade constitutes the basis of the several spirituous liquors called brandy, rum, gin, whiskey, and cordials, however variously denominated or disguised.

Lavoisier concluded from his experiments, that alcohol consisted of the same principles as sugar, oxigen, hidrogen, and carbon; only containing a much larger proportion of carbon. By transmission through an ignited porcelain tube it yields olefiant and hydro-carburet gases, with a small proportion of carbonic acid gas; and a portion of fine light sooty charcoal remains in the tube. Mr. Sage put into a glass retort, large enough to contain at least twelve times the quantity, one part of alcohol and three parts of nitrous acid, adapted the retort to a series of globular receivers not luted, and applied a slow heat to the sand bath containing the retort. At 100° of Fahr. the mixture was decomposed; an effervescence with large bubbles and red fumes of nitrous gas arose; the ether passed into the receivers with an explosion, and perfumed the laboratory. The fire being kept up, and the distillation continued, till about a thirty-second part of the mixture remained, the whole was left to cool, when beautiful crystals of oxalic acid in tetraëdral prisms were found at the bottom of an acidulous water. From sixteen ounces of alcohol Mr. Sage thus obtained one ounce and four scruples of oxalic acid. During the combustion of alcohol a quantity of water exceeding the alcohol in weight is produced, and carbonic acid is generated.

We are neither able to compound alcohol immediately from its constituent principles, nor to obtain it directly in a pure state from the fluids in which it is contained: so that we are obliged to have recourse to the process of fermentation, by which its principles are first extricated from the substances in which they were combined, and then united into a new compound; to distillation, by which this new compound, the alcohol, is separated in a state of dilution with water, and contaminated with essential oil; and to rectification, by which it is ultimately freed from these.

It appears to be essential to the fermentation of alcohol, that the fermenting fluid should contain saccharine matter, which is indispensable to that species of fermentation called vinous. In France, where a great deal of wine is made, particularly at the commencement of the vintage, that is too weak to be a saleable commodity, it is a common practice to subject this wine to distillation, in order to draw off the spirit; and as the essential oil that rises in this process is of a more pleasant flavour than that of malt or melasses, the French brandies are preferred to any other; though even in the flavour of these there is a difference according to the wine from which they are produced. In the West Indies a spirit is obtained from the juice of the sugar-cane, which is highly impregnated with its essential oil, and well known by the name of *rum*. The distillers in this country use grain, or melasses, whence they distinguish the products by the name of *malt spirits*, and *melasses spirits*. It is said that a very good spirit may be extracted from the husks of gooseberries or currants, after wine has been made from them.

As the process of malting develops the saccharine principle of grain, it would appear to render it fitter for the purpose; though it is the common practice to use about three parts of raw grain with one of malt. For this two reasons may be assigned: by using raw grain the expense of malting is saved, as well as the duty on malt; and the process of malting requires some nicety of attention, since, if it be carried too far, part of the saccharine matter is lost, and if it be stopped too soon, this matter will not be wholly developed. Besides, if the malt be dried too quickly, or by an unequal heat, the spirit it yields will be less in quantity and more unpleasant in flavour. Another object of œconomical consideration is, what grain will afford the most spirit in proportion to its price, as well as the best in quality. Barley appears to produce less spirit than wheat; and if three parts of raw wheat be mixed with one of malted barley, the produce is said to be particularly fine. This is the practice of the distillers in Holland for producing a spirit of the finest quality; but in England they are expressly prohibited from using more than one part of wheat to two of other grain. Rye however affords still more spirit than wheat.

Whatever be the grain employed, it may be coarsely ground, and then mixed carefully with a little cold water, to prevent its running into lumps; water about 90° F. may then be added, till it is sufficiently diluted; and lastly a sufficient quantity of yeast. The whole is then to be allowed to ferment in a covered vessel, to which however the air can have access. Attention must be paid to the temperature; for if it exceed 77° F. the fermentation will be too rapid; if it be below 60° the fermentation will cease. The mean between these will generally be found most favourable. In this country it is the more common practice to mash the grain as for brewing malt liquors, and boil the wort. But in whichever way it be prepared, or if the *wash*, so the liquor intended for distillation is called, be made from melasses and water, due attention must be paid to the fermentation, that it be continued till the liquor grows fine, and pungent to the taste, which will generally be about the third day, but not so long as to permit the acetous fermentation to commence.

In this state the wash is to be committed to the still, of which, including the head, it should occupy at least three-fourths; and distilled with a gentle heat as long as any spirit comes over, which will be till about half the wash is consumed. The more slowly the distillation is conducted, the less will the product be contaminated with essential oil, and the less danger will there be of empyreuma. A great saving of time and fuel, however, may be obtained, by making the still very broad and shallow, and contriving a free exit for the steam. This has been carried to such a pitch in Scotland, that a still measuring 43 gallons, and containing 16 gallons of wash, has been charged and worked no less than four hundred and eighty times in the space of twenty-four hours. This would be incredible, were it not established by unquestionable evidence. See LABORATORY, article STILL.

The first product, technically termed *low wine*, is again to be subjected to distillation, the latter portions of what comes over, called *faints*, being set apart, to put into the wash still at some future operation. Thus a large portion of the watery part is left behind. This second product, termed *raw spirit*, being distilled again is called *rectified spirit*. It is calculated, that a hundred gallons of malt or corn wash will not produce above twenty of spirit, containing 60 parts of alcohol to 50 of water; the same of cider wash, 15 gallons; and of melasses wash, 22 gallons. The most spirituous wines of France, those of Languedoc, Guienne, and Rousillon, yield according to Chaptal from 20 to 25 gallons of excellent brandy from 100; but those of Burgundy and Champagne much less. Brisk wines, containing much carbonic acid, from the fermentation having been stopped at an early period, yield the least spirit.

The spirit thus obtained ought to be colourless, and free from any disagreeable flavour; and in this state it is fittest for pharmaceutical purposes, or the extraction of tinctures. But for ordinary sale something more is required. The brandy of France, which is most in esteem here, though perfectly colourless when first made, and often preserved so for use in that country by being kept in glass or stone bottles, is put into new oak casks for exportation, whence it soon acquires an amber colour, a peculiar flavour, and something like an unctuosity of consistence. As it is not only prized for these qualities, but they are commonly deemed essential to it, the English distiller imitates by design these accidental qualities. The most obvious and natural method of doing this would be by impregnating a pure spirit with the extractive, resinous, and colouring matter of oak shavings; but other modes have been contrived. The dulcified spirit of nitre, as it is called, is commonly used to give the flavour; and catechu, or burnt sugar, to impart the desired colour. A French writer has recommended three ounces and a half of finely powdered charcoal, and four ounces and a half of ground rice, to be digested for a fortnight in a quart of malt spirit.

The finest gin is said to be made in Holland from a spirit drawn from wheat mixed with a third or fourth part of malted barley, and twice rectified over juniper berries: but in general rye meal is used instead of wheat. They pay so much regard to the water employed, that many send vessels to fetch it on purpose from the Meuse: but all use the softest and clearest river water they can get. In England it is the common practice to add oil of turpentine, in the proportion of two ounces to ten gallons of raw spirit, with three handfuls of bay salt, and draw off till the faints begin to rise.

But corn or melasses spirit is flavoured likewise by a variety of aromatics, with or without sugar, to please different palates; all of which are included under the general technical term of *compounds*, or *cordials*.

Other articles have been employed, though not generally, for the fabrication of spirit, as carrots and potatoes; and we are lately informed by prof. Proust, that from the fruit of the carob tree he has obtained good brandy in the proportion of a pint from five pounds of the dried fruit.

To obtain pure alcohol different processes have been recommended; but the purest rectified spirit obtained as above described, being that which is least contaminated with foreign matter, should be employed. Rouelle recommends to draw off half the spirit in a water bath: to rectify this twice more, drawing off two thirds each time: to add water to this alcohol, which will turn it milky by separating the essential oil remaining in it: to distil the spirit from this water; and finally rectify it by one more distillation.

Baumé sets apart the first running, when about a fourth is come over, and continues the distillation till he has drawn off about as much more, or till the liquor runs off milky. The last running he puts into the still again, and mixes the first half of what comes over with the preceding first product. This process is again repeated, and all the first products being mixed together are distilled afresh. When about half the liquor is come over, this is to be set apart as pure alcohol.

Alcohol in this state, however, is not so pure as when, to use the language of the old chemists, it has been *dephlegmated*, or still further freed from water, by means of some alkaline salt. Boerhaave recommended for this purpose the muriate of soda, deprived of its water of crystallization by heat, and added hot to the spirit. But the subcarbonat of potash is preferable. About a third of the weight of the alcohol should be added to it in a glass vessel, well shaken, and then suffered to subside. The salt will be moistened by the water absorbed from the alcohol; which being decanted, more of the salt is to be added, and this is to be continued till the salt falls dry to the bottom of the vessel. The alcohol in this state will be reddened by a portion of the pure potash, which it will hold in solution, from which it must be freed by distillation in a water bath. Dry muriat of lime may be substituted advantageously for the alkali.

As alcohol is much lighter than water, its specific gravity is adopted as the test of its purity. Fourcroy considers it as rectified to the highest point when its specific gravity is 829, that of water being 1000: and perhaps this is nearly as far as it can be carried by the process of Rouelle or Baumé simply. Mr. Bories found the first measure that came over from twenty of spirit at 836 to be 820, at the temperature of 71° F. Sir Charles Blagden, by the addition of alkali, brought it to 813, at 60° F. Chaussier professes to have reduced it to 798; but he gives 998·35 as the specific gravity of water. Lowitz asserts, that he has obtained it at 791, by adding as much alkali as nearly to absorb the spirit; but the temperature is not indicated. In the shops it is about 835 or 840: according to the London College it should be 815.

It is by no means an easy undertaking to determine the strength or relative value of spirits, even with sufficient accuracy for commercial purposes. The following requisites must be obtained before this can be well done: the specific gravity of a certain number of mixtures of alcohol and water must be taken so near each other, as that the intermediate specific gravities may not perceptibly differ from those deduced from the supposition of a mere mixture of the fluids: the expansions or variations of specific gravity in these mixtures must be determined at different temperatures: some easy method must be contrived of determining the presense and quantity of saccharine or oleaginous matter which the spirit may hold in solution, and the effect of such solution on the specific gravity: and lastly, the specific gravity of the fluid must be ascertained by a proper floating instrument with a graduated stem, or set of weights; or, which may be more convenient, with both.

The strength of brandies in commerce is judged by the phial, or by burning. The phial proof consists in agitating the spirit in a bottle, and observing the form and magnitude of the bubbles that collect round the edge of the liquor, technically termed the *bead*, which are larger the stronger the spirit. These probably depend on the solution of resinous matter from the cask, which is taken up in greater quantities, the stronger the spirit. It is not difficult, however, to produce this appearance by various simple additions to weak spirit. The proof by burning is also fallacious; because the magnitude of the flame, and quantity of residue, in the same spirit, vary greatly with the form of the vessel it is burned in. If the vessel be kept cool, or suffered to become hot, if it be deeper or shallower, the results will not be the same in each case. It does not follow, however, but that manufacturers and others may in many instances receive considerable information from these signs, in circumstances exactly alike, and in the course of operations wherein it would be inconvenient to recur continually to experiments of specific gravity.

The importance of this object, as well for the purposes of revenue as of commerce, induced the British government to employ Dr. Blagden, now Sir Charles, to institute a very minute and accurate series of experiments. These may be considered as fundamental results; for which reason, I shall give a summary of them in this place, from the Philosophical Transactions for 1790.

The first object to which the experiments were directed was to ascertain the quantity and law resulting from the mutual penetration of water and spirit.

All bodies in general expand by heat; but the quantity of this expansion, as well as the law of its progression, is probably not the same in any two substances. In water and spirit they are remarkably different. The whole expansion of pure spirit from 30° to 100° of Fahrenheit's thermometer is not less than 1-25th of its whole bulk at 30°; whereas that of water, in the same interval, is only 1-145th of its bulk. The laws of their expansion are still more different than the quantities. If the expansion of quicksilver be, as usual, taken for the standard (our thermometers being constructed with that fluid), the expansion of spirit is, indeed, progressively increasing with respect to that standard, but not much so within the abovementioned interval; while water kept from freezing to 30°, which may easily be done, will absolutely contract as it is heated for ten or more degrees, that is, to 40° or 42° of the thermometer, and will then begin to expand as its heat is augmented, at first slowly, and afterward gradually more rapidly, so as to observe upon the whole a very increasing progression. Now, mixtures of these two substances will, as may be supposed, approach to the less or the greater of these progressions, according as they are compounded of more spirit or more water, while their total expansion will be greater, according as more spirit enters into their composition; but the exact quantity of the expansion, as well as law of the progression, in all of them, can be determined only by trials. These were, therefore, the two other principal objects to be ascertained by experiment.

The person engaged to make these experiments was Dr. Dollfuss, an ingenious Swiss gentleman then in London, who had distinguished himself by several publications on chemical subjects. As he could not conveniently get the quantity of spirit he wanted lighter than 825, at 60° F., he fixed upon this strength as the standard for alcohol.

These experiments of Dr. Dollfuss were repeated by Mr. Gilpin, clerk of the Royal Society; and as the deductions in this account will be taken chiefly from that last set of experiments, it is proper here to describe minutely the method observed by Mr. Gilpin in his operation. This naturally resolves itself into two parts: the way of making the mixtures, and the way of ascertaining their specific gravity.

1. The mixtures were made by weight, as the only accurate method of fixing the proportions. In fluids of such very unequal expansions by heat as water and alcohol, if measures had been employed, increasing or decreasing in regular proportions to each other, the proportions of the masses would have been sensibly irregular: now the latter was the object in view, namely, to determine the real quantity of spirit in any given mixture, abstracting the consideration of its temperature. Besides, if the proportions had been taken by measure, a different mixture should have been made at every different degree of heat. But the principal consideration was, that with a very nice balance, such as was employed on this occasion, quantities can be determined to much greater exactness by weight than by any practicable way of measurement. The proportions were therefore always taken by weight. A phial being provided of such a size as that it should be nearly full with the mixture, was made perfectly clean and dry, and being counterpoised, as much of the pure spirit as appeared necessary was poured into it. The weight of this spirit was then ascertained, and the weight of distilled water required to make a mixture of the intended proportions was calculated. This quantity of water was then added, with all the necessary care, the last portions being put in by means of a well-known instrument, which is composed of a small dish terminating in a tube drawn to a fine point: the top of the dish being covered with the thumb, the liquor in it is prevented from running out through the tube by the pressure of the atmosphere, but instantly begins to issue by drops, or a very small stream, upon raising the thumb. Water being thus introduced into the phial, till it exactly counterpoised the weight, which having been previously computed, was put into the opposite scale, the phial was shaken, and then well stopped with its glass stopple, over which leather was tied very tight, to prevent evaporation. No mixture was used till it had remained in the phial at least a month, for the full penetration to have taken place; and it was always well shaken before it was poured out to have its specific gravity tried.

2. There are two common methods of taking the specific gravity of fluids; one, by finding the weight which a solid body loses by being immersed in them; the other, by filling a convenient vessel with them, and ascertaining the increase of weight it acquires. In both cases a standard must have been previously taken, which is usually distilled water; namely, in the first method by finding the weight lost by the solid body in the water, and in the second method, the weight of the vessel filled with water. The latter was preferred for the following reasons:

When a ball of glass, which is the properest kind of solid body, is weighed in any spirituous or watery fluid, the adhesion of the fluid occasions some inaccuracy, and renders the balance comparatively sluggish. To what degree this effect proceeds is uncertain; but from some experiments made by Mr. Gilpin, with that view, it appears to be very sensible. Moreover, in this method a large surface must be exposed to the air during the operation of weighing, which, especially in the higher temperatures, would give occasion to such an evaporation as to alter essentially the strength of the mixture. It seemed also as if the temperature of the fluid under trial could be determined more exactly in the method of filling a vessel, than in the other; for the fluid cannot well be stirred while the ball to be weighed remains immersed in it; and as some time must necessarily be spent in the weighing, the change of heat which takes place during that period will be unequal through the mass, and may occasion a sensible error. It is true, on the other hand, that in the method of filling a vessel, the temperature could not be ascertained with the utmost precision, because the neck of the vessel employed, containing about ten grains, was filled up to the mark with spirit not exactly of the same temperature, as will be explained presently: but this error, it is supposed, would by no means equal the other, and the utmost quantity of it may be estimated very nearly. Finally, it was much easier to bring the fluid to any given temperature when it was in a vessel to be weighed, than when it was to have a solid body weighed in it; because in the former case the quantity was smaller, and the vessel containing it more manageable, being readily heated with the hand or warm water, and cooled with cold water: and the very circumstance, that so much of the fluid was not required, proved a material convenience. The particular disadvantage in the method of weighing in a vessel, is the difficulty of filling it with extreme accuracy; but when the vessel is judiciously and neatly marked, the error of filling will, with due care, be exceedingly minute. By several repetitions of the same experiments, Mr. Gilpin seemed to bring it within the 1-15000th part of the whole weight.

The above-mentioned considerations induced Dr. Blagden, as well as the gentlemen employed in the experiments, to give the preference to weighing the fluid itself; and that was accordingly the method practised both by Dr. Dollfuss and Mr. Gilpin in their operations.

The vessel chosen as most convenient for the purpose was a hollow glass ball, terminating in a neck of small bore. That which Dr. Dollfuss used held 5800 grains of distilled water; but as the balance was so extremely accurate, it was thought expedient, upon Mr. Gilpin's repetition of the experiments, to use one of only 2965 grains capacity, as admitting the heat of any fluid contained in it to be more nicely determined. The ball of this vessel, which may be called the weighing-bottle, measured about 2·8 inches in diameter, and was spherical, except a slight flattening on the part opposite to the neck, which served as a bottom for it to stand upon. Its neck was formed of a portion of a barometer tube, ·25 of an inch in bore, and about 1½ inch long; it was perfectly cylindrical, and on its outside, very near the middle of its length, a fine circle or ring was cut round it with a diamond, as the mark to which it was to be filled with the liquor. This mark was made by fixing the bottle in a lathe, and turning it round with great care, in contact with the diamond. The glass of this bottle was not very thick; it weighed 916 grains, and with its silver cap 936.

When the specific gravity of any liquor was to be taken by means of this bottle, the liquor was first brought nearly to the required temperature, and the bottle was filled with it up to the beginning of the neck only, that there might be room for shaking it. A very fine and sensible thermometer was then passed through the neck of the bottle into the contained liquor, which showed whether it was above or below the intended temperature. In the former case the bottle was brought into colder air, or even plunged for a moment into cold water; the thermometer in the mean time being frequently put into the contained liquor, till it was found to sink to the right point. In like manner, when the liquor was too cold, the bottle was brought into warmer air, immersed in warm water, or more commonly held between the hands, till upon repeated trials with the thermometer the just temperature was found. It will be understood, that during the course of this heating or cooling, the bottle was very frequently shaken between each immersion of the thermometer; and the top of the neck was kept covered, either with the finger, or a silver cap made on purpose, as constantly as possible. Hot water was used to raise the temperature only in heats of 80° and upwards, inferior heats being obtained by applying the hands to the bottle: when the hot water was employed, the ball of the bottle was plunged into it, and again quickly lifted out, with the necessary shaking interposed, as often as was necessary for communicating the required heat to the liquor; but care was taken to wipe the bottle dry after each immersion, before it was shaken, lest any adhering moisture might by accident get into it. The liquor having by these means been brought to the desired temperature; the next operation was to fill up the bottle exactly to the mark upon the neck, which was done with some of the same liquor, by means of a glass funnel with a very small bore. Mr. Gilpin endeavoured to get that portion of the liquor which was employed for this purpose, pretty nearly to the temperature of the liquor contained in the bottle; but as the whole quantity to be added never exceeded ten grains, a difference of ten degrees in the heat of that small quantity, which is more than it ever amounted to, would have occasioned an error of only 1-30th of a degree in the temperature of the mass. Enough of the liquor was put in to fill the neck rather above the mark, and the superfluous quantity was then absorbed to great nicety, by bringing into contact with it the fine point of a small roll of blotting paper. As the surface of the liquor in the neck would be always concave, the bottom or centre of this concavity was the part made to coincide with the mark round the glass; and in viewing it care was taken, that the near and opposite sides of the mark should appear exactly in the same line, by which means all parallax was avoided. A silver cap, which fitted tight, was then put upon the neck, to prevent evaporation; and the whole apparatus was in that state laid in the scale of the balance, to be weighed with all the exactness possible.

The spirit employed by Mr. Gilpin was furnished to him by Dr. Dollfuss, under whose inspection it had been rectified from rum supplied by government. Its specific gravity, at 60 degrees of heat, was ·82514. It was first weighed pure, in the abovementioned bottle, at every five degrees of heat, from 30 to 100 inclusively. Then mixtures were formed of it, and distilled water, in every proportion, from 1-20th of the water to equal parts of water and spirit; the quantity of water added being successively augmented, in the proportion of five grains to one hundred of the spirit; and these mixtures were also weighed in the bottle, like the pure spirit, at every five degrees of heat. The numbers hence resulting are delivered in the following table; where the first column shows the degrees of heat; the second gives the weight of the pure spirit contained in the bottle at those different degrees; the third gives the weight of a mixture in the proportions of 100 parts by weight of that spirit to 5 of water, and so on successively till the water is to the spirit as 100 to 5. They are the mean of three several experiments at least, as Mr. Gilpin always filled and weighed the bottle over again that number of times, if not oftener. The heat was taken at the even degree, as shown by the thermometer, without any allowance in the first instance, because the coincidence of the mercury with a division can be perceived more accurately than any fraction can be estimated; and the errors of the thermometers, if any, it was supposed would be less upon the grand divisions of 5 degrees than in any others. It must be observed, that Mr. Gilpin used the same mixture throughout all the different temperatures, heating it up from 30° to 100°; hence some small error in its strength may have been occasioned in the higher degrees, by more spirit evaporating than water; but this, it is believed, must have been trifling, and greater inconvenience would probably have resulted from interposing a fresh mixture.

The precise specific gravity of the pure spirit employed was ·82514; but to avoid an inconvenient fraction, it is taken, in constructing the table of specific gravities, as ·825 only, a proportional deduction being made from all the other numbers. Thus the following table gives the true specific gravity, at the different degrees of heat, of a pure rectified spirit, the specific gravity of which at 60° is ·825, together with the specific gravities of different mixtures of it with water, at those different temperatures.

Real Specific Gravities at the different Temperatures.

From this table, when the specific gravity of any spirituous liquor is ascertained, it will be easy to find the quantity of rectified spirit of the abovementioned standard, contained in any given quantity of it, either by weight or measure.

Dr. Blagden concludes this part of the report with observing, that as the experiments were made with pure spirit and water, if any extraneous substances are contained in the liquor to be tried, the specific gravity in the tables will not give exactly the proportions of water and spirit in it. The substances likely to be found in spirituous liquors, where no fraud is suspected, are essential oils; sometimes empyreumatic, mucilaginous or extractive matter, and perhaps some saccharine matter. The effect of these, in the course of trade, seems to be hardly such as would be worth the cognizance of the excise, nor could it easily be reduced to certain rules. Essential and empyreumatic oils are nearly of the same specific gravity as spirit, in general rather lighter, and therefore, notwithstanding the mutual penetration, will probably make little change in the specific gravity of any spirituous liquor in which they are dissolved. The other substances are all heavier than spirit; the specific gravity of common gum being 1·482, and of sugar 1·606, according to the tables of M. Brisson. The effect of them therefore will be to make spirituous liquors appear less strong than they really are. An idea was once entertained of endeavouring to determine this matter with some precision; and accordingly Dr. Dollfuss evaporated 1000 grains of brandy, and the same quantity of rum, to dryness; the former left a residuum of 40 grains, the latter only of 8½ grains. The 40 grains of residuum from the brandy, dissolved again in a mixture of 100 of spirit, with 50 of water, increased its specific gravity ·00041: hence the effect of this extraneous matter upon the specific gravity of the brandy containing it, would be to increase the fifth decimal by 6 nearly, equal to what would indicate in the above-mentioned mixture, about one seventh of a grain of water more than the truth, to 100 of spirit; a quantity much too minute for the consideration of government.

The most remarkable characteristic property of alcohol, is its solubility or combination in all proportions with water; a property possessed by no other combustible substance. When it is burned in a chimney which communicates with the worm-pipe of a distilling apparatus, the product which is condensed is found to consist of water, which exceeds the spirit in weight about one eighth part. If alcohol be burned in closed vessels with vital air, the product is found to be water and carbonic acid. Whence it is inferred that alcohol consists of hidrogen, united either to carbonic acid or its acidifiable base; and that the oxigen uniting on the one part with the hidrogen, forms water; and on the other with the base of the carbonic acid, forms that acid.

A considerable number of the uses of this fluid as a menstruum, will pass under our observation in the various articles of this work. The mutual action between alcohol and acids produces a light, volatile, and inflammable oil, called ether. See ETHER. Pure alkalis unite with spirit of wine, and form alkaline tinctures. Few of the neutral salts unite with this fluid, except such as contain ammonia. The carbonated fixed alkalis are not soluble in it. From the strong attraction which exists between alcohol and water, it unites with this last in saline solutions, and in most cases precipitates the salt. This is a pleasing experiment, which never fails to surprise those who are unacquainted with chemical effects. If, for example, a saturated solution of nitre in water be taken, and an equal quantity of strong spirit of wine be poured upon it, the mixture will constitute a weaker spirit, which is incapable of holding the nitre in solution; it therefore falls to the bottom instantly, in the form of minute crystals.

The degrees of solubility of many neutral salts in alcohol are exactly ascertained by experiments made by Macquer, of which an account is published in the Memoirs of the Turin Academy. The alcohol he employed was carefully freed from superabundant water by repeated rectifications, without addition of any intermediate substance. The salts employed in his experiments were previously deprived of their water of crystallization by a careful drying. He poured into a matrass, upon each of the salts thus prepared, half an ounce of his alcohol, and set the matrass in a sand-bath. When the spirit began to boil, he filtrated it while it was hot, and left it to cool, that he might observe the crystallizations which took place. He then evaporated the spirit, and weighed the saline residuums. He repeated these experiments a second time, with this difference, that instead of evaporating the spirit in which the salt had been digested, he set fire to it in order to examine the phænomena which its flame might exhibit. The principal results of his experiments are subjoined.

Quantity of grains.	*Salts soluble in 200 grains of spirit.*	*Peculiar phænomena of the flame.*
4	Nitrate of potash	Flame larger, higher, more ardent, yellow and luminous
5	Muriate of potash	Large, ardent, yellow, and luminous
9	Sulphate of soda	Considerably red

Quantity of grains.	*Salts soluble in 200 grains of spirit.*	*Peculiar phænomena of the flame.*
15	Nitrate of soda	Yellow, luminous, detonating
0	Muriate of soda	Larger, more ardent, and reddish
0	Sulphate of ammonia	None
108	Nitrate of ammonia	Whiter, more luminous
24	Muriate of ammonia	None
288	Nitrate of lime	Larger, more luminous, red and decrepitating
228	Muriate of lime	Like that of the calcareous nitre
84	Nitrate of silver	None
204	Muriate of mercury	Large, yellow, luminous and decrepitating
4	Nitrate of iron	Red and decrepitating
86	Muriate of iron	More white, luminous and sparkling
44	Nitrate of copper	More white, luminous and green, much smoke. The saline residuum became black and burnt
48	Muriate of copper	Fine green, white, and red fulgurations

Macquer accompanies the relation of his experiments with many judicious reflections, not easily capable of abridgment.

If sulphur in sublimation meet with the vapour of alcohol, a very small portion combines with it, which communicates a hidrosulphurous smell to the fluid. The increased surface of the two substances appears to favour the combination. It had been supposed, that this was the only way in which they could be united: but Mr. Favre has lately asserted, that, having digested two drams of flowers of sulphur in an ounce of alcohol, over a gentle fire not sufficient to make it boil, for twelve hours, he obtained a solution that gave twenty-three grains of precipitate. A similar mixture left to stand for a month in a place exposed to the solar rays afforded sixteen grains of precipitate; and another, from which the light was excluded, gave thirteen grains. If alcohol be boiled with one fourth of its weight of sulphur for an hour, and filtered hot, a small quantity of minute crystals will be deposited on cooling; and the clear fluid will assume an opaline hue on being diluted with an equal quantity of water, in which state it will pass the filter, nor will any sediment be deposited for several hours. The alcohol used in the last-mentioned experiment did not exceed ·840.

Phosphorus is sparingly soluble in alcohol, but in greater quantity by heat than in cold. The addition of water to this solution affords an opake milky fluid, which gradually becomes clear by the subsidence of the phosphorus.

Earths seem to have scarce any action upon alcohol. Quick-lime, however, produces some alteration in this fluid, by changing its flavour and rendering it of a yellow colour. A small portion is probably taken up.

Soaps are dissolved with great facility in alcohol, with which they combine more readily than with water. None of the metals, or their oxides, are acted upon by this fluid. Resins, essential oils, camphor, bitumen, and various other substances, are dissolved with great facility in alcohol, from which they may be precipitated by the addition of water. From its property of dissolving resins it becomes the menstruum of one class of varnishes. See VARNISH.

Camphor is not only extremely soluble in alcohol, but assists the solution of resins in it. Fixed oils, when rendered drying by metallic oxides, are soluble in it, as well as when combined with alkalis.

Wax, spermaceti, biliary calculi, urea, and all the animal substances of a resinous nature are soluble in alcohol: but it curdles milk, coagulates albumen, and hardens the muscular fibre and coagulum of the blood.

The uses of alcohol are various. As a solvent of resinous substances and essential oils it is employed both in pharmacy and by the perfumer. When diluted with an equal quantity of water, constituting what is called proof spirit, it is used for extracting tinctures from vegetable and other substances, the alcohol dissolving the resinous parts and the water the gummy. From giving a steady heat without smoke when burnt in a lamp, it was formerly much employed to keep water boiling on the tea-table. In thermometers for measuring great degrees of cold it is preferable to mercury, as we cannot bring it to freeze. It is in common use for preserving many anatomical preparations, and certain subjects of natural history; but to some it is injurious, the molluscæ for instance, the calcareous covering of which it in time corrodes. It is of considerable use too in chemical analysis; as appears under the different articles to which it is applicable.

From the great expansive power of alcohol, it has been made a question, whether it might not be applied with advantage in the working of steam engines. From a series of experiments made by Betancourt, it appears, that the steam of alcohol has in all cases of equal temperature, more than double the force of that of water; and that the steam of alcohol at 174° F. is equal to that of water at 212°: thus there is a considerable diminution of the consumption of fuel, and where this is so expensive as to be an object of great importance, by contriving the machinery so as to prevent the alcohol from being lost, it may possibly at some future time be used with advantage, if some other fluid of great expansive power, and inferior price, be not found more economical.

It was observed at the beginning of this article, that alcohol might be decomposed by transmission through a red-hot tube: it is also decomposable by the strong acids, and thus affords that remarkable product, Ether, and Oleum Vini; which see.—*Lavoisier.—Henry.—Sage.—Fourcroy.—Phil. Trans.—Nich. Journ.—Parliament. Reports.*

Ale. See Beer.

Alembic, *or* **Still.** This part of chemical apparatus, used for distilling or separating volatile products by first raising them by heat, and then condensing them into the liquid state by cold, is of extensive use in a variety of operations. It is described under the article Laboratory; which see.

Alembroth Salt. Corrosive muriat of mercury is rendered much more soluble in water by the addition of muriat of ammonia. From this solution crystals are separated by cooling, which were called sal alembroth by the earlier chemists, and appear to consist of ammonia, muriatic acid, and mercury; but in what state the muriatic acid may be, whether the common or oxigenated, does not seem to have been ascertained.

Algaroth (Powder of). Among the numerous preparations which the alchemical researches into the nature of antimony have afforded, the powder of algaroth is one. When butter of antimony is thrown into water, it is not totally dissolved; but part of the metallic oxide falls down in the form of a white powder, which is the powder of algaroth. It is violently purgative, and emetic in small doses of three or four grains. See Antimony.

Alkahest. The pretended universal solvent, or menstruum, of the ancient chemists. Kunckel has very well shown the absurdity of searching for a universal solvent, by asking, "If it dissolve all substances, in what vessels can it be contained?"

Alkalescent. Any substance in which alkaline properties are beginning to be developed, or to predominate, is termed alkalescent. The only alkali usually observed to be produced by spontaneous decomposition is the volatile; and from their tendency to produce this, some species of vegetables, particularly the cruciform, are styled alkalescent, as are some animal substances. See Fermentation (Putrid).

Alkali. Modern chemistry has discovered many acids, and has succeeded in decomposing them into simpler substances, and recomposing them. But the alkalis still remain in number only three, Ammonia, Potash, and Soda, which see; and nothing has yet been effected to show an unequivocal decomposition of the two fixed alkalis. Guyton-Morveau and Desormes indeed have inferred from certain experiments, that potash is composed of lime and hidrogen; soda, of magnesia and hidrogen; and ammonia, of azot and hidrogen: whence they are inclined to consider hidrogen as the alkalizing principle, and entitled to the name of *alkaligen.* The general characters in which the three alkalis agree are the following:

1. They have a peculiar taste, which is disagreeably caustic, even when diluted with water. 2. They change blue vegetable colours to a green. 3. They have a very strong attraction for water, with which they unite in all proportions, and even attract it in sufficient quantities from the atmosphere to become fluid. 4. They combine with acids in the humid way, by a stronger affinity than is possessed in general by any other substances. 5. They melt in a moderate heat, and in a stronger heat they are volatilized. 6. In the dry way, they dissolve all earths and metallic oxides.

The volatile alkali or ammonia possesses the above general properties, except so far as its disposition to rise in the aëriform state at a heat less than that of boiling water prevents its being exhibited in the dry way. Its affinities are also less strong.

All the alkalis when uncombined are caustic, and in this state are sometimes coupled with the epithet *pure* or *caustic,* to distinguish them from their carbonats, to which the term *mild* is applied.

The usual tests of alkalis are the tincture of turnsole, or litmus, and the sirup of violets. For the salts they form with acids, see the different Acids respectively.

Alkali (Phlogisticated, *or* **Prussian).** When a fixed alkali is ignited with bullock's blood, or other animal substances, and lixiviated, it is found to be in a great measure saturated with the prussic acid: from the theories formerly adopted respecting this combination, it was distinguished by the name of phlogisticated alkali. See Acid (Prussic).

Alkali (Volatile). See Ammonia.

Alkanet. The alkanet plant is a kind of bugloss, which is a native of the warmer parts of Europe, and cultivated in some of our gardens. The greatest quantities are raised in Germany and France, particularly about Montpelier, whence we are chiefly supplied with the roots. These are of a superior quality to such as are raised in England. This root imparts an elegant deep red colour to pure alcohol, to oils, to wax, and to all unctuous substances. The aqueous tincture is of a dull brownish colour; as is likewise the spirituous tincture when inspissated to the consistence of an extract. The principal use of alkanet root is, that of colouring oils, unguents, and lip-salves. Wax tinged with it, and applied on warm marble, stains it of a flesh colour, which sinks deep into the stone; as the spirituous tincture gives it a deep red stain.

As the colour of this root is confined to the bark, and the small roots have more bark in proportion to their bulk than the great ones, these also afford most colour.

Allay, or Alloy. Where any precious metal is mixed with another of less value; the assayers call the latter the alloy, and do not in general consider it in any other point of view than as debasing or diminishing the value of the precious metal. Philosophical chemists have availed themselves of this term to distinguish all metallic compounds in general. Thus brass is called an alloy of copper and zinc; bell metal an alloy of copper and tin.

Almonds. Almonds consist chiefly of an oil of the nature of fat oils, together with farinaceous matter. The oil is so plentiful, and so loosely combined or mixed with the other principles, that it is obtained by simple pressure, and part of it may be squeezed out with the fingers. Five pounds and a half have yielded one pound six ounces of oil by cold expression, and three quarters of a pound more on heating them. There are two kinds of almonds, the sweet and bitter. The bitter almonds yield an oil as tasteless as that of the other, all the bitter matter remaining in the cake after the expression. Great part of the bitter matter dissolves by digestion, both in watery and spirituous liquors; and part arises with both in distillation. Rember obtained from them 1-3d of watery extract, and 3-32ds of spirituous. Bitter almonds are poisonous to birds, and to some animals. A water distilled from them, when made of a certain degree of strength, has been found from experiment to be poisonous to brutes; and there are instances of cordial spirits impregnated with them being poisonous to men. It seems, indeed, that the vegetable principle of bitterness in almonds and the kernels of other fruits is destructive to animal life, when separated by distillation from the oil and farinaceous matter. The distilled water from laurel leaves appears to be of this nature, and its poisonous effects are well known.

Sweet almonds are made into an emulsion by trituration with water, which on standing separates a thick cream floating on the top. The emulsion may be curdled by heat, or the addition of alcohol or acids. The whey contains gum, extractive matter, and sugar, according to prof. Proust: and the curd, when washed and dried, yields oil by expression, and afterward by distillation the same products as cheese. The whey is a good diluent.

Aloes. This is a bitter juice, extracted from the leaves of a plant of the same name. Three sorts of aloes are distinguished in the shops, by the names of aloe soccotrina, aloe hepatica, and aloe caballina. The first denomination, which is applied to the purest kind, is taken from the island of Zocotora; the second, or next in quality, is called hepatica, from its liver colour; and the third, caballina, from the use of this species being confined to horses. These kinds of aloes are said to differ only in purity, though, from the difference of their flavours, it is probable that they may be obtained in some instances from different species of the same plant. It is certain, however, that the different kinds are all prepared at Morviedro in Spain, from the same leaves of the common aloe. Deep incisions are made in the leaves, from which the juice is suffered to flow, and this, after decantation from its sediment, and inspissation in the sun, is exposed to sale in leathern bags by the name of soccotrine aloes. An additional quantity of juice is obtained by pressure from the leaves, and this, when decanted from its sediment and dried, is the hepatic aloes. And lastly, a portion of juice is obtained by strong pressure of the leaves, and is mixed with the dregs of the two preceding kinds to form the caballine aloes. The first kind is said to contain much less resin. The principal characters of good aloes are these: it must be glossy, not very black, but brown; when rubbed or cut, of a yellow colour; compact, but easy to break; easily soluble; of an unpleasant peculiar smell, which cannot be described, and an extremely bitter taste.

Aloes appears to be an intimate combination of gummy and resinous matter, so well blended together, that watery or spirituous solvents, separately applied, dissolve the greater part of both. It is not determined whether there be any difference in the medical properties of these solutions. Both are purgative, as is likewise the aloes in substance; and, if used too freely, are apt to prove heating, and produce hemorrhoidal complaints.

Althea, or Marsh Mallow. Two ounces of the dry root yielded, with water, ten drams fifty grains of mucilaginous extract; and afterwards, with spirit, forty-one grains of resin. The same quantity, treated with spirit, gave six drams of a resinous extract, a considerable portion of the mucilage dissolving in that menstruum along with the resin; the remainder, boiled in water, gave out five drams and forty-eight grains of pure mucilage. The insoluble matter amounts to somewhat more than one fourth of the weight.

Aludel. The process of sublimation differs from distillation in the nature of its product which instead of becoming condensed in a fluid assumes the solid state, and the form of the receivers may of course be very different. The receivers for sublimates are of the nature of chimneys, in which the elastic products are condensed, and adhere to their internal surface. It is evident, that the head of an alembic will serve very well to receive and condense such sublimates as are not very volatile. The earlier chemists, whose notions of simplicity were not always the most perfect, thought proper to use a number of similar heads, one above the other, communicating in succession by means of a perforation in the superior part of each, which received the neck of the capital immediately above it. These heads differing in no respect from the common heads of alembics, excepting in their having no nose or beak, and in the other circumstances here mentioned, were called aludels. They are seldom now to be seen in chemical laboratories, because the operations of this art may be performed with greater simplicity of instruments, provided attention be paid to the heat and other circumstances. See LABORATORY.

ALUM. This is a crystallizable salt composed of sulphuric acid united with alumine, and about 20 per cent. of sulphat of potash, or of ammonia or of both together. It has an austere, sweetish, and strongly astringent taste, which seems to proceed chiefly from a portion of the sulphuric acid, which is necessary to its solubility in water and crystalline form, though it is more than requisite to produce neutralization. If the excess of acid in alum be taken away, the taste, the solubility, and the original properties of the salt, are greatly changed, or lost.

Crystallized alum requires, in a mean heat, about fourteen times its weight of water to dissolve it; but boiling water dissolves one third more than its own weight of this salt, most of which consequently separates by cooling. If crystallized alum be exposed to a gradual heat, it first becomes fluid by a kind of aqueous fusion, in which its own water of crystallization is the principal agent; the remaining mass, after most of the water has been expelled, grows opake, swells, foams, and at length remains quiet, spongy, and friable. Ignition drives off some of its superabundant acid. The quantity of earthy basis in alum may be determined by precipitation with fixed or volatile alkali. In this way, however, there is a source of inaccuracy arising from the insolubility of the alum, which takes place as soon as its superabundant acid has combined with the alkali. At this period, a portion of the neutral combination of clay and sulphuric acid falls down without further decomposition. Long continued digestion in an alkaline lixivium is necessary to separate the whole of the acid. The volatile alkali is preferable in clearing the base of alum, because it would unite to fixed alkalis. The most commodious method of obtaining pure argillaceous earth consists in precipitating it in this manner from alum.

In this way Bergman found one hundred parts of crystallized alum to contain forty-four of water, eighteen of alumine, and consequently thirty-eight of sulphuric acid and alkali.

Alum is produced, but in a very small quantity, in the native state; and this is mixed with heterogeneous matters. It effloresces in various forms upon ores during calcination, but it seldom occurs crystallized. The greater part of this salt is factitious, being extracted from various minerals called alum ores, such as, 1. Sulphurated clay. This constitutes the purest of all aluminous ores, namely, that of la Tolfa, near Civita Vecchia, in Italy. It is white, compact, and as hard as indurated clay; whence it is called petra aluminaris. It is tasteless and mealy: one hundred parts of this ore contain above forty of sulphur and fifty of clay, a small quantity of potash, and a little iron. Bergman says it contains forty-three of sulphur in one hundred, thirty-five of clay, and twenty-two of siliceous earth. This ore is first torrefied to acidify the sulphur, which then acts on the clay, and forms the alum.

2. The pyritaceous clay, which is found at Schwemsal, in Saxony, at the depth of ten or twelve feet. It is a black and hard, but brittle substance, consisting of clay, pyrites, and bitumen. It is exposed to the air for two years; by which means the pyrites are decomposed, and the alum is formed. The alum ores of Hesse and Liege are of this kind: but they are first torrefied, which is said to be a disadvantageous method.

3. The shistus aluminaris contains a variable proportion of petroleum and pyrites intimately mixed with it. When the last are in a very large quantity, this ore is rejected as containing too much iron. Professor Bergman very properly suggested, that by adding a proportion of clay this ore may turn out advantageously for producing alum. But if the petrol be considerable, it must be torrefied. The mines of Becket in Normandy, and those of Whitby in Yorkshire, are of this species.

4. Volcanic aluminous ores. Such is that of Solfaterra near Naples. It is in the form of a white saline earth, after it has effloresced in the air; or else it is in a stony form.

5. Bituminous alum ore is called shale, and is in the form of a shistus, impregnated with so much oily matter, or bitumen, as to be inflammable. It is found in Sweden, and also in the coal mines at Whitehaven, and elsewhere.

6. Alum might also be extracted from many species of pyrites; but so contaminated with iron, as scarce to pay the expenses of the operation.

The preparation of alum consists in rendering the ores aluminous in the first place, and next in dissolving and purifying the salt. Most of the alum ores contain clay and sulphur, which last requires to be converted into acid before it can form the aluminous combination. For this purpose exposure to the air and occasional watering is effectual, and is in many places used: but it is less expeditious than the conversion of the sulphur into acid by actual combustion. The chief difficulty of this process is, that the sulphur must be gradually and sufficiently burned without expelling it by too great a heat, which would likewise be attended with a fusion of the earthy parts, that would render them capable of resisting the subsequent action of the water. After the ore has been, partly by calcination, and partly by spontaneous efflorescence, reduced to such a state as that it can be made into a paste by the hand, it is fit for boiling, which is usually performed in large leaden caldrons. In many manufactories a cold elixation is performed, until the saline solution is saturated; after which it is boiled until it is sufficiently strong for crystallization. This should not be too much loaded, because otherwise it would begin to deposit crystals by cooling before its earthy impurities had subsided. Some take the floating of a newly laid egg as a token of the boiling being finished; a rough method indeed, as well because the part above the liquor may be very different, and likewise because the specific gravity of eggs soon changes. The specific gravity of a fluid which just prevents a newly laid egg from sinking is about 1·081. When the ore itself does not contain potash, as that of la Tolfa does, it is necessary to add a sufficient portion of this alkali, or of ammonia; to furnish which many use putrid urine. Some of the English manufacturers use a lixivium of the ashes of kelp; but this is a bad practice, as only the potash in these is of any service.

The lixivium, sufficiently concentrated by evaporation, is conveyed through channels into coolers, where, in about an hour, it is freed, by deposition, from the grosser heterogeneous particles; it is then put into either stone or wooden receptacles. In eight or ten days the lixivium, commonly called magistral water, flows into another vessel, leaving behind a number of crystals, generally small and impure, which incrust the bottom and sides of the vessel. These are collected, and washed from the impurities, which adhere externally, with cold water; the impurities remaining in the reservoir after washing are kept by themselves.

The washed crystals are then put into the boiler used for purifying them, and are dissolved in a quantity of water so small as barely to suspend the salt when boiling hot; and sometimes bullock's blood is added to clarify the solution. The alum liquor is then poured into large strong wooden casks, the staves and hoops of which are all numbered, that they may be more readily put together. In these the alum gradually shoots into large crystals about the sides; the liquor in the middle is then let off by a cock in the bottom, and the vessel turned upside down for the more effectual draining of the remaining fluid. Lastly, the crystals are dried in a stove, and packed up in casks for sale.

Chaptal has fabricated alum on a large scale from its component parts. For this purpose he constructed a chamber 91 feet long, 48 wide, and 31 high in the middle. The walls are of common masonry, lined with a pretty thick coating of plaster. The floor is paved with bricks, bedded in a mixture of raw and burnt clay: and this pavement is covered with another, the joints of which overlap those of the first, and instead of mortar the bricks are jointed with a cement of equal parts of pitch, turpentine, and wax, which, after having been boiled till it ceases to swell, is used hot. The roof is of wood, but the beams are very close together, and grooved lengthwise, the intermediate space being filled up by planks fitted into the grooves, so that the whole is put together without a nail. Lastly, the whole of the inside is covered with three or four successive coatings of the cement above mentioned, the first being laid on as hot as possible; and the outside of the wooden roof was varnished in the same manner. The purest and whitest clay being made into a paste with water, and formed into balls half a foot in diameter, these are calcined in a furnace, broken to pieces, and a stratum of the fragments laid on the floor. A due proportion of sulphur is then ignited in the chamber, in the same manner as for the fabrication of sulphuric acid; and the fragments of burnt clay, imbibing this as it forms, begin after a few days to crack and open, and exhibit an efflorescence of sulphat of alumine. When the earth has completely effloresced, it is taken out of the chamber, exposed for some time in an open shed that it may be the more intimately penetrated by the acid, and is then lixiviated and crystallized in the usual manner. The cement answers the purpose of lead on this occasion very effectually, and according to M. Chaptal costs no more than lead would at three farthings a pound.

Curaudau has lately recommended a process for making alum without evaporation. One hundred parts of clay and five of muriat of soda are kneaded into a paste with water, and formed into loaves. With these a reverberatory furnace is filled, and a brisk fire is kept up for two hours. Being powdered, and put into a sound cask, one fourth of their weight of sulphuric acid is poured over them by degrees, stirring the mixture well at each addition. As soon as the muriatic gas is dissipated, a quantity of water equal to the acid is added, and the mixture stirred as before. When the heat is abated, a little more water is poured in, and this is repeated till eight or ten times as much water as there was acid is added. When the whole has settled, the clear liquor is drawn off into leaden vessels, and a quantity of water equal to this liquor is poured on the sediment. The two liquors being mixed, a solution of potash is added to them, the alkali in which is equal to one fourth of the weight of the sulphuric acid. Sulphat of potash may be used, but twice as much of this as of the alkali is necessary. After a certain time the liquor by cooling affords crystals of alum equal to three times the weight of the acid used. It is refined by dissolving it in the smallest possible quantity of boiling water. The residue may be washed with more water, to be employed in lixiviating a fresh portion of the ingredients.

As the mother water still contains alum, with sulphat of iron very much oxided, it is well adapted to the fabrication of Prussian blue. This mode of making alum is particularly advantageous to the manufacturers of Prussian blue, as they may calcine their clay at the same time with their animal matters, without additional expense: they will have no need in this case to add potash; and the presence of iron, instead of being injurious, will be very useful. If they wished to make alum for sale, they might use the solution of sulphat of potash arising from the washing of their Prussian blue, instead of water, to dissolve the combination of alumine and sulphuric acid.

The residuums of distillers of aqua fortis are applicable to the same purposes, as they contain the alumine and potash requisite, and only require to be reduced to powder, sprinkled with sulphuric acid, and lixiviated with water, in the manner directed above. The mother waters of these alums are also useful in the fabrication of Prussian blue. As the residuum of aqua fortis contains an over-proportion of potash, it will be found of advantage to add an eighth of its weight of clay calcined as above.

Alum is used in large quantities in many manufactories. When added to tallow, it renders it harder. Printers' cushions, and the blocks used in the calico manufactory, are rubbed with burnt alum to remove any greasiness, which might prevent the ink or colour from sticking. Wood sufficiently soaked in a solution of alum does not easily take fire; and the same is true of paper impregnated with it, which is fitter to keep gunpowder, as it also excludes moisture. Paper impregnated with alum is useful in whitening silver, and silvering brass without heat. Alum mixed in milk helps the separation of its butter. If added in a very small quantity to turbid water, in a few minutes it renders it perfectly limpid, without any bad taste or quality; while the sulphuric acid imparts to it a very sensible acidity, and does not precipitate so soon, or so well, the opake earthy mixtures that render it turbid, as I have often tried. It is used in making pyrophorus, in tanning, and many other manufactories, particularly in the art of dyeing, in which it is of the greatest and most important use, by cleansing and opening the pores on the surface of the substance to be dyed, rendering it fit for receiving the colouring particles (by which the alum is generally decomposed), and at the same time making the colour fixed. Alum constitutes the basis of crayons, which generally consist of the earth of alum, finely powdered, and tinged for the purpose. In medicine it is employed as an astringent, and when calcined as an escharotic.

Alum is prepared in England, and many other parts of the world, and was formerly distinguished by various names. The rock alum is supposed to derive its name from an ancient city in Syria, called Roccho, at present Edessa, where one of the earliest manufactories was carried on. The Roman alum has been considered as the best sort. It has a rosy tinge, which arises from about 1-20th of its weight of a rose-coloured earth, the nature of which was not ascertained by Bergman, though he found that the goodness of the alum does not depend upon it. This alum is not preferred to other good alum by our manufacturers. Plume alum is a name given to two very different substances. The one appears to be true alum produced by the desiccation of aluminous waters, which transude through grottoes and caverns, and leave this salt behind in feathery crystals. This is seldom met with. The other substance to which this name has been given is the fibrous asbestos, which contains no alum; but from half to three fourths of its weight of silex, from one eighth to one third of carbonat of magnesia, and the rest lime, with a minute proportion of clay, and sometimes iron.

M. Vauquelin has lately instituted a set of experiments to ascertain the differences between various kinds of alums, and according to him they are very trifling, notwithstanding the Roman is double the price of the French. It is true the Roman is most free from iron, but none contained more than ·003; the Roman contained no ammonia, the English rather the most; and in the rose coloured earth of the Roman a little nickel was found. The proportions of the component parts of alum he gives are; alumine 10·50, sulphuric acid 30·52, potash 10·40, water 48·58. We must observe, however, that it appears to have been his object, to prove to the French manufacturers, that the alum of their own country is equal in quality to the English, which, next to the Roman, they decidedly prefer. To get rid of the last portions of iron he recommends, either to disturb the lixivium in the first crystallization, or precipitate it by the addition of a small quantity of prussiat of potash: Clement and Desormes calcine and crystallize it, but this deprives it of part of the superabundant acid. Thenard and Roard affirm, that a thousandth part of iron influences the effect of alum in dyeing.

Alumine. See Earths.

Aluta montana. This is one of the names of the coriaceous asbestos, or mountain cork. It is easily distinguished by its elasticity and lightness, for it floats a long time on water. Its colour is either white, yellow, brown, green, or black; and its texture resembles those substances from which it has received its names: 100 parts of it contain from 56 to 62 of silex; from 22 to 26 of carbonat of magnesia; from 10 to 12 of carbonat of lime; from 2 to 2·8 of alumine; and about 3 of iron.

Amalgam. This name is applied to the combinations or mixtures of mercury with other metallic substances. As this metal is so exceedingly fusible as to be always in the fluid state in climates of a moderate temperature, it unites with many of the metals, without any greater heat than that which it usually possesses. For this purpose, therefore, nothing more is necessary, than to triturate thin leaves, or plates, or filings of the metallic substance with mercury. In other instances, where the disposition to combine is less powerful, it is found necessary either to fuse or ignite the metal intended to be amalgamated. When a small quantity of mercury is combined with any metal, it renders it brittle, or rather friable; a greater quantity of mercury produces a kind of imperfect fluidity resembling that of butter. This is commonly called the consistence of an amalgam. A still greater quantity of mercury renders the mass more fluid, but not uniformly so; for a portion of the amalgam either floats at the top, or sinks to the bottom, instead of intimately combining with the whole of the mercury. This fact is of the same kind as that wherein salts are soluble in water in limited quantities, beyond which they cease to be taken up. Mercury very readily combines with gold, silver, lead, tin, bismuth, and zinc. In making an amalgam of gold or silver, the clippings of the leaves from the gold-beaters may be used, or thin plates of the metals may be ignited, and plunged in mercury previously heated, so as to smoke. When the quantity of mercury is so large as to be fluid when cold, the superfluous mercury may be strained off by pressure through a leathern bag. The remaining amalgam of gold contains about one third of its weight of mercury, but is perfectly white. The amalgam of silver sinks in mercury, and consequently is heavier than either mercury or silver. Equal parts of lead and mercury, and of bismuth and mercury, form solid amalgams; but if these be mixed together, they become fluid; and after this fluid has stood a few days in a temperature not exceeding 40° F., cubic crystals of nearly pure bismuth will be formed in it.

Mercury unites with difficulty into an amalgam with copper and arsenic; and scarcely at all with platina, or with iron. This latter metal, however, does not absolutely refuse to combine with mercury, for it adheres to, and coats the ends of iron pestles used for the trituration of amalgams; and Dr. Lewis has observed, that a plate of tough iron is rendered brittle by keeping it immersed in mercury for some days; a fact which has been experienced in another way by M. de Luc, who found that springs immersed under mercury, in the construction of a barometer, were rendered brittle and useless by its action. Iron ignited to a white heat, and thrown into a large mass of mercury, becomes completely covered with a ferruginous bright amalgam. Mr. Arthur Aikin has formed an amalgam of iron by uniting an amalgam of zinc with iron filings, and adding muriat of iron, the acid of which combines with the zinc, which may thus be separated. Antimony unites with mercury, though with great difficulty. Nickel, cobalt, rhodium, and manganese, are said to unite with mercury; and its action on tungsten, chrome, molybdena, and some of the other metals, is not known.

Amalgams are applied to a considerable number of useful purposes. The amalgam of gold is used in the process called water gilding, in which the mercury first serves as the medium of adhesion between the gold and copper, and is afterward driven off by heat. See Gilding. Looking-glasses are silvered by an amalgam of tin. See Silvering. The amalgam of zinc, triturated with tallow, is found to assist the excitation or production of electricity, by the friction of a cushion against glass, in a wonderful degree; insomuch that the quantity of electricity is 20 or 30 times as great as without it.

When mercury is contaminated with any imperfect metal, it is found, that by agitation, in contact with oxigen gas, or the air of the atmosphere, the imperfect metal becomes converted into a black powdery calx, which separates from the mercury.

Amandola. This is a green marble, having the appearance of a honey-comb; and containing white spots: 100 parts of it contain 76 of carbonat of lime; 20 of shistus; 2 of iron, partly calcined. The cellular appearance proceeds from the shistus.

Amber is a hard, brittle, tasteless substance, sometimes perfectly transparent, but mostly semitransparent or opake, and of a glossy surface: it is found of all colours, but chiefly yellow or orange, and often contains leaves or insects; its specific gravity is from 1·065 to 1·100; its fracture is even, smooth, and glossy; it is capable of a fine polish, and becomes electric by friction; when rubbed or heated, it gives a peculiar agreeable smell, particularly when it melts, that is at 550° of Fahrenheit; but it then loses its transparency; projected on burning coals, it burns with a whitish flame, and a whitish yellow smoke, but gives very little soot, and leaves brownish ashes; it is insoluble in water and alcohol, though the latter, when highly rectified, extracts a reddish colour from it; but it is soluble in the sulphuric acid, which then acquires a reddish purple colour, and is precipitable from it by water; no other acid dissolves it, nor is it soluble in essential or expressed oils, without some decomposition and long digestion; but pure alkali dissolves it. By distillation it affords a small quantity of water, with a little acetous acid, an oil, and a peculiar acid. See Acid (Succinic). The oil rises at first colourless; but, as the heat increases, becomes brown, thick, and empyreumatic. The oil may be rectified by successive distillations: or it may be obtained very light and limpid at once, if it be put into a glass alembic with water, as the elder Rouelle directs, and distilled at a heat not greater than 212° F. It requires to be kept in stone bottles, however, to retain this state; for in glass vessels it becomes brown by the action of light.

Amber is met with plentifully in regular mines in some parts of Prussia. The upper surface is composed of sand, under which is a stratum of loam, and under this a bed of wood partly entire, but chiefly mouldered or changed into a bituminous substance. Under the wood is a stratum of sulphuric or rather aluminous mineral, in which the amber is found. Strong sulphureous exhalations are often perceived in the pits.

Amber having been formerly considered as a valuable substance, and the specimens, which are large, or contain entire or perfect insects within them, being still of considerable price, the methods of softening it so as to introduce these extraneous bodies, or of uniting smaller pieces together, have been kept as profitable secrets, if it be true that they ever were discovered. It is said, that two pieces of this substance may be united by wetting them with the solution of potash (called oil of tartar), and applying them together with heat; and Wallerius mentions, that pieces of yellow amber may be softened, formed into one, and even dissolved, by means of oil of turnip-seed, in a gentle heat; and that, according to some authors, it may be rendered transparent by boiling in rapeseed oil, linseed oil, salt water, &c. Neumann, however, denies that either salt water or linseed oil produces this effect; though he states, as the common practices of workmen, the following methods: the one consists in surrounding the amber with sand in an iron pot, and cementing it with a gradual fire for forty hours, some small pieces placed near the sides of the vessel being occasionally taken out for judging of the effect of the operation: the second method, which he says is that most generally practised, is by digesting and boiling the amber about twenty hours with rapeseed oil, by which it is rendered both clear and hard.

Both the oil and powder of amber were formerly used in medicine, but are now disregarded. The oil, however, is used for making *eau de luce*; one dram being added to two ounces of alcohol, in which six grains of white soap have been dissolved, and this solution being well shaken with eight ounces of water of pure ammonia, so as to form a milky liquid. Dr. Hopson directs as much as eight scruples of soap to this quantity of the other ingredients; and the proportions are varied by different chemists. In France, the acid liquor that comes over has been made into a sirup, with the addition of opium, and much vaunted, under the name of *sirup of amber*.

Amber is also used in varnishes. See Varnish.

Ambergris is found in the sea, near the coasts of various tropical countries; and has also been taken out of the intestines of the physeter macrocephalus, the spermaceti whale. As it has not been found in any whales but such as are dead or sick, its production is generally supposed to be owing to disease, though some have a little too peremptorily affirmed it to be the cause of the morbid affection. As no large piece has ever been found without a greater or less quantity of the beaks of the sepia octopodia, the common food of the spermaceti whale, interspersed throughout its substance, there can be little doubt of its originating in the intestines of the whale; for if it were occasionally swallowed by it only, and then caused disease, it must much more frequently be found without these, when it is met with floating in the sea, or thrown upon the shore.

Ambergris is found of various sizes; generally in small fragments, but sometimes so large as to weigh near two hundred pounds. When taken from the whale it is not so hard as it becomes afterward, on exposure to the air. Its specific gravity ranges from 780 to 926. If good, it adheres like wax to the edge of a knife with which it is scraped, retains the impression of the teeth or nails, and emits a fat odoriferous liquid on being penetrated with a hot needle. It is generally brittle; but, on rubbing it with the nail, it becomes smooth like hard soap. Its colour is either white, black, ash-coloured, yellow, or blackish; or it is variegated; namely, gray with black specks, or gray with yellow specks. Its smell is peculiar, and not easy to be counterfeited. At 144° it melts; and, at 212°, is volatilized in the form of a white vapour. But, on a red-hot coal, it burns, and is entirely dissipated. Water has no action on it: acids act feebly on it: alkalis combine with it, and form a soap: ether and the volatile oils dissolve it: so do the fixed oils, and also ammonia, when assisted by heat: alcohol dissolves a portion of it, and is of great use in analysing it, by separating its constituent parts. According to Bouillon la Grange, who has given the latest analysis of it, 3820 parts of ambergris consist of adipocere 2016 parts, a resinous substance 1167, benzoic acid 425, and coal 212.

It has occasionally been employed in medicine, but its use is now confined to the perfumer. Dr. Swediaur took thirty grains of it without perceiving any sensible effect. A sailor, who took half an ounce of it, found it a good purgative.

Mr. Magellan mentions an undoubtedly vegetable ambergris gathered from a tree which grows in Guyana, and is called Cuma. Specimens of this were presented to him by M. Aublet, author of the Histoire de la Guyane, published in 1774, who himself collected it on the spot; and Mr. Magellan presented part of it to the late Dr. Fothergill, and also to Dr. Combe. It was of a whitish brown colour, with a yellowish shade; melted and burned like wax on the fire, but was rather of a more powdery consistence than any other ambergris he had seen.

Amer. This name has been given to a principle supposed to occasion the bitter taste of certain vegetables, and to be distinguished by peculiar properties. It may be obtained from several plants by infusion for some time in cold water. Its characters, as originally described by Welther, and since examined by Dr. Thomson, are thus given: If water, impregnated with this principle, be evaporated gently to dryness, it leaves a brownish yellow substance, which retains a certain degree of transparency, continues for some time ductile, but at length becomes brittle. Its taste is intensely bitter. When heated, it softens, swells, grows black, burns away without much flame, and leaves a small quantity of ashes. It is very soluble both in water and alcohol. It does not affect blue vegetable colours. It is not precipitated by the waters of lime, barytes, or strontian; and is not changed by alkalis. Neither the tincture, infusion, nor pure acid of galls has any effect on it. Nitrat of silver, and acetit of lead, are the only metallic salts that precipitate it; and as the acetit of lead produces with it a copious precipitate, this is the best test for discovering the bitter principle, when no other substance that will decompose the acetit is present.

In Mr. Hatchett's experiments on the formation of tan by the action of nitric acid on different substances, the bitter principle appears to have been formed, along with tan, from indigo and some others.—*Henry*.

Amethyst. The amethyst is a gem of a violet colour and great brilliancy, said to be as hard as the ruby or sapphire, from which it only differs in colour. This is called the oriental amethyst, and is very rare. When it inclines to the purple or rosy colour, it is more esteemed than when it is nearer to the blue. These amethysts have the same figure, hardness, specific gravity, and other qualities, as the best sapphires or rubies, and come from the same places, particularly from Persia, Arabia, Armenia, and the West Indies. The occidental amethysts are merely coloured crystals or quartz.

Amianthus, Mountain Flax. This fossil is commonly of a grayish or greenish white, somewhat greasy to the feel, and of a fibrous texture. It breaks into long splintery fragments, and its fibres are sufficiently flexible to be made into cloth. It is often confounded with asbestos, from which it differs, chiefly in being more fusible, in being less acted upon by acids, and in its fibres being commonly more flexible. See Asbestos.

Ammonia. This alkali, commonly distinguished by the epithet *volatile*, on account of its tendency to assume the form of gas, in which only it can be obtained unmixed, may be procured by the destructive distillation of all animal substances that have not undergone spontaneous decomposition, as well as from some plants, chiefly the fungi, and those of the cruciform kind. Putrefaction likewise disengages it from these substances. It appears to be a compound of azot and hidrogen. See Gas (Ammoniacal).

For use, it is generally kept in a liquid form, in which it is usually obtained in large manufactories from refuse bones, and the pith of horns, the residuum of which is afterward made into bone black, or, by calcining to whiteness, into burnt bone, or burnt hartshorn. Urine likewise, and other refuse animal matters, are used for the same purpose. The ammonia at first is greatly contaminated by the animal oil that rises with it; and after it is freed from great part of this, by re-distilling it once or twice, it is commonly sold by the name of *spirit of hartshorn*. The apparatus employed consists of a large iron pot, to which a head is affixed, with its worm refrigeratory and receiver. It is said, that, if no lute be employed, five times as much ammonia may be procured, as when the parts of the apparatus are closely luted together; owing, probably, to the absorption of nitrogen from the atmosphere.

The volatile alkali thus obtained, however, is rendered in some degree mild by the presence of carbonic acid, from which it may be freed, as well as from the animal oil, by adding a little lime, and rectifying it with a gentle fire.

If to this alkali be added, in due quantities, first diluted sulphuric acid, and afterward muriate of soda, the soda takes the sulphuric acid from the ammonia with which it had united, and the ammonia combines with the muriatic acid. Thus sulphat of soda and muriat of ammonia are formed, and may be separated by evaporation and crystallization. The muriat commonly called *sal ammoniac*, is sublimed into cakes for sale. The greater part, if not the whole of this salt, which was formerly imported from Egypt, is now thus made here for home consumption.

Messrs. Minish have, for many years, used the preceding process, with the improvement of substituting the sulphat of lime or plaster of Paris instead of sulphuric acid. In this case the products are chalk, sulphat of soda, and sal ammoniac, or muriat of ammonia.

It has likewise been manufactured by Dr. H. Campbell, by adding sulphat of magnesia to muriat of soda, and adding carbonat of ammonia to the muriat of magnesia thus formed; so that the products obtained were muriat of ammonia, sulphat of soda, and carbonat of magnesia.

From this muriat the purest ammonia may be obtained. Mix two parts of powdered and sifted lime with one of muriat of ammonia, and put them into a retort, the neck of which is to be luted to a tubulated receiver, with slips of moistened bladder, bound round with pack-thread. From the other opening of the receiver a right-angled tube, with Welter's addition, is to proceed, and terminate in a bottle with two necks. This bottle should contain a quantity of water, equal in weight to one fourth of the muriat of ammonia, and the aperture of the tube should be beneath the surface of the water. A second right-angled tube should connect this with a similar bottle, containing a like quantity of water. By applying heat to the retort, a decomposition will take place, and the ammoniacal gas will be absorbed by the water in the bottles, which should be surrounded with snow or pounded ice.

It may be made also, by adding the muriat dissolved in six parts of water, to the quicklime previously slacked in an equal weight of water, and then distilling off one part of the liquid; but the former process is preferable.

Ammonia may be combined with sulphur by mixing together two parts of muriat of ammonia, two of lime, and one of sulphur, and distilling in the pneumatic apparatus, with a small quantity of water in the receiver. A yellow liquor is obtained, containing sulphuret of ammonia, formerly known by the name of Boyle's fuming liquor. With fat oils it forms soaps. It has a striking property of forming fulminating precipitates, and of reducing the oxides of several metals, either wholly or partially, to the metallic state. When in excess, it redissolves most of the oxides it had before thrown down. It dissolves a small portion of alumine.

As a test it is of very extensive use. In medicine it is seldom employed pure, on account of its causticity, except externally combined with twice or thrice its quantity of oil, which makes the *linimentum ammoniæ*, or *volatile liniment*, prescribed as a stimulant and discutient. Greatly diluted with water, however, it is recommended internally against the effects of the bites of serpents; as it is in doses of a few drops, in as much water as will allow it to be swallowed with ease, in some cases of debility of the stomach, where a stimulant of speedy effect is required.

As the quality of pure ammonia in a liquid form depends on its strength, this is best known by its specific gravity, which, when the water is saturated, should be about 0·905, at 60° F. The following table, drawn up by Mr. Davy, exhibits the proportion of water and ammonia contained in 100 parts of liquid ammonia of different specific gravities.

Specific Gravity.	Ammonia.	Water.
0·9054	25·37	74·63
0·9166	22·07	77·98
0·9255	19·54	80·46
0·9326	17·52	82·48
0·9385	15·88	84·12
0·9435	14·53	85·47
0·9476	13·46	86·54
0·9513	12·40	87·60
0·9545	11·56	88·44
0·9573	10·82	89·18
0·9597	10·17	89·83
0·9619	9·60	90·40
0·9631	9·50	90·50
0·9639	9·09	90·91
0·9713	7·17	92·83

If any carbonic acid be present with it, this may be detected by its precipitating a solution of muriat of lime.

The *spirit of hartshorn* is sometimes adulterated by mixing with it the water of pure ammonia, to increase the pungency of its smell, and enable it to bear an addition of water. This may be detected by adding alcohol; for if no considerable coagulation ensue, the adulteration is proved. It may also be discovered by the usual effervescence not happening with acids. Its specific gravity should be about 1·5.

Ammoniac (Gum). This is a gum resin, from an ounce of which six drams may be dissolved in ardent spirit, or six drams two scruples and a half by water, according to Neumann.

Ammonites. These petrifactions, which have likewise been distinguished by the name of cornu ammonis, and are called *snakestones* by the vulgar, consist chiefly of lime-stone. They are found of all sizes, from the breadth of half an inch to more than two feet in diameter; some of them rounded, others greatly compressed, and lodged in different strata of stones and clays. They appear to owe their origin to shells of the nautilus kind.

Amomum. See Pimento.

Ampelites. A solid, dry, hard, opake, black fossil coal, not fusible, but easily inflammable, and burning with a bright vivid white flame, with much smoke, and a bituminous or pitchy smell. In the north of England it is called cannel coal, perhaps by corruption, instead of candle coal, as it is used to supply the place of candles in poor families. An alum ore found in Burgundy, and consisting of clay, pyrites, and bitumen, is also distinguished by this name.

Amygdaloides, or **Mandel-stein.** A stone of the siliceous genus, which consists of a martial jasper, in which elliptical kernels of calcareous spar and serpentine stone are included.

Anacardium, Cashew Nut, or Marking Nut. At one extremity of the fruit of the cashew tree is a flattish kidney-shaped nut, between the rind of which and the thin outer shell is a small quantity of a red, thickish, inflammable, and very caustic liquor. This liquor forms a useful marking ink, as any thing written on linen or cotton with it is of a brown colour, which gradually grows blacker, and is very durable.

Analysis. Chemical analysis consists of a great variety of operations performed for the purpose of separating the component parts of bodies. In these operations, the most extensive knowledge of such properties of bodies as are already discovered must be applied, in order to produce simplicity of effect, and certainty in the results. Chemical analysis can hardly be executed with success by one who is not in possession of a considerable number of simple substances in a state of great purity, many of which, from their effects, are called reagents. The word analysis is applied by chemists to denote that series of operations, by which the component parts of bodies are determined, whether they be merely separated, or exhibited apart from each other; or whether these distinctive properties be exhibited by causing them to enter into new combinations, without the perceptible intervention of a separate state. The forming of new combinations is called synthesis; and, in the chemical examination of bodies, analysis or separation can scarcely ever be effected, without synthesis taking place at the same time.

As most of the improvements in the science of chemistry consist in bringing the art of analysis nearer to perfection, it is not easy to give any other rule to the learner, than the general one of consulting and remarking the processes of the best chemists, such as Scheele, Bergman, Berthollet, Kirwan, and others. The bodies which present themselves more frequently for examination than others, are minerals and mineral waters. In the examination of the former, it was the habit of the earlier chemists to avail themselves of the action of fire, with very few humid processes, which are such as might be performed in the usual temperature of the atmosphere. Modern chemists have improved the process by fire, by a very extensive use of the blow-pipe (see Blowpipe); and have succeeded in determining the component parts of minerals to great accuracy in the humid way. For the method of analysing mineral waters, see Waters (Mineral); and for the analysis of metallic ores, see Ores.

Several authors have written on the examination of earths and stones: the following is the method of Mr Kirwan:

When earths, or pulverulent mineral substances, are well dried, and separated from every visible heterogeneous substance, a portion of them should be weighed, and distilled in a glass retort until the bottom begins to grow red hot. In some cases it may be proper to receive the air that arises in a pneumatic apparatus; and in all it will be proper to examine what distils over or sublimes, whether it be acid or alkaline, with paper tinged blue by litmus, and part of its surface reddened by distilled vinegar. If the blue be reddened, an acid exists in the distilled liquid; if the red be effaced, and the blue restored, a volatile alkali is the cause of it; if the liquor precipitate lime-water, but does not precipitate a solution of nitrat of lime, then it contains carbonic acid; if it precipitate also nitrat of lime, it contains the sulphuric acid; if it contain the muriatic acid, it will not precipitate nitrat of lime, but it will nitrat of silver. The loss of weight of the residuum in the retort, and the weight of water in the receiver, will show the proportion of the volatile ingredients.

Another portion of the earth to be examined should be digested in about six or eight times its weight of pure water, and the properties of that water examined, to find whether the earth contain neutral salts. See Waters (Mineral).

The first step in the examination of consistent earths or stones is somewhat different from that of such as are pulverulent. Their specific gravity should first be examined; also their hardness, whether they will strike fire with steel, or can be scratched by the nail, or only by crystal, or stones of still greater hardness; also their texture, perviousness to light, and whether they be manifestly homogeneous or compound species, &c.

2d. In some cases, we should try whether they imbibe water, or whether water can extract any thing from them by ebullition or digestion.

3d. Whether they be soluble in, or effervesce with, acids, before or after pulverization; or whether decomposable by boiling in a strong solution of potash, &c., as gypsums and ponderous spars are.

4th. Whether they detonate with nitre.

5th. Whether they yield the fluor acid by distillation with sulphuric acid, or ammonia by distilling them with potash.

6th. Whether they be fusible per se with a blowpipe, and how they are affected by soda, borax, and microcosmic salt; and whether they decrepitate when gradually heated.

7th. Stones that melt per se with the blowpipe are certainly compound, and contain at least three species of earth, of which the calcareous is probably one; and if they give fire with steel, the siliceous is probably another.

The best general solvent for stones or earths appears to be aqua regia, composed of two parts nitric and one of muriatic acid: if the stone or earth effervesce strongly with acids, no other preparation is requisite, than a separation of such parts as are visibly heterogeneous, and pulverization; the solution is then easily performed in a digesting heat, if requisite. The undissolved residuum, if purely siliceous, will melt into a transparent glass with about ½ its weight of soda; if not, it is still compounded, and its soluble parts will yield to a reiterated digestion.

If the stone do not effervesce, or easily dissolve in acids after pulverization and digestion, but leaves an insoluble residuum evidently compound, or but slightly altered, it will require to be pulverized, and mixed with twice or thrice its weight of soda, and to be exposed to a low red heat for one or two hours. Mica was found to require a mixture of 4 times its weight of soda; after which it is to be separated from the alkali by lixiviation and filtration, washing it with distilled water until the water is absolutely tasteless, and precipitates no metallic solution.

The powdered stone, thus edulcorated, is to be dried by heating it to redness, and then weighed, and 100 grains taken for subsequent experiments: it were better if still more were used, but the analysis would be more expensive.

The powder is next to be digested in 8 or ten times its weight of aqua regia, in a boiling heat, in a retort to which a receiver is luted, and the digestion reiterated as long as any thing appears to be dissolved by fresh portions of the acid. Mica was found to require 50 times its weight of aqua regia before it was entirely decomposed, as the acid is so volatile as very soon to distil over. Sulphuric acid has the advantage of bearing a greater heat, dissolving sulphat of barytes, and of acting more powerfully on clay than aqua regia; but a large retort must be used, for often towards the end it puffs and throws up the earth or stone, and carries it into the receiver; besides, it does not sufficiently act on calces of iron, if these be much oxided. Nitric acid affects them still less: hence Mr. Kirwan often uses the sulphuric first; then what has been dissolved he precipitates by an alkaline carbonat, and redissolves the precipitate in aqua regia. A perfect solution being thus effected, the residuum is to be well washed, and the washings added to the solution: the residuum well dried and weighed, gives the weight of siliceous earth in the compound.

The solution is next to be examined; which we will suppose to contain the four soluble earths, lime, magnesia, barytes, and alumine; and also an oxide of iron. It always contains an excess of acid, of which it is in great measure deprived by boiling for a considerable time, as both acids are very volatile; and indeed of the muriatic none remains but what is combined with the oxide of iron, as the nitric chases it from the earths. By getting rid of this excess of acid, less alkali will be required for the succeeding precipitation, and less carbonic acid set loose, which would retain much of the precipitate by redissolving it: the solution should then be evaporated to about half a pint.

The solution being thus prepared, it is usual to precipitate the calx of iron from it by the prussiat of potash; but to this method Mr. Kirwan has two objections: 1st. that the barytes, if any, would also be precipitated and confounded in the Prussian blue; and, 2d. that this precipitation, beside being exceeding slow, seldom fails of leaving some iron still in the solution, as the excess of the prussiat of potash, which must necessarily be added to be certain that all the iron is precipitated, never fails to redissolve a portion of the Prussian blue, which thus remains in the liquor, and cannot be got rid of. Hence the method he uses is as follows: First, he prepares the prussiat of potash after the manner of Mr. Bergman, by digesting and boiling a pure alkaline solution over Prussian blue, until the alkali no longer effervesces with acids, or precipitates a solution of nitrat of lime, or any other earth, except barytes: he even makes it a little stronger; for if it be barely saturated with the prussic acid, it soon spoils, and precipitates other earths; the prussic acid evaporating. He next examines how much of this alkali is necessary to precipitate one grain of iron from its solution in dilute sulphuric or muriatic acid, and marks this on the label of the bottle that contains the alkali. Next follows the application.

The solution of the earths being weighed, take 100 grains of it, and on these gradually pour the prussiat of potash (a portion of which is also previously weighed), until all the iron, or barytes and iron, is precipitated; the weight of the alkali used gives that of the iron contained in 100 grains of the solution, and the quantity contained in 100 grains of the solution gives that contained in the whole solution, by the rule of proportion, from which the barytes, if any be found in subsequent experiments, is to be deducted.

The quantity of iron being thus found, the remainder of the solution is to be precipitated by the subcarbonat of soda, and then boiled for half an hour, to expel as much as possible of the carbonic acid; by this means the whole of its contents are precipitated, and nothing remains in solution but nitrat of soda and a little common salt: when the precipitate has settled, after one or two days rest, the liquor is to be poured off, and the last portions taken up with a glass syringe. Distilled water is then to be added to the precipitate, and boiled over it, and afterward poured off and taken up, until it comes off tasteless.

The precipitate, being sufficiently dried, is to be redissolved in nitric acid twice, and evaporated to dryness; then calcined for one hour in a white heat; and, lastly, treated with about six or eight times its weight of distilled vinegar, in a heat of about 60 degrees, for one or two hours: by this means the barytic, calcareous, and magnesian earths will be extracted and separated from the clay and oxide of iron, which will remain undissolved.

Of this acetous solution 100 grains should be taken and examined with the prussiat of potash: if any part be precipitated it is barytes, and by heating this to redness its weight may be known; or still better, by a previous experiment determining the quantity requisite to precipitate one grain of acetit of barytes, and, by the rule of proportion, the quantity of it in the whole solution may be found.

The remainder of the acetous solution is to be evaporated to dryness, and heated white in a clean polished iron crucible for two hours, then weighed and thrown into hot distilled water: the lime (if any) will be dissolved in a sufficient quantity of this water, of which an ounce can scarcely dissolve one grain, so that frequent affusions of hot water may be requisite; the magnesia will remain undissolved, and is to be dried and weighed; its weight gives that of the pure lime, from which that of the barytes (if any) is to be deducted: the lime-water may also be precipitated by an alkaline carbonat.

Lastly, the clay, and oxide of iron, which remained undissolved by the acetous acid, are to be heated slightly, to prevent their cohering, and reiteratedly boiled in nitric acid to dryness, and finally dissolved in that acid, which will then take up only the alumine, which may be precipitated, dried, and weighed; though indeed this troublesome operation may be unnecessary, as the weight of the martial part being known by the experiment with the prussiat of potash, that of the alumine is known of course when only the two remain. This is even better, as the oxide always increases in weight by these operations.

Beside this general method, some others may be used in particular cases.

Thus, to discover a small proportion of alumine or magnesia in a solution of a large quantity of lime, pure ammonia may be applied, which will precipitate the alumine or magnesia (if any be), but not the lime. Distilled vinegar applied to the precipitate will discover whether it be alumine or magnesia.

2dly. A minute portion of lime or barytes, in a solution of alumine or magnesia, may be discovered by the sulphuric acid, which precipitates the lime and barytes: the solution should be dilute, else the alumine also would be precipitated. If there be not an excess of acid, the oxalic acid is still a nicer test of lime: 100 grains of gypsum contain about 32 of lime: 100 grains of sulphat of barytes contain 67 of barytes; 100 grains of oxalat of lime contain 45 of lime. The insolubility of sulphat of barytes in 500 times its weight of boiling water sufficiently distinguishes it. From these data the quantities are easily investigated.

3dly. A minute proportion of alumine in a large quantity of magnesia may be discovered, either by precipitating the whole, and treating it with distilled vinegar; or by heating the solution nearly to ebullition, and adding more carbonat of magnesia, until the solution is perfectly neutral, which it never is when alumine is contained in it, as this requires an excess of acid to keep it in solution. By these means the alumine is precipitated in the state of embryon alum, which contains about half its weight of alumine (or for greater exactness it may be decomposed by boiling it in volatile alkali). After the precipitation the solution should be largely diluted, as the sulphat of magnesia, which remained in solution while hot, would precipitate when cold, and mix with the embryon alum.

4thly. A minute portion of magnesia in a large quantity of alumine is best separated by precipitating the whole, and treating the precipitate with distilled vinegar.

Lastly, Lime and barytes are separated either by precipitating the barytes by the prussiat of potash, or the lime by a caustic fixed alkali; or by precipitating both with the sulphuric acid, and evaporating the solution to a small compass, pouring off the liquor, and treating the dried precipitate with 500 times its weight of boiling water; what remains undissolved is sulphat of barytes.

But many refractory stones require in the first instance to be resolved by means of alkalis. For this purpose the common subcarbonat was usually employed, till Klaproth showed the alkali itself to be preferable. The stone, being reduced to an impalpable powder, and mixed with three times its weight of potash and a portion of water, is commonly set over the fire in a silver or platina crucible, and after the water is evaporated, kept for some hours at a red heat, after which it is lixiviated and tested with various reagents. Vauquelin indeed exposes the powdered stone and potash dry to a heat sufficient to convert it to a frit. The inconveniences of employing so great a heat, however, are obvious, and Mr. Lowitz informs us, that they may be avoided without the least disadvantage. Over the flame of a spirit lamp, that will hold an ounce and half, and is placed in a cylindrical tin furnace four inches high and three in diameter, with air-holes, and a cover perforated to hold the crucible, he boils the stone prepared as directed above, stirring it frequently. His crucible, which, as well as the spatula, is of very fine silver, holds two ounces and half, or three ounces. As soon as the matter is boiled dry, he pours in as much hot water as he used at first; and this he repeats two or three times more, if the refractoriness of the fossil require it. Large tough bubbles arising during the boiling are in general a sign that the process will be attended with success. Even the sapphire, though the most refractory of all Mr. Lowitz tried, was not more so in this than in the dry way.

Mr. Davy observes, that the boracic acid is very useful in analysing stones that contain a fixed alkali; as its attraction for the different earths at the heat of ignition is considerable, and the compounds it forms with them are easily decomposed by the mineral acids dissolved in water. His process is as follows: Let 100 grains of the stone to be examined be reduced to a fine powder, mixed with 200 grains of boracic acid, and fused for about half an hour at a strong red heat in a crucible of platina or silver. Digest the fused mass in an ounce and half of nitric acid diluted with seven or eight times the quantity of water, till the whole is decomposed; and then evaporate the solution till it is reduced to an ounce and half, or two ounces. If the stone contained silex, it will separate in this process, and must be collected on a filter, and edulcorated with distilled water, to separate the saline matter. The fluid, mixed with all the water that has been passed through the filter, being evaporated till reduced to about half a pint, is to be saturated with carbonat of ammonia, and boiled with an excess of this salt, till all that will precipitate has fallen down. The earths and metallic oxides being separated by filtration, mix nitric acid with the clear fluid till it has a strongly sour taste, and then evaporate till the boracic acid remains free. Filter the fluid, evaporate it to dryness, and expose it to a heat of 450° F., when the nitrat of ammonia will be decomposed, and the nitrat of potash or soda will remain in the vessel. The earths and metallic oxides, that remained on the filter, may be distinguished by the common processes. The alumine may be separated by solution of potash, the lime by sulphuric acid, the oxide of iron by succinat of ammonia, the manganese by hidrosulphuret of potash, and the magnesia by pure soda.

Under the head of mineral analysis nothing is of so much general importance as the examination of soils, with a view to the improvement of such as are less productive, by supplying the ingredients they want in due proportions to increase their fertility. To lord Dundonald and Mr. Kirwan we are much indebted for their labours in this field of inquiry; but Mr. Davy, assisted by the labours of these gentlemen, the facts and observations of Mr. Young, and his own skill in chemistry, having given at large, in a manner best adapted for the use of the practical farmer, an account of the methods to be pursued for this purpose, we shall here copy them.

The substances found in soils are certain mixtures or combinations of some of the primitive earths, animal and vegetable matter in a decomposing state, certain saline compounds, and the oxide of iron. These bodies always retain water, and exist in very different proportions in different lands, and the end of analytical experiments is the detection of their quantities and mode of union.

The earths commonly found in soils are principally silex, or the earth of flints; alumine, or the pure matter of clay; lime, or calcareous earth; and magnesia: for the characters of which see EARTHS. Silex composes a considerable part of hard gravelly soils, hard sandy soils, and hard stony lands. Alumine abounds most in clayey soils, and clayey loams; but even in the smallest particles of these soils it is generally united with silex and oxide of iron. Lime always exists in soils in a state of combination, and chiefly with carbonic acid, when it is called carbonat of lime. This carbonat in its hardest state is marble; in its softest, chalk. Lime united with sulphuric acid is sulphat of lime, or gypsum; with phosphoric acid, phosphat of lime, or the earth of bones. Carbonat of lime, mixed with other substances, composes chalky soils and marles, and is found in soft sandy soils. Magnesia is rarely found in soils: when it is, it is combined with carbonic acid, or with silex and alumine. Animal decomposing matter exists in different states, contains much carbonaceous substance, volatile alkali, inflammable aëriform products, and carbonic acid. It is found chiefly in lands lately manured. Vegetable decomposing matter usually contains still more carbonaceous substance, and differs from the preceding principally in not producing volatile alkali. It forms a great proportion of all peats, abounds in rich mould, and is found in larger or smaller quantities in all lands. The saline compounds are few, and in small quantity: they are chiefly muriat of soda, or common salt, sulphat of magnesia, muriat and sulphat of potash, nitrat of lime, and the mild alkalis. Oxide of iron, which is the same with the rust produced by exposing iron to air and water, is found in all soils, but most abundantly in red and yellow clays, and red and yellow siliceous sands.

The instruments requisite for the analysis of soils are few. A pair of scales capable of holding a quarter of a pound of common soil, and turning with a single grain when loaded: a set of weights, from a quarter of a pound troy to a grain: a wire sieve, coarse enough to let a peppercorn pass through: an Argand lamp and stand: a few glass bottles, Hessian crucibles, and china or queen's ware evaporating basins: a Wedgwood pestle and mortar: some filters made of half a sheet of blotting paper, folded so as to contain a pint of liquid, and greased at the edges: a bone knife: and an apparatus for collecting and measuring aëriform fluids.

The reagents necessary are muriatic acid, sulphuric acid, pure volatile alkali dissolved in water, solution of prussiat of potash, soap lye, and solutions of carbonat of ammonia, muriat of ammonia, neutral carbonat of potash, and nitrat of ammonia.

1. When the general nature of the soil of a field is to be ascertained, specimens of it should be taken from different places, two or three inches below the surface, and examined as to the similarity of their properties. It sometimes happens, that on plains the whole of the upper stratum of the land is of the same kind, and in this case one analysis will be sufficient. But in valleys, and near the beds of rivers, there are very great differences, and it now and then occurs, that one part of a field is calcareous, and another part siliceous; and in this and analogous cases, the portion different from each other should be analysed separately. Soils when collected, if they cannot be examined immediately, should be preserved in phials quite filled with them, and closed with ground glass stopples The most convenient quantity for a perfect analysis is from two hundred grains to four hundred. It should be collected in dry weather, and exposed to the air till it feels dry. Its specific gravity may be ascertained, by introducing into a phial, which will contain a known quantity of water, equal bulks of water and of the soil; which may easily be done, by pouring in water till the phial is half full, and then adding the soil till the fluid rises to the mouth. The difference between the weight of the water, and that of the soil, will give the result. Then if the bottle will contain four hundred grains of water, and gains two hundred grains when half filled with water and half with soil, the specific gravity of the soil will be 2; that is, it will be twice as heavy as water: and if it gained one hundred and sixty-five grains, its specific gravity would be 1825, water being 1000. It is of importance that the specific gravity of a soil should be known, as it affords an indication of the quantity of animal and vegetable matter it contains, these substances being always most abundant in the lighter soils. The other physical properties of soils should likewise be examined before the analysis is made, as they denote, to a certain extent, their composition, and serve as guides in directing the experiments. Thus siliceous soils are generally rough to the touch, and scratch glass when rubbed upon it: aluminous soils adhere strongly to the tongue, and emit a strong earthy smell when breathed upon: and calcareous soils are soft, and much less adhesive than aluminous soils.

2. Soils, when as dry as they can be made by exposure to the air, still retain a considerable quantity of water, which adheres with great obstinacy to them, and cannot be driven off without considerable heat: and the first process of analysis is to free them from as much of this water as possible, without affecting their composition in other respects. This may be done by heating the soil for ten or twelve minutes in a china basin over an Argand lamp, at a temperature equal to 300° F.; and if a thermometer be not used, the proper degree of heat may easily be ascertained by keeping a piece of wood in the basin in contact with its bottom; for as long as the colour of the wood remains unaltered, the heat is not too high; but as soon as it begins to be charred, the process must be stopped. In several experiments, in which Mr Davy collected the water that came over at this degree of heat, he found it pure, without any sensible quantity of other volatile matter being produced. The loss of weight in this process must be carefully noted; and if it amount to 50 grains in 400 of the soil, this may be considered as in the greatest degree absorbent and retentive of water, and will generally be found to contain a large proportion of aluminous earth: if the loss be not more than 10 or 20 grains, the land may be considered as slightly absorbent and retentive, and the siliceous earth as most abundant.

3. None of the loose stones, gravel, or large vegetable fibres, should be separated from the soil, till the water is thus expelled; for these bodies are often highly absorbent and retentive, and consequently influence the fertility of the land. But after the soil has been heated as above, these should be separated by the sieve, after the soil has been gently bruised in a mortar. The weights of the vegetable fibres or wood, and of the gravel and stones, should be separately noted down, and the nature of the latter ascertained: if they be calcareous, they will effervesce with acids; if siliceous, they will scratch glass; if aluminous, they will be soft, easily scratched

with a knife, and incapable of effervescing with acids.

4. Most soils, beside stones and gravel, contain larger or smaller proportions of sand of different degrees of fineness; and the next operation necessary is to separate this sand from the parts more minutely divided, such as clay, loam, marle, and vegetable and animal matter. This may be done sufficiently by mixing the soil well with water; as the coarse sand will generally fall to the bottom in the space of a minute, and the finer in two or three; so that by pouring the water off after one, two, or three minutes, the sand will be for the most part separated from the other substances; which, with the water containing them, must be poured into a filter. After the water has passed through, what remains on the filter must be dried and weighed; as must also the sand; and their respective quantities must be noted down. The water must be preserved, as it will contain the saline matter, and the soluble animal or vegetable matter, if any existed in the soil.

5. A minute analysis of the sand thus separated is seldom or never necessary, and its nature may be detected in the same way as that of the stones and gravel. It is always siliceous sand, or calcareous sand, or both together. If it consist wholly of carbonat of lime, it will dissolve rapidly in muriatic acid with effervescence: but if it consist partly of this and partly of siliceous matter, a residuum will be left after the acid has ceased to act on it, the acid being added till the mixture has a sour taste, and has ceased to effervesce. This residuum is the siliceous part; which being washed, dried, and heated strongly in a crucible, the difference of its weight from that of the whole, will indicate the quantity of the calcareous sand.

6. The finely divided matter of the soil is usually very compound in its nature: it sometimes contains all the four primitive earths of soils, as well as animal and vegetable matter; and to ascertain the proportions of these with tolerable accuracy, is the most difficult part of the subject. The first process to be performed in this part of the analysis is the exposure of the fine matter of the soil to the action of muriatic acid. This acid, diluted with double its bulk of water, should be poured upon the earthy matter in an evaporating basin, in a quantity equal to twice the weight of the earthy matter. The mixture should be often stirred, and suffered to remain for an hour, or an hour and half, before it is examined. If any carbonat of lime, or of magnesia, exist in the soil, they will have been dissolved in this time by the acid, which sometimes takes up likewise a little oxide of iron, but very seldom any alumine. The fluid should be passed through a filter; the solid matter collected, washed with distilled or rain water, dried at a moderate heat, and weighed. Its loss will denote the quantity of solid matter taken up. The washings must be added to the solution; which, if not sour to the taste, must be made so by the addition of fresh acid; and a little solution of prussiat of potash must be mixed with the liquor. If a blue precipitate occur, it denotes the presence of oxide of iron, and the solution of the prussiat must be dropped in, till no further effect is produced. To ascertain its quantity, it must be collected on a filter in the same manner as the other solid precipitates, and heated red: the result will be oxide of iron. Into the fluid freed from oxide of iron a solution of carbonat of potash must be poured till all effervescence ceases in it, and till its taste and smell indicate a considerable excess of alkaline salt. The precipitate that falls down is carbonat of lime; which must be collected on a filter, dried at a heat below that of redness, and afterward weighed. The remaining fluid must be boiled for a quarter of an hour, when the magnesia, if there be any, will be precipitated combined with carbonic acid, and its quantity must be ascertained in the same manner as that of the carbonat of lime. If any minute proportion of alumine should, from peculiar circumstances, be dissolved by the acid, it will be found in the precipitate with the carbonat of lime, and it may be separated from it by boiling for a few minutes with soap lye sufficient to cover the solid matter: for this lye dissolves alumine, without acting upon carbonat of lime. Should the finely divided soil be sufficiently calcareous to effervesce very strongly with acids, a simple method of ascertaining the quantity of carbonat of lime, sufficiently accurate in all common cases, may be adopted. As carbonat of lime in all its states contains a determinate quantity of acid, which is about 45 parts in a hundred by weight, the quantity of this acid given out during the effervescence occasioned by its solution in a stronger acid will indicate the quantity of carbonat of lime present. Thus, if you weigh separately one part of the matter of the soil, and two parts of the acid diluted with an equal quantity of water, and mix the acid slowly in small portions with the soil, till it ceases to occasion any effervescence, by weighing the mixture and the acid that remains, you will find the quantity of carbonic acid lost; and for every four grains and half so lost you will estimate ten grains of carbonat of lime. You may also collect the carbonic acid in the *pneumatic apparatus for the analysis of soils*, described in the article LABORATORY; and allow for every ounce measure of the carbonic acid two grains of carbonat of lime.

7. The quantity of insoluble animal and vegetable matter may next be ascertained with sufficient precision by heating it to a strong red heat in a crucible over a common fire, till no blackness remains in the mass,

stirring it frequently meanwhile with a metallic wire. The loss of weight will ascertain the quantity of animal and vegetable matter there was, but not the proportions of each. If the smell emitted, during this process, resemble that of burnt feathers, it is a certain indication of the presence of some animal matter; and a copious blue flame almost always denotes a considerable proportion of vegetable matter. Nitrat of ammonia, in the proportion of twenty grains to a hundred of the residuum of the soil, will greatly accelerate this process, if the operator be in haste; and not affect the result, as it will be decomposed and evaporate.

8. What remains after this decomposition of the vegetable and animal matter, consists generally of minute particles of earthy matter, which are usually a mixture of alumine and silex with oxide of iron. To separate these, boil them two or three hours in sulphuric acid diluted with four times its weight of water, allowing a hundred and twenty grains of acid for every hundred grains of the residuum. If any thing remain undissolved by this acid, it may be considered as silex, and be separated, washed, dried, and weighed, in the usual manner. Carbonat of ammonia being added to the solution in quantity more than sufficient to saturate the acid, the alumine will be precipitated; and the oxide of iron, if any, may be separated from the remaining liquid by boiling it. It scarcely ever happens, that any magnesia or lime escapes solution in the muriatic acid; but, if it should, it will be found in the sulphuric acid; from which it may be separated as directed above for the muriatic. This method of analysis is sufficiently precise for all common purposes: but if very great accuracy be an object, the residuum after the incineration must be treated with potash, and in the manner in which stones are analysed, as given in the first part of this article.

9. If the soil contained any salts, or soluble vegetable or animal matter, they will be found in the water used for separating the sand. This water must be evaporated to dryness at a heat below boiling. If the solid matter left be of a brown colour, and inflammable, it may be considered as partly vegetable extract. If its smell, when exposed to heat, be strong and fetid, it contains animal mucilaginous or gelatinous matter. If it be white and transparent, it may be considered as principally saline. Nitrat of potash or of lime is indicated in this saline matter by its sparkling when thrown on burning coals: sulphat of magnesia may be detected by its bitter taste: and sulphat of potash produces no alteration in a solution of carbonat of ammonia, but precipitates a solution of muriat of barytes.

10. If sulphat or phosphat of lime be suspected in the soil, a particular process is requisite to detect it. A given weight of the entire soil, as four hundred grains for instance, must be mixed with one third as much powdered charcoal, and kept at a red heat in a crucible for half an hour. The mixture must then be boiled a quarter of an hour in half a pint of water, and the solution, being filtered, exposed some days to the open air. If any soluble quantity of sulphat of lime, or gypsum, existed in the soil, a white precipitate will gradually form in the fluid, and the weight of it will indicate the proportion.

Phosphat of lime, if any be present, may be separated from the soil after the process for gypsum. Muriatic acid must be digested upon the soil in quantity more than sufficient to saturate the soluble earths. The solution must be evaporated, and water poured upon the solid matter. This fluid will dissolve the compounds of earths with the muriatic acid, and leave the phosphat of lime untouched.

11. When the examination of a soil is completed, the products should be classed, and their quantities added together; and if they nearly equal the original quantity of soil, the analysis may be considered as accurate. It must however be observed, that when phosphat or sulphat of lime is discovered by the independent process, No. 10, just mentioned, a correction must be made for the general process, by subtracting a sum equal to their weight from the quantity of carbonat of lime obtained by precipitation from the muriatic acid. In arranging the products, the form should be in the order of the experiments by which they are obtained. Thus 400 grains of a good siliceous sandy soil may be supposed to contain

		grains.
Of water of absorption - -		18
Of loose stones and gravel, principally siliceous - - - - - -		42
Of undecompounded vegetable fibres		10
Of fine siliceous sand - - -		200
Of minutely divided matter, separated by filtration, and consisting of		
Carbonat of lime - -	25	
Carbonat of magnesia -	4	
Matter destructible by heat, principally vegetable - -	10	
Silex - - - - - -	40	
Alumine - - - - -	32	
Oxide of iron - - - -	4	
Soluble matter, principally sulphat of potash and vegetable extract - - - - -	5	
Gypsum - - - - -	3	
Phosphat of lime - -	2	
	—	125
Amount of all the products		395
Loss - - - - -		5
		400

In this instance the loss is supposed small; but in general, in actual experiments, it will be found much greater, in consequence of the difficulty of collecting the whole quantities of the different precipitates; and when it is within thirty for four hundred grains, there is no reason to suspect any want of due precision in the processes.

12. When the experimenter is become acquainted with the use of the different instruments, the properties of the reagents, and the relations between the external and chemical qualities of soils, he will seldom find it necessary to perform, in any one case, all the processes that have been described. When his soil, for instance, contains no notable proportion of calcareous matter, the action of the muriatic acid, No 6, may be omitted: in examining peat soils, he will principally have to attend to the operation by fire and air, No. 7: and in the analysis of chalks and loams, he will often be able to omit the experiment with sulphuric acid, No. 8.

In the first trials that are made by persons unacquainted with chemistry, they must not expect much precision of result. Many difficulties will be met with: but in overcoming them the most useful kind of practical knowledge will be obtained; and nothing is so instructive in experimental science, as the detection of mistakes. The correct analyst ought to be well grounded in general chemical information; but perhaps there is no better mode of gaining it, than that of attempting original investigations. In pursuing his experiments, he will be continually obliged to learn from books the history of the substances he is employing or acting upon; and his theoretical ideas will be more valuable in being connected with practical operation, and acquired for the purpose of discovery.

The *analysis of vegetables* requires various manipulations, and peculiar attention, as their principles are extremely liable to be altered by the processes to which they are subjected. It was long before this analysis was brought to any degree of perfection. Formerly they were treated by fire alone; but the inadequacy of this instrument is obvious, as it not only changes their principles, but gives nearly similar products from vegetable substances of very different qualities. As an auxiliary, however, it is still of great use. The vegetable was first exposed to the gentle heat of a water-bath, to expel its aqueous parts: it was treated with boiling water, to extract its volatile oil, which distilled over with the water: and lastly it was exposed to destructive distillation in a retort, in which a coal remained, while in the receiver adapted to it were found a more or less saline phlegm, an empyreumatic oil, and the volatile salt, if they afforded any. The coal was after this lixiviated, to extract its fixed alkali, and frequently different metals may be detected in it. This process has been improved since the introduction of pneumatic chemistry, by collecting the aëriform products. Nitrat of potash is sometimes burnt with vegetable substances, to destroy their hidrogen and carbon more completely, to extract from them their fixed saline and earthy substances, and to detect the existence of some metallic oxides, particularly those of manganese and iron.

The action of the acids on vegetables is very striking. That the powerful acids may act only as simple solvents of the vegetable substances, it is necessary that they should be very dilute. There is scarcely any vegetable substance, that is not susceptible of being dissolved by all the acids when diluted with water, either with or without the aid of heat. If this solution be effected without sensible decomposition, there is no change of colour in the vegetable substance, and no alteration in the acid, from which it may frequently be separated by means of an earth or alkali. If such a solution be kept, however, the vegetable substance will be found gradually to alter, till its properties are the same as if it had been treated by the acid in a stronger state. The sulphuric acid appears to alter vegetable substances to which it is applied, by attracting a portion of their oxigen and hidrogen, so as to form water, with which it becomes considerably weakened, without any alteration of its own properties; while thus it sets free a portion of their carbon, so that they appear more or less charred. A portion of the vegetable substance too is converted into the state of an acid, which is commonly the acetous.

The muriatic acid appears to act upon them in a similar manner; and when, after remaining long in contact with them, muriat of ammonia is extracted from the mixture, we may conclude, not that this alkali previously existed in it, but that it has been formed in the process by a combination of its principles.

Very strong nitric acid burns vegetable substances with such activity, that it inflames several. According to the nature of the substance, therefore, on which it is intended to act, it must be diluted with half its weight of water, or even twice or thrice its weight; and its action, if necessary, may be promoted, or made to commence, by a greater or less increase of temperature. If the action be but slight, nitrous oxide mixed with a small quantity of carbonic acid will be evolved, with a slow and gentle effervescence: if it be more powerful, these airs will be evolved more speedily, and in larger quantity: if it be still further augmented, a portion of the acid will be completely decomposed; for, as we employ from three to six times the quantity of the vegetable substance thus treated, there is always more present than is necessary to obtain the products we seek. The stronger the acid is, the more carbonic acid and nitrous oxide are generally obtained; consequently the more oxigen is separated from the nitric acid, and the more carbon is taken from the vegetable substance and burned by the oxigen. The general and most abundant product of this reciprocal decomposition is a series of different vegetable acids, sometimes three or four, at others, perhaps, a single one, all consisting of oxigen, hidrogen, and carbon, in various proportions.

Beside converting them into acids, there are some vegetable substances, a portion of which the nitric acid converts into a kind of fat oil; others from which it produces a fat of resin. In the first, it forms powders insoluble in water, but soluble in the alkalis, though not fusible like fats: in the last it disengages and compresses prussic acid, and almost always evolves ammonia at the same time.

Some of the immediate materials of vegetables are separated to our hands by Nature in a state of greater or less purity, as the gums, resins, and balsams, that exude from plants. The expressed juices contain various matters, that may be separated by the appropriate reagents. Maceration, infusion, and decoction in water, take up certain parts soluble in this menstruum; and alcohol will extract others that water will not dissolve. The mode of separating and distinguishing these materials will easily be collected from their characters, as given under the head VEGETABLE KINGDOM, and under the different articles themselves.

The nature of the vegetable substance we wish to examine, and the particular object of our inquiry, will determine to which of the methods above indicated we must have recourse, either singly or combined: but we cannot expect a complete analysis without employing various means.

The *analysis of animal substances*, like that of vegetables, was formerly conducted by fire alone, and has since been greatly improved by the employment of reagents. When an animal substance is heated in a retort, water is first repelled from it, more or less in quantity, according to the state of the substance, and impregnated with its aroma. This water soon begins to come over brown and turbid, containing different ammoniacal salts; and is presently accompanied with carbonat of ammonia, which at first dissolves in it, and then crystallizes in the neck of the retort and against the sides of the receiver. This is succeeded by an oil, which grows thicker and deeper coloured as the operation proceeds. When this oil rises, little or no water comes over: but the carbonat of ammonia continues to sublime, and gases are evolved. When nothing more is extricated, the fire is put out, the vessels are left to cool, and a coaly matter is found in the retort. All these products require a separate examination.

If the colour, and turbid water that comes over after the evaporation of the mere aqueous part, be rectified by a subsequent distillation, it generally comes over more clear, if not transparent; and carbonat of ammonia is frequently separated from it. If treated with the metallic solutions, it precipitates them; if with lime, ammonia is disengaged; and by adding phosphoric acid after the lime, and dissolving in water, a portion of acetous acid, combined with animal matter, will be obtained, which Berthollet mistook for a peculiar acid, and called the zoonic. In fact, this liquor always contains an ammoniacal soap, and carbonat of ammonia; beside which, the ammonia is sometimes in combination with the muriatic, prussic, sebacic, and acetous acids.

The oil differs from that obtained from vegetables in a similar way, by its abundance, consistency, and ammoniacal nature; it has a very fetid smell, and turns blue vegetable colours green. By repeated distillations it may be rendered limpid, odorous, and very volatile. In this rectification the carbon that coloured it is separated from it.

The gasses, which are very fetid, very combustible, and frequently burn with an oily flame, are a mixture of carbonated hidrogen, frequently too sulphurated and even phosphorated at the same time, and carbonic acid gas.

The coal, which frequently adheres so firmly to the retort that its weight cannot be ascertained but by weighing them together, is generally less in proportion than is left after the destructive distillation of a vegetable substance; and it is so difficult of incineration, that the strong fire necessary for this purpose frequently changes the nature of its residuum, and volatilizes a part of its salts. It is advisable, therefore, to detonate this coal with nitrat or oximuriat of potash, in vessels proper for collecting the gaseous products, and the pulverulent residuum. The incombustibility of this coal may be attributed to the little carbon it contains, its dense state, and its union with the phosphats of lime and soda, and oxides of iron and maganese.

Most of the animal fluids are miscible with water; but a heat of 160° F. or upward, separates albumen from it by coagulating it, while gelatine is more easily dissolved in water in proportion as the heat employed is greater. Water likewise loosens the texture of the soft parts, but, by long maceration, completely alters their nature. See ADIPOCERE.

Alcohol dissolves the resinous parts of animal substances, and powerfully coagulates the albuminous.

The weaker acids, and the more powerful acids, if much diluted, coagulate and thicken the albuminous fluids, quickly dissolve the gelatinous and membranous parts, and by the assistance of heat dissolve the fibrin. This solution, if it contain a large proportion of fibrin, is of a gelatinous consistence. They dissolve and partly decompose the harder solids, converting their phosphat of lime into an acidulous salt. If they remain long in contact with the soft membranous or fibrous substance, they will be found partly saturated with ammonia.

But the action of the nitric acid is most eminent. If five ounces, troy, of muscular flesh be put into a matrass, with an equal weight of nitric acid at 32°, and of water, and boiled gently, it will give out a hundred cubic inches of gas, ninety of which will be azot, and ten carbonic acid. The residuum will consist of matter retaining its original fibrous structure, a yellowish liquor, and a yellow greasy substance floating on it. If the grease be separated, and the liquor filtered off, the solid residuum will impart a yellow colour to boiling water, and the property of reddening vegetable blues. After repeated washings, it does not render the water acid, though it continues to tinge it. Washing renders its colour deeper than at first; and when diffused in a little water, it still reddens litmus paper. Dissolved in an alkali, it assumes a deep blood colour, and acids precipitate it in yellow flakes. This flaky matter feels fat and pitchy, has a rancid smell, and a very bitter taste. Placed on burning coals, it melts, swells emits a greasy fetid vapour, and leaves but little coal. It saturates alkalis so as nearly to conceal their properties; and forms, with potash, or ammonia, a soap that lathers in water, is not decomposed by carbonic acid, and precipitates the solutions of lead and mercury in yellowish white flakes. It decomposes alkaline carbonats with effervescence; and by the assistance of water and a gentle heat it decomposes acetit of potash.

This yellow matter being exposed to the action of alcohol, a small quantity of fat, which it contained, is dissolved, and an acid is left behind. This acid is of a deeper colour than when combined with the fat, reddens litmus paper more quickly, does not melt as before, or exhale the same rancid smell, but emits a fetid ammoniacal vapour. By distillation, it affords the usual products of animal substances, so that it appears to be a compound of nitrogen, hidrogen, carbon, and oxigen.

The colour of the nitric acid, with which the muscular flesh was decomposed, resembles that of a solution of chromat of potash. On being saturated with carbonat of potash, the liquor at first assumes an orange colour, after which it becomes turbid, and lastly deposits a small quantity of an orange red powder. This mixture on distillation affords a clear colourless liquid, of a rancid smell, containing a little ammonia, probably formed by the nitric acid, and leaves in the retort a blackish brown residuum.

If the nitric solution itself be distilled, a similar limpid liquor comes over; and the liquor remaining in the retort becomes yellower by concentration, and at length flattish crystals form in it, when the mother water attains the consistency of a solution of gum. Nitric acid occasions a copious emission of red fumes from the concentrated solution.

The mother water has an acid and bitter taste: on the addition of a little potash it becomes of a blood red colour: alcohol throws down from it a flaky precipitate, which afterward forms itself into fine semi-transparent grains of a pleasant acid flavour. Half a gramme of this salt, being calcined, left ·21 of a gramme of a very light yellowish residuum, which dissolved with effervescence in nitric acid, and on evaporation produced crystals of sulphat of lime and nitrat of potash. It was ascertained to be a mixture of sulphat of lime and acidulous oxalat of potash.

After this precipitation, by means of alcohol, the mother water affords a second precipitate on the addition of lime-water, which consists of oxalat of lime. After this, gentle evaporation converts it into a brown viscid fluid like a sirup, which has a bitter taste, resembling that of the outer husks of walnuts. A considerable portion of alcohol coagulates this, and a copious white precipitate is thrown down, which is pure malat of lime, the yellow acrid substance being dissolved in the alcohol. The alcohol likewise holds in solution a small portion of nitrat of lime. If this alcoholic solution be concentrated, carbonat of potash separates from it a small portion of granulated crystals, very inflammable, and very detonant, like those obtained from indigo.

Thus, on treating the muscular part of animals with nitric acid, we obtain a considerable portion of nitrogen, and some carbonic acid gas; fatty matter; a bitter substance; a yellow insipid matter, of little solubility, though acid; another acid yellow matter, bitter, and more soluble; an inflammable detonating substance; and oxalic and malic acids.

This yellow acid matter, which has been recently detected by Fourcroy and Vauquelin, appears, according to them, to have considerable analogy with the coloured matter of bilious concretions, and that found in the urine of icteric patients; and they observe, that acetat of soda, alkaline carbonats, and yolks of eggs, all of which have been found serviceable in jaundice, are its best solvents. They add, that it likewise resembles the acids that may be obtained from fat grown rancid and yellow by keeping, or lard mixed with nitric acid to form oxigenated pomatum.

See ANIMAL KINGDOM, and the different kinds of animal substances under their respective names.

Angelica. The roots have a pungent agreeable bitterish taste, and a strong aromatic smell, somewhat of the musky kind. Their activity resides in an essential oil and a resinous matter. The oil is obtained by distillation with water. The oil and the resin are totally extracted by digestion in alcohol; and water, by the like treatment, extracts them, though in part only.

These roots, like those of most of the umbelliferous plants, are very apt to be preyed upon by worms, to become carious, and fall into powder. So long as they are merely worm-eaten, and not powdery, they are as fit for making the essential oil, or the tinctures in ardent spirit or water, as in their most perfect state; the insects preying first upon the mucilaginous and insipid parts, and not upon the resinous and oily parts. When such roots are made use of, care must be taken to beat out the worms and dust as much as possible. To preserve the roots of angelica, they must be thoroughly dried and kept in close vessels or packages in a dry place.

Anil, or Nil. This plant, from the leaves of which indigo is prepared, grows in America. It has several slender knotty stalks, which spread into small branches, clothed each with from eight to ten pair of leaves, and an odd one at the end. The leaf is small, fleshy, and soft, of a greenish brown colour on the upper side, pale and as it were silvery-coloured beneath. The plant rises to the height of about two feet, and produces reddish flowers, in shape resembling those of broom, but smaller, followed by oblong pods containing the seeds.

The culture of this plant is as follows: The ground being thoroughly cleared of weeds, which is a principal object, a number of slaves, ranged in a line, march across, making little trenches of the width of their hoes, and two or three inches deep, about a foot distant from each other every way. Then, returning, they drop some seeds in each trench, and afterward cover them with the earth taken out. In moist weather the plant comes up in two or three days; and in about two months it is fit for cutting. If suffered to stand till it runs into flower, the leaves become too dry and too hard, and the indigo obtained from them proves less in quantity, and less beautiful. The due point of maturity is known by the leaves beginning to grow less supple or more brittle. In a rainy season the cutting may be repeated every six weeks. Cutting in dry weather kills the plant, which, if this be avoided, continues to afford fresh crops for two years. For the preparation of Indigo, see that article.

Animal Kingdom. The various bodies around us, which form the objects of chemical research, have all undergone a number of combinations and decompositions before we take them in hand for examination. These are all consequences of the same attractions or specific properties that we avail ourselves of, and are modified likewise by virtue of the situations and temperatures of the bodies presented to each other. In the great mass of unorganized matter, the combinations appear to be much more simple than such as take place in the vessels of organised beings, namely plants and animals: in the former of which there is at least a peculiar structure of tubes conveying various fluids; and in the latter there is not only an elaborate system of vessels, but likewise, for the most part, an augmentation of temperature. From such causes as these it is, that some of the substances afforded by animal bodies are never found either in vegetables or minerals; and so likewise in vegetables are found certain products never unequivocally met with among minerals. Hence, among the systematical arrangements used by chemists, the most general is that which divides bodies into three kingdoms, the animal, the vegetable, and the mineral.

Animal as well as vegetable bodies may be considered as peculiar apparatus for carrying on a determinate series of chemical operations. Vegetables seem capable of operating with fluids only, and at the temperature of the atmosphere, as we have just noticed. But most animals have a provision for mechanically dividing solids by mastication, which answers the same purpose as grinding, pounding, or levigation does in our experiments; that is to say, it enlarges the quantity of surface to be acted upon by solvents. The process carried on in the stomach appears to be of the same kind as that which we distinguish by the name of digestion; and the bowels, whatever other uses they may serve, evidently form an apparatus for filtering or conveying off the fluids; while the more solid parts of the aliments, which are probably of such a nature as not to be rendered fluid, but by an alteration which would perhaps destroy the texture of the machine itself, are rejected as useless. When this filtered fluid passes into the circulatory vessels, through which it is driven with considerable velocity by the mechanical action of the heart, it is subjected, not only to all those changes which the chemical action of its parts is capable of producing, but is likewise exposed to the air of the atmosphere in the lungs, into which that elastic fluid is admitted by the act of respiration. Here it undergoes a change of the same nature as happens to other combustible bodies when they combine with its vital part, or oxigen. This vital part becomes condensed, and combines with the blood; at the same time that it gives out a large quantity of heat, in consequence of its own capacity for heat being diminished. A small portion of azot likewise is absorbed, and carbonic acid is given out. Some curious experiments of Spallanzani show, that the lungs are not the sole organs by which these changes are effected. Worms, insects, shells of land and sea animals, eggshells, fishes, dead animals, and parts of animals, even after they have become putrid, are capable of absorbing oxigen from the air, and giving out carbonic acid. They deprive atmospheric air of its oxigen as completely as phosphorus. Shells, however, lose this property when their organization is destroyed by age. Amphibia, deprived of their lungs, lived much longer in the open air, than others in air destitute of oxigen. It is remarkable, that a larva, weighing a few grains, would consume almost as much oxigen in a given time as one of the amphibia a thousand times its bulk. Fishes, alive and dead, animals, and parts of animals confined under water in jars, absorbed the oxigen of the atmospheric air over the water. Muscles, tendons, bones, brain, fat, and blood, all absorbed oxigen in different proportions, but the blood did not absorb most; and bile appeared not to absorb any.

It would lead us too far from our purpose, if we were to attempt an explanation of the little we know respecting the manner in which the secretions or combinations that produce the various animal and vegetable substances are effected, or the uses of those substances in the œconomy of plants and animals. Most of them are very different from any of the products of the mineral kingdom. We shall therefore only add, that these organized beings are so contrived, that their existence continues, and all their functions are performed, as long as the vessels are supplied with food or materials to occupy the place of such as are carried off by evaporation from the surface, or otherwise, and as long as no great change is made, either by violence or disease, in those vessels or the fluids they contain. But as soon as the entire process is interrupted in any very considerable degree, the chemical arrangements become altered; the temperature in land animals is changed, the minute vessels are acted upon and destroyed, life ceases, and the admirable structure, being no longer sufficiently perfect, loses its figure, and returns, by new combinations and decompositions, to the general mass of unorganized matter, with a rapidity which is usually greater, the more elaborate its construction.

The parts of vegetable or animal substances may be obtained, for chemical examination, either by simple pressure, which empties the vessels of their contents; by digestion in water, or in other fluids, which dissolve certain parts, and often change their nature; by destructive distillation, in which the application of a strong heat alters the combination of the parts, and causes the new products to pass over into the receiver in the order of their volatility; by spontaneous decomposition or fermentation, wherein the component parts take a new arrangement, and form compounds which did not for the most part exist in the organized substance; or, lastly, the judicious chemist will avail himself of all these several methods singly, or in combination. He will, according to circumstances, separate the parts of an animal or vegetable substance by pressure, assisted by heat; or by digestion or boiling in various fluids added in the retort which contains the substance under examination. He will attend particularly to the products which pass over, whether they be permanently elastic, or subject to condensation in the temperatures we are able to produce. In some cases, he will suffer the spontaneous decomposition to precede the application of chemical methods; and in others he will attentively mark the changes which the products of his operations undergo in the course of time, whether in closed vessels, or exposed to the open air. Thus it is that, in surveying the ample field of nature, the philosophical chemist possesses numerous means of making discoveries, if applied with judgment and sagacity; though the progress of discovery, so far from bringing us nearer the end of our pursuit, appears continually to open new scenes, and, by enlarging our powers of investigation, never fails to point out additional objects of inquiry. See ANALYSIS of animal substances.

Animal and vegetable substances approach each other by insensible gradations; so that there is no simple product of the one which may not be found in greater or less quantity in the other. The most general distinctive character of animal substances is that of affording volatile alkali by destructive distillation. Some plants however afford it likewise. Neither contain it ready formed; but it appears to be produced by the combination of hidrogen and azot, during the changes produced either by fire, or by the putrefactive process. See AMMONIA; and GAS (AMMONIACAL).

Our knowledge of the products of the animal kingdom by the help of chemical analysis, is not yet sufficiently matured to enable us to arrange them according to the nature of their component parts, which appear to consist chiefly of hidrogen, oxigen, carbon, and azot; and with these, sulphur, phosphorus, lime, magnesia, and soda, are frequently combined in variable proportions. Animal substances may therefore be conveniently divided into, 1. Such as are usually obtained without destroying life. These are milk, eggs, urine, excrement, the matter of perspiration, ambergris, &c. wax, honey, lac, silk, hair, horn, feathers, &c. Or, 2. Such parts of animals as are obtained by destroying them, or depriving them of life. These are blood; various solids confounded under the name of flesh; fat, adipocere, gluten, gelatine, bile, the gastric juice, and several acids; together with calcareous earth, and other substances common to the mineral and vegetable kingdoms. For the properties of which, see the respective articles.

When animal substances are left exposed to the air, or immersed in water or other fluids, they suffer a spontaneous change, which is more or less rapid according to circumstances. The spontaneous change of organized bodies is distinguished by the name of fermentation. In vegetable bodies there are distinct stages or periods of this process, which have been divided into the vinous, acetous, and putrefactive fermentations. Animal substances are susceptible only of the latter, during which, as in all other spontaneous changes, the combinations of chemical principles become in general more and more simple. There is no doubt but much instruction might be obtained from accurate observations of the putrefactive processes in all their several varieties and situations; but the loathsomeness and danger attending on such inquiries has hitherto greatly retarded our progress in this department of chemical science. See FERMENTATION (PUTREFACTIVE).

ANIME, improperly called gum anime, is a resinous substance imported from New Spain and the Brasils. There are two kinds, distinguished by the names of oriental and occidental. The former is dry, and of an uncertain colour, some specimens being greenish, some reddish, and some of the brown colour of myrrh. The latter is in yellowish, white, transparent, somewhat unctuous tears, and partly in larger masses, brittle, of a light pleasant taste, easily melting in the fire, and burning with an agreeable smell. Like resins, it is totally soluble in alcohol, and also in oil. Water takes up about 1-16th of the weight of this resin by decoction. The spirit, drawn off by distillation, has a considerable degree of the taste and flavour of the anime; the distilled water discovers on its surface some small portion of essential oil.

This resin is used by perfumers, and also in certain plasters, wherein it has been supposed to be of service in nervous affections of the head and other parts; but there are no reasons to think that, for medical purposes, it differs from common resins.

ANISEED contains, beside its essential odorous oils, a gross one of the expressible kind. The essential oil, and the smell and taste of the seeds which depend upon it, are confined to the outer thin skin: the inner kernel, which is commonly divided longitudinally into two portions, has little or no smell, and exceeding little taste: in this resides the gross oil, naturally inodorous and insipid, but which, nevertheless, in its separation from the seed by the press, brings with it a part of the essential oil, so as to become strongly impregnated with the peculiar flavour of the aniseed; its colour is greenish.

The essential oil, though mild in taste, has an extremely strong smell, which it communicates to whatever it touches in such a degree as scarcely to be overpowered. It coagulates in a temperature much warmer than is necessary to freeze water. The term of its congelation, which seems to be about 50 degrees of Fahrenheit's thermometer, but is not very easy to be determined with great accuracy, because it is a bad conductor of heat, was proposed by Boyle, in the infancy of the thermometer, to be used as a fixed point in the graduation of that instrument. This oil, like other essential oils, is soluble in alcohol, from which it in part separates by cooling. Neumann observes, that it dissolves sulphur in greater quantity than any other oil expressed or distilled. Another singular fact is noticed by the same author, viz. that whereas the distillation of essential oil from other vegetables is in general facilitated by the addition of salt to the water which is added to the vegetable substance, such an addition is particularly hurtful in this process, the aniseed yielding only half as much oil as it does when distilled with pure water.

ANNEAL. We know too little of the arrangement of particles to determine what it is that constitutes or produces brittleness in any substance. In a considerable number of instances of bodies which are capable of undergoing ignition, it is found that sudden cooling renders them hard and brittle. This is a real inconvenience in glass, and also in steel, when this metallic substance is required to be soft and flexible. The inconveniencies are avoided by cooling them very gradually, and this process is called annealing. Glass vessels, or other articles, are carried into an oven or apartment over the great furnace, called the leer, where they are permitted to cool, in a greater or less time, according to their thickness and bulk. The annealing of steel, or other metallic bodies, consists simply in heating them, and suffering them to cool again either upon the hearth of the furnace, or in any other situation where the heat is moderate, or at least the temperature is not very cold.

ANNOTTO. The pellicles of the seeds of the *bixa orellana*, a liliaceous shrub, from 15 to 20 feet high in good ground, afford the red masses brought into Europe under the name of Annotto, Orlean, and Roucou. The red seeds, cleared from the pods, are first pounded, and then steeped in water for a few weeks, or even months, when the coloured liquor is pressed through sieves. The seeds thus strained out are then left to ferment, when they are again pounded, steeped in water, and strained; and this is repeated till no more of the colouring matter is left. The liquor is then set by till the colour is deposited, which it usually is in about a fortnight; it is poured off, to be used again for the same purpose. The sediment is boiled to the consistence of a paste, continually stirring it, and is then dried in the shade in cakes, 7 or 8 inches thick.

Mr. Leblond, who gives this account in the An. de Chemie, justly reprobates this practice of the planters in French Guyana, and recommends that the seeds be simply washed, to divest them of the colouring matter, which is entirely on their surface: to pass the water through fine sieves, in order to free it from the pellicles: to precipitate the colour by lemon-juice or vinegar: and then to dry it in the ordinary way, or by setting it to drain in bags like indigo. According to the testimony of Vauquelin, and of some dyers at Paris, the annotto thus prepared goes at least four times as far as that of the shops, is more soluble, and affords a purer colour.

The annotto commonly met with among us is moderately hard, of a brown colour on the outside, and a dull red within. It is difficultly acted upon by water, and tinges the liquor only of a pale brownish yellow colour. In rectified spirit of wine it very readily dissolves, and communicates a high orange or yellowish red. Hence it is used as an ingredient in varnishes, for giving more or less of an orange cast to the simple yellows. Alkaline salt renders it perfectly soluble in boiling water, without altering its colour.

Labat informs us, that the Indians prepare an annotto greatly superior to that which is brought to us. of a bright shining red colour, almost equal to carmine; that, for this purpose, instead of steeping and fermenting the seeds in water, they rub them with the hands, previously dipped in oil, till the pellicles come off and are reduced into a clean paste, which is scraped off from the hands with a knife, and laid on a clean leaf in the shade to dry. De Laet, in his notes on Margrave's Natural History of Brazil, mentions also two kinds of annotto; one of a permanent crimson colour (coccineus), used as a fucus; and another, which gives a colour inclining more to that of saffron. This last, which is our annotto, he supposes to be a mixture of the first sort with certain resinous matters, and with the juice of the roots of the tree.—The goodness of annotto is commonly tried by rubbing it on the nail, soaping the place, and washing it with water, when it ought to leave a stain.

Beside its use in dyeing, (see that article,) it is employed for colouring cheese

Anthemis, Chamomile. Two species of this plant are used in medicine, and one in dyeing. The flowers of the *anthemis nobilis*, common chamomile, are much used as a warm bitter. They give out 3-8ths of their weight to spirit, and ½ their weight to water. The root of the *anthemis pyrethrum*, pellitory of Spain, is a very warm stimulant aromatic, but it is used only as a masticatory, in tooth-ach, rheumatic pains of the face, or paralytic affections of the mouth and tongue. According to Neumann, it yields 1-48th of spirituous extract, and 7-32ds of watery; but Cartheuse says, 1-24th of spirituous, and 3-8ths of watery.

The *anthemis tinctoria*, oxeye chamomile, according to Schæffer, gives a fine yellow to silk, if a little solution of tin, mixed with tartar sufficient to turn it yellow, be dropped into a decoction of it. The dye is to be kept warm, but not boiling; and soft water, that does not precipitate solution of tin, should be employed.

Anthracite of Hauy.
Anthracolite, of Some. } A species of stone coal, found only, according to Dolomieu, in the primitive mountains. It consists of about 64 oxide of carbon, 32·5 silex, and 3·5 iron.

Antimony. The word antimony is always used in commerce to denote a metallic ore, consisting of sulphur combined with the semimetal which is properly called antimony. Sometimes this sulphuret is termed crude antimony, to distinguish it from the pure metal, or regulus, as it was formerly called. According to prof. Proust, the sulphuret contains 26 per cent. of sulphur. He heated 100 parts of antimony with an equal weight of sulphur in a glass retort, till the whole was well fused and the excess of sulphur expelled, and the sulphuret remaining was 135. The result was the same after repeated trials: 100 parts of antimony, with 300 of red sulphuret of mercury, afforded 135 to 136 of sulphur. These artificial sulphurets lost nothing by being kept in fusion an hour: and heated with an equal weight of sulphur they could not be made to take up more. Some of the native sulphurets of the shops, however, appear to have a small portion more of sulphur united with them, as they will take up an addition of 7 or 8 per cent. of antimony.

Antimony is of a dusky white colour, very brittle, and of a plated or scaly texture. Its specific gravity, according to Brisson, is 6·7021, but Bergman makes it 6·86. Soon after ignition it melts, and by a continuance of the heat it becomes oxided, and rises in white fumes, which may afterward be volatilized a second time, or fused into a hyacinthine glass, according to the management of the heat: the first were formerly called argentine flowers of regulus of antimony. In closed vessels, the antimony rises totally without decomposition. This metallic substance is not subject to rust by exposure to air, though its surface becomes tarnished by that means. Its oxides are a little soluble in water; and in this respect they resemble the oxide of arsenic, probably by an approach toward the acid state.

If antimony be brought to a white heat, and then shaken, it takes fire with a kind of explosion. If a little be fused on a bit of charcoal before the blowpipe, and thrown out, it will divide into globules, and burn with a brilliant white light as it falls to the ground.

The white oxide has somewhat of acidity to the taste, and is used for giving to gas or enamel an orange or saffron colour. M. Thenard calculates, that this oxide contains 0·20 of oxigen; and he adds, if it be carefully and gently heated in a crucible, it first passes to a yellow oxide, very vitrifiable, and containing 0·19 of oxigen; then to an orange, containing 0·18; next to a chesnut brown, holding 0·16; and, lastly, to black oxide, having only 0·02; before it resumes the metallic state. Antimony, however, appears capable, as will be seen below, of taking up 30 per cent. of oxigen.

If the nitric sulphuret of antimony be roasted slowly in a broad shallow vessel, it loses the greater part of its sulphur, and is converted into a gray oxide; formerly the *gray calx*, now *gray sulphurated oxide of antimony*. This, which consists of about 78 parts of antimony, 16 of oxigen, and 6 of sulphur, being melted quickly in a strong heat, is converted into *glass of antimony*, or *vitreous sulphurated oxide*.

The sulphuret of antimony forms a triple compound with potash, either by fusion, or in the humid way. Lemery directs pure alkali, in a liquid state, to be diluted with thrice as much water, put in a clean iron pan, and set over the fire. When it has begun to boil, well levigated sulphuret of antimony, equal in weight to a sixteenth of the alkali, is to be stirred in. After it has boiled seven or eight minutes, it is to be filtered as soon as removed from the fire, and, as it cools, the hidrosulphuret, or *kermes mineral*, will fall down. This being separated from the cold solution, a further precipitation will ensue on the addition of dilute sulphuric acid, the *golden sulphur of antimony*. According to Thenard, the first consists of 72·760 of brown oxide of antimony, 20·298 of sulphurated hidrogen, and 4·156 of sulphur; 2·786 being lost in water, &c.: the last of 68·300 of orange oxide, 17·877 of sulphurated hidrogen, and 11 or 12 of sulphur.

If crude antimony, finely powdered, be mixed with thrice its weight of nitrat of potash, and projected gradually into a red-hot crucible, it detonates, and a white oxide combined with sulphat of potash is the result. This, the *solvent of Rotrou*, or *unwashed calx of antimony* of the old chemists, is somewhat deliquescent; and if the sulphat of potash be separated from it by repeated affusion of water, we have the *calcined antimony* of the London Pharmacopœia, or the *ceruse of antimony*, *diaphoretic antimony* of others, a substance apparently inert, at least in doses of a dram or two. Some oxide of antimony is dissolved in the water, which may be precipitated by acids, and is then the *materia perlata* of Kerkrinius. The compound salt obtained by evaporation and crystallization after the precipitation of the oxide was very improperly called the *antimoniated nitre* of Stahl.

If, however, the nitrat of potash be only thrice the weight of the antimony, we have the *mild antimonial emetic* of Boerhaave, which occasions slight nausea and gentle vomiting, with a considerable discharge of saliva and thick urine. When equal parts are used, the produce is of a dark brownish red colour. This, the *crocus antimonii* *, *crocus metallorum*, or *hepar antimonii*, is an extremely violent emetic, given from one grain to five or six. When the nitrat is only half the weight of the antimony, we have the *crocus antimonii mitior*, which is still strongly emetic in a similar dose: if the nitrat be but one sixth, the product is in general more mildly emetic, and likewise purgative, in doses of eight or ten grains: and when the nitrat is only one eighth, it is said to act chiefly as an alterative or diaphoretic in doses of fifteen or twenty grains. The last has been termed *crocus antimonii medicinalis*.

When four parts of nitrat to one of antimony are taken, the oxide contains 32 per cent. of oxigen, and acquires, in some measure, the character of an acid, as it forms a crystallizable compound with potash, though it appears to be of itself the least soluble of the antimonial oxides.

As a considerable portion of the matter, sometimes as much as half of it, is left by detonating antimony with nitrat of potash in the open air, Bergman recommends the mixture to be put into a cold crucible, the crucible to be covered over; and the fire to be increased till the matter is fused. Thus there is very little left, and this is the mode generally practised by operative chemists.

If sulphuret of antimony be mixed with thrice its weight of corrosive muriat of mercury, noxious fumes begin immediately to rise very copiously, which must be carefully avoided. The mixture being put into a wide-necked retort, and the fire cautiously increased, a muriat of antimony will rise, and congeal in the neck of the retort. This, on exposure for some time to the air, will become fluid: or, it may be melted from the neck of the retort, by cautiously applying a live coal, and be rendered permanently fluid by distillation in another re-

---

* The London college add a twelfth part of muriat of soda to one part each of the nitrat and sulphuret.

tort. In the former way it is somewhat less corrosive. This was formerly called *butter of antimony*, or *antimonial caustic*. It acts exceeding quickly, the eschar coming off in general the same day, but is now seldom if ever used except by farriers. The London college direct two parts of muriat of soda, and one of *crocus antimonii* to be mixed and added gradually to one part of sulphuric acid in a retort, which is then to be placed on a sand heat. The distilled matter is to remain some days exposed to the air, and the fluid part to be then poured off from the dregs. If this muriat be diluted with a considerable quantity of water, a white oxide is precipitated; formerly called *mercurius vitæ*, on account of the muriat of mercury employed in the original mode of making it, though no mercury really entered into its composition; or powder of *algaroth*, from the name of its inventor, a Veronese physician. This oxide is a violent emetic, and has consequently fallen into disuse; but some chemists prefer it as the basis of tartarised antimony. If nitrous acid were dropped into the muriat of antimony till no further effervescence was excited, or if it were poured on the precipitate from the muriat, and all the acid were expelled by distillation, and exposure for some time to a red heat, the remaining oxide was termed *mineral bezoar*. After the distillation of the muriat of antimony from the mercurial muriat, a black powder consisting of mercury and sulphur remained in the retort. This being urged to a red heat, was sublimed into a mass of a needly structure, and a little darker hue than the common red sulphuret of mercury, from which it differs only in containing a somewhat larger proportion of sulphur, though it was distinguished by the name of *cinnabar of antimony*.

In all the various ways, however, in which antimony has been tortured by the ingenuity of chemists, we are acquainted with no preparation of it more valuable than the *tartarised antimony*, formerly *emetic tartar*, or *stibiated tartar*, for which we are indebted to Mynsicht. To prepare this, the London college directs a pound and half of powdered crocus of antimony, and two pounds of acidulous tartrit of potash, to be boiled in two gallons of water, in a glass vessel, about a quarter of an hour. The liquor is then to be filtered, and set by to crystallize. The Edinburgh college orders an oxide to be formed by precipitating the muriat of antimony with hot water, in which potash enough to precipitate all the antimony has been dissolved. The precipitate being well washed and dried, nine drams are to be boiled with two ounces and half of acidulous tartrit of potash, finely powdered, in five pounds of water, till the powders are dissolved. The solution, being strained, is to be evaporated to a pellicle, and set by to crystallize. Some of the continental chemists prefer the vitreous sulphurated oxide for the basis of this preparation, as more soluble in the tartarous acid: but with them it has far from generally superseded the use of the hidrosulphurated brown and orange oxides. The tartarised antimony crystallizes in regular tetraëdra, triangular pyramids, or elongated octaëdra: but it effloresces on exposure, loses its transparency, and becomes white and pulverulent. It is soluble in eighty parts of water at 60° Fahr. To ascertain its purity, Mr. Henry directs a few drops of sulphuret of ammonia to be added to its solution, which will immediately throw down a gold-coloured sulphuret of antimony: or acetat of lead, which should give with it a precipitate perfectly soluble in dilute nitrous acid.

About the middle of the last century Dr. Robert James, a physician in London, invented a preparation of antimony, which he kept a secret, and for which he afterward took out a patent. He called it his *fever powder*, and was so successful in his practice with it, that it obtained very great reputation, which it still in some measure retains. Probably, however, his success was in great measure owing to his free use of the bark, which he always gave as largely as the stomach would bear, as soon as he had completely evacuated the primæ viæ by the use of his antimonial preparation, with which at first he used to combine a little mercurial. His specification, lodged in chancery, is as follows: "Take antimony, calcine it with a continued protracted heat, in a flat, unglazed, earthen vessel, adding to it from time to time a sufficient quantity of any animal oil and salt, well dephlegmated: then boil it in melted nitre for a considerable time, and separate the powder from the nitre by dissolving it in water." The preparation sold as *James's powder*, however, appears from a careful analysis by Dr. Pearson, given in the Phil. Trans., to be an oxide of antimony combined with calcareous phosphat. Accordingly both the London and Edinburgh colleges have directed an *antimonial powder* to be prepared by mixing the sulphuret of antimony coarsely powdered with an equal weight of hartshorn shavings (or those of bone or ivory, Ed.), putting the mixture into a broad iron pot, heated to a white (red, Ed.) heat, and constantly stirring till the mass has acquired a grayish colour. When this is cold, it is to be powdered, and put into a coated crucible, with another, having a small hole in the bottom, inverted over it. The crucibles being luted together, the fire is to be kindled under them, and gradually increased to a white heat, at which it is to be kept for two hours. When cold it is to be powdered. This powder, however, is certainly more active than that of Dr. James. We have known three grains with one of calomel operate with considerable violence both upward and downward. Mr. Chenevix recommends to dissolve in the least possible quantity of muriatic acid equal parts of phosphat of lime and the oxide precipitated by water from the muriat of antimony. These, either dissolved together, or dissolved separately and then mixed, are to be poured gradually into water alkalizated with a sufficient quantity of pure ammonia. The precipitate, well washed and dried, is his substitute for James's powder. This has the advantage of not being liable to variation in its quality from those unavoidable differences in the operation, to which all preparations by means of fire are exposed; and it is milder than the *antimonial powder*, as it seldom produces nausea or vomiting in doses of less than eight or ten grains.

As it is frequently convenient to have antimony in a liquid form, different tinctures of it have been devised; but the British colleges have discarded all except the *antimonial wine* prepared by digesting the vitreous sulphurated oxide, finely powdered, in white wine, which is an excellent medicine; and they have added of late years a solution of tartarised antimony in the same menstruum, under the name of *wine of tartarised antimony*.

While on this subject we must not omit to mention the *perpetual pill and cup*, once in some repute. These were made of the pure metal, cast into the shape of a cup and of a pill: the former imparted an emetic quality to wine suffered to stand in it a little time, without any apparent diminution of its substance for ages; and the latter, though it often proved violently emetic, might be transmitted from generation to generation, without its virtues being at all impaired, however frequently it was employed as a purgative.

The reader may have remarked, that the complete oxides of antimony are inert, and the sulphuret of antimony appears to be equally so; though, from the instance last given, the pure metal seems to possess powers of very great activity, at least with no other preparation than it undergoes in the stomach and intestines, or by the action of wine. It may appear singular too, that sulphuret of antimony calcined with an equal weight of nitrat of potash is an active medicine; while either an increase or diminution of the proportion of nitrat diminishes the activity of the product, till it becomes altogether inert. May we not account for this by ascribing the action of antimonials to the pure metal contained in them alone? so that the calcination with nitrat of potash renders it active in proportion as it robs the metal of the sulphur that rendered it bland; and, when it is employed more largely, destroys its activity in a different way, by oxiding a greater portion of it? This too might account for its variable action, which is most conspicuous when the solid preparations are administered; since, however accurately the medicine may be prepared, the state of the fluids in the primæ viæ must be always liable to variation.

Beside the extensive use of antimony in medicine, it enters into the composition of some alloys, as those used for printers' types, small shot, and mirrors of telescopes; it is employed in colouring glass and enamels, and painting on china; and for its use in scorifying copper and other metals mixed with gold was styled by the alchemists *balneum regis*, or *balneum solis*.

For its ores, and the reduction of the metal, see Ores.

Ants. See Acid (Formic).

Aplanatic. The researches of chemists and manufacturers to remove those defects in glass (see that article), which have prevented the accomplishment of a complete correction of the aberration of the rays of light in the telescopes termed achromatic, induced Dr. Robert Blair to try the effects of fluid mediums; and his success in this respect was such, as to induce him to give the term *aplanatic*, or 'free from error,' to the glasses he thus constructed.

In the course of his inquiry he found, that the solutions of metals proved in all cases more dispersive than crown glass. Some of the salts, as the muriat of ammonia for instance, greatly increased the dispersive power of water. The muriatic acid disperses very considerably, and this in proportion to its strength. And accordingly the most dispersive fluids are found to be those in which metals are combined with this acid. The muriat of antimony in its most concentrated state, when it has attracted just sufficient humidity to render it fluid, disperses the rays of light to such a degree, that three wedges of crown glass are necessary to remove the colour produced by one wedge of this substance of an equal refracting angle opposed to them. The muriat of mercury added to a solution of muriat of ammonia in water ranked next in dispersive power among the fluids examined by the doctor. It may be made so strong as to require a wedge of crown glass of double the refracting angle to counteract its effect.

Essential oils came next to the metallic solutions; and the most dispersive were those obtained from bituminous minerals. When the refraction is without colour, the proportion of the refracting angle of a prism of the latter to the refracting angle of a prism of crown glass acting in opposition is about two to three. The essential oil of sassafras is little inferior to these. Genuine oil of lemons requires the angles to be as three to four; oil of turpentine as seven to six. Oil of rosemary is still less dispersive.

Some of the expressed oils, rectified spirit, and nitrous and vitriolic ether did not differ sensibly from crown glass.

In applying these principles to practice, Dr. Blair took two double convex lenses of crown glass, the radii of convexity in each of which were as two to one; turned their less convex sides toward each other; kept them at a proper distance by means of a glass ring; and filled the cavity with the strongest muriat of antimony. Thus, the wedges of glass being to those of the muriat as three to one, the colour was removed; but on directing the instrument to a planet, and using a deep eyeglass, the fluid was found to be subject, like flint glass, to great irregularities of density, discoverable by streams of light radiating from the disk of the planet. This may be remedied by reducing the muriat to a sufficient degree of fluidity by means of alcohol, or vitriolic ether, into which a small quantity of muriatic acid had been previously dropped: but solutions of this or other saline substances so diluted do not differ materially in dispersive power from the essential oils.

It is sometimes advantageous, however, to employ those fluids that have least density, as for instance where it is required to produce a single refraction, in which there shall be no difference of refrangibility of heterogeneous light: for Dr. Blair has shown, that there are cases of single refraction, in which the violet rays are the least refrangible; others in which all the rays are equally refrangible; and others in which the red are refracted from the perpendicular, the violet toward it, and the mean refrangible rays neither way. By the doctor's experiments too it appears, that, in mediums which disperse the light but little, green is the mean refrangible ray; in most of the more dispersive, including flint glass, metallic solutions, and essential oils, the green is one of the less refrangible rays; and in another class, including the nitrous and muriatic acids, the green is among the more refrangible. It was found necessary, therefore, to apply mediums of different orders to correct each other; and as the metallic solutions and acids are of this description, by combining them together the complicated structure of refracting the rays first through one medium then through the other is avoided. Thus an addition of muriatic acid to the muriat of antimony removes the green and purple fringes arising from the irregular refraction of those two intermediate rays by the muriat alone; but if too much of the acid be added, they reappear in an inverted order. Thus, too, from a solution of the muriats of ammonia and mercury mixed in a certain proportion the rays emerge equally refracted: but if the muriatic acid predominate from an excess of the muriat of ammonia, the green rays will emerge less refracted than the united red and violet; and if the metal predominate from an excess of the mercurial muriat, the opposite effect will be produced.—*Edinburgh Transactions, vol. ii.* —*Nicholson's Journal, 4to, vol. i.*

Apparatus. See Laboratory.

Apples. See Acid (Malic).

Apyrous. Bodies which sustain the action of a strong heat for a considerable time, without change of figure or other properties, have been called apyrous; but the word is seldom used in the art of chemistry. It is synonymous with *refractory*.

Aqua Fortis. This name is given to a weak and impure nitric acid, commonly used in the arts. It is distinguished by the terms *double* and *single*, the single being only half the strength of the other. The artists who use these acids call the more concentrated acid, which is much stronger even than the double aqua fortis, *spirit of nitre*. This distinction appears to be of some utility, and is therefore not improperly retained by chemical writers. See Acid (Nitric).

The manufacturers of soap in France and elsewhere call their lixivium or soap-lees by the name of strong water; and this name, *eau forte*, which is likewise employed by artists of a different description for our aqua fortis, being consequently used to denote the caustic alkali in recipes for dyeing and other processes, has given rise to several mistakes.

Aqua Marine, or Augites. The Beryl of some. A precious stone of a transparent green blue, fusible by the blow-pipe; it is nearly the same both in form and specific gravity with the Peruvian emerald, and the chrysolite. Its specific gravity is from 2·65 to 2·72, and its hardness nearly the same as that of quartz. According to Vauquelin's analysis it contains silex ·69, alumine ·13, glucine ·16, lime ·005, oxide of iron ·01. In value it ranks low among the gems.

Aqua Regia, or Regis. This acid, being compounded of a mixture of the nitric and muriatic acids, is now termed by chemists nitro-muriatic acid. When one or two parts of pale concentrated nitric acid are mixed with four of muriatic acid, an effervescence soon takes place, and oxigenated muriatic acid flies off in the elastic form, at the same time that the mixture becomes of a deep red colour: it has obtained its name from its property of dissolving gold, the royal metal of the alchemists, which is not perceptibly acted upon by either of the acids that compose it. See Acid (Nitric).

Aqua secunda. This name is sometimes given to an exceedingly diluted aqua fortis, used in the arts for cleaning the surface of metals and some other bodies.

Aqua Vitæ. Ardent spirit of the first distillation has been distinguished in commerce by this name. The distillers of malt and melasses spirits call it low wines.

Aquila alba. One of the names given to the combination of muriatic acid and mercury in that state which is more commonly known by the denomination of *mercurius dulcis, calomel,* or *mild muriat of mercury*.

Arabic (Gum). This is reckoned the

purest of gums, and does not greatly differ from gum Senegal, vulgarly called gum seneca, which is supposed to be the strongest, and is on this account, as well as its greater plenty and cheapness, mostly used by calico-printers and other manufacturers. The gums of the plum- and the cherry-tree have nearly the same qualities as gum arabic. All these substances facilitate the mixture of oils with water, and they are said to suffer a decomposition, or considerable change, by freezing, but of what nature has not been clearly explained.

Arable Lands. It is a problem in chemistry, and by no means one of the least importance to society, to determine what are the requisites which distinguish fruitful lands from such as are less productive. Since vegetable substances evidently imbibe from the earth and surrounding atmosphere the principles of oils, mucilages, and other peculiar products only found in organized substances; it can scarcely be doubted, but that manure, or the remains of other decayed organized substances, renders lands fruitful, by supplying these materials ready formed. It may happen, however, that the putrefactive process in a considerable quantity of manure may be so effective as to overcome the vital powers, or destroy the organization of the plant; and on this account an excess of manure must be hurtful. In those cases wherein vegetation is performed without the presence of any thing which may be called manure, it seems proper, as far as the few and imperfect lights of chemistry can serve to direct us, to ascribe the growing or augmentation of vegetables to the decomposition of water, or the air of the atmosphere, rather than to any considerable addition of earthy particles; more especially, as it appears from good experiments that the earth in which vegetables grow suffers very little loss of its weight in consequence of their increase. From the indispensable necessity of water in vegetation, it appears, that this fluid either supplies the greatest part of the mass of vegetables, or is at least the vehicle or medium by which aërial fluids are condensed and conveyed into the vegetable substance; which leads to a conclusion, that, generally speaking, those earths which are the best adapted to imbibe and retain water, and at the same time admit the access of air, are most fruitful. Sand or small particles of siliceous earth are evidently the least adapted to this purpose. Clays of considerable purity will be too stiff, impenetrable, and adhesive. Chalky or calcareous soils are not only hard and permanent, so as to be with considerable difficulty penetrated by the roots of vegetables, but are little adapted either to imbibe more water than they naturally possess, or to part with that they already have. Little need be said of barytes and magnesia, as they do not enter in any notable proportions as ingredients in soils: but lime made from a limestone containing a certain portion of magnesia, when used to improve the fertility of land, as pure lime would do, has been found to prove injurious.

If we might therefore overlook the presence of saline and combustible matter, which are indeed necessary to fertility, and the latter of which is the cause of the dark colour of mould, our attention would be naturally directed to a mixture of the siliceous, calcareous, and argillaceous earths, that is to say, of sand, chalk or lime, and clay. The first being totally insoluble in water, can scarcely be expected to answer any other purpose than that of mechanically separating the parts of the mass, or at least of rendering them more easily separable by frost and other atmospherical changes. The calcareous and argillaceous earths form the composition distinguished by the name of marle, and this will vary in its properties according to the nature of its composition; the friability and solubility of the lime in water serving greatly to correct the bad effects of the mere clay, while this on the other hand produces a change of equal advantage in the chalk or lime. It may easily be apprehended, that the presence of sulphuric acid or other acidifiable substances, together with the access of air, cannot but produce changes by combination with these two earths, which will be still more considerable, and cannot indeed be followed by any conjectural reasoning, though the little we know of the subject sufficiently evinces the great utility of experiments in this department of chemical inquiry. See Soils.

Arbor Dianæ. All bodies whatever, in their transition from the fluid to the solid state, are disposed to arrange themselves in peculiar symmetrical figures. See Crystallization. When one body is precipitated from its solvent by the addition of another, the transition to solidity is usually so quick, that the parts have not time to arrange themselves, excepting in such minute masses as constitute the pulverulent form. When silver is dissolved in nitric acid, and mercury is added, the elective attraction between the mercury and the acid acts with such a degree of slowness, that the silver in certain cases is separated in the form of a tree or shrub, which the earlier chemists in their usual fanciful way called the tree of Diana. In this, as in all precipitations, there are a variety of concomitant circumstances, which influence the peculiar form, and for this reason one process usually succeeds better than another. Lemery directs, that an ounce of fine silver be dissolved in a sufficient quantity of pure and moderately strong nitric acid. This solution must then be mixed in a matrass with about twenty ounces of distilled water; and lastly, two ounces of mercury are to be added to the mixture; after which the whole must be suffered to remain at rest. During a space of about forty days, a kind of tree of silver will be formed on the surface of the mercury, with branches greatly resembling a vegetable substance in its ramifications. Macquer affirms, that this process succeeds very well, but the following of Homberg is much shorter.

Make an amalgam, without heat, of four drams of leaf silver, with two drams of mercury. Dissolve this amalgam in four ounces, or a sufficient quantity of pure nitric acid of a moderate strength; dilute this solution in about a pound and a half of distilled water, agitate the mixture, and preserve it for use in a glass bottle with a ground stopper. When this preparation is to be used, the quantity of one ounce is put into a phial, and the size of a pea of an amalgam of gold or silver, as soft as butter, is to be added; after which the vessel must be left at rest: soon afterward, small filaments appear to issue out of the ball of amalgam, which quickly increase, and shoot out branches in the form of shrubs.

In the above experiment of Lemery, the nitric acid deposits its silver, at the same time that it takes up mercury; and, in consequence of the liquor being so much diluted, the process goes on slowly, and the precipitated silver has time to arrange itself according to the laws of its crystallization, whether this depend on the polarity of its particles, or on any other property not yet explained. In the process of Homberg, there are two circumstances which appear calculated to forward the process: in the first place, the nitric acid already contains mercury in solution, which may probably render it more disposed to part with the silver; and in the next place, the mercury is combined with silver or gold in the form of an amalgam. These may, perhaps, facilitate the precipitation of the silver, by presenting a base for it to combine with, which may be more perfectly at repose, because less agitable than the fluid mercury in the former experiment. After all, however, though the general theory of the experiment is not difficult, yet it does not seem easy to point out the effectual cause of the differences between the two results.

Arcanum Corallinum. This name has been given to red nitrat of mercury, on which alcohol has been two or three times burnt, with an intention of rendering it milder. See Mercury.

Arcanum Duplicatum. A name formerly given to the combination of potash and sulphuric acid, more commonly called vitriolated tartar, and now sulphat of potash.

Archil, Archilla, Rocella, Orseille. A whitish moss growing upon rocks in the Canary and Cape Verd islands, which yields a rich purple tincture, fugitive indeed, but extremely beautiful. This weed is imported to us as it is gathered: those who prepare it for the use of the dyer grind it betwixt stones, so as thoroughly to bruise, but not to reduce it into powder, and then moisten it occasionally with a strong spirit of urine, or urine itself mixed with quicklime: in a few days it acquires a purplish red, and at length a blue colour; in the first state it is called archil, in the latter, lacmus or litmus.

The dyers rarely employ this drug by itself, on account of its dearness, and the perishableness of its beauty. The chief use they make of it is for giving a bloom to other colours, as pinks, &c. This is effected by passing the dyed cloth or silk through hot water lightly impregnated with the archil. The bloom thus communicated soon decays upon exposure to the air. Mr. Hellot informs us, that by the addition of a little solution of tin, this drug gives a durable dye; that its colour is at the same time changed toward a scarlet; and that it is the more permanent, in proportion as it recedes the more from its natural colour.

Prepared archil very readily gives out its colour to water, to volatile spirits, and to alcohol; it is the substance principally made use of for colouring the spirits of thermometers. As exposure to the air destroys its colour upon cloth, the exclusion of the air produces a like effect in those hermetically sealed tubes, the spirits of large thermometers becoming in the compass of a few years colourless. The abbé Nollet observes (in the French Memoirs for the year 1742), that the colourless spirit, upon breaking the tube, soon resumes its colour, and this for a number of times successively; that a watery tincture of archil, included in the tubes of thermometers, lost its colour in three days; and that in an open deep vessel it became colourless at the bottom, while the upper part retained its colour.

A solution of archil, in water, applied on cold marble, stains it of a beautiful violet or purplish blue colour, far more durable than the colour which it communicates to other bodies. Mr. du Fay says, he has seen pieces of marble stained with it, which in two years had suffered no sensible change. It sinks deep into the marble, sometimes above an inch, and at the same time spreads upon the surface, unless the edges be bounded by wax or some similar substance. It seems to make the márble somewhat more brittle.

Linnæus informs us, in the Swedish Transactions for the year 1742, that the true archil moss is to be found on the western coasts of England; and suspects, that there are several other more common mosses, from which valuable colours might be extracted. A quantity of sea moss having rotted in heaps upon the shore, he observed the liquor in the heaps to look like blood; the sea-water, and the sun, and the putrefaction having brought out the colour. Mr. Kalm, in an Appendix to Linnæus's Paper in the year 1745, mentions two sorts of mosses actually employed in some parts of

Sweden for dyeing woollen red: one is the lichenoides coralliforme apicibus coccineis of Ray's Synopsis; the other, the lichenoides tartareum, farinaceum, scutellarum umbone fusco of Dillenius. This last is a white substance, like meal clotted together, found on the sides and tops of hills. It is shaved off from the rocks after rain; purified from the stony matters intermixed among it, by washing with water; then dried in the sun, ground in mills, and again washed and dried: it is then put into a vessel with urine, and set by for a month. A little of this tincture added to boiling water makes the dyeing liquor.—In the same Transactions, for the year 1754, there is an account of another moss, which, prepared with urine, gives a beautiful and durable red or violet dye to wool and silk. This is the lichen foliaceus, umbilicatus subtus lacunesus Linn. Flor. Suec. It grows upon rocks, and is readily distinguished from others of that class, by its looking as if burnt or parched, consisting of leaves as thin as paper, convex all over on the upper side, with corresponding cavities underneath; adhering firmly to the stones by a little root under the leaves, and coming asunder, when dry, as soon as touched. It is gathered after rain, as it then holds best together, and parts easiest from the stone.

In France, a crustaceous moss, growing upon rocks in Auvergne, is prepared with lime and urine, and employed by the dyers as a succedaneum to the Canary archil, to which it is said to be very little inferior: it is called Orseille d'Auvergne, or Perelle, but appears from the experiments of Dr. Westring not to be prepared from the lichen parellus. Mr. Hellot relates, that he has met with several other mosses, which, on being prepared in the same manner, acquire the same colour. The most expeditious way, he says, of trying whether any moss will yield an archil or not, is, to moisten a little of it with a mixture of equal parts of ammonia and strong lime water, and add a small proportion of muriat of ammonia. The glass is then to be tied over with a piece of bladder, and set by for three or four days. If the moss is of the proper kind, the little liquor which runs from it upon inclining the vessel will appear of a deep crimson colour; and this afterward evaporating, the plant itself acquires the same colour.

Lewis tried a good number of the common mosses, both of the crustaceous and foliaceous kind, and not a few of the fungi; as also the herbs chamomile and milfoil, which yield a blue essential oil; and thyme, the oil of which becomes blue by digestion with volatile alkali; but did not meet with any that yielded a colour like archil. Most of them gave a yellow or reddish brown tincture; and if there were a scarcity of other drugs for these kind of dyes, some of the mosses might be made to afford not inelegant ones. A few gave a deep red colour to the liquor; but when diluted it showed a yellowish cast, and when applied on cloth it gave only a yellowish red.

Dr. Westring has likewise made various experiments on the lichens in Sweden, related in different volumes of the Memoirs of the Swedish Academy, and says, there are several superior to archil, and that equal parts of nitre and common salt are of great use in improving and fixing their colours. The lichen pustulatus he considers as little inferior to cochineal: and from the lichen pulmonarius he obtained beautiful orange and carmelite dyes.

There is a considerable consumption of an article of this kind manufactured in Scotland, and sold by the name of cudbear. It fetches about 19*d.* or 20*d.* a pound in London. We have seen beautiful specimens of silk thus dyed, the colours of which were said to be very permanent, of various shades from pink and crimson to a bright Mazarin blue.

Litmus is likewise used in chemistry as a test, either staining paper with it, or by infusing it in water, when it is very commonly, but with great impropriety, called *tincture of turnsole.* The persons by whom this article was prepared formerly gave it the name of turnsole, pretending that it was extracted from the turnsole, heliotropium tricoccum, in order to keep its true source a secret. The tincture should not be too strong, otherwise it will have a violet tinge, which however may be removed by dilution. The light of the sun turns it red even in close vessels. It may be made with spirit instead of water. This tincture, or paper stained with it, is presently turned red by acids: and if it be first reddened by a small quantity of vinegar, or some weak acid, its blue colour will be restored by an alkali.

Archil is never used alone as a dye, except for lilacs, because it is not sufficiently permanent: but it is very extensively employed for deepening and improving the beauty of other dyes, and giving a fine bloom, which is not to be obtained by other means. When silk is dyed with archil only, a quantity proportionate to the colour required is boiled in a proper vessel: and the clear liquor is poured quite hot into a trough, in which the silk, carefully cleansed from soap, is to be turned with great care till it has acquired the proper shade. The silk is then to be beetled once in the river. The solution of tin, which gives it a red approaching to scarlet, is the only thing capable of increasing the durability of this dye.

Ardent Spirit. See Alcohol.

Areometer. See Hydrometer.

Argal. Crude tartar, in the state in which it is taken from the inside of wine vessels, is known in the shops by this name.

Argentate of Ammonia, fulminating silver.

Argillaceous Earth, or Alumine. See **Earths.**

Armenus Lapis. Armenian Stone. This is a soft blue stone, which does not admit of a polish, and consists of calcareous earth, or gypsum, penetrated with the blue oxide of copper. Hence it sometimes effervesces with acids, and sometimes not. It is too soft to give fire with steel, and loses its colour when heated. In its hardest state it approaches the lapis lazuli, but is not speckled with gold, though it is sometimes with green spots. It is used in mosaic work, and likewise in painting.

Aroma. The supposed principle of smell in vegetables, formerly called *Spiritus Rector.*

Aromatics. Plants which possess a fragrant smell united with pungency, and at the same time are warm to the taste, are called aromatics. Their peculiar flavour appears to reside in their essential oil, and rises in distillation either with water or spirit.

Arrack. A spirituous liquor imported from the East Indies. It is chiefly manufactured at Batavia, and at Goa upon the Malabar coast. There are various accounts of the processes and materials used in making it; and the disagreement of these accounts seems to arise from the general appellation of *arrack* being given, in the East Indies, to every kind of spirituous liquor; and also from the disposition which the Dutch so eminently possess of endeavouring to keep their manufacturing processes to themselves. It is certain, that the flavours of the several kinds of arrack differ as much from each other, as those of brandy, rum, corn spirits, or any other of the spirituous liquors of Europe. The materials from which ardent spirit is distilled in the East Indies are rice, melasses, and toddy, or the juice of the cocoa-nut tree. The Chinese distil a spirit from rice, which they distinguish by the name of sam shu, and of which considerable quantities are exported to Batavia, for the purpose, as it is said, of being converted into arrack by a second distillation: though perhaps it may be consumed among the numerous Chinese who inhabit that city. The common Batavia arrack appears to be distilled from a mixture of the wort or infusion of rice and the toddy, after both have passed through the vinous process. And to these, according to circumstances, it seems they add other ingredients, particularly spices.

Of European spirits the common malt spirit before rectification resembles arrack the most. Arrack is reckoned less intoxicating than rum or brandy; but this difference arises from its being very seldom of equal strength. Of five specimens procured from different channels, I found the specific gravity between 965 and 967, water being 1000; whence it follows, that proof spirit lowered with about ¼ of its bulk of water would have been of the same strength as this arrack.

Arsenic in the metallic state is of a blueish white colour, subject to tarnish and grow first yellowish, then black by exposure to air. It is brittle, and when broken exhibits a laminated texture. Its specific gravity, according to Muschenbroeck and Bergman, is 8·310, but Brisson gives it at no more than 5·763. This Kirwan attributes to the blebs with which it commonly abounds. In close vessels it sublimes entire; but burns with a small flame if respirable air be present.

The arsenic met with in commerce has the form of a white oxide. It is brought chiefly from the cobalt works in Saxony, where zaffre is made. Cobalt ores contain much arsenic, which is driven off by long torrefaction. The ore is thrown into a furnace resembling a baker's oven, with a flue, or horizontal chimney, nearly two hundred yards long, into which the fumes pass, and are condensed into a grayish or blackish powder. This is refined by a second sublimation in close vessels, with a little potash, to detain the impurities. As the heat is considerable, it melts the sublimed flowers into those crystalline masses which are met with in commerce.

The oxide of arsenic is so far in the saline state, as to be soluble in about eighty times its weight of water, at the temperature of 60°, or in fifteen times its weight of boiling water. See **Acid (Arsenious).**

The metal may be obtained from this, either by quickly fusing it together with twice its weight of soft soap and an equal quantity of alkali, and pouring it out, when fused, into a hot iron cone; or by mixing it in powder with oil, and exposing it in a matrass to a sand heat. This process is too offensive to be performed, except in the open air, or where a current of air carries off the fumes. The decomposed oil first rises; and the arsenic is afterwards sublimed, in the form of a flaky metallic substance. It may likewise be obtained by mixing two parts of the arsenious acid with one of black flux; putting the mixture into a crucible, with another inverted over it, and luted to it with clay and sand; and applying a red heat to the lower crucible. The metal will be reduced, and line the inside of the upper crucible.

It is among the most combustible of the metals, burns with a blue flame, and garlic smell, and sublimes in the state of arsenious acid.

Concentrated sulphuric acid does not attack arsenic when cold; but if it be boiled upon this semi-metal, sulphurous acid gas is emitted, a small quantity of sulphur sublimes, and the arsenic is reduced to an oxide.

Nitrous acid readily attacks arsenic, and converts it into arsenious acid, or, if much be employed, into arsenic acid.

Boiling muriatic acid dissolves arsenic, but affects it very little when cold. This solution affords precipitates upon the addition of alkalies. The addition of a little nitric acid expedites the solution; and this solution, first heated and condensed in a close vessel, is wholly sublimed into a thick liquid, formerly termed *butter of arsenic*. Thrown in powder into oxigenated muriatic acid gas, it burns with a bright white flame, and is converted into arsenous acid; which readily passes to the state of arsenic acid, on the addition of liquid oxigenated muriatic acid, this being deoxigenated by it.

None of the earths or alkalies act upon it, unless it be boiled a long while in fine powder, in a large proportion of alkaline solution.

Nitrats detonate with arsenic, convert it into arsenic acid, and this, combining with the base of the nitrat, forms an arseniat, that remains at the bottom of the vessel.

Muriats have no action upon it; but if three parts of superoxigenated muriat of potash be mixed with one part of arsenic in fine powder, which must be done with great precaution, and a very light hand, a very small quantity of this mixture, placed on an anvil, and struck with a hammer, will explode with flame and a considerable report: if touched with fire, it will burn with considerable rapidity: and if thrown into concentrated sulphuric acid, at the instant of contact a flame rises into the air like a flash of lightning, which is so bright as to dazzle the eye.

Arsenic readily combines with sulphur by fusion and sublimation, and forms a yellow compound called *orpiment*, or a red called *realgar*. The nature of these, and their difference, are not accurately known: but Fourcroy considers the first as a combination of sulphur with the oxide, and the second as a combination of sulphur with the metal itself, as he found the red sulphuret converted into the yellow by the action of acids.

Arsenic is soluble in fat oils in a boiling heat: the solution is black, and has the consistence of an ointment when cold. Most metals unite with arsenic; which most probably exists in the metallic state in such alloys as possess the metallic brilliancy.

Arsenic is used in a variety of arts. It enters into metallic combinations wherein a white colour is required. Glass manufacturers use it; but its effect in the composition of glass does not seem to be clearly explained. Orpiment and realgar are used as pigments. See ACIDS (ARSENIC, and ARSENIOUS.)

ARUM. The common *Arum*, or Wake-robin, is a plant of extreme acrimony: the fresh root, slightly chewed, seems to burn and corrode the tongue; and oftentimes its pungent impression continues for two or three days. The seat of this acrimony has hitherto eluded our inquiries: the distilled water and spirit have nothing of it, and the watery and spirituous extracts exceedingly little; and yet the root is, by these operations, deprived of it.

Greatest part of the acrimony is destroyed by simple exsiccation: the dry root appears white and farinaceous, and affects the tongue but little. In this state it is given medicinally for attenuating viscid juices: formerly it was used as starch for linen, before the discovery of that from wheat; and it is said to have occasioned a rawness and soreness of the hands very difficultly relievable by ointments. If this have been the case, however, it was probably owing to some neglect in the preparation, as we never heard any complaint of this kind in a part of England where it has been long in use, and continues so to this day. A few years ago, the Society of Arts gave a premium to a person for making it known. In some parts of France, it is still employed in bleaching; being supposed by its corrosive quality to dissolve unctuosities, and make the linen white.

From an ounce of the dry root Neumann obtained scarcely a scruple of spirituous extract: the same quantity yielded of watery extract near three drams. The first had some slight pungency; the latter none.

ASAFŒTIDA is obtained from a large umbelliferous plant growing in Persia. The root resembles a large parsnep externally, of a black colour: on cutting it transversely, the asafœtida exudes in form of a white thick juice, like cream; which, from exposure to the air, becomes yellower and yellower, and at last of a dark brown colour. It is very apt to run into putrefaction; and hence those who collect it carefully defend it from the sun. The fresh juice has an excessively strong smell, which grows weaker and weaker upon keeping: a single dram of the fresh fluid juice smells more than a hundred pounds of the dry asafœtida brought to us. The Persians are commonly obliged to hire ships on purpose for its carriage, as scarcely any one will receive it along with other commodities, its stench infecting every thing that comes near it.

The common asafœtida of the shops is of a yellowish or brownish colour, unctuous and tough, of an acrid or biting taste, and a strong disagreeable smell, resembling that of garlic. From four ounces Neumann obtained, by rectified spirit, two ounces six drams and a half of resinous extract; and afterward, by water, three drams and half a scruple of gummy extract; about six drams and a scruple of earthy matter remaining undissolved. On applying water at first, he gained, from four ounces, one ounce three scruples and a half of gummy extract. The same quantity yielded, with strong French wine, two ounces and a half and fifteen grains; from which about one fifth may be deducted, for the solid matter contained in the wine. Schroder says, that asafœtida may be dissolved over the fire, in water, vinegar, or wine; but only a part of it can be dissolved in any of these liquors. The smell of the asafœtida resides wholly in an essential oil, which arises in distillation both with water and spirit: four ounces, distilled with water, yielded about a dram of oil.

Asafœtida is administered in nervous and hysteric affections, as a deobstruent, and sometimes as an anthelmintic. A tincture of it is kept in the shops, and it enters into the composition of the compound galbanum pill of the London college, the gum pill of former dispensatories.

Asbestos, or Asbestus. The most obvious characters of the asbestos are, a greater or less degree of flexibility, and their resisting the fire. The *Amianthus* is often confounded with it. Cronstedt distinguishes two kinds:—The asbestos which is composed of soft and thin membranes, and is the amianthus of Wallerius. The membranes of this are either parallel, in which case he calls it Mountain Leather; or twisted, which he distinguishes by the name of Mountain Cork. Both these kinds are white when pure; or of a yellowish brown when contaminated with iron. The impure sort melts pretty easily into a black slag.—The second kind of asbestos distinguished by Cronstedt has its fibres fine and flexible, and either parallel, of a light green or white colour; or of a greenish colour, somewhat more brittle, and contaminated with iron. This last is fusible into a semitransparent glass. There is also a light green martial asbestos, with broken fibres, which belongs to this kind.

The ancients manufactured cloth out of the fibres of asbestos, for the purpose, it is said, of wrapping up the bodies of the dead, when exposed on the funeral pile. Several moderns have likewise succeeded in making this cloth; the chief artifice of which seems to consist in the admixture of flax and a liberal use of oil; both which substances are afterward consumed by exposing the cloth for a certain time to a red heat. Although the cloth of asbestos, when soiled, is restored to its primitive whiteness by heating in the fire; it is found, nevertheless, by several authentic experiments, that its weight diminishes by such treatment. The fibres of asbestos, exposed to the violent heat of the blow-pipe, exhibit slight indications of fusion; though the parts, instead of running together, moulder away, and part fall down, while the rest seem to disappear before the current of air. Ignition impairs the flexibility of asbestos in a slight degree.

According to Bergman, the fibrous asbestos contains from 53 to 74 parts of siliceous earth, from 12 to 28 of carbonat of magnesia, from 7 to 14 of carbonat of lime, from 2 to 6 of alumine, and from 1 to 10 of iron; the whole mass being supposed to be divided into 100 parts. The martial asbestos contains 62 of siliceous earth, 1·37 of magnesia, 12 of calcareous earth, 1·7 of alumine, and 10·6 of iron. This affords a white slag by fusion.

The mountain cork or leather contains in the hundred from 56 to 62 parts of siliceous earth, from 22 to 26 of carbonate of magnesia, from 10 to 12 of carbonat of lime, from 2 to near 3 of alumine, and about 3 of iron.

Ashes. The fixed residue of combustible substances, which remains after they have been burned, is called ashes. In chemistry it is most commonly used to denote the residue of vegetable combustion. Vegetable ashes contain alkali; which may be washed out with water, and the insoluble part is found to consist of a calcareous earth, for the most part some alumine, and a much less portion of magnesia. All these products vary in the different species of vegetables. Most plants afford likewise iron and manganese; and Mr. Sage, by experiments which have been verified by other chemists, has proved, that gold is a very common ingredient, though in so small a quantity as by no means to pay the charge of extracting it. See Potash, Soda, and the respective articles that afford ashes of use in the arts.

Asparagus. A new vegetable principle has lately been said to have been discovered in this well-known plant by M. Robiquel, of Paris. At the suggestion of M. Parmentier, he had begun to subject the juice of asparagus to chemical analysis, and some of it, concentrated by evaporation, produced, on standing some time, a considerable number of crystals. These were of two sorts; one of them was probably manna; the other was cool and slightly nauseous to the taste, so as to occasion a secretion of saliva; hard, brittle, and regularly crystallized in right rhomboidal prisms, with facets on the borders of the base and at its two acute angles, the obtuse angles being about 130°. They were moderately soluble in water, but not in alcohol; and the solution gave no signs of either acid or alkali; and was not at all affected by infusion of galls, acetat of lead, oxalat of ammonia, muriat of barytes, or hidrosulphuret of potash. Caustic potash triturated with it disengaged no ammonia, but appeared to render it more soluble in water. Burnt in a crucible, at first it swelled up, and emitted penetrating vapours affecting the eyes and nose like smoke of wood. It afforded a large portion of charcoal, which had no taste, and left nothing after its incineration but an almost imperceptible trace of earth, which, no doubt, was casually present. Toward the end, the odour emitted was somewhat similar to that of animal matter, and likewise inclining to that of ammonia. Nitric acid decomposes it, and nitrous gas being evolved, while the fluid assumes a yellow colour and bitter taste like that of animal substances. When the action of the nitric acid is completed, lime disengages abundance of ammonia from the liquid. This alkali must be formed in the operation just described, since the substance afforded no perceptible signs of it before.

Hence, as it contains neither earth nor alkali, it is not a neutral salt; and it is not an acid. M. Vauquelin therefore infers, that it is an immediate principle of the asparagus, composed of hidrogen, oxigen, and carbon, in particular proportions, with probably a small quantity of nitrogen.—*Annals de Chimie*, Jan. 1806.

Asphaltum. This substance, likewise called Bitumen Judaicum, or Jews Pitch, is a smooth, hard, brittle, black or brown substance, which breaks with a polish, melts easily when heated, and when pure burns without leaving any ashes. It is found in a soft or liquid state on the surface of the Dead Sea *, but by age grows dry and hard. The same kind of bitumen is likewise found in the earth in other parts of the world; in China; America, particularly in the island of Trinidad; and some parts of Europe, as the Carpathian hills, France, Neufchatel, &c. Its specific gravity, according to Boyle, is 1·400, to Kirwan, from 1·07 to 1·65. A specimen from Albania, of the specific gravity of 1·205, examined by Mr. Klaproth, was found to be soluble only in oils and in ether. Five parts of rectified oil of petroleum dissolved one of the asphaltum, without heat, in 24 hours. Analysed in the dry way, 100 grains afforded 32 of bituminous oil, 6 of water faintly ammoniacal, 30 of charcoal, 7¼ of silex, 7½ of alumine, ¾ of lime, 1¼ oxide of iron, ½ oxide of manganese, and 36 cubic inches of hidrogen gas.

According to Neumann, the asphaltum of the shops is a very different compound from the native bitumen; and varies, of course, in its properties, according to the nature of the ingredients made use of in forming it. On this account, and probably from other reasons, the use of asphaltum, as an article of the materia medica, is almost totally laid aside.

Aspic. A plant which grows in plenty in Languedoc, in Provence, and especially on the mountain of St. Baumé in France. It is a kind of lavender, pretty much like that which grows in our gardens, both with regard to its flowers, which are blue, and to the figure and green colour of its leaves. The botanists call it male lavender, lavendula mas in Latin. They also give it other names, as spica nardi, pseudo-nardus, &c. The oil of aspic that painters, farriers, and other artificers use, which is likewise of some use in medicine, being employed in several Galenical compositions, is extracted from the flowers and small leaves of this plant. It is very inflammable, and when once on fire it is almost impossible to extinguish it.

The true oil of aspic is white, and of an aromatic scent. It is the only dissolvent of sandarac; by which means it may be easily distinguished from that which is counterfeited, and which is nothing but oil of turpentine mixed with a little oil of petroleum.

In the above article, which is taken from Postlethwaite, the author, who refers to Savary as his authority, affirms, that as sandarac, or gum sandarac, is very soluble in spirit of wine, he concludes that Mr. Savary is mistaken, and must have meant karabé, or yellow amber. I find, in fact, that gum sandarac, though it differs from resins in several essential respects, particularly in not being soluble in olive oil, agrees with them, nevertheless, in this particular, that alcohol dissolves it.

Assay, *or* **Essay.** This operation consists in determining the quantity of valuable or precious metal contained in any mineral or metallic mixture, by analysing a small part thereof. The practical difference between the analysis and the assay of an ore, consists in this: The analysis, if properly made, determines the nature and quantities of all the parts of the compound; whereas, the object of the assay consists in ascertaining how much of the particular metal in question may be contained in a certain determinate quantity of the material under examination. Thus, in the assay of gold or silver, the baser metals are considered as of no value or consequence; and the problem to be resolved is simply, how much of each is contained in the ingot or piece of metal intended to be assayed. The examination of metallic ores may be seen under their respective titles; the present article will therefore consist of an account of the assaying of gold and silver.

To obtain gold or silver in a state of purity, or to ascertain the quantity of alloy it may contain, it is exposed to a strong heat, together with lead, in a porous crucible. This operation is called cupellation, and is performed as follows: The precious metal is put, together with a due propor-

---

* In the Mem. of the Academy of Sciences of Paris for 1778, there is an analysis of the water of this sea by Messrs. Macquer, Lavoisier, and Sage, by which it appears to contain 22 per cent. of muriat of magnesia, 16¼ of muriat of lime, and 6½ of muriat of soda. Its specific gravity is 1·25. It is limpid, and without smell.

he assayers weights; and the
called fine. Thus, if gold be
carats fine, it is to be under-
a mass weighing 24 carats,

the quantity of pure gold amounts to 23 carats.

In such small works as cannot be assayed by scraping off a part, and cupelling it, the assayers endeavour to ascertain its quality or fineness by the touch. This is a method of comparing the colour, and other properties, of a minute portion of the metal, with those of small bars the composition of which is known. These bars are called touch-needles; and they are rubbed upon the black basaltes, which, for this reason, is called the touchstone. Black flint or pottery will serve the same purpose. Sets of gold needles may consist of — Pure gold; pure gold 23½ carats, with half a carat of silver; 23 carats of gold, with one carat of silver; 22½ carats gold, with 1½ carat silver; and so on, till the silver amounts to four carats; after which the additions may proceed by whole carats. Other needles may be made in the same manner, with copper instead of silver; and other sets may have the addition consisting either of equal parts silver and copper, or such proportions as the occasions of business require. The examination by the touch may be advantageously employed previous to quartation, to indicate the quantity of silver necessary to be added.

In foreign countries, where trinkets and small work are required to be submitted to the assay of the touch, a variety of needles are necessary; but they are not much used in England. They afford, however, a degree of information which is more considerable than might at first be expected. The attentive assayer not only compares the colour of the stroke made upon the touchstone by the metal under examination, with that produced by his needle; but will likewise attend to the sensation of roughness, dryness, smoothness, or greasiness, which the texture of the rubbed metal excites, when abraded by the stone. When two strokes, perfectly alike in colour, are made upon the stone, he may then wet them with aqua fortis, which will affect them very differently, if they be not similar compositions; or the stone itself may be made red-hot by the fire, or by the blowpipe, if thin black pottery be used; in which case the phænomena of calcination will differ, according to the nature and quantity of the alloy.

The French Government has from time to time caused various experimental inquiries to be made respecting the art of assaying gold, which have thrown much light on this subject, and greatly tend to produce uniformity in the results of the operation. The latest report on this subject may be seen in the Annales de Chimie, vol. vi. p. 64; which may be consulted for a full account of the experiments and history of former proceedings. The general result is as follows, nearly in the words of the authors;

Six principal circumstances appear to effect the operation of parting: namely, the quantity of acid used in parting, or in the first boiling; the concentration of this acid; the time employed in its application; the quantity of acid made use of in the reprise, or second operation; its concentration; and the time during which it is applied. From the experiments it has been shown, that each of these unfavourable circumstances might easily occasion a loss of from the half of a thirty-second part of a carat or two thirty-second parts. The writers explain their technical language by observing that, the whole mass consisting of twenty-four carats, this thirty-second part denotes 1-768th part of the mass. It may easily be conceived, therefore, that if the whole six circumstances were to exist, and be productive of errors falling the same way, the loss would be very considerable.

It is therefore indispensably necessary, that one uniform process should be followed in the assays of gold; and it is a matter of astonishment, that such an accurate process should not have been prescribed by Government for assayers in an operation of such great commercial importance, instead of every one being left to follow his own judgment. The process recommended in the report before us is as follows.

Twelve grains of the gold intended to be assayed must be mixed with thirty grains of fine silver, and cupelled with 108 grains* of lead. The cupellation must be carefully attended to, and all the imperfect buttons rejected. When the cupellation is ended, the button must be reduced by lamination into a plate of 1½ inch, or rather more, in length, and four or five lines in breadth. This must be rolled up upon a quill, and placed in a matrass capable of holding about three ounces of liquid, when filled up to its narrow part. Two ounces and a half of very pure aqua fortis, of the strength of 20 degrees of Baumé's areometer, must then be poured upon it; and the matrass being placed upon hot ashes, or sand, the acid must be kept gently boiling for a quarter of an hour: the acid must then be cautiously decanted, and an additional quantity of 1½ ounce must be poured on the metal, and slightly boiled for twelve minutes. This being likewise carefully decanted, the small spiral piece of metal must be washed with filtered river-water, or distilled water, by filling the matrass with this fluid. The vessel is then to be reversed, by applying the extremity of its neck against the bottom of a crucible of fine earth, the internal surface of which is very smooth. The annealing must then be made, after having separated the portion of water which had fallen into the crucible; and, lastly, the annealed gold must be weighed. For the certainty of this operation, two assays must be made in the same manner, together with a third assay upon gold of twenty-four carats, or upon gold the fineness of which is perfectly and generally known.

No conclusion must be drawn from this assay, unless the latter gold should prove to be of the fineness of twenty-four carats exactly, or of its known degree of fineness; for, if there be either loss or surplus, it may be inferred, that the other two assays, having undergone the same operation, must be subject to the same error. The operation being made according to this process, by several assayers, in circumstances of importance, such as those which relate to large fabrications, the fineness of the gold must not be depended on, nor considered as accurately known, unless all the assayers have obtained a uniform result, without communication with each other. The authors observe, however, that this identity must be considered as existing to the accuracy of half of the thirty-second part of a carat. For, notwithstanding every possible precaution or uniformity, it very seldom happens that an absolute agreement is obtained between the different assays of one and the same ingot, because the ingot itself may differ in its fineness in different parts of its mass.

The assaying of silver does not differ from that of gold, excepting that the parting operation is not necessary. A certain small portion of the silver is absorbed by the cupel, and the more when a larger quantity of lead is used, unless the quantity of lead be excessive; in which case most of it will be scorified before it begins to act upon the silver. Mess. Hellot, Tillet, and Macquer, from their experiments made by order of the French Government, have ascertained, that four parts of lead are requisite for silver of eleven pennyweights twelve grains fine, or containing this weight of pure silver, and twelve grains of alloy, in twelve pennyweights; six parts of lead for silver of eleven pennyweights; eight parts lead for silver of ten pennyweights; ten parts lead for silver of nine pennyweights; and so on in the same progression.

Astringent Principle. The effect, called astringency, considered as distinguish-

---

* 1½ gross. Though these doses of silver and lead appeared to be proper for all operations of assaying gold, the commissaries observe, nevertheless, that gold of a lower title than eighteen carats may be alloyed with two parts, and even less, of silver; in order that the small mass of metal, when it comes to be laminated, may not be too thin, so as to break in pieces during the parting.

ole by the taste, is incapable of being de-
ned. It is perceived in the husks of nuts,
walnuts, in green tea, and eminently in
e nut gall. This is probably owing to
e circumstance, that acids have likewise
e property of corrugating the fibres of
e mouth and tongue, which is considered
characteristic of astringency as it relates
taste; and hence the gallic acid, which
commonly found united with the true
tringent principle, was long mistaken for
Seguin first distinguished them, and,
om the use of this principle in tanning
ins, has given it the name of *tannin*. Their
aracteristic differences are, the gallic acid
rms a black precipitate with iron; the
tringent principle forms an insoluble

ATHANOR. A kind of furnace, which has
ng since fallen into disuse. The very long
d durable operations of the ancient che-
ists rendered it a desirable requisite, that
eir fires should be constantly supplied
ith fuel in proportion to the consumption.
he athanor furnace was peculiarly adapt-
l to this purpose. Beside the usual parts,
was provided with a hollow tower, into
hich charcoal was put. The upper part
f the tower, when filled, was closely shut
y a well-fitted cover; and the lower part
ommunicated with the fire-place of the
urnace. In consequence of this disposition,
he charcoal subsided into the fire-place
gradually as the consumption made room
or it; but that which was contained in
he tower was defended from combustion
y the exclusion of a proper supply of
ur.

ATMOSPHERE. See AIR (ATMOSPHERI-
CAL).

ATTRACTION. The instances of attraction which are exhibited by the phænomena around us are exceedingly numerous, and continually present themselves to our observation. The effect of gravity, which causes the weight of bodies, is so universal, that we can scarcely form an idea how the universe could subsist without it. Other attractions, such as those of magnetism and electricity, are likewise observable; and every experiment in chemistry tends to show, that bodies are composed of various principles or substances, which adhere to each other with various degrees of force, and may be separated by known methods. It is a question among philosophers, whether all the attractions which obtain between bodies be referable to one general cause modified by circumstances, or whether various original and distinct causes act upon the particles of bodies at one and the same time. The philosophers at the beginning of the present century were disposed to consider the several attractions as essentially different, because the laws of their action differ from each other; but the moderns appear disposed to generalize this subject, and to consider all the attractions which exist between bodies, or at least those which are permanent, as depending upon one and the same cause, whatever it may be, which regulates at once the motions of the immense bodies that circulate through the celestial spaces, and those minute particles that are transferred from one combination to another in the operations of chemistry. The earlier philosophers observed, for example, that the attraction of gravitation acts upon bodies with a force which is inversely as the squares of the distances; and from mathematical deduction they have inferred, that the law of attraction between the particles themselves follows the same ratio: but, when their observations were applied to bodies very near each other, or in contact, an adhesion took place, which is found to be much greater than could be deduced from that law applied to the centres of gravity. Hence they concluded, that the cohesive attraction is governed by a much higher ratio, and probably the cubes of the distances. The moderns, on the contrary, among whom are Bergmann, Gayton-Morveau, and others, have remarked, that these deductions are too general, because for the most part drawn from the consideration of spherical bodies, which admit of no contact but such as is indefinitely small, and exert the same powers on each other, whichever side may be obverted. They remark likewise, that the consequence depending on the sum of the attractions in bodies not spherical, and at minute distances from each other, will not follow the inverted ratio of the square of the distance taken from any point assumed as the centre of gravity, admitting the particles to be governed by that law; but that it will greatly differ, according to the sides of the solid which are presented to each other, and their respective distances; insomuch that the attractions of certain particles indefinitely near each other will be indefinitely increased, though the ratio of the powers acting upon the remoter particles may continue nearly the same.

This doctrine, which however requires to be much more strictly examined by the application of mathematical principles, obviously points to a variety of interesting consequences. The polarity of particles, or their disposition to present themselves in their approach to each other in certain aspects, though it has been treated as a chimerical notion by a few superficial writers, is one of the first of these results; and may be not unaptly shown by the experiment of floating bodies upon water, which depress the surface of that fluid, and form a cavity into which they subside, and produce an appearance of attraction by rushing together; in which case their mode of application to each other is considerably governed by their figure, which causes them to turn round, and apply themselves to each other in such a manner as that the sum of the forces that act upon the two bodies may be nearly in equilibrio.

As a proof that gravitation and chemical attraction are two distinct properties, instead of the latter being a modification of the former, it has been noticed that this last is not governed by the masses or specific gravities of the particles. Thus, for example, since alcohol dissolves resin, and water does not; it would follow as an inference upon this system, that the particles of the alcohol are denser than those of the water; whereas the opposite conclusion might have been drawn, if the experiment had been made with gum instead of resin; this substance being dissolved by water, and not by alcohol. Nevertheless, it is a good answer to this objection, that admitting the masses to govern the attractions, yet the modifications of figure may be such as even to have a greater influence in the total effect than the mass itself. Thus it may be conceived that two cubes of lead may adhere more strongly by their flat surfaces than two spheres of gold, which cannot touch each other but in a point; and the superiority of attraction in the one case over the other may prevail in all the small distances to which chemical effects extend themselves; not to mention, that magnitude of particles will as greatly modify the consequences as figure itself.

These are speculations, which, with regard to the present state of chemistry, stand in much the same situation as the theory of gravity, which is minutely described in Plutarch, did with regard to astronomy before the time of Newton. As the celestial phænomena were formerly arranged from observation merely, but are now computed from the physical cause, gravitation; so, at present, chemistry is the science of matter of fact duly arranged, without the assistance of any extensive theory immediately deduced from the figures, volumes, densities, or mutual actions of the particles of bodies. What it may hereafter be, must depend on the ability and research of future chemists; but at present we must dismiss this remoter part of theory, to attend more immediately to the facts.

That the parts of bodies do attract each other, is evident from that adhesion which produces solidity, and requires a certain force to overcome it. For the sake of perspicuity, the various effects of attraction have been considered as different kinds of affinity, or powers. That power which physical writers call the attraction of cohesion, is generally called the attraction of aggregation by chemists. Aggregation is considered as the adhesion of parts of the same kind. Thus a number of pieces of brimstone united by fusion form an aggregate, the parts of which may be separated again by mechanical means. These parts have been called integrant parts; that is to say, the minutest parts into which a body can be divided, either really or by the imagination, so as not to change its nature, are called integrant parts. Thus, if sulphur and an alkali be combined together, and form liver of sulphur, we may conceive the mass to be divided and subdivided to an extreme degree, until at length the mass consists of merely a particle of brimstone and a particle of alkali. This then is an integrant part; and if it be divided further, the effect which chemists call decomposition will take place; and the particles, consisting no longer of liver of sulphur, but of sulphur alone and alkali alone, will be what chemists call component parts or principles.

The union of bodies in a gross way is called mixture. Thus, sand and an alkali may be mixed together. But, when the very minute parts of a body unite with those of another so intimately as to form a body which has properties different from those of either of them, the union is called combination, or composition. Thus, if sand and an alkali be exposed to a strong heat, the minute parts of the mixture combine, and form glass.

The earlier chemists were very desirous of ascertaining the first principles, or elements of bodies; and they distinguished by this name such substances as their art was incapable of rendering more simple. They seem however to have overlooked the obvious circumstance, that the limits of art are not the limits of nature. At present we hear little concerning elements. Those substances which we have not hitherto been able to analyse, or which, if decomposed, have hitherto eluded the observation of chemists, are indeed considered as simple substances relative to the present state of our knowledge, but in no other respect; for a variety of experiments give us reason to hope, that future inquiries may elucidate their nature and composition. Some writers, calling these simple substances by the name of Primary Principles, have distinguished compounds of these by the name of Secondary Principles, which they suppose to enter again into combinations without decomposition or change. It must be confessed, nevertheless, that no means have yet been devised to show whether any such subordination of principles exists. We may indeed discover, that a compound body consists of three or more principles; but whether two of these be previously united, so as to form a simple substance with relation to the third, or what in other respects may be their arrangement, we do not know. That it does exist, however, seems clear by making combinations in varied orders. Thus a weak solution of alkali will not dissolve oil; but a combination of oil and alkali will not separate by the addition of water. The alkali therefore adheres to that with which it was ee also the article VEGE-

emperature of the experi-
ill successively unite with
solid, which will by that
led in the fluid, and disap-
uid is called a solvent or
the solid body is said to

es unite together in all pro-

portions. In this way the acids unite with water. But there are likewise many substances, which cannot be dissolved in a fluid, at a settled temperature, in any quantity beyond a certain proportion. Thus, water will dissolve only about one fourth of its weight of common salt; and if more salt be added, it will remain solid. A fluid which holds in solution as much of any substance as it can dissolve is said to be saturated with it. But saturation with one substance is so far from preventing a fluid from dissolving another body, that it very frequently happens, that the solvent power of the compound exceeds that of the original fluid itself. Chemists likewise use the word saturation in another sense; in which it denotes such a union of two bodies as produces a compound the most remote in its properties from the properties of the component parts themselves. In other combinations, where one of the principles predominates, the other is said to be supersaturated, and the other principle is said to be undersaturated.

Heat in general increases the solvent power of fluids, probably by preventing part of the dissolved substance from congealing, or assuming the solid form.

It often happens, that bodies which have no tendency to unite are made to combine together by means of a third, which is then called the medium. Thus, water and fat oils are made to unite by the medium of an alkali, in the combination called soap. Some writers, who seem desirous of multiplying terms, call this tendency to unite the *affinity of intermedium*. This case has likewise been called *disposing affinity*; but Berthollet more properly styles it *reciprocal affinity*. He likewise distinguishes affinity into *elementary*, when it is between the elementary parts of bodies; and *resulting*, when it is to a compound only, and would not take place with the elements of that compound.

It very frequently happens, on the contrary, that the tendency of two bodies to unite, or remain in combination together, is weakened or destroyed by the addition of a third. Thus, alcohol unites with water in such a manner as to separate most salts from it. A striking instance of this is seen in a saturated or strong solution of nitre in water. If to this there be added an equal measure of alcohol, the greater part of the nitre instantly falls down. Thus magnesia is separated from a solution of Epsom salt by the addition of an alkali which combines with the sulphuric acid, and separates the earth. The principle which falls down is said to be precipitated, and in many instances is called a precipitate. Some modern chemists use the term precipitation in a more extended, and rather forced sense; for they apply it to all substances thus separated. In this enunciation therefore they would say, that potash precipitates soda from a solution of common salt, though no visible separation or precipitation takes place; for the soda, when disengaged from its acid, is still suspended in the water by reason of its solubility.

From a great number of facts of this nature it is clearly ascertained, not as a probable hypothesis, but as simple matter of fact, that some bodies have a stronger tendency to unite than others; and that the union of any substance with another will exclude, or separate, a third substance, which might have been previously united with one of them; excepting only in those cases wherein the new compound has a tendency to unite with that third substance, and form a triple compound. This preference of uniting, which a given substance is found to exhibit with regard to other bodies, is by an easy metaphor called elective attraction, and is subject to a variety of cases, according to the number and the powers of the principles which are respectively presented to each other. The cases which have been most frequently observed by chemists are those called simple elective attractions, and double elective attractions.

When a simple substance is presented or applied to another substance compounded of two principles, and unites with one of these two principles so as to separate or exclude the other, this effect is said to be produced by simple elective attraction.

It may be doubted whether any of our operations have been carried to this degree of simplicity. All the chemical principles we are acquainted with are simple only with respect to our power of decomposing them; and the daily discoveries of our contemporaries tend to decompose those substances, which chemists a few years ago considered as simple. Without insisting however upon this difficulty, we may observe, that water is concerned in all the operations which are called humid; and beyond a doubt modifies all the effects of such bodies as are suspended in it; and the variations of temperature, whether arising from an actual igneous fluid, or from a mere modification of the parts of bodies, also tend greatly to disturb the effects of elective attraction. These causes render it difficult to point out an example of simple elective attraction, which may in strictness be reckoned as such.

Double elective attraction takes place when two bodies, each consisting of two principles, are presented to each other, and mutually exchange a principle of each; by which means two new bodies, or compounds, are produced, of a different nature from the original compounds.

Under the same limitations as were pointed out in speaking of simple elective attraction, we may offer instances of double elective attraction. Let mercury be dissolved to saturation in the nitric acid, the water will then contain nitrat of mercury. Again, let potash be dissolved to saturation in the sulphuric acid, and the result will be a solution of sulphat of potash. If mercury were added to the latter solution, it would indeed tend to unite with the acid, but would produce no decomposition; because the elective attraction of the acid to the alkali is the strongest. So likewise, if the nitric acid alone be added to it, its tendency to unite with the alkali, strong as it is, will not effect any change, because the alkali is already in combination with a stronger acid. But if the nitrat of mercury be added to the solution of sulphat of potash, a change of principles will take place, the sulphuric acid will quit the alkali, and unite with the mercury, while the nitric acid combines with the alkali; and these two new salts, namely nitrat of potash, and sulphat of mercury, may be obtained separately by crystallization.

The most remarkable circumstance in this process is, that the joint effects of the attractions of the sulphuric acid to mercury, and the nitric acid to alkali, prove to be stronger than the sum of the attractions between the sulphuric acid and the alkali, and between the nitrous acid and the mercury; for, if the sum of these two last had not been weaker, the original combinations would not have been broken.

Mr. Kirwan, who first in the year 1782 considered this subject with that attention it deserves, calls the affinities which tend to preserve the original combinations, the quiescent affinities. He distinguishes the affinities or attractions which tend to produce a change of principles, by the name of the divellent affinities.

Some eminent chemists are disposed to consider as effects of double affinities those changes of principles only which would not have taken place without the assistance of a fourth principle. Thus, the mutual decomposition of sulphat of soda and nitrat of potash, in which the alkalis are changed, and sulphat of potash and nitrat of soda are produced, is not considered by them as an instance of double decomposition; because the nitre would have been decomposed by simple elective attraction, upon the addition of the acid only.

There are various circumstances which modify the effects of elective attraction, and have from time to time misled chemists in their deductions. The chief of these is the temperature, which, acting differently upon the several parts of compounded bodies, seldom fails to alter, and frequently reverses the effects of the affinities. Thus, if alcohol be added to a solution of nitrat of potash, it unites with the water, and precipitates the salt at a common temperature. But if the temperature be raised, the alcohol rises on account of its volatility, and the salt is again dissolved. Thus again, if sulphuric acid be added, in a common temperature, to a combination of phosphoric acid and lime, it will decompose the salt, and dis-

sphoric acid; but if this

acid gives place to acids which are weaker than the nitric acid: the sulphurous acid gives place to acids greatly inferior in attractive power or affinity to the sulphuric acid. The deception arising from effects of this nature is in a great measure produced by the want of discrimination on the part of chemical philosophers; it being evident, that the properties of any compound substance depend as much upon the proportion of its ingredients, as upon their respective nature.

The presence and quantity of water is probably of more consequence than is yet supposed. Thus bismuth is dissolved in nitrous acid, but falls when the water is much in quantity. The same is said of silver. Ribaucout has shown the last (Annales de Chimie, xv. 122.) in alum, and it is likely that the fact is more common than is suspected. Whether the attraction and strength as to quantity in saturation be not variable by the presence or absence of water, must be referred to experiment.

The power of double elective attractions too is disturbed by this circumstance. If muriat of lime be added to a solution of carbonat of soda, they are both decomposed, and the results are muriat of soda and carbonat of lime. But if lime and muriat of soda be mixed with just water sufficient to make them into a paste, and this be exposed to the action of carbonic acid gas, a saline efflorescence consisting of carbonat of soda will be formed on the surface, and the bottom of the vessel will be occupied by muriat of lime in a state of deliquescence.

Mr. Berthollet has lately made a great number of experiments, from which he further deduces the following anomaly: that in elective attractions the power exerted is not in the ratio of the affinity simply, but in a ratio compounded of the force of affinity and the quantity of the agent; so that quantity may compensate for weaker affinity. Thus an acid which has a weaker affinity than another for a given base, if it be employed in a certain quantity, is capable of taking part of that base from the acid which has a stronger affinity for it; so that the base will be divided between them in the compound ratio of their affinity and quantity. This division of one substance between two others, for which it has different affinities, always takes place, according to him, when three such are present under circumstances in which they can mutually act on each other. And hence it is, that the force of affinity acts most powerfully when two substances first come into contact, and continues to decrease in power as either approaches the point of saturation. For the same reason it is so difficult to separate the last portions of any substance adhering to another. Hence, if the doctrine laid down by Mr. Berthollet be true, to its utmost extent, it must be impossible ever to free a compound completely from any one of its constituent parts by the agency of elective attraction; so that all our best established analyses are more or less inaccurate.

The solubility or insolubility of principles, at the temperature of any experiment, has likewise tended to mislead chemists of inferior accuracy, who have deduced consequences from the first effects of their experiments. It is evident, that many separations may ensue without precipitation; because this circumstance does not take place unless the separated principle be insoluble, or nearly so. The soda cannot be precipitated from a solution of sulphat of soda, by the addition of potash, because of its great solubility; but, on the contrary, the new compound itself, or sulphat of potash, which is much less soluble, may fall down, if there be not enough water present to suspend it. No certain knowledge can therefore be derived from the appearance or the want of precipitation, unless the products be carefully examined. In some instances all the products remain suspended, and in others they all fall down, as may be instanced in the decomposition of sulphat of iron by lime. Here the acid unites with the lime, and forms sulphat of lime, which is scarcely at all soluble; and the still less soluble oxide of iron, which was disengaged, falls down along with it.

Many instances present themselves, in which decomposition does not take place, but a sort of equilibrium affinity is perceived. Thus, soda, added to the supertartrit of potash, forms a triple salt by combining with its excess of acid. So likewise ammonia combines with a portion of the acid of muriat of mercury, and forms the triple compound formerly distinguished by the barbarous name of sal alembroth.

When we reflect maturely upon all the circumstances enumerated, or slightly touched upon, in the foregoing pages, we may form some idea of the extensive field of research, which yet remains to be explored by chemists. If it were possible to procure simple substances, and combine two together, and to this combination of two to add one more of the other simple substances, the result of the experiment would in many cases determine, by the exclusion of one of the three, that its affinity to either of the remaining two was less than that between those two respectively. In this way it would be ascertained, in the progress of experimental inquiry, that the simple attractions of a series of substances were gradually increasing or diminishing in strength. Thus, ammonia separates alumine from the sulphuric acid; magnesia, in like manner, separates the ammonia; lime predominates, in the strength of affinity, over magnesia, as appears by its separating this last earth; the soda separates the lime, and itself gives place to the potash; and, lastly, potash yields its acid to barytes. The simple elective attractions of these several substances to sulphuric acid are therefore in the inverted order of their effects; barytes is the strongest; and this is succeeded regularly by potash, soda, lime, magnesia, ammonia, and alumine. It is evident that results of this nature, being tabulated, as was first done by the celebrated Geoffroy, and afterward by Bergman, must afford a valuable mass of chemical knowledge It must be remarked, however, that these results merely indicate, that the powers are greater or less than each other; but how much greater or less is not determined, either absolutely or relatively. Tables of this nature cannot therefore inform us of the effects which may take place in the way of double affinity, for want of the numerical relations between the attracting powers. Thus, when we are in possession of the order of the simple elective attractions between the sulphuric acid and a series of substances, and also between the nitrous acid and the same substances; and when, in addition to this, the respective powers of each of the acids upon every one of the substances singly taken, are known, so far as to determine which will displace the other—yet we cannot thence foretel the result of applying two combinations to each other, each containing an acid united with one of the number of simple substances. Or, more concisely, a table of simple elective attractions can be of no use to determine the effects of double elective attraction, unless the absolute power of the attractions be expressed by number instead of their order merely.

It appears therefore, that the present state of chemistry affords us no indication, by which we may come at the results of double elective attraction without actual experiment; and, in this way, we may ascertain, whenever a double decomposition takes place, that the sum of the attractions which tend to produce the new combinations is greater than the sum of those attractions which tend to preserve the compounds in their original form. But as these attractions, in the simplest cases, are four in number, and the effect may arise from an excess or defect of any one of the four, or may be distributed in an infinity of proportions among them, it must easily be seen how numerous the difficulties are which attend these researches, and what ample space is left for exercising the sagacity of philosophers in chemical analysis.

There have not been wanting a number of eminent philosophers, who have exerted themselves in attempting to discover data, by which the phænomena of chemistry might be subjected to computation; and though the difficulty of the subject has hitherto prevented any thing of a conclusive nature from being done, their researches have nevertheless thrown great light on the subject. Mr. Guyton-Morveau first attempted to ascertain the proportional powers of attraction between mercury and other metals, by

hem. Most of the errors
indeed of the cultivators
of any science, arise from the subject being viewed in too confined a light; so that some essential object is overlooked. Nothing can be clearer than that the more simple the description or enunciation of these objects, the less the mind will be burdened, and the less probable it will be that any thing of importance will be overlooked. Hence the advantage of a concise, simple, and accurate style, which may direct the mind steadily to the subject in contemplation, without misleading by ambiguous terms, or the language of the vulgar, which is applicable to so many and such various ideas. The advantages of this are strongly felt in the mathematical sciences, where by diagrams exhibited to the eye, by terms constantly appropriated to the expression of the same ideas, or by symbols, the quantity, value, and application of which vary with their relative positions, the mind is occupied by no other objects than such as tend to forward the desired investigation. This has in some degree been effected in chemical science by Geoffroy, in his first table of simple elective attractions; by Bergman, in his Symbolical Expression of the Effects of Compound Attractions; and by others, in their tables of the component parts of bodies. A description of the tables contained in the ensuing pages, will sufficiently explain their nature and application.

Tables I to VI contain in substance the two tables of Attractiones Electivæ Simplices, placed at the end of Bergman's treatise upon elective attractions, as given by Dr. Pearson, with such corrections and additions as subsequent discoveries have rendered necessary, and arranged in such a manner, as has tended to facilitate the insertion of them in the regular pages of the book, instead of adopting the much less convenient method of printing upon a large sheet, to be occasionally folded out. It will be seen therefore that I have avoided repetitions, and altered the arrangement of the columns; but have in no material respect changed the substance of the tables themselves.

These tables require no other explanation, than that the substances enumerated are considered to be simple, as far as relates to the facts exhibited in these sketches. The order of position denotes that the higher any substance stands in any column, the stronger is its elective attraction to the substance at the head of that column. The under part of each table exhibits the attractions in the dry way, and must be considered as entirely distinct from the upper part.

sion of compound affinities, it is clear, from what has already been said
hat the sketches must either be made from actual experiment in every
deduction from the numerical expressions of the forces of attraction. I
some of the difficulties which oppose the deduction of these numbers; but
l set of numbers, inferred from such facts as we possess, may be useful in
to point out the probability of decompositions previous to trial, I have
Ir. Guyton-Morveau's table of the numerical expression of affinity between
soluble earths and the five principal acids.

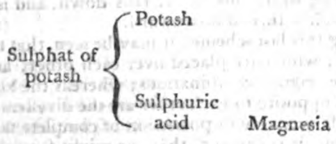
is according to the last corrections of its author, and will be found to
rhaps most cases of double elective attraction, but not in all: when it is
wever, that it embraces near 500 different cases, we cannot wonder at its
ct.

d of exemplifying or exhibiting simple or compound affinities by symbols,
Bergman, consists in placing those substances which are applied to each
e same horizontal line of direction; the component parts of the substances
t the two extremities of a vertical bracket; and the new products, if any, are
ove the other, at the middle part of a horizontal bracket, connecting their
inciples. This will be rendered clearer by an example.

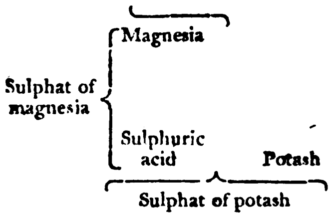
nagnesia to be presented to a solution of sulphat of potash, it will be found
position takes place. These facts are expressed as follows:



e scheme, the sulphat of potash is placed opposite the point of a vertical
ts two component parts, potash and sulphuric acid, are placed within the ex-
he same bracket. Horizontally opposite the sulphuric acid is placed mag-
ote, that it is presented to that acid. And as these two substances are not

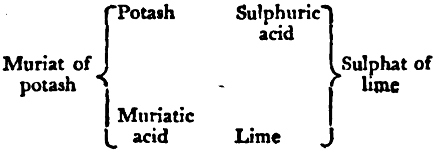
connected by a bracket, it is to be understood from the scheme, that they do not unite, and consequently that the sulphat of potash remains undecomposed.

II. On the contrary, if to a solution of sulphat of magnesia, potash be added, a decomposition will ensue, which is expressed as follows:



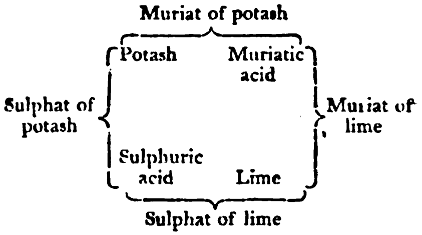
The arrangements in this scheme depend on the same principles as those of the foregoing: but the bracket underneath the sulphuric acid and potash denotes, that these two substances unite, and form sulphat of potash, which is accordingly placed beneath the middle of the bracket. The point of the bracket being turned up, is made to denote that the compound remains suspended, or in solution. The magnesia is of course disengaged: and half a bracket, with the point downward, is placed over it, to denote, that it falls to the bottom, or is precipitated.

III. The above instances exhibit simple elective attractions: but this method is more particularly applicable to the compound attractions; for example, Suppose a solution of the muriat of potash be added to sulphat of lime, no decomposition will take place. This is expressed as under:



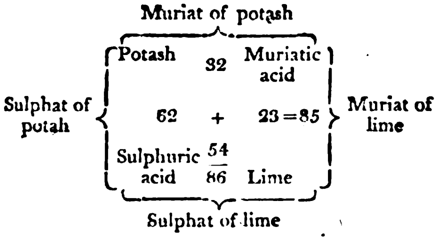
The want of horizontal brackets in this scheme denotes, that the principles presented to each other do not unite, and consequently that no decomposition ensues.

IV. On the contrary, if sulphat of potash be presented to the muriat of lime, a mutual decomposition will ensue: thus,



In this scheme we see, that the principles presented to each other do unite, as is shown by the horizontal brackets, and form the new compounds, muriat of potash and sulphat of lime; the former of which remains in solution, as is shown by its bracket being turned upward; while the latter, being nearly insoluble, falls down, and is accordingly denoted by a bracket the point of which is turned downward.

V. By attentively observing this last scheme, it may be seen, that the attractions exerted between the simple substances, which are placed over each other, are the quiescent affinities, and tend to preserve the original combinations; whereas the attractions between the simple substances which stand opposite to each other are the divellent affinities, and tend to produce new combinations. If we were in possession of complete tables of the numerical expression of simple attraction, it is evident, that we might foretel every result, which might be produced by the application of compound substances to each other; and we shall see the utility of Guyton-Morveau's table, by applying the numbers to the preceding scheme.



ction between the potash and sulphuric acid is expressed by the number 62;
raction between the muriatic acid and lime is expressed by the number 23.
he quiescent affinities, and their sum 85 expresses the tendency to preserve the
ms of sulphat of potash and muriat of lime. On the other hand, the attrac-
en the potash and muriatic acid is expressed by 32, and the attraction
phuric acid and lime by 54. The sum of 32 and 54 amounts to 86, and ex-
divellent affinities, which tend to produce new combinations. And as this
ceeds the sum of the quiescent affinities, it follows, that the double decomposi-
ce place.

ese examples we have designedly taken them the reverse of each other; but
nce, singly exhibited, does in fact point out both the affirmative and the ne-
positions. Thus, from the facts first exhibited, that magnesia does not de-
e combination of potash and sulphuric acid, it likewise follows, that potash
ose the combination of sulphuric acid and magnesia. And accordingly,
wo schemes of double affinity, it it clearly ascertained, from the mutual de-
of sulphat of potash and muriat of lime, that the muriat of potash and sul-
e will not decompose each other.

horizontal bracket, which in the humid way was used to denote solution, is
ote sublimation in experiments in the dry way.

wing schemes from Bergman will requre no explanation, after the instances
nibited.

Schemes of Elective Attractions in the Dry Way.

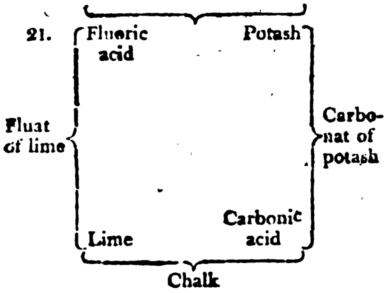
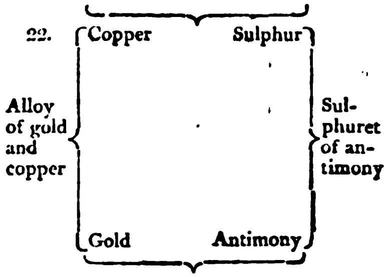
21.



22.



I have inserted the whole of Bergman's schemes, excepting those numbered 17 a, 38 a, 39 a, in the humid way, and 5 a, 8 a, 9 a, 15 a, 16 a, 19 a, in the dry way, which are merely schemes according to the phlogistic doctrine, the duplicates of which, according to the modern theory, are here retained; 25, which includes the acid of sorrel, at present known to be a compound; and 55 and 56, which relate to experiments with the nitrous acid, which may be considered as doubtful, because a large part of the product assumes the permanently elastic state, and has not been examined. My chief inducement for inserting all the others is, that the whole together form so considerable a body of chemical knowledge, expressed with so much perspicuity by virtue of this happy arrangement, that their value and effect cannot but greatly tend to promote the researches of experienced chemists, as well as the advancement of the learner. I speak on this occasion as if the sketches were now first published; and this, with respect to the greater number of chemical readers, is really the case: for Bergman published them in characters; a method which is indeed attended with peculiar advantages both in the enunciation and practice of chemistry; but which, never having been in general use, is very far from being familiar even to the learned. The tables have not, that I know of, been before printed in words at length. I have also inserted the numbers of Mr. Morveau, which answer as far as they can be applied; and the contemplation of those schemes which contain only partial numbers, will show what experiments require to be made to extend them farther. Thus, in scheme 7, it is seen that the adhesion of muriatic acid to the oxide of mercury, in the humid way, will require a less numerical expression than 32; and in scheme 8, that the attraction of sulphuric acid to oxide of iron is less than 54; and the numerical expressions of these indeterminate quantities must be taken so as to agree with all the experiments known, as we have no other method of ascertaining them. The intelligent chemist will find no difficulty in extending them to more particular cases, by attending to the rules of arrangement already described and exemplified.

Augites. See Aqua Marina.

Aurum Fulminans. See Gold.

Aurum Musivum, *or* Mosaicum. A combination of tin and sulphur, which is thus made: Melt twelve ounces of tin, and add to it three ounces of mercury; triturate this amalgam with seven ounces of sulphur, and three of muriat of ammonia. Put the powder into a matrass, bedded rather deep in sand, and keep it for several hours in a gentle heat; which is afterward to be raised, and continued for several hours longer. If the heat have been moderate, and not continued too long, the golden-coloured scaly porous mass, called Aurum Musivum, will be found at the bottom of the vessel; but if it have been too strong, the aurum musivum fuses to a black mass of a striated texture. This process is thus explained: As the heat increases, the tin, by stronger affinity, seizes and combines with the muriatic acid of the muriat of ammonia; while the alkali of that salt, combining with a portion of the sulphur, flies off in the form of a sulphuret. The combination of tin and muriatic acid sublimes, and is found adhering to the sides of the matrass. The mercury, which served to divide the tin, combines with part of the sulphur, and forms cinnabar, which also sublimes; and the remaining sulphur, with the remaining tin, forms the aurum musivum which occupies the lower part of the vessel. It must be admitted, however, that this explanation does not indicate the reasons why such an indirect and complicated process should be required to form a simple combination of tin and sulphur.

It does not appear that the proportions of the materials require to be strictly attended to. The process of the marquis de Bullion, as described by Chaptal in his Elements of Chemistry, consists in amalgamating eight ounces of tin with eight

nercury, and mixing this with
f sulphur, and four of muriat
. This mixture is to be exposed
urs on a sand heat sufficient to
ottom of the matrass obscurely
ut Chaptal himself found, that
s containing the mixture were
a naked fire, and violently
mixture took fire, and a sub-
formed in the neck of the ma-
ting of the most beautiful aurum
large hexagonal plates. The
Bullion obtained a good aurum
dissolving eight ounces of tin
tic acid, precipitating it by car-
da, and mixing the precipitate
unces of sulphur. He used this
ead of the foregoing, but found
musivum unfit to increase the
e electric machine, as the former
ivum did, which he found to
parts out of seven of mercury,
h, accordingly, he attributes the
ctrical excitation.

musivum has no taste, though
nens exhibit a sulphureous smell.
uble in water, acids, or alkaline
But in the dry way it forms a
huret, soluble in water. It de-
th nitre. Bergman mentions a
m musivum from Siberia, con-
sulphur, and a small proportion

musivum is used as a pigment
a golden colour to small statue
figures. It is likewise said to be
mixed with melted glass to imitate lapis lazuli.

Avidity. This term is in common use among chemists, who apply it to denote that kind of tendency to combination, which exerts its effects in a short time. It does not therefore denote the power of attraction, or that by which combinations are most strongly maintained; but that modification of the attractive powers, which conduces most to their speedy exertion. Thus, metallic bodies not being soluble in acids but at a certain determinate degree of calcination, and the nitric acid being more easily decomposed than the muriatic, it is found, that the nitric acid dissolves most metallic substances with considerable rapidity, though the muriatic does not; but, on the other hand, the attraction of the muriatic acid to many of the metallic oxides is such, that it takes them from the nitric. The nitric acid, therefore, is said to dissolve the metals with more avidity than the muriatic acid, notwithstanding the attraction of the latter appears to be stronger.

Azot. See Gas (Nitrogen).

Azure. This term, which was formerly applied to the fine blue extracted from lapis lazuli, and at present known by the name of Ultramarine, is now more generally applied to denote the blue glass made by the combination of calx of cobalt with glass. When this is in masses, or a coarse powder, it is called Smalt. See Cobalt and Ultramarine.

B.

E. The beginning and end of
act chemical process consists in
With imperfect instruments this
will be tedious and inaccurate;
good balance, the results will be
; and much time, which is so
experimental researches, will be

nce is a lever, the axis of motion
formed with an edge like that

of suspension are supposed to be
stances from the fulcrum, and
ed with equal weights when

fulcrum be placed in the centre
f the beam, and the three edges
same right line, the balance
will have no tendency to one position more than another, but will rest in any position it may be placed in, whether the scales be on or off, empty or loaded.

2. If the centre of gravity of the beam, when level, be immediately above the fulcrum, it will overset by the smallest action; that is, the end which is lowest will descend; and it will do this with more swiftness, the higher the centre of gravity, and the less the points of suspension are loaded.

3. But if the centre of gravity of the beam be immediately below the fulcrum, the beam will not rest in any position but when level; and, if disturbed from this position, and then left at liberty, it will vibrate, and at last come to rest on the level. Its vibrations will be quicker, and its horizontal tendency stronger, the lower the centre of gravity, and the less the weight upon the points of suspension.

4. If the fulcrum be below the line joining the points of suspension, and these be loaded, the beam will overset, unless prevented by the weight of the beam tending to produce a horizontal position, as in § 3,

In this last case, small weights will equilibrate, as in § 3; a certain exact weight will rest in any position of the beam, as in § 1; and all greater weights will cause the beam to overset, as in § 2. Many scales are often made this way, and will overset with any considerable load.

5. If the fulcrum be above the line joining the points of suspension, the beam will come to the horizontal position, unless prevented by its own weight, as in § 2. If the centre of gravity of the beam be nearly in the fulcrum, all the vibrations of the loaded beam will be made in times nearly equal, unless the weights be very small, when they will be slower. The vibrations of balances are quicker, and the horizontal tendency stronger, the higher the fulcrum.

6. If the arms of a balance be unequal, the weights in equipoise will be unequal in the same proportion. It is a severe check upon a workman to keep the arms equal, while he is making the other adjustments in a strong and inflexible beam.

7. The equality of the arms of a balance is of use, in scientific pursuits, chiefly in making of weights by bisection. A balance with unequal arms will weigh as accurately as another of the same workmanship with equal arms, provided the standard weight itself be first counterpoised, then taken out of the scale, and the thing to be weighed be put into the scale, and adjusted against the counterpoise; or when proportional quantities only are considered, as in chemical and in other philosophical experiments, the bodies and products under examination may be weighed against the weights, taking care always to put the weights into the same scale. For then, though the bodies may not be really equal to the weights, yet their proportions among each other may be the same as if they had been accurately so.

8. But though the equality of the arms may be well dispensed with, yet it is indispensably necessary, that their relative lengths, whatever they may be, should continue invariable. For this purpose, it is necessary, either that the three edges be all truly parallel, or that the points of suspension and support should be always in the same part of the edge. This last requisite is the most easily obtained.

The balances made in London are usually constructed in such a manner, that the bearing parts form notches in the other parts of the edges; so that the scales being set to vibrate, all the parts naturally fall into the same bearing. The balances made in the country have the fulcrum edge straight, and confined to one constant bearing by two side plates. But the points of suspension are referred to notches in the edges, like the London balances. The balances here mentioned, which come from the country, are enclosed in a small iron japanned box; and are to be met with at the Birmingham and Sheffield warehouses, though less frequently than some years ago; because a pocket contrivance for weighing guineas and half-guineas has got possession of the market. They are, in general, well made and adjusted, turn with the twentieth of a grain when empty, and will sensibly show the tenth of a grain, with an ounce in each scale. Their price is from five shillings to half a guinea; but those which are under seven shillings have not their edges hardened, and consequently are not durable. This may be ascertained by the purchaser, by passing the point of a penknife across the small piece which goes through one of the end boxes; if it makes any mark or impression, the part is soft.

9. If a beam be adjusted so as to have no tendency to any one position, as in § 1, and the scales be equally loaded; then, if a small weight be added in one of the scales, that balance will turn, and the points of suspension will move with an accelerated motion, similar to that of falling bodies, but as much slower, in proportion, very nearly, as the added weight is less than the whole weight borne by the fulcrum.

10. The stronger the tendency to a horizontal position in any balance, or the quicker its vibrations, § § 3, 5, the greater additional weight will be required to cause it to turn, or incline to any given angle. No balance therefore can turn so quick as the motion deduced in § 9. Such a balance as is there described, if it were to turn with the ten thousandth part of the weight, would move at quickest ten thousand times slower than falling bodies; that is, the dish containing the weight, instead of falling through sixteen feet in a second of time, would fall through only two hundred parts of an inch; and it would require four seconds to move through one third part of an inch: consequently, all accurate weighing must be slow. If the indexes of two balances be of equal lengths, that index which is connected with the shorter balance will move proportionally quicker than the other. Long beams are the most in request, because they are thought to have less friction; this is doubtful: but the quicker angular motion, greater strength, and less weight of a short balance, are certainly advantages.

11. Very delicate balances are not only useful in nice experiments, but are likewise much more expeditious than others in common weighing. If a pair of scales with a certain load be barely sensible to one tenth of a grain, it will require a considerable time to ascertain the weight to that degree of accuracy, because the turn must be observed several times over, and is very small. But if no greater accuracy were required, and scales were used which would turn with the hundredth of a grain, a tenth

ore or less, would make so great
in the turn, that it would be
ately.
alance be found to turn with a

ain decimally, downwards, $\frac{9}{10}$
ual to 675 rings, $\frac{8}{10}$ would be

equal to 600 rings, $\frac{7}{10}$ to 525 rings, &c. Small weights may be made of thin leaf brass. Jewellers foil is a good material for weights below $\frac{1}{10}$ of a grain, as low as to $\frac{1}{100}$ of a grain; and all lower quantities may be either estimated by the position of the index, or shown by actually counting the rings of wire, the value of which has been determined.

17. In philosophical experiments, it will be found very convenient to admit no more than one dimension of weight. The grain is of that magnitude as to deserve the preference. With regard to the number of weights the chemist ought to be provided with, writers have differed according to their habits and views. Mathematicians have computed the least possible number, with which all weights within certain limits might be ascertained; but their determination is of little use. Because, with so small a number, it must often happen, that the scales will be heavily loaded with weights on each side, put in with a view only to determine the difference between them. It is not the least possible number of weights which it is necessary an operator should buy to effect his purpose, that we ought to inquire after, but the most convenient number for ascertaining his inquiries with accuracy and expedition. The error of adjustment is the least possible, when only one weight is in the scale; that is, a single weight of five grains is twice as likely to be true, as two weights, one of three, and the other of two grains, put into the dish to supply the place of the single five; because each of these last has its own probability of error in adjustment. But, since it is as inconsistent with convenience to provide a single weight, as it would be to have a single character for every number; and as we have nine characters, which we use in rotation, to express higher values according to their position, it will be found very serviceable to make the set of weights correspond without numerical system. This directs us to the set of weights as follows: 1000 grains, 900 g. 800 g. 700 g. 600 g. 500 g. 400 g. 300 g. 200 g. 100 g. 90 g. 80 g. 70 g. 60 g. 50 g. 40. g. 30 g. 20 g. 10 g. 9 g. 8 g. 7 g. 6 g. 5. g. 4 g. 3 g. 2 g. 1 g. $\frac{9}{10}$ g. $\frac{8}{10}$ g. $\frac{7}{10}$ g. $\frac{6}{10}$ g. $\frac{5}{10}$ g. $\frac{4}{10}$ g. $\frac{3}{10}$ g. $\frac{2}{10}$ g. $\frac{1}{10}$ g. $\frac{9}{100}$ g. $\frac{8}{100}$ g. $\frac{7}{100}$ g. $\frac{6}{100}$ g. $\frac{5}{100}$ g. $\frac{4}{100}$ g. $\frac{3}{100}$ g. $\frac{2}{100}$ g. $\frac{1}{100}$ g. With these the philosopher will always have the same number of weights in his scales as there are figures in the number expressing the weights in grains.

Thus 742·5 grains will be weighed by the weights 700, 40, 2, and $\frac{5}{10}$.

I shall conclude this chapter with an account of some balances I have seen or heard of, and annex a table of the correspondence of weights of different countries.

Muschenbroek, in his Cours de Physique (French translation, Paris, 1769), tom. ii. p. 247, says, he used an ocular balance of great accuracy, which turned (trebuchoit) with $\frac{1}{20}$ of a grain. The substances he weighed were between 200 and 300 grains. His balance therefore weighed to the [illegible] part of the whole; and would ascertain such weights truly to four places of figures.

In the Philosophical Transactions, vol. lxvi. p. 509, mention is made of two accurate balances of Mr. Bolton; and it is said that one would weigh a pound, and turn with $\frac{1}{10}$ of a grain. This, if the pound be avoirdupois, is $\frac{1}{70000}$ of the weight; and shows, that the balance could be well depended on to four places of figures, and probably to five. The other weighed half an ounce, and turned with $\frac{1}{100}$ of a grain. This is $\frac{1}{20000}$ of the weight.

In the same volume, p. 511, a balance of Mr. Read's is mentioned, which readily turned with less than one pennyweight, when loaded with 55 pounds, before the Royal Society; but very distinctly turned with four grains, when tried more patiently. This is about $\frac{1}{96000}$ part of the weight; and therefore this balance may be depended on to five places of figures.

Also, page 576, a balance of Mr. Whitehurst's weighs one pennyweight, and is sensibly affected with $\frac{1}{300}$ of a grain. This is [illegible] part of the weight.

I have a pair of scales of the common construction, § 8, made expressly for me by a skilful workman in London. With 1200 grains in each scale, it turns with $\frac{1}{10}$ of a grain. This is $\frac{1}{12000}$ of the whole; and therefore about this weight may be known to five places of figures. The proportional delicacy is less in greater weights. The beam will weigh near a pound troy; and when the scales are empty, it is affected by $\frac{1}{1000}$ of a grain. On the whole, it may be usefully applied to determine all weights between 100 grains and 4000 grains to four places of figures.

A balance belonging to Mr. Alchorne of the Mint in London, is mentioned, vol. lxxvii. p. 205, of the Philosophical Transactions. It is true to 3 grains with 15lb. an end. If these were avoirdupois pounds, the weight is known to $\frac{1}{35000}$ part, or to four places of figures, or barely five.

A balance (made by Ramsden, and turning on points instead of edges) in the possession of Dr. George Fordyce, is mentioned in the seventy-fifth volume of the Philosophical Transactions. With a load of four or five ounces, a difference of one division in the index was made by $\frac{1}{1000}$ of a grain. This is [illegible] part of the weight, and consequently this beam will ascertain such weights to five places of figures, beside an estimate figure.

I have seen a strong balance in the possession of my friend Mr. Magellan, of the kind mentioned in § 15, which would bear several pounds, and showed $\frac{1}{10}$ of a grain, with one pound an end. This is $\frac{1}{70000}$ of the weight, and answers to five figures. But I think it would have done more by a more patient trial than I had time to make.

The Royal Society's balance, which was lately made by Ramsden, turns on steel edges, upon planes of polished crystal. I was assured, that it ascertained a weight to the seven-millionth part. I was not present at this trial, which must have required great care and patience, as the point of suspension could not have moved over much more than the $\frac{1}{10}$ of an inch in the first half minute. but, from some trials which I saw, I think it probable, that it may be used in general practice to determine weights to five places and better.

From this account of balances, the student may form a proper estimate of the value of those tables of specific gravities, which are carried to five, six, and even seven places of figures, and likewise of the theoretical deductions in chemistry, that depend on a supposed accuracy in weighing, which practice does not authorise. In general, where weights are given to five places of figures, the last figure is an estimate, or guess figure; and where they are carried farther, it may be taken for granted, that the author deceives either intentionally, or from want of skill in reducing his weights to fractional expressions, or otherwise.

Among the numerous public exertions, which our learned neighbours, the French, have made in favour of the sciences, the determination of the relative proportions of the weights used in various parts of Europe is by no means one of the least. The most exact standard weights were procured by means of the ambassadors of France, resident in various places; and these were compared by Mons. Tillet with the standard mark in the pile preserved in the Cour de Monnoies de Paris. His experiments were made with an exact balance made to weigh one marc, and sensible to one quarter of a grain. Now, as the mark contains 18432 quarter grains, it follows, that this balance was a good one, and would exhibit proportions to four places, and a guess figure. The results are contained in the following table, extracted from Mons. Tillet's excellent Paper in the Memoirs of the Royal Academy of Sciences for the year 1767. I have added the two last columns, which show the number of French and English grains contained in the compound quantities against which they stand. The English grains are computed to one tenth of a grain, although the accuracy of weighing came no nearer than about two tenths.

The weights of the kilogramme, gramme, decigramme, and centigramme, which are now frequently occurring in the French chemical writers, are added at the bottom of this table, according to the latest determination of their respective values.

L 4

Balas, or Balais Ruby. A precious stone of a pale red colour, inclining to violet. It comes chiefly from the Brazils; although some likewise come from the East Indies. The value of the Balas ruby is about thirty shillings per carat, according to Dutens.

Balloon. Receivers of a spherical form are called Balloons, by the French, and likewise by several translators from that language.

Balloon (Air, or Aerostatical). The first experiment for floating bodies in the atmosphere, by including within them a fluid specifically less heavy than common air, was made by Messrs. Stephen and John Mongolfier, at Avignon, in the month of November 1782. They raised a bag of silk, by inflating it with common air heated or altered by combustion; it being evident that such a bag must rise on the same principle as smoke ascends from a chimney. This experiment led several French philosophers to the consideration, that hidrogen gas, of which the great levity had been ascertained by Mr. Cavendish in 1766, might, with more permanent advantage, be applied to this purpose; and, accordingly, M. Faujas St. Fond constructed a machine on this principle by public subscription at Paris, which was suffered to rise into the atmosphere from the Champ de Mars, in the month of August 1783. Pilatre de Rozier first ascended into the air with a balloon on Mongolfier's principle; and Messrs. Charles and Robert made the first experiment of ascending with a balloon filled with hidrogen gas.

Cavallo's Treatise on the History and Practice of Aerostation may be consulted for an account of the methods of constructing and filling these machines. The most usual means of obtaining the hidrogen gas, has been to dissolve iron shavings or turnings in diluted sulphuric acid; but it appears probable, that the calcination of ignited iron by steam would prove the cheapest, if the demand for machines of this kind were ever to become considerable.

Balls (Martial). A medical composition, consisting of iron filings and cream of tartar, used to impregnate water, or other liquids, with iron dissolved by the tartarous acid. To make these balls, one part of filings of iron and two parts of powdered cream of tartar are mixed well together, and put into an earthen or iron vessel with some water. This mixture is to be stirred from time to time, until it becomes almost dry, and then it is to receive more water, and to be stirred as before. This treatment is to be continued until it acquires, when nearly dry, somewhat of the consistence and tenacity of softened resin. Then it is to be rolled up into the form of a ball, which is generally kept tied up in a rag; and when intended to be used, it is to be infused in water until it gives some colour to that liquid.

In this composition, part of the tartarous acid, which is redundant in the cream of tartar, combines with part of the iron; and the remaining or greater part of the cream of tartar and iron continues solid in this way of proceeding. The infusion of the martial ball in water does not therefore differ, as Macquer observes, from the tartarized tincture of iron. Its virtues are much the same as those of other martial medicines. These balls are unknown to us in England.

Balls (Mercurial). These consist of an amalgam of tin and mercury, in which the former metal so far predominates, as to give the mass a solid form. Macquer mentions the use of them by travellers to purify water, in which they are boiled for this purpose. I do not see, however, in what respect they would produce any material advantage. The mercurial impregnation, which the water would slightly receive from this treatment, does not seem likely to counteract, in any considerable degree, the bad qualities of another nature, which may predominate in water.

Balsam. The several vegetable principles in commerce have been distinguished by various names, which bear no relation to their properties, considered with regard to scientific arrangement. Balsams have been usually considered to be oily aromatic substances, imperfectly fluid, obtained from incisions made in certain trees. Several French chemists, among whom are Fourcroy and Chaptal, have adopted the distinction of Bucquet, who has confined this denomination to such resinous matters alone as possess a fragrant smell, and more especially contain acid, odorant, and concrete salts, that may be extracted by decoction or sublimation. The principal balsams, according to this division, are Benzoin, balsam of Tolu or Peru, and storax; which see, as well as the proper names of those fluid substances, which still generally retain the name of balsams in this country.

Balsam of Sulphur. A solution of sulphur in oil.

All oils, whether expressed or essential, can dissolve sulphur. To make this solution, the oil must be poured on the sulphur, and sufficient heat applied to melt the substance. While the oil dissolves the sulphur, it acquires a reddish or brown colour, an acrid, disagreeable taste, and a strong fetid smell, somewhat hepatic, resembling that of the combination of oil with sulphuric acid.

It is not well ascertained what happens in this combination. The fixed oils deposit sulphur in the crystallized state; but when the balsam of sulphur is distilled, the sulphur itself is totally decomposed, or at least it is no where found in a disengaged state.

the columnar basaltes, which
nse masses, composed of co-
, forty, or more feet in height,
ous thickness. Nay, those at
two hundred and fifty feet
constitute some of the most
cenes in nature for the im-
regularity of their parts. The
im in Ireland, for the space of
n length, exhibits a very mag-
ty of columnar cliffs: and the
way consists of a point of that

coast formed of similar columns, and projecting into the sea upon a descent for several hundred feet. These columns are, for the most part, hexagonal, and fit very accurately together, being in some instances united by a stony cement, but most frequently not adherent to each other, though water cannot penetrate between them; which proves, that they cannot have been thus fissured by the shrinking of the mass on cooling. And the basaltic appearances on the Hebrides islands on the coast of Scotland, as described by sir Joseph Banks, who visited them in 1772, are upon a scale still more striking for its vastness and variety.

An extensive field of inquiry is here offered to the geological philosopher, in his attempts to ascertain the alterations to which the globe has been subjected. The inquiries of the chemist equally cooperate in these researches, and tend likewise to show to what useful purposes this and other substances may be applied. Bergman found, that the component parts of various specimens of basaltes were, at a medium, 52 parts silex, 15 alumine, 8 carbonat of lime, and 25 iron. The differences seem, however, to be considerable; for Faujas de St. Fond gives these proportions:—46 silex, 30 alumine, 10 lime, 6 magnesia, and 8 iron. The amorphous basaltes known by the name of rowley rag, the ferrilite of Kirwan, of the specific gravity of 2·748, afforded Dr. Withering 47·5 of silex, 32·5 of alumine, and 20 of iron, at a very low degree of oxidation, probably. Dr. Kennedy, in his analysis of the basaltes of Staffa, gives the following as its component parts:—silex 48, alumine 16, oxide of iron 16, lime 9, soda 4, muriatic acid 1, water and volatile parts, 5. Klaproth gives, for the analysis of the prismatic basaltes of Hasenberg: silex 44·5, alumine 16·75, oxide of iron 20, lime 9·5, magnesia 2·25, oxide of manganese 0·12, soda 2·60, water 2. On a subsequent analysis, with a view to detect the existence of muriatic acid, he found slight indications of it, but it was in an extremely minute proportion.

Basaltes, when calcined and pulverized, is said to be a good substitute for puzzolana in the composition of mortar, giving it the property of hardening under water. Wine bottles have likewise been manufactured with it, but there appears to be some nicety requisite in the management to ensure success. Mr. Castelveil, who heated his furnace with wood, added soda to the basaltes, to render it more fusible: while Mr. Giral, who used pitcoal, found it necessary to mix with his basaltes a very refractory sand. The best mode probably would be, to choose basaltes of a close fine grain and uniform texture, and to employ it alone, taking care to regulate the heat properly; for, if this be carried too high, it will drop from the iron almost like water.

Basis, or Base. The chemical philosophers have, for a long time, been in the habit of considering the acids as bodies possessing an activity peculiar to themselves; and have, in general, overlooked the circumstance, that an equal activity, or power of attraction, must exist in those substances with which they combine, and are by this means deprived of their distinctive properties. The substances with which acids enter into combination, and are said to be neutralized, are for the most part less volatile than the acids themselves; and accordingly communicate a degree of fixity to those acids. From both these reasons, writers have been led to distinguish the substance, which is united with any acid, by the name of the basis of the compound, or neutral salt. As a considerable advantage, with regard to chemical language, is obtained from the use of this term, which is not altogether improper, it is still much used by chemical authors. Thus, we say, salts with earthy bases, salts with alkaline bases, or salts with metallic bases, accordingly as the case may be; by which it is to be understood, that these substances are united with an acid.

Base is likewise used sometimes for that which forms an acid by its union with oxigen; but which is now more generally called the *radical* of the acid: and hence we meet with the distinction of salifiable and acidifiable bases There would be more of precision, no doubt, in confining base to the former significations; but when it is employed as synonymous to radical, there can be little danger of its occasioning mistake or obscurity.

Bath. The heat communicated from bodies in combustion must necessarily vary according to circumstances; and this variation not only influences the results of operations, but in many instances endangers the vessels, especially if they be made of glass. Among the several methods of obviating this inconvenience, one of the most usual consists in interposing a quantity of sand, or other matter, between the fire and the vessel intended to be heated. The sand bath and the water bath are most commonly used; the latter of which was called Balneum Mariæ by the elder chemists. A bath of steam may, in some instances, be found preferable to the water bath. Some chemists have proposed baths of melted lead, of tin, and of other fusible substances. These may perhaps be found advantageous in a few peculiar operations, in which the intelligent operator must indeed be left to his own sagacity.

The water bath is nothing more than a pot or vessel containing water, which is kept boiling, and in which the digesting or distillatory vessels are kept immersed. As the heat of boiling water is nearly stationary, this temperature is found very advantageous in the distillation of essential oils, and all other substances in which an empyreumatic taint is to be feared. It may easily be imagined, that the form of the bath, as well as of the vessels, may be varied according to the purposes respectively aimed at.

The sand bath consists of sand placed either in an iron pot, or upon an iron hearth with fire underneath. In this the heat is gradually communicated, although less uniformly than by the water bath; and it may likewise be carried to ignition. As the heat is greatest towards the bottom of the sand, the operator possesses a power of moderating it by raising the vessels when necessary. The extensive sand bath which is formed by spreading sand upon an iron hearth is very useful for digestion, solution, evaporation, and other chemical processes, which may be carried on at the same time in a considerable number of vessels.

Bdellium. A gum resin, supposed to be of African origin. The best bdellium is of a yellowish brown, or dark brown colour, according to its age; unctuous to the touch, brittle, but soon softening, and growing tough betwixt the fingers; in some degree transparent, not unlike myrrh; of a bitterish taste, and a moderately strong smell. It does not easily take flame, and, when set on fire, soon goes out. In burning, it sputters a little, owing to its aqueous humidity; but cannot be said to explode, much less to explode like gunpowder, as Hermann Valentini reports.

An ounce of picked bdellium, treated with water, afforded Neumann six drams two scruples of gummy extract; and afterward, with alcohol, two scruples of resin, two scruples remaining undissolved. Another scruple, treated first with alcohol, yielded two drams of resinous extract; and afterward, with water, five drams two scruples of gum, only one scruple remaining undissolved. The distilled spirit has no taste or smell of the bdellium, and the distilled water very little.

Bee-glue. A soft unctuous glutinous matter, used by the bees for cementing the combs to the hives, and closing up the cells. See Propolis.

Beer is the wine of grain. Malt is usually made of barley. The grain is steeped for two or three days in water until it swells, becomes somewhat tender, and tinges the water of a bright reddish brown colour. The water being then drained away, the barley is spread about two feet thick upon a floor, where it heats spontaneously, and begins to grow, by first shooting out the radicle. In this state, the germination is stopped by spreading it thinner, and turning it over for two days; after which it is again made into a heap, and suffered to become sensibly hot, which usually happens in little more than a day. Lastly, it is conveyed to the kiln, where, by a gradual and low heat, it is rendered dry and crisp. This is malt; and its qualities differ according as it is more or less soaked, drained, germinated, dried, and

157	Twenty months.
162	Two years.

Beer is made from malt previously ground, or cut to pieces, by a mill. This is placed in a tun, or tub with a false bottom; hot water is poured upon it, and the whole stirred about with a proper instrument. The temperature of the water in this operation, called Mashing, must not be equal to boiling; for, in that case, the malt would be converted into a paste, from which the impregnated water could not be separated. This is called Setting. After the infusion has remained for some time upon the malt, it is drawn off, and is then distinguished by the name of Sweet Wort. By one or more subsequent infusions of water, a quantity of weaker wort is made, which is either added to the foregoing, or kept apart, according to the intention of the operator. The wort is then boiled with hops, which gives it an aromatic bitter taste, and is supposed to render it less liable to be spoiled in keeping; after which it is cooled in shallow vessels, and suffered to ferment, with the addition of a proper quantity of yeast. The fermented liquor is beer; and differs greatly in its quality, according to the nature of the grain, the malting, the mashing, the quantity and kind of the hops and the yeast, the purity or admixtures of the water made use of, the temperature and vicissitudes of the weather, &c.

Beside the various qualities of malt liquors of a similar kind, there are certain leading features by which they are distinguished, and classed under different names, and to produce which, different modes of management must be pursued. The principal distinctions are into beer, properly so called; ale; table or small beer; and porter, which is commonly termed beer in London. Beer is a strong, fine, and thin liquor; the greater part of the mucilage having been separated by boiling the wort longer than for ale, and carrying the fermentation farther, so as to convert the saccharine matter into alcohol. Ale is of a more sirupy consistence, and sweeter taste; more of the mucilage being retained in it, and the fermentation not having been carried so far as to decompose all the sugar. Small beer, as its name implies, is a weaker liquor; and is made, either by adding a large portion of water to the malt, or by mashing with a fresh quantity of water what is left after the beer or ale wort is drawn off. Porter was probably made originally from very high dried malt; but it is said, that its peculiar flavour cannot be imparted by malt and hops alone. As long ago as the reign of Queen Anne, brewers were not to mix sugar, honey, Guinea pepper, essentia bina, occulus Indicus, or any other unwholesome ingredient, in beer, under a certain penalty; from which, we may infer, that such at least was the practice of some; and writers, who profess to discuss the secrets of the trade, mention most of these and some other articles as essentially necessary. The essentia bina is sugar boiled down to a dark colour, and empyreumatic flavour. Broom tops, wormwood, and other bitter plants, were formerly used to render beer fit for keeping, before hops were introduced into this country; but are now prohibited to be used in beer made for sale.

Beer appears to have been of ancient use, as Tacitus mentions it among the Germans, and has been usually supposed to have been peculiar to the northern nations; but the ancient Egyptians, whose country was not adapted to the culture of the grape, had also contrived this substitute for wine; and Mr. Park has found the art of making malt, and brewing from it very good beer, among the negroes in the interior parts of Africa.

Beet. The root of the beet affords a considerable quantity of sugar, and has lately been cultivated for the purpose of extracting it to some extent in Germany. See Sugar. It is likewise said, that if beet roots be dried in the same manner as malt, after the greater part of their juice is pressed out, very good beer may be made from them.

Belly. When a metallic ore is found, not in veins, but in distinct masses, these are called Bellies or Stock Works, by the miners. In the iron-founderies, likewise, the large air vessels which receive the air from iron bellows, worked by steam engines, and transmit it in an equal stream to the furnace by the reaction of water, are called, by the workmen, Regulating Bellies.

Bellmetal. The basis of the composition called Bellmetal, is copper, which is alloyed chiefly with tin. Silver is said to be sometimes added. A small proportion of tin, added to copper, deprives it of its malleability so far as to render it quite brittle; and the specific gravity of the compound is always greater than would be deduced by computation from the quantities and specific gravities of its component parts. In certain proportions, it even exceeds that of the heavier metal. The colour of bellmetal is much whiter than might be expected from the proportion of tin which enters into its composition; and when this last metal constitutes one third of the mass, the compound is so perfectly white, as to reflect the images of all coloured bodies without alteration, when duly polished. See Speculum.

Ben (Oil of). This is obtained from the ben nut, by simple pressure. It is remarkable for its not growing rancid in keeping, or at least not until it has stood for a number of years; and on this account it is used in extracting the aromatic principle of such odoriferous flowers as yield little or no essential oil in distillation. These preparations are made in Spain, Portugal, and more especially Italy, by the following method, according to Neumann:—Some fine carded cotton is dipped in oil, and laid in the bottom of a proper vessel: on this is spread a pretty thick layer of fresh flowers, above these some more of the dipped cotton; and thus alternately till the vessel is full. The whole is then digested, for a day and a night, in the heat of a water bath; after which the flowers are taken out, the cotton stratified in the same manner with fresh flowers, and the process repeated until the oil squeezed out from the cotton is found to be sufficiently impregnated with the odour of the subject. The digesting vessel is either of tin, with a cover to screw upon it; or of porcelain, composed of two parts which are closely luted together. Most of them have an air-hole in the top, which is stopped with a dossil of the oiled cotton, which retains such of the odorous effluvia as would otherwise make their escape. Some, instead of the oil of ben, take the ben itself, cut it in pieces, stratify it repeatedly with the flowers, and then press out its oil; but the oil thus obtained is greatly inferior in fragrance to the other.

Benzoin, *or* Benjamin. The tree which produces Benzoin is a native of the East Indies, particularly of the island Siam and Sumatra[*]. The juice exsudes from incisions, in the form of a thick white balsam. If collected as soon as it has grown somewhat solid, it proves internally white like almonds, and hence it is called Benzoë Amygdaloides: if suffered to lie long exposed to the sun and air, it changes more

solves benzoin without heat.
ivium of potash or soda im-
rms a dark brown solution
, which becomes turbid after
posure to the air. No alteration is produced in these solutions by diluting them largely with water; but the acids form precipitates in them which are redissolved on the application of heat, if nitric or acetic acid be added in excess. Ammonia dissolves a small quantity of benzoin, which is precipitated by the acids.

The products Mr. Brande obtained by distillation were from a hundred grains; benzoic acid 9 grains, acidulated water 5·5, butyraceous and empyreumatic oil 60, brittle coal 22, and a mixture of carburetted hidrogen and carbonic acid gas computed at 3·5. On treating the empyreumatic oil with water, however, 5 grains more of acid were extracted, making 14 in the whole.

The oil obtained by the distillation of benzoin possesses a strong empyreuma, but when rectified by a second distillation its smell is exceedingly fragrant and pleasant. Its taste is acrimonious and very disagreeable. Distilled with water it imparts to it some of its taste. It is perfectly soluble in alcohol, and this solution is rendered turbid by water. It sinks in water; and forms soaps with the alkalis.—*Nicholson's Journal.*

Beryl. A precious stone of a blue green colour, by many authors confounded, and perhaps justly, with the aqua marine. Cronstedt, however, calls the lighter-coloured stone Aqua Marine, and the darker the Beryl. See Aqua Marine. The Saxon Beryl was the stone in which professor Tromsdorf supposed he had discovered a new earth, which, from the insipidity of its compounds with the acids, he named *ugustine*. According to this analysis, it contained 78 of this earth, 4·5 alumine, and 15 silex: but Vauquelin afterward found that this earth was the phosphat of lime, and M. Chenevix likewise has demonstrated the fact. What is called Saxon beryl, therefore, is properly an apatite.

Bezoar. This name, which is derived from a Persian word implying an antidote to poison, was given to a concretion found in the stomach of an animal of the goat kind, which was once very highly valued for this imaginary quality, and has thence been extended to all concretions found in animals. The medical bezoar has been distinguished into oriental, or such as is brought from the east, and occidental, or that which is brought from South America and the Spanish West Indies. The oriental bezoar has a smooth glossy surface, and a dark green or olive hue. The occidental is uneven on the surface, of a dirty green colour, heavier, and more brittle. The hog bezoar, found in the gall bladder of the wild boar in the East Indies, has likewise been highly valued, selling for ten times its weight in gold: and the biliary calculi of the porcupine and monkey, called likewise Malacca stones, have been valued much higher.

The bezoar was formerly much prized in medicine, but has gradually grown into disuse, and is now totally rejected by our college. A composition of it with absorbent powders has been much in repute, as a popular remedy for disorders in children, by the name of Gascoigne's powder, and Gascoigne's ball; but the real Bezoar was rarely if ever used for these, its price offering such a temptation to counterfeit it. Some have employed for this purpose a resinous composition, capable of melting in the fire, and soluble in alcohol: but Neumann supposed, that those nearest resembling it were made of gypsum, chalk, or some other earth, to which the proper colour was imparted by some vegetable juice. We understand, however, that tobaccopipe clay tinged with ox-gall is commonly employed, at least for the Gascoigne's powder, this giving a yellow tint to paper rubbed with chalk, and a green to paper rubbed over with quicklime, which are considered as proofs of genuine bezoar, and which a vegetable juice would not effect.

Bezoar (Bovine). A yellowish concretion found in the gall-bladder of the ox, and used as a yellow pigment in miniature painting.

Bezoar (Jovial). A compound of oxide of antimony and oxide of tin, made by melting three parts of antimony with two of tin; levigating the mixture; adding five parts of corrosive muriat of mercury; distilling in a retort; and, lastly, distilling the muriat of antimony and tin three times with thrice its weight of nitric acid. The powder is then to be calcined, thrown into alcohol while in a state of ignition, and dried. It differs very little from the antihectic of Poterius, like which it has fallen into disuse.

Bezoar (Mineral). This preparation is an oxide of antimony, produced by distilling the nitric acid several times to dryness from the muriat of antimony. See Antimony.

Bile. See Gall.

Birdlime. This substance has been classed among the immediate productions of vegetables. Fourcroy has considered it as a gluten; but it had never been fully examined, till it was analysed by Bouillon Lagrange.

The best birdlime is made of the middle bark of the holly, boiled seven or eight hours in water, till it is soft and tender; then laid in heaps in pits in the ground and covered with stones, the water being previously drained from it; and in this state left for two or three weeks to ferment till it is reduced to a kind of mucilage. This being taken from the pit is pounded in a mortar to a paste; washed in river water; and kneaded, till it is freed from extraneous matters. In this state it is left four or five days in earthen vessels, to ferment and purify itself, when it is fit for use.

It may likewise be obtained from the misleto, the viburnum lantana, young shoots of elder, and other vegetable substances.

It is sometimes adulterated with turpentine, oil, vinegar, and other matters.

Good birdlime is of a greenish colour, and sour flavour; gluey, stringy, and tenacious; and in smell resembling linseed oil. By exposure to the air it becomes dry and brittle, so that it may be powdered; but its viscidity is restored by wetting it. It reddens tincture of litmus. Exposed to a gentle heat it liquefies slightly, swells in bubbles, becomes grumous, emits a smell resembling that of animal oils, grows brown, but recovers its properties on cooling, if not heated too much. With a greater heat it burns, giving out a brisk flame and much smoke. The residuum contains sulphat and muriat of potash, carbonat of lime and alumine, with a small portion of iron. If birdlime be boiled in water, it acquires a little increase of fluidity, which it loses on cooling; the water merely taking from it a little mucilage, with a small portion of extractive matter, and becoming slightly acid. A concentrated lixivium of potash dissolves it at once into a white magma, which is rendered brown by evaporation, and gives out ammonia. This grows hard by exposure to the air, resembles soap in taste and smell, and is almost wholly soluble both in water and alcohol. The weak acids soften birdlime, and partly dissolve it. Concentrated sulphuric acid chars it; and if powdered lime be then added, so as to form a thick magma, acetic acid and ammonia are obtained. Part of this acid is naturally present in the birdlime. Nitric acid acts little upon it cold, but by heat converts it into a hard brittle mass, which an additional quantity of nitric acid dissolves, part being converted into malic and oxalic acids. By continuing the evaporation a yellow substance like wax is obtained, which forms a brown soap with potash, partly soluble in alcohol. Muriatic acid does not act upon birdlime cold: with heat it turns black. Oxigenated muriatic acid converts it into a white pulverable substance, insoluble in water, not liquefiable by heat, and not convertible into a resin by nitric acid. Acetous acid softens birdlime, and dissolves a certain portion. Some metallic oxides are easily reduced when heated with it. Litharge may be incorporated into a plaster with it. Boiling alcohol dissolves it, but on cooling becomes turbid, and deposits a kind of wax. The filtered liquor is bitter, nauseous, and acid, and leaves a resin on evaporation. Sulphuric ether is the proper solvent of birdlime. On adding a little water the mixture thickens, and the ether swims on the top; but if water enough to dissolve the ether be poured in, a body of oil, considerably analogous to that of linseed, is formed on the surface. If the solution of ether be evaporated, a greasy yellow substance is obtained, of the softness of wax. It appears, therefore, that birdlime differs considerably from gluten.—*Annales de Chimie.*

Bismuth is a semimetal of a yellowish or reddish white colour, little subject to change in the air. It is somewhat harder than lead, and is scarcely, if at all, malleable; being easily broken, and even reduced to powder, by the hammer. The internal face, or place of fracture, exhibits large shining plates, disposed in a variety of positions; thin pieces are considerably sonorous. At a temperature not exceeding the 460th degree of Fahrenheit, it melts; and its surface becomes covered with a greenish gray or brown calx. A stronger heat ignites it, and causes it to burn with a small blue flame; at the same time that a yellowish oxide, known by the name of Flowers of Bismuth, is driven up. This oxide appears to rise in consequence of the combustion; for it is very fixed, and runs into a greenish glass when exposed to heat alone. Bismuth urged by a strong heat in a closed vessel, sublimes entire. This semimetal crystallizes very distinctly when gradually cooled.

The sulphuric acid has a slight action upon bismuth when it is concentrated and boiling. Sulphurous acid gas is exhaled, and part of the bismuth is converted into a white oxide. A small portion combines with the sulphuric acid, and affords a deliquescent salt in the form of small needles.

The nitric acid dissolves bismuth with the greatest rapidity and violence; at the same time that much heat is extricated, and a large quantity of nitric oxide escapes. The solution, when saturated, affords crystals as it cools; the salt detonates weakly, and leaves a yellow oxide behind, which effloresces in the air. Upon dissolving this salt in water, it renders that fluid of a milky white, and lets fall an oxide of the same colour.

The nitric solution of bismuth exhibits the same property when diluted with water, most of the metal falling down in the form of a white calx, called Magistery of Bismuth. M. Buckholtz asserts, that the nitric solution, if prepared by means of heat, is not decomposable by water: and that the solution prepared without will deposit its oxide in a crystalline form merely by warming it gradually. This precipitation of the nitric solution, by the addition of water, is the criterion by which bismuth is distinguished from all other metals. The magistery or oxide is a very white and subtile powder: when prepared by the addition of a large quantity of water, it is used as a paint for the complexion, and is thought gradually to impair the skin. The liberal use of any paint for the skin seems indeed likely to do this; but there is reason to suspect, from the resemblance between the general properties of lead and bismuth, that the oxide of this semimetal may be attended with effects similar to those which the oxides of lead are known to produce. If a small portion of muriatic acid be mixed with the nitric, and the precipitated oxide be washed with but a small quantity of cold water, it will appear in minute scales of a pearly lustre, constituting the *pearl powder* of perfumers. These paints are liable to be turned black by sulphuretted hidrogen gas.

The muriatic acid does not readily act upon bismuth. It is necessary that the acid should be concentrated, and kept a long time in digestion upon it; or that it should be distilled from the semimetal. The residue, when washed with water, affords a saline combination, which does not easily crystallize, but may be sublimed in the form of a soft fusible salt, called Butter of Bismuth. The muriatic solution of bismuth likewise affords a precipitate of oxide by the addition of water. Muriatic acid seizes the oxide of bismuth, when added to its solution in nitric acid, and forms a compound of sparing solubility, which falls to the bottom. Alkalis likewise precipitate its oxide; but not of so beautiful a white colour as that afforded by the affusion of pure water.

The gallic acid precipitates bismuth of a greenish yellow, as prussiat of potash does of a yellowish colour.

The effects of earths and alkalis upon bismuth, in the dry way, have been little attended to. Silex unites with its oxide into a clear greenish yellow glass. Nitre oxides it, with scarcely any perceptible detonation. Muriat of ammonia is not decomposed by bismuth in the metallic state, although its oxide readily combines with the acid of this salt, and disengages the volatile alkali. Sulphur unites with bismuth by fusion, and forms a blueish gray brilliant mass, of a needle-formed texture.

This semimetal unites with most metallic substances, and renders them in general more fusible. When calcined with the imperfect metals, its glass dissolves them, and produces the same effect as lead in cupellation; in which process it is even said to be preferable to lead.

Bismuth is used in the composition of pewter, in the fabrication of printers' types, and in various other metallic mixtures. With an equal weight of lead it forms a brilliant white alloy, much harder than lead, and more malleable than bismuth, though not ductile; and if the proportion of lead be increased, it is rendered still more malleable. Eight parts of bismuth, five of lead, and three of tin, constitute the fusible metal, sometimes called Newton's from its discoverer, which melts at the heat of boiling water, and may be fused over a candle in a piece of stiff paper without burning the paper. One part of bismuth, with five of lead, and three of tin, forms plumbers' solder. It forms the basis of a sympathetic ink. The oxide of bismuth precipitated from nitric acid has been recommended in spasmodic disorders of the stomach, and given in doses of four grains four times a day. A writer in the Jena Journal says he has known the dose carried gradually to one scruple without injury.

Bismuth is sometimes found native; and may be analysed in the humid way by solution in nitric acid, and precipitation by the addition of water, which throws down one hundred and thirteen grains of oxide for every hundred of metallic bismuth. It is likewise found in the calciform state; and mineralized by sulphur, of a gray colour, resembling galena, but heavier. These ores may also be analysed by nitric acid, like the foregoing.

Bismuth is easily separable, in the dry way, from its ores, on account of its great fusibility. It is usual, in the processes at large, to throw the bismuth ore into a fire of wood; beneath which a hole is made in the ground to receive the metal, and defend it from oxidation. The same process may be imitated in the small way, in the examination of the ores of this metal; nothing more being necessary, than to expose it to a moderate heat in a crucible, with a quantity of reducing flux; taking care, at the same time, to perform the operation as speedily as possible, that the bismuth may be neither oxided nor volatilized.

Bistre. A brown pigment, consisting of the finer parts of wood soot, separated from the grosser by washing. The soot of the beech is said to make the best.

Bit-noben. See Bitumen (Salt of).

Bitter Principle. See Amer.

Bittern. The mother water which remains after the crystallization of common salt in sea water, or the water of salt springs. It abounds with sulphat of magnesia, to which its bitterness is owing. See Water (Sea).

Bitumen. This term includes a considerable range of inflammable mineral substances, of an oily or resinous nature; burning with flame in the open air, without being converted into an acid like sulphur, or into an oxide like the metals. They are of different consistency, from a thin fluid to a solid; but the solids are for the most part liquefiable at a moderate heat. The fluid are, 1. Naphtha; a fine, white, thin, fragrant, colourless oil, which issues out of white, yellow, or black clays in Persia and Media. This is highly inflammable, and is decomposed by distillation. It dissolves resins, and the essential oils of thyme and lavender; but is not itself soluble either in alcohol or ether. It is the lightest of all the dense fluids, its specific gravity being 0·708. 2. Petroleum, which is a yellow, reddish, brown, greenish, or blackish soil, found dropping from rocks, or issuing from the earth, in the duchy of Modena, and in various other parts of Europe and Asia. This likewise is insoluble in alcohol, and seems to consist of naphtha, thickened by exposure to the atmosphere. It contains a portion of the succinic acid. 3. Barbadoes tar, which is a viscid, brown, or black inflammable substance, insoluble in alcohol, and containing the succinic acid. This appears to be the mineral oil in its third state of alteration. The solid are, 1. Asphaltum, mineral pitch, of which there are three varieties: the cohesive; the semicompact, maltha; the compact, or asphaltum. These are smooth, more or less hard or brittle, inflammable substances, which melt easily, and burn without leaving any or but little ashes, if they be pure. They are slightly and partially acted on by alcohol and ether. 2 Mineral tallow, which is a white substance of the consistence of tallow, and as greasy, although more brittle. It was found in the sea on the coasts of Finland, in the year 1786; and is also met with in some rocky parts of Persia. It is near one fifth lighter than tallow; burns with a blue flame, and a smell of grease, leaving a black viscid matter behind, which is more difficultly consumed. 3. Elastic bitumen, or mineral caoutchouc, of which there are two varieties. Beside these, there are other bituminous substances, as jet and amber, which approach the harder bitumens in their nature; and all the varieties of pitcoal, and the bituminous schistus, or shale, which contain more or less of bitumen in their composition. See the different kinds of bitumen and bituminous substances in their respective places in the order of the alphabet.

A different species of bitumen from any yet enumerated appears to be found accompanying the Bovey coal. It was first noticed by Dr. Milles, who says, that among the clay, but adhering to the coal, are found lumps of a bright yellow loam, extremely light, and so saturated with petroleum, that they burn like sealing-wax, emitting a very agreeable aromatic scent. Mr. Hatchett has since examined this more minutely, and analysed it. According to his description, it is of a pale brownish ochraceous yellow. Its fracture is imperfectly conchoidal. It appears earthy externally; but, when broken, exhibits a slight degree of vitreous lustre. The fragments are irregularly angular, and completely opaque at the edges. It is extremely brittle. It does not apparently become softened, when held for some time in the hand, but emits a faint resinous odour. Its specific gravity, at 65° F. is 1·135. Placed on a heated iron, it immediately melts, smokes much, burns with a bright flame, and yields a very fragrant odour like some of the sweet scented resins, but which at last becomes slightly tainted with that of asphaltum. The melted mass, when cold, is black, very brittle, and breaks with a glossy fracture.

A hundred grains, distilled till the bulb of the retort became red-hot, afforded of water slightly acid 3; thick brown oily bitumen, very similar to that obtained from Bovey coal, but possessing slightly the odour of vege-

ight spongy coal, 23; mixed

The native farriers always administer water after it, to extricate the sulphuretted hidrogen gas, on which its virtues appear to depend.—*Philosophical Magazine.*—*Nicholson's Philosophical Journal.*

BLACKNESS. Lewis, in his Philosophical Commerce of Arts, has given a history of the means of producing black colours. Since blackness, in general, is the consequence of a defect of light, any circumstance, that prevents the reflection of most of the luminous rays which fall upon bodies, will cause such bodies to exhibit what is commonly called a Black Colour. Opticians have shown, that this effect may arise either from the exquisite polish of bodies, which causes all the light to be reflected in one direction; or from the smallness of the primary particles, which transmit the light to the internal part of the body, instead of reflecting it. In this way we find, that all metallic substances, and likewise several other bodies, may be rendered black by mere mechanical trituration; and it is on account of the smallness of the particles, that black pigments are capable of completely covering and destroying the effect of other colours. The substances described by Lewis, are—1. The black chalk of the shops, which seems to consist of an argillaceous earth, impregnated with bituminous matter, reduced to the state of coal. 2. Pitcoal, which affords a brown black, and is not easily ground to a sufficient fineness. 3. The black ferruginous sands, which are of little use as pigments. 4. Plumbago, or black lead, used for pencils. 5. Black vegetable juices; of which he enumerates the anacardium, or marking nut, from the East Indies, the juice of which stains linen or cotton of a reddish brown colour, that soon changes to a black, not to be discharged by alkalis; and various species of the toxicodendron, or poison tree, from North America, which produces a deep black permanent stain. 6. The cuttle-fish ink, or black fluid contained in a peculiar vessel of that animal; but whether this ink was of considerable value for its permanency, he had no opportunity of ascertaining.

Among the blacks produced by fire, the Doctor found, that the coals of wood, and of animal substances, possess various properties, according to their nature, or original texture, when used as crayons or as pigments. The soot blacks are in general much softer, and more easily unite with oils. Several of the metals, such as manganese, cobalt, and iron, are of a black colour in certain states of calcination. On the subject of blackness, see INK, VARNISH, and DYEING.

BLACK JACK. The miners distinguish blende, or mock lead, by this name. It is an ore of zinc, containing that metal in combination with iron and sulphur, and occasionally other ingredients.

BLACK LEAD. See PLUMBAGO.

BLACK WADD. One of the most remarkable ores of manganese. It is of a dark brown colour, partly in powder, and partly indurated and brittle. If half a pound of it be dried before a fire, and afterward suffered to cool for about an hour, and then two ounces of linseed oil be gradually poured on it, mixing the whole loosely, like barm with flour, little clots will be formed: and, in something more than half an hour, the whole will grow hot, and at last burst into a flame. The temperature of the room, where this experiment was repeated, was about 30 degrees of Fahrenheit; and the heat this ore was exposed to, while drying, might be about 130 degrees.

According to Wedgewood's analysis, 100 parts of black wadd contain 43 of manganese, as much of iron, 4·5 of lead, and near 5 of micaceous earth.

BLEACHING is the art of rendering the various kinds of thread, cloths, &c., white, by depriving them of the colour they usually possess in their original state. In this article I shall first describe the usual, or old processes, and then proceed to the improvements, which modern chemistry has made in the art.

The method of bleaching silk.—The silk, being still raw, is put into a bag of thin linen, and thrown into a vessel of boiling river water, in which has been dissolved good Genoa or Toulon soap.

After the silk has boiled two or three hours in that water, the bag being frequently turned, it is taken out to be beaten, and is then washed in cold water. When it has been thus thoroughly washed and beaten, they wring it slightly, and put it for the second time into the boiling vessel, filled with cold water, mixed with soap and a little indigo; which gives it that blueish cast commonly observed in white silk.

When the silk is taken out of this second water, they wring it hard with a wooden peg, to press out all the water and soap; after which they shake it to untwist it, and separate the threads. Then they suspend it in a kind of stove, constructed for that purpose, where they burn sulphur; the vapour of which gives the last degree of whiteness to the silk.

The method of bleaching woollen stuffs.—There are three ways of doing this. The first is with water and soap; the second with the vapour of sulphur; and the third with chalk, indigo, and the vapour of sulphur.

Bleaching with soap and water.—After the stuffs are taken out of the fuller's mill, they are put into soap and water, a little warm, in which they are again worked by the strength of the arms over a wooden bench: this finishes; giving them the whitening which the fuller's mill had only begun. When they have been sufficiently worked with the hands, they are washed in clear water and put to dry.

This method of bleaching woollen stuffs is called the Natural Method.

Bleaching with sulphur.—They begin with washing and cleaning the stuffs thoroughly in river water; then they put them to dry upon poles or perches. When they are half dry, they stretch them out in a very close stove, in which they burn sulphur; the vapour of which diffusing itself, adheres by degrees to the whole stuff, and gives it a fine whitening; this is commonly called Bleaching by the Flower, or Bleaching of Paris, because they use this method in that city more than any where else.

Bleaching with chalk, indigo, and sulphur.—When the stuffs have been well washed in clear water, they throw them into a bucket of cold water, containing chalk and a little indigo, wherein the stuffs are well stirred and agitated: then they take them out, and wash them again in clear water; after which they hang them on poles: when they are half dry, they put them into a stove to receive the vapour of sulphur, which finishes their perfect whitening.

This bleaching, which is not the best, though very agreeable to the eye, is called Bleaching of Beauvais; because the inhabitants of that city were the first who practised this method of bleaching woollen stuffs.

It must be observed that, when woollen stuffs have once imbibed the vapour of sulphur, it is a difficult matter to make them take a good colour in dyeing, unless it be a black or blue.

The manner of bleaching fine linen cloths, with the method of preparing them, as practised in Picardy, and particularly near St. Quintin.—After the linens are taken from the loom, they are put to soak in clear water for a whole day: when they have been well washed and cleaned, they are taken out, and thrown into a bucking-tub filled with cold lye, made of wood ashes and water, which has been used in former processes.

When they are taken out of that lye, they are washed again in clear water, and spread in a meadow, where they are occasionally watered with clear water out of small canals, made for that purpose in the grounds. They water them with scoops, or hollow and narrow wooden peels, with a long handle.

After lying a certain time on the ground, they pass them through a fresh lye, poured on hot: this lye is of different strength, according to the quality of the linens.

Being taken out of this second lye, they are washed in clear water, and laid again in the meadow; all which several operations are repeated until the linen has acquired the desired degree of whiteness.

They are afterward put into a weak lye, to restore the softness which the preceding strong lyes had deprived them of; and

e observed that, the fairer the
the easier are the linens bleach-

ed. In fair weather they may be bleached in a month's time; but, in foul weather, six weeks, or more, are hardly sufficient to complete the operation.

It must also be observed, that all the linens, of whatever kind they are, which are bleached in Holland, Flanders, and Picardy, are dipped in cows' milk after the cream is taken off; it being certain, that it is this liquor which gives them that delicate whiteness so much admired in the linens which come from those different countries.

It is customary with the merchants who send their linens to the bleaching-grounds of Flanders and Picardy, to mark them at each end with one or more letters of their names (which marks are made with thread of Epinay, worked with the needle); and to fasten at the places where these marks are put, some small twists, made also of the same thread of Epinay; which twists have a certain number of knots, at some distance from each other; each knot having its particular value, according as every merchant thinks proper. The marks are put, in order to know to whom each piece belongs; and the twists, to remember the prices.

The method of bleaching common linens, as it is practised in Anjou.—Immediately after the pieces are taken from the loom, they are carried to the whitster, or bleacher, who puts them directly into wooden troughs, full of cold clear water; where, with wooden mallets, which are moved by a water-mill, they are so well agitated and beaten, that they are insensibly cleared from all their impurities.

Being taken out of the mill, they are spread on a meadow, where the dew which they receive during a week begins to bleach them.

Then they are put into a kind of wooden tubs, when they throw over them a common lye, quite hot.

The linens having thus gone through the lye, they take them out of the tub, to clean them again in the mill; then they spread them a second time in the meadow, where they leave them a week, after which they give them a second lye: all these several operations are repeated until the linens have acquired a perfect degree of whiteness. Then they fold them up, after a manner proper to each sort, and to the places for which they are designed.

I do not find, that any very considerable improvement in the whitening of silk and woollens has been lately made, excepting that it is asserted, that silk may be cleared of its impurities to better advantage by the mild alkali of soda than by soap-lees or soap; the former of which is apt to injure its texture, and the latter is expensive. It is even said, that mere water will accomplish the same, especially if its vapour be confined, when heated in a vessel upon the principle of Papin's Digester. In all probability, however, a process of this nature must require peculiar management; because the water thus confined would doubtless be as active in dissolving the silk itself, as caustic alkali might be. The remedy or precaution will consist in suffering the steam to escape through an aperture, covered by a valve, loaded with no greater weight than experiment shall show to be sufficient for the intended purpose.

The oxigenated muriatic acid, first discovered by Scheele, has since been applied to the art of bleaching linens and cottons. Several chemists of the first eminence have attended to the properties of this substance. Mr. Berthollet was the first who made this use of the acid; and he was followed in France by Chaptal, Descroizilles, Fourcroy, and Pajot des Charmes; in Germany by Gren, Westrumb, and others; and in this country by Kirwan, Henry, Higgins, Rupp, and other chemists or manufacturers, who have written on the subject, or carried it into practice.

Under the head Oxigenated Muriatic Acid we have already described the preparation of this article; and the chief difference respecting it to be noticed here is the apparatus, which must be on an extensive scale, and adapted to the purpose of immersing and agitating the goods to be bleached. The proportions of the ingredients are varied too, and must in some measure depend on the goodness of the articles. Mr. Rupp of Manchester recommends manganese 3 parts, more or less according to its quality, common salt 8, oil of vitriol 6, water 12. Mr. Tennant of Glasgow equal weights of manganese, salt, and sulphuric acid, with a quantity of water equal to the acid in measure. In Ireland, the common proportions are said to be manganese 6 parts, common salt 6, sulphuric acid 5, water 5. In France and Germany we understand they vary little from the following: manganese 20 parts, common salt 64, sulphuric acid 44, water 54. It must be observed, however, that, as the efficacy of the acid depends upon the oxigen imparted to it by the manganese, a deficiency of this article must render it less efficacious. The process of distillation may be performed in a large leaden alembic, *g g*, Plate I. fig. 1. supported by an iron trevet *f*, in an iron boiler *e*. This is heated by a furnace *b*, of which *a* is the ashhole, *c* the place for introducing the fuel: *d* is the handle of a stopper of burnt clay, for regulating the draught. To the top of the alembic is fitted a leaden cover *i*, which is luted on, and has three perforations; one for the curved glass or leaden funnel *h*, through which the sulphuric acid is to be poured in; one in the centre for the agitator *k*, made of iron coated with lead; and the third for the leaden tube *l*, three inches in diameter internally, through which the gas is conveyed into the tubulated leaden receiver *m*. To prevent the agitator from reaching to the bottom of the alembic, it is furnished with a conical leaden collar, adapted to a conical projection round the hole in the centre of the cover, to which it becomes so closely fitted by means of its rotatory motion, as to prevent the escape of the gas. The tube *l*, passing through the aperture *m*, to the bottom of the intermediate receiver nearly, which is two thirds full of water, deposits there the little sulphuric acid that may arise; while the oxigenated muriatic acid gas passes through the tube *n* into the wooden condenser *o o*. The agitator *p*, turned by its handle *t*, serves to accelerate the combination of the gas with the lime water, to which the horizontal pieces *q q*, projecting from the inside of the gas, likewise contribute. The cover of this receiver has a sloping groove *r*, to fit close on its edge, which is bevilled on each side; and a cock *s* serves to draw off the liquor.

Instead of this apparatus, which is peculiarly adapted for making a solution of hyperoxigenated muriat of lime, some employ a series of large barrels disposed in the manner of a Woulfe's apparatus, disengaging the oxigenated muriatic acid gas in one or more tubulated retorts, either of lead or stone, properly arranged for the purpose; or receive the gas thus disengaged into the vessels in which the goods are to be bleached. But whatever mode be adopted, every possible precaution should be employed, to prevent the escape of the gas into the air, to the injury of the workmen.

If the bleaching liquor be not made in the vessel in which it is to be used, it is proper to draw off the liquor from the cask as soon as it is prepared, because it acts upon the wood, and not only becomes by this means weaker, but likewise hastens the destruction of the cask: but when it is conveyed into a vessel in which cloths are properly placed, these speedily weaken it to such a degree, that it does not perceptibly act upon the wood.

The cloths are to be prepared by leaving them twenty-four hours in water, or still better in the old lixivium, to extract the dressing; after which they must be once or twice well washed in alkaline lixiviums, because all that part which can be extracted by the lixiviums would have neutralised a portion of the liquor, which requires to be carefully used. After this the cloth must be carefully washed, and disposed upon sticks in such a manner, that it may be impregnated with the liquor poured on it, without any part being compressed. The framing of the sticks, as well as the cask and vessel intended to contain the cloths, ought to be constructed without iron; because this metal becomes calcined by the oxigenated muriatic acid, and would produce iron-moulds, not to be taken out but by means of oxalic acid, or dilute sulphuric.

The first immersion must be longer than the following ones; it may last three hours: after which, the cloth is to be taken out,

, and then put into a shallow

ortion is not well ascertained;
thinks, from his experiments,
of the acid by weight, with

fifty parts of water, may be employed successfully, and without danger. The cloths are to be kept about half an hour in this fluid, warmed; after which, they must be strongly pressed, or wrung, and immediately plunged into common water: for, if they were suffered to dry by evaporation, the sulphuric acid, becoming concentrated, would attack them. When the cloths are well washed, they must be passed through a weak alkaline lixivium, and rinsed a second time; after which nothing more is necessary than to dry and prepare them in the usual manner.

It is an obvious precaution, that this acid water be not too strong, as it would of course injure the texture of the stuffs: and soap must not be used after it as a lixivium, for this would render them yellow.

To avoid the inconveniences arising from the escape of the gas, which we have mentioned above, potash was added to the water in the receivers. But this was found to add considerably to the expense, and diminish the strength of the liquor. Mr. Tennant of Glasgow employed a cheaper material, quicklime, added to the water in the receiver, and kept in continual agitation. As lime is very little soluble in water, what is not saturated with the acid will subside to the bottom, if the liquor be left to stand after all the gas is come over. If thirty pounds each of manganese, salt, and sulphuric acid be used, Mr. Tennant puts sixty pounds of finely powdered quicklime into his receiver, which is capable of containing a hundred and forty wine gallons of water. He likewise previously dissolves thirty pounds of common salt in the water, but this does not appear to us to be necessary. Indeed by increasing the specific gravity of the water the lime does not subside in it so quickly, and probably a small portion of hyperoximuriat of potash is formed.

In bleaching with the oxigenated muriatic acid, it is of consequence to ascertain its relative strength, in order that the experiments may at all times be equally successful. Mr. de Croisille made use of a solution of indigo in the sulphuric acid; for which purpose he took one part of finely pulverized indigo, with eight parts of concentrated sulphuric acid This mixture is kept in a matrass for several hours on the water bath; and, when the solution is complete, it is diluted with a thousand parts of water. In order to ascertain the force of the oxigenated muriatic acid, one measure of this solution is put into a graduated tube of glass, and the liquor or impregnated water is added, until the colour of the indigo is completely destroyed. In this way it is ascertained, by means of the graduations, how many measures of any liquor, the goodness of which has been found by direct experiments upon linen or cotton, are necessary to destroy the colour of one measure of the solution of indigo; and this number will serve to ascertain the respective force of all the liquors, which are required to be compared together. Mr. Watt makes use of a decoction of cochineal for the same purpose.

All the colours of calicoes or printed goods may be discharged by the oxigenated muriatic acid, or hyperoxigenised muriat of potash. The blues, yellows, and blacks indeed require a previous bath of water acidulated with sulphuric acid; and according to their shade two or three immersions in the oxigenated muriatic acid, alternately with this bath, may be necessary. The Adrianople reds will always retain a ruddy tinge, on account of the oily matter that enters into their preparation, let them be immersed ever so often. All other colours require only a single immersion, without any previous lixiviation.

Silk too, and woollen dyed of certain colours, may thus be rendered white; but they must be exposed to the action of sulphurous acid gas, to remove the yellow colour left by the oxigenated muriatic acid.

The rags or other materials for making paper may be bleached in a similar manner: but it is best to reduce them first to the state of pulp, as then the acid acts more uniformly upon the whole substance.

For bleaching old printed paper, to be worked up again, Pajot des Charmes gives the following directions: Boil your printed paper for an instant in a solution of caustic soda. That from kelp may be used. Steep it in soap-suds, and then wash it; after which it may be reduced to pulp. The soap may be omitted without much inconvenience. For old written papers to be worked up again: steep it in water acidulated with sulphuric acid, and then wash it well before it is taken to the mill. If the water be heated it will be more effectual. To bleach printed paper, without destroying its texture. Steep the leaves in a caustic solution of soda, either hot or cold, and then in a solution of soap. Arrange them alternately between cloths, as papermakers do thin sheets of paper when delivered from the form, and subject them to the press. If one operation do not render them sufficiently white, it may be repeated as often as necessary. To bleach old written paper, without destroying its texture: steep the paper in water acidulated with sulphuric acid, either hot or cold; and then in a solution of oxigenated muriatic acid; after which immerge it in water, that none of the acid may remain behind. This paper, when pressed and dried, will be fit for use as before.

Blende. An ore of zinc, likewise known by the name of Mock Lead, False Galena, or Black Jack. There are several varieties of this ore. In general, they contain about half their weight of zinc, about one fourth sulphur, and the rest iron, copper, lead, and some earth in varied proportions. An ore of this kind lately found in one of the Gwennap mines in Cornwall, yielded on analysis ·66 oxide of zinc, ·23 sulphur, and a very minute portion of iron. 50 grains of this in powder being exposed to a moderate forge heat in a small platina crucible, enclosed in another of earthen ware, the platina when in contact with the mineral was completely fused, and the remaining part was covered with an iridescent pellicle, and made soft and brittle throughout its substance.

Blood. The fluid which first presents itself to observation, when the parts of living animals are divided or destroyed, is the blood, which circulates with considerable velocity through vessels, called veins and arteries, distributed into every part of the system. It can scarcely admit of doubt, that the component parts, or immediate principles, of the blood must differ in the various and exceedingly dissimilar genera and species of animals, which occupy the land and waters of the globe; and that there are likewise differences in the state or composition of this fluid in the same animal, according to its state of health. These differences can be ascertained only by the united efforts of the anatomist and the chemist. But as the difficulty and extent of the subject have hitherto prevented any considerable progress, it becomes an object of necessity, to confine our attention to the blood of man, or of such quadrupeds as afford this fluid in a state not obviously different from that of the human species.

Recent blood is uniformly fluid, and of a saline or slightly ferruginous taste. Under the microscope it appears to be composed of a prodigious number of red globules, swimming in a transparent fluid. After standing for a short time, its parts separate into a thick red matter, or crassamentum, and a fluid called serum. If it be agitated till cold, it continues fluid; but a consistent polypous matter adheres to the stirrer, which by repeated ablutions with water becomes white, and has a fibrous appearance: the crassamentum becomes white and fibrous by the same treatment. If blood be received from the vein into warm water, a similar filamentous matter subsides, while the other parts are dissolved. Alkalis prevent the blood from coagulating; acids, on the contrary, accelerate that effect. In the latter case, the fluid is found to contain neutral salts, consisting of the acid itself, united with soda, which consequently must exist in the blood, probably in a disengaged state. Alcohol coagulates blood. On the water bath, blood affords an aqueous fluid, neither acid nor alkaline, but of a faint smell, and easily becoming putrid. A stronger heat gradually dries it, and at the same time reduces it to a mass of about one eighth of its original weight. In this state it slightly attracts the humidity of the air, and effervesces with acids; but by a longer exposure

hs it becomes covered with an
of carbonated soda. By de-
lation, this animal fluid affords
or, holding in solution ammo-
and pungent vapour of car-
onia; a yellowish thick smoke,
d manifestly oily and inflam-
vard prussic acid, recognisable
; then phosphoric acid, an-
ome flames emitted from the

many of its properties; though
it in not being soluble in wa-
ng hard by a very gentle heat,
mbining with alkalis. Acids
and in particular the nitric
it, and extricates nitrogen gas,

and nitrous oxide; while the residue, by evaporation, affords oxalic acid in crystals, a peculiar oil in flocks, and the phosphat of lime. Its volatile products, by destructive distillation, are nearly the same as those of serum: but its residue contains no salt, except the combination of lime and phosphoric acid; the other salts it might have contained having probably been carried off during the washing. Muriatic acid forms a green jelly with the fibrous part of the blood. It is among those animal substances, that furnish the greatest proportion of oil, and of ammonia.

Blood contains much iron. The experiments of Menghini, Bucquet, and Lorry prove, that this metal is capable of passing into the blood by the first passages, since patients who are under a course of martial medicines void it by the way of urine. When the coagulated part of the blood has been washed, if that part which has retained the colouring matter be burned, and the coal be lixiviated, the residue of this lixivium is in the state of saffron of Mars, of a fine colour, and usually obedient to the magnet.

The colour of blood has been attributed to this iron; and it is very true, that the colour appears to be entirely formed of it; for there exists no vestige of this metal in the washed and discoloured coagulum: but as, on the other hand, the blood does not become coloured without the concourse of air, and as oxigen alone is absorbed in respiration, it appears that the colour is owing to iron oxided by the air, and reduced to the state of red oxide.

Dr. Carbonel of Barcelona has employed serum of blood on an extensive scale in painting. Mixed with powdered quicklime, or slaked lime, to a proper consistence, it is easily applied on wood, to which it thus gives a coating of a stone colour, that dries quickly, without any bad smell, and resists the action of sun and rain. The wood should be first covered with a coating of plaster, the composition must be mixed as it is used, and the serum must not be stale. It may be used too as a cement for water-pipes, and for stones in building under water.

Blowpipe. This useful instrument will be described under the article Laboratory, which see. The present article will therefore consist of an account of the materials, or subjects, upon which experiments are made with it. The bodies intended to be heated by the blowpipe must not in general exceed the size of a pepper-corn, unless bellows and a very large flame be used. The proper supports are either a piece of smooth close-grained charcoal, for such bodies as are not subject to an alteration of their properties, from the inflammability of the coal, as might be contrary to the nature of the investigation. This support is therefore most frequently used; as it is properly adapted for saline, earthy, and many metallic bodies. The other support consists of a spoon, somewhat less than a quarter of an inch in diameter, made of a metal not subject to calcination; that is to say pure gold, silver, or platina, or such a mixture of these metals as might be found to be least deficient in the requisite degree of hardness, which gold or silver alone does not possess. Bergman advised to add one tenth of platina to a given mass of silver. I find, however, that this mixture, with picked grains of crude platina, forms a compound harder indeed than pure silver, but subject to blister at a low red heat, and perhaps more fusible than silver itself. There is, however, no very considerable inconvenience resulting from the use of a small spoon, either of gold, or of silver; and platina, purified to such a degree as to be perfectly malleable, and to exceed 21 in specific gravity, possesses every quality which can be wished for. The small metallic spoon must of course be properly fixed in a socket of metal, provided with a wooden handle.

Very small or pulverulent substances are apt to be carried away by the current of flame. These may be secured by making a small hole in the charcoal, into which the powder is to be put, and covered with another small piece of charcoal, which partly protects them from the flame. Some experiments of reduction are made by binding two small pieces of charcoal together, cutting a channel along the piece intended to be the undermost, and making a cavity in the middle of this channel to contain the subject matter of examination. With this apparatus the flame is urged through the channel between the two pieces of coal, and violently heats the substance in the cavity, which may be considered as a closed vessel.

A great number of mineral bodies are not fusible by mere flame, urged by common air through the blowpipe; though oxigen gas subdues most bodies. See GAS (OXIGEN).

Whenever therefore the fusion of any refractory substance is to be attempted, some other substance must be added which is more fusible, and capable of dissolving the former. These solvents in the dry way are distinguished by the name of fluxes, and, like the solvents used in the humid way, are mostly saline. It may easily be imagined, that the nature of the products will greatly vary, according to that of the flux which enters into combination with them; and accordingly they are varied in experiments as well as in operations in the large way. The blowpipe experiments, though conducted upon the same principles as those upon a larger scale, differ nevertheless from them in two particulars; namely, that the whole of the phænomena are visible throughout, and that the residues are of no value, otherwise than as they serve to indicate facts. For these reasons, every flux without exception might be used with the blowpipe, provided it were not of such a nature as to sink into the charcoal. We may therefore select a certain small number of the most convenient fluxes, and note the effects which they respectively produce upon the various mineral bodies; and these will serve as indications to enable the chemical inquirer to distinguish them again with a much greater degree of accuracy than by their external figures, not to mention, that he may also derive the greatest advantage with regard to the more extensive operations he might be disposed to undertake. A considerable part of this preliminary labour has already been performed by Engestrom, Bergman, Mongez, and others; and it is now become usual for chemists, among their other experiments on minerals, to mention their habitudes with the blowpipe. In the following general sketch, I shall chiefly recur to Bergman's Treatise on the Blowpipe, of which we have an English translation, in the second volume of his Essays. A good treatise on this subject by Engestrom may likewise be consulted at the end of the English edition of Cronstedt's Mineralogy; and the habitudes of a very great number of bodies with the blowpipe may be seen in the French edition of Bergman's Sciagraphia Regni Mineralis, by the abbé Mongez, under the title of Manuel du Minéralogiste.

The fluxes which have obtained the general sanction of chemists, on account of the extensive use they have been applied to by Bergman, are:

1. *The phosphoric acid*, or rather the microcosmic salt, as it is generally called, which contains that acid, partly saturated with mineral, partly with volatile alkali, and loaded besides with much water and a gelatinous fat. This salt, when exposed to the flame, boils and foams violently with a continual crackling noise, until the water and volatile alkali have flown off: afterward it is less agitated, sending forth somewhat like black scoriæ, arising from the burned gelatinous part: these are soon dispelled, and exhibit a pellucid spherule, encompassed by a beautiful green cloud, which is occasioned by the deflagration of the phosphorus arising from the extrication of the acid by means of the inflammable matter.

The clear globule, which remains upon the removal of the flame, continues longer soft than that formed by borax, and therefore is more fit for the addition of the matter to be dissolved. The volatile alkali is expelled by the fire, and leaves an excess of acid, which easily attracts moisture in a cool place.

2. *The mineral alkali*, or soda, which, when fused upon charcoal, melts superficially with a crackling noise, penetrates the charcoal, and disappears. This, in the spoon, yields a permanent spherule, so long as it is

by the blue apex of the flame;
he heat is diminished, it assumes
acity, and cannot be employed
oal. This alkali attacks several
particularly siliceous matters.

llized borax, exposed to the flame

ng salts. These salts, which always abound with nitric acid, liquefy in the spoon, and persist even on the charcoal, unless it take fire; for, when ignited, they immediately take fire on the contact of inflammable matter, sending forth a violent flame with a detonating noise. During this operation, the acid is dissipated, and the basis, if fixed, remains alone. If the base be volatile, scarce any detonation is excited; for the salt flies totally off.

Nitrat of potash shows a blue flame; but the nitrats of soda and ammonia a yellow one.

Carbonaceous salts. These, by the combustion of their acid, yield spongy coals, which when ignited soon grow white, leaving behind the alkaline base: such are, acid of tartar, crude tartar, sal acetosellæ, and tartarised vegetable and mineral alkali.

Sulphureous salts. These, exposed to the flame on the charcoal, flow, and yield a yellow or red mass, which diffuses an hepatic smell, especially when moistened by any acid. To this class belong all those fixed in the fire, containing sulphuric acid, which, when disoxigenated by the charcoal, generate sulphur: these are, sulphats of potash and soda.

Middle earthy salts. Of the middle earthy salts, few flow so perfectly as to be reduced to a globule; nor do they all fuse actually, though the water of crystallization in its departure excites a foam: those which contain sulphuric acid effervesce violently with borax and microcosmic salt, but are difficultly dissolved by soda.

Decrepitating earthy salts. Gypsum spathosum.

Intumescent earthy salts. Sulphat of magnesia swells, foams, and, when repeatedly exposed to the flame, may be fused.

Alum is somewhat different; for finally all ebullition ceases, and the mass remains immovably at rest, and it undergoes no other change than to split: when hot, it is variegated with blue spots.

Acetat of lime swells much like alum, but scarcely adheres to the charcoal.

Nitrat of magnesia swells with a crackling noise, but without any detonation.

Muriat of magnesia, in a dry state, belongs to this class.

Fusible salts. Although gypsum eluded the force of fire in Pott's furnace, yet it may be fused in a moment if a section of the lamella be exposed in the blue flame: though naturally pellucid, it instantly acquires an opacity; the water goes off without ebullition.

Carbonaceous earthy salts. Tartrits of lime and magnesia: nay, all the earths united with tartarous acid.

Soluble in borax and microcosmic salt, with effervescence. Lime, magnesia, sulphat of alumine, and acetat of lime.

Middle metallic salts. Some of the middle metallic salts, either containing a large quantity of water, or retaining pertinaciously the acid, flow in the fire; others only foam: most of them recover, at least partly, their metallic appearance, especially when they touch the coal, leaving at the same time an irregular scoria. By the addition of borax, the scoriæ are dissolved, and the metal better collected; but here we consider the salts alone: the fluxes are tinged in the same way as by the metallic oxides.

Decrepitating metallic salts. Nitrated lead, tartarized antimony.

Volatile metallic salts. To this belong the salts the base of which is mercury, as they are dissipated by fire: those which contain muriatic acid, in general, fly off more quickly than those which are loaded by any other menstruum.

Detonating metallic salts. Silver, mercury, lead, and bismuth, united with nitric acid.

Intumescent metallic salts. At the first approach of fire they swell with noise, and a certain ebullition, but then remain immovable. Sulphats of copper, iron, cobalt, and zinc; and nitrats of copper and zinc.

Fusible metallic salts. These are by the exterior flame easily reducible to globules. By this method, muriats of silver and lead, in the spoon, put on the corneous appearance; but by a long violent fusion they again put it off, the acid being too much diminished: hence it appears with what caution these metals are to be made horny in the crucible. Sulphats of silver and lead, muriats of copper and zinc.

Carbonaceous metallic salt. Tartarized antimony.

Metallic salts tinging the flame. Sulphat of copper, and also nitrat of copper, produce a greenness; but muriat of copper acts with far more efficacy. The green crystals of this first grow red by the exterior flame; they soon liquefy and grow black; they make the flame first of a deep blue, which afterward verges to a green. The flame, thus tinged, expands much, and remains so until the whole mass of the salt is dissipated: this green salt, added to microcosmic salt in fusion, immediately shows a beautiful flame; the clear globule is tinged green, and does not grow opake or brown, unless a large quantity of the microcosmic salt be added; a circumstance which takes place much sooner upon the addition of a smaller quantity of borax.

HABITUDES OF THE PRIMITIVE EARTHS.

Lime.

This (which by itself is infusible), by a sufficient degree of heat, loses its property of effervescing in acids; it acquires solubility in water, the power of generating heat with it, and of suffering spontaneous calcination. These last properties, however, it loses, if too much urged by heat. The heat it generates with water may easily be tried by a drop of water on the back of the hand, with the addition of a small piece of lime, just cooled after burning.

Carbonat of lime effervesces a little with soda, and is divided into small particles, but sparingly dissolved: when overburned, it seems not to be divided or diminished.

In borax the former dissolves with effervescence; the latter scarcely generates any bubbles.

In microcosmic salt the same phenomena appear; but the effervescence is somewhat greater.

It is also observable, that a very small piece of calcareous earth is easily dissolved in borax and microcosmic salt, yielding spherules altogether pellucid: but if more earth be gradually added, the flux, at length saturated, retains the dissolved matter, indeed, while in perfect fusion; but on removing the flame, the part, which was taken up by means of the heat alone, separates; hence clouds arise at first, and the whole globule becomes opake, and recovers its transparency again by fusion. This is entirely correspondent to what happens in the humid way; for warm water saturated with nitrat of potash, or sulphat of soda, upon cooling, is obliged to deposit that part which it had taken up in virtue of its warmth. If the fused pellucid globule (which would grow opake upon cooling) be quickly plunged into melting tallow, water, or any other substance hot (for cold generally cracks it), so as to grow suddenly hard, it retains its transparency; the particles being as it were fixed into that state which is necessary to transparency. This is a phenomenon highly worthy of observation, which cannot be seen in the crucible.

Barytes.

Barytes, exposed alone to the flame, becomes like calcareous earth, caustic, soluble in water, and noneffervescent in acids.

In carbonat of soda it effervesces only a little, but is sensibly diminished.

In borax it dissolves with slight effervescence, as also in microcosmic salt; but here it effervesces magnesia somewhat more violently.

The phenomena observed on saturation with calcareous earth have place here also. Carbonat of magnesia ignited alone loses its carbonic acid, together with the property of effervescing in acids; in carbonat of soda it effervesces a little, but is scarcely diminished.

Alumine.

Common argillaceous earth abounds with heterogeneous particles, and always contains a considerable quantity of siliceous earth, which generally amounts to half; hence, when clay is required pure, as in this instance, the earth of alum, digested in an alkaline lixivium and well washed, must be employed.

Exposed to the flame, it grows hard, contracts its bulk, but does not fuse.

In carbonat of soda it effervesces a little, but is sparingly dissolved.

In general it is to be observed, 1. That when the effervescence is to be examined, only a very small piece of the matter is to

---

ellowish crystalline matter which fills up the interstices of the native Siberian
ts the same properties with respect to fire as the crysolite.

be added to the flux, as the most subtile powder contains air, which, being expelled by the heat, forms the appearance of effervescence. 2. That the solution is often accelerated by lime, sulphat of barytes, gypsum, and other additaments, both in borax and microcosmic salt. 3. That gypsum alone is sometimes an excellent and very useful flux. This salt, with an equal portion of spath fluor, is easily reduced to a pellucid globule, which yet upon cooling grows white and opaque. The sulphat of barytes also unites with spath fluor, but the mass does not become pellucid.

Blue (Prussian). A combination of iron with an acid, distinguished by the name of the *prussic*. See Acid (Prussic), and Iron (Prussiat of).

A casual circumstance occasioned the discovery of this pigment. Diesbach, a chemist of Berlin, being desirous of precipitating a decoction of cochineal with fixed alkali, borrowed a quantity of alkali of Dippel, from which he had several times distilled his animal oil; and as the decoction of cochineal contained sulphat of iron, a beautiful blue precipitate fell down. An account of Prussian blue was given in the Memoirs of the Academy of Berlin, in the year 1710, but with no intimation of the process. It was afterward rendered public by Woodward, in the Philosophical Transactions, who declared that he had received it from one of his friends in Germany.

To make Prussian blue, four ounces of alkali are mixed with an equal weight of dried bullock's blood, and the mixture is exposed to ignition in a covered crucible. By this treatment a coal is obtained, which is afterward lixiviated in water, filtered, and concentrated by evaporation. The liquor, formerly known by the name of the phlogisticated alkali, is now more properly termed prussiat of potash. On the other hand, two ounces of sulphat of iron and four ounces of alum are dissolved in a pint of water. The two solutions are then mixed, and a blueish deposition falls down, which is rendered still more intensely blue by washing it with muriatic acid.

This is the process used in chemical laboratories; but another method is followed in the manufactories. The raspings of horns, clippings of skins, or other animal substances, are converted into charcoal, by heating them in covered vessels. Thirty pounds of potash are then mixed with ten pounds of this coal, and the mixture calcined in an iron vessel. After twelve hours ignition, the mixture acquires the form of a soft paste, which is poured out into vessels of water. The water is then filtered, and the solution mixed with another, consisting of three parts of alum, and one of sulphat of iron.

Blue (Saxon). The best Saxon blue colour may be given by the following composition:

Mix one ounce of the best powdered indigo with four ounces of sulphuric acid, in a glass body or matrass, and digest it for one hour with the heat of boiling water, shaking the mixture at different times: then add twelve ounces of water to it, and stir the whole well, and, when grown cold, filter it. This produces a very rich deep colour. If a paler blue be required, it may be obtained by the addition of more water. The heat of boiling water is sufficient for this operation, and can never spoil the colour: whereas a sand heat, which is commonly used, is often found to damage the colour. Indigo which has been digested with a large quantity of alcohol, and then dried, will produce a finer colour than the former, if treated in the same manner with sulphuric acid.

This colour, which was discovered by counsellor Barth, of Saxony, about 1740, is said to be very liable to fade. Bergman, however, affirms, that if 8 parts of sulphuric acid of the specific gravity of 1·9 be added to 1 of indigo, and digested with it at a heat of 100° or 120° F. for twenty hours, so as to form an opake black solution, this diluted with water will give various shades, the deepest of which will be as permanent as Coventry blue. Mr. Poerner makes the solution in the proportions directed above, but adds one ounce of good dry potash at the end of twenty-four hours, and lets this stand as much longer, before he dilutes it with water. The cloth should be prepared with alum and tartar.

Bog Ores. These are ores of iron, consisting of a calx of the metal in a state of greater or less purity, mixed with earth chiefly of the argillaceous kind. They appear to have been deposited by water, and are usually disposed in strata, separated into small prismatic parts by the contraction of the clay.

The chief of these are, the ætites, or eagle-stone, with other round pieces or pebbles; and the hæmatites, or blood-stone. See Ores.

Bole. Various indurated clays have been distinguished by this name, which was formerly much used: but, as it has been very little noticed, as a term, by the later improvers of mineralogical and chemical science, its present signification is very indeterminate. That commonly known by the name of *bole armenic*, or armenian bole, which is tinged red by an oxide of iron, was once much used. The French bole, which resembles it, but is paler coloured, is still retained in the materia medica of the London college.

Bolognian Stone. Lemery reports, that an Italian shoemaker, named Vincenzo Casciarolo, first discovered the phosphoric property of the Bolognian stone. It is the ponderous spar, or native sulphat of barytes. This man found it at the foot of mount Paterno; and, from its brilliancy and weight, was led to suppose that it contained silver. Having exposed it to the fire, doubtless with the intention of discovering that precious metal, he observed that it was luminous in the dark; a discovery which engaged his attention, and was frequently repeated with success. Many philosophers and chemists have since examined this phænomenon, and have varied the method of calcining the Bolognian stone in several respects. It seems as if the greatest degree of phosphorescence depended on a due application of the heat; but many trivial circumstances were noticed by the earlier chemists, which in all probability had little to do in producing this effect. An extreme degree of heat fuses this stone. If it be first heated to ignition, then finely powdered and made into a paste with mucilage; and this paste, divided into pieces a quarter of an inch thick, and dried in a moderate heat, be exposed to the heat of a wind furnace by placing them loose in the midst of the charcoal; a phosphorus will be obtained, which, after a few minutes exposure to the sun's rays, will give light enough in the dark to render the figures on the dial-plate of a watch visible. The fuel should be replenished when half consumed, the whole suffered to burn out, and the pieces of phosphorus, which may be separated by blowing away the ashes with a pair of bellows, should be kept in a phial closely stopped.

Bone. The bones of men and quadrupeds owe their great firmness and solidity to a considerable portion of the phosphat of lime which they contain. When these are rasped small, and boiled in water, they afford gelatinous matter, and a portion of fat or oil, which occupied their interstices. By destructive distillation they afford alkaline phlegm, a fetid oil, and much volatile alkali, leaving a coal not easily burned. In an open fire, bones are inflamed by virtue of their oil, and emit an offensive empyreumatic smell. The white, friable, and incombustible residue consists chiefly of lime and phosphoric acid in combination. It affords a small quantity of carbonat of soda by washing with water. This white matter is decomposable by fusion with mild fixed alkalis, which unite with the phosphoric acid at the same time that their carbonic acid converts the lime into chalk. Acids likewise disengage the phosphoric acid by uniting with the lime. The nitric or the sulphuric acid is most commonly used in this process. See Acid (Phosphoric). According to Mr. Accum, the bones of fishes contain upwards of one sixth more of phosphoric acid than those of quadrupeds.

It may be supposed, particularly when shells are included under the name, that bones differ considerably in the proportions of their ingredients, if not in the ingredients themselves. Merat-Guillot made a number of comparative analyses for the purpose of ascertaining this difference, the results of which he has tabulated; and we shall annex his table, as it gives a clear view of the subject.

The loss he ascribes chiefly to water; but in part to gelatine, and a small quantity of a saline substance, which he did not examine. He adds too, that what he has given as gelatine in the articulated coralline was not wholly that substance, and he suspects therefore was in part analogous to the matter that forms the polypi inhabiting the lithophytes.

Fourcroy and Vauquelin have farther discovered, that the bones of animals contain phosphat of magnesia. They found it in all the bones they examined, except human bones. Those of the ox, according to their analysis, contain dry gelatine ·51, phosphat of lime ·377, carbonat of lime ·1, phosphat of magnesia, ·13. The bones of the horse and sheep afford about 1-36th of phosphat of magnesia; those of fowls and fish nearly the same quantity as those of the ox. They account for this by observing, that phosphat of magnesia is found in the urine of man, but not in that of animals, though both equally take in a portion of magnesia with their food.

The experiments of Mr. Hatchett show, that the membranous or cartilaginous substance, which retains the earthy salts within its interstices, and appears to determine the shape of the bone, is albumen. This Merat-Guillot, in the table above given, has confounded with the gelatine of the bone under the head Gelatinous Matter. Mr. Hatchett too confirms the remark of John Hunter, that the enamel of tooth is altogether an earthy substance, not included in a membranous structure; and observes, that in this respect it is analogous to the porcellaneous shells, while mother of pearl approaches in its nature to the true bone.

A curious phænomenon with respect to bones is the circumstance of their acquiring a red tinge, when madder is given to animals with their food. The bones of young pigeons will thus be tinged of a rose colour in twenty-four hours, and of a deep scarlet in three days; but the bones of adult animals will be a fortnight in acquiring a rose colour. The bones most remote from the heart are the longest in acquiring this tinge. Mr. Gibson informs us, that extract of logwood too, in considerable quantity, will tinge the bones of young pigeons purple. On desisting from the use of this food, however, the colouring matter is again taken up into the circulation, and carried off, the bones regaining their natural hue in a short time. It was said by Du Hamel, that the bones would become coloured and colourless in concentric layers, if an animal were fed alternately one week with madder, and one week without; and hence he inferred, that the bones were formed in the same manner as the woody parts of trees. But he was mistaken in the fact; and indeed had it been true, with the inference he naturally draws from it, the bones of animals must have been out of all proportion larger than they are at present.

Bones are of extensive use in the arts. In their natural state, or dyed of various colours, they are made into handles of knives and forks, and numerous articles of turnery. We have already noticed the manufacture of volatile alkali from bones, the coal of which forms bone black; or, if they be afterward calcined to whiteness in the open air, they constitute the bone ashes, of which cupels are made, and which, finely levigated, are used for cleaning articles of paste and some other trinkets, by the name of burnt hartshorn. The shavings of hartshorn, which is a species of bone, afford an elegant jelly; and the shavings of other bones, of which those of the calf are the best, are often employed in their stead.

On this principle, Mr. Proust has recommended an œconomical use of bones, particularly with a view to improve the subsistence of the soldier. He first chops them into small pieces, throws them into a kettle of boiling water, and lets them boil about a quarter of an hour. When this has stood till it is cold, a quantity of fat, excellent for culinary purposes when fresh, and at any time fit for making candles, may be taken off the liquor. This in some instances amounted to an eighth, and in others even to a fourth, of the weight of the bones. After this the bones may be ground, and boiled in eight or ten times their weight of water, of which that already used may form a part, till about half is wasted, when a very nutritious jelly will be obtained. The boiler should not be of copper, as this metal is easily dissolved by the jelly; and the cover should fit very tight, so that the heat may be greater than that of boiling water, but not equal to that of Papin's digester, which would give it an empyreuma. The bones of meat that has been boiled are nearly as productive as fresh bones; but Dr. Young found those of meat that had been roasted afforded no jelly, at least by simmering, or gentle boiling.—*Annales de Chimie—Philos. Trans.—Manchester Memoirs—Gehlen's Journal—Journals of the Royal Institution.*

Boracite. The cubic quartz of many mineralogists. Magnesio-calcareous borat, or, according to Vauquelin, native borat of magnesia. See Acid (Boracic).

Borax. The origin of borax was for a long time unknown in Europe; and many chemists still continue to copy from each other, that its origin has not yet been ascertained. Mr. Grill Abrahamson, however, sent some to Sweden in the year 1772, in a crystalline form, as dug out of the earth in Thibet, where it is called Pounnxa, Mypoun, and Houipoun: it is said to have been also found in Saxony in some coal pits. But the most particular accounts we possess concerning the origin of borax, are found in the Philosophical Transactions for 1787. Mr. Blane, who had an opportunity of inquiring of some of the inhabitants of the place where the borax is made, gives the following account:

duces considerable quantities of
per, and sulphur. After being
it sells in the market for about
oees per maund; and he was assured by many of the natives, that all the borax in India comes only from the place above mentioned.

The other account of borax, in the same volume of the Transactions, is contained in a letter from father Joseph de Rovato, father prefect of the mission in Thibet, who received the information from a native of the country where the borax is prepared, sent expressly for that purpose to him by the brother of the king of Nepal, a kingdom on the borders of Thibet.

This man, partly in the Nepalese, and partly in the Hindoo language, both which are understood by the prefect, gave the following account:—In the province or territory of Marmé, twenty-eight days journey to the north of Nepal, and twenty-five to the west of Lassa, the capital of Thibet, there is a vale about eight miles broad. In a part of this vale there are two villages or castles, the one named Scierugh, and the other Kanglé, the inhabitants of which are wholly employed in digging the borax, which they sell in Thibet and Nepal, they having no other means of subsistence, the soil being so barren as to produce nothing but a few rushes. Near the two above-mentioned castles there is a pool of moderate size, and some smaller ones, where the ground is hollow, in which the rain water collects. In these pools, after the water has been some time detained in them, the borax is formed naturally: the men wading into the water, feel a kind of pavement under their feet, which is a sure indication that borax is there formed, and there they accordingly dig it.

Where there is little water, the layer of borax is thin; and where it is deep, it is thicker; and over the latter there is always an inch or two of soft mud, which is probably a deposit of the water after it has been agitated by rain or wind. Thus is the borax produced merely by nature, without either boiling or distillation. The water in which it is formed is so bad, that the drinking a small quantity of it will occasion a swelling of the abdomen, and in a short time death itself. The earth that yields the borax is of a whitish colour; and in the same valley, about four miles from the pools, there are mines of salt, which is there dug in great abundance for the use of all the inhabitants of these mountains, who live at a distance from the sea. The natives, who have no other subsistence on account of the sterility of the soil, pay nothing for digging borax; but strangers must pay a certain retribution, and usually agree at so much a workman. This is paid to a Lama, named Pema Tupkan, who owns the pits in Marmé.

Ten days journey farther north there is another valley, named Tapré, where they dig borax, and another still farther, called Cioga; but of this latter the prefect did not mark the situation. Borax is, in the

Hindoo and Nepalese languages, called Soga. If it be not purified, it will easily deliquesce; and in order to preserve it any time till they have an opportunity of selling it, the people often mix it with earth and butter.

It does not appear that borax was known to the ancients, their chrysocolla being a very different substance, composed of the rust of copper, triturated with urine. The word borax is found for the first time in the works of Geber.

Borax is not only found in the East, but likewise in South America. Mr. Anthony Carera, a physician established at Potosi, informs us, that this salt is abundantly obtained at the mines of Riquintipa, and those in the neighbourhood of Escapa, where it is used by the natives in the fusion of copper ores.

The purification of borax by the Venetians and the Hollanders was for a long time among those secrets, which the want of a sufficient spirit of research prevented from becoming general; chemical writers have been satisfied in asserting, that the processes consisted of solution, filtration, crystallization, and calcination. Chaptal, however, informs us, from his own extensive experience, that the destruction of the oily part of borax by calcination is attended with considerable loss. He finds, after trying all the processes in the large way, that the simplest method consists in boiling the borax strongly, and for a long time, with water. This solution being filtered affords by evaporation crystals, which are somewhat foul, but may be purified by repeating the operation.

Purified borax is white, transparent, rather greasy in its fracture, affecting the form of six-sided prisms, terminating in three-sided or six-sided pyramids. Its taste is styptic; it converts sirup of violets to a green; and, when exposed to heat, it swells up, boils, loses its water of crystallization, and becomes converted into a porous, white, opaque mass, commonly called Calcined Borax. A stronger heat brings it into a state of quiet fusion: but the glassy substance thus afforded, which is transparent, and of a greenish yellow colour, is soluble in water, and effloresces in the air. It requires about eighteen times its weight of water to dissolve it at the temperature of sixty degrees of Fahrenheit; but water at the boiling heat dissolves three times this quantity. Its component parts, according to Kirwan, are, boracic acid ·34, soda ·17, water ·47. For an account of the neutral borat of soda, and other compounds of this acid, see Acid (Boracic).

Borax is used as an excellent flux in docimastic operations. It enters into the composition of reducing fluxes, and is of the greatest use in analyses by the blowpipe. It may be applied with advantage in glass manufactories; for when the fusion turns out bad, a small quantity of borax reestablishes it. It is more especially used in soldering: it assists the fusion of the solder, causes it to flow, and keeps the surface of the metals in a soft or clean state, which facilitates the operation. It is scarcely of any use in medicine. Its acid, called *Sedative Salt*, is used by some physicians; and its name sufficiently indicates its supposed effects. Mixed with shell lac, in the proportion of one part to five, it renders the lac soluble by digestion in water heated near boiling.

Borax has the inconvenience of swelling up, and requires the greatest attention on the part of the artist who uses it in delicate works, more especially when designs are to be formed with gold of different colours. It has been long a desideratum, to substitute some composition in the room of borax, which might possess its advantages without its defects.

Mr. Georgi has published the following process:—"Soda, mixed with muriat and sulphat of soda, is to be dissolved in lime water; and the crystals which separate by the cooling of the fluid may be set apart. The lixivium is then to be evaporated; and the salt afterward dissolved in milk. The evaporation affords scarcely one eighth of the soda employed; and the residue may be applied to the same uses as borax."

Messrs. Struve and Exchaquet have proved, that the combination of phosphoric acid and vegetable alkali, fused with a due proportion of phosphat of lime, forms an excellent glass for soldering metals.

Bovey Coal. Xylanthrax. This is of a brown or brownish black colour, and lamellar texture; the laminæ are frequently flexible when first dug, though generally they harden when exposed to the air. It consists of wood penetrated with petroleum or bitumen, and frequently contains pyrites, alum, and vitriol; its ashes afford a small quantity of fixed alkali, according to the German chemists; but according to Mr. Mills, they contain none. By distillation it yields an ill-smelling liquor, mixed with volatile alkali and oil, part of which is soluble in alcohol, and part insoluble, being of a mineral nature.

It is found in England, France, Italy, Switzerland, Germany, Iceland, &c.

Brain of Animals. The brain has long been known to anatomists; but it is only of late years that chemists have paid it any attention. It is a soft, white substance, of a pulpy, saponaceous feel, and little or no smell. Exposed to a gentle heat, it loses moisture, shrinks to about a fourth of its original bulk, and becomes a tenacious mass of a greenish brown colour. When completely dried, it becomes solid, and friable like old cheese. Exposed to a strong heat, it gives out ammonia, swells up, melts into a black pitchy mass, takes fire, burns with much flame and a thick pungent smoke, and leaves a coal difficult of incineration.

Y. This well-known fluid is the
spirit distilled from wine. The greatest quantities are made in Languedoc, where this manufacture, upon the whole so pernicious to society, first commenced. It is obtained by distillation in the usual method, by a still, which contains five or six quintals of wine, and has a capital and worm tub applied. Its peculiar flavour depends, no doubt, on the nature of the volatile principles, or essential oil, which come over along with it, and likewise, in some measure, upon the management of the fire, the wood of the cask in which it is kept, &c. It is said, that our rectifiers imitate the flavour of brandy, by adding a small proportion of nitrous ether to the spirit of malt or melasses. See ALCOHOL.

BRASS. An elegant yellow-coloured compound metal, consisting of copper combined with about one third of its weight of zinc. The best brass is made by cementation of calamine, or the ore of zinc, with granulated copper. See COPPER.

BRASSICA RUBRA. Mr. Watt finds, that the red cabbage affords a very excellent test both for acids and alkalis; in which it is superior to litmus, being naturally blue, turning green with alkalis, and red with acids; beside which it possesses the advantage of not being affected by the fuming nitrous acid, any farther than as it acts as a real acid. The management of the leaves to procure this test is as follows:

To extract the colouring matter, take those leaves of the cabbage which are freshest, and have most colour; cut out the larger stems, and mince the thin parts of the leaves very small; then digest them in water, of about the heat of one hundred and twenty degrees, for a few hours, and they will yield a blue liquor, which, if used immediately as a test, will be found to possess great sensibility. But as this liquor is very apt to turn acid and putrid, and to lose its sensibility when it is wanted to be preserved for future use, the following processes succeed the best:

1. After having minced the leaves, spread them on paper, and dry them in a gentle heat; when perfectly dry, put them up in glass bottles well corked; and when you want to use them, acidulate some water with sulphuric acid, and digest or infuse the dry leaves in it until they give out their colour; then strain the liquor through a cloth, and add to it a quantity of fine whiting or chalk, stirring it frequently until it becomes of a true blue colour, neither inclining to green nor purple; as soon as you perceive that it has acquired this colour, filter it immediately, otherwise it will become greenish by long standing on the whiting.

This liquor will deposit a small quantity of gypsum, and by the addition of a little alcohol will keep good for some days, after which it will become a little putrid and reddish. If too much spirit be added, it destroys the colour. If the liquor be wanted to be kept longer, it may be neutralized by means of a fixed alkali instead of chalk.

2. But as none of these means will preserve the liquor long, without requiring it to be neutralized afresh, just before it is used; and as the putrid and acid fermentation which it undergoes, and perhaps the alkalis or spirit of wine mixed with it, seem to lessen its sensibility; in order to preserve its virtues while it is kept in a liquid state, some fresh leaves of the cabbage, minced as has been directed, may be infused in a mixture of sulphuric acid and water, of about the degree of the acidity of vinegar: and it may be neutralized, as it is wanted, either by means of chalk, or of the fixed or volatile alkali. But it is necessary to observe, that if the liquor have an excess of alkali, it will soon lose its colour, and become yellow, from which state it cannot be restored; therefore care should be taken to bring it very exactly to a blue, and not to let it verge towards a green. The infusions of red cabbages and of various flowers in water, acidulated by means of sulphuric acid, are apt to turn mouldy in the summer season, but the moulding is prevented by the addition of spirits of wine.

By the same process Mr. Watt made a red infusion of violets, which, on being neutralized, formed a very sensible test: but how long it will preserve its properties he had not determined. Probably the coloured infusions of other flowers may be preserved in the same manner, by the antiseptic power of the sulphuric acid, so as to lose little of their original sensibility. The petals of the scarlet rose, and those of the pink coloured lychnis, treated in this manner afford very sensible tests. Paper fresh stained with these tests in their neutral state, has sufficient sensibility for many experiments: but the alum and glue which enter into the preparation of writing-paper, seem in some degree to fix the colour; and paper which is not sized becomes somewhat transparent when wetted, which renders small changes of colour imperceptible; so that, where accuracy is required, the test should be used in a liquid state.

Brazil Wood. The tree that affords this wood, the Cæsalpina crista, is of the growth of the Brazils in South America, and also of the Isle of France, Japan, and elsewhere. It is chiefly used in the process of dyeing. The wood is considerably hard, is capable of a good polish, and is so heavy that it sinks in water. Its colour is pale when newly cut, but it becomes deeper by exposure to the air. The various specimens differ in the intensity of their colour; but the heaviest is reckoned the most valuable. It has a sweetish taste when chewed, and is distinguished from red sanders, or sandal, by its property of giving out its colour with water, which this last does not.

If the Brazil wood be boiled in water for a sufficient time, it communicates a fine red colour to that fluid. The residue is very dark-coloured, and gives out a considerable portion of colouring matter to a solution of alkali. Alcohol extracts the colour from Brazil wood, as does likewise the volatile alkali; and both these are deeper than the aqueous solution. The spirituous tincture, according to Dufay, stains warm marble of a purplish red, which on increasing the heat becomes violet: and if the stained marble be covered with wax, and considerably heated, it changes through all the shades of brown, and at last becomes fixed of a chocolate colour.

The recent decoction of Brazil wood, according to Berthollet, affords, by the addition of sulphuric acid, a precipitate, small in quantity, and of a red colour inclining to yellow; the liquor remaining transparent, and of a yellow colour. The nitric acid first converts the tincture to a yellow; but if the quantity of acid be increased, the liquor assumes a deep orange yellow, and becomes transparent, after depositing a precipitate of the same colour nearly as the foregoing, but more abundant. The muriatic acid has the same effect as the sulphuric. The oxalic acid affords an orange red, or almost ruddy precipitate, nearly as abundant as that thrown down by the nitric acid, and the liquor remains transparent and yellow. Distilled vinegar affords a very sparing precipitate of the same colour; the fluid continuing transparent, but rather of a deeper orange. Tartar affords still less precipitate; and the remaining liquor is turbid and more reddish than the last. Fixed alkali converts the colour of the decoction to a crimson or deep violet inclining to brown, and affords a precipitate of the same colour, though very small in quantity. Volatile alkali affords a brighter violet or purple, and a little precipitate of a fine purple. Alum throws down a red precipitate inclining to crimson, which is abundant and subsides very slowly; while the supernatant fluid preserves its fine red colour, like that of the recent decoction: this liquor affords another abundant precipitate, if the acid of the alum be saturated with an alkali. In this manner is prepared a kind of carmine, inferior in beauty to the common carmine, and likewise a liquid lake for miniature painters. Alum and tartar together afford a brownish red precipitate in small quantity, while the fluid remains of a bright orange red. Sulphat of iron gives the tincture a black colour, inclining to violet, at the same time that an abundant precipitate of the same colour falls down. Sulphat of copper likewise affords a plentiful brown precipitate, and converts the fluid to a transparent brownish red. Sulphat of zinc throws down a sparing brown precipitate, leaving the fluid of an amber colour. Solution of acetit of lead affords a precipitate of a deep red, of considerable beauty, and the liquor becomes of an orange red. The solution of tin in aqua regia occasions an abundant precipitate of a fine rose colour, and the fluid remains clear and quite colourless. Lastly, corrosive muriat of mercury occasions a slight brown precipitate; the liquor remaining transparent, and of a fine yellow colour.

The Journal de Physique, for February 1785, contains some curious experiments respecting the action of acids upon the colour of Brazil wood. If the aqueous tincture of this wood be first rendered yellow, by means of tartar and the acetous acid, and the solution of tin in aqua regia be then poured, a very abundant rose-coloured precipitate is obtained: if to the solution rendered yellow by an acid there be added a greater quantity of the same or a stronger acid, the red colour is restored; the sulphuric acid is best adapted to this effect. Several salts likewise cause the red colour of Brazil wood to appear again, after it has been destroyed by the action of acids.

It has been observed, that the recent decoction of Brazil wood is less proper for dyeing than that which is older, or even fermented; it assumes a yellowish red colour by age. Hellot recommends the hardest waters for making this decoction; but it must be observed, that such waters deepen the colour, by virtue of the earthy salts they contain. After boiling the chips of this wood for three hours, this first decoction is put into a cask. More water is then added to the wood, which is boiled for a second three hours, and the decoction added to the foregoing. In this, as in all decoctions of colouring, the wood is kept in a bag of porous cloth.

Wool plunged in the decoction of Brazil wood acquires a weak colour, which soon goes off. It therefore requires a preparation to render the dye permanent.

The wool must be boiled in a solution of alum, to which one fourth or even a less quantity of tartar has been added. A larger proportion of tartar would render the colour deeper. The impregnated wool is kept at least eight days in a cool place; after which it is dyed in the decoction of Brazil wood by a gentle boiling. As the colouring matter first deposited affords an inferior dye, it is proper to dip a coarser stuff first. In this way a lively red dye is obtained, which resists the air very well.

If the red colour of Brazil wood be destroyed by an acid, it communicates a very durable fawn colour to woollen stuffs.

Mr. Poerner prepares the stuff by boiling it in a solution of tin, alum, and a little tartar; and he makes his bath with the Brazil wood and a considerable proportion of alum. In the residue of this bath he dips another piece which has received the same preparation. The first piece receives a fine brick colour, and the second a dye approaching to scarlet. The shades may be greatly varied by altering the proportion of the ingredients.

By these means the dyes obtained from Brazil wood may be rendered considerably solid, but by no means comparable in this respect to those afforded by cochineal or madder. The dye afforded by this last substance is sometimes rendered brighter, by passing the dyed stuff through a decoction of Brazil; but the effect soon goes off.

Mr. Guhliche describes a process, which, as he affirms, is capable of affording more beautiful and more durable colours than those before used: he directs, that vinegar, or the aceto-citric [*] acid, or aqua regia, be poured upon the Brazil wood, reduced into powder, or thin shavings or chips, until it is covered to a certain depth. This mixture must be well agitated, then left at rest for twenty-four hours, and lastly decanted, filtered, and preserved for use. A vegetable acid, or simple water, is poured on the residue, and left to repose for a day or two, after which it is filtered; and in this manner the process is continued until no more colour is given out; the wood is then black: the several liquors are to be mixed together.

The stuff is prepared by a weak galling with sumach, or the white nut-gall: after this it is slightly alumed, simply rinsed, and immersed wet with the following bath:

The acid solution of Brazil wood is taken and diluted with a certain quantity of water, depending on the quantity of goods and the intensity of the colour intended to

---

[*] This acid, so called by Mr. Berthollet, but distinguished by Mr. Guhliche by the name of the vegetable acid spirit, is much used by this last chemist in his dyeing processes, and is prepared as follows:

He takes lemons, not rejecting even those the skin of which is quite rotten; pares them, slices them into an earthen or metallic (but not a wooden) vessel; sprinkles them with good vinegar, of the strength which he judges to be equal to that of lemon-juice; expresses the juice from the lemons, exposed to the action of a press in a flannel bag; and lastly filters it through paper. In this state the liquor may be employed with success; but it has the inconvenience of becoming mouldy, and is aqueous. To remedy these defects, he recommends it to be purified and concentrated as follows: The liquor is left exposed to the sun until it has become clear, and deposited a sediment. It is then filtered and distilled on a sand bath. As soon as the drops which come over are perceived to be acid, the receiver is changed, and the distillation is continued until oily striæ are perceived in the neck of the retort. The acid which is thus obtained must be preserved for use.

be produced. It is then heated to such a degree, that the hand may be held in it; solution of tin is then poured in until it has acquired a fine colour; the bath being then agitated, the stuff is to be plunged in and kept immersed for half an hour, after which time it is to be taken out and washed. The remaining bath will serve for weaker shades, and the stuff must not be galled for these light tinges.

Brazil wood is used for dyeing silk of a crimson colour. This is called the false dye, to distinguish it from the crimson obtained by cochineal, which is much more durable.

The silk must be boiled with twenty pounds of soap for every hundred of silk, and afterward alumed. The aluming need not be so strong as for the fine crimson. It is then washed in a running stream, and immersed into a bath, more or less charged with the decoction of Brazil wood, according to the intended shade of colour. When water containing no earthy salt has been made use of, the colour is too red to imitate crimson. This quality, however, is given to the water by passing the silk through a slight alkaline solution, or by adding a little alkali to the bath. It might likewise be washed in hard water till it had obtained the required shade.

To make a deeper crimson of the false or red brown kind, the decoction of logwood is added to the bath of Brazil wood, after the silk is impregnated. A small quantity of alkali is likewise added, according to the shade intended to be produced.

To imitate the wild poppy, or fiery red, the silk must first receive a ground of rocou (better known in England by the name of ANNOTTO, which see), even deeper than when the dye with carthamus is intended; after which it is washed, alumed, and dyed with the decoction of Brazil wood, to which a little soap water is usually added.

The solution of tin cannot, as Mr. Berthollet observes, be employed with the decoction of Brazil wood, for dyeing silk in the same manner as with cochineal, because the colouring particles are too quickly separated to be able to fix themselves on the silk, which has not so strong an attraction for them as wool has. But, as Bergman remarks, in his notes upon Scheffer's Essay on the Art of Dyeing, it is possible to make great improvement in the colours afforded by the dyeing woods, by macerating the silk in a cold solution of tin. A strong decoction of Brazil wood gives to yellow silk a scarlet colour, inferior indeed to that of cochineal, but much more lively and solid than is had by mere maceration in alum, and capable of resisting the proof of vinegar, like the fine crimson and poppy colours. Instead of using the raw silk, it is requisite to give a yellow ground to boiled silk, or to mix a yellow substance with the decoction of Brazil wood. Several manufacturers have lately busied themselves with this process, and have produced a variety of effects, by applying it to different colouring matters, which afford colours of very little solidity, whether they be employed alone, or in forming different mixtures.

Mr. Guhliche, nevertheless, describes a process, in which he makes an immediate use of the solution of tin, to give a fire colour to silk. He directs, that it should be galled by a solution of nut-galls in white wine. He affirms, that this solution preserves much more of that brilliancy, so much in request in the colour of silk, than the solution made in water. He adds such a quantity of this solution to water as may give the whole a yellow colour; with this he carefully impregnates the silk, leaving it in the cold for twelve hours, after which he expresses the liquor very well, but without the action of washing. The silk being then dried is steeped in a solution of alum, in the proportion of four ounces of alum for every pound of the silk, where it remains for twelve hours. He then presses out the acid, and immerses the silk, wet as it is, into a bath prepared in the way already described, after having added an ounce of the solution of tin. The remaining force of the bath may be exhausted for lighter shades. If the fire colour be required more inclining to orange, he does not gall the silk, but alums it in a cold solution of two ounces of alum, of the strength of two ounces of the salt for every pound of the silk; after which he dyes it of an orange colour with annotto, without boiling, and plunges it still wet into the before-mentioned bath of Brazil wood. The author confesses, that these colours, more especially the last, do not possess much solidity. For rose colours he omits the galling, and uses no more than two ounces of alum. For light shades he recommends to decant the solution of alum from the deposition it may have made; and he prefers dyeing without heat, by employing a bath more highly charged with colour, out of which the silk may be taken when it has received the intended shade, and which may be afterward exhausted in producing other shades. He affirms that, by the assistance of these precautions, beautiful shades may be obtained of sufficient solidity.

Mr. Poerner has made a great number of essays on the methods which may be used to dye cotton by means of Brazil wood, with different mordants, such as alum, the solution of tin, sal ammoniac, alkali, &c., either in the bath or in the preparation of the stuff; but he could not produce colours capable of resisting the action of soap, though several among them withstood the action of the air and washing in water. He advises, that the cottons dyed with these colours should be dried in the shade.

The following process, used in some manufactories for dyeing cotton of a crimson

r, was communicated to M. Berthollet
r. Brown.

olution of tin is made in these propor-
of the ingredients: nitric acid two
ds, muriatic acid one pound, tin eight
es, water one pound; the fluids are
mixed, and the tin dissolved in the
ire by adding a little at a time.

r a piece of cotton velvet, weighing
n or sixteen pounds, the operation is
n by preparing a bath composed of four
boiling water, and two parts of a
g decoction of nut-galls. The bath is
stirred with the rake, the piece plunged
worked for half an hour, left immersed
vo hours, and afterward taken out and
ed. Another bath is also prepared
three parts of boiling water, and one
e decoction of Brazil wood likewise
g; this is raked, and the piece worked

ht shades.

The colouring parts of Brazil wood are very sensible to the action of alkalis, which give them a purple tinge; and there are many processes in which fixed or volatile alkalis are used to form violets and purples: but the colours, though obtained with ease in various shades by this method, are perishable, and possess only a transient brightness. Alkalis do not appear to injure the colours afforded by madder, but they hasten the destruction of most other colours.

It is usual in England to rasp or pulverize the dyeing woods in mills appropriated to that purpose. They are commonly kept moistened with urine; and when urine has not been used, a small quantity of alkali is added at the time of boiling. This method of proceeding, as M. Berthollet observes, is very advantageous; but the use of putrefied urine, or alkali, tends to deepen the colour, to render it less permanent, and may, on various occasions, be contrary to the nature of the processes intended to afford certain effects.

Mr. Julia has given a process for dyeing cottons of a beautiful amaranthine colour by means of Brazil. The cotton being cleansed by boiling in water till it sinks, rinsed, and wrung out, is to be saturated with the following mordant: Dissolve 10 pounds of Roman and 6 of English alum, 6 of acetat of lead, 1 of pure potash, and 24 ounces of Alicant soda, in 8 gallons of hot water; when cooled down to 104° F add 9 ounces of white arsenic in powder, and 13 of muriat of ammonia; and when these are dissolved, add a decoction of four ounces of Brazil in a gallon of water. This is to stand for four days, when the clear liquor is to be poured off, and the cotton well worked in it, slightly wrung out, and dried, turning it frequently. When dry, it is to be dipped several times into warm water, and wrung out. Twelve pounds of this cotton are next to be maddered in a bath of 50 gallons of water and 16 pounds of Dutch grape madder at a moderate heat, in which it is to be kept an hour and a half, toward the end increasing the heat so that the hand cannot be kept in the bath, but it must by no means be made to boil. The cotton, being taken out to drain, is to be rinsed two hours after in a stream of water till no more colour comes out, when it is to be wrung, passed through the mordant again, and well washed. Lastly, five pounds of rasped Brazil, enclosed in a coarse bag to which a stone is tied, are to be boiled for three hours and a half in 50 gallons of very hard water, and, after this decoction is drawn off, in a fresh quantity of water, till three fourths are wasted. The bag being taken out, and the first decoction poured into the boiler, the maddered cotton is to be put into it when hot, and the bath made to boil. Having boiled an hour, the cotton is to be taken out, and set to drain. When cold, it is to be washed and wrung till no more colour comes out, and then dried.

This colour, according to Messrs. Julia and Favier, is one of the most brilliant that can be conceived; and so fixed that nothing can injure it.

Bread. I am not acquainted with any set of experiments regularly instituted and carried into effect, for ascertaining what happens in the preparation of bread. Farinaceous vegetables are converted into meal by trituration, or grinding in a mill; and when the husk or bran has been separated by sifting or bolting, the powder is called flour. This is composed of a small quantity of mucilaginous saccharine matter, soluble in cold water, much starch, which is scarcely soluble in cold water, but combines with that fluid by heat, and an adhesive gray substance insoluble in water, alcohol, oil, or ether, and resembling an animal substance in many of its properties. See Wheat, Starch, Gluten (Vegetable), Mucilage.

When flour is kneaded together with water, it forms a tough paste, containing these principles very little altered, and not easily digested by the stomach. The action of heat produces a considerable change in the gluten, and probably in the starch, rendering the compound more easy to masticate, as well as to digest. Hence the first approaches towards the making of bread consisted in parching the corn, either for immediate use as food, or previous to its trituration into meal; or else in baking the flour into unleavened bread, or boiling it into masses more or less consistent; of all which we have sufficient indications in the histories of the earlier nations, as well as in the various practices of the moderns. It appears likewise from the Scriptures, that the practice of making leavened bread is of very considerable antiquity; but the addition of yeast, or the vinous ferment, now so generally used, seems to be of modern date.

Unleavened bread in the form of small cakes, or biscuit, is made for the use of shipping in large quantities; but most of the bread used on shore is made to undergo, previous to baking, a kind of fermentation, which appears to be of the same nature as the fermentation of saccharine substances; but is checked and modified by so many circumstances, as to render it not a little difficult to speak with certainty and precision respecting it. See Fermentation.

When dough or paste is left to undergo a spontaneous decomposition in an open vessel, the various parts of the mass are differently affected, according to the humidity, the thickness or thinness of the part, the vicinity or remoteness of fire, and other circumstances less easily investigated. The saccharine part is disposed to become converted into alcohol, the mucilage has a tendency to become sour and mouldy, while the gluten in all probability verges toward the putrid state. An entire change in the chemical attractions of the several component parts must then take place in a progressive manner, not altogether the same in the internal and more humid parts as in the external parts, which not only become dry by simple evaporation, but are acted upon by the surrounding air. The outside may therefore become mouldy or putrid, while the inner part may be only advanced to an acid state. Occasional admixture of the mass would of course not only produce some change in the rapidity of this alteration, but likewise render it more uniform throughout the whole. The effect of this commencing fermentation is found to be, that the mass is rendered more digestible and light; by which last expression it is understood, that it is rendered much more porous by the disengagement of elastic fluid, that separates its parts from each other, and greatly increases its bulk. The operation of baking puts a stop to this process, by evaporating great part of the moisture which is requisite to favour the chemical attraction, and probably also by still farther changing the nature of the component parts. It is then bread.

Bread made according to the preceding method will not possess the uniformity which is requisite; because some parts may be mouldy, while others are not yet sufficiently changed from the state of dough. The same means are used in this case as have been found effectual in promoting the uniform fermentation of large masses. This consists in the use of a leaven or ferment, which is a small portion of some matter of the same kind, but in a more advanced stage of the fermentation. After the leaven has been well incorporated by kneading into fresh dough, it not only brings on the fermentation with greater speed, but causes it to take place in the whole of the mass at the same time: and as soon as the dough has by this means acquired a due increase of bulk from the carbonic acid, which endeavours to escape, it is judged to be sufficiently fermented, and ready for the oven.

The fermentation by means of leaven or sour dough is thought to be of the acetous kind, because it is generally so managed that the bread has a sour flavour and taste. But it has not been ascertained that this acidity proceeds from true vinegar. Bread raised by leaven is usually made of a mixture of wheat and rye, not very accurately cleared of the bran. It is distinguished by the name of rye bread; and the mixture of these two kinds of grain is called bread-corn, or meslin, in many parts of the kingdom, where it is raised on one and the same piece of ground, and passes through all the s of reaping, thrashing, grinding, his mixed state.

or barm is used as the ferment for kinds of bread. This is the muci- froth, which rises to the surface of its first stage of fermentation When ed with dough, it produces a much peedy and effectual fermentation at obtained by leaven, and the bread dingly much lighter, and scarcely r. The fermentation by yeast seems lmost certainly of the vinous or spi- kind.

d is much more uniformly miscible ater than dough, and on this cir- ce its good qualities most probably great measure depend.

ry great number of processes are cooks, confectioners, and others, to kes, puddings, and other kinds of n which different qualities are re- Some cakes are rendered brittle, or called *short*, by an admixture of r of starch. Another kind of brit- s given by the addition of butter or hite of egg, gum-water, isinglass, ner adhesive substances are used, is intended that the effect of fer- on shall expand the dough into an ngly porous mass. Dr. Percival has nended the addition of salep, or the us powder of the orchis root. He at an ounce of salep, dissolved in a f water, and mixed with two pounds r, two ounces of yeast, and eighty of salt, produced a remarkably good eighing three pounds two ounces; loaf made of an equal quantity of ner ingredients, without the salep, d but two pounds twelve ounces. WING. See BEER, also ALCOHOL.

K. Among the numerous branches general art of fashioning argillaceous into useful forms, and afterward ing them by fire, the art of making nd tiles is by no means one of the least useful. By this art we possess the advantage of obtaining the materials for constructing edifices at cheap rates, in almost every situation, without the expense of carrying stone from remote quarries; and this is so far from being the only advantage, that it is extremely probable, that these artificial compositions, if properly made, would prove superior in durability to every natural stone. The streets in Holland are every where paved with a hard kind of brick, known by us under the name of clinkers, and used in this country for paving stables and court-yards; and the houses in Amsterdam appear to be not at all decayed, but are perfectly fresh, as if new, though most of those in the vicinity of the Exchange have stood at least two centuries. The spirit of improvement may perhaps effect at some future period, in this country, what the stimulus of necessity has done on that naturally poor spot.

The art of brickmaking has for the most part been confined to the manufactories, no one having attended to it in a direct chemical way, except the celebrated Bergman. I shall therefore in the present article give an account of the leading facts and observations in his treatise.

The pottery made use of in the construction of edifices may be considered as of two forms; tiles for the roof, or bricks for the walls; to which may be added another kind of bricks for pavements. Softness and porosity are the greatest fault of tiles. The water retained in the pores of tiles becomes frozen in winter; and as ice occupies a larger space than water, the expansion of the water, at the instant of its congelation, does not fail to split and destroy such porous and brittle substances as tiles which are ill made. This has been remedied by covering them with a glaze, which adds considerably to the expense. Bergman is of opinion, that a stronger heat used in the baking would render them so close as to absorb very little moisture.

This illustrious chemist did not find that pure clay, or argillaceous earth, was fusible either alone or when mixed in any proportion with lime, though the addition of the smallest quantity of siliceous earth brought the mass into fusion. Neither was clay fusible with pure quartz alone. Spath fluor renders it fusible; as does likewise feld spar.

Common clay is scarcely ever found in a state approaching to purity on the surface of the earth. It usually contains a large proportion of siliceous earth. Bergman examined several clays in the neighbourhood of Upsal, and made bricks, which he baked with various degrees of heat, suffered them to cool, immersed them in water for a considerable time, and then exposed them to the open air for three years. They were formed of clay and sand. The hardest were those, into the composition of which a fourth part of sand had entered. Those which had been exposed for the shortest time to the fire were almost totally destroyed, and crumbled down by the action of the air: such as had been more thoroughly burned, suffered less damage; and in those which had been formed of clay alone, and were half vitrified by the heat, no change whatever was produced.

On the whole, he observes, that the proportion of sand to be used to any clay, in making bricks, must be greater, the more such clay is found to contract in burning; but that the best clays are those which need no sand. Bricks should be well burned; but no vitrification is necessary, when they can be rendered hard enough by the mere action of the heat. Where a vitreous crust might be deemed necessary, he recommends the projection of a due quantity of salt into the furnace, which would produce the effect in the same manner as is seen in the fabrication of the English pottery called stoneware.

It is of considerable importance to examine clay before it is made into tiles. This is done in a rough way by the manufacturers; but Bergman advises the following as the most expeditious process: Nitric acid poured upon unburned clay detects the presence of lime, by producing an effervescence. Calcareous clays, or marles, are often the fittest materials for making bricks. In the next place, a lump of clay, of a given weight, is to be diffused in water by agitation. The sand will subside, and the clay remain suspended. Other washings of the residue will carry off some clay, and by due management in this way, the sand, or quartzose matter, may be had separate. Nitric acid by digestion will take up the lime from a part of the clay, previously weighed, and this may be precipitated by volatile alkali. The clay, the sand, and the lime may thus be well enough ascertained by weight, so as to indicate the quantity of sand or other material requisite to be added in order to form that compound, which, from other experiments, may have been found best adapted to produce good tiles and bricks. An examination with the microscope will show whether the sand contain feld spar, or other stones of known figure.

The brickmakers in the vicinity of London collect the refuse cinders and ashes of the coal fires of that metropolis, and employ women to sift them. The cinders, called breeze, are used as fuel in the burning, and the smaller powder, or black ashes, enter into the composition of the bricks instead of sand. The proper management of the clay is of considerable importance with respect to the quality of the bricks; and various acts have been passed, to prohibit its use when recently dug. The clay is best if dug in the fall of the year, and exposed to the frosts during the winter, turning it over once or oftener during the time. Indeed the more it is turned and worked with the spade the better. When thus mellowed, it may be thrown into shallow pits in the spring, and left to soak in water some days. It is then to be tempered, and wrought into a smooth paste, with as little water as possible. This is usually done by a horsemill. All the stones ought to be picked out; but this is seldom done, except in the finer articles. When the materials are properly mixed and wrought, the bricks are fashioned in wooden moulds; and then piled up in long double rows to the height of four or five feet, the bricks being so arranged as to admit a free access of air between them, and covered at top with straw, to defend them from the rain. When sufficiently dried in this manner, they are commonly built up into large square heaps, called clamps, stratified with fuel between the rows, and leaving room for the fire to play between the bricks. Two or more arches likewise, according to the size of the clamp, are formed at the bottom, for holding the fuel, and kindling the fires. In this way it is obvious the bricks cannot be uniformly burnt; and to deficiencies in the management of this process, and negligences in tempering and working the materials, we may probably ascribe the bad qualities of too many bricks. A few of the finest kinds of bricks, for particular uses, as well as tiles, are burnt in kilns erected for the purpose, where the fire can be managed with much more regularity.

A kind of bricks called fire-bricks are made near Windsor, which are very hard, heavy, and contain a large proportion of sand. These are chiefly used in the construction of furnaces for steam-engines, or other large works, and in lining the ovens of glass-houses, as they will stand any degree of heat. Indeed they should always be employed where fires of any intensity are required.

Bricks (Floating). See Agaric (Mineral).

Bricks (Oil of). This oil, which once bore the imposing epithets of *sanctum*, *divinum*, *benedictum*, and *philosophorum*, is nothing more than common olive oil, rendered empyreumatic by quenching red-hot bricks in it, breaking these to pieces, and expelling the oil they had imbibed by distillation in a retort. It has long fallen into disuse.

Brimstone. See Sulphur.

Brocatello. A calcareous stone or marble, composed of fragments of four colours, white, gray, yellow, and red.

Bronze. A mixed metal, consisting chiefly of copper, with a small proportion of tin, and sometimes other metals. It is used for casting statues, cannon, bells, and other articles, in all which the proportions of the ingredients vary. The addition of tin to copper renders it brittle and hard, singularly augments its density, and makes it more fusible. The compound possesses likewise the advantage of being less subject to corrosion, or rust, by exposure to the air. Cannon and statues have less tin in their composition than bells; and in speculum metal the proportion of tin is greatest of all. See SPECULUM.

The operation by which large works of bronze are cast, as described by Macquer, is sufficiently simple. For this purpose a brick furnace is used, nearly in the shape of a baker's oven. The floor of this furnace is concave, and consists of a composition of sand and clay. In this hollow floor the metals are placed. The furnace has four openings. The first is a lateral mouth, at which the flame of the fuel enters, which is placed in a second furnace on one side of the first. The second opening is a chimney placed on the side opposite the mouth, by means of which the flame is drawn over the metal. The third opening is a hole, which can be shut or opened at pleasure, to inspect the state of the inside of the furnace and its contents. When the metal is in the state required, a fourth aperture is opened, communicating with the hollow floor, through which the melted metal flows by channels into the moulds prepared to receive it.

The recovery of copper from old bell metal is an object which is sometimes desirable. Chemistry affords various methods of doing this, an interesting detail of which may be seen in the ninth volume of the Annales de Chimie.

The ancients used bronze for many purposes, for which we employ steel and iron; as, for surgeons' instruments, swords, springs, and nails. According to Mongez, who has analysed several specimens, their bronze consisted of copper alloyed with tin in different proportions, as from four thousandth parts to thirteen hundredth parts. Traces of zinc too were found, but none of arsenic or iron, to which their hardness has been ascribed by some. Their cutting instruments of bronze, however, appear to have been hammer-hardened, as traces of this tool are found on them. The broad spring plate of the catapulta for throwing darts was formed of a bronze, according to Philo of Byzantium, consisting of copper alloyed with three hundredth parts of tin.

BRUNSWIC GREEN. This is an ammoniaco-muriat of copper, much used for paper-hangings, and on the continent in oil painting. See COPPER.

BUTTER. The oily inflammable part of milk, which is prepared in many countries as an article of food. This substance appears to be diffused through milk, either mechanically, or, which is more probable, by an imperfect chemical union; that is, by combination with the caseous, saccharine, and acid parts, which form the medium of its suspension in the aqueous fluid. When milk is suffered to remain at rest for several hours, a thick fluid rises to the top, well known by the name of cream, and consisting of the butter, together with a considerable mass of caseous and serous particles. It has not been ascertained whether this ascent of the cream be attended with any chemical change or ferment of the whole fluid, but it seems very probable that this is the case.

Butter as it exists in cream does not form continued masses, but has its parts separated by the interposition of the other principles. Some butter will however be separated without any operation, further than the mere continuance of standing undisturbed. But the common method of separating it consists in agitating the cream, for a certain time, in a vessel called a churn, the form of which is various, but its essential purpose the same. By this treatment it is collected in a uniform soft mass, possessing scarcely any smell; of a mild agreeable taste, easily fusible, and suffering no perceptible disengagement of any of its principles by any degree of heat not exceeding that of boiling water.

We do not possess any direct experiments to show what it is that occasions the difference between the obvious qualities of butter and those of other oils, distinguished by the name of fat or fixed oils, from their not rising by a low heat. It resembles them in its habitudes as nearly as they resemble each other respectively. By distillation on the water bath it gives out a portion of watery fluid, that either remained interposed between its parts from the first, or was taken up during the washing it undergoes in the making. A stronger heat, carefully managed, expels first a strong acid of a penetrating smell, which is followed by a concrete coloured oil possessing the same odour. Very little coal remains. The acid appears to be of the same nature as that distinguished by the name of the sebacic: and it may also be obtained from butter by means of lime or an alkali. See ACID (SEBACIC).

Butter becomes rancid sooner than most other fat oils, probably on account of the water, which may favour the development of its acid. Washing with water or alcohol restores it in some measure to its former state, by carrying off the disengaged part of the acid. The common mode of preserving it is by the addition of salt, which will keep it good a considerable time, if in sufficient quantity. Mr. Eton informs us, in his Survey of the Turkish Empire, that most of the butter used at Constantinople is brought from the Crimea and Kirban, and that it is kept sweet by melting it while fresh over a very slow fire, and removing the scum as it rises. He adds, that by melting butter in the Tartarian manner, and then salting it in ours, he kept it good and fine-tasted for two years; and that this melting, if carefully done, injures neither the taste nor colour. Thenard, too, recommends the Tartarian method. He directs the melting to be done on a water-bath, or at a heat not exceeding 180° F.; and to be continued till all the caseous matter has subsided to the bottom, and the butter is transparent. It is then to be decanted, or strained through a cloth, and cooled in a mixture of pounded ice and salt, or at least in cold spring water, otherwise it will become lumpy by crystallizing, and likewise not resist the action of the air so well. Kept in a close vessel, and in a cool place, it will thus remain six months or more nearly as good as at first, particularly after the top is taken off. If beaten up with one sixth of its weight of the cheesy matter when used, it will in some degree resemble fresh butter in appearance. The taste of rancid butter, he adds, may be much corrected by melting and cooling in this manner.

Dr. Anderson has recommended another mode of curing butter, which is as follows: Take one part of sugar, one of nitre, and two of the best Spanish great salt, and rub them together into a fine powder. This composition is to be mixed thoroughly with the butter, as soon as it is completely freed from the milk, in the proportion of one ounce to sixteen; and the butter thus prepared is to be pressed tight into the vessel prepared for it, so as to leave no vacuities. This butter does not taste well till it has stood at least a fortnight; it then has a rich marrowy flavour, that no other butter ever acquires; and with proper care may be kept for years in this climate, or carried to the East Indies, if packed so as not to melt.

In the interior parts of Africa, Mr. Park informs us, there is a tree much resembling the American oak, producing a nut in appearance somewhat like an olive. The kernel of this nut, by boiling in water, affords a kind of butter, which is whiter, firmer, and of a richer flavour, than any he ever tasted made from cows' milk, and will keep without salt the whole year. The natives call it *shea toulou*, or tree butter. Large quantities of it are made every season.

Butter of Antimony. The combination of oxide of antimony with the oxigenated muriatic acid. It is usually made by distilling a mixture of oxigenated muriat of mercury and antimony. See Antimony.

Butter of Arsenic. A combination of the oxide of arsenic with oxigenated muriatic acid; obtained by a process similar to that used in making the butter of antimony.

Butter of Cacao. An oily concrete white matter, of a firmer consistence than suet, obtained from the cacao nut, of which chocolate is made. The method of separating it consists in bruising the cacao and boiling it in water. The greater part of the superabundant and uncombined oil contained in the nut is by this means liquefied, and rises to the surface, where it swims, and is left to congeal, that it may be the more easily taken off. It is generally mixed with small pieces of the nut, from which it may be purified by keeping it in fusion without water in a pretty deep vessel, until the several matters have arranged themselves according to their specific gravities. By this treatment it becomes very pure and white.

Butter of cacao is without smell, and has a very mild taste, when fresh; and in all its general properties and habitudes it resembles fat oils; among which it must therefore be classed. It is used as an ingredient in pomatums.

Butter of Tin. When granulated tin, or an amalgam of tin and mercury, is distilled with corrosive muriat of mercury, the tin rises in combination with the oxigenated muriatic acid, partly in the form of a liquor, and partly in butyraceous flowers. The liquor is called the fuming liquor of Libavius, and is not essentially different from the flowers. Many chemists distinguish the whole product by the name of the fuming liquor of Libavius. See Tin.

Butter of Wax. Wax, though differing very considerably from fat oils, resembles them in affording an acid by distillation, while the remaining oleaginous part becomes more limpid, in proportion as the number of distillations is repeated. The first distillation leaves it of a butyraceous consistence, and this is called butter of wax. It has a strong smell, and is said by Macquer not to recover its consistence by long exposure to the air; in which particular he observes that it differs from resinous substances.

Button. The round mass of metal obtained in small reductions or other chemical experiments, and found at the bottom of the crucible or vessel wherein the operation is performed, is called the button by chemists.

Byssus. The asbestus, composed of parallel fibres, is distinguished by some under this name.

C.

CABBAGE (Red). See Brassica Rubra.

Cabochôn. The French use this word to denote the figure of precious stones when polished with a convex surface.

Cacao (Butter of). See Butter.

Cacholong. A very hard compact white agate. It is semitransparent, and in this respect differs from the moonstone, which has a milky white, with a few various shades of light proceeding from an internal blueish ground. The cacholong is vitrifiable and capable of a good polish. It is found in the river Cache in the Calmucks' country, whence in their language it takes its name.

Cadmia. A word scarcely met with in the writings of the later chemists. It has been given to various substances. The cadmia of the furnaces is matter that sublimes when ores containing zinc, like those of Rammelsberg, are smelted. This consists of the flowers of zinc, which rise by the violent heat of combustion, and adhere to the inside of the walls of the furnace; which being hot do not condense them immediately into the solid state, but cause them to pass through a state of fluidity intermediate between the elastic and the solid state. On this account they have a much less interrupted solidity than the flowers of zinc usually possess. The quantity collected at Rammelsberg is so considerable, as to form a very thick crust, requiring to be frequently removed. The name of cadmia has also been given to other sublimates that rise in the smelting of ores.

Calamine, or lapis calaminaris, which is an ore of zinc, has also been called native cadmia. This, as well as the cadmia of the furnaces, is used in the converting copper into brass. See Copper.

The ore of cobalt is sometimes, but very improperly, called fossil cadmia.

Cæruleum Montanum. An ore of copper classed by Cronstedt among the calcareous earths, as a combination of that earth with the metal, which is indeed occasionally contaminated with it. There are different varieties of it, containing from 66 to 70 per cent. of copper, 1 or 2 of water, and the remainder carbonic acid. It is found in Cornwall, as well as in different parts of Europe. It is most frequently found of a loose pulverulent form, though sometimes indurated and even crystallized, but it is then mixed with quartz. It may be analysed by solution in acids, and precipitation by immersing a piece of iron in the solution, which will throw down the copper in the metallic state.

Cæsalpinia. See Brazil.

Cajeput Oil. The volatile oil obtained from the leaves of the Cajeput tree. Cajeputa officinarum, the Melaleuca Leucadendron of Linn. The tree which furnishes the cajeput oil is frequent on the mountains of Amboyna, and other Molucca islands. It is obtained by distillation from the dried leaves of the smaller of two varieties. It is prepared in great quantities, especially in the island of Banda, and sent to Holland in copper flasks. As it comes to us it is of a green colour, very limpid, lighter than water, of a strong smell, resembling camphor, and a strong pungent taste, like that of cardamons. It burns entirely away, without leaving any residuum. It is often adulterated with other essential oils, coloured with the resin of milfoil. In the genuine oil, the green colour depends on the presence of copper; for when rectified it is colourless.

Calamine. An ore of zinc of a white, gray, yellow, brown, or red colour, of various hardness, though scarcely ever hard enough to strike fire with the steel. Its texture is either equable or cellular, and its form irregular, or crystallized, or in stalactites. It does not lose weight by calcination, unless mixed with charcoal; and then the zinc rises in flowers. Acids dissolve it, and with the sulphuric it affords sulphat of iron as well as of zinc. The specific gravity of the best sort, that is the gray, is 5·000; and 100 parts of this afforded Bergman 84 of oxide of zinc, 3 iron, 1 clay, and 12 siliceous earth; but in other specimens the proportions are very different. Most of the English calamines contain lead.

Mr. Smithson has lately analysed several specimens of calamine, chiefly with a view to confirm or refute the assertion of Haüy, that all calamines were simple oxides of zinc, without any carbonic acid. White calamine of Bleyburg, of the specific gravity of 3·59, afforded oxide of zinc ·714, carbonic acid ·135, water ·151: a very small portion of the carbonats of lead and of lime were present. Greenish yellow calamine, from Mendip in Somersetshire, of the sp. gr. of 4·336, oxide of zinc ·648, carbonic acid ·352. Pale yellow calamine in small crystals from Derbyshire, sp. gr. 4·333, oxide of zinc ·652, carbonic acid ·348. These crystals were not rendered electric by heat. Electrical calamine from Regbania in Hungary, sp. gr. 3·434, oxide of zinc ·683, quartz ·250, water ·044. This species is likewise found in Derbyshire, in small brown crystals.—*Phil. Trans.*

Calcareous Earth. See Earths.

Calces (Metallic). Metals which have undergone the process of calcination or combustion, or any other equivalent operation, now termed oxides.

Calcination. The fixed residues of such matters as have undergone combustion are called cinders in common language, and calces, or now more commonly oxides, by chemists; and the operation, when considered with regard to these residues, is termed calcination. In this general way it has likewise been applied to bodies not really combustible, but only deprived of some of their principles by heat. Thus we hear of the calcination of chalk, to convert it into lime, by driving off its carbonic acid and water; of gypsum or plaster stone, of alum, of borax, and other saline bodies, by which they are deprived of their water of crystallization; of bones, which lose their volatile parts by this treatment; and of various other bodies. See Combustion and Oxidation.

Calculus, or Stone. This name is generally given to all hard concretions, not bony, formed in the bodies of animals. Of these the most important, as giving rise to one of the most painful diseases incident to human nature, is the *urinary calculus*, or stone in the bladder. Different substances occasionally enter into the composition of this calculus, but the most usual is the lithic acid, under which article we have already given Scheele's analysis of the stone. The mulberry calculi, as they are called from the roughness of their coat, always contain oxalat of lime. Fourcroy enumerates twelve different substances, which he found in calculi of various kinds. The lithic acid already mentioned: Lithat of ammonia, which according to him sometimes forms the whole of a calculus: Phosphat of lime, which frequently occurs: Ammoniaco-magnesian phosphat, which, as was shown by Dr. Wollaston, forms projecting points on some urinary calculi, and the external strata of others, as well as of a great part of the intestinal bezoars of the elephant, horse, and larger mammalia: Oxalat of lime, found only in human urinary calculi: Silex, which occurred in very small quantity, in two out of six hundred calculi, and may be considered as accidental: Gelatine, which accompanies most of the other ingredients as a connecting medium: Superphosphat of lime, which is confined chiefly to the bezoars: Lithat of soda, discovered by Mr. Tennant in arthritic concretions: Carbonat of lime, which occurs in the urinary calculi of other mammalia, but not in those of man: Adipocere, found only in human biliary calculi: the animal resin of the bezoars.

Dr. Pearson, by dissolving urinary calculi in caustic alkali, and precipitating by acids, found a substance, which he thus characterizes:—It does not indicate acidity to the most sensible tests: it is inodorous, tasteless, and scarcely soluble in cold water: it does not unite with the alkali of carbonat of potash, soda, or ammonia, the oxide of mercury, or the lime of limewater: it does not decompound soap or prussiat of iron; and its combination with caustic soda more resembles a soap than a neutral salt: before the blowpipe it burns away without any sign of fusion, and stains the platina spoon black: distilled in close vessels it affords the distinguishing products of animal matter, particularly ammonia and prussic acid: it does not appear to be putrescible. Accordingly Dr. Pearson considers it as an animal oxide, which he thinks should be called *ouric* or *uric* oxide: and gives as its distinguishing characters, imputrescibility, facility of crystallization, insolubility in cold water, and above all the production of a pink or red matter on evaporation of its solution in nitric acid.

Out of 200 specimens, not more than six were wholly without this animal matter; but they contained it in different proportions, varying from $\frac{1}{200}$ to $\frac{188}{200}$, but commonly between $\frac{10}{200}$ and $\frac{140}{200}$.

The urinary calculus of a dog, examined by Dr. Pearson, was found to consist principally of the phosphats of lime and ammonia, with animal matter. Several taken from horses were of a similar composition. One of a rabbit consisted chiefly of carbonat of lime and animal matter, with perhaps a little phosphoric acid. A quantity of sabulous matter, neither crystallized nor concrete, is sometimes found in the bladder of the horse: in one instance there were nearly 45 pounds. These appear to consist of carbonat of lime and animal matter. A calculus of a cat gave Fourcroy three parts of carbonat, and one of phosphat of lime. That of a pig, according to Bertholdi, was phosphat of lime.

The renal calculus in man appears to be of the same nature as the urinary. In that of the horse Fourcroy found 3 parts of carbonat and one of phosphat of lime: Dr. Pearson, in one instance, carbonat of lime and animal matter; in two others, phosphats of lime and ammonia, with animal matter.

Arthritic calculi, or those formed in the joints of gouty persons, were once supposed to be carbonat of lime, whence they were called chalkstones; afterward it was supposed, that they were phosphat of lime; but Dr. Wollaston has shown, that they are lithiat of soda. The calculi found sometimes in the pineal, prostate, salivary, and bronchial glands, in the pancreas, in the corpora cavernosa penis, and between the muscles, as well as the tartar as it is called that encrusts the teeth, appear to be phosphat of lime. Dr. Crompton, however, examined a calculus taken from the lungs of a deceased soldier, which consisted of lime ·45, carbonic acid ·37, albumen and water ·18. It was very hard, irregularly spheroidal, and measured about 6½ inches in circumference.

For the biliary calculi, see Gall. Those called *bezoars* have been already noticed under that article.

It has been observed, that the lithic acid, which constitutes the chief part of most human urinary calculi, and abounds in the arthritic, has been found in no phytivorous animal; and hence has been deduced a practical inference, that abstinence from animal food would prevent their formation. But we are inclined to think this conclusion too hasty. The cat is carnivorous; but it appeared above, that the calculus of that animal is equally destitute of lithic acid, which indeed seems peculiar to man. If therefore we would form any deduction with respect to regimen, we must look for something used by man exclusively of all other animals; and this is obviously found in fermented liquors, but apparently in nothing else: and this practical inference is sanctioned by the most respectable medical authorities.

The property of forming calculi is observed likewise in vegetables. Several botanists have described these vegetable concretions, particularly in the cocoa, the palm, &c. Jussieu had many in his collection. They are called vegetable bezoars, and credulity has extolled them as powerful remedies. The concretion found in the joints of the bamboo cane, and known by the name of torbasheer, was shown by Mr. Macie to consist of siliceous earth.

It is well known that several fruits, more especially pears, are very subject to contain a quantity, sometimes considerable, of granulated, irregular, hard concretions, which are known by the name of Stones. Vauquelin has made a number of experiments on these, which prove, that they are of the same nature as wood.—*Phil. Trans.*—*Annal. de Chimie.*

Call. A word used by the miners to denote schoerl or cockle, and also other matters; but Da Costa says that, definitely speaking, it denotes the mineral called tungsten.

Calomel. The mild muriat of mercury. See Mercury.

Caloric. By this term is understood what has been usually called heat, and sometimes fire, by those philosophers who have considered it merely as a quality, or power of producing certain effects, inherent in bodies; and matter of heat, or igneous fluid, by those who have held it to be a peculiar substance. With a view to determine, whether caloric, or heat, be or be not a substance, attempts have been made to weigh it: but nothing satisfactory on this head is deducible from the experiments of Dr. Fordyce or Mr. Davy, Morveau or Lavoisier, Fontana or count Rumford. Indeed there is sufficient evidence, in the different states of bodies, that caloric renders them specifically lighter: but a mere repulsive power, enlarging their bulk without the addition of any substance, would have the same effect; this therefore proves nothing. All the phænomena, however, appear to admit of explanation in a simple manner, on the supposition, that caloric is a substance; except in the large quantity of heat that may be produced by friction or percussion. In the well-known practice of the smith, who kindles a fire by hammering a piece of iron till red hot, much more heat is evolved than the iron could possibly contain; but this may be derived from the surrounding substances. The same may be said of the experiment of count Rumford, in which he fixed a cylinder of brass in a trough filled with water, and adapted a borer to it, which was made to revolve in the usual manner at the rate of thirty-two times in a minute. The apparatus weighed 15 pounds, and the water 18. In an hour the temperature was raised from 60° to 107°, and in two hours and a half the water boiled. Boyle and Pictet, however, had found, that heat was equally produced by friction in an exhausted receiver; and Mr. Davy has shown the same. But neither is this a substantial objection; for the apparatus must have been in contact with other bodies: and beside, it has been shown that heat, like light, pervades even the Torricellian vacuum. This last-mentioned fact, and still more the radiation of caloric from heated bodies, which is capable of reflection and condensation, seem to show its materiality. We shall now proceed to the facts which illustrate its properties.

The most general and extensive property of caloric is its tendency to equilibrium, or to diffuse itself equally through all bodies; so that whatever substances, by direct or successive contact, communicate with each other, they must either have the same temperature, in other words the same relative proportion of caloric, or the hotter will communicate heat to the others, till a common temperature is produced among them.

The disposition or power of quickly transmitting heat in the production of a common temperature is not the same in different bodies. If a number of straight wires of equal sizes, but different metals, be covered each with a thin coat of wax, and their ends be plunged into the same heated fluid, for example, melted lead, the fusion of the coat of wax will show, that caloric is more quickly transmitted through some metals than others. Thus also it is found, that the end of a glass rod may be kept red-hot for a very long time, without any inconvenience to the hand that holds the other end; though a similar metallic rod, heated in the same manner, would very soon become too hot to be held. Bodies that quickly alter their temperature by communication, are said to be better conductors of caloric than such as alter more slowly. In general, the more dense a body is, the more rapidly it conducts caloric: but this does not hold true in all cases, so as to enable us to estimate the conducting power by the specific gravity.

Count Rumford has made many experiments on the transmission of caloric through fluids, from which he inferred, that they were absolute nonconductors; and that, when a body of fluid is heated throughout, it is owing to the ascent of the heated part, and the consequent successive action of the heating body on fresh portions of the fluid coming into contact with it; or to the transmission of caloric through the sides of the containing vessel. These conclusions, however, have been shown to be erroneous; though it is sufficiently proved that fluids are bad conductors of caloric; and therefore, that the heating body should be applied to the bottom of the fluid, in order that the heated part, ascending by its relative lightness, should make way for the colde and denser portions to come into contact with the body that communicates its caloric to it.

Beside the practical deduction just mentioned, the difference in the conducting power of bodies is of extensive application to various economical purposes. Hence we perceive the advantage of employing metals, when we wish to communicate heat quickly: and on the contrary their disadvantage, when heat is to be retained. Hence the utility of coating furnaces, to prevent the dissipation of heat; and glass vessels, in chemical operations, to prevent the sudden alterations of temperature, which would crack them. And hence the superiority of some articles of clothing over others, in defending us from the cold, or against the effects of sudden changes of temperature. In some experiments made by count Rumford on the following articles, hare's fur, eider down, beaver's fur, raw silk, wool, cotton, and fine lint, he found them to be in the order in which they here stand, with regard to the slowness with which they transmitted heat. But it is to be observed, that the looseness of their texture is of more importance than the nature of the substance itself in this respect.

The general effects of a change of temperature are these: a solid is rendered fluid by an increase of temperature, and a still greater increase converts it into elastic fluid, or vapour. If the body be composed of parts which become solid, fluid, or vapourous, at different temperatures; and the elective attraction, by which these parts are held together, be insufficient to prevent their assuming these states by the change of temperature, a separation will then take place: thus a diminished temperature separates salts from water, by their becoming solid; and an increased temperature separates water from salts, by causing the former to fly off in vapour. Lastly, if neither the change of temperature be considerable enough to alter the state of solidity, fluidity, or vapour, which the body under consideration may happen to possess, nor the body itself be of the nature to undergo a separation of its parts by the change, then an increase of temperature will cause an increase in the bulk or dimensions of the body, which will last no longer than during the time of the increase.

It has already been observed, that the temperature at which the different bodies change their form is various. Neither this property, nor the expansion of bodies by heat, has been observed to have any correspondence with their density, hardness, specific gravity, or other evident properties. There are, likewise, some irregularities in the contraction or expansion, which depend on circumstances not yet well ascertained, near the freezing point of water, and probably other substances. Pure water, when cooled, is observed to contract till within about eight degrees of the freezing temperature, where it begins to expand; and it may be cooled eleven degrees below that temperature, and still continue fluid. An adequate explanation of the circumstances that attend the conversion of bodies from their several states of solidity, fluidity, and vapour, seems to promise a more intimate acquaintance with the nature and properties of the particles of bodies, than has hitherto been obtained.

Permanently elastic fluids, or gases, appear to differ from vapour in the circumstance, that they take and retain the elastic form at a lower temperature. There are facts which render it probable, from analogy, that a great degree of cold would convert them into dense fluids.

It is a self-evident truth, that, if two bodies be perfectly equal and alike in all respects, and have the same temperature, they will possess equal quantities of caloric.

Thus, a pound of gold will possess an equal quantity of caloric with another pound of gold at the same temperature; a pound of water will possess an equal quantity of caloric with another pound of water at the same temperature, and so forth. From this it will also be clear, that two pounds of gold will possess twice as much caloric as one pound of gold, at the same temperature; and generally, that the quantities of caloric in bodies of the same kind, and at the same temperature, will be in proportion to their quantities of matter, or their weights.

If two such equal and similar bodies, that differ in temperature, be brought together, they will, by communication, acquire a common temperature, and their quantities of caloric will by this means be rendered equal. For this purpose, it is clear that the hotter of the two bodies must have communicated half its excess to the colder. The quantity of caloric in one of the two equal bodies will therefore be an arithmetical mean between the two quantities originally possessed by each of them; that is to say, its temperature, or the common temperature, will exceed that of the colder exactly as much as it falls short of the hotter body.

If the two bodies had been unequal, they would nevertheless have acquired a common temperature by communication; but the excess of caloric would not have been equally divided between them. For we have shown, that the quantities of caloric in such bodies, at the same temperature, are in proportion to the quantities of matter. If the surplus of caloric had been entirely taken away, it is obvious that their temperature would have been made equal, and their quantities of caloric would have been in that proportion; and there is no other way of adding the surplus to them, so as to preserve the same proportion, but by giving more to the larger than to the smaller body, according to its quantity. The common temperature that they acquire shows that this is done; and consequently that, when

e fundamental experiments cannot
ctly examined, the following doubt
o be discovered, namely, Whether
tion to give out or to receive ca-
the same in water at all tempera-
cause it is clear, that, if this dis-
e changed by heating or cooling, the temperature, or power to heat or cool other bodies, will not follow the same proportion as the quantities of caloric; though it may be imagined, not without probability in this case, that correspondent irregularities in the expansions of the mercury may cause the thermometer to indicate the arithmetical means between the two expansions produced by an extreme temperature. But whatever irregularities may be supposed to counteract each other in these experiments with mercury and water, it is to the last degree improbable, that the same compensation would be found, when the mean temperature is obtained by other methods. With this view, the celebrated Dr. Crawford very carefully repeated and confirmed Mr. de Luc's experiments, made others with a like result, by using linseed oil instead of water, and also by producing the mean temperature permanently in air included in a cylinder formed of two equal parts, the upper of which was kept to the freezing point, by surrounding it with pounded ice, and the lower to the boiling water point, by surrounding it with a greater supply of steam than could be condensed by its contact. The near correspondence of these several methods shows, that the expansions of mercury in the thermometer are correspondent with the caloric it receives.

Thus far we have attended only to the communication of caloric between bodies of the same kind; but when two equal bodies of different kinds produce a common temperature by communication, it seldom happens that it proves to be an arithmetical mean between the two original temperatures. In such cases, it is evident, that the caloric, which was communicated from one to the other, has not altered their temperatures equally, but has raised or lowered that of the one more than it has lowered or raised that of the other. And as the proportion between the number of degrees through which one of the two bodies is thus raised, and the other lowered, is found, by experiment, to be the same, however different the two original temperatures may have been, provided no change of form or chemical combination has been produced in either of them; it is a general consequence, that the quantity of caloric required to alter the temperature of one of the bodies a single degree, or any other equal part, will be greater or less than would be required to produce the same change in the other body, in proportion as the changes produced by the communicated caloric were less or greater.

The whole of the caloric in each body, when they have the same temperature, must consist of the same number of degrees: the proportion between the whole quantities of caloric of the bodies will, therefore, be the same as between the quantities required to raise each of them a single degree: that is to say, the comparative quantities of caloric of bodies, at the same temperature, will be in the inverse proportion of the number of degrees their temperature is altered by the transmission of the same quantity of caloric.

To illustrate this by an example in round numbers: Suppose a pint of mercury, at the temperature of 136°, be mixed with a pint of water at 50°, the mean temperature will be 76°. The water, therefore, has been heated 26°, and the mercury has been cooled 60°, by the loss of the caloric it imparted to the water. The absolute caloric in one degree of the mercury will, consequently, be proportionally less than that of one degree of the water; because the very same caloric which has raised the water 26° in temperature, would raise the mercury 60°, if it could be returned again; and the whole of the caloric contained in the mercury will be to that of the water in the same proportion of 26 to 60. But in the present experiment, equal bulks were used; and mercury is about thirteen times as heavy as water; and equal weights of mercury would contain only one thirteenth part of the heat. Twenty-six, divided by 13, quotes 2. Whence, the comparative quantities of caloric, of mercury, and water, are in the proportion of about 2 to 60, or one to 30; that is to say, a pound of mercury, at the same temperature, contains no more than one thirtieth part of the caloric contained in a pound of water.

It may be observed, that the term comparative quantity of caloric is used to denote the proportion of the absolute quantity of caloric in one body to that of another equal mass of matter at the same temperature, considered as a standard. The standard made use of is pure water in a fluid state. Some writers call this specific heat. The disposition or property by which bodies severally require more or less caloric to produce equal changes in their temperature, is called their capacity for caloric, or for heat. These capacities are considered as the unknown cause of the difference in their comparative quantities of caloric, to which they are consequently proportional.

It is found by experiment, that the capacity of the same body for caloric is least when solid, greater when fused or fluid, and greatest of all when it becomes converted into vapour, or elastic fluid.

Also, when bodies unite by virtue of chemical attraction, their capacities are seldom the same as the sum of the capacities of the bodies, but almost always either greater or less.

As the experiments relating to the capacities of bodies cannot be here given at large, it will be proper to mention, by way of inference, some of the chief consequences of this most luminous doctrine; first premising, however, that these inductions have all been verified by experiment.

The capacities of ice and fluid water are found to be as 9 to 10. Ice cannot, therefore, be converted into water, unless it be supplied with as much caloric as is sufficient to answer the difference of capacity. Thus, if equal quantities of ice and water, both at the temperature of 32°, or the freezing point, be exposed in similar vessels, at the same distance from a fire, both will receive caloric alike, and the ice will be melted into water at 32°, while the water in the other vessel will have its temperature raised to 178°. Here it is obvious, that the same heat which raised the water 146°, was merely sufficient to supply the increased capacity of the ice; for which reason this last had not its temperature raised at all. If the experiment be more accurately made, by mixing equal weights of water at 178° and ice at 32°, the same consequence will follow; for the ice will be melted, and the common temperature will be 32°; because the ice in melting receives no augmentation of temperature by absorbing the whole 146° of heat from the water, by virtue of its increased capacity when it becomes fluid.

And so, likewise, when water is frozen by the loss of its caloric, communicated to a cold atmosphere or other contiguous bodies, the process of cooling goes on till ice begins to be formed; but during the whole time of the conversion of the water into ice, the temperature remains stationary, because the diminished capacity of the ice causes it to give out caloric, the continual evolution of which supplies the refrigerating bodies with as much as their energy of cooling might otherwise have taken to cause a diminution of the temperature. When the whole is frozen, this supply of extricated caloric ceases; and therefore the cause that cooled the water at first, goes on in cooling the ice, till the common temperature is produced.

In all experiments, wherein the capacities of the same bodies are changed, and the difference between the quantities of caloric in the same body, in both states, at one common temperature, is known in the degrees of the thermometer, we may derive the advantage of finding the absolute quantities of caloric in degrees of the thermometer, or the number of degrees which any particular point or temperature is remote from the true zero, or point of absolute privation of all caloric. To illustrate this curious position, the experiments on ice and water, just related, may be made use of. The whole quantities of caloric, in these two states, are as 9 to 10. It is plain, therefore, when water freezes, it must give out one tenth of its whole caloric; and this tenth part, by the experiment, is found to amount to 146° of Fahrenheit's thermometer; consequently its whole heat is ten times 146°, or 1460°, when its temperature is 32° above Fahrenheit's zero. Whence the natural zero is at 1428°.

No direct experiment has yet been made to show the capacity of steam with relation

.An indirect experiment of Dr.,
makes it as 15⅓ to 10. It is ac-
found, that steam, in its conden-
water, gives out as much caloric
raise the temperature of an equal
of non-evaporable matter, of the
acity as water, 914 degrees. This
must have taken up at its forma-
henever water is heated, we may,

nd ether, being more evaporable,
stationary point of temperature lower than water in similar circumstances of exposure. The freezing of water by means of ether affords a striking instance of this effect. Water is included in a thin glass tube, and the outside of the tube is kept continually wetted with ether, by means of a bottle with a capillary tube in its neck, through which the ether is poured. The consequence of the speedy evaporation of this very volatile fluid is, that in a very short time the included water is suddenly converted into ice, even before a fire, or in the midst of summer.

There seems to be no difficulty in accounting for the cold produced by the evaporation of water from the surface of the hand; because it is perfectly analogous to the fact where a stationary temperature, or boiling point, is produced over a fire. But in the experiment of ether it may seem remarkable, that the refrigeration is carried to a point so far beneath that of every one of the surrounding bodies. This may, however, be explained from an attention to what is observed to happen with water. If water were enclosed in a strong metallic vessel, and surrounded on all sides with ignited coals, there is no doubt, from the general course of facts, but that it would become gradually hotter, until it either burst the vessel by its expansive force, or acquired a temperature equal to that of the coals. But if a hole be suddenly opened, after the temperature has increased beyond the common boiling-water point, it is found, that a sudden extrication of steam takes place, and the fluid immediately falls to the temperature of boiling water. Now the ether, being much more volatile than water, may be considered, when confined in a bottle, to be in a state similar to that of water in Papin's Digester; and the surrounding bodies act upon the bottle like the coals in the former instance. The included ether acquires the common temperature, because it is prevented from assuming the vaporous state, and has not elasticity enough to break the vessel. But as soon as this fluid is set at liberty, it evaporates readily, and becomes cooled down towards a stationary degree of temperature; at which, if acquired, the caloric carried off by the vapour would be accurately equal to that supplied by the surrounding bodies. This temperature, at the surface of ether exposed in our climate, is, on account of its volatility, considerably below the freezing point of water; and therefore, whenever a thin stratum of ether is made to surround a small vessel of water, it is no wonder it robs it of so much caloric as to congeal it in a short time.

The effect of freezing mixtures is another evident consequence of this doctrine of the change of capacities of bodies for caloric. When common salt is added to water, in as large a quantity as can be dissolved, the brine is much more difficult of congelation than mere water; so much so, that it does not acquire the solid state until it is cooled as low as 6° below 0° on Fahrenheit's scale; or 38° below the freezing point of water. Suppose now, that the salt be mixed, not with water, but with snow, or pounded ice. These two substances will be disposed to combine together as before, but much of the effect will depend on the temperature. If this be so low, as that the combination may preserve the solid state, the external parts in contact of each will indeed unite; but they will form a solid combination, that will effectually prevent the internal parts from approaching each other, and accordingly little or no perceptible progress will be made towards the union of the whole mass. But if, on the contrary, the temperature be higher than this, the combination will be the fluid brine, though the snow and ice were solid before; and this for the plain reason, that the brine requires less caloric to fuse it, than would have been requisite to fuse the ice alone. The assumption of the fluid state in these bodies will increase their capacity, and they will be disposed to deprive the surrounding bodies of caloric; that is to say, they will be colder than before. If the quantity of snow and salt be considerable, and there be no bodies at hand which can readily supply the caloric required, the brine first produced will cool the snow and salt in its vicinity; and these, when liquefied, will cool the rest of the snow and salt still more effectually. When the temperature of the whole is by this process reduced as low as —6°, or the freezing point of the brine, the liquefaction will stop, or it will proceed more slowly or faster, in proportion as the requisite caloric can be supplied. It may therefore be easily understood, that if a mixture of this kind be placed in a vessel, and a smaller vessel containing water be plunged into it, the cooling process will freeze the water. It is likewise evident, that such mixtures can descend in temperature no lower than a certain fixed degree, which is their own freezing point.

There are other freezing processes effected by the mere liquefaction or solution of salts in water, which also appear to depend on the increased capacity of the salt, or more probably of the water contained in them. Among a variety of processes of this kind the following may be selected, not as the most powerful, but because the materials are cheap, and well known. Equal parts of saltpetre and sal-ammoniac are to be reduced to a fine powder. If four ounces of water be poured on three ounces of this mixture, the solution will sink the thermometer 36 degrees: and as it is easy in this country to have pump water, at any season, as cool as 50°, this addition will cool it to 14°, which is therefore sufficient to freeze water in a phial plunged into it. If the water cooled in a first process be used to reduce other water and salts to the temperature of about 32°, and these be applied to the performance of a second process, the temperature will be much lower, viz. 4° below 0°. The table of freezing mixtures, at the conclusion of this article, shows the effects of most of the experiments of this kind that have been tried. It is observable, that deliquescent salts produce much more cold than such as are efflorescent: and they should possess the whole of their water of crystallization, for if deprived of this they produce heat instead of cold, according to Lowitz.

Without entering more largely into examples of the change of capacity for caloric in bodies which are changed in their form or state of chemical combination, it may be observed in general, that as the powers of gravity and projection, in continual opposition to each other, produce all the varied effects of position, and its consequences, in the great system to which they are essential, so among the actions of the minute parts of bodies, the cohesive attraction and the energy of caloric are in continual opposition, and are concerned in every process of change in their peculiar properties. It is certain, that the particles of bodies do not touch each other, but are held in equilibrio at a certain distance, which varies with the temperature, as is deduced from the expansions and contractions dependent on this cause. What might be the consequences of an extreme depression of temperature, we are not likely ever to discover, and conjecture leads us very little into the doctrine of caloric. It may be observed, that the changes of capacity in bodies, when they take the solid, fluid, or vaporous state, are greatly conducive to the preservation of a more equal temperature, than would otherwise be found in the districts around us. The cold produced by evaporation mitigates and conducts to other parts the strong heats of the torrid zone, and the heat developed on the freezing of water prevents the cold countries from being cooled as far below the freezing point as might otherwise happen. If the capacities of water and ice were equal, the freezing of immense bodies of water would scarcely be progressive, but would take place the instant the whole was cooled to 32°; and so likewise the thawing of immense bodies of snow, and of mountains of ice, would be performed in the short time of the transmission of caloric requisite to elevate its temperature the minutest portion of a degree above the temperature of solidity.

There are various methods used to increase the temperature of bodies. The friction of two pieces of wood against each other in a turner's lath produces heat and flame. A nail may be made red hot by quickly hammering it, or by the action of a dry grindstone; and when flint and steel are struck together, small particles of the steel are separated, which are in a strong

deflagration; and upon examina-
h the microscope are found to have
ed into hollow grayish balls. From
cts it appears, that as caloric in-
the dimensions of bodies, so the di-
n of the magnitude of bodies by
ical action, causes them to give out
which if suddenly extricated will
oduce a strong state of ignition. The
ght, concentrated by a lens or mir-
ound to produce the most astonish-
cts, by raising the temperature of
as does likewise the electric shock,
which far exceed those of our fur-
Many chemical mixtures, wherein
ombination and change of capacity

state of combustion. See Combus-
nd Gas (Oxigen).

and caloric differ from each other
chemical effects, as many experi-
now. The heat produced in the
a mirror or lens is not exactly in
on to the quantity of light, but in
asure depends on its direction; so
same quantity of light at the focus,
over an equal surface, will heat
an if either within or beyond it.
he caloric of a fire, though not lu-
is thrown off in rays subject to the
s of reflection as light, but not like
itted through glass. This is plain-
by interposing a pane of glass be-
fire and the face of an observer. The
l pass through, but the caloric will
cepted, and will be employed in
he temperature of the glass. And
gly the heat of the fire will not be
in the focus of a speculum of glass,
metallic speculum will produce a
ct. A bright table spoon may be
is experiment, instead of a mirror.
etallic concave speculums be so
t a distance from each other, that
s may coincide, and an iron heated
nition be placed in the focus (of parallel rays) of one mirror, there will be an image of the iron formed in the focus of the other; at which if a thermometer be applied, its temperature will be raised. Whence it follows, that the caloric radiating invisibly from the iron, is governed by the same laws as the light which forms the image. Even hot water will have a similar effect. It is likewise found, that a freezing mixture, placed in the same situation, will depress the thermometer by the action of its focal image. This has been thought to evince the material nature of cold, which has in every theory been supposed to be the mere negation of heat. It does not, however, appear to prove any thing more, than that, in the present constitution of the world, caloric is emitted in all directions by all bodies; and that the freezing mixture intercepts a portion, which would have passed through the focus of one mirror, and proceeded to the other. The freezing mixture does the same thing as to the caloric, which a black substance would have effected with regard to light. A black substance in one focus would have been visible in the other; not by the emission of rays of darkness, but by the interruption and privation of as much light as would else have proceeded from its apparent place. See Light.

The separation of compounds by the action of caloric is among the most common of its applications to chemical purposes, and the modification of this action by pressure is well known. Sir James Hall has lately applied this to illustrate the Huttonian theory of geology; and to prove, that compounds, which are readily decomposed in our fires under the pressure of the atmosphere alone, may be made to undergo very great heat, without having their combination destroyed. Thus pounded chalk, exposed to 21° or 22° of Wedgwood's pyrometer, was consolidated into limestone, or a semitransparent marble, without having its carbonic acid separated from it. His experiments may be seen at length in the Edinburgh Transactions, or in Nicholson's Journal.

Calorimeter. An instrument contrived by Lavoisier and La Place, to measure the heat given out by a body in cooling by the quantity of ice it melts. It consists of two vessels, one to be placed within the other, so as to leave a cavity between them; and a frame of iron network, to be suspended in the middle of the inner vessel. This network is to hold the heated body, and is to be surrounded with ice broken to pieces so as to fill the rest of the inner vessel. As the ice melts, the water runs off through the bottom of the inner vessel, which is grated, and terminates in the shape of a funnel, with a stopcock. The space between the two vessels is filled with pounded ice, to prevent the access of caloric from the external air; and the cover is made double so as to contain ice for the same purpose, with a perforation to let any water that may be formed drop into the cavity.

Two sources of fallacy in this instrument have been pointed out by Mr. Wedgwood. One, that water is retained among the broken ice by capillary attraction: the other, that the water formed by the thawing of the ice in the upper portions of the vessel is again frozen in part as it filters through the lower, so as even to endanger stopping up the passage.—*Mem. de l'Acad. des Sciences.—Phil. Trans.*

Cameleon Mineral. The combination of fixed alkali and oxide of manganese has been so called, on account of the changes of colour it is subject to when dissolved in water.

Camomile. A small quantity of blue essential oil resides in the cup of the flowers. This colour changes to a brownish green by age, and that more readily in half filled or imperfectly closed vessels than in such as are entirely full. Camomile flowers boiled in wine give it a manifestly saline taste, and the decoction precipitates silver and mercury from nitric acid. But as the precipitates were different from those afforded by common salt, Neumann is justly of opinion, that the precipitating salt was afforded by the wine. They afford half their weight of watery extract, and three eighths of spirituous.

Berthollet observes, that as a dye they afford a weak yellow colour, of a tolerably pleasant hue, but without durability. Mordants give it a little, the best of which are alum, tartar, and sulphat of lime.

Sir John Pringle finds, by his experiments, that the soluble part of camomile flowers is one hundred and twenty times as antiseptic as common salt.

Campan Marble. The green campan from the Pyrenean mountains is slightly magnetic, and contains, according to Mr. Bayen, in the centenary sixty-five parts of carbonat of lime, thirty-two of alumine, and three of iron partially oxided. The red campan is not magnetic, and contains eighty-two parts of carbonat of lime, eleven of alumine, and seven of oxide of iron.

Campeachy Wood. See Logwood.

Camphor. This singular vegetable substance comes to us from China. There are two kinds grow in the East, the one produced in the islands of Sumatra and Borneo, and the other produced in Japan and China. The Sumatran camphor, which the Europeans obtain, is carried to the China market, where it bears a better price than the Japanese. This has given rise to an opinion, that the Chinese buy it, to convert it, by some manipulation, into the other. The properties of the camphor we receive render this in the highest degree improbable.

Camphor is extracted from the roots, wood, and leaves of two species of laurus, the roots affording by far the greatest abundance. The method consists in distilling with water in large iron pots, serving as the body of a still, with earthen heads adapted, stuffed with straw, and provided with receivers. Most of the camphor becomes condensed in the solid form among the straw, and part comes over with the water. It is said by some to be sublimed without water; but Neumann thinks, perhaps without foundation, that such treatment would give an empyreumatic smell to the camphor. The rough camphor, as imported, resembles crude nitre or bay salt. It is imported in canisters.

The refining of camphor was long a secret in the hands of the Venetians, at the time when most of the commodities of the East were brought into Europe by that people. The Hollanders have since appropriated to themselves this, with various other manufactures dependent on chemistry; and I do not find that it is purified in large quantities elsewhere. Neumann mentions one of the largest refineries at Amsterdam, in which were fifty furnaces, all managed by women. He was permitted to see the whole operation, except the charging of the vessels. The sublimation was performed in low flat-bottomed glass vessels placed in sand; and the camphor became concrete in a pure state against the upper part, whence it was afterward separated with a knife, after breaking the glass. Lewis, in a note on this passage, asserts, that no addition is requisite in the purification of camphor; but that the chief point consists in managing the fire so that the upper part of the vessel may be hot enough to bake the sublimate together into a kind of cake. He thinks it more commodious to dissolve the crude camphor in alcohol, and, after decantation or filtration, to distil off the spirit, and fuse the camphor into a cake in a glass vessel. This is practised to advantage. Chaptal says the Hollanders mix an ounce of quicklime with every pound of camphor previous to the distillation.

Purified camphor is a white concrete crystalline substance, not brittle, but easily crumbled, having a peculiar consistence resembling that of spermaceti, but harder. It has a strong lively smell, and an acrid taste; is so volatile as totally to exhale when left exposed in a warm air; is light enough to swim on water; and is very inflammable, burning with a very white flame and smoke, without any residue.

The roots of zedoary, thyme, rosemary, sage, the inula helenium, the anemony, the pasque flower or pulsatilla, and other vegetables, afford camphor by distillation. It is observable, that all these plants afford a much larger quantity of camphor, when the sap has been suffered to pass to the concrete state by several months drying. Thyme and peppermint, slowly dried, afford much camphor; and Mr. Achard has observed, that a smell of camphor is disengaged when volatile oil of fennel is treated with acids. The combination of diluted nitric acid with the volatile oil of anise afforded him a large quantity of crystals, that possessed most of the properties of camphor; and he obtained a similar precipitate by pouring the vegetable alkali upon vinegar saturated with the volatile oil of angelica.

From all these facts, Chaptal concludes, that the base of camphor forms one of the constituent parts of some volatile oils, in which it exists in the liquid state, and does not become concrete but by combining with oxigen.

Mr. Kind, a German chemist, endeavouring to incorporate muriatic acid gas with oil of turpentine, by putting this oil into the vessels in which the gas was received when extricated, found the oil change first yellow, then brown, and lastly to be almost wholly coagulated into a crystalline mass, which comported itself in every respect like camphor. Tromsdorff and Boullay confirm this. A small quantity of camphor may be obtained from oil of turpentine by simple distillation at a very gentle heat. Other essential oils however afford more. By evaporation in shallow vessels at a heat not exceeding 57° F. Mr. Proust obtained from oil of lavender ·25, of sage ·21, of marjoram ·1014, of rosemary ·0625. He conducted the operation on a pretty large scale.

Camphor is not soluble in water in any perceptible degree, though it communicates its smell to that fluid, and may be burned as it floats on its surface. It is said, however, that a surgeon at Madrid has effected its solution in water by means of the carbonic acid.

Camphor may be powdered by moistening it with alcohol, and triturating it till dry. It may be formed into an emulsion by previous grinding with near three times its weight of almonds, and afterward gradually adding the water. Yolk of egg and mucilages are also effectual for this purpose; but sugar does not answer well.

It has been observed by Romieu, that small pieces of camphor floating on water have a rotatory motion, which he ascribes to electricity.

Alcohol, ethers and oils, dissolve camphor very plentifully. The former of these dissolves much more by heat, though when cold it takes up three fourths of its own weight. The surplus taken up by heat is separated, in crystals of a plumose form, by cooling.

Nitric acid, which acts so violently on essential oils as to cause inflammation, dissolves camphor without producing heat or agitation. The camphor becomes fluid, and floats on the surface of the acid like oil, and has been called oil of camphor. Neumann says, it combines with the most concentrated part of the acid. Other acids also dissolve it. Alkalis precipitate it heavier, harder, and much less combustible.

The addition of water to the spirituous or acid solutions of camphor instantly separates it.

When equal parts, by weight, of a saturated solution of camphor in alcohol and of dense sulphuric acid are distilled on a sand bath, a camphorated ether comes over, which does not deposit camphor when agitated with water; and a black tenacious bitumen remains behind, which becomes more firm and solid by washing in water. Mr. Mounet, the author of the experiment, thinks the camphor is decomposed. Mr. Hatchett has particularly examined the action of sulphuric acid on camphor. A hundred grains of camphor were digested in an ounce of concentrated sulphuric acid for two days. A gentle heat was then applied, and the digestion continued for two days longer. Six ounces of water were then added, and the whole distilled to dryness. Three grains of an essential oil, having a mixed odour of lavender and peppermint came over with the water. The residuum being treated twice with two ounces of alcohol each time, fifty-three grains of a compact coal in small fragments remained undissolved. The alcohol being evaporated in a water bath yielded forty-nine grains of a blackish brown substance, which was bitter, astringent, had the smell of caramel, and formed a dark brown solution with water. This solution threw down very dark brown precipitates with sulphat of iron, acetit of lead, muriat of tin, and nitrat of lime. It precipitated gold in the metallic state. Isinglass threw down the whole of what was dissolved in a nearly black precipitate.

When nitric acid is distilled repeatedly in large quantities from camphor, it converts it into a peculiar acid. See ACID (CAMPHORIC).

Camphor is much used in medicine, parernally as a discutient. Discetic acid, with some essential ns the aromatic vinegar, for re indebted to the elder Mr. remarkably promotes the solu- l. Its effluvia are very noxious to which account it is much used ubjects of natural history from s.—*Journ. de Phys.*—*Van Mons's nales de Chimie.*—*Phil. Trans.*

. See LIGHT.

COAL. A coal which burns with e, much smoke, and a smell re- tch. It probably owes its name a substitute for candles in many r families in the north of Eng- n their store of coals take care ded with a separate portion of d on the fire at night. Kirwan breaks easily in any direction, racture presents a smooth con- ace, if broken transversely. Its ity is about 1·27.

IDES. A well known fly with , very common in hot countries, sed as an article of the materia he powder of this insect applied causes blisters, excites urine, ever. They produce the same taken in a small dose internally. es have occasioned priapisms, blood, and lastly death. The ve formerly administered this o excite venereal emotions, but ut much danger.

venel has made some valuable on cantharides. Water extracts dant principle, which gives it llow colour, and also separates oily principle. Ether takes up ery acrid oil, wherein the virtue arides most eminently resides. f cantharides afforded

has since attempted to analyse more accurately, and he gives ponent parts of the French k matter 74 grs. yellow matter natter 80; parenchyma 324; lime 12; carbonat of lime 2; muriat of lime 4; oxide of iron leterminate quantity of an acid, d not ascertained. He informs queous extract produces nearly ects as the insects themselves, r doses. His researches, how- appear to be completed.

it extracts, by digestion, a tinc- antharides, which possesses all f the insects themselves. When this tincture is distilled, the spirit which comes over has the smell of the cantharides.

Alcohol takes up the caustic part only; whence it follows, that the intensity of the tincture may be varied, as well by varying the strength as the quantity of the spirit to a given dose of the insects. This tincture has the character of warming and increasing the circulation of the parts to which it may be applied in rheumatic pains, sciatica, the wandering gout, &c.

Neumann was acquainted with the resinous substance of cantharides, and that the virtue of this medicament resided in it.

CAOUTCHOUC. This substance, which has been improperly termed *elastic gum*, and vulgarly, from its common application to rub out pencil marks on paper, *India rubber*, is obtained from the milky juice of different plants in hot countries. The chief of these are the *Jatropha elastica*, and *Urceola elastica*. The juice is applied in successive coatings on a mould of clay, and dried by the fire or in the sun; and when of a sufficient thickness the mould is crushed, and the pieces shaken out. Acids separate the caoutchouc from the thinner part of the juice at once by coagulating it. The juice of old plants yields nearly two thirds of its weight; that of younger plants less. Its colour, when fresh, is yellowish white, but it grows darker by exposure to the air.

The elasticity of this substance is its most remarkable property: when warmed, as by immersion in hot water, slips of it may be drawn out to seven or eight times their original length, and will return to their former dimensions nearly. Cold renders it stiff and rigid, but warmth restores its original elasticity. Exposed to the fire it softens, swells up, and burns with a bright flame. In Cayenne it is used to give light as a candle. Its solvents are ether, volatile oils, and petroleum. The ether, however, requires to be washed with water repeatedly, and in this state it dissolves it completely. Pelletier recommends to boil the caoutchouc in water for an hour; then to cut it into slender threads; to boil it again about an hour; and then to put it into rectified sulphuric ether in a vessel close stopped. In this way he says it will be totally dissolved in a few days, without heat, except the impurities, which will fall to the bottom, if ether enough be employed. Berniard says the nitrous ether dissolves it better than the sulphuric. If this solution be spread on any substance, the ether evaporates very quickly, and leaves a coating of caoutchouc unaltered in its properties. Naphtha, or petroleum, rectified into a colourless liquid, dissolves it, and likewise leaves it unchanged by evaporation. Oil of turpentine softens it, and forms a pasty mass, that may be spread as a varnish, but is very long drying. A mixture of volatile oil and alcohol dissolves it better, and dries more speedily. Of the essential oils that called cajeput appears to dissolve it best; and from this it may be separated by washing with alcohol and exposure to the air. Oil of spike is said to act upon it in a similar manner. The expressed vegetable oils, wax, butter, and animal oil, by the assistance of a boiling heat, form with it viscid inelastic compounds. A solution of caoutchouc in five times its weight of oil of turpentine, and this solution dissolved in eight times its weight of drying linseed oil by boiling, is said to form the varnish of air-balloons Alkalis act upon it so as in time to destroy its elasticity. Sulphuric acid is decomposed by it; sulphurous acid being evolved, and the caoutchouc converted into charcoal. Nitric acid acts upon it with heat; nitrous oxide being given out, and oxalic acid crystallizing from the residuum. On distillation it gives out ammonia, and carburetted hidrogen.

Caoutchouc may be formed into various articles without undergoing the process of solution. If it be cut into a uniform slip of a proper thickness, and wound spirally round a glass or metal rod, so that the edges shall be in close contact, and in this state be boiled for some time, the edges will adhere so as to form a tube. Pieces of it may be readily joined by touching the edges with the solution in ether: but this is not absolutely necessary, for, if they be merely softened by heat, and then pressed together, they will unite very firmly.

If linseed oil be rendered very drying by digesting it upon an oxide of lead, and afterward applied with a small brush on any surface, and dried by the sun or in the smoke, it will afford a pellicle of considerable firmness, transparent, burning like caoutchouc, and wonderfully elastic. A pound of this oil, spread upon a stone, and exposed to the air for six or seven months, acquired almost all the properties of caoutchouc: it was used to make catheters and bougies, to varnish balloons, and for other purposes.

If mastic be digested in alcohol, about one fifth remains undissolved; and this, though somewhat glutinous, possesses properties similar to those of caoutchouc when chemically examined.

Humboldt found a kind of caoutchouc in the earth, in some parts of South America. It occurred, however, only at the roots of certain trees, from which it was an exudation; and differs therefore from what is extracted from some of the mines in Derbyshire, the only place whence the *mineral caoutchouc*, or *elastic bitumen*, has yet been obtained.

Of the mineral caoutchouc there are several varities: 1. Of a blackish brown inclining to olive, soft, exceedingly compressible, unctuous, with a slightly aromatic smell. It burns with a bright flame, leaving a black oily residuum, which does not bethe come dry. 2. Black, dry, and cracked on surface, but, when cut into, of a yellowish white. A fluid resembling pyrolignic acid exudes from it when recently cut. It is pellucid on the edges, and nearly of a hyacinthine red colour. 3. Similar to the preceding, but of a somewhat firmer texture, and ligneous appearance, from having acquired consistency in repeated layers. 4. Resembling the first variety, but of a darker colour, and adhering to gray calcareous spar with some grains of galana. 5. Of a liver-brown colour, having the aspect of the vegetable caoutchouc, but passing by gradual transition into a brittle bitumen, of vitreous lustre, and a yellowish colour. 6. Dull reddish brown, of a spongy or corklike texture, containing blackish gray nuclei of impure caoutchouc. Many more varieties are enumerated.

One specimen of this caoutchouc has been found in a petrified marine shell enclosed in a rock, and another enclosed in crystallized fluor spar.

The mineral caoutchouc resists the action of solvents still more than the vegetable. The rectified oil of petroleum affects it most, particularly when by partial burning it is resolved into a pitchy viscous substance. A hundred grains of a specimen analysed in the dry way by Klaproth afforded carburetted hidrogen gas 38 cubic inches, carbonic acid gas 4, bituminous oil 73 grains, acidulous phlegm 1·5, charcoal 6·25, lime 2, silex 1·5, oxide of iron ·75, sulphat of lime ·5, alumine ·25.—*Journal de l'Institut. Nat. et du Muscum Nat.—Asiatic Researches.—Nich. Journal.—Klaproth's Analyses.*

Cap. The piece which terminates the top of a melting furnace is called the cap. It has the figure of an oblong dome, with a large oval door on one side for the introduction of fuel, of which this furnace requires a quick and large supply. The upper part terminates in a tube or chimney, which may be lengthened accordingly as a greater or less draught is required.

Capacity. See Caloric.

Capital. The upper part of an alembic, likewise called the head. See Laboratory.

Caput Mortuum. A fanciful term much used by the old chemists, but now entirely rejected. It denoted the fixed residue of operations. As the earlier chemists did not examine these, they did not find any inconvenience in one general term to denote them; but the most slender acquaintance with modern chemistry must show, that it is utterly impracticable to denote, by one general term, all the various matters that remain fixed in certain degrees of heat.

Carat. See Karat.

Carbon. When vegetable matter, particularly the more solid, as wood, is exposed to heat in close vessels, the volatile parts fly off, and leave behind a black porous substance, which is charcoal. If this be suffered to undergo combustion in contact with oxigen, or with atmospheric air, much the greater part of it will combine with the oxigen, and escape in the form of gas; leaving about a two-hundredth part, which consists chiefly of different saline and metallic substances. This pure inflammable part of the charcoal is what is commonly called *carbon*; and if the gas be received into proper vessels, the carbon will be found to have been converted by the oxigen into an acid, called the carbonic. See ACID (CARBONIC).

From the circumstance, that inflammable substances refract light in a ratio greater than that of their densities, Newton inferred, that the diamond was inflammable. Experiments afterward proved this to be the fact; and as the diamond is completely dissipated by combustion in oxigen gas in a close vessel, and the product is carbonic acid, it is inferred, that the diamond is perfectly pure carbon. The quantity of the inflammable part of charcoal requisite to form a hundred parts of carbonic acid was calculated by Lavoisier to be twenty-eight parts, though by subsequent experiments he found it to be but twenty-four. From a careful experiment of Mr. Tennant, 27·6 parts of diamond, and 72·4 of oxigen formed 100 of carbonic acid: and hence, as the proportions of Lavoisier first given were then supposed to be true, he inferred the identity of diamond and the inflammable part of charcoal. Guyton-Morveau has since made experiments on some diamonds taken on board a ship from Senegal, which were deemed by the jewellers unfit to be cut, and according to him 17·88 of diamond produce 100 parts of carbonic acid. He found it become black, and apparently charred on its surface at 18° or 20° of Wedgwood, and require a heat of 30° to burn with a feeble flame. In an experiment by Mr. Francillon, too, a diamond partly consumed was found to be studded over with a substance of a metallic brilliancy, which appeared through a magnifier to be plumbago.

Thus according to Guyton diamond is the only pure carbon; and the combustible part of charcoal is an oxide of carbon, containing 36 per cent. or rather 25·5, of oxigen. Plumbago, or black lead, exclusive of the iron it contains amounting to 5 or 10 per cent., he considers as an oxide of carbon likewise, but with a very small portion of oxigen. And the coaly matter of mineral carbon, anthracite, or anthracolite, is according to him an oxide of carbon, approaching to that of plumbago.

From a number of experiments Mr. Biot has made on the refraction of different substances he has been led to form a still different opinion. According to him, if the elements of which a substance is composed be known, their proportions may be calculated with the greatest accuracy from their refractive power. Thus he finds, that the diamond cannot be pure carbon, but requires at least one fourth of hidrogen, which has the greatest refractive power of any substance, to make its refraction commensurate to its density. This assumption accounts for one of the facts advanced by Guyton-Morveau, that the diamond consumes more oxigen in combustion than charcoal.

Berthollet, on the contrary, considers charcoal as a compound of carbon with hidrogen, and containing a small quantity of oxigen. The action of heat alone expels this oxigen, with a certain portion of the hidrogen, and also of the carbon; after which, he says it ought to be deemed a combination of carbon with a small proportion of hidrogen, so retained by its affinity to the carbon, that the action of heat cannot separate it without the addition of oxigen.

From the apparently discordant facts adduced by various chemists of high authority, it cannot yet be considered as decided whether pure carbon, or the base of carbonic acid, has ever been obtained in a separate state: but as without all dispute it exists abundantly in charcoal, the mode of preparing and economical uses of which will be given under that article, and charcoal is the substance almost always employed in chemistry when carbon is wanted, we shall proceed to consider it in this form.

Well-burned charcoal is a conductor of electricity, though wood simply deprived of its moisture by baking is a nonconductor: it is likewise an excellent conductor of galvanism, but a very bad conductor of caloric, a property of considerable use on many occasions, as in lining crucibles.

It is insoluble in water, and hence the utility of charring the surface of wood exposed to that element, in order to preserve it; a circumstance not unknown to the ancients, who sometimes availed themselves of it. This preparation of timber has been proposed as an effectual preventive of what is commonly called the dry rot. It has an attraction, however, for a certain portion of water, which it retains very forcibly. Heated red-hot, or nearly so, it decomposes water; forming with its oxigen carbonic acid, or carbonous oxide, according to the quantity present; and with the hidrogen a gaseous carburet, sometimes called hidrocarbonat, and heavy inflammable air.

Charcoal is infusible by any heat. If exposed to a very high temperature in close vessels it loses little or nothing of its weight, but shrinks, becomes more compact, and acquires a deeper black colour.

Recently prepared charcoal has a remarkable property of absorbing different gasses, and condensing them in its pores, without any alteration of their properties or its own. If charcoal heated to ignition be allowed to cool without exposure to air, and the gas be then admitted to it, it will absorb it in the following proportion: one part of charcoal will absorb 2·25 times its bulk of atmospheric air immediately, and ·75 more in four or five hours. of oxigen gas about 1·8 immediately, and slowly 1 more: of nitrogen gas 1·65 immediately: of nitric oxide 8·5 very slowly: of hidrogen gas about 1·9 immediately: carbonic acid gas 14·3 immediately: a low temperature promotes the absorption. The greater part of the gas thus absorbed may be expelled unaltered by a heat below 212°, and a portion of it even by immersing the charcoal in water. If charcoal thus saturated with oxigen gas be introduced into hidrogen gas, or the contrary, water is formed, with an increase of temperature; and other affinities between the condensed bases of different gasses may be made to take place.

Charcoal has a powerful affinity for oxigen, whence its use in disoxigenating metallic oxides, and restoring their base to its original metallic state, or reviving the metal. Thus too it decomposes several of the acids, as the phosphoric and sulphuric, from which it abstracts their oxigen, and leaves the phosphorus and sulphur free. A pleasing experiment is shown by throwing finely powdered charcoal into recently prepared oximuriatic acid gas, as thus it takes fire, and falls to the bottom of the vessel in a burning shower. The alkaline and earthy salts with decomposable acids are remarkably altered by charcoal at a red heat. The sulphats are thus converted into sulphurets, the nitrats into carbonats: while others, as the muriats and fluats, remain unchanged.

Carbon is capable of combining with sulphur, and with hidrogen. With iron it forms steel; and it unites with copper into a carburet, as observed by Dr. Priestley, who called it charcoal of copper.

A singular and important property of charcoal is that of destroying the smell, colour, and taste of various substances: for the first accurate experiments on which we are chiefly indebted to Mr. Lowitz of Petersburgh, though it had been long before recommended to correct the fœtor of foul ulcers, and as an antiseptic. On this account it is certainly not a bad dentifrice. Water that has become putrid by long keeping in wooden casks is rendered sweet by filtering through charcoal powder, or by agitation with it; particularly if a few drops of sulphuric acid be added. Common vinegar boiled with charcoal powder becomes perfectly limpid. Saline solutions, that are tinged yellow or brown, are rendered colourless in the same way, so as to afford perfectly white crystals. The impure carbonat of ammonia obtained from bones is deprived both of its colour and fetid smell by sublimation with an equal weight of charcoal powder. Malt spirit is freed from its disagreeable flavour by distillation from charcoal; but if too much be used part of the spirit is decomposed. Simple maceration, for eight or ten days, in the proportion of about $\frac{1}{150}$ of the weight of the spirit, improves the flavour much. It is necessary, that the charcoal be well burned, brought to a red heat before it is used, and used as soon as may be, or at least be carefully excluded from the air. The proper proportion too should be ascertained by experiment on a small scale. The charcoal may be used repeatedly, by exposing it for some time to a red heat before it is again employed.

Charcoal is used on particular occasions as fuel, on account of its giving a strong and steady heat without smoke. It is employed to convert iron into steel by cementation. It enters into the composition of gunpowder. In its finer states, as in ivory black, lamp black, &c., it forms the basis of black paints, Indian ink, and printers' ink.—*Phil. Trans.*—*Mem. de l'Instit. Nat.*—*An. de Chim.*—*Journ. de Phys.*—*Phil. Mag.*—*Trans. of Soc. of Arts.*—*Murray's Chem.*

Carbuncle. The ancients called all red gems by this name; but the carbunculus of Pliny was the same as the oriental ruby of our jewellers. Its colour is of a deep red inclining to purple. See Ruby.

Cardamom. Neumann examined the lesser cardamom. One ounce yielded a scruple of essential oil, containing the whole of their pungency and smell, with fourteen or fifteen grains of resinous, and forty-five grains of mucilaginous extract. The spirituous tincture and extract are both grateful aromatics.

The greater cardamoms, or grains of Paradise, are more pungent, but less agreeably aromatic, and rarely if ever used, except by farriers.

Carduus Benedictus. Centaurea benedicta. Four ounces of the leaves afforded four drachms and a half of extract to alcohol: the same quantity gave out six drachms and a half of mucilaginous extract with water. The expressed juice, depurated and evaporated to the consistence of a sirup, afforded Neumann saline crystals, approaching to the nature of tartar.

Carica Papaya. Papaw tree. Every part of the papaw tree, except the ripe fruit, affords a milky juice, which is used in the Isle of France as an effectual remedy for the tape worm. In Europe, however, whither it has been sent in the concrete state, it has not answered, perhaps from some change it had undergone, or not having been given in a sufficient dose. It has been analysed by Vauquelin, and by C. L. Cadet. The concrete juice may be dried so as to be pulverable, but it attracts the moisture of the air very powerfully. It dissolves in the mouth, and excites a peculiar sensation, with a considerable discharge of saliva. It is very soluble in water, but coagulates on boiling, and is precipitated by alcohol. On distillation it gives out a great deal of carbonat of ammonia, a black fetid oil, carbonic acid gas, and carburetted hidrogen. A light,

y coal is left behind, resembling

Rouge is prepared from carthamus. For this purpose the red colour is extracted by a solution of the subcarbonat of soda, and precipitated by lemon juice, previously depurated by standing. This precipitate is dried on earthen plates, mixed with talc, or French chalk, reduced to a powder by means of the leaves of shave-grass, triturated with it till they are both very fine, and then sifted. The fineness of the powder and proportion of the precipitate constitute the difference between the finer and cheaper rouge. It is likewise spread very thin on saucers, and sold in this state for dyeing.

Carthamus has lately been analysed by Mr. Dufour, who was led to it from the difficulty he found in preparing rouge according to the directions generally given. He operated on 16 ounces troy of carthamus of Alexandria, and its products were, per cent. of moisture, 6·2; dust and sand, 3·4; vegetable albumen of a greenish yellow colour, 5·5; extract soluble only in water, consisting of yellow colouring matser, sulphat of lime, and sulphat of potash, 26·8; extract soluble both in water and alcohol, mixed with yellow colouring matter, and muriat and acetit of potash, 4·2; resin, ·3; wax of a particular kind, ·9; red colouring matter, ·5; ligneous substance, 49·6; alumine and magnesia, ·5; red oxide of iron, ·2; sand, 1·2; loss, ·7. There is great difficulty in separating the last portions of yellow matter, and the mixture of albumen occasions the red to precipitate in a flocculent form. Mr. Dufour tried various expedients to remedy this, but succeeded only by macerating carthamus, deprived of as much as possible of its yellow matter by washing in cold water, in an equal weight of water, and ·15 of carbonat of soda, for one hour only. The feculencies having subsided, he decanted the liquor, put into it some pieces of cotton, and added as much lemon juice as gave it a fine cherry colour. At the end of twenty four hours, the cotton, having taken up all the colouring matter, was rinsed in warm water three or four times; and then lixiviated for an hour in twenty times its weight of water, and a tenth of their weight of carbonat of soda. This lixivium was precipitated by lemon juice, and gave very fine red feculæ, which subsided very slowly. It is probable, that the manufacturers use acid of tartar instead of lemon juice.

Carthamus is used for dyeing silk of a poppy, cherry, rose, or bright orange red. After the yellow matter is extracted as above, and the cakes opened, it is put into a deal trough, and sprinkled at different times with pearl ashes, or rather soda well powdered and sifted, in the proportion of six pounds to a hundred, mixing the alkali well as it is put in. The alkali should be saturated with carbonic acid. The carthamus is then put on a cloth in a trough with a grated bottom, placed on a larger trough, and cold water poured on, till the large trough is filled. And this is repeated, with the addition of a little more alkali toward the end, till the carthamus is exhausted and become yellow. Lemon juice is then poured into the bath, till it is turned of a fine cherry colour, and after it is well stirred the silk is immersed in it. The silk is wrung, drained, and passed through fresh baths, washing and drying after every operation, till it is of a proper colour; when it is brightened in hot water and lemon juice. For a poppy or fire colour a slight annotta ground is first given; but the silk should not be alumed. For a pale carnation a little soap should be put into the bath. All these baths must be used as soon as they are made; and cold, because heat destroys the colour of the red feculæ.

Caryophylloides. A name given to a specimen of mica, the scales of which are concentric and perpendicular.—*Cronstedt.*

Case-Hardening. Steel when hardened is brittle, and iron alone is not capable of receiving the hardness steel may be brought to possess. There is nevertheless a variety of articles in which it is desirable to possess all the hardness of steel, together with the firmness of iron. These requisites are united in the art of case-hardening, which does not differ from the making of steel, except in the shorter duration of the process. Tools, utensils, or ornaments intended to be polished, are first manufactured in iron and nearly finished, after which they are put into an iron box, together with vegetable or animal coals in powder, and cemented for a certain time. This treatment converts the external part into a coating of steel, which is usually very thin, because the time allowed for the cementation is much shorter, than when the whole is intended to be made into steel. Immersion of the heated pieces into water hardens the surface, which is afterward polished by the usual methods. Moxon's Mechanic Exercises, p. 56, gives the following receipt:—Cow's horn or hoof is to be baked or thoroughly dried, and pulverized. To this add an equal quantity of bay salt: mix them with stale chamberley, or white wine vinegar: cover the iron with this mixture, and bed it in the same in loam, or enclose it in an iron box: lay it then on the hearth of the forge to dry and harden: then put it into the fire, and blow till the lump have a blood red heat, and no higher, lest the mixture be burned too much. Take the iron out, and immerse it in water to harden.

Cassia Fistularis. The fruit of a tree growing in Egypt and in the East Indies. It is a large cylindrical pod or cane, containing, under a hard rind, a soft pulp lodged in a number of transverse cells, with a flat roundish seed in each. Out of four drams of the dried pulp Neumann found water take up three drams fifteen grains. Alcohol took up as much, or nearly so, but acted more slowly. It is a mild purgative, and forms the basis of an electuary of the London college. It also enters into the electuary of senna, formerly called lenitive electuary.

Cassia Lignea. The bark of a tree of the same kind as the cinnamon tree. It contains an essential oil of the same flavour and qualities as that of cinnamon; but much less in quantity. Cassia is very commonly sold under the name of cinnamon, from which however its external appearance is sufficient to distinguish it. The cassia is thick, rough, and breaks crosswise without splitting; but the cinnamon is smoother, thinner, and cannot easily be broken crosswise without causing it to split into many thin fragments.

Castor. A soft grayish yellow or light brown substance found in four bags in the inguinal region of the beaver. In a warm air it grows by degrees hard and brittle, and of a darker colour, especially when dried in chimneys, as is usually done. According to Bouillon La Grange it consists of a mucilage, a bitter extract, a resin, an essential oil, in which its peculiar smell appears to reside, and a flaky crystalline matter, much resembling the adipocere of biliary calculi.

Castor is regarded as a powerful antispasmodic.

Castor Oil. An oil extracted from the seeds of the *ricinus communis*, or *palma Christi*, which contain a third or fourth of their weight of it. The oil is extracted by expression, or by gentle boiling in water. That by expression is said to become in some degree acrimonious, in consequence of the mucilage it contains. It is commonly thick and viscid, of a light amber colour, and with little smell or taste. That which has least smell, taste, and colour, is the mildest and best. If it have become acrimonious by keeping, shaking it in a bottle with a little warm water, and then pouring it off, will improve it.

Castor oil is a very useful purgative in doses of half an ounce or an ounce, operating in general very gently and speedily, if good. It should be taken floating unmixed in a glass of water.

Catechu. A brown astringent substance formerly known by the name of *Japan earth*. It is a dry extract, prepared from the wood of a species of sensitive plant, the *mimosa catechu*. It is imported into this country from Bombay and Bengal. According to Mr. Davy, who has lately analysed it, that from Bombay is of a uniform texture, red brown colour, and specific gravity 1·39: that from Bengal is more friable and less consistent, of a chocolate colour externally, but internally chocolate streaked with red brown, and gravity 1·28. The catechu from both places differs little in its properties. Its taste is astringent, leaving behind a sensation of sweetness. It is almost wholly soluble in water. Eighteen ounces of water at 52° dissolve 100 grains, leaving about $\frac{1}{14}$ of earthy matter, which was mixed with it either accidentally or by design. A considerable portion is soluble in alcohol, but this leaves behind a mucilaginous matter soluble in water. When a small quantity of water is put to a large quantity of catechu, it takes up much more of the tannin contained in it, than of the extractive matter. The extractive matter is softened by heat; and at a temperature below ignition gives out carbonic acid, carburetted hidrogen, and water holding in solution acetous acid and a little extractive matter. A light and very porous coal is left behind.

Two hundred grains of picked catechu from Bombay afforded 109 grains of tannin, 68 extractive matter, 13 mucilage, 10 residuum, chiefly sand and calcareous earth. The same quantity from Bengal, tannin 97 grains, extractive matter 73, mucilage 16, residual matter, being sand, with a small quantity of calcareous and aluminous earths, 14. Of the latter the darkest parts appeared to afford most tannin, the lightest most extractive matter. The Hindoos prefer the lightest coloured, which has probably most sweetness, to chew with the betel nut.

Of all the astringent substances we know, catechu appears to contain the largest proportion of tannin, and Mr. Purkis found, that one pound was equivalent to seven or eight of oak bark for the purpose of tanning leather.

As a medicine it has been recommended as a powerful astringent, and a tincture of it is used for this purpose, but its aqueous solution is less irritating. Made into torches with gum arabic and sugar it is an elegant preparation, and in this way is said much to assist the clearness of the voice, and to be remarkably serviceable in disorders of the throat.—*Phil. Trans.*—*Red. Obs.*

Cat's Eye. Pseudopalus. A semi-opake stone of the siliceous order, and reckoned among the gems. It is whitish, and reflects green and yellowish rays, varying according to the position of the observer. It is very hard, and is usually cut by jewellers of the figure of a plano-convex lens, and set with the convex side outwards. The best of these stones are very scarce. Bomare informs us that there was one in the cabinet of the Grand Duke of Tuscany, of one inch diameter.

Caustic (Common). A fixed alkali deprived of carbonic acid and most of its water. If the lixivium of the soap-boilers be evaporated to dryness in a silver or copper vessel, then fused in a crucible, poured out into a basin, and, when solid, cut into small pieces, it forms the common caustic. This must be kept in a close bottle, to prevent its deliquescing. When a piece of this alkali is applied to the skin, for the space of three quarters of an hour, it corrodes it, no doubt by forming a saponaceous compound with its fat parts. It was much used in making issues, before that practice was laid aside. See **Alkali.**

Caustic (Lunar). This is likewise, though improperly, called lapis infernalis. It consists of the crystals of silver obtained by solution in nitric acid, and afterward fused in a crucible. To make this preparation, very pure silver must be dissolved to saturation in nitric acid, and the crystals separated by evaporation and cooling. These are to be fused in an earthen crucible, sufficiently large to admit of the frothing and swelling that happen at the commencement of the fusion. The heat must be gentle, because the crystals are very fusible, and the acid easily decomposed and driven off. It requires, however, to be somewhat raised after the ebullition has ceased. As soon as the matter is in quiet fusion, it is to be poured into a mould, consisting of five or six small cylindrical cavities, by which it acquires the form of small pencils, and may conveniently be held in a case instead of touching it with the fingers.

Lunar caustic is black, which seems to arise from part of the acid being driven off, and a portion of the silver revived. Its causticity or action on animal substances appears to depend on the strong disposition of the silver to recover its metallic state, and consequently is a true combustion.

Causticity. All substances which have so strong a tendency to combine with the principles of organized substances, as to destroy their texture, are said to be caustic. The chief of these are the concentrated acids, pure alkalis, and the metallic salts.

Cawk. A term by which the miners distinguish the opake specimens of sulphat of barytes, or marmor metallicum.

Cement. Whatever is employed to unite or cement together things of the same or different kinds may be called a *cement*. In this sense it includes **lutes**, **glues**, and **solders** of every kind, which see; but it is more commonly employed to signify those of which the basis is an earth or earthy salt. See **Lime.** We shall here enumerate, chiefly from the Philosophical Magazine, some cements that are used for particular purposes.

Seven or eight parts of resin, and one of wax, melted together, and mixed with a small quantity of plaster of Paris, is a very good cement to unite pieces of Derbyshire spar, or other stone. The stone should be made hot enough to melt the cement, and the pieces should be pressed together as closely as possible, so as to leave as little as may be of the cement between them. This is a general rule in cementing, as the thinner the stratum of cement interposed, the firmer it will hold.

Melted brimstone used in the same way will answer sufficiently well, if the joining be not required to be very strong.

It sometimes happens, that jewellers, in setting precious stones, break off pieces by accident: in this case they join them so that it cannot easily be seen, with gum mastic, the stone being previously made hot enough to melt it. By the same medium cameos of white enamel or coloured glass are often joined to a real stone as a ground, to produce the appearance of an onyx. Mastic is likewise used to cement false backs, or doublets, to stones, to alter their hue.

The jewellers in Turkey, who are generally Armenians, ornament watch-cases and other trinkets with gems by glueing them on. The stone is set in silver or gold, and the back of the setting made flat to correspond with the part to which it is to be applied. It is then fixed on with the following cement. Isinglass, soaked in water till it swells up and becomes soft, is dissolved in French brandy, or in rum, so as to form a strong glue. Two small bits of gum galbanum, or gum ammoniacum, are dissolved in two ounces of this by trituration: and five or six bits of mastic, as big as pease, being dissolved in as much alcohol as will render them fluid, are to be mixed with this by means of a gentle heat. This cement is to be kept in a phial closely stopped; and when used, it is to be liquefied by immersing the phial in hot water. This cement resists moisture.

A solution of shell lac in alcohol added to a solution of isinglass in proof spirit makes another cement that will resist moisture.

So does common glue melted without water with half its weight of resin, with the addition of a little red ochre to give it a body. This is particularly useful for cementing hones to their frames.

If clay and oxide of iron be mixed with oil, according to Mr. Gad of Stockholm they will form a cement, that will harden under water.

A strong cement, insoluble in water, may be made from cheese. The cheese should be that of skimmed milk, cut into slices, throwing away the rind, and boiled till it becomes a strong glue, which however does not dissolve in the water. This water being poured off, it is to be washed in cold water, and then kneaded in warm water. This process is to be repeated several times. The glue is then to be put warm on a levigating stone, and kneaded with quicklime. This cement may be used cold, but it is better to warm it; and it will join marble, stone, or earthen-ware, so that the joining is scarcely to be discovered.

Boiled linseed oil, litharge, red lead, and white lead, mixed together to a proper consistence, and applied on each side of a piece of flannel, or even linen or paper, and put between two pieces of metal before they are brought home, or close together, will make a close and durable joint, that will resist boiling water, or even a considerable pressure of steam. The proportions of the ingredients is not material, but the more the red lead predominates the sooner the cement will dry, and the more the white lead the contrary. This cement answers well for joining stones of any dimensions.

The following is an excellent cement for iron, as in time it unites with it into one mass. Take 2 ounces of muriat of ammonia, 1 of flowers of sulphur, and 16 of cast iron filings or borings. Mix them well in a mortar, and keep the powder dry. When the cement is wanted for use, take one part of this mixture, twenty parts of clear iron borings or filings, grind them together in a mortar, mix them with water to a proper consistence, and apply them between the joints.

Powdered quicklime mixed with bullock's blood is often used by coppersmiths, to lay over the rivets and edges of the sheets of copper in large boilers, as a security to the junctures, and also to prevent cocks from leaking.

Six parts of clay, one of iron filings, and linseed oil sufficient to form a tough paste, make a good cement for stopping cracks in iron boilers.

Temporary cements are wanted in cutting, grinding, or polishing optical glasses, stones, and various small articles of jewellery, which it is necessary to fix on blocks, or handles, for the purpose. Four ounces of resin, a quarter of an ounce of wax, and four ounces of whiting made previously red hot, is a good cement of this kind; as any of the above articles may be fastened to it by heating them, and removed at pleasure in the same manner, though they adhere very firmly to it when cold. Pitch, resin, and a small quantity of tallow, thickened with brick-dust, is much used at Birmingham for these purposes. Four parts of resin, one of bees wax, and one of brick-dust, likewise make a good cement. This answers extremely well for fixing knives and forks in their hafts; but the manufacturers of cheap articles of this kind too commonly use resin and brick dust alone. On some occasions, on which a very tough cement is requisite, that will not crack though exposed to repeated blows; as in fastening to a block metallic articles, that are to be cut with a hammer and punch; workmen usually mix some tow with the cement, the fibres of which hold its parts together.

Cement Copper. Copper precipitated from vitriolic waters by iron. The name is said to be derived from a vitriolic water in Hungary called Ziment.

Cementation. A chemical process, which consists in surrounding a body in the solid state with the powder of some other bodies, and exposing the whole, for a time, in a closed vessel, to a degree of heat not sufficient to fuse the contents. Thus iron is converted into steel by cementation with charcoal: green bottle glass is converted into porcelain by cementation with sand, &c. See Iron (Porcelain).

The effects of cementation appear to be chiefly produced by one or more of the bodies being converted into vapour, and acting upon the others. The change in the solid is chiefly attended to. The powder is called by the name of a cement.

Centaury. The leaves of the lesser centaury contain a bitter substance, soluble in water and in alcohol. The green colour of the plant resides in the resinous part, being extracted by alcohol, but not by water. It affords nearly ½ of spirituous and ⅔ of watery extract.

Cerite. Messrs Hisinger and Berzelius, analysing the pseudotungsten of Bastnas, discovered in it a new metallic substance; and their discovery has been fully confirmed by Vauquelin, who has since examined it in company with Tassaert and Bergman. The discovery of a new planet, which has received the name of Ceres, about the same time, induced Messrs. H. and B. to give the metal the name of *cerium*, and to alter that of the mineral in which it was found to *cerite*.

Cerite is semitransparent, or nearly opake, of a slight rosy, or carnation tinge, and sometimes, though rarely, yellowish. It is in some specimens sufficiently hard to scratch glass, strikes fire with difficulty, is of no determinate crystalline figure, and in specific gravity 4·530. Its fracture is compact, unequal, angular, and a little shining. Its powder is grayish, becomes yellow by calcination, and loses from six to twelve per cent. Its component parts, as given by Messrs. H. and B. are silex 23, carbonat of lime 5·5, oxide of iron 22, and oxide is of cerium after calcination more than 50. The increase of weight they ascribe to the oxigen absorbed. The purest specimens analysed by Vauquelin gave oxide of cerium 63, silex 17·5, oxide of iron 2, lime 3 or 4, water 12. Other specimens he found mixed with green actinote, and cupreous pyrites.

To obtain the oxide of the new metal the cerite is calcined, pulverized, and dissolved in nitromuriatic acid. The filtered solution, being neutralized with pure potash, is to be precipitated by tartrit of potash; and the precipitate, well washed and afterward calcined, is oxide of cerium.

Cerium is susceptible of two stages of oxidation: in the first it is white, and this by calcination becomes of a fallow red.

The white oxide exposed to the blowpipe soon becomes red, but does not melt, or even agglutinate. With a large proportion of borax it fuses into a transparent globule.

The white oxide becomes yellowish in the open air, but never so red as by calcination, because it absorbs carbonic acid, which prevents its saturating itself with oxigen, and retains a portion of water, which diminishes its colour.

Alkalis do not act on it: but caustic potash in the dry way takes part of the oxigen from the red oxide, so as to convert it into the white without altering its nature.

Equal parts of the sulphuric acid and red oxide, with four parts of water, unite by the assistance of heat into a crystalline mass; which may be completely dissolved by adding more acid, and heating them together a long time. This solution yields by gentle evaporation small crystals, some of an orange, others of a lemon colour. The sulphat of cerium is soluble in water only with an excess of acid. Its taste is acid and saccharine. The sulphuric acid combines readily with the white oxide, particularly in the state of carbonat. The solution has a saccharine taste, and readily affords white crystals.

Nitric acid does not readily dissolve the red oxide without heat. With an excess of acid white deliquescent crystals are formed, which are decomposable by heat. Their taste is at first pungent, afterward very sugary. The white oxide unites more readily with the acid.

Muriatic acid dissolves the red oxide with effervescence. The solution crystallizes confusedly. The salt is deliquescent, soluble in an equal weight of cold water, and in three or four times its weight of alcohol. The flame of this solution, if concentrated, is yellow and sparkling; if not, colourless; but on agitation emits white, red, and purple sparks.

The oxigenated muriatic acid does not dissolve the red oxide, but does the white, without parting with any of its oxigen.

Carbonic acid readily unites with the oxide. This is best done by adding carbonat of potash to the nitric or muriatic solution of the white oxide, when a light precipitate will be thrown down, which on drying assumes a shining silvery appearance.

Sulphuretted hidrogen does not combine with cerium; but hidrosulphurets will precipitate from its solutions any iron that may be mixed with it.

The white oxide unites directly with tartarous acid, but requires an excess to render it soluble.

Vauquelin made several unsuccessful attempts to reduce the metal: however, having mixed tartrit of cerium with a very small quantity of oil and lampblack, he put it into a crucible of charcoal bedded in sand in an earthen crucible, and heated it for an hour and a half in a forge furnace. A metallic globule scarcely as big as a pin's head was left in the coal, but no other trace of cerium could be discovered, though the sand was examined with the utmost care.

None of the simple acids acted on this globule; but it dissolved, though with extreme difficulty, in aqua regia, after being triturated. The solution was reddish, and exhibited unequivocal marks of iron; but it likewise gave evident signs of the existence of cerium, both by its saccharine taste, and by the white precipitates which tartrit of potash and oxalat of ammonia threw down. The metallic globule too was harder, whiter, much more fragile, and more scaly in its fracture, than pure cast iron.

As from these experiments cerium appeared to be volatile, Vauquelin attempted to sublime it. With this view he heated a similar mixture, with the addition of borax, in a porcelain retort, to the neck of which a porcelain tube was adapted. But whether the heat were insufficient, or the metal were volatilized without adhering to the neck of the retort, no trace of sublimate was found. Several very small metallic globules remained in the retort, adhering to a black varnish formed by the borax; and there were some about the upper part of the vessel, to which they had been raised apparently by the fire: but all together would not have amounted to a fiftieth part of the cerium employed.—*Annal. de Chim.* —*Van Mons's Journ.*

Cerium. A metal lately discovered in the pseudotungsten of Bastnas, or cerite. See the preceding article.

Ceruse, or White Lead. An oxide of lead produced by exposing this metal to the vapours of vinegar. To prepare this colour, the lead is cast into plates about one twentieth part of an inch thick, four or five inches wide, and two feet long. These are rolled up in a spiral form, in such a manner that the space of half an inch is left between each revolution. They are then placed in earthen pots, which have three projections within, to prevent them from resting on the bottom. Some good vinegar is then poured in, so as to reach no higher than the lower edge of the leaden spiral, and the pots are then buried in dung beneath sheds. A great number of these are disposed beside each other, each pot being covered with a leaden plate and boards, by which contrivance the number of pots is multiplied by placing them above each other in strata. At the expiration of a month or six weeks they are taken out, and the white lead separated by unrolling the coils. It is then ground in mills, and dried in the shade for use.

Some writers distinguish this oxide by the name of white lead, and apply the term ceruse to denote a mixture of white lead and chalk.

Lead is found native in the form of ceruse, or the white oxide.

Ceruse of Antimony. A white oxide of this semimetal, which separates from the water in which diaphoretic antimony has been washed.

Chalcedony, or White Agate. A flint of a white colour, resembling milk diluted with water, and more or less opake, with veins, circles, or spots. It is said to be softer than the onyx, but much harder than the agates of the same colour as the onyx. Bergman observes, that it varies greatly in specific gravity; from 2·5 to 4·6. He found the chalcedony of Ferro to contain 84 parts silex, and 16 alumine.

Chalk. A very common species of calcareous earth, of an opake white colour, very soft, and without the least appearance of a polish in its fracture. Its specific gravity is from 2·4 to 2·6, according to Kirwan, who likewise informs us that this substance contains more carbonic acid than any other variety of the calcareous class; generally about forty per cent. It contains a little siliceous earth, and about two per cent. of clay. Some specimens, and perhaps most, contain a little iron, and Bergman affirms that muriat of lime, or magnesia, is often found in it; for which reason he directs the powder of chalk to be several times boiled in distilled water, before it is dissolved for the purpose of obtaining pure calcareous earth.—*Sciag. Regni Min.* § 92.

Chalk (Red). This is a clay coloured by the oxide of iron, of which it contains from 16 to 18 parts in the hundred, according to Rinman.

Chalk (Spanish). The soap rock, or lapis ollaris, is frequently distinguished by this name.

Characters (Chemical). Language in its usual construction is very far from being capable of expressing our conceptions with the rapidity and perspicuity necessary for the adequate communication of ideas. Writing is still slower and less perfect. But as the language and the writing we possess are capable of supplying our grosser and more immediate wants, it is much to be feared, that neither the one nor the other will ever be carried to those degrees of perfection, of which they are certainly susceptible. A few attempts have nevertheless been made from time to time; but they have in general been frustrated by the indolence of the multitude, who are at all times more disposed to use a bad instrument, than take the trouble to learn the use of a good one. The chemical characters are, in some measure, an instance of this. They were invented by the earlier chemists, probably with no other view than to save time in writing the names of substances that frequently occurred, in the same manner as we avoid repetitions by the use of pronouns. But the moderns seem to have considered them as relics of alchemistical obscurity, and have almost totally rejected their use, without inquiring whether they may not possess advantages far superior to those of the common literal enunciation.

We need not have recourse to the remote field of Chinese literature, to show how admirably the simplicity, relative position, and connection of characters are calculated to expreſs ideas at one glance of the eye, with a degree of accuracy and precision not to be obtained by the use of many written words. Neither need we recur to the science of algebra, where by the use of characters the mind receives the proof, and assents to propositions almost instantaneously, which would have required a long series of verbal deductions in any other way. Our own science, chemistry, will afford us instances of the most striking nature. The tables at the end of Bergman's Essay on the Affinities exhibit, in the most speedy and intelligible manner, the greater part of many volumes of chemical results; and I know, from my own experience, that it is easy, by a simple combination of chemical and algebraical characters, to write the whole contents of any chemical work in the small margin usually left by the printer; and that in a manner so full, clear, and perspicuous, that whole pages may be read and understood in a few seconds. This will be readily allowed by any chemist, who will make the trial, and will be done with ease by those who are acquainted with the characters and methods of the two sciences; for which reason I hope to be acquitted of the contemptible spirit of reserve, when I say, that the limits of the present work, and a wish to pursue the subject a little further, prevent me from entering into it at present.

Characters are either entirely arbitrary, or they have some resemblance to the idea they represent. The latter property is naturally aimed at, where it can be obtained, because it cannot but tend to assist the memory. Thus a number of dots were used to denote sand or powder; the figure of a retort, to denote the retort, &c.; and the combination of characters is used to denote similar combinations of the substances they represent. Very little of system appears in the ancient characters of chemists: the characters of Bergman are chiefly grounded on the ancient characters, with additions and improvements. But the characters of Hassenfratz and Adet are systematical throughout. The two former are exhibited in Plate III, and the latter in Plate IV.

Charcoal. When vegetable substances are exposed to a strong heat in the apparatus for distillation, the volatile principles fly off, but combustion does not take place for want of air. The fixed residue is the inflammable substance called charcoal. For general purposes, wood is converted into charcoal by building it up in a pyramidal form, covering the pile with clay or earth, and leaving a few air-holes, which are closed as soon as the mass is well lighted; and by this means the combustion is carried on in an imperfect manner. In the forest of Benon, near Rochelle, great attention is paid to the manufacture, so that the charcoal made there fetches 25 or 30 per cent. more than any other. The wood is that of th black oak. It is taken from ten to fifteen years old, the trunk as well as the branches cut into billets about four feet long, and not split. The largest pieces, however, seldom exceed six or seven inches in diameter. The end that rests on the ground is cut a little sloping, so as to touch it merely with an edge, and they are piled nearly upright, but never in more than one story. The wood is covered all over about four inches thick with dry grass or fern, before it is enclosed in the usual manner with clay; and when the wood is charred half a barrel of water is thrown over the pile, and earth to the thickness of five or six inches is thrown on, after which it is left four-and-twenty hours to cool. The wood is always used in the year in which it is cut.

In charring wood it has been conjectured, that a portion of it is sometimes converted into a pyrophorus, and that the explosions that happen in powder-mills are sometimes owing to this.

Charcoal is black, sonorous, and brittle, and in general retains the figure of the vegetable it was obtained from. If, however, the vegetable consist for the most part of water or other fluids, these in their extrication will destroy the connection of the more fixed parts. In this case the quantity of charcoal is much less than in the former. The charcoal of oily or bituminous substances is of a light pulverulent form, and rises in soot. This charcoal of oils is called lamp-black. A very fine kind is obtained from burning alcohol.

Turf or peat has been charred lately in France, it is said, by a peculiar process, and, according to the account given in Sonnini's Journal, is superior to wood for this purpose. Charcoal of turf kindles slower than that of wood, but emits more flame, and burns longer. It boiled a given quantity of water four times, while an equal weight of wood charcoal boiled the same quantity but once. In a goldsmith's furnace it fused eleven ounces of gold in eight minutes, while wood charcoal required sixteen. The malleability of the gold, too, was preserved in the former instance, but not in the latter. Iron heated red-hot by it in a forge was rendered more malleable.

From the scarcity of wood in this country pitcoal is charred, and much used instead of charcoal by the name of Coak.

The residue of charcoal burned in the open air consists of a small quantity of ashes, which contain alkaline and neutral salts. The vegetable alkali is found in the ashes of various plants, and is known under the names of pot-ash, pearl-ash, cendres gravelées, &c. It is not easy to purify it by a cheap process from the neutral salts it may be contaminated with. Soda is found in the ashes of none but marine plants. The neutral salts found in the ashes of vegetables are sulphats of potash, soda, and lime, muriat of soda, and acetat of potash. Oxides of iron and manganese, with an earthy substance, compose the insoluble residue. For the chemical properties of charcoal, see CARBON.

CHATOYANT. A term applied, by the French, to denote that affection of semitransparent stones, by which their colours vary according to the position of the eye of the observer. We have not a correspondent English word; for which good reason this word has been adopted by several writers on mineralogy.

CHAY, OR CHAYA-ROOT. This is the root of the *Oldenlandia umbellata*, which grows wild on the coast of Coromandel, and is likewise cultivated there for the use of the dyers and calico-printers. It is used for the same purposes as madder with us, to which it is said to be far superior, giving the beautiful red so much admired in the Madras cottons. The Indian method of using it is very operose: but a piece of cotton being prepared by a species of galling, or boiling in a decoction of powdered *hurr*, the astringent fruit of the *myrobolana citrona*; then washed and dried; a design pencilled on it with acetit of alumine in a solution of gum arabic; the cloth again rinsed in cold water, and lastly boiled with two ounces of the chay root coarsely powdered, in a quart of water, about half an hour; after it was well rinsed in cold water and dried, the design appeared of a good bright red, which was much improved by washing with soap and water, and drying in the sun.—*Trans. of Soc. of Arts.*

CHEESE. It is a well known fact, that milk consists of butter, cheese, a saccharine matter called sugar of milk, and a small quantity of common salt, together with much water. Our chemical knowledge of this fluid, before the time of Scheele, consisted of little more than the common operations of the dairy, and the results of the inaccurate method of decomposition by fire.

If any vegetable or mineral acid be mixed with milk, the cheese separates, and, if assisted by heat, coagulates into a mass. The quantity of cheese is less when a mineral acid is used. Neutral salts, and likewise all earthy and metallic salts, separate the cheese from the whey. Sugar and gum arabic produce the same effect. Caustic alkalis will dissolve the curd by the assistance of a boiling heat, and acids occasion a precipitation again. It does not appear, however, that the cheesy part is dissolved in milk by means of an alkali, as was ascertained by adding an acid to milk, which ought to have produced a neutral salt, if this had been the case, but did not. The true reason why acids cause the cheesy matter to separate is, that they combine with it, and form a compound much less soluble in water than the cheese itself. Eight parts of water dissolved one part of the curd precipitated by a mineral acid; so much of the acid having been previously mixed with the water as to give it a sour taste. Vegetable acids have very little solvent power upon curd. This accounts for a greater quantity of curd being obtained when a vegetable acid is used. But what answers best is rennet, which is made by macerating in water a piece of the last stomach of a calf, salted and dried for this purpose.

Scheele thinks that neutral salts, gums, and sugar produce a coagulation of curd by virtue of their stronger attraction for the water.

He observed, that cheese has a considerable analogy to albumen, which it resembles in being coagulable by fire and acids, soluble in ammonia, and affording the same products by distillation or treatment with nitric acid. There are however certain differences between them. Rouelle observed likewise a striking analogy between cheese and the gluten of wheat, and that found in the feculæ of green vegetables. By kneading the gluten of wheat with a little salt and a small portion of a solution of starch, he gave it the taste, smell, and unctuosity of cheese, so that after it had been kept a certain time, it was not to be distinguished from the celebrated Rochefort cheese, of which it had all the pungency. This caseous substance from gluten, as well as the cheese of milk, appears to contain acetit of ammonia, after it has been kept long enough to have undergone the requisite fermentation, as may be proved by examining it with sulphuric acid, and with potash. The pungency of strong cheese, too, is destroyed by alcohol.

Darcet has recommended cheese as a substitute for glue, or size, in distemper painting. He takes 144 parts of new cheese, or curd well drained, and beats it in a mortar to the consistence of an ointment; with this he mixes 7 parts of fine powder of lime just slaked with as little water as possible: and to these he adds 280 parts of whiting and 2 of finely powdered charcoal, previously mixed with 80 parts of water. When it is used, about 210 parts more of water must be added, or as much as will dilute it sufficiently for working. Red or yellow ochre, or lamp-black, may be mixed with the curd and lime instead of the whiting and charcoal directed above, but of these only 200 parts should be taken.

With quicklime, and perhaps still better with calcined barytes or strontian, cheese makes an excellent cement for porcelain. See CEMENT.

CHEMISTRY. It is usual with writers to define the science of chemistry, before they proceed to treat on it. It seldom happens, however, that descriptions of very complicated objects can possess that neatness and precision, which are essential to a good definition. Chemistry was formerly consi-

IE. An acidifiable metal, first dis-
n the red lead ore of Siberia by
n in 1797, and so named from the
colours it affords. In this ore it
the acid state, forming chromat of
romat of alumine is the colouring
f the spinel ruby; as the green
chrome is of the Peruvian emerald:
green oxide is united with lead in the green crystals commonly found with the red lead ore of Siberia. Beside these it has been found in the stones called meteoric by Laugier and Thenard, and combined with iron in an ore dug near Toulon.

If the red lead ore be treated with muriatic acid it will be totally dissolved, forming a fine deep red solution. On evaporating the liquor the muriat of lead will fall to the bottom, till the supernatant liquor contains only the oxide of chrome, which gives it a fine green colour, and may be obtained by further evaporation. By heating either this oxide, or the chromic acid, for the mode of obtaining which see ACID (CHROMIC), with charcoal, the metal will be reduced, and found in a grayish white mass, formed of a number of needles crossing each other. It is very hard, very brittle, and extremely difficult of fusion. With oxigen it unites in three different proportions: in its first stage of oxidation it is green, in the second brown, and in the third it is the ruby-coloured acid.

Gmelin precipitated the green oxide from its solution in muriatic acid by means of zinc, prussic acid, sulphat of potash, carbonat of potash, and potash alone. The latter threw it down of a mountain blue colour; and this precipitate fused with saline substances into a green mass. As it is very soluble in saline fluxes, he found it difficult to fuse into a metallic button by their means, without precipitating it, while in fusion by means of zinc. The button thus obtained, when fused with borax, rendered it green.—*Annales de Chimie.—Philos. Mag.—Fourcroy.*

CHRYSOCOLLA. The Greek name for Borax; which see. The ancients likewise used it to denote Mountain Green, Viride Montanum.

CHRYSOLITE. The oriental chrysolite and peridot are the same gem. It becomes electric by being rubbed: its form is prismatic, of six and sometimes of five striated faces. It is found in the East Indies, Brazil, Bohemia, Saxony, and Spain; in Bourbon and Auvergne in France; and in Derbyshire in England. Some are likewise found with volcanic lavas, as in the Vivarais, where some large lumps have been seen of twenty and thirty pounds weight. But it is remarkable, that some of these chrysolites are partly decomposed into an argillaceous substance.

However, all chrysolites are far from being of the same kind: the oriental ones differ only on account of their green hue, from those sapphires, topazes, and rubies of the same denomination. These do not lose their colour or their transparency in the fire: but the chrysolite either becomes opake by a strong heat, or is entirely fusible; and it phosphorises in the instant it melts, like the basis of alum and gypseous spar: with borax it produces a thin colourless glass.

Its specific gravity is between 3·600 and 3·700, according to Brisson; and that of the Spanish chrysolite 3·0989.

Its substance is lamellated in the direction of the axis of its primitive form; but the chrysolite from Saxony is foliated in a perpendicular position to the same axis.

The chrysolite of the ancients was the same gem which is now called topaz. The name of itself indicates, that it must have been so; and Pliny very plainly says, (b. 37. c. 9.) that the colour of the chrysolite is yellow like gold.

Chrysoprase. Mr. Achard has made the analysis of chrysoprase from Koseinitz in Silesia, which lost its colour and transparency in the fire, becoming cracked and white in its surface, but without melting. Its powder, either with carbonat of potash or soda, nitre, or borax, gave a diaphanous glass; and with other substances produced opake masses of different colours.

The chrysoprase is of a green colour, deeper than the chrysolite, but with a yellowish tinge, inclining to blue, like the green leek, as Pliny says (b. 37. c. 8). Mr. Achard says, that it never is found crystallized, and that it is semitransparent. Mr. Romé de Lisle reckons it among the quartz; and says, that its colour is owing to the mixture of cobalt, as it gives a fine blue glass when fused with borax, or with fixed alkali. But Mr. Achard found the glass of a deep yellow, when the fusion was made with borax; and that it really contains some oxide of copper instead of cobalt. Mr. Dutens says, that some gold has been found in this kind of stone: but this last, in all probability, belongs to some other class of substances, viz. to the vitreous spars.

Cimolite, or Cimolian Earth. The *cimolia* of Pliny, which was used both medicinally and for cleaning cloths by the ancients, and which has been confounded with fuller's earth and tobaccopipe clay, has lately been brought from Argentiera, the ancient Cimolus, by Mr. Hawkins, and examined by Klaproth.

It is of a light grayish white colour, acquiring superficially a reddish tint by exposure to the air; massive; of an earthy, uneven, more or less slaty fracture; opake; when shaved with a knife, smooth and of a greasy lustre; tenacious, so as not without difficulty to be powdered or broken; and adhering pretty firmly to the tongue. Its specific gravity is 2. It is immediately penetrated by water, and develops itself into thin laminæ of a curved slaty form. Triturated with water it forms a pappy mass; and 100 grains will give three ounces of water the appearance and consistence of a thickish cream. If left to dry after thus ground, it detaches itself in hard bands, somewhat flexible, and still more difficult to pulverise than before.

It appeared on analysis to consist of silex 63, alumine 23, oxide of iron 1·25, water 12.

Ground with water, and applied to silk and woollen greased with oil of almonds; the oil was completely discharged by a slight washing in water, after the stuffs had been hung up a day to dry, without the least injury to the beauty of the colour. Mr. Klaproth considers it as superior to our best fuller's earth; and attributes its properties to the minutely divided state of the silex, and its intimate combination with the alumine. It is still used by the natives of Argentiera for the same purposes as of old.

According to Olivier the island of Argentiera is entirely volcanic, and the cimolian earth is produced by a slow and gradual decomposition of the porphyries, occasioned by subterranean fires. He adds, that he collected specimens of it in all the states through which it passes.—*Klaproth's Essays.* —*Mem. de l'Institut.*

Cinchona. Peruvian Bark. The cinchona officinalis Linn. which furnishes this bark, is generally about fifteen feet high and six inches thick, somewhat resembles our cherry-tree, grows promiscuously in forests, particularly in the hilly parts of Quito in Peru, and is spontaneously propagated from its seeds.

The bark has some odour, to most people not unpleasant; and very perceptible in the distilled water, in which floating globules, like essential oil, have been observed. Its taste is bitter and astringent, accompanied with a degree of pungency, and leaving a considerable lasting impression on the tongue.

Two species are mentioned, viz. the coloured and the white. The coloured includes the pale, the red, the yellow, and the knotty; their bark being coloured, having the cinchona taste and smell, and the trees having very smooth leaves and purplish flowers. The white includes four varieties, their bark being of a whitish colour, with very little taste or smell: the trees have broad hairy leaves, and very fragrant flowers with hairs on the inside.

The proper red bark and one of the white kind have been found in the province of Santa Fé.

The cinchona Caribbæa Linn., cinchona Jamaicensis Phil. Trans. vol. lxxvii. p. 11, is called the seaside beech in Jamaica, and grows from 20 to 40 feet high. The white, furrowed, thick outer bark is not used; the dark brown inner bark has the common flavour, with a mixed kind of taste, at first of horseradish and ginger, becoming at last bitter and astringent. It seems to give more extractive matter than the cinchona officinalis. Some of it was imported from St. Lucia, in consequence of its having been used with advantage in the army and navy during the last war. The fresh bark is found to be considerably emetic and ca-

According to Deschamps of Lyons, cinchona contains a considerable quantity of a calcareous salt, which he calls cinchonat of lime. From 12 lbs. of yellow bark, which affords the most, he obtained regularly eleven drachms of this salt. He obtained it by simply infusing this quantity of bark 24 hours first in 50 quarts of water, then in 30, and afterward in 20; mixing and filtering these infusions; evaporating to about half, filtering again, and washing out any salt that may have remained on the filters; and then evaporating the filtered liquor and washings to 6 or 7 quarts. The filtering, washing, and evaporation were then repeated, till the liquor acquired a sirupy consistence; and this being left to stand in a cool place for a fortnight, the salt was found crystallized among the extractive matter. Being purified by washing, dissolving and recrystallizing, it will be obtained in white laminæ, truncated at their extremities, and adhering obliquely to one another. This salt is not soluble in alcohol, and therefore may be obtained, perhaps with less difficulty, from cinchona of which the resin has been extracted.

Mr. Seguin has found in cinchona a principle that precipitates solution of tannin, but neither that of gelatine, nor of sulphat of iron. This he considers as pure gelatine, and ascribes to it the febrifuge properties of bark. To confirm this opinion, he adds, that he has cured thirty-seven patients, and a committee of physicians at Paris have cured a great many more, with gelatine alone. It was given in somewhat larger doses, however, than could have been contained in any reasonable quantity of cinchona, namely from 2 drams to 32, according to the age and circumstances of the patient, dissolved in water, and taken at once when the fit was coming on.

Dr. And. Duncan, jun. however, has made experiments tending to show, that cinchona does not contain any gelatine; though he found in it a principle, which like gelatine indeed precipitates tannin, but does not form a jelly with water, is not precipitated from it by carbonat of potash, and is soluble in alcohol. Considering it as a peculiar substance, he calls it cinchona.—*Ann. de Chim.—Bulletin des Sciences.—Nich. Journal.*

Cinchonin. See the preceding article.

Cinis. According to Dr. Mitchill of New York, the greater part of the residuum of lixiviated wood ashes consists of a peculiar earth, which he would distinguish by this name. In America it is much esteemed as a manure, thrown over barren land at the rate of twelve loads to an acre and ploughed in, as its fertilizing effects both for grass and corn are very great, and perceptible from seven to twenty years.—*Trans. of the Board of Agriculture.—Phil. Mag.*

Cinnabar. An ore of mercury, consisting of that metal united with sulphur.

This combination is also made by art. The native cinnabar is of different shades, from yellowish to a deep red, and even black. It is found either in hard or friable masses, irregularly figured or crystallized in cubes, sometimes though rarely transparent, and its texture is either radiated, striated, scaly, or granular. One hundred parts contain pretty regularly eighty parts mercury and twenty sulphur. In closed vessels it sublimes by heat, but in open vessels it is decomposed.

The principal cinnabar mines which are wrought in Europe are those of the Palatinate, and those of Spain. In the Palatinate the ore is decomposed by mixing it with one third of its weight of lime, and distillation in iron cucurbits one inch thick, three feet nine inches long, one foot wide, with an aperture of five inches. These vessels are disposed in a gallery; forty-eight being arranged in two parallel lines, a second row above the first. An earthen pot is one third part filled with water, adapted to the neck of each cucurbit, and accurately luted on. The gallery is heated by a fire lighted at the two ends, and several apertures, formed in the upper part, serve the purpose of chimneys. The heat is kept up for ten or twelve hours before the process is finished.

The above process was also followed at Almaden in Spain, till the year 1647, when the following was adopted on account of its greater simplicity and economy. The furnace is twelve feet high, and four feet and a half diameter within. At the distance of five feet and a half from the ground is an arched floor, upon which the ore is deposited, and a fire is kindled in the ash-hole. The sublimed mercury escapes through twelve apertures, formed in the upper part of the laboratory. To these apertures rows of aludels inserted one in the other are adjusted, and disposed parallel upon a terrace, which terminates in a small building separated into as many chambers as there are files of aludels. Each chamber has a cavity in the middle, to receive the small quantity of mercury which may arrive to that distance.

Every furnace contains two hundred quintals of cinnabar, and the fire is kept up for three days. The sulphur which burns is disengaged in the form of sulphureous acid, and escapes through small chimneys made in each chamber. Every repetition of the process affords from twenty-five to sixty quintals of mercury.

The mine of Almaden has been wrought from time immemorial. Its veins are from three to fourteen feet in breadth; and their breadth is even larger where they join.

Artificial cinnabar is known in commerce by the name of vermilion, and ought to be used in all cases wherein this compound is meant to be applied to medical purposes, on account of its greater purity. The manufacture of this pigment has long been in the hands of the Hollanders, who kept it a secret; and as there is some difficulty in perfectly succeeding in the process, chemical writers have given various methods of performing it, most of which, according to Mr. Tuckert, are inaccurate. This gentleman has given a full account of the method used at Amsterdam, which I find extracted from Crell's Chemical Journal, and inserted in the fourth volume of the Annales de Chimie. It is as follows:

The manufactory, at which Mr. Tuckert several times assisted in the preparation of artificial cinnabar, is without the Utrecht port at Amsterdam, and is one of the most considerable in Holland. Forty-eight thousand pounds of vermilion are annually made in three furnaces by four workmen, beside other mercurial preparations.

The ethiops mineral is first prepared by mixing together 150 pounds of sulphur with 1080 pounds of pure mercury, and then exposing the mixture to a moderate heat in a flat-bottomed polished iron vessel, one foot in depth, and two feet and a half in diameter: its form is that of a chocolate machine. Mr Tuckert does not enter into the particular manipulations of the Hollanders in this part of the process, because the methods of producing the black combination of mercury with sulphur are well known.

The mercurial ethiops thus prepared is in the next place pounded, in order that it may more readily be put into small earthen bottles, capable of holding each about 24 ounces of water. Thirty or forty of these bottles are filled to be in readiness for the subsequent operation.

In the next place three large pots, or sublimatory vessels, made of clay and very pure sand, are taken. These vessels are previously covered with a coating of lute, which is suffered to become perfectly solid and dry before the vessel is used. Mr. Tuckert refers to a German translation of a work of Mr. Machy for the figure of these vessels, as well as for the composition of the lute. As we have not that translation, it is impossible for us to give any further information on these heads than may be gathered from the rest of his memoir. These pots are placed over three furnaces, upon iron circles. The sublimatory vessels may be of different sizes, and the furnaces are constructed in such a manner as that the flame circulates freely round the vessels to two thirds of their height.

When the vessels are duly placed in their furnaces, a moderate fire is first lighted, which is gradually raised until they become red hot. The fuel is turf, or rather peat, commonly used throughout the United Provinces. As soon as the vessels are red hot, a bottle of the ethiops is poured into the first, another into the second, and another into the third. In the subsequent progress of the operation, two, three, and perhaps more bottles may be poured in at a time; but this depends on the strength of the inflammation exhibited by the ethiops after its introduction, the flame of which sometimes rises to the height of four, and even six feet. When this is a little diminished, the mouth of the vessel is covered with a plate of iron, one foot square, and an inch and a half thick, which perfectly closes it. In this way, during thirty-four hours, the whole of the prepared matter is introduced into the three pots; that is to say, for each pot three hundred and sixty pounds of mercury, and fifty of sulphur.

After all the ethiops has been introduced, the fire is duly kept up; and when the whole sublimation has taken place, it is suffered to go out; which requires thirty-six hours from first to last. The workmen know when the fire is too strong or too weak by the appearance of the flame when the iron cover is taken off: if too strong, the flame rises to the height of several feet; if, on the contrary, it be too weak, the flame barely appears playing about the edges of the pot The proper degree of heat is when, upon taking off the cover, a brisk flame appears, but does not rise more than three or four inches above the opening.

In the last thirty-six hours, the mass was stirred every quarter or half hour with an iron rod, to accelerate the sublimation. The workmen do this with so much courage, that Mr. Tuckert was every time apprehensive they would fall into the vessels.

When the whole is cool, the vessels are taken out by means of the iron circles, which prevent their breaking. The cinnabar is taken out by breaking the vessel. Each vessel constantly affords four hundred pounds of cinnabar, the loss of original weight in each being ten pounds.

The cinnabar does not attach itself to the plates of iron, because they are so frequently taken off, excepting towards the end, when the vessels were left untouched. These plates are not in the least corroded.

Cinnamon is the bark of a tree of the bay kind, the laurus cinnamomum, growing in the island Ceylon. Though the bark is one of the most grateful spices, the wood is insipid and inodorous, and used only as firewood: the root is impregnated with aromatic matter, and yields in distillation not only an essential oil, but a portion of camphor. The bark is taken off twice a year; in the spring, before the tree begins to blossom, and in autumn, after the fruit has fallen. It is taken only from young trees, that of the old being woody and bitterish.

It has been observed that the thin membrane, which invests the internal surface of the bark, is much stronger in smell and taste than the bark itself. Some suppose, that the aromatic matter is originally confined wholly to this membrane, and thence communicated to the exterior parts in drying.

Cinnamon has a very agreeable pungent, somewhat astringent taste, and a delightful smell. Its essential oil is extremely pungent and fiery, but in small quantity, sixteen ounces of the very best cinnamon scarcely yielding two scruples and a half. The distilled water appears milky, and retains in it greatest part of the oil, which on long standing it deposits to the bottom, and then becomes clear. Oftentimes, though several pounds of cinnamon be committed to distillation, we shall scarcely be able to separate any oil till the water has been kept for some months. Mr. Stoll of Leipsick pretends to have a method of collecting all the oil from the water in a very little time; how justly, I cannot determine. If this should be found practicable, it would be a very useful discovery, provided the oil received no injury. The Dutch are the only persons who prepare the oil of cinnamon in quantity; but it never comes from their hands unadulterated. We seldom meet with oil of cinnamon that holds less than half its weight either of expressed oil or of alcohol.

The oil of this spice does not arise in distillation with alcohol: on distilling pure spirit from cinnamon, it received no sensible impregnation; on drawing it over repeatedly from fresh parcels of the spice, it smelt and tasted a little, but very weakly. An extract made by spirit contains the whole of the taste and flavour of the cinnamon. The watery extract has nothing valuable; sixteen ounces yield two or more of spirituous extract, and about one and a half of watery.

Cipolin. The cipolin from Rome is a green marble with white zones: it gives fire with steel, though difficultly. One hundred parts of it contains 67·8 of carbonat of lime, 25 of quartz, 8 of schistus, 0·2 of iron, beside the iron contained in the schistus. The cipolin from Autun, 83 parts carbonat of lime, 12 of green mica, and one of iron.

Circumcision-Stone. A variety of the jade or jaspachates, which comes from the Amazon river. It melts by the solar heat into a brown opake glass, less hard than the stone itself.

Civet is collected betwixt the anus and the organs of generation of a fierce carnivorous quadruped met with in China and the East and West Indies, called a civet-cat, but bearing a greater resemblance to a fox or marten than a cat.

Several of these animals have been brought into Holland, and afford a considerable branch of commerce, particularly at Amsterdam. The civet is squeezed out, in summer every other day, in winter twice a week; the quantity procured at once is from two scruples to a drachm or more. The juice thus collected is much purer and finer than that which the animal sheds against shrubs or stones in its native climates.

Good civet is of a clear yellowish or

brownish colour, not fluid, nor hard, but about the consistence of butter or honey, and uniform throughout; of a very strong smell, quite offensive when undiluted, but agreeable when only a small portion of civet is mixed with a large one of other substances.

This commodity is rarely or never to be met with genuine, notwithstanding the sealed bottles in which it is purchased at Amsterdam. Nor have we any certain criteria for distinguishing its adulteration. Some look upon it as genuine, if when rubbed upon paper it sinks in, without leaving any thing upon the surface; and if, when melted in hot water, it totally swims at top: but lard and butter, the substances principally mixed with it, have both these properties equally with the civet itself.

Civet unites easily with oils, both expressed and distilled, but not at all with alcohol or with water: nor is it rendered miscible with water by the mediation of sugar. Boecler relates, that sugar and alcohol are its two best menstrua; but he has certainly never made the experiment with either. The yolk of an egg seems to dispose it to unite with water; but in a very little while the civet separates from the liquor, and falls to the bottom, though it does not prove of such a resinous tenacity as when treated with sugar and alcohol.

It communicates, however, some share of its smell both to watery and spirituous liquors; hence a small portion of it is often added in odoriferous waters and spirits; as those of lilies of the valley, roses, rhodium wood, orange flowers, orange peel, yellow sanders, &c. The Italians make it an ingredient in perfumed oils, and thus obtain the whole of its scent; for oils dissolve the whole substance of the civet.—*Neumann.*

CLARIFICATION. The process of freeing a fluid from heterogeneous matter or feculencies, though the term is seldom applied to the mere mechanical process of straining, for which see FILTRATION.

Albumen, gelatine, acids, certain salts, lime, blood, and alcohol, in many cases serve to clarify fluids, that cannot be freed from their impurities by simple percolation.

Albumen or gelatine, dissolved in a small portion of water, is commonly used for fining vinous liquors, as it inviscates the feculent matter, and gradually subsides with it to the bottom. Albumen is particularly used for fluids, with which it will combine when cold, as sirups; it being coagulated by the heat, and then rising in a scum with the dregs. Isinglass is commonly employed for wine, either dissolved as mentioned above, or put in without dissolving, in the proportion of about a quarter of an ounce to a cask. Care should be taken, however, that the whole of the isinglass is separated from the wine before it is drunk, otherwise it may excite nausea, vomiting, and giddiness, even in small quantity.

One or two spoonfuls of fresh cream will clarify a quart of spirit in a few hours, but it requires to be filtered afterward.

Heat alone clarifies some fluids, as the juices of plants, in which however the albumen they contain is probably the agent.

A couple of handfuls of marle, thrown into the press, will clarify cider, or water-cider.

One thing must be observed with respect to clarification, that the medium employed seldom unites with the feculencies alone, but frequently carries off more or less of what is essential to the liquor, particularly in medicinal preparations. Care must be taken too, when albumen is used, that the clarified liquor is not left to stand upon the feculent matter, otherwise it will render it more foul than before, and perhaps noxious, from undergoing the putrid fermentation.—*Neumann.—Ann. de Chim.*

CLAY. See EARTHS, ALUMINE.

CLOVES. The pungency of cloves resides in their resin, or rather in a combination of resin with essential oil, for the spirituous extract is very pungent; but if the oil and the resin contained in this extract be separated from each other by distillation, the oil will be very mild; and any pungency which it does retain proceeds from some small portion of adhering resin, and the remaining resin will be insipid. No plant, or part of any plant, contains so large a portion of essential oil as cloves. From sixteen ounces Neumann obtained by distillation two ounces and two drachms; and Hoffman obtained from the same quantity an ounce and a half. The oil is specifically heavier than water.

CLYSSUS. A word formerly used to denote the vapour produced by the detonation of nitre with any inflammable substance.

Other clyssi were also produced, which had their names from the inflammable substance made use of; such as the clyssus of antimony and the clyssus of sulphur.

COAK. Coal charred in the same manner as wood is to convert it into charcoal. An oblong square hearth is prepared by beating the earth to a firm flat surface, and puddling it over with clay. On this the pieces of coal are piled up, inclining toward one another, and those of the lower strata are set up on their acutest angle, so as to touch the ground with the least surface possible. The piles are usually from thirty to fifty inches high, from nine to sixteen feet broad, and contain from 40 to 100 tons of coal. A number of vents are left, reaching from top to bottom, into which the burning fuel is thrown, and they are then immediately closed with small pieces of coal beaten hard in. Thus the kindled fire is forced to creep along the bottom, and when that of all the vents is united, it rises gradually, and bursts out on every side at once. If the coal contain pyrites, the combustion is allowed to continue a considerable time

disappearance of the smoke, to

t appears to be a general opinion,
ubstance owes its origin to the de-
on of vegetable bodies. And in-
n we attend to the inflammable
found in the earth, or in the
ingdom, we may perceive that
and most probably none of them,
ly said to belong to it, but have
orated in the bodies of animals
or vegetables. From the turf that is pared from the surface of the earth, and owes its inflammability to the roots of vegetables which are mixed with it, we may descend to the peat, or black earth, of the moors, in many specimens of which vegetable remains are still perceptible; though in most they appear to be deprived of every appearance of their organic texture, their oily and inflammable nature only remaining; and thence the transition to pit-coal is easy. For if we reflect on the vast revolutions which the earth has certainly undergone through a long course of ages, by means of which its surface has been broken, displaced and inverted, from the actions of floods, earthquakes, and the great convulsions of nature caused by volcanic eruptions, it will be no improbable inference, that the thin, though extensive strata of pit-coal, as well as the exsudations of naphtha, petroleum, and their modifications, have all arisen from the burying of extensive woody tracts of the surface, such as are common in all uncultivated countries. And this probability will be reduced to a certainty, when we advert to the natural history of pit-coal, which is met with in all the various states of transformation. Whole trees are converted into pit-coal, in such quantities together as to exhibit entire forests; in which the roots, trunks, branches, bark, and even species, are discernible. The experiments of Mr. Hatchett on the action of acids on vegetable substances, and those of Sir James Hall on the action of heat on vegetable and animal matter under great pressure, tend greatly to confirm this opinion.

Coal pits and slate quarries exhibit innumerable marks of impressions of leaves, and other indications of their vegetable origin; and the analysis of this combustible substance tends still further to confirm this truth. On the other hand, if we attend to such inferences as chemical theory might point out from the facts around us, we shall see how small the probability is, that the mineral kingdom should, after a certain limited time, contain inflammable bodies, if they were not occasionally thrown into it, in consequence of the operations carried on within organised substances. For all inflammable substances, tending to decompose the oxigen of the atmosphere, would, in process of time, revert to the class of uninflammable bodies, if the operation of organised bodies, particularly of the vegetable kind, did not tend to disengage the oxigen again, and render bodies combustible, which were not so when they became parts of those substances.

COATING, *or* LORICATION. Glass being a brittle substance, and at the same time a bad conductor of heat, is always liable to be broken by the expansion of its outer surface, where heat is so suddenly applied, that the expansion of the inner part does not immediately take place. To prevent this, and also to obviate the same inconvenience arising from variations in the intensity of the fire, it is usual to have recourse either to a sand-bath, or to coating the vessel.

Retorts may be coated in the following manner: Take of sand and clay equal parts; make them into a thin paste with fresh blood prevented from coagulating by agitation till it is cold, and diluted with water; add to this paste some hair, and powdered glass; with a brush dipped in this mass besmear the retort; and when this first layer is dry, let the same operation be repeated twice or oftener, till the coat applied is about one third part of an inch thick.

Chaptal recommends a soft mixture of marly earth, first soaked in water, and then kneaded with fresh horse-dung, as a very excellent coating.

The valuable method used by Mr. Willis of Wapping to secure or repair his retorts used in the distillation of phosphorus deserves to be mentioned here. The retorts are smeared with a solution of borax, to which some slaked lime has been added, and when dry, they are again smeared with a thin paste of slaked lime and linseed oil. This paste being made somewhat thicker, is applied with success, during the distillation, to mend such retorts as crack by the fire.

Cobalt is a semimetal, of a whitish gray or steel colour, hard and brittle; of a dull, close-grained fracture, and moderate specific gravity. It is rather more difficult of fusion than copper; does not easily become calcined; and its oxide is of so deep a blue colour as to appear black. The most remarkable and most valuable property of this metallic substance is, that its oxide, when fused with borax, or with alkali and sand, produces a blue glass, known by the name of smalt. The action of air soon tarnishes cobalt; but water has little or no effect upon it. When reduced into thin plates it is said to be capable of being rendered magnetic, but many suspect this to be owing to the presence of iron.

To obtain the metal pure, Tromsdorff recommends to mix eight parts of finely pulverized zaffre with two of dry nitrat of potash, and one of charcoal powder, and project them by small quantities into an ignited crucible: to repeat this process three times with the detonated residuum and fresh quantities of nitre and charcoal: to mix the mass with an equal weight of black flux, and keep this mixture at a red heat for an hour. The metal thus obtained is to be pulverized, mixed with three times its weight of nitrat of potash, and detonated as before. This being powdered and washed to separate the arseniat of potash, the filtered residue is to be digested in nitric acid, which will dissolve the cobalt, and leave the highly oxidized iron untouched. Then evaporate the solution to dryness, redissolve in nitric acid, refilter lest some oxide of iron should have been retained, decompose the nitrat of cobalt by potash, wash the precipitate, and reduce it by heat.

Brugnatelli supposed he had discovered an acid in zaffre, which he called the cobaltic, but it appears to have been only arseniat of cobalt.

Concentrated and boiling sulphuric acid, distilled nearly to dryness, combines with this semimetal. Much sulphurous acid gas flies off; and the cobalt is in part calcined, and in part conveyed into a crystallizable salt, soluble in water, and precipitable by lime and by alkalis in the form of a rose-coloured powder or oxide. Diluted sulphuric acid acts upon the oxide of cobalt, and forms the same salt.

Nitric acid dissolves cobalt by the assistance of a moderate heat. Nitrous oxide is disengaged, and the solution affords deliquescent crystals by evaporation, which do not detonate on ignited coals, but boil up and leave a red oxide. Lime and the alkalis precipitate the solution; and, if the alkali be added in excess, it dissolves the precipitate.

The muriatic acid has scarcely any action on cobalt, unless it is boiling; in which case it dissolves a small portion. It dissolves the oxide more readily, with which it forms a red brown fluid, that becomes green when heated. This solution affords deliquescent crystals by evaporation.

Aqua regia dissolves cobalt more easily than the muriatic acid, though not so readily as the nitric. This solution is well known as one of the most celebrated sympathetic inks afforded by chemistry.

The acid of borax does not act immediately on cobalt, in the humid way: but borax itself, added to either of the foregoing solutions, effects a decomposition by double affinity; the alkali uniting with the solvent acid, while the acid of borax seizes the cobalt, and forms a scarcely soluble compound, which falls down.

The oxalic acid precipitates cobalt from its solutions, in the form of a pale rose-coloured powder.

Whether alkalis or earths combine with this metal directly, by the intervention of water, has not been determined.

Cobalt does not act on neutral salts in general. It detonates feebly with nitre, when projected into a red hot crucible, with twice or thrice its weight of that salt.

Sulphur does not unite with cobalt but with difficulty. Alkaline sulphurets combine more readily with it. Phosphuret of cobalt may be formed by fusing equal parts of glacial phosphoric acid and cobalt with an eighth of their weight of charcoal powder: or by projecting small bits of phosphorus on cobalt ignited in small fragments in a crucible.

This semimetal unites by fusion with most of the metals and semimetals, as has before been noticed. Silver, lead, and bismuth, do not mix with it; and zinc does not but

is collected in a long horizontal chimney, built for that purpose. If the ore contain bismuth, this fusible semimetal is collected at the bottom of the furnace. The cobalt, after a sufficient torrefaction, remains in the form of a dark gray oxide, called zaffre. The zaffre of commerce always contains twice or thrice its weight of powdered flints. The flint is pulverized for this and other purposes by means of previous ignition, and quenching in water, which renders it friable. Smalt is a blue glass, composed of one part of the calcined cobalt, fused with two of the flint powder, and one of potash.

The use of this metallic substance is confined chiefly to the production of the blue glass for enamels, and other purposes. The powder blue, and a bad sort of stone blue, used by laundresses, is a preparation made by the Dutch from the coarse smalt.

Coccus. A genus of insects, among which are the *cochineal*, c. cacti; *kermes*, c. ilicis; the *lac* insect, c. lacca; and Polish scarlet grain, c. polonicus, which is now scarcely used in Europe, being superseded by the c. cacti. See Cochineal, Kermes, and Lac.

Cochineal was at first supposed to be a grain, which name it still retains by way of eminence among dyers, but naturalists soon discovered that it was an insect. It is brought to us from Mexico, where the insect lives upon different species of the opuntia.

Two sorts of cochineal are gathered at Mexico, the sylvestris, there known by the Spanish name grana sylvestra, and the fine, or grana fina, called also mesteque, from the name of a province in Mexico, and which are bred upon the nopal. The first is smaller, and covered with a cottony down, which increases its weight with a substance useless in dyeing: an equal weight of it therefore gives less colour, and is of a lower price than the fine cochineal; but these disadvantages are perhaps compensated by its being reared with greater facility, and at less expense, and even by the effects of its down, which enables it better to resist rain and storms.

Both the nopal and the cochineal have been introduced into some of the West India islands, and even into the *Jardin des Plantes* at Paris, so that the French expect to raise enough for their own consumption in the neighbourhood of their metropolis.

Fine cochineal, which has been well dried and properly kept, ought to be of a gray colour inclining to purple. The gray is owing to a powder which covers it naturally, a part of which it still retains: the purple tinge proceeds from the colour extracted by the water in which it has been killed. Cochineal will keep a long time in a dry place. Hellot says, that he tried some one hundred and thirty years old, and found it produce the same effect as new.

The decoction of cochineal is of a crimson colour, inclining to violet. A small quantity of sulphuric acid made this liquor assume a red colour, inclining to yellow, and a small quantity of a beautiful red precipitate was formed. Muriatic acid produced nearly the same change in the colour, but no precipitate. Solution of tartar changed the liquor to a yellowish red. A little precipitate of a pale red colour formed slowly: the supernatant liquor remained yellow; but, on pouring in a little alkali, it became purple. The small quantity of precipitate was quickly dissolved by the alkali, and the solution was purple. Solution of tin formed a rose-coloured precipitate with the yellow liquor. Solution of alum brightened the colour of the infusion, and gave it a redder hue; a crimson precipitate was formed, and the supernatant liquor retained a crimson colour, somewhat reddish. Alum and tartar mixed produced a brighter colour, more lively, and inclining to a yellowish red. A precipitate was formed, but much less abundant, and much more pale than in the preceding experiment. Solution of tin produced a copious sediment of a beautiful red. The liquor remaining above it was as clear as water, and suffered no change of colour on adding alkali. Having poured in a solution of tartar, and after that a solution of tin, a precipitate of a rose colour, inclining to black, was formed more quickly than in the foregoing experiment; and, though solution of tin in excess was added, the supernatant liquor remained a little yellow. Solution of common salt rendered the colour somewhat deeper, but did not make the liquor turbid. Sal ammoniac gave a purple tinge, without occasioning any precipitate. Sulphat of soda produced no perceptible change in the liquor. Having boiled a little cochineal with half its weight of tartar, the liquor was more inclining to red, and had a colour much less deep than that obtained from an equal quantity of cochineal without tartar; but the former gave a more abundant precipitate with solution of tin, and its colour was more rosy; so that tartar favours the solution of the colouring part of the cochineal; for, though the colour of the solution is less deep, the precipitate produced from it by solution of tin is of a deeper and more rosy hue. This experiment deserves notice, in judging of the influence of tartar in dyeing scarlet.

Sulphat of iron formed a brown violet precipitate. The supernatant liquor remained clear, with a tinge of feuille-mort. Sulphat of zinc formed a deep violet precipitate. The supernatant liquor remained clear and colourless. Acetit of lead produced a purple violet precipitate, less deep than the preceding. The supernatant liquor remained limpid. Sulphat of copper produced a violet sediment, which formed slowly. The liquor remained clear, and of a violet colour.

If the extract which decoction of cochineal affords on evaporation be digested in alcohol, the colouring part dissolves, and leaves a residuum of the colour of wine lees, of which fresh alcohol cannot deprive it. This residuum, analysed by fire, affords the common products of animal substances.

The alcoholic tincture of cochineal leaves on evaporation a transparent residuum of a deep red, which when dry has the appearance of a resin. This also, if distilled, yields the product of animal substances; which shows, that the colouring matter is an animal production.

Yet the decoction of cochineal does not easily putrefy. Berthollet has kept some of it more than two months, both in an open vessel, and in a bottle corked. At the end of that time the former showed no signs of putrefaction, the latter had a slight putrid smell. The first grew turbid in a few days, and left a brown violet sediment on the filter: the second preserved its transparency a long time, and probably lost it only from the effect of an incipient putrefaction, or rather of a slight combustion, produced by means of a little oxigen, probably united with the red particles of the cochineal. The colour of each had become crimson; but that of the former was more weak, because a greater part of the colouring matter had precipitated, in consequence of the effects produced on it by the air.

In some experiments by Hermbstaedt, muriat of barytes, used as a mordant in kerseymere, gave a pleasing violet with cochineal: the nitrat of barytes, a very pleasing poppy red: the acetit of barytes, a deep but bright poppy colour: muriat of strontian, a crimson: nitrat of strontian, a bright reddish brown: acetit of strontian, a bright poppy. He likewise found, that a solution of fine English tin in pure muriatic acid being exposed to the air in an open vessel for a month, a piece of kerseymere boiled in it, and then immersed in a warm cochineal bath, took a bright scarlet colour.

A distinguishing characteristic between cochineal and madder may be observed in the manner in which they are acted upon by the reagents. Both receive a yellow colour from acids; but if the colouring matter of cochineal be separated by a substance which precipitates it from the acid liquor, it reappears with its natural colour little altered; while that of madder, treated in the same manner, retains a yellow or fawn tinge. Hence mordants abounding in acid, as solution of tin, are much more successfully employed with cochineal than with madder. The cause of this probably is, that the colouring matter of madder united with oxide of tin retains a portion of acid, while that of cochineal combined with it retains none, or a much smaller quantity.—*Berthollet on Dyeing.—Scherer's Journal.*

Cockle. A Cornish mineral term applied to various substances, but most generally to the substance called schorl or shrill, from the German; which see.

Coffee. Neumann obtained from one pound of coffee by distillation five ounces five drachms and a half of water, six ounces and half a drachm of a fœtid oil, and four ounces two drachms of coal. It afforded him $\frac{5}{16}$ of watery extract, and $\frac{7}{32}$ of spirituous.

According to Seguin it consists of albumen, oil, a peculiar principle which he calls the bitter principle, and a green matter which is a combination of this principle with albumen. He found the proportions of these variable in different specimens: that torrefaction augmented the bitter principle by destroying the albumen: that both these contain nitrogen: and that the bitter principle is antiseptic. The oil is white, congealable, and without smell. He has found albumen in many other vegetables, most of which contain a bitter principle in many respects similar to that of coffee.

Mr. Chenevix discovered this bitter principle, and examined it more minutely. He obtained it by heating water on raw coffee in a close vessel, filtering, and evaporating. or by precipitating a decoction of raw coffee with muriat of tin, and separating the tin from the filtered precipitate by putting it into water, and passing a current of sulphuretted hidrogen slowly through the liquor, which Mr. Chenevix conceived afforded this principle in still greater purity.

It is of a pale yellow colour, transparent like horn, bitter but not unpleasant, and neither acid nor alkaline. Its solution is turned red by alkalis, and by nitric acid: alkaline carbonats do not precipitate it; neither does gelatine: it cannot therefore be tannin. Sulphuric acid merely changes its colour to a dirty brown. Solution of iron gives a fine green precipitate; muriat of tin, a yellowish; water of barytes, a fawn coloured. Neither lime water nor strontian precipitated it.

As a decoction of well roasted coffee evidently contains tannin, as is shown by the addition of gelatine, Mr. Chenevix conjectures, that this principle is converted into tannin by the action of heat, though he did not find this to be the case after it was separated from the coffee.

Coffee is diuretic, sedative, and a corrector of opium. It should be given as a medicine in a strong infusion, and is best cold. In spasmodic asthma it has been particularly serviceable: and it has been recommended in gangrene of the extremities arising from hard drinking.—*Bulletin des Sciences.*—*Nich. Journ.*—*Percival's Essays.*

Cohesion. The power by which the parts of bodies become attached to each other, and form consistent masses. We know scarcely any thing concerning attraction but its effects, there being very few instances indeed wherein we can consider ourselves as authorised to refer this property to any more remote cause deducible by our researches. The various kinds of attraction have been classed relative to their effects, and considered as distinct, and in a certain sense independent properties. It has however been made a question by chemists of undoubted sagacity, whether all attractions, and more particularly the cohesive and chemical attractions, ought not to be referred to one general property of matter, modified by variations in the figures, relative distances, &c. of bodies. See Attraction.

Cohobation. It is frequently required in chemical operations, that a substance should be for a long time boiled, or digested in a volatile fluid considerably heated. This necessarily supposes a great loss of the fluid, if the operation be performed in an open vessel. To prevent this, the ancient chemists employed a kind of still, called a pelican. The head of this vessel was provided with two beaks, which by a gradual incurvation returned into the body, and conveyed thither whatever volatile matter had risen into the head, and there became condensed. The views and practices of the moderns do not require these long digestions; but many valuable experiments of Priestley and others, of the nature of repeated distillation, have been made by a simpler apparatus. A glass tube, three or four feet in length, supplies the place of the pelican. A mineral acid, water, or any other requisite fluid, is put into the tube, in such a quantity as to occupy an inch or more of its lower end; the upper end is then hermetically sealed, and heat applied to the lower by a sand bath. The fluid partly rises, and is partly changed in other respects by the heat. The vapours as they arrive towards the upper part of the tube become condensed, and return again to the lower in a kind of circulation down the cooler side of the vessel. In this way Scheele has shown, that the pretended conversion of water into earth by repeated distillation is in fact nothing more than an abrasion or decomposition of the glass vessels; and Priestley has made a variety of experiments on the mineral acids.

Colcothar. The brown red oxide of iron, which remains after the distillation of the acid from sulphat of iron: it is used for polishing glass and other substances by artists, who call it crocus, or crocus martis.

Cold. The privation of heat. See Caloric.

Colophony. Colophony, or black resin, is the resinous residuum after the distillation of the light oil, and thick dark reddish balsam, from turpentine.

Columbium. A mineral in the British Museum, sent to Sir Hans Sloane with some iron ores from Massachusetts, was lately examined by Mr. Hatchett, and a new metallic substance discovered in it, to which he has given the name of columbium.

The mineral is heavy, of a dark gray nearly black, and in some measure like the

Siberian chromat of iron. The mineral acids act on it very feebly: the sulphuric rust dissolving some iron. Melted with five or six parts of carbonat of potash it is partly decomposed; but to effect a complete decomposition the ore must be alternately melted with potash and digested with muriatic acid, which takes up the iron. During the fusion carbonic acid is expelled, and the potash is partly neutralized by a metallic acid, which may be separated after solution in water by adding nitric acid to excess, when it will appear in the form of a copious white flocculent precipitate.

The ore consists of more than three fourths of this substance combined with iron. When recently separated it is soluble in muriatic or sulphuric acid with heat. Alkalis precipitate it white; prussiat of potash, olive green; tincture of galls, a deep orange. If the sulphuric solution be copiously diluted, it falls down in the state of a sulphat, which as it dies changes from white to blue, and lastly to gray. Zinc precipitates it white. Hidrosulphuret of ammonia forms a chocolate-coloured precipitate with its alkaline solutions.

The white precipitate combines with potash and soda, both in the dry and humid way, and expels the carbonic acid from them. With potash it forms a glittering scaly salt, which has much the appearance of the boracic acid. With phosphat of ammonia it forms a purplish blue glass. It is extremely difficult to reduce: and it reddens litmus paper.—*Nich. Journal.*

Combination. When two bodies unite together in such a manner as that most of the original properties of the bodies respectively disappear, and the compound exhibits new properties not immediately deducible from those before existing, the bodies are said to be combined together. Combination is therefore the most intimate union of bodies, and is to be distinguished from the grosser union called mixture.

Combustion. There is a remarkable distinction in bodies with regard to the effects of heat upon them. Some bodies will admit of being heated to such a degree as even to become luminous or red hot without any permanent or considerable change of their properties or component parts; and as soon as the communication of heat ceases, the bodies immediately begin to cool. On the other hand, there are a great number of bodies, which, when heated with access of oxigen to such a degree as to become luminous, undergo a change in their properties, insomuch that their temperature even increases, and they continue to give out heat until the general state of the combination of their parts is changed. These bodies are distinguished by the name of combustible bodies, and the alteration produced by this apparently spontaneous production of heat is called combustion.

It must always have been a problem of the first importance in natural philosophy, to ascertain what happens in combustion. The division of substances into combustible and incombustible is as striking and distinct as any we are acquainted with; and it is a natural inference, that the one class of bodies must possess some general property, or identical substance, not to be found in the other. The philosophy of the middle ages, probably in consequence of their logical classifications, was much more disposed to attach itself to substances than habitudes or properties. It is less to be wondered at, therefore, that Beccher and Stahl should have assigned a substance eminently combustible, or fire itself, as resident in all combustible bodies, and occasioning the difference between them and other bodies, instead of inquiring whether the general effect might not have arisen from some effect of the chemical affinities. Modern chemists have however very amply and successfully maintained this last doctrine. Still it will be proper to give a short statement of the two doctrines as applied to combustion in general.

The modern maintainers of phlogiston, or the principle of inflammability, do not teach exactly the same doctrine as Stahl. This chemist supposed combustion to consist in the escape of fire from bodies. Various facts have compelled the moderns to modify this position. The most generally received statement is, that a substance called phlogiston and very strongly attractive of oxigen, resides in all combustible bodies; that a certain degree of heat weakens the adherence between phlogiston and the combustible substance, and consequently disposes it to a more speedy union with the oxigen of the atmosphere; that the capacity of oxigen for heat is diminished by this union, and consequently an increase of temperature follows, which serves to accelerate the disengagement of more of the phlogiston; and in this way heat continues to be extricated until the body has become dephlogisticated, or incombustible.

The modern or antiphlogistic theory is exactly the same, excepting that instead of supposing combustible bodies to contain a principle of inflammability, which attracts the oxigen of the atmosphere, it infers, that the body itself attracts and combines with oxigen; and as no difficulty ensues from this statement, it seems clear that the phlogiston is redundant and unnecessary in accounting for the effects.

The consideration of these doctrines and their consequences embraces nearly the whole science of Chemistry; but the reader may more especially recur to the articles Acids, Metals, and Caloric.

Combustion, as already observed, is commonly occasioned by the application of a body already ignited to the combustible; and when this is not the case it has been termed *spontaneous.* But this would include the mechanical means, as friction, and the concentration of the solar rays, which cannot with propriety be called spontaneous; we would confine it therefore to combustions that arise simply from the play of chemical affinities. Such of these as have hitherto been observed we shall proceed to enumerate, as they lead to cautions of importance for preventing serious accidents.

If quicklime in any quantity be laid in contact with any combustible, as wood, and be wetted by accident, or to make it into mortar, a sufficient quantity of heat may be extricated to set fire to the wood. Animal or vegetable substances laid together damp in large heaps undergo a fermentation, which often excites combustion, as in the case of hay-ricks. Woollen cloth, not freed from the oil used in dressing it, and laid up damp in large heaps, has been known to take fire; and so has painted canvass. Flowers and herbs boiled in oil, as is done by druggists, and then laid in heaps, sometimes do the same. The mixture of linseed oil and lampblack, or of linseed oil and black wadd, is very liable to inflame. Torrefied vegetables, as malt, coffee, or bran, put while hot into coarse bags, are apt to take fire. The spontaneous combustion of phosphorus, and various pyrophori, is well known. It is suspected to be owing to the presence of one or other of these, that charcoal sometimes takes fire without any apparent cause; and the charcoal of peat is said to be particularly liable to this. Hyperoxigenated muriat of potash mixed with sulphur, or with sulphur and charcoal, is apt to detonate spontaneously.

Many cases of spontaneous combustion taking place in the human body too are on record: and it has been observed, that all the persons, who thus suffered, were much addicted to the use of spirituous liquors.

Concentration. This term is used to denote the privation of a part of the water usually contained in certain fluids, more particularly saline solutions. Thus, by evaporation of part of the water of a solution of sea salt, we obtain a concentrated brine; by evaporation in a nearly closed vessel, or by distillation, part of the water of sulphuric acid is driven off, and the remainder is concentrated sulphuric acid. Thus, again, if vinegar be exposed to freeze, the aqueous part congeals first, leaving the concentrated vinegar behind.

Condensation. The approach of the particles of a body to each other, so as to cause the whole to occupy less space than before. It is most commonly applied in chemistry to denote the transition from the vaporous or aërial to the solid state, as happens in distillation, sublimation, &c.

Congelation. The formation of ice. The term is applied in general to every transition from the fluid to the solid state. Thus we say the congelation of sulphuric acid, of oils, of metals, &c. It appears to be owing to the abstraction of caloric. See Caloric.

Cone (Melting). This is a hollow cone formed of copper or of brass, with a handle, and with a flat bottom adjoining to the apex of the cone, upon which it is intended to rest. Its use is to receive a mass of one or more metals melted together and poured into it. This mass, when cold, may be easily shaken out of the cone from the figure of the vessel. Also if a melted mass, consisting of two or more metals, or other substances not combined together, be poured into this vessel, the conical figure facilitates the separation of these substances according to their respective densities. The cone ought to be well heated before the melted mass is poured into it, that no moisture may be contained, by which a dangerous explosion might be occasioned. It ought also to be greased internally with tallow, to prevent the adhesion of the fluid matter.

Contrayerva. The leaves of this plant are said to afford a poison employed by Indians for poisoning arrows, to which poison the root of the said plant is said to be an antidote. From an ounce of the root Neumann extracted with water three drams and half a scruple; and from the same quantity with alcohol five scruples and two grains.

Copal, improperly called gum copal, is a hard, shining, transparent, citron-coloured, odoriferous, concrete juice of an American tree, but which has neither the solubility in water common to gums, nor the solubility in alcohol common to resins, at least in any considerable degree. By these properties it resembles amber. It may be dissolved by digestion in linseed oil with a heat very little less than sufficient to boil or decompose the oil. This solution, diluted with oil of turpentine, forms a beautiful transparent varnish, which, when properly applied and slowly dried, is very hard, and very durable. This varnish is applied to snuff-boxes, tea-boards, and other utensils. It preserves and gives lustre to paintings, and greatly restores the decayed colours of old pictures by filling up the cracks and rendering the surfaces capable of reflecting light more uniformly.

In Gehlen's Journal we are informed, that copal may easily be dissolved either in alcohol, or in oil of turpentine, by suspending bits of copal by threads over either of these in an alembic, and then boiling the fluid. The vapour liquefies the copal, which drops into the liquor beneath, and when cold the limpid and colourless solution is to be decanted from the undissolved part of the copal.

Mr. Tim. Sheldrake has found, that camphor has a powerful action on copal; for if powdered copal be triturated with a little camphor, it softens, and becomes a coherent mass; and camphor added either to alcohol or oil of turpentine, renders it a solvent of copal. Half an ounce of camphor is sufficient for a quart of oil of turpentine, which should be of the best quality; and the copal, about the quantity of a large walnut, should be broken into very small pieces, but not reduced to a fine powder. The mixture should be set on a fire so brisk as to make the mixture boil almost immediately: and the vessel Mr. S. recommends to be of tin or other metal, strong, shaped like a wine-bottle with a long neck, and capable of holding two quarts. The mouth should be stopped with a cork, in which a notch is cut to prevent the vessel from bursting. It is probably owing to the quantity of camphor it contains, that oil of lavender is a solvent of copal. Camphor and alcohol dissolve copal still more readily than camphor and oil of turpentine.

Lewis had observed, that solution of ammonia enabled oil of turpentine to dissolve copal: and Mr. Sheldrake found it did, when added in the proportion of an eighth part. But it requires such nice management of the fire, as the mixture must be kept boiling, yet so that the bubbles may be counted as they rise, that it seldom succeeds completely.

Copper is a metal of a peculiar reddish brown colour; hard, sonorous, very malleable and ductile; of considerable tenacity, and of a moderate specific gravity. At a degree of heat far below ignition the surface of a piece of polished copper becomes covered with various ranges of prismatic colours, the red of each order being nearest the end which has been most heated; an effect which must doubtless be attributed to oxidation, the stratum of oxide being thickest where the heat is greatest, and growing gradually thinner and thinner towards the colder part. A greater degree of heat oxides it more rapidly, so that it contracts thin powdery scales on its surface, which may be easily rubbed off; the flame of the fuel becoming at the same time of a beautiful blueish green colour. In a strong white heat, nearly the same as is necessary to melt gold or silver, it melts, and exhibits a blueish green flame; by a violent heat it boils, and is volatilized partly in the metallic state.

Copper rusts in the air; but the corroded part is very thin, and preserves the metal beneath from further corrosion.

The sulphuric acid, when concentrated and boiling, dissolves copper. A brown thick fluid, containing oxide of copper and a portion of the oxide combined with sulphuric acid, is found at the bottom of the solvent. If water be added to this, it forms a blue solution of copper, which by evaporation affords blue crystals, that require about four times their weight of water to dissolve them. This solution lets fall an oxide of copper of a green colour by long exposure to the air.

The solutions of copper in sulphuric acid are slightly caustic. Magnesia, lime, and the fixed alkalis, precipitate the metal from them in the form of oxide. Volatile alkali precipitates all the solution of copper; but redissolves the oxide and produces a deep blue colour. Copper is precipitable from most of its solutions, in the metallic state, by the addition of iron: a clean plate of iron soon becomes covered with a coating of copper, when immersed in the solution: hence the volatile alkali and the application of iron are considered as the tests of the presence of copper. There are certain mineral waters in Hungary, Sweden, Ireland, and in various parts of England, which contain sulphat of copper, and from which it is precipitated by the addition of pieces of old iron. Gay-Lussac however has observed, that iron very much oxided is precipitated by oxide of copper; and that thus sulphat of copper may be freed from an iron with which it is contaminated by strongly oxiding the iron, either with nitric acid, or with the oxigenated muriatic, which is preferable.

Nitric acid dissolves copper with great rapidity, and disengages a large quantity of nitrous gas. Part of the metal falls down in the form of an oxide; and the filtrated or decanted solution, which is of a much deeper blue colour than the sulphuric solution, affords crystals by slow evaporation. This salt is deliquescent, very soluble in water, but most plentifully when the fluid is heated. Its solution, exposed to the air in shallow vessels, deposits an oxide of a green colour. Lime precipitates the metal of a pale blue; fixed alkalis of a blueish white. Volatile alkali throws down blueish flocks, which are quickly redissolved, and produce a lively blue colour in the fluid.

Muriatic acid does not readily dissolve copper, unless it be concentrated and boiling. The solution is of a deep brown colour; but on standing for some time it deposits a sediment, and becomes green. By careful evaporation it yields crystals; or when inspissated, it affords a greenish mass, which deliquesces in the air, is readily dissolved in water, gives a green tincture to alcohol, melts in a gentle heat, takes fire from a candle, and burns with a blue flame. The muriatic acid dissolves the oxides of copper more readily than the metal itself; but the solution does not differ from the foregoing.

Vegetable acids dissolve copper slowly; but in considerable quantity, if oxigen be present. In this, as in a number of other metallic solutions, it appears, that the disposition of the air to oxide the metal is greatly assisted by the elective attraction of the acid for the metallic oxide. Vinegar does not dissolve copper when boiling, because the steam prevents the access of the air; but the same acid standing for a day in a copper vessel will contract a dangerous metallic impregnation. This circumstance accounts for the unhappy consequences produced in some instances by copper vessels, which in other cases have produced no noxious effects. Confectioners boil pickles, and even lemon-juice, in clean copper vessels, without observing any bad taste or noxious consequence to follow. We cannot however avoid heartily concurring in the general opinion which now prevails, in the rejection of copper vessels for culinary purposes.

Verdigris is an oxide of copper, prepared in large quantities near Montpellier in France, by stratifying copper-plates with the husks of grapes which remain after the juice has been pressed out. These soon become acid, and corrode the copper. A solution of this oxide in distilled vinegar affords permanent crystals of acetat of copper, improperly called distilled verdigris. At Grenoble, verdigris, which is considered somewhat superior in quality, particularly for dyeing, is prepared by sprinkling plates of copper repeatedly with distilled vinegar. The component parts of this verdigris, as analysed by Chaptal, were, copper 20·9, carbonic acid 9·1, water slightly acidulated 13·05, strong coloured acid 53·95, carbon 3.

Prussic acid unites with the oxide of copper, and forms a brown paint, superior both in oil and water, as Mr. Hatchett informs us, to any other in use. It has also a purple tinge, so as to form various shades of bloom or lilac when mixed with white, which are not so liable to fade as those made with lake. The best mode of preparing the prussiat of copper is to dissolve the green muriat in ten parts of distilled water, and precipitate with prussiat of lime. It may be prepared also from sulphat of copper and prussiat of potash.

Fixed alkalis have some action on copper, with which they form a light blue solution. This, as well as the ammoniacal solution, appears to succeed better in the cold than by the assistance of heat, for the same reason as the cold acetous acid acts upon copper; namely, the facility with which the metal is calcined by the access of air.

Ammonia dissolves copper with much greater rapidity than fixed alkalis, whether it be in the metallic or oxided state, and forms a beautiful blue solution. This fluid has long attracted the notice of chemists, on account of its becoming colourless in closed vessels; and recovering its colour, which gradually extends from the surface downwards, when the vessel is opened. This effect is explained by the supposition, that the perfect solution of oxide of copper in ammonia is colourless when the alkali is in excess; but that it is blue when it abounds with oxide of copper: and accordingly it is found, that the loss of colour on keeping the vessel closed for some time, and its reappearance on opening the vessel, do not succeed with old solutions, which are permanently blue.

The air oxides more perfectly a portion of the suspended copper, which gives a blue colour to the fluid until it has more intimately combined with the alkali. If this combination be made in the closed vessel, the colour disappears; if it be made in the open vessel, the oxidation of another portion goes on, and continues until the alkali is saturated, and can combine with no more: so that the last portion of perfect oxide, which causes the blue colour, does not seem to have entered into so intimate a combination, for want of an excess of alkali. The alkali does not take up any considerable quantity, when applied to copper filings; but it dissolves much more of the oxides of copper. The solution does not very readily afford crystals.

Oils do not seem to act upon copper until they become rancid, in which case their disengaged acid corrodes the copper, and the oil assumes a blueish green colour. Verdigris is soluble in alcohol. Copper, in the metallic state, does not unite with earths or alkalis in the dry way. Its oxides enter into the composition of glass. In general it does not act on the neutral salts by fusion. Nitre detonates with it but difficultly. Filings of copper are thrown upon red hot nitre; and the residue is a brownish gray oxide, mixed and partly combined with vegetable alkali. If this be washed with water, the remaining oxide may be fused without other addition into a deep opake brown glass, used by enamellers.

Muriate of ammonia is decomposed by copper filings. The produce which comes over consists of ammonia, rendered blue by a small portion of copper, together with pure ammonia, hidrogen, and nitrogen: the residue consists partly of muriat of copper and oxide. In the wet way Brunswic or Friezland green is prepared by pouring a saturated solution of muriat of ammonia over copper filings or shreds in a close vessel, keeping the mixture in a warm place, and adding more of the solution from time to time, till 3 parts of muriat to 2 of copper have been used. After standing a few weeks, the pigment is to be separated from the unoxided copper by washing through a sieve; and then it is to be well washed, and dried slowly in the shade. This green is almost always adulterated with ceruse.

A solution of alum boiled in a copper vessel deposits some earth, and the fluid exhibits signs of the presence of copper by the test of ammonia. This does not seem to be a perfect decomposition of the alum; but appears to be effected by virtue of the acid, which that salt contains in excess. The neutral salt or alum saturated with its own basis falls down, because less soluble; while the excess of acid, forming sulphat of copper, exhibits the blue tinge when ammonia is added.

Copper unites very readily with sulphur. If copper filings be mixed with flowers of sulphur and a little water, the combination takes place; but it is much more readily effected in the dry way. This cannot be done by direct fusion, because the sulphur is burned at a much less heat than is required to fuse the copper. It may be prepared by mixing equal parts of sulphur and copper filings together, and exposing them to heat gradually raised to ignition: or plates of copper may be stratified in a crucible with sulphur, and gradually heated as before. This compound is a blackish gray mass, and is used by dyers and calico-printers: it is distinguished by the name of æs veneris. Alkaline sulphurets dissolve copper both in the humid and dry way.

Phosphorus unites with the oxide of copper; or if the glacial phosphoric acid be exposed to heat in a crucible, together with its weight of copper filings and about one quarter of its weight of charcoal, the phosphorus which is formed combines with the copper, and forms a kind of pyrites, which changes by exposure to air. It loses its metallic state, and assumes a black colour. Mr. Sage took one part of copper chips, and put it into a crucible in alternate layers with two parts of the glacial acid powdered and mixed with a twelfth of a part of charcoal. On breaking the crucible after cooling, a button of phosphuret of copper, of the hardness, grain, and colour of steel, was found at the bottom. It was easily turned in a lathe, took a beautiful polish, and did not appear to be changed by contact with fat bodies, or to be tarnished after fifteen years exposure to the air in his laboratory. It is more fusible than copper; may be melted several times under charcoal powder without losing its properties; and exposed for a long time under a muffle parts with its phosphorus with difficulty. Over the button was a deep red enamel, that did not change colour in the fire.

This metal combines very readily with gold, silver, and mercury. It unites imperfectly with iron in the way of fusion. Tin combines with copper, at a temperature much lower than is necessary to fuse the copper alone. On this is grounded the method of tinning copper vessels. For this purpose, they are first scraped or scoured; after which they are rubbed with sal ammoniac. They are then heated, and sprinkled with powdered resin, which defends the clean surface of the copper from acquiring the slight film of oxide, that would prevent the adhesion of the tin to its surface. The melted tin is then poured in, and spread about. An extremely small quantity adheres to the copper; which may, with great justice, be supposed insufficient to prevent the noxious effects of the copper as perfectly as might be wished.

When tin is melted with copper it composes the compound called bronze. In this metal the specific gravity is always greater than would be deduced by computation from the quantities and specific gravities of its component parts. The uses of this hard, sonorous and durable composition in the fabrication of cannon, bells, statues, and other articles, are well known. Bronzes and bell-metals are not usually made of copper and tin only, but have other admixtures, consisting of lead, zinc, or arsenic, according to the motives of profit, or other inducements of the artist. But the attention of the philosopher is more particularly directed to the mixture of copper and tin, on account of its being the substance of which the speculums of reflecting telescopes are made. See SPECULUM. The ancients made cutting instruments of this alloy. A dagger analysed by Mr. Hielm consisted of 83¾ copper, and 16¼ tin.

Copper unites with bismuth, and forms a reddish white alloy. With arsenic it forms a white brittle compound, called tombac. With zinc it forms the compound called brass, and distinguished by various other names, according to the proportions of the two ingredients. It is not easy to unite these two metals in considerable proportions by fusion, because the zinc is burned or volatilized at a heat inferior to that which is required to melt copper; but they unite very well in the way of cementation. In the brass works, copper is granulated by pouring it through a plate of iron, perforated with small holes and luted with clay, into a quantity of water about four feet deep and continually renewed: to prevent the dangerous explosions of this metal, it is necessary to pour but a small quantity at a time. There are various methods of combining this granulated copper, or other small pieces of copper, with the vapour of zinc. Calamine, which is an ore of zinc, is pounded, calcined, and mixed with the divided copper, together with a portion of charcoal. These being exposed to the heat of a wind furnace, the zinc becomes revived, rises in vapour, and combines with the copper, which it converts into brass. The heat must be continued for a greater or less number of hours, according to the thickness of the pieces of copper, and other circumstances; and at the end of the process, the heat being suddenly raised causes the brass to melt, and occupy the lower part of the crucible. The most scientific method of making brass seems to be that mentioned by Cramer. The powdered calamine, being mixed with an equal quantity of charcoal and a portion of clay, is to be rammed into a melting vessel, and a quantity of copper, amounting to two thirds of the weight of the calamine, must be placed on the top, and covered with charcoal. By this management the volatile zinc ascends, and converts the copper into brass, which flows upon the rammed clay: consequently, if the calamine contain lead, or any other metal, it will not enter into the brass, the zinc alone being raised by the heat.

A fine kind of brass, which is supposed

to be made by cementation of copper-plates with calamine, is hammered out into leaves, in Germany; and is sold very cheap in this country, under the name of Dutch gold, or Dutch metal. It is about five times as thick as gold leaf; that is to say, it is about one sixty-thousandth of an inch thick.

Mr. Sage says, that fifty parts of oxide of copper, left after distilling acetic acid from verdigris, 100 of calamine, 400 of black flux, and 30 of charcoal powder, mixed together, and kept in fusion till no blue flame appears round the top of the crucible, will give a very fine brass, consisting of 6 parts copper and 1 zinc, which he esteems the best proportions. Some fine Geneva brass, however, used for the finer parts of watch-work, analysed by Dize, gave 3 parts copper only to one of zinc. The common French brass contains about 13 per cent. only of zinc.

The readiest mode of analysing brass is by dissolving it in sulphuric acid diluted with 20 parts of water, and immersing a plate of zinc in the solution, which will precipitate the copper.

Copper may be coated with platina, as well as with tin. Mr. Strauss precipitated a solution of platina by muriat of ammonia; washed, dried, and exposed the precipitate to a graduated red heat for half an hour in a covered crucible; and triturated it with 5 parts of mercury in a warm mortar into an amalgam, to which he added 2 parts more of mercury. A plate of copper coated with this, and then ignited to drive off the mercury, was covered with the platina. Mr. Strauss then mixed a little of the amalgam with chalk, sprinkled it with water, coated the plate of copper a second time, and again ignited it. The coating was now very perfect, and assumed a shining colour under the burnisher.

Copper unites readily with antimony, and affords a compound of a beautiful violet colour. It does not readily unite with manganese. With tungsten it forms a dark brown spongy alloy, which is somewhat ductile.

Copper is either found native, mostly in an impure state, or in the form of an oxide, of a red, green, or blue colour. The native solutions of copper frequently impregnate calcareous earths, in which they deposit the metal. Phosphat of copper has been found native: and likewise arseniat and carbonat. Many ores of copper contain sulphur. Among these, the vitreous copper ore is of a red, brown, blue, or violet colour; sometimes crystallized, but usually soft enough to be cut with a knife. Some of the pyrites contain a considerable proportion of copper, together with iron, sulphur, and clay. The gray copper ore is a sulphureous combination containing arsenic; it is of a white, gray, or brown colour, heavy, and difficult of fusion. Blendose copper ore is of a brown colour, hard, solid, compact, and granulated: it contains the metal, with sulphur, arsenic, zinc, and iron. Some slates, and one species of coal, afford copper; and several waters contain this metal, dissolved in sulphuric or muriatic acid.

Native copper may be assayed, in the humid way, by solution in nitric acid. If it contain gold, this metal falls untouched to the bottom, in the form of a black powder; if silver, it is soon precipitated by more copper; if iron, by boiling the solution for some time, it is gradually oxided, and falls to the bottom.

The calciform copper ores are soluble in acids, and may be precipitated either by iron, which affords the copper in the metallic state, or by mild alkali, which throws down 194 grains of precipitate for every 100 grains of copper.

Sulphureous copper ores may be powdered, and gently boiled to dryness in five times their weight of concentrated sulphuric acid. The whole, or most part of the sulphur, flies off by this heat. The sulphat of copper requires at least four times its weight of water to dissolve it. A sufficient quantity being therefore added, and a polished iron plate boiled in the solution, the copper will be precipitated. If iron be found to be mixed with the precipitate, it must be again dissolved, to obtain a richer solution. This will deposit pure copper, if the operation be conducted as before. If it contain other metals, they may be easily separated by solution in nitric acid.

In the dry way, the sulphureous ores of copper must be first pulverized, and separated as much as possible from the earthy and stony particles, then roasted, to separate the sulphur and arsenic; and lastly, melted with an equal weight of Tillet's flux, which consists of two parts pounded glass, one calcined borax, and one eighth of charcoal. More borax may be added if the ore be poor. Alkaline fluxes are hurtful in the fusion of copper ores, because the salt combines with the sulphur, and forms a sulphuret, which dissolves part of the copper.

In the large way copper is roasted in a close furnace, by a slow fire, to scorify the mixtures of iron and other substances. By repeated fusions with sulphur and charcoal, the scorified metal rises to the top, and is scummed off. The copper, in the great Hungarian mines, is said to undergo fusion fourteen times before it is fit for sale. The roasted ore in the isle of Anglesey is deprived of its sulphat by washing, and the copper is precipitated by means of old iron immersed in the water. This precipitated copper is, however, but small in proportion to the whole produce.

Copper is found in various parts of the world; in Spain, France, England, Norway, Hungary, Sweden, and elsewhere. The Japan copper is said to be purer, and has a greater specific gravity, than any other copper. The wire-drawers, who require copper of extraordinary ductility, use the Swedish copper. Fine Swedish copper is much used by jewellers for alloying gold: it is of a pale colour, and sells as high as six shillings a pound. The copper mines in England are exceedingly numerous and productive. Paris Mountain, on the isle of Anglesey, contains a bed of ore forty feet in thickness, and is said to produce upwards of four thousand tons of copper annually.

It is of importance in many cases, as for alloying gold, to have copper very pure: and for this perhaps Pelletier's method is the best. He fuses the copper, and projects upon it black oxide of manganese in powder, frequently stirring the metal, so as to oxidate the metals usually combined with it, without proceeding so far as to oxidate the copper itself.

The uses of this metal are too numerous to be distinctly specified. It has for some years past been applied with great success and advantage for sheathing the bottoms of ships; and several builders have lately endeavoured to introduce it as a covering for houses. It is the lightest of all coverings; but whether it be more durable than slate, which is nearly as light, has not yet been ascertained by experience.

Copperas. Sulphat of iron is called green copperas in commerce. The sulphat of copper is called blue copperas, or frequently blue vitriol; and the sulphat of zinc is called white copperas.

Coral and **Coralline** are shells of marine animals of the polypus kind, and possess the same chemical properties as the shells of oysters and other fish; that is, they consist of calcareous earth combined with mucilage and other animal matter.

Cork is a bark of a tree of the oak kind, very common in Spain and the other southern parts of Europe. By boiling in water Neumann obtained from cork one twelfth part of its weight of extract, and by digestion in alcohol he obtained rather a larger quantity of resinous matter.

Mr. Brugnatelli has examined this substance in the more accurate methods of modern chemistry. The cork upon which he made his experiments was white and very smooth. In the focus of the burning glass it was quickly burned with a white brilliant flame, leaving a light spongy coal, easily and almost totally consumed in a crucible, the residue of ashes being scarcely perceptible. Cork, when treated in the way of destructive distillation, was entirely or very nearly converted into hidrogen. Boiling water only softened it. The action of the sulphuric and also of the muriatic acid, even when assisted by heat, was scarcely sensible. By the action of the nitric acid it was found to be acidified. See **Acid** (**Suberic**).

Cork (**Fossil**), Suber Montanum. This name is given to a stone which is a species of amianthus, consisting of flexible fibres loosely interwoven, and somewhat resembling vegetable cork. It is the lightest of all stones. By fire it is fusible, and forms a black glass. It possesses the general properties of amianthus.

Coro-Shut Marle. A kind of marle of a brown colour mixed with chalk and blue veins.

Corrosive Sublimate. A combination of oxide of mercury with muriatic acid. See **Mercury.**

Corundum, or **Corrindon.** The name of a stone brought from the East Indies, and commonly called **Adamantine Spar**, which see. Some make it a genus, including, beside the adamantine spar, the ruby and the sapphire.

Countries. An English mine term for the sides or enclosures of a vein or load of ore: *e. g.* the country of lead is limestone, killas, &c.

Cream of Lime. When lime water is exposed to the air, a portion of carbonic acid combines with the lime near the surface, and converts it into chalk, which first forms a pellicle at the top, and afterward falls down. This substance, which is either not at all soluble in water, or much less so than lime, is separated on that account. The term is at present seldom met with.

Cream of Milk. A portion of milk which rises to the surface of the fluid by repose: most probably in consequence of an incipient fermentation. It contains all the butter, some of the cheese, together with a portion of the other principles of the milk. See **Butter** and **Milk.**

Cream of Tartar. The supertartrit of potash in its purified state. See **Acid** (**Tartarous**).

Crimson. See **Dyeing.**

Crocus. The yellow or saffron-coloured oxides of iron and copper were formerly called crocus martis and crocus veneris. That of iron is still called crocus simply by the workers in metal who use it.

Crucible. A pot or vessel formed either of earth, of plumbago, or of some suitable metal. It is used for fusions, cementations, and other operations in the dry way. See **Laboratory.**

Cryolite. A triple salt, consisting of soda 36, alumine 24, fluoric acid and water of crystallization 40. It was found in Greenland: is of a bright whitish gray colour, semitransparent, soft to the touch, and very fragile; breaks into cubic fragments with a vitreous splendour; and its mean specific gravity is 2·95. It fuses at first before the blowpipe, but afterward loses this property, and resembles an earth strongly calcined.—*Klaproth's Analyses.*

Crystal. This word is used extensively to denote those portions of bodies which have assumed a symmetrical form at the time of acquiring the solid state. Thus we have crystals of salts, of metals, of earths, and of every other substance that possesses a considerable degree of simplicity in its composition. It is likewise used as the name of various substances to which we shall proceed.

Crystal (Factitious). The very fine clear glasses made in imitation of precious stones are sometimes called factitious crystals, but much more commonly pastes. Our opticians and other artists distinguish the dense white glass, which contains much calx of lead, by the name of crystal glass, and frequently enough by that of white flint. See Glass.

Crystal (Mineral). In the ancient dispensatories we find a formula for making a salt under this name, by fusing nitre, projecting a little sulphur thereon, and afterward casting it into cakes.

Crystal (Rock). The purest specimen of siliceous earth. This is either colourless and crystallized in hexagonal pyramids, and then called mountain crystal, or in various other forms. Its specific gravity is from 2·65 to 2·7. Its texture lamellated, and frequently shattered. The application of heat, unless extremely gradual, causes it to crack and lose its transparency. Some of these crystals have been found to consist of pure siliceous earth. Bergman extracted about six of argillaceous and one of calcareous earth from 100 parts of these crystals. The most violent heat of a furnace has not been found to diminish the weight or hardness of rock crystal; but professor Errhmann fused it by flame, urged with a stream of oxigen gas; and by the same means Mr. Francillon fused two pieces into one, but on cooling they flew to pieces, and in part even to a white powder.

The formation of crystal has much engaged the attention of chemists. There seems to be little doubt that this earth is suspended in water, most probably by a true solution, and afterward deposited in the same manner as other soluble bodies are: the only peculiarity appears to be, that so very large a quantity of the water is required to suspend a small quantity of the earth, that this last has eluded the attention of philosophers. The effects of water in the extensive operations of nature, relative to this earth, are however very considerable. The vast basin chiefly composed of siliceous materials deposited by the water of the prodigious fountain of Geyser, in Iceland, described by Von Troil, affords a proof that hot water suspends siliceous earth, and points out a series of experiments to be made with Papin's digester, though not yet undertaken by any one. And the observations of Mr. Genssane, quoted by Chaptal in his Elements of Chemistry, with others of the professor himself, prove that rock crystal is formed in a way not at all differing from that of calcareous spars. Mr. Genssane shows, that a quartzose gurh is formed by simple transudation upon ferruginous rocks; and the same naturalist has taken notice, that when the gurh is worn and deposited by water, rock crystals are formed. The waters which work their way through the quartzose rocks of the mine of Chamillat, near Planche les Mines in Franche Comté, form quartzose stalactites to the roof of the works, and even upon wood. The extremities of these stalactites, which have not assumed a solid consistence, are of a granulated and crystalline substance, easily crushed between the fingers.

In these cavities, called craques by the miners, a fluid gurh is often found, and still oftener crystals ready formed. Chaptal observed at Saint Sauveur, in the work of Laboissiere near Bramebiaou, several incrustations of gurh on the side of the gallery; and these spreading incrustations were terminated by well-formed crystals, whereever the wall overhung, or deviated from the perpendicular. This gurh, when handled, and minutely examined, had no other appearance than that of a siliceous paste of considerable purity.

Bergman obtained crystals resembling rock crystal, but not so hard, by dissolving siliceous earth in the fluoric acid, and leaving it to spontaneous evaporation. Chaptal has observed a fact of the same nature. Mr. Achard obtained a crystal as hard and as transparent as rock crystal, by dissolving the earth of alum in water impregnated with carbonic acid, the fluid filtrating very slowly through the bottom of a porous vessel of baked clay. A crystal of this kind was sent by him to my late friend Mr. Magellan, who exhibited it to the Royal Academy of Sciences at Paris, in the year 1778; and from whom I received it, and still retain it in my possession. Others have since attempted to repeat the experiment, though without success; and there have not been wanting several writers who have questioned the validity of the fact, though in my opinion very rashly; the character of this chemist, and the obscurity of the subject, in which so many unheeded circumstances might have conspired either to produce or vary the results, being amply sufficient to defend him from any imputation of so degrading a nature. It has been thought in particular, that a very perfect state of repose is necessary for the success of this experiment of a crystallization so extremely slow; and indeed if it be considered how greatly the phænomena of crystallization are influenced by the slightest agitation, and at the same time how considerable the agitations of the grounds and buildings are in great towns, it will not appear at all wonderful, that the Parisian chemists should not have succeeded in attempting to repeat this experiment. Any one may satisfy himself as to these vibrations, by observing the reflection of objects in a basin of mercury, which, however defended from the impressions of the external air, does not remain a moment in tranquillity, unless at a very great distance from all workshops or roads where carriages pass.

Since that time Guyton-Morveau, having enclosed rock crystals with a bar of iron in a bottle filled with carbonated water, perceived a vitreous point fixed to the iron, which he supposed to be a rock crystal formed by this operation; so that he considers iron as a necessary intermedium to enable the carbonic acid to dissolve quartz.

Rock crystal, though the softest among transparent stones, is harder than most of the opake stones, and much harder than glass.

Crystallization. Whenever the parts of bodies are separated from each other, and suspended in a medium or solvent, in which they can freely move, they either remain at a distance from each other by virtue of their attraction to the solvent, or they come together by their own mutual attraction, and form consistent masses. See Attraction.

From the facts there appears to be just ground to conclude that the particles of bodies demand certain relative positions at like distances, in order that the energy of their attraction may be the greatest possible; in a manner similar to what we observe in the attractions of magnetism and electricity. This polarity of the particles deducible by mathematical reasoning from their supposed figures, but no doubt in a great measure dependent on their component parts likewise, will cause the aggregate masses to assume some determinate figure, in similar circumstances or situations, and this figure will be modified in a great variety of ways accordingly as those circumstances are changed. If the particles be suspended or kept fluid, either by a due quantity of solvent, or by heat, or by both of these agents, a separation or deposition will ensue, whenever the quantity of the solvent or of the heat is sufficiently diminished. If this diminution be sudden, the particles will suddenly come together, with their sides or faces presented to each other in the order they happened to possess at the instant or short time of coagulation; subject likewise to all the accidental irregularities of agitation in the mass of the fluid. In such cases the particles will form a solid, possessing little or no symmetry in its figure. This is called confused crystallization.

On the other hand it may happen, that by gradual evaporation, or cooling, the diminution of the quantities of solvent, or of heat, may take place so slowly as to occasion a degree of motion altogether inconsiderable among the parts of the fluid. In this case, the particles which are about to separate will approach each other with extreme slowness, and no circumstance will interfere to prevent their applying such sides or faces towards each other as are best adapted to the governing laws of attraction. As soon as the particles have arrived to a distance less than is sufficient for their mutual attraction to overcome the power of the fluid which suspends them, they will rush together, and form symmetrical bodies possessing figures originating in, and dependent on the properties or nature of the particles which form them, and the symmetry will be more perfect the less the crystallization is influenced by disturbing causes. This is called regular crystallization, and the symmetrical bodies are called crystals.

As the agitation arising from the causes just mentioned is sufficient to prevent the regular formation of crystals, so likewise it is found, that mechanical agitation is still more destructive of their regularity. Slow crystallization produces sugar candy; a quicker crystallization affords loaf sugar. When a balloon some years ago was inflated at Moorfields by inflammable air, extricated by the action of sulphuric acid upon zinc, the white vitriol of commerce was afforded in beautiful transparent crystals, which the shops refused to purchase; but when by subsequent solution and mechanical agitation a white mass of confused crystals was obtained, the shop-keepers recognised the *white copperas* they had been used to deal in. The presence or absence of external impulse is of so much consequence in crystallization, that it may be doubted whether the action of light, which considerably impedes the formation of regular crystals, may not be attributed to this cause. The electric state of the atmosphere is said to influence crystallization: and the contact of air appears to be necessary, as salts that will not shoot in a fluid covered with a pellicle, begin to form crystals as soon as the pellicle is broken.

In a paper in the Journal de Physique Mr. Leblanc gives instructions for obtaining crystals of large size. His method is to employ flat glass or china vessels: to pour into these the solutions boiled down to the point of crystallization: to select the neatest of the small crystals formed, and put them into vessels with more of the motherwater of a solution that has been brought to crystallize confusedly: to turn the crystals at least once a day: and to supply them from time to time with fresh motherwater. If the crystals be laid on their sides they will increase most in length: if on their ends, most in breadth. When they have ceased to grow larger, they must be taken out of the liquor, or they will soon begin to diminish. It may be observed in general, that very large crystals are less transparent than those that are small.

The permanent texture of bodies, their fracture, and other circumstances, appear to depend upon the state of crystallization at the time of assuming the solid form. In metals, for example, the crystals are smaller and more confused the hastier the cooling. Thus steel suddenly cooled breaks with a r fracture, possesses a diminished gravity, and is very hard, whereas e steel, more slowly cooled, will be softer, difficult to be broken asunder, hen broken exhibits a very different l texture. The crystals of other me- y be obtained by fusing them in a e with a hole in its bottom closed by er, which is to be drawn out after sel has been removed from the fire, e surface of the metal has begun to l. The same effect may be observed metal be poured into a plate or dish, inclined, which is to be suddenly in- n the opposite direction, as soon as al begins to congeal round its edges. first method, the fluid part of the uns out of the hole, leaving a kind lined with crystals: in the latter e superior part, which is fluid, runs leaves a plate of metal studded over ystals.

e is scarcely any experiment in che- which does not afford some appear- a curious nature, referable to cry- tion.

n bodies dissolved in any fluid are ed by crystallization, they are always o retain a part of the fluid. The thus retained by saline crystals is the water of crystallization. This appears to be essential to the trans- crystalline form of salts, and is no retained by virtue of their attraction t fluid. From some experiments, in a much greater degree of cooling oduced by the solution of crystallized an of such as had lost its water of lization, it may be inferred, that this xists in crystals in the congealed or ate, and perhaps much denser than ce. Most salts may be deprived of ater of crystallization by mere heat. ose it in the common temperature of nosphere, and fall into a pulverulent called an efflorescence. Other salts water so strongly, that they draw it he atmosphere, and gradually become a phænomenon distinguished by the of deliquescence. Mr. Baumé affirms, e water of crystallization in all neu- ts with bases of fixed alkali is pure, ey are not capable of taking up a re- cy of either principle in their cry- This however may be doubted.

crystallization of salts is usually d by evaporating part of the water; may likewise be made to take place traction of the water in the way of al affinity. Thus if alcohol be added qual volume of a strong solution of he spirit combines with the water, nost the whole of the nitre separates stant in the crystalline form. There oubt but appearances of this kind ration have misled chemists on vari- asions.

operation of crystallizing, or crystallization, is of great utility in the purifying of various saline substances. Most salts are suspended in water in greater quantities at more elevated temperatures, and separate more or less by cooling. In this property, and likewise in the quantity of salt capable of being suspended in a given quantity of water, they differ greatly from each other. It is therefore practicable in general to separate salts by due management of the temperature and evaporation. For example, if a solution of nitre and common salt be evaporated over the fire, and a small quantity be now and then taken out for trial, it will be found, at a certain period of the concentration, that a considerable portion of salt will separate by cooling, and that this salt is for the most part pure nitre. When this is seen, the whole fluid may be cooled to separate part of the nitre, after which, evaporation may be proceeded upon as before. This manipulation depends upon the different properties of the two salts with regard to their solubility and crystallization in like circumstances. For nitre is considerably more soluble in hot than in cold water, while common salt is scarcely more soluble in the one case than in the other. The common salt consequently separates in crystals as the evaporation of the heated fluid goes on, and is taken out with a ladle from time to time, whereas the nitre is separated by successive coolings at proper periods.

Those chemists who consider heat as a peculiar substance, and not a modification of matter, are in general inclined to reckon the fluid state a solution in this matter; and the crystallization of bodies merely fused is by them accounted for by the abstraction of this supposed solvent.

It was natural for the earlier mineralogists and chemists to distinguish bodies by their symmetrical figures. Subsequent experience has however shown, that the crystallization of bodies is variable by so many and such minute circumstances, that a considerable dependance on this single attribute must necessarily be productive of error. Modern chemists, as the methods of analysis became more perfect, seem to have adopted a prejudice of the contrary nature, by almost totally rejecting the external figures of bodies as indications of their component parts. Romé de Lisle in his Crystallographie, Bergman in one of his Essays, and the abbe Haüy, have treated expressly and scientifically upon the formation of those geometrical figures which constitute crystals; but the subject is very far from being enough simplified to admit of any ready application. The miner, the mineralogist, and the chemist will perceive a number of circumstances in natural and artificial bodies relative to their configuration, grouping, colour, fracture, specific gravity, &c., by means of which he may form very probable conjectures as to their contents, and the experiments requisite to be instituted upon them: but in the present state of science there is no method, which can be substituted instead of actual inspection, and the attentive consideration of minerals and chemical products, the contents of which are previously known.

An ingenious and handy graphometer, or instrument for measuring the angles of crystals, by Mr. Bancks in the Strand, is described in my Journal, vol. xii. p. 374.

Culm. A term exclusively applied by dealers in pit-coal, to denote such coal as does not cake, or adhere together, when heated. Small pieces of coal of this kind are of much less value than larger pieces; and on this account the duties on culm are less than upon coal. See Coal.

Cupel. A shallow earthen vessel somewhat resembling a cup, from which it derives its name. It is made of phosphat of lime, or the residue of burned bones rammed into a mould, which gives it its figure. This vessel is used in assays wherein the precious metals are fused with lead, which becomes converted into glass, and carries the impure alloy with it. See Assay.

Cupellation. The refining of gold by scorification with lead, upon the cupel is called cupellation. See Assay.

Curd. The coagulum which separates from milk upon the addition of acid or other substances. See Milk, also Cheese.

D.

DAMPS. The permanently elastic fluids which are extricated in mines, and are destructive to animal life, are called damps by the miners. The chief distinctions made by the miners, are choak-damp, which extinguishes their candles, hovers about the bottom of the mine, and consists for the most part of carbonic acid gas; and fire-damp, or hidrogen gas, which occupies the superior spaces, and does great mischief by exploding whenever it comes in contact with their lights. The stithe, or styth, a kind of choak-damp not unfrequent in our coalmines in the north, is said by some to be nitrogen gas. The history of the effects of these fluids is very curious, and has been given much in detail by various writers. But the general properties of elastic fluids having of late years been much elucidated by the experiments of Dr. Priestley and others, it is at present found as easy to account, in a general way, for the wonderful effects of these fluids, as for any other appearances that take place in chemistry. See Gas.

Daurite. A rose-coloured stone, crystallized in hexaëdra, with a triangular apex, so called by Delametherie because it came from Dauria. Like the tourmalin it is rendered electric by heat. It consists of alumine 48 parts, silex 36, lime 3·5, oxide of manganese 9.—*Journ. de Physique.*

Daze, or Glimmer. A mine term applied to micaceous substances.

Decantation. The action of pouring off the clearer part of a fluid by gently inclining the vessel after the grosser parts have been suffered to subside. Some chemists avoid the use of the filter altogether, and separate solids from fluids by decantation. But there are situations, in which either method may be preferable to the other.

Decoction. The operation of boiling. This term is likewise used to denote the fluid itself which has been made to take up certain soluble principles by boiling. Thus we say a decoction of the bark, or other parts of vegetables, of flesh, &c.

Decoction is chiefly applied to organised substances, and is rather a culinary or pharmaceutical than a chemical operation. It serves to soften and considerably alter the parts of vegetables and animals; but its effects in general are too gross and complicated, to afford satisfactory theoretical results. In this process the volatile parts, if any be present, fly away and are lost; and it is attended with other inconveniences, which the chemical practitioner will very readily perceive.

Decomposition. This word was formerly used in a sense almost opposite to that which universally prevails at present. Newton, Boyle, and other earlier English writers, as the annotator on Macquer's Chemical Dictionary observes, used it to denote the composition or junction of two or more bodies which were previously compounded of other parts. But it is now understood to imply the separation of the component parts or principles of bodies from each other.

It is distinguishable from division, because this last may consist in the separation of parts of the same nature as the body itself, which decomposition does not. Thus common salt may be divided by pulverizing or otherwise, into parts of extreme minuteness, which still continue to be common salt: but it cannot be said to be decomposed, until its alkali and acid are separated from each other.

The decomposition of bodies forms a very large part of chemical science. It seems probable from the operations we are acquainted with, that it seldom takes place but in consequence of some combination or composition having been effected. It would be difficult to point out an instance of the separation of any of the principles of bodies which has been effected, unless in consequence of some new combination. The only exceptions seem to consist in those separations which are made by mere heat; and these cannot be admitted as exceptions, if we attend to the means by which the temperature was originally raised, or if we admit heat to be a peculiar substance.

DECREPITATION. The small and successive explosions afforded in many chemical operations are distinguished by this name. They are either produced by heating metallic substances with nitre, which take fire and explode, or else by suddenly heating crystallized bodies. Thus common salt, which has been deprived of its water of crystallization by heat, is called decrepitated. See SALT.

DELFT WARE. A kind of pottery made at Delft in Holland, which formerly supplied all Europe, until it was supplanted by a yellow pottery made in France, which has since given place to the queen's ware, and various kinds of china fabricated in Great Britain.

Pottery may be distinguished into two kinds; namely, that which has a transparent varnish or glaze, and that which has an opake glaze. The queen's ware, the stone ware, and various kinds of china are of the former sort. The Delft ware and other kinds of china ware are of the latter kind. In every kind of pottery it is an object of great importance, that the expansions and contractions of the glaze and the body should be nearly the same at like temperatures: but this desirable property is seldom found in vessels covered with an opake glaze or enamel.

As the Delft pottery has fallen into disuse, it seems of less consequence to inquire into its composition, more especially as this disuse has been occasioned by the production of better potteries.

DELIQUESCENCE. The spontaneous assumption of the fluid state by certain saline substances, when left exposed to the air, in consequence of the water they attract from it.

We know of no criterions to determine, à priori, whether any combination shall be consistent, efflorescent, or deliquescent in the air. It appears, that, whenever any salt attracts moisture more strongly than the air is disposed to retain it, it is deliquescent; and, on the contrary, if the air be more attractive of moisture, it will cause the salt to effloresce. Salts, which are not commonly deliquescent, will be liquefied in a very humid air, and other salts strongly attractive of humidity may be dried in proper situations.

Generally speaking, the simpler substances are more deliquescent than such as are compounded. So the acids and pure alkalis are all strongly attractive of water; most of the former being disposed to rise in distillation, long before they are deprived of the last portions of water, and consequently they are constantly in the fluid state, unless when congealed by cold.

DELIQUIUM. Deliquescent salts are by some writers said to fall into a deliquium.

DEMIMETAL. A word sometimes used for semimetal, which see.

DEPHLEGMATION. Any method by which bodies are deprived of water. The term is nearly synonymous with concentration. It is effected either by evaporation or congelation, and was chiefly used in speaking of very aqueous fluids, whereas the word concentration is usually applied to the extreme dephlegmation of acids.

DEPHLOGISTICATED. A term of the old chemistry implying deprived of phlogiston, or the inflammable principle, and nearly synonymous with what is now expressed by *oxigenated*, or *oxided*.

DEPHLOGISTICATED AIR. The same with oxigen gas.

DERBYSHIRE SPAR. A combination of calcareous earth with a peculiar acid called the FLUORIC, which see.

DESTRUCTIVE DISTILLATION. When organised substances or their products are exposed to distillation until the whole has suffered all that the furnace can effect, the process is called destructive distillation. As this method decomposes bodies so as to separate their component parts from each other into a state of considerable simplicity: and as the original principles of organised bodies seem to be few, the products of substances of the vegetable kingdom, though much differing from each other at first, are found to possess characters so similar as to render the method of no great use, unless in conjunction with other processes. The same may be observed of the destructive distillation of animal substances.

DETONATION. A sudden combustion and explosion. The detonations observed in chemical experiments are mostly caused by the destruction of the acid of nitre in contact with some combustible substance. This acid takes fire spontaneously, when applied to charcoal or to volatile oils (see ACID, NITRIC): but the sudden explosion called detonation requires, that the acid should be in a state nearly or completely dry, and the inflammable substance of considerable fixity.

Various theories of detonation exhibiting considerable ingenuity have been maintained by the earlier chemists, in which the facts are accurately stated and plausibly accounted for. The discoveries of the moderns were however wanting to elucidate this subject. Nitrats are decomposable by mere heat, the acid being separated into its component parts, nitrogen and oxigen. It is this oxigen which so strongly and suddenly destroys combustible substances in the way of detonation. The detonation of common nitre and charcoal is one of the most common, and is seen in the effects of *gunpowder* (which see). In experiments of this kind it is remarkable, that the combustion is maintained by oxigen, which is not in the elastic state, but fixed in the nitre: whence it should follow, that either the oxigen or the combustible body, even in the fixed state, has a great capacity for caloric, of which they contain a large quantity.

The oxigenated muriatic acid, being much more ready to part with its oxigen than the nitric, is found to afford a much more sudden and stronger detonation. A new kind of gunpowder has accordingly been made out of the salt produced by the combination of this acid and potash, for which recourse may be had to the article Gunpowder.

The most remarkable detonations in chemistry are afforded by *gunpowder*, *fulminating powder*, certain metallic oxides, and the *gunpowder* of oxigenated muriatic acid. See Fulminating Powders, and Gunpowder.

Dew. Formerly this name was given to the phlegm that rose first in the distillation of several substances: thus the dew of vitriol, the dew of honey, were the watery liquors, which rise first when these substances are distilled.

Diamond. The diamond is a mineral, which was long considered as a stone, but has since been proved to be an inflammable substance, and is now classed accordingly. See Carbon. It is found in a sandy earth in the hither peninsula of India, in the island of Borneo, and in the Brazils. The form of the diamond, when perfect, is that of an eight-sided prism. There are also cubical diamonds, which are suspected to be of a different nature from the others. Diamonds are of a lamellated texture, and may be easily split by a blow in a proper direction. The consent of mankind has fixed an immense value upon this stone. The inimitable qualities, to which this preference is attached, are its hardness, which is such that it easily cuts all other substances, and takes an exquisite and lasting polish; and its very great refracting power, which is so considerable, as to occasion all the light to be reflected that falls on any of its interior surfaces at a greater angle of incidence than 24¼ degrees. Hence its lustre, when cut into the form of a regular solid, is very great. This may be easily understood, when it is considered, that an artificial gem does not reflect the light from its hinder surface, until that surface is inclined in an angle of 41 degrees. The diamond therefore will not only throw back all the light which an artificial gem would reflect, but likewise half as much more; which, falling between the angles of 41 degrees and 24¼, would have been suffered to pass through by the false gem. It is not surprising, therefore, that the effect of the diamond should be so much greater; more especially when we attend to its extreme transparency, and the accuracy of its polish.

No solvent but the sulphuric acid has any effect on this gem; in which if diamond powder be triturated, and evaporation carried on nearly to dryness, the acid grows black, and deposits pellicles that burn, and are entirely consumed.

Diamonds are of all colours: the clear transparent stones are the most esteemed; and, next to them, those of a deeper tinge. Whether these coloured stones be really of the same nature as the clear diamond, has not been ascertained. The lapidaries reckon them to be diamonds from their hardness and lustre. Those that are tinged throughout are said to draw colour. Some acquire an appearance of being coloured, from having cavities in them filled with red, yellow, or brown earths, which are called fouls, or specks: and the defect in these may be cured by exposure to heat, which changes the earth black, after which the diamond plays colourless.

The value of diamonds is reckoned by weight, at so much the carat. The carat used in this valuation is divided into four parts, called grains; but less than troy grains by one fifth; for 150 carats are equal to the troy ounce of 480 grains. Rough diamonds, without any flaw or blemish, are valued at two pounds sterling the single carat; and the expense of cutting amounts to 3¼ pounds the carat. The value is greatly diminished if the diamond be imperfect, or of a bad figure; and it increases rapidly with the size. To find the worth of a rough diamond, its weight in carats must be squared, and multiplied by two, and the product will be pounds sterling. A cut or finished diamond is worth four times as much as one that is still rough. Those of the greatest brilliancy are sometimes valued at a higher rate; but this value has never been applied to stones of excessive magnitude. It does not appear, that any sum exceeding one hundred and fifty thousand pounds has been given for a diamond. See Magellan's improved edition of Cronstedt's Mineralogy, for a considerable mass of entertaining information on this subject.

Diaphoretic Antimony. This is a white oxide of antimony, made by calcining antimony with thrice its weight of nitre. See Antimony.

Diaspore. An aluminous stone containing according to Vauquelin nearly 80 parts of alumine, 3 of oxide of iron, and 16 or 17 of water, of which it may be deprived by heating it to ignition.

Digestion. The slow action of a solvent upon any substance for a length of time is called digestion by chemists. In this operation the action of the solvent is frequently assisted by heat, in some instances stronger than in others, but seldom equal to that of boiling water. Chemical writers frequently mention a digesting heat. No definite application is made of these terms, but they usually signify a degree of heat exceeding that of living animals, and less than that of boiling water, such as may be produced by a vessel in hot ashes. It may re be taken to be somewhere about rees.

stive Salt. Muriat of potash.

ster. The digester is an instrument d by Mr. Papin about the beginning last century, and usually called digester. It is a strong vessel of or iron, with a cover adapted to on with pieces of felt or paper inter- In some vessels of this kind the s made of an elliptical form, and is l through an opening of the same which it completely closes by appli- of its upper surface to the internal of the vessel. A valve with a small e is made in the cover, the stopper h valve may be more or less loaded by actual weights, or by pressure a apparatus on the principle of the d. Instead of the common valve N. Edelcrantz employs a cylinder in er, with a steam-tight piston. This nay be loaded with any weight, and inder is perforated with small holes rent heights, and a larger hole near , to allow an exit to the steam re- to the pressure it exerts.

purpose of this vessel is to prevent of heat by evaporation. The solvent of water when heated in this vessel is increased, chiefly no doubt on ac- of its increased temperature, and like- a all probability on account of the re exerted by the reaction of the water or steam which is upon the of being generated.

not hear of many experiments made s engine. The inventor proposed it ulinary utensil, by which the grisly ny parts of animals might be com- with water in the form of a jelly, as ct the case. But whether a food so with the phosphoric salt of lime be wholesome may perhaps admit of doubts: it is likewise very liable to e an empyreuma, if the heat be car- ittle too high. See Bones.

rman thought that the digester might a considerable solvent power of upon the pure earths, and he consi- he deposition of siliceous earth from water of the stupendous fountain of in Iceland, mentioned by Von Troil, oof of such a solution.

illation. The separation of a vo- uid from other substances, which are atile, by applying a due degree of the mixture, and afterward con- the vapours in another part of the us by cooling. The older chemical distinguished three kinds of distilla- er ascensum, per descensum, and per

distillation per ascensum is performed alembic: here the elastic vapours rpendicularly, and are condensed in d of the vessel, from which they run into the receiver through the beak. Large stills are constructed on this principle. The chief advantage it seems to possess consists in the facility with which the residues of the distillation may be come at; and in those few instances wherein considerable quantities of flowers or pulverulent matter rise along with other vapours which are condensed into the fluid form, it may perhaps afford some facility in separating them.

The distillation formerly denominated per descensum consisted in placing certain herbs or other substances in a shallow tray or cullender, which was applied like a cover to a tall cylindrical glass vessel. Another cover was then laid over this cullender, which consisted of a pan containing lighted charcoal. The heat was therefore applied above the materials, and the volatile parts were forced to descend, and became condensed against the sides of the vessel. Philosophical chemists at present consider this method as entirely useless; but there are several instances of its convenient and advantageous application in large works, as in the distillation of zinc, of pit-coal, and other substances.

The distillation per latus is the simplest and most extensively used: a retort and a receiver are the fewest vessels which can be used; and where the heat is properly managed, every operation of the other methods may be performed in this way with great facility. It has accordingly happened, that most of the improvements of distillation for philosophical purposes have been made in this method. See Laboratory.

The general rule for performing all distillations in the most safe, accurate, and perfect manner, consists in applying no more heat than is necessary to raise the volatile matter, and in keeping the receiving apparatus sufficiently cool, either by surrounding it with wet cloths, immersing it in water, occasionally renewed or kept cold by putting ice or snow into it, &c., that the whole of what rises may be condensed, and not escape into the air in the state of vapour.

Dittany of Crete. Sixteen ounces of the leaves of this plant yield about half a drachm of a strong, aromatic, essential oil, which coagulates by cold, resembling camphor. From an ounce of this plant Neumann obtained with water two drachms and a scruple of extract; and from the same quantity, with alcohol, he obtained a drachm and a half of resinous extract. He observes, that the green colour of the leaves resides in the resin, and is extractible by alcohol, especially after water had previously extracted the gummy part, some of which, being also soluble by alcohol along with the resin, alters the colour of the spirituous tincture.

Division. Some writers use this word as a term to denote every mechanical separation of the parts of bodies. According to this notion, clipping, pounding, trituration, levigation, and the like, are methods of division.

Docimastic Art. This name is given to the art of assaying, or determining, by experiments, in the small way, the quantities and nature of the component parts of bodies intended to be used in commerce. See Assay, Blowpipe, Analysis, and the several metals.

Dolomite. The elastic marble, or supercarbonat of lime, first analysed by Dolomieu. Its colour is grayish or yellowish white, or light red, with little lustre or transparency: fracture conchoidal or granularly foliated: gravity 2·85 or 2·86. Some varieties are phosphorescent. It consists of lime 44·29, carbonic acid 46·1, alumine 5·86, magnesia 1·4, iron ·074. It effervesces slowly with acids.

Dome. A hemispherical covering of forged iron, with a tube or chimney proceeding from its upper part. The cavity between the dome and the fuel, and likewise the internal space in the chimney, being filled with air much rarefied by heat, produce a strong draught, and greatly increase the intensity of the fire. It has also been supposed to reflect the heat or flame upon the vessels, and on this account a furnace with a cover of this form is called a reverberatory furnace.

Doronicum. From two ounces of the dry root were obtained by water fourteen drachms of extract; and from the same quantity, with alcohol, four drachms and a half. This root is supposed by some to be poisonous, especially when fresh.—*Neumann.*

Dragon's Blood is a red-coloured, inodorous, and insipid resin, insoluble in water, soluble in alcohol and in oils, to both which liquors it communicates a red colour. By fire it is fusible, inflammable, and it emits an acid vapour, like that of benzoin. A solution of dragon's blood in alcohol is used for staining marble, to which it gives a red tinge, which penetrates more or less deeply according to the heat of the marble during the application. But as it spreads at the same time that it sinks deep, for fine designs the marble should be cold. Mr. du Fay says, that, by adding pitch to this solution, the colour may be rendered deeper.

Drake- or Druse-Hol. A Swedish denomination used to express a cluster of crystals which line a cavity in any mineral.

Drying Oil. Fat oils require a very long time to become consistent by exposure to the atmosphere; but painters render them more disposed to dry, by boiling them with oxides of lead. Linseed oil holding oxide of lead in solution, which it takes up by boiling with litharge, is called drying oil, from this property.

Ductility. That property or texture of bodies, which renders it practicable to draw them out in length, while their thickness is diminished without any actual fracture of their parts. This term is almost exclusively applied to metals, and implies that they are capable of being made into wire, by drawing a portion of the metal through a hole in a plate of steel or other proper composition. The ductility of a metal depends therefore on two circumstances, namely, its malleability or property of extending by pressure, and its tenacity or power of resisting an actual separation of its parts. If the metal be not malleable enough, it will resist the action of the wire-drawer's plate, and not change its figure to a sufficiently small diameter to come through: if, on the other hand, it be very malleable, but at the same time deficient in tenacity, the part which has been put through the hole may not be strong enough to bear, without breaking, that pull which is necessary to form the wire.

Gold, silver, platina, copper, and iron have tenacity and malleability enough to afford very fine wire. Lead and tin have not tenacity enough to be wrought in this way to any advantage, though the hammer and the laminating rollers are capable of extending them to extreme thinness. Zinc laminates very well, but scarcely supports the sudden action of the hammer without breaking, and is altogether unfit to be drawn into wire.

Most authors confound the words malleability, laminability, and ductility together, and use them in a loose indiscriminate way; but they are very different. Malleability is the property of a body which enlarges one or two of its three dimensions, by a blow or pressure very suddenly applied. Laminability belongs to bodies extensible in dimension by a gradually applied pressure. And ductility is properly to be attributed to such bodies as can be rendered longer and thinner by drawing them through a hole of less area than the transverse section of the body so drawn.

Duckstein. The duckstein of the Germans is a white calcareous stone, formed by the deposition of chalk from water, in which it is diffused. It is generally formed on branches or roots of trees, and stones of different kinds, and differs from the stalactites in its mode of formation, this last being deposited by water in the act of evaporation as it transudes through the roofs of caverns.

Dulcification. A medical process consisting in combining the mineral acids with alcohol by digestion, or more frequently by distillation. The processes for this purpose are not in general very scientific. When ether is made, the first produce is very pure alcohol, little altered, or slightly combined with some acid; next the ether, then partly decomposed acid, with some vinegar, according to the management of the operation. The dulcified acids of the dispensatories consist of an admixture of these products, which in all probability is seldom the same.

t laboratories, where the degrees ie time of charging the receiver, essential circumstances, are liable ed.

g. The art of dyeing is considered t importance to society, according sent habits and usages. It consists upon cloths of various kinds any hich may be required, in such a s that they shall not be easily al- those agents, to which the cloth probably be exposed during its wear.

re can be no probable cause by y colouring matter can adhere to , except an attraction subsisting he two substances, it must follow, e will be few tingeing matters f indelibly or strongly attaching s by simple application. For such nent would imply, that the elec- tion by which it was effected was han all or most others; a circum- the order of events not likely to ften. On this account it is, that he dyeing processes appear to con- lying some substance or principle th, which forms a colouring mat- y insoluble, by combining with er principle applied to it in its dhesion to the cloth.

g is therefore a chemical art; and erations were no more complicated ere expressed, it would be easy, not cquire a perfect theory of its pro- ut likewise to bring many of them ction, which at present constitute st reproach. But the effects and tions produced in this way being to all appearance dependent on d actions of chemical affinity, but n general produced by means dis- by mere and almost casual trial, it that no small degree of sagacity uous research is necessary, to de- the uses and advantages of the ngredients. In addition to these ents, the theory of dyeing has been mpeded in its progress, by the little men of science have found in at- to repeat its manipulations, and usy of manufacturers, who, with tice, are inclined to estimate their in their own gainful discoveries as ion which they have a right to ze by keeping them secret. It has gly happened from these causes, ing has been merely a practical ery lately, that it has been culti- a few eminent chemists.

earlier theories of dyeing, like nencements of the other branches l philosophy, have been deduced s apparently too remote for our neans of investigation, namely, the tion of the particles of bodies. from observations on the colours by light reflected from, or transmitted through, thin transparent bodies, as exhibited in experiments too few and imperfect to have afforded satisfactory conclusions in the hands of a philosopher of less sagacity, formed a general inference, that the colours of all bodies are governed by the magnitude of their particles. He likewise brought their densities into consideration, as a modifying circumstance, but this only in a conjectural way, and he altogether overlooked that property, which on another occasion he had noticed as increasing their refracting power, namely their combustibility. Mr. Delaval, in his Treatise on Light and Colours, and a subsequent paper in the Manchester Memoirs, has displayed this doctrine very much at large, with many valuable improvements and discoveries. It is evident, however, that much remains to be done before any clear and practical application of this theory can take place. If we suppose, that a due magnitude and refractive power be all that is necessary for the particles of bodies to exhibit a determinate colour in white light, which indeed seems to be nearly proved, we shall find no data among our present acquisitions sufficient to afford any determination of these requisites. To produce a green colour there will be no constant thickness or magnitude of particles required; for this will vary with the reflective power. We know, that the reflective and refractive powers are the same, and are not governed by the mere density, but are greatest in combustible bodies. And when, in addition to these difficulties with grosser bodies, we observe, that there is no possibility of determining either the magnitude, figure, density, or other obvious properties of indiscernible particles, we may justly conclude, that it will be a long time before we shall be able to apply the Newtonian theory to the art of dyeing.

The theory of the celebrated Hellot supposed, that the pores of bodies are opened by the heat used in dyeing, that the colouring matter was deposited in these interstices, and there firmly held by the subsequent contraction of cooling, assisted by a kind of varnish or covering deposited by the salts used. This theory has not met with much success, though, like other hypothetical speculations on obscure objects, it may not be difficult to apply it to most of the known facts. It is moreover contradicted not only by the circumstance, that the stuff does not in all instances take the colour of the dyer's bath, but some other colour; and that it sometimes happens that the bath, instead of sharing its colour with the stuff, as it ought to do, is rendered as clear as water by an entire privation of all its tingeing matter: both which circumstances evidently prove, that a chemical combination takes place in consequence of an attraction exerted between the stuff and the colouring matter.

The attention of philosophers is not therefore at present much directed toward the mechanism of the particles of bodies used in dyeing, but to the elective attractions exercised between them, and the nature of the compounds they form. In this inquiry they have naturally endeavoured to extend their researches by endeavouring to generalize particular facts. Some have supposed the various colours of bodies to be in a very great measure owing to the presence of iron; a body the most universally diffused, and susceptible of a great variety of shades of colour, according to the degree of oxidation it may have undergone. It does not however appear, that this metal, though so widely diffused, is found in sufficient quantity to be admitted as the efficient cause of the tinges induced upon bodies. But the more modern chemists have with no small degree of probability applied the doctrines of combustion and revivification, or the combination and disengagement of oxigen, to the fixation and discharging of colours.

The most remarkable general fact in the art of dyeing consists in the different degrees of facility, with which animal and vegetable substances attract and retain colouring matter; or rather the degree of facility, with which the dyer finds he can tinge them with any intended colour. The chief materials of stuff to be dyed are wool, silk, cotton, and linen, of which the former two are more easily dyed than the latter. This has been usually attributed to their greater attraction to the tingeing matter; though it does not appear to be true in all cases, because the stuffs more difficult to be dyed will absorb a greater quantity of that matter, before they acquire the requisite intensity of colour obtainable in the former by a less proportion of the same drug. In every attempt to deduce the causes of these different effects, it is proper to inquire into the properties of these bodies by experiment.

Wool, silk, cotton, and linen, though in various respects similar to each other, are nevertheless found to differ exceedingly in others. In the method of destructive distillation, wool yields much impure volatile alkali, a portion of empyreumatic oil, leaving about one fifth of incombustible fixed residue. Silk affords less volatile alkali and oil, and more residue. Cotton affords no volatile alkali and little oil, but some acid, leaving little coal, which may for the most part be burned by calcination in the air. Here we observe a very considerable difference in the habitudes and products of the several substances; but the scientific experiments of Berthollet show it still more evidently. He distilled nitric acid from silk, and obtained oxalic acid, with a greasy matter, which, though it at first congealed on the surface of the liquor in the receiver, was afterward dissolved in it by means of heat, even though diluted with water with which it passed through the filter. Wool also afforded the same greasy matter, and oxalic acid; the last of which was more abundant in quantity than he obtained by the same treatment from any other substance. But the oily part of vegetables was totally destroyed by similar treatment, no greasy matter being afforded; and on analysing cotton, he obtained oxalic acid, but no other product, and the quantity was far inferior to that yielded by animal substances. It was remarkable, that the cotton left no residue, but was entirely converted into elastic fluid and oxalic acid, which last is likewise easily convertible into carbonic acid and charcoal.

Mr. Henry, in his remarks on these experiments, appears to think, that the chief difference between the animal and vegetable substances consists in the former containing a more abundant greasy principle, soluble in a watery menstruum, which the more sparing portion of oil in the latter is not; and likewise in the animal substance containing alkali, or at least one of its component parts: whereas the vegetable affords acid. On these circumstances indeed the different modes of treatment evidently depend. So that it is remarkable, that vegetable substances, the oil of which is wholly destroyed by nitric acid, and to the texture of which the mineral acids are in general injurious, will bear steeping in solutions of caustic alkali of such strength as would prove totally destructive to wool.

Wool is naturally so much disposed to combine with colouring matter, that it requires but little preparation for the immediate processes of dyeing; nothing more being required than to cleanse it, by scouring, from a fatty substance, called the yolk, which is contained in the fleece. For this purpose an alkaline liquor is necessary; but as alkalis injure the texture of the wool, a very weak solution may be used. For if more alkali were present than is sufficient to convert the yolk into soap, it would attack the wool itself. Putrid urine is therefore generally used, as being cheap, and containing a volatile alkali, which, uniting with the grease, renders it soluble in water.

Silk when taken from the cocoon is covered with a kind of varnish, which, because it does not easily yield either to water or alcohol, is usually said to be soluble in neither. It is therefore usual to boil the silk with an alkali, to disengage this matter. Much care is necessary in this operation, because the silk itself is easily corroded or discoloured. Fine soap is commonly used, but even this is said to be detrimental; and the white China silk, which is supposed to be prepared without soap, has a lustre superior to that of Europe. It is however more than probable that the Chinese have a different kind of silk-worm beside that cultivated in Europe. A weak solution of car-

soda has been used with success

fluid or dissolved to the precipi-
olid state; by which means a per-
ring of the black inky matter will
be applied in close contact with the surface of the most minute fibres of the cotton. This dye will therefore not only be more intense, but likewise more adherent and durable.

The French dyers, and after them the English, have given the name of *mordant* to those substances which are previously applied to piece goods, in order that they may afterward take a required tinge or dye.

It is evident, that, if the mordant be universally applied over the whole of a piece of goods, and this be afterward immersed in the dye, it will receive a tinge over all its surface; but if it be applied only in parts, the dye will strike in those parts only. The former process constitutes the art of dyeing, properly so called; and the latter, the act of painting, staining, or printing, woollens, cottons, or linens.

In the art of printing piece goods, the mordant is usually mixed with gum seneca, and applied by means of blocks or wooden engravings in relief, or from copper plates, and the colours are brought out by immersion in vessels filled with suitable compositions. Dyers call the latter fluid the bath. The art of printing affords many processes, in which the effect of mordants, both simple and compound, is exhibited. The following is taken from Berthollet.

The mordant employed for linens, intended to receive different shades of red, is prepared by dissolving in eight pounds of hot water, three pounds of alum, and one pound of acetit of lead, to which two ounces of potash, and afterward two ounces of powdered chalk, are added.

In this mixture the sulphuric acid combines with the lead of the acetit and falls down, because unsoluble, while the argillaceous earth of the alum unites with the acetous acid disengaged from the acetit of lead. The mordant therefore consists of an argillaceous acetous salt, and the small quantities of alkali and chalk serve to neutralize any disengaged acid, which might be contained in the liquid.

Several advantages are obtained by thus changing the acid of the alum. First, the argillaceous earth is more easily disengaged from the acetous acid, in the subsequent processes, than it would have been from the sulphuric. Secondly, this weak acid does less harm when it comes to be disengaged by depriving it of its earth. And thirdly, the acetit of alumine not being crystallizable like the sulphat, does not separate or curdle by drying on the face of the blocks for printing, when it is mixed with gum or starch.

When the design has been impressed by transferring the mordant from the face of the wooden blocks to the cloth, it is then put into a bath of madder, with proper attention, that the whole shall be equally exposed to this fluid. Here the piece becomes of a red colour, but deeper in those places where the mordant was applied. For some of the argillaceous earth had before quitted the acetous acid, to combine with the cloth; and this serves as an intermedium to fix the colouring matter of the madder, in the same manner as the acid of galls, in the former instance, fixed the particles of oxide of iron. With the piece in this state, the calico-printer has only therefore to avail himself of the difference between a fixed and a fugitive colour. He therefore boils the piece with bran, and spreads it on the grass. The fecula of the bran takes up part of the colour, and the action of the sun and air renders more of it combinable with the same substance. The operations of boiling with bran and exposure in the field are alternately repeated, till the ground becomes white, and the design only remains. It seems evident, that this discharge of the colour is performed nearly in the same way as bleaching, the bran being substituted instead of the alkali, because this last would act upon the printed colour and partly discharge it.

In the foregoing instance the mordant was completely formed by the effect of the double elective attraction of the principles of the acetit of lead and of the alum. In other cases however the elective attraction of the stuff to be dyed has a more marked agency. A very common mordant for woollens is made by dissolving alum and tartar together; neither of which is decomposed, but may be recovered by crystallization upon evaporating the liquor. Wool is found to be capable of decomposing a solution of alum, and combining with its earth: but it seems as if the presence of disengaged sulphuric acid served to injure the wool, which is rendered harsh by this method of treatment, though cottons and linens are not, which have less attraction for the earth. Wool also decomposes the alum, in a mixture of alum and tartar: but in this case there can be no disengagement of sulphuric acid, as it is immediately neutralized by the alkali of the tartar.

Alum is an exceedingly useful agent in dyeing processes, and Mr. Berthollet has satisfactorily proved, by a variety of experiments, that its earth has a strong tendency to unite with animal matters, and that its attraction for vegetable substances is very weak, excepting to their colouring parts.

Metallic oxides have so great an attraction for many colouring substances, that they quit the acids in which they were dissolved, and are precipitated in combination with them. These oxides are also found by experiment to be strongly disposed to combine with animal substances; whence in many instances they serve as mordants, or the medium of union between the colouring particles and animal bodies. But it has not been shown, that any considerable attraction is exerted between these oxides and vegetable substances.

A considerable progress has been made of late years in the investigation of such facts as tend to afford a theory of the art of dyeing. The following general abstract of this theory is taken from Berthollet.

Metallic colours must be distinguished from those which are peculiar to vegetable and animal substances.

The colours of metals are modified and changed by oxidation, according to the degree to which it is carried.

Vegetable and animal substances may themselves possess a peculiar colour, which varies in the different states through which they pass; or they may owe their colours to tingeing particles, either combined or simply mixed with them. These are the particles extracted from different substances, and which undergo different preparations, to fit them for the purposes of dyeing.

The colouring particles have chemical properties, which distinguish them from all other substances: the attractions which they have for acids, alkalis, earths, metallic oxides, oxigen, wool, silk, cotton, and linen, constitute the chief of these properties.

According to the attraction which the colouring particles have for wool, silk, cotton and linen, they unite more or less readily, and more or less intimately with each of these substances; and thence arises the first cause of variation in the processes employed, according to the nature of the stuff and of the colouring substance.

By the attraction which the colouring particles have for argillaceous earth and metallic oxides, they form compounds with these substances, in which their colour is more or less modified, becomes more fixed, and more difficultly affected by external agents, than before. This compound being formed of principles, which have separately the power of uniting with vegetable substances, and more especially with animal substances, preserves this property, and forms a triple compound with the stuff; and the colour which has been again modified by the formation of this triple union acquires a greater degree of fixity, and of indestructibility by external agents.

The colouring particles have frequently so great an attraction for alumine and metallic oxides, that they separate them from acids which held them in solution, and fall down with them; but the attraction of the stuff is sometimes necessary, in order to produce this separation.

The metallic oxides which combine with the colouring particles modify their colours, not only by their own, but also by acting upon their composition by means of their oxigen. The change which the colouring particles thereby suffer is similar to that occasioned by the air, which injures all colours more or less.

Of the two principles which compose the air of the atmosphere it is only the oxigen which acts upon the colouring particles:

ines with them, weakens their co-
d renders it paler; but its action is
lly exerted on the hidrogen, which
nto their composition, and it then
ater. This effect ought to be consi-
s a true combustion, whereby the

rticles.

colours which the compounds of
oxides and colouring particles as-
en, are the product of the colour
to the colouring particles, and of
liar to the metallic oxide; but the
particles and metallic oxides must
dered in that state to which they
n reduced by the diminution of
the oxide, and the diminution of
in the colouring particles.

it follows: First, that the metallic
which the oxigen is only slightly
are not fit to serve as connecting
for the colouring particles, because
duce in them too great a degree of
on; such are the oxides of silver,
mercury.

t the oxides which undergo con-
changes of colour, by giving off more or less of their oxigen, are also bad intermediums, especially for light shades, because they produce changeable colours; such are the oxides of copper, of lead, and of bismuth.

3d. That the oxides which strongly retain their oxigen, and suffer very little change of colour by the loss of a part of it, are best fitted to answer this purpose: such is particularly the oxide of tin, which quits its menstruum easily, which has a strong attraction for the colouring particles, and which affords them a basis that is very white, and proper for giving a brightness to their shades, without altering them by the admixture of another colour. The oxide of zinc possesses some of these qualities.

In order to account for the colours which result from the union of the colouring particles with the basis which a mordant gives them, we must attend to the proportion in which the colouring particles unite to that basis; thus the solution of tin, which produces a very copious precipitate with a solution of colouring particles, and thereby proves that the oxide of tin enters in a large proportion into the precipitate, has a much greater influence on the colour of the precipitate, by the whiteness of its basis, than the solution of zinc, or that of alum, both of which generally produce much less copious precipitates. The precipitates produced by these two last substances retain very nearly the natural tint of the colouring particles.

We must then distinguish, in the action of mordants, the combinations that may take place by their means between the colouring particles, the stuff, and the intermedium; the proportions of the colouring substance and intermedium; the modifications of colour, which may arise from the mixture of the colour of the colouring particles, and of that of the basis to which they are united; and finally, the changes which the colouring particles may suffer from the combustion that may be produced by the intermedium.

Astringents do not derive their characteristic property from an acid, or from any other individual principle which is always the same, but from the property which they possess of uniting with the oxide of iron, of reducing it to the state of black oxide, and of acquiring themselves a dark colour, by the combustion they experience. Galls, which are to be considered as the representatives of all astringents, readily undergo a slight combustion, which gives them a deep brown colour; but this combustion, which requires but a small quantity of oxigen, soon ceases without injuring their properties.

Galls owe their stability to the large proportion of carbon they contain; and as they have the property of combining with some vegetable substances, with several colouring matters, and particularly with am-mal substances, they serve as an intermedium for them, and impart to them their own firmness of colour.

For the modes of using the different articles used in dyeing, see them under their respective names in the order of the alphabet.

E.

EAGLE STONE. See ÆTITES.

EARTH. Chemists have sometimes in a gross and inaccurate way called those substances earths, which remain after the volatile products of distillation have arisen, and which are not soluble in water. This is not however sufficiently exact, though it is difficult to exhibit a good positive definition. Earths are bodies simple with respect to the present powers of chemical analysis, brittle, incombustible, infusible by the heat of furnaces, and destitute of that opake brilliancy which characterizes metals.

We are at present acquainted with at least nine distinct substances, that are classed as earths: alumine, barytes, glucine, lime, magnesia, silex, strontia, yttria, and zircon, which we shall here describe in this order, after some general remarks. The agustine earth, which Trommsdorf imagined he had discovered in the Saxon beryl, Vauquelin has shown to be phosphat of lime: and the ochroit, which Klaproth supposed he had found in the tungsten of Bastnas, appears to be a metal. See CERITE. As four of these earths, barytes, lime, magnesia, and strontian, have some affinity to alkalis, certain chemists have proposed to class them as alkalis; while others distinguish them by the term alkaline earths.

The attention of the chemical world was once strongly excited by some experiments of Mess. Ruprecht and Tondi, who affirmed, that they had reduced alumine, lime, barytes, and magnesia to the metallic state, by strongly heating them with charcoal. But however probable it may be from analogy, that such reductions may be within the limits of possibility, it is now universally admitted, that the metal obtained in these experiments consisted of iron from the crucibles used.

In some systems a distinction is made between earths and stones; but this is of no utility in the chemical inquiry respecting their component parts and properties. A stone is nothing more than a hard earthy mass, and an earth in powder is an aggregate of very minute stones.

Earths appear to have an affinity for each other in the humid way, which has not yet however been sufficiently examined. The affinity of alumine for magnesia is the most powerful. It has also an affinity for silex and lime. Scheele was the first who observed this; and Chenevix and Darracq have made farther experiments on the subject. So has Guyton-Morveau; but Mr. Chenevix observes, that he was led into errours probably by using earths precipitated from sulphuric acid, of which they still retained a little.

Alumine, or *Argillaceous Earth*. The principal natural specimens of this earth are, clays, properly so called, marles, boles, slates or schistus, and mica. In none of these, except the flag stone, does the alumine amount to so much as half their weight, though their predominating qualities appear to depend upon it. A fossil has been found in Devonshire, however, containing 70 per cent. of alumine. See HIDRARGILLITE. The most obvious characters of this earth are, an adhesion to the tongue, or any wet and soft body, in the more solid specimens; and a remarkable tenacity, ductility, or kneadability serve to distinguish moistened clays in a very eminent degree. It is soluble in acids; but alkalis act much less upon it, either in the dry or moist way, than they do on silex. Alum is a combination of this earth with sulphuric acid. If the concrete volatile alkali be added to a solution of pure alum, the alkali and acid unite, while the alumine falls to the bottom, united only with a small quantity of carbonic acid. The fluid must be abstracted by decantation, and the precipitate washed with distilled water, and dried. If we would have it very pure, alum may be dissolved in four times its weight of boiling water, and precipitated by liquid ammonia. Heat the mixture nearly to the boiling point for a few minutes, and pour it into a filter. As the water runs off add more, till it passes without taste. Transfer the precipitate while still wet to a basin, and add muriatic acid in small quantities till the whole is dissolved. Evaporate the solution, till a drop cooled on a plate of glass yields crystals. Let the solution cool; remove the crystals that form; and evaporate again, till no more crystals can be obtained by cooling. Dilute this solution, which contains nearly pure muriat of alumine; precipitate by liquid ammonia, adding this in excess; and the precipitate, when well washed, will be alumine white as snow, without taste or smell, somewhat unctuous to the touch, and affording no sulphuretted hidrogen when heated with charcoal powder. As this method is operose, a more ready way is to procure it from such of the natural clays as contain only silex and alumine, by solution in muriatic acid, and precipitation by ammonia.

Alumine has a considerable affinity for metallic oxides, particularly that of iron;

for vegetable or animal colouring matter; and for the extractive matter of vegetables: hence its uses as a mordant in dyeing, and as the bases of the pigments termed lakes.

Clays may be easily diffused and suspended in water, but are not soluble in any sensible degree. The sudden application of strong heat hardens their external parts, which afterward burst by the explosion of the moisture within. By a more gradual heat pure clay contracts very much, becomes hard, and full of cracks or fissures. The presence of siliceous earth in common clays, where it usually constitutes above half the weight, renders the contraction more uniform throughout, and prevents the cracks; probably in no other way than by rendering them more numerous, and too small to be perceived. When thus baked, it constitutes all the varieties of bricks, pottery, and porcelain. These, if baked in a strong heat, give fire with steel; a property that may be attributed to the siliceous earth they contain, which cannot act on the steel unless firmly set in the hardened clay. The dimensions of pottery are less, the greater the heat to which the article has been subjected. On this property is constructed a thermometer for measuring the heat of furnaces, by igniting a small brick of known dimensions therein, and afterward measuring its contraction. Baked clay is no longer kneadable with water, though as finely pulverized as mechanical means can go. Hence it has been inferred, that clays owe their ductility to a kind of gluten, which is supposed to be dissipated by heat. They recover that property, however, by solution in an acid and precipitation; whence it should seem to depend either on a minute portion of acid contained in clays, or the smallness of the particles when precipitated.

For the habitudes of clay with acids, see the several acids.—See also BRICKS, POTTERY, PYROMETER.

Barytes. This earth, which derives its name from the weight of its compounds, whence it has been called likewise *heavy* or *ponderous* earth, has never been found native in a pure state. Its sulphat is most common, and has long been known by the names of *heavy spar* and *marmor metallicum*. At a mine at Anglezark, near Chorly, in Lancashire, the carbonat of barytes is found in large quantity. This may be decomposed by intense heat. Mr. Henry gives the following process, which is nearly the same with Pelletier's, for procuring the pure earth.

Let the native carbonat be powdered and sifted through a fine sieve; mix it with an equal bulk of wheaten flour; and make it into a ball with water. Put this ball into a crucible one third full of charcoal powder; cover it and surround it with more of the powder; lute on a cover; and expose it for two hours to the most violent heat that can be raised in a wind furnace. When cold, take out the ball, and on adding water to it great heat will be emitted, and the barytes dissolved. The filtered solution on cooling will shoot into beautiful crystals.

Barytes has a sharp caustic taste, changes vegetable blues to green, forms a soap with oils, and combines with sulphur, like the fixed alkalis. It unites with phosphorus also. When recently prepared, it absorbs water rapidly, and gives out much heat. If the water be small in quantity it hardens into a solid mass; a little more water converts it into a light powder; and if the water be sufficient to cover it completely, the barytes will dissolve, and shoot into crystals on cooling. These are flat hexagonal prisms, terminated by quadrangular pyramids.

The crystals are soluble by heat in their own water of crystallization, which amounts to 53 per cent., and may be expelled by continuing the heat, leaving a white powder. They are efflorescent, and require 17½ parts of water at 60° to dissolve them. They communicate a yellow colour to the flame of alcohol.

In the dry way three parts of barytes and one of silex mixed and fused together produce a yellowish green mass, entirely soluble in nitric, muriatic, or acetous acid, from which the silex may be precipitated. In the humid way with alumine it forms a compound insoluble in water, but readily soluble if an additional portion of barytes be added. It likewise dissolves certain metallic oxides, especially those of lead.

Barytic water, like limewater, abstracts carbonic acid from the air, till the whole of the earth is converted into carbonat, and precipitated.

Barytes is an active poison, as are most of its salts, particularly the carbonat.

Glucine. This earth was discovered by Vauquelin, first in the aqua marina, and afterward in the emerald, in the winter of 1798. Its name is derived from its distinguishing character of forming with acids salts that are sweet to the taste. The following is his method of obtaining it:

Let 100 parts of beryl, or emerald, be reduced to a fine powder, and fused in a silver crucible with 300 of pure potash. Let the mass be diffused in water, and dissolved by adding muriatic acid. Evaporate the solution, taking care to stir it toward the end: mix the residuum with a large quantity of water, and filter, to separate the silex. Precipitate the filtered liquor, which contains the muriats of alumine and glucine, with carbonat of potash; wash the precipitate, and dissolve it in sulphuric acid. Add a certain quantity of sulphat of potash, evaporate, and crystals of alum will be obtained. When no more alum is afforded by adding sulphat of potash and evaporating, add solution of carbonat of ammonia in excess, shake the mixture well, and let it stand some hours, till the glucine is redissolved by the excess of carbonat of ammonia, and nothing but the alumine remains at the bottom of the vessel. Filter the solution, evaporate to dryness, and expel the acid from the carbonat of glucine by slight ignition in a crucible. Thus 15 or 16 per cent. of pure glucine will be obtained.

Glucine thus obtained is a white, soft powder, light, insipid, and adhering to the tongue. It does not change vegetable blues. It does not harden, shrink, or agglutinate by heat; and is infusible. It is insoluble in water, but forms with it a slightly ductile paste. It is dissolved by potash, soda, and carbonat of ammonia; but not by pure ammonia. It unites with sulphuretted hidrogen. Its salts have a saccharine taste, with somewhat of astringency.

Lime, or calcareous earth, predominates in most stones which are soft enough to be scratched with a knife. These are chalk, limestone, marble, spars, gypsum, or plasterstone, and various others. As the lime is most frequently combined with carbonic acid, it is usual for mineralogists to drop a small quantity of nitric acid upon the stones they are desirous of classing; and if they froth by the escape of the acid, they conclude that lime enters into the composition. To obtain pure calcareous earth, powdered chalk must be repeatedly boiled in water, which will deprive it of the saline impurities it frequently contains. It must then be dissolved in distilled vinegar, and precipitated by the addition of concrete volatile alkali. The precipitate, when well washed and dried, will consist of lime united to carbonic acid; the latter of which may be driven off by heat, if necessary.

If chalk, marble, limestone, spar, or any other specimens of this earth, containing carbonic acid, be exposed to continued ignition, they give out carbonic acid and water, to the amount of near half their weight. The remainder, consisting chiefly of lime, has a strong tendency to combination, and attracts water very powerfully. The addition of water to lime produces a very considerable heat, attended with noise, and agitation of the parts, which break asunder; a considerable vapour arises, which carries up with it part of the lime; and a phosphoric light is seen, if the experiment be made in the dark. Lime thus saturated with water is said to be slaked. Water dissolves about one five-hundredth part of its weight of lime, and is then called lime-water. This solution has an acrid taste, and turns sirup of violets to a green colour. If lime-water be exposed to the open air, the lime attracts carbonic acid, and is by this means converted into chalk; which, not being soluble in water, forms a crust on the surface, formerly called cream of lime, which, when of a certain thickness, breaks, and falls to the bottom: and in this way the whole of the lime will in time be separated. If the fire have been too violent in the burning of lime, the stone becomes hard, sonorous, and incapable of absorbing water with the requisite degree of avidity. This effect seems to arise from part of the calcareous earth having entered into fusion with the clay, flint, or other contaminating earths, with which it forms a glass that covers and defends the rest.

The paste of lime and water, called mortar, has a degree of adhesion and ductility, though much less than clay. When dry, it is more or less friable, like chalk. A mixture of sand, or broken earthen vessels, greatly increases its firmness, which it seems to effect by rendering it more difficult for the parts to be removed with respect to each other. When mortar is left to dry by the gradual evaporation of its superfluous water, it is very long before it obtains its utmost degree of firmness. But if dry quick-lime be mixed with mortar, it gradually absorbs the superfluous water, and the mass becomes solid in a very short time.

Lime has an affinity for tannin, whence it is probable that a portion of it is retained in tanned leather, perhaps not to the improvement of its quality. It has an edulcorative power with respect to animal oils, by combining with the putrid gelatine in them; but its coagulative action on them is too strong to admit of its being used for this purpose with advantage, unless in small quantity. Feathers, however, may be very conveniently cleaned by steeping three or four days in strong lime-water, and afterward washing and drying them.

Though infusible in the strongest heats of our furnaces, it is nevertheless a very powerful flux with regard to mixtures of the other earths. These are all fusible by a proper addition of lime. Compounds are still more fusible; for any three of the five well-known earths may be fused into perfect glass, if they be mixed together in equal portions, provided the calcareous be one of them.

The earthy part of animals is chiefly, if not altogether, calcareous: in most cases it is united with phosphoric acid, but frequently with the carbonic.

Magnesia. This earth is of modern discovery. Bergman has written a treatise upon it in his usual masterly manner. It first began to be known at Rome under the name of Count Palma's powder, where it was offered by a regular canon as a remedy for all disorders. Its resemblance in many respects to calcareous earth induced many to consider it at first as the same thing; but Mr. F. Hoffman first proved it to be essentially different. This was afterward discovered by Dr. Black of Edinburgh, and Margraaf of Berlin, unknown to each other.

Magnesia is a white powder, perfectly void of taste or smell. It is very little soluble, water taking up about a two thousandth part only: yet it appears to have some affinity for water, as, if it be moistened with water, and then dried, it gains about 18 per cent. It changes sirup of violets green, but its filtered solution does not. With the acids it forms very soluble and bitter salts. It is not soluble in caustic alkalis. It has a great affinity for alumine.

No effervescence or loss of weight should ensue on adding dilute sulphuric acid to pure magnesia; it should dissolve entirely in the acid; and, when largely diluted, oxalat of ammonia should occasion no precipitate in the solution. For the mode of preparing it see Ammonia.

The carbonat of magnesia shows signs of fusion in a strong heat; but pure magnesia resists the most powerful focus of the burning glass, without either contracting in its dimensions, or undergoing any other change. It flows easily with borax and the microcosmic salt: with equal parts of flint and borax it assumes the form of a beautiful coloured glass, resembling the topaz. With equal parts of flint and fluor spar it affords a glass resembling the chrysolite: and with an equal portion of fluor alone it corrodes and runs through the crucible. Almost any proportion of lime, pure clay, and flint is made by it to flow in the fire; and with four times its weight of green glass it affords a mass resembling porcelain, and hard enough to give fire with steel. It will not flow with an equal weight singly, either of flint, quicklime, barytes, glass, lead, potash, or sulphat of potash: but common clay runs with it into a hard mass.

Magnesia combines very sparingly with sulphur in the dry as well as in the humid way, and the combination possesses the characters of sulphurets.

Though this earth appears to be very extensively diffused over the surface of the globe, yet it is undoubtedly less plentiful than the calcareous, siliceous, or aluminous earths. Most of the native specimens of the magnesian genus are remarkable for a certain soapy or greasy feel. Of these the most common are steatites of a greenish colour, and soft enough to be scraped with the nail; soap rock, lapis ollaris, or Spanish chalk, of a yellow or whitish colour, or black, though rarely, rather harder than steatites, and so easily wrought and turned that pots are made of it. Asbestos, amianthus, and the Venetian and Muscovy talc are included in this genus.

In the state of phosphat it is said by Fourcroy and Vauquelin to exist in the bones of all the animals they examined, those of man excepted. Giobert has found, that a white earth employed near Turin in the fabrication of porcelain, and considered as pure alumine, contains 80 per cent. of subcarbonat of magnesia, and sometimes 90, without a grain of alumine. According to him it contains, on an average, magnesia 68, carbonic acid 12, silex 15·6, sulphat of lime 1·6, water. It is said to be of extraordinary good quality for making pottery. This is dug at Baudissero, and a somewhat similar earth is found at Castellamonte, in the same neighbourhood.

Under the name of calcined magnesia the pure earth is much used in medicine, where absorbents are indicated, and the carbonic acid might be detrimental.

Silex. The most eminent characters of this earth are its hardness and insolubility in almost every acid. It exists nearly in a state of purity in rock-crystal, and abounds in all natural bodies which are hard enough to strike fire with the steel. In the pulverulent form it possesses a singular degree of asperity to the touch, and has not the least disposition to adhere and become kneadable by the addition of water. It has been thought, however, by Bergman and others, that water may dissolve a minute proportion of it. See Crystal (Rock). No acid dissolves it but that of the fluor spar, which suspends it abundantly while in the aëriform state, less so when dissolved in hot water, and very sparingly when cold. The fixed alkalis dissolve it both in the humid and the dry way. In the humid way they combine with about one sixth part of their weight, when the siliceous earth is in a state of extreme division. And in the dry way they take up a very large proportion, according to the degree of heat made use of. From one to two parts of alkali, with one part of silex, form hard permanent glass; but if the salt exceed this proportion, the compound will attract humidity from the air, and assume the liquid state. This fluid, or combination of silex with water by the medium of alkali, is known by the name of the liquor of flints. The addition of an acid will seize the alkali, and throw down the siliceous earth in a state of purity; and accordingly this is the process by which it is to be obtained in a disengaged state. That is to say, let rock crystal be dissolved by strong fusion in four times its weight of fixed alkali, and the mass dissolved in water: let muriatic acid be then added in excess; this will seize the alkali, and form soluble salts with any other earths that may be present; but the siliceous earth will fall to the bottom. Repeated ablutions in distilled water will separate all the extraneous saline fluid, which may be interposed between these particles after decantation, and the dried powder will consist of pure silex.

When a solution of silex in potash is mixed with a solution of barytes, strontia, or lime, in water, or of alumine in alkali, a precipitation ensues, whence silex may be inferred to have an affinity for all these earths in the humid way.

Pure silex has not been fused either by the heat of a furnace or of the burning mirror; but rock crystal was fused by Professor Errhmann, by means of a flame urged by a stream of oxigen. With borax it is easily fused; but requires a longer time with microcosmic salt. With metallic oxides, more especially those of lead, it combines by fusion, and forms glass of a dense texture and strong refractive power. See Glass.

Rock crystal, quartz, flint, gritstone, jasper, and most of the precious stones or gems, owe their distinguishing qualities to siliceous earth, and are therefore considered as specimens of this genus. The respective titles of these may be consulted for accounts of their component parts and habitudes.

Strontia. About twenty years ago a mineral was brought to Edinburgh by a dealer in fossils from a lead-mine at Strontian in Argyleshire, which was generally considered as a carbonat of barytes. It has since been found near Bristol, in France, in Sicily, and in Pennsylvania. Dr. Crawford first observed some differences between its solution in muriatic acid, and that obtained from the carbonat of barytes of Anglezark, and thence supposed it to be a new earth. Dr. Hope of Edinburgh had entertained the same opinion, and confirmed it by experiments in 1791. Kirwan, Klaproth, Pelletier, and Sulzer did the same. The carbonic acid may be expelled by a heat of 140° of Wedgwood, leaving the strontia behind: or by dissolving in the nitric acid, and driving this off by heat.

Pure strontia is of a grayish white colour; a pungent, acrid taste; and when powdered in a mortar the dust that rises irritates the lungs and nostrils. Its specific gravity approaches that of barytes. It requires rather more than 160 parts of water at 60° to dissolve it; but of boiling water much less. On cooling it crystallizes in thin, transparent, quadrangular plates, generally parallelograms, seldom exceeding a quarter of an inch in length, and frequently adhering together. The edges are most frequently bevilled from each side. Sometimes they assume a cubic form. These crystals contain about ·68 of water; are soluble in 51·4 times their weight of water at 60°, and in little more than twice their weight of boiling water. They give a blood red colour to the flame of burning alcohol. The solution of strontia changes vegetable blues to a green. Strontia combines with sulphur either in the wet or dry way, and its sulphuret is soluble in water.

In its properties strontia has a considerable affinity to barytes. It differs from it chiefly in being infusible, much less soluble, of a different form, weaker in its affinities, and not poisonous. Its saline compounds afford differences more marked.—*Edinburgh Trans.*—*Crawford on the Mur. of Barytes.*—*Kirwan.*—*Klaproth.*—*Mem. of the Nat. Instit.*

Yttria. This also is a new earth, discovered in 1794 by Prof. Gadolin in a stone from Ytterby in Sweden: see Gadolinite.

It may be obtained most readily by fusing the gadolinite with two parts of caustic potash, washing the mass with boiling water, and filtering the liquor, which is of a fine green. This liquor is to be evaporated, till no more oxide of manganese falls down from it in a black powder; after which the liquid is to be saturated with nitric acid. At the same time digest the sediment, that was not dissolved, in very dilute nitric acid, which will dissolve the earth with much heat, leaving the silex, and the highly oxided iron, undissolved. Mix the two liquors, evaporate them to dryness, redissolve, and filter, which will separate any silex or oxide of iron that may have been left. A few drops of a solution of carbonat of potash will separate any lime that may be present, and a cautious addition of hidrosulphuret of potash will throw down the oxide of manganese that may have been left; but if too much be employed it will throw down the yttria likewise. Lastly, the yttria is to be precipitated by pure ammonia, well washed, and dried.

Yttria is perfectly white, when not contaminated with oxide of manganese, from which it is not easily freed. Its specific gravity is 4·842. It has neither taste nor smell. It is infusible alone; but with borax melts into a transparent glass, or opake white if the borax were in excess. It is insoluble in water, and in caustic fixed alkalis: but it dissolves in carbonat of ammonia, though it requires five or six times as much as glucine. It is soluble in most of the acids. The oxalic acid, or oxalat of ammonia, forms precipitates in its solutions perfectly resembling the muriat of silver. Prussiat of potash, crystallized and redissolved in water, throws it down in white grains; phosphat of soda, in white gelatinous flakes; infusion of galls, in brown flocks.

Some chemists are inclined to consider yttria rather as a metallic than as an earthy substance; their reasons are its specific gravity, its forming coloured salts, and its property of oxigenizing muriatic acid after it has undergone a long calcination.—*Crell's Chem. An.*—*Scherer's Journ.*—*Annales de Chimie.*

Zircon—was first discovered in the jargon of Ceylon by Klaproth, in 1789, and it has since been found in the jacinth. To obtain it the stone should be calcined and thrown into cold water, to render it friable, and then powdered in an agate mortar. Mix the powder with nine parts of pure potash, and project the mixture by spoonfuls into a redhot crucible, taking care that each portion is fused before another is added. Keep the whole in fusion, with an increased heat, for an hour and half. When cold, break the crucible, separate its contents, powder, and boil in water, to dissolve the alkali. Wash the insoluble part; dissolve in muriatic acid; heat the solution, that the silex may fall down; and precipitate the zircon by caustic fixed alkali. Or the zircon may be precipitated by carbonat of soda, and the carbonic acid expelled by heat.

on is a fine white powder, without smell, but somewhat harsh to the It is insoluble in water; yet if slowly it coalesces into a semitransparent sh mass, like gum arabic, which re- one third its weight of water. It with all the acids. It is insoluble in lkalis; but the alkaline carbonats e it. Heated with the blowpipe it ot melt, but emits a yellowish phos- light. Heated in a crucible of char- edded in charcoal powder, placed in e crucible, and exposed to a good ire for some hours, it undergoes a usion, which unites its particles into opake mass, not truly vitreous, but esembling porcelain. In this state it ciently hard to strike fire with steel, ratch glass; and is of the specific gra- f 4·3.—*Journn. de Phys.*—*Fourcroy.*—

TH (FULLERS). Among the useful hes, for which we are indebted to the ous Bergman, we find one upon narga, or stone marle; which seems r from common marle in its compo- chiefly in possessing a much larger n of siliceous and less of calcareous Fullers earth is one of the most use- ieties of Lithomarge.

nstedt describes Lithomarge under the ing general characters: First, When t is smooth and slippery like hard Secondly, It is not perfectly diffusi- water; but when immersed in that it falls into pieces of greater or less tude, or in such a manner as to as- he appearance of curds. Thirdly, In e it easily melts into a white or red- othy slag, which is considerably larger efore, in consequence of its porosity. ly, Its fracture is irregularly convex cave.

author describes only the Litho- e of Osmund, of Tartary, and of Lem- he Hampshire fullers earth not having to his hands, probably on account of vere penalties imposed by the English ture on its exportation. Bergman ned them all, except the second, which Keffekil of the Crim Tartars, who are o use it instead of soap, and of which s not provided with a sample. Wieg- n Crell's Journal, quoted by Kirwan, that it consists of equal parts magne- d silex.

e Lemnian earth, highly esteemed for centuries for its supposed medical s, and till lately sold in Europe under eal of the Grand Signior, has the ex- appearance of clay with a smooth e, resembling agate, especially in its fractures, which are usually either ve or convex. It may be scraped with ail, is composed of impalpable parti- though a little gritty between the under which it feels like tallow. immersed in water, it is spontaneously divided into small pieces with a slight crackling noise, but they do not become so small as to be invisible or impalpable. Pulverization and boiling in water diffuse it in the fluid, which passes almost perfectly clear through doubled filtering paper. The water examined by the usual tests is found to be neither acid nor alkaline, but exhibits the presence of muriatic acid in combination.

This earth removes impurities like soap, though it affords no froth. When urged by the blowpipe, it does not decrepitate, but turns black, melts with ebullition, and becomes converted into a dark frothy slag. With microcosmic salt there is a commencement of solution with effervescence; but the remainder is scarcely affected. Borax acts more effectually, though slowly, on the residuum. Soda occasions a considerable effervescence with noise. By the humid analysis, Bergman found it to contain forty-seven parts in the hundred of silex, $5\frac{4}{10}$ of carbonat of lime, $6\frac{2}{10}$ of carbonat of magnesia, 10 of alumine, $5\frac{4}{10}$ oxide of iron, and 17 of moist volatile matter expellable by drying.

The Osmundic earth comes from mount Osmund, in the parish of Ratwick in East Dalecarlia. Its colour is gray, like cinders, its surface rough, and as if greased. It is harder than the Lemnian earth, breaks into angular pieces, adheres strongly to the lip, and is more gritty between the teeth than that earth. In water it separates into smaller particles, and is detergent.

This earth decrepitates before the blowpipe, turns black, and melts with ebullition, leaving a white frothy slag. It exhibits the same phenomena as the Lemnian earth with the blowpipe; but a grain of it thrown into the solution becomes white. It effervesces less with soda.

From the humid analysis, Bergman found one hundred parts of the Osmundic earth to contain 60 parts white siliceous powder, $5\frac{7}{10}$ lime, $0\frac{5}{10}$ magnesia, $11\frac{1}{10}$ alumine, $4\frac{7}{10}$ oxide of iron, and 18 of moist volatile matter.

The Hampshire fullers earth, examined by Bergman, was of a dark colour, a little inclined to green, and faintly marked with yellowish veins, less hard than the Osmundic and Lemnian earths, capable of being polished with the nail, of a rough fracture with dark pointed eminences, adhering to the lip, and a little siliceous between the teeth. When immersed in water, it fell to pieces like the other earths. It produced no froth when rubbed with water, but was exceedingly detergent.

Water in which pulverized fullers earth was boiled passed still turbid through several folds of paper, and the water indicated the presence of combined muriatic acid. Before the blowpipe it decrepitated, but less than the Osmundic earth; after which it turned black, was fused with ebullition into a dark-coloured spongy mass. Its habitudes with borax, microcosmic salt, and soda, were the same as those of the Lemnian earth.

Bergman's method of analysing this and the two preceding earths was the following: A hundred parts or docimastic pounds of the earth were pulverized, and inserted into a small glass cucurbit with twice its weight of highly concentrated sulphuric acid; after which a capital and receiver being adapted, the distillation was performed on a sand bath. An acid vapour arose by the first gentle heat, which was found to be muriatic acid; doubtless, says Bergman, arising from decomposed sea-salt. A greater heat did not exhibit any signs of volatile alkali. He then decanted off the superfluous acid, washed the residuum in distilled water, dried it, and found its weight. This was found to be siliceous earth contaminated with iron.

The next object consisted in ascertaining the contents of the acid which had been decanted off. For this purpose he divided it into two parts. To one part, made very warm, he gradually added finely pulverized chalk, taking great care not to exceed the due quantity. The chalk precipitated whatever clay or iron might be present; but left the magnesia in solution, because the sum of the quiescent attractions of lime to carbonic acid, and of sulphuric acid to magnesia, are greater than the divellent attractions of the carbonic acid to magnesia, and sulphuric acid to lime; so that the presence of the carbonic acid prevented that decomposition of sulphat of magnesia, which would have taken place if mere lime had been used.

After the precipitation of clay and iron from the solution, he evaporated the liquor, which occasioned the separation of sulphat of lime, and sulphat of magnesia; the latter of which, on account of its much greater solubility, was taken up by a little warm water. Another evaporation and solution of the sulphat of magnesia was made, to clear it entirely of the sulphat of lime. Mild fixed alkali was used to precipitate the earths from the respective solutions of these two salts, and the remaining liquors were subjected to ebullition for a quarter of an hour, to throw down the small portion of earth which might be suspended by the redundant fixed air. In this way, consequently, the true quantities by weight of magnesia and of lime, contained in half the centenary, were ascertained, taking care to deduct the weight of chalk made use of in the precipitation.

In the foregoing process the iron and clay were precipitated, that they might be no impediment to an examination of the quantities of lime and magnesia. The separation of the clay from the iron not being a very direct operation, the other half of the original solution was reserved for the purpose of determining their weights. Prussiat of potash was therefore added to this half of the solution; in consequence of which the iron fell down in the form of Prussian blue, leaving the earths suspended. The quantity of iron was determined by allowing ten grains of iron, for each fifty-nine grains of blue precipitate.

In the next place the solution was filtered, now containing clay, magnesia, and lime, all combined with sulphuric acid; out of which the quantity of the first only was required to be found. The solution was therefore concentrated by evaporation, and the excess of acid then saturated, by the addition of carbonat of magnesia, till paper stained with litmus was not affected by it. An excess of magnesia was guarded against, by suffering each small portion to be entirely dissolved before any more was added. After half an hour's boiling, the neutral combination of alumine and sulphuric acid fell down, it being well known, that the solubility and other properties of alum depend on its excess of acid: and this combination being digested with alkaline carbonat afforded the pure alumine.

By this management he found, that the Hampshire fullers earth contained of silex $51\frac{8}{10}$ parts; of carbonat of lime $3\frac{1}{10}$; of carbonat of magnesia $0\frac{7}{10}$; of alumine 25; of oxide of iron $3\frac{7}{10}$; and of moist volatile matter $15\frac{1}{2}$ parts.

The properties required in a good fullers earth are, that it should contribute to the washing away all impurities, and promote that curling and intermixture of the hairs of the woollen cloth, which thicken its texture, and give it the desired firmness. Both probably depend on its detergent quality, that clears away all the unctuous matter of the wool, and renders its parts capable of becoming more perfectly entangled together by the mechanical action of fulling; an effect not so likely to take place when the fibres or hairs are disposed by grease to slide easily over each other. The detergent power resides in all clays, but is doubtless greatly increased by the siliceous earth, which may be considered as the brush, while the clay serves as the soap. This is familiarly shown, by the common practice of adding sand to soap, which renders it much more detergent; but at the same time more capable of injuring the substances to which it is applied, and that more especially when the sand is coarse. Fullers earth is bad, if the sand be not exceedingly fine; and the superior excellence of the Hampshire fullers earth seems to depend more on the fineness of its parts, than on their proportions, as is shown by the experiment of boiling it in water; after which it passes more plentifully through the filter than any of the other lithomargæ.

EARTH (LEMNIAN), or TERRA LEMNIA. A bolar earth from the island of Lemnos, formerly in great esteem for its supposed medical qualities. Cronstedt reckons it among the lithomargæ or stone marrow. Bergman has given a good analysis of it; for which see Earth (Fullers).

Earth (Mercurial). A substance which, according to Becher and other alchemical philosophers, is a common principle of metals and some other bodies. In conformity with this obscure theory, we find frequent mention of the mercuries of gold, of silver, or of other metals. The facts and discoveries subsequent to the time of the illustrious Becher have not afforded any foundation to conclude, that any such common principle as the mercurial earth exists; and it was so far from being satisfactorily exhibited by Becher himself, that his disciple, the great Stahl, did not include it in his modification of the Becherian system.

Earth (Vegetable). This appellation has been given to the insoluble residue which remains after the incineration of vegetables, and likewise to the mould or soil best suited to the propagation and growth of these organized beings.

Vegetables contain but a small proportion of earth of any kind, the much greater part of their substance being found by experiment to consist of oxigen, hidrogen, nitrogen, and carbon, in the concrete or combined state, as remote principles; a small portion of fixed alkali, usually either neutralized by the vegetable acids or combined with the oils or mucilage, and a few other neutral salts.

The earth of vegetables is for the most part either calcareous, or a mixture of various earths, and sometimes of the oxides of iron and manganese, in different proportions, according to the species of the vegetable. These earths may be obtained either by incineration or putrefaction, and are not therefore the product of the fire.

Vegetable mould or earth, as far as the same may consist of fixed parts, appears therefore, from these analytical facts, to be merely the vehicle, by which the aqueous or aërial substances are conveyed into the vessels of plants. Other synthetical experiments of plants supported and nourished by the mere immersion in water, and some which thrive, though their roots and branches have no other body in contact with them but the air of the atmosphere, are sufficiently strong in confirmation of this truth.

Chaptal has treated this subject in a manner so singularly perspicuous and concise, that I shall follow him in the remainder of the present article.

Although it is well proved, that pure water is sufficient for the support of plants, it must not be concluded, that the soil or earth is of no utility. Its use is similar to that of the placenta, which of itself affords no support to the fœtus, but prepares and disposes the blood of the mother to become a suitable nutriment; or it resembles, in its useful application, the various receptacles which are placed in the human body, to preserve the several humours, and emit them when required. The earth imbibes and retains water. It is the reservoir destined by nature to preserve the elementary fluid, which the plant continually requires, and to supply it in proportion to its wants, without exposing it to the equally fatal alternatives of being either inundated or dried up.

We may even observe, that the young plant or embryo of a vegetable is not intrusted by nature with the labour of digestion. The seed is formed of a parenchyma, which imbibes water, elaborates it, and does not transmit it to the germen, until it is converted into a humour of a suitable quality. By insensible gradations this seed is destroyed; and the plant, having become sufficiently strong, is left to perform the digestive function without farther assistance. So likewise it is, that we observe the fœtus supported in the womb by the fluids of the mother herself; but when it has seen the light, it receives for its nourishment a fluid less animalized; its organs are gradually strengthened, and at length become capable of digesting a stronger and less assimilated nutriment.

But on this very account, namely, that the earth is destined to afford a due supply of water to the plant, the nature of the soil cannot be a matter of indifference, but must be varied accordingly as the plant requires a more or less considerable quantity of that fluid in a given time, in proportion to the magnitude and extent of its roots.

A proper soil is that, 1st, which affords a support to the plant, of sufficient firmness to prevent its being too much agitated, or overthrown, by the winds or other causes; 2d, which is capable of admitting the roots to be easily extended; 3d, which is suited to receive and absorb moisture, that the plant may on no occasion suffer from the want of this essential requisite. To answer these conditions, it is necessary to make a due mixture of the primitive earths, because no one in particular is equal to the accomplishment of them. Siliceous and calcareous earths may be considered as hot and drying, the argillaceous as moist and cold, and the magnesian as possessing intermediate properties. Each in particular has its imperfections, that render it unfit for culture. Clay absorbs water, but does not communicate it; calcareous earth receives and gives it too quickly; but the properties of these earths are so happily opposed, that they correct each other by mixture. Accordingly we find, that by adding lime to an argillaceous earth, this last is divided; and the drying quality of the lime is mitigated, while the stiffness of the clay is diminished. On these accounts also it is, that any single earth cannot constitute manure to be applied in all cases; but the character of the soil intended to be meliorated ought first to be examined and considered, before any decision is made concerning the manure to be applied. Mr. Tillet has ascertained, that the best proportions of a fertile earth for corn are three-eighths clay, two-eighths sand, and three-eighths fragments of hard stone.

The advantage of labour or cultivation consists in dividing the earth, impregnating it with air, destroying useless and noxious plants, and converting them into manure by facilitating their decomposition. See Arable Land, and Soils.

Earth (Vitrifiable). Every earth is in fact vitrifiable with proper additions, and none without. But siliceous earth has been generally distinguished by this name, on account of the superior facility with which it is converted into a good glass by fusion with an alkali. See Earths, Silex, also Glass.

Earthen-ware. See Pottery.

Earthworms are plentifully found in moist fat grounds, but rarely, if ever, in dry sands. Mr. Reaumur proposed collecting them as a cheap substitute for grain in feeding domestic poultry. The physicians, who appear to have overlooked scarcely any produce of the three kingdoms of nature, have used these creatures, under the notion of their possessing an antispasmodic and diuretic virtue. Neumann relates several experiments made with them. They are cleansed by washing, and suffering them to creep through dry woollen cloths. Unless hastily dried by the heat of the sun or a fire, they are very apt to putrefy. Moistened with wine or vinous spirit, to prevent their putrefaction, and set in a cellar in a wide-mouthed glass, they are almost wholly resolved in a few days into a slimy liquor. When this liquamen or solution is mixed with a little fixed alkali, and after due evaporation set by to shoot, the crystals are no other than saltpetre. Neumann did not in direct terms assert, that he himself made this experiment, and from the context there seems to be some slight reason to suspect he had it from Stahl.

He made however his usual set of experiments with them by digestion in water and alcohol, and by destructive distillation. When repeated digestion with the spirit was used first, the quantity of extract from four ounces of the dried worms, and the residuum treated with water, yielded three drachms and a scruple. But the same quantity treated first with water afforded one ounce, six drachms, and a scruple, after which rectified spirit extracted two scruples.

Thirty-two ounces of dried earthworms yielded, by destructive distillation, thirteen ounces and a half of an alkaline fluid, one ounce of concrete volatile alkali, and four ounces and a half of empyreumatic oil. The remainder, burned in the open air, afforded, by lixiviation, one ounce and a half of fixed alkali. The earthy residuum weighed six ounces and a half, which, at that early period of chemistry, Neumann did not possess the methods of examining. If the worms were putrefied, by distillation the volatile product was scarcely any thing but mere water, with very little oil and volatile alkali.

Eau de Luce. The smell of the volatile alkali is rendered considerably more grateful by an imperfect combination with oil. Eau de luce is a compound of this nature, consisting chiefly of the essential oil of amber and the volatile alkali. There is some difficulty in compounding this fluid, so that it shall possess the desired quality of a beautiful milky whiteness. For if the combination be too perfect by a due proportion of the materials, it will approach to transparency; and if it be less perfect by a redundancy of oil, this last will separate in the form of globules, or in a kind of cream. See Ammonia.

Echini. Calcareous petrifactions of the echinus, or sea hedgehog.

Edulcoration. This word imports the same thing as dulcification, properly speaking; namely, the rendering things more mild: but chemists use the terms very differently. Dulcification consists in the obtunding of acids by combination with alcohol (see the word). Edulcoration consists in carrying off superfluous acid, or other saline matter, by one or more washings with water. Metallic oxides and other insoluble precipitates are usually edulcorated previous to drying them.

Effervescence. According to its derivation, this term implies the boiling over of any fluid by heat. In chemistry it is appropriated to the commotion and increase of volume produced in fluids by some part of the mass suddenly taking the elastic form, and escaping in numerous bubbles. Thus, when any other acid is poured on chalk, the carbonic is disengaged in the elastic state with bubbles, vapour, and a hissing noise.

Effervescences are more or less violent, according to circumstances, and are usually attended with a change of the temperature. If the capacity of the mixture or new combination for heat be diminished by the change the bodies have undergone, in a greater degree than that of the elastic fluid is enlarged, the temperature will be increased: but if, on the contrary, the mixture retain its original or acquire an increased capacity, the elastic fluid will carry off so much of the heat, as to produce a greater or less degree of cold in the remainder. Chemistry affords many instances of both effects taking place.

Efflorescence is the effect which takes place when solid or consistent bodies gradually and spontaneously become converted into a powder. It is almost always occa-

by the loss of the water of crystalli-
in saline bodies. Thus carbonat and
of soda, and many other salts, are
cent; that is, they become dry and
lent when left exposed to the air.
efflorescences are occasioned not sim-
the loss of moisture, but by pro-
of a more compounded nature, such
efflorescence of alum-slate by the
sion of its sulphur into sulphuric
y roasting and exposure to the air;
efflorescence of the martial pyrites,
by the same treatment become con-
into sulphat of iron, though origi-
omposed of iron and sulphur.

e of this nature from any other vege-
It resembles camphor in some re-
but not in all. Water does not
affect it. Alcohol totally dissolves it. When laid on burning coals, it exhales without leaving any residue. Held over a gentle fire in a ladle, it flows like wax or tallow, and when cold, appears softer and more unctuous than at first. The younger Geoffroy observes, that this matter resides in the exterior parts of the root near the bark.

Alcohol distilled from the root carries nothing over, and water leaves more behind it than it takes up. One ounce of the dry root afforded six drachms and a half of extract with water; but the same quantity gave only two drachms and a half with spirit.

ELECTRUM. Amber. See the article.

ELEMENTS. A term used by the earlier chemists, nearly in the same sense as the moderns use the terms first principle. The chief, and indeed very essential difference between them is, that the ancients considered their elements as bodies possessing absolute simplicity, and capable of forming all other bodies by their mutual combination; whereas the first principles of the moderns are considered as simple merely in respect to the present state of the art of analysing bodies. That is to say, the ancients almost totally overlooked the imperfection of the art in their general deductions; but the moderns pretend to keep it in view.

The experiments made in the infancy of chemistry had for their object the phenomenon of combustion, referred by them to a substance called fire; the extrication of elastic fluid, considered to be of the same nature as the immense mass which composes the atmosphere; water, neither compoundable nor destructible by any experiments then known or understood; and substances not volatile in the strongest heat of furnaces, confounded by them, with a few exceptions, under the general term of earth. In this way they obtained four elements or first principles, fire, air, water, and earth.

Subsequent experiments and inquiries have multiplied the number of elements, and have alternately shown the inutility of any exclusive general arrangement of bodies, as absolutely simple, because not yet analysed. See PRINCIPLES, also ATTRACTION.

ELIQUATION. An operation, by means of which a more fusible substance is separated from another which is less fusible. It consists in the application of a degree of heat sufficient to fuse the former, but not the latter. It may be effected either by using a perforated crucible, or in the large way, by a furnace constructed to answer the same purpose. In order that a separation may follow by this method, it is necessary, that the combination between the two substances should be by no means intimate. Thus sulphur may be separated from its earthy admixtures by the gentle heat necessary to fuse it; but it cannot, in the same manner, be separated from its metallic combinations. So likewise lead may be separated by eliquation from copper; but tin cannot.

Elutriation. This word is used by chemists to denote the process of washing, as practised by metallurgists and others; and indeed this last and more familiar term is most frequently used. Thus the metallic ores are cleared of earthy admixtures by elutriation, that is to say, washing with water, which carries off the lighter earthy parts, while the heavier metallic parts subside to the bottom.

Emerald. A transparent precious stone, of a green colour, nearly of the same hardness as the garnet, or agate; but inferior to the topaz and ruby. Its specific gravity is 2·775. In its rough, or native state, it consists of six-sided prisms, commonly truncated at both ends. Engestrom says, that they become of an opake white in a strong fire, without the least mark of fusion: but Wallerius asserts, that this stone, when heated to a white heat, becomes of a deep blue colour, and phosphorescent, and recovers its green colour when cold. With oxigen gas, however, it fuses into an opake globule, resembling what is called a dead pearl. Friction produces electricity in the emerald. Some emeralds, of the dark green sort, resemble the tourmalin in the property of attracting small bodies, by an electricity produced by heating and cooling.

When crystallized cockle, or shirl, is found of a green colour, transparent, and free from cracks or flaws, it is commonly called emerald by the jewellers, though it is generally of a deeper colour than the true emerald, and also wants their lustre; and hence it is, that the cockle spar from Egypt is called the mother of emeralds. However, it is probable that this cockle was, in ancient times, fashionable in Egypt, under the name of emerald, though at present it is not so much valued as the emerald of this (siliceous) kind.

The true emerald is not acted upon by soda in the dry way, but it yields to borax and microcosmic salt, with which, according to Quist and Wallerius, it affords a colourless glass.

According to Vauquelin, 100 parts of this stone contain 64 of silex, 15 of alumine, 14 of glucine, 1·6 of lime, and 4·25 of oxide of chrome.

Emery. The best sort is of a dark gray colour, but becomes brown, and in a great measure magnetical, by calcination. Other sorts are of a reddish rusty white or yellowish colour. This mineral scarcely yields to any substance in hardness, excepting the diamond. It is brought to us in large quantities from the Archipelago, particularly the Isle of Naxos, and is much used for grinding and polishing. It seems to resemble corundum very much in its hardness, as well as in the foreign matters that accompany it. Mr. Tennant has analysed different specimens of emery, one of which gave ·80 alumine, ·03 silex, ·04 iron, and ·03 insoluble matter: a second, ·65 alumine, ·032 silex, ·08 iron, ·18 insoluble residuum: a third, ·50 alumine, ·08 silex, ·32 iron, ·04 residuum.—*Phil. Trans.*

Empyreuma. This term is applied to denote the peculiar smell produced by a considerable heat upon vegetable or animal substances, in closed vessels, or when burned under circumstances which prevent the access of air to a considerable part of the mass, and consequently occasion an imperfect combustion, or destructive distillation of the parts so covered up by the rest of the mass.

Mr. Macquer observes, that empyreuma is the peculiar smell of burned oils, and that no other but oily substances can produce it. He even proposes this indication as a test of the presence of oil, in bodies which contain too small a quantity of that fluid to admit of any other way of exhibiting it.

Emulsion. An imperfect combination of oil and water, by the intervention of some other substance capable of combining with both these substances. The substances are either saline or mucilaginous. Thus the volatile alkali with certain management forms the emulsive liquors called volatile liniment, and eau de luce. Gum arabic, or sugar, triturated with oils, renders them miscible with water, as do likewise white of egg and other animal mucilages. The vegetable juices obtained by compression from various seeds and other parts of vegetables are of an emulsive nature. But it does not seem probable, that they exist in the vegetable under the emulsive form, but rather that the several distinct vessels respectively contain oil, water, mucilage, or sugar, the confused mixture of which produces the emulsion. On the same principle it seems to be, that the gum resins afford emulsions when triturated with water.

Sir Isaac Newton has shown by experiment, that all bodies are transparent, the particles of which do not exceed a certain magnitude, which he has deduced by computation in his Optics. When opacity is the result of a combination of two transparent bodies, it affords a considerable proof, that their union is little more than mechanical. It is well known how slowly small particles either sink, or rise to the surface of any fluid in which they may be suspended. Atwood, in his Treatise on the rectilinear and rotatory Motion of Bodies, and other writers, have shown the methods of ascertaining these velocities, when the densities of the particles and of the fluid, together with the magnitude of the former, are known. Whence it is not to be wondered, that a slight tendency to chemical combination, assisted by minute mechanical division, should occasion the respective parts of emulsive liquors to remain for a

ne without separation. It is found,
er, that in process of time they do

enamel is afforded by the oxide of
nd also by that of iron. The former
most beautiful, and stands the fire
ell, which the latter does not.

le of copper affords a green; man-
, a violet; cobalt, a blue; and iron, a
ne black. A mixture of these dif-
enamels produces a great variety of
ediate colours, according to their
and proportion. In this branch of
the coloured enamels are sometimes
with each other, and sometimes the
are mixed before they are added to
reous bases.

enameller, who is provided with a
good colours, is very far from being
uation for practising the art, unless
killed in the methods of applying
and the nature of the grounds upon
they are to be laid. Many of the
are too fusible to be enamelled, and
all of them are corroded by the
of the fused glass. For this reason,
f the metals are used but gold, silver,
pper. Platina has indeed been used;
its effects and habitudes with enamels
ttle can be said, for want of a suffi-
umber of experiments.

purest gold of 24 carats is calculated
duce the best effect with enamel. 1.
e it entirely preserves the metallic bril-
without undergoing any oxidation in
e. 2. Being less fusible, it will admit
ore refractory, and consequently a
harder and more beautiful enamel. It is not usual, however, to enamel upon finer gold than 22 carats; and the operation would be very defective, if a coarser kind than that of 18 carats were used. For in this case more alkali must be added to the enamel, to render it more fusible, and this addition would at the same time render it softer and less brilliant.

Rejecting all these exceptions, the author gives the following description, by way of example, of fixing a transparent blue enamel upon gold of 22 carats.

The artist begins his operation by breaking the enamel into small pieces in a steel mortar, and afterward pulverising it in a mortar of agate. He is careful to add water in this part of his process, which prevents the splinters of glass from flying about. There are no means of explaining the point at which the trituration ought to be given up, as this can be learned only by experience. Some enamels require to be very finely triturated; but others may be used in the form of a coarse powder. As soon as he apprehends that his enamel is sufficiently pounded, he washes it by agitation in very clear water, and pouring off the fluid as it becomes turbid. This operation, which is made for the purpose of carrying off dust and every other impurity from the enamel, is continued until the water comes off as clear as it was poured on.

The workman puts his enamel, thus prepared, in a white china or earthen saucer, with water poured on it to the depth of about one tenth of an inch. He afterward takes up this enamel with an iron spatula, as equally as possible. As the enamel here spoken of is transparent, it is usual to ornament the surface of the gold with rose work, or other kinds of works, calculated to produce a good effect through the enamel.

The thickness of this first layer depends entirely upon its colour: delicate colours, in general, require that it should have no great thickness.

The moist enamel, being thus placed, is dried by applying a very clean half-worn linen cloth to it, which must be very carefully done, to avoid removing the enamel by any action of wiping.

In this state the piece is ready for the fire. If it be enamelled on both sides, it is placed upon a tile, or iron plate, hollowed out in such a manner, that the uncovered edges of the piece alone are in contact with the support. But if it be enamelled on one side only, it is simply laid upon the plate, or on a tile. Two things, however, require to be attended to. 1. If the work be very small, or not capable of being enamelled on its opposite side, the iron plate must be perfectly flat, in order that the work may not bend when softened by heat. 2. If the work be of considerable size, it is always counter-enamelled if possible; that is to say, an enamel is applied on the back surface, in order to counteract the effect which the other coating of glass might produce on the soft metal, when it came to contract by cooling.

The enameller's furnace is square and built of bricks, bedded in an earth proper for the purpose. It may be considered as consisting of two parts, the lower part, which receives a muffle, resting on the floor of the furnace, and open on both sides.

The upper part of the furnace consists of a fire-place, rather larger and longer than the dimensions of the muffle. This fire-place contains the charcoal, which must surround the muffle on all sides, excepting at the bottom. The charcoal is put in at a door above the muffle, which is closed when the fire is lighted. A chimney proceeds from the summit of the furnace with a moderate aperture, which may be closed at the pleasure of the artist, by applying a cast iron plate to it. This furnace differs from that of the assayer in the circumstance, that it is supplied with air through the muffle itself: for, if the draught were beneath the muffle, the heat would be too strong, and could not be stopped when requisite.

As soon as the fire is lighted, and the muffle has obtained the requisite degree of ignition, the charcoal is disposed toward the lower part of the muffle in such a manner, as that it shall not fall upon the work, which is then conveyed into the muffle with the greatest care upon the plate of iron or earthen-ware, which is taken up by long spring pincers. The work is placed as near as possible at the farther extremity of the muffle; and as soon as the artist perceives a commencement of fusion, he turns it round with great delicacy, in order that the fusion may be very uniform. And as soon as he perceives that the fusion has completely taken place, he instantly removes it out of the furnace: for the fusion of gold happens so very near that of the enamel, that a neglect of a few seconds might be attended with considerable loss.

When the work is cooled, a second coat of enamel is applied in the same manner as the first, if necessary. This, and the same cautious management of the fire, are to be repeated for every additional coat of enamel the nature of the work may demand.

As soon as the number of coatings are sufficient, it becomes necessary to give an even surface to the enamel, which, though polished by the fire, is nevertheless irregular. This is done with an English fine-grained file and water. As the file wears smooth, sand is used. Much precaution and address are required in this part of the work, not only because it is easy to make the enamel separate in splinters from the metal, but likewise because the colour would not be uniform if it were to be ground thinner at one part than at another.

The deep scratches of the file are in the next place taken out, by rubbing the surface with a piece of deal wood and fine sand and water. A polish is then given by a second ignition. This polish, however, is frequently insufficient, and not so perfectly uniform as the delicacy of the work may require.

The substance used by the enamellers, as a polishing material, is known by the name of rotten-stone; which is prepared by pounding, washing, decanting off the turbid water, suffering the fine suspended particles to subside from this water, and lastly levigating it upon a glass plate.

The work is then cemented to a square piece of wood with a mixture of resin and brick-dust, and by this means fixed in a vice.

The first operation of polishing is made by rubbing the work with rotten-stone upon a small straight bar of pewter. Some delicacy is here required, to avoid scratching or producing flaws in the enamel, by pressing it too hard. In this way the piece is rendered perfectly even: but the last brilliant polish is given by a piece of deal wood and the same rotten-stone.

This is the general method of applying enamels; but some colours require more precaution in the management of the fire. Opake colours require less management than the transparent. A variety of circumstances must be attended to in the management of transparent colours; every colour requires gold of a particular fineness.

When different colours are intended to be placed beside one another, they are kept separate by a small edge or prominency, which is left in the gold for that purpose, and is polished along with the enamel.

The enamelling upon silver is effected nearly in the same manner as that of gold; but the changes sustained by the colours upon the silver, by the action of fire, are much more considerable than when gold is used.

Copper is not much used by enamellers, on account of the difficulty which attends the attempt to fix beautiful colours upon it. When this metal is used, the common practice is to apply a coating of opake white enamel, and upon this other colours, which are more fusible than the white.

A good effect is produced in toys, by leaving part of the gold bare. For this purpose its surface is cut into suitable compartments by the engraver. This, however, is an expensive method, and is for this reason occasionally imitated by applying small and very thin pieces of gold upon the surface of the enamel, where they are fixed by the fire, and afterward covered by a transparent vitreous coating.

After this detail of the art of enamelling, Mr. Brogniart describes a method of taking off the enamel from any toy, without injuring its metallic part. For this pur-mixture of common salt, nitre, and n powder, is applied upon the ena- d the piece put into the furnace. n as the fusion has taken place. the sudden! thrown into water, which he enamel to fly off either totally or . The part which may remain is to oved by repeating the same opera- second time. See **Glass**; also Por- .

oat vessels of iron or copper for cu- purposes with an enamel capable of ng the metal from the action of any , and enduring any heat, or transi- m heat to cold, appears a desirable and many experiments have been n the subject by Mr. Soen Rinman; oyal Academy of Stockholm.

following compositions he found very well on copper. 1. The white nsparent fluor spar and sulphat of equal quantities, powdered, mixed, cined in a white heat; then powder- e into a thin paste with water, and a little warm to the vessel also l. When dried and heated gradually ertain point, a very strong heat, than is commonly obtained in an g furnace, is to be applied as quickly ble. 2. Sixty parts of lime, 100 of ar, 60 of gypsum, 20 of quartz, and manganese, were calcined, ground, plied in a similar manner. 3. Four f fluor spar, four of gypsum, and one rge, melted into a straw-coloured round, and applied in the same way, d a still stronger heat. 4. Five parts r spar, 5 of gypsum, 2 of minium, 2 glass, ½ a part of borax, the same of f tin, and $\frac{1}{15}$ of a part of oxide of melted together, made an enamel; when ground and applied as the fused with a less degree of heat. Ir. Rinman imagines would have ted upon in length of time by sul- acid. The oxide of cobalt was ed by saturating a solution of cobalt fortis with common salt, and eva- g to dryness.

ese would not do for iron, he tried lowing. 1. Minium 9 parts, flint pure potash 2, nitre 2, borax 1, round together, put into a covered which they only half filled, and to a glass. This poured out on a of marble, quenched in water, ed, and made into a thin paste, was both sides of an iron vessel. After been dried and heated gradually, sel was put under a muffle well in an assaying furnace, and in half te the enamel melted. The vessel nen withdrawn, was found enamelled autiful black colour, which appear- e owing to a thin layer of oxided en through the transparent glaze. same with one hundredth part of f cobalt, prepared as above, covered the vessel more perfectly with a blue enamel. 3. The same ground with potters white lead, which consists of 4 parts lead and 1 tin, produced a very smooth gray enamel, more firm and hard than the preceding. A small quantity of red oxide of iron gave it a fine dark red colour. 4. Flint glass 12 parts, minium 18, potash 4, nitre 4, borax 2, oxide of tin 3, oxide of cobalt $\frac{1}{8}$ of a part, gave a smooth pearl-coloured enamel, not brittle or subject to crack, and capable of enduring sudden changes of heat and cold, as well as the action of oils, alkalis, and weak acids; but it cannot resist the stronger vegetable acids, and still less the mineral.

These enamels can be applied only on hammered iron, cast iron being too thick to be heated with sufficient quickness. It may be unnecessary to add, none of them will bear hard blows.

Ens Martis. A name anciently given to the oxide of iron which arises in sublimation with twice its quantity of sal ammoniac. Medical practice does not at present place this preparation in a higher rank of estimation than other oxides of iron.

Ens Veneris. The ens martis is in many dispensatories called by this name; others direct a sublimation to be made with sal ammoniac, and the calx of cupreous vitriol, a process which it is well known affords no flowers, or at least a quantity proportioned merely to the iron with which the vitriol of copper may be contaminated. It appears, therefore, that there is properly no ens veneris.

Entrochi. A genus of extraneous fossils, usually of about an inch in length, and made up of a number of round joints, which, when separate and loose, are called trochitæ: they are composed of the same kind of plated spar with the fossil shells of the echini, which is usually of a blueish gray colour; and are very bright where fresh broken: they are all striated from the centre to the circumference, and have a cavity in the middle. They seem to be the petrified arms of that singular species of the sea star-fish, called Stella arborescens.

Epidermis. If the human skin be macerated in hot water, it separates into two parts, the *cutis*, or true skin, and the *epidermis*, or scarf skin. The continued action of warm water at length dissolves the cutis, but does not affect the epidermis, neither does alcohol. Caustic alkali, however, dissolves it; and so does lime, but more slowly. Hence it appears to be analogous to the kind of varnish that covers silk. It has no affinity with tannin, so that tan would penetrate the flesh side of skin only, if the epidermis were not previously removed by the limewater employed to take off the hair. —*Chaptal.—An. de Chim.*

Epsom Salt. Sulphat of magnesia.

Essay. See Assay.

Essences. Several of the volatile or essential oils are called essences by the perfumers.

Ether. A very volatile fluid, produced by the distillation of alcohol with an acid. The sulphuric ether is upon the whole best known, though there are various ethers made by means of other acids. As some advantages may be gained by treating of the whole under one article, I shall accordingly pursue that method.

Various passages in the writings of the earlier chemists sufficiently evince, that the sulphuric ether was among their secrets; but it was scarcely attended to before the year 1730, when a certain quantity was presented to the Royal Society by Dr. Frobenius, and certain experiments were made of its most obvious qualities.

When strong sulphuric acid is poured upon an equal weight of alcohol, the fluids unite with a hissing noise and the production of heat, at the same time that a fragrant vegetable smell is perceived, resembling that of apples. It is much better and safer, however, to add the acid by small portions at a time, at such intervals as that no perceptible heat may be produced. The mixture may be made in a glass retort, and the distillation performed by regulated heat on a sand-bath, a large tubulated receiver being previously well adapted and kept cool by immersion in water, or the frequent application of wet cloths. A bent glass tube luted to the tubulure of the receiver, and having its extremity immersed in a little water or mercury, will allow the gasses to escape, and confine the condensible vapour. The first product is a fragrant spirit of wine, which is followed by the ether, as soon as the fluid in the retort begins to boil. At this period the upper part of the receiver is covered with large distinct streams of the fluid, which run down its sides. After the ether has passed over, sulphurous acid arises, which is known by its white fumes and peculiar smell. At this period the receiver must be unluted and removed, care being taken to avoid breathing the penetrating fumes of the acid; and the fire must at the same time be moderated, because the residue in the retort is disposed to swell. A light yellow oil, called sweet oil of wine, comes over after the ether, and is succeeded by black and foul sulphuric acid. The residue varies in its properties according to the management of the heat. If the fire be much increased toward the end of the process, the sulphurous acid that comes over will be mixed with vinegar.

The ether comes over mixed with alcohol and some sulphurous acid. It was usual to add some distilled water to this product, which occasioned the ether to rise to the top. Rectification is absolutely necessary, if the ether have a sulphurous smell; and this is indeed the better method in all cases, because the water added in the old method always absorbs about one tenth part of its weight of ether, which cannot be recovered without having recourse to distillation; and also, because the ether is found to absorb a quantity of the water. Previous to the rectification a small quantity of black oxide of manganese should be added, shaking the mixture occasionally during 24 hours. Proust prefers clean slaked lime, as recommended by Woulf: observing that the bottle must not be above three parts filled, and that it must be moved about in cold water for some minutes before the cork is taken out.

The inexperienced chemist must be reminded, that the extreme inflammability of alcohol, and still more of ether; the danger of explosion which attends the sudden mixture and agitation of concentrated acids and alcohol; and the suffocating effect of the elastic fluids, which might fill the apartment if inadvertently disengaged; are all circumstances which require cautious management.

Sulphuric ether is one of the lightest and most volatile of all non-elastic fluids. Its dissipation into the air by evaporation is so sudden as to produce extreme cold. It is highly inflammable, burns with a more luminous flame than alcohol, which is of a deep blue, and emits more smoke. At 46° below 0 of Fahr. it becomes solid.

The action of this fluid upon saline substances has been little attended to. It does not appear to act upon lime or fixed alkalis. Caustic volatile alkali combines with it in all proportions. Sulphuric acid combines with it, and extricates heat; and from this compound the sweet oil of wine may be obtained by distillation. Nitric acid causes an effervescence, and renders it more oily. It dissolves essential oils and resins, and camphor very plentifully. By long digestion it dissolves $\frac{1}{12}$ of sulphur in the light, and $\frac{1}{17}$ in the dark. This preparation Mr. Favre recommends as an excellent test of lead in wine, which it throws down in a black precipitate. He has also administered it on sugar as a medicine, as well as in different vehicles. Mixed with the muriatic solution of gold it retains a portion of the metal in solution for some time.

Nitric acid has so strong a disposition to combine with alcohol, that a considerable danger of explosion attends the mixture of these fluids. Both these circumstances have given rise to a number of processes for forming nitric ether. It has been made by mixing the two fluids in a retort, connected with very capacious receivers; a method in which it is probable, that no ordinary degree of precaution would be sufficient to secure the operator from the danger of the vessel's being blown in pieces by the elastic fluid that is so suddenly extricated. It may also be obtained without distillation, from a mixture of nitric acid and alcohol. For this purpose, six ounces of highly rectified spirit of wine are put into a strong bottle, capable

ining one pound of water, and im-
up to the neck in a vessel of very
ter, into which it will be advan-
to put three or four pounds of ice,
small. Upon the spirit, in this si-
and kept continually agitated, four
of nitric acid, of the specific gravity
re to be poured, in four or five suc-
portions, or even more gradually.
as the mixture is completed, the

On the eighth day, after the first
, a greenish ether was seen to cover
or in the retort, to the depth of
lf an inch; but the addition of ni-
id was still continued, till on the
day one pound and five ounces of
cid had been introduced into the
. The mixture then began to be
with a brisker motion, when the ether was taken off, and weighed one pound and one ounce. Upon the residuum he then poured, drop by drop, as before, two drachms of nitrous acid morning and evening, till the acid fell to the bottom in the form of perfectly green globules. Dr. Dehne, in consequence of much experience, affirms, that these bubbles are a sign, that no more ether will be separated by any subsequent addition of nitrous acid; but that the mixture is saturated with nitrous acid, and will yield no farther produce, unless alcohol be added. The quantity of ether separated the second time amounted to eight ounces and three drachms. So that the whole produce of ether was one pound, nine ounces, and three drachms, afforded by adding one pound, ten ounces, and three drachms of nitrous acid to two pounds of alcohol. The residuum weighed one pound twelve ounces, and five ounces were lost, which were probably ether. The operation succeeds best in cold weather; and it has frequently been observed, that alcohol, distilled from oily bodies, yields more ether than when pure. This nitric ether, like the foregoing, is commonly still acid, and may be treated with a solution of alkali, and subsequent rectification.

We shall barely mention the other less direct processes for forming nitric ether: 1. A mixture of two parts sulphuric acid and four alcohol, added to four parts dry nitre, affords by distillation a dulcified nitrous acid, mixed with ether, of which two parts may be had by rectification. 2. If nearly one part of diluted nitric acid be carefully poured upon two parts of dense nitrous acid; and upon this there be poured, with the same caution, three parts of strong alcohol; and this compound fluid be left to stand in a phial loosely corked, the acid and spirit will gradually act upon each other, and ether will in a day or two be formed at the top. The whole being put into a retort, affords two parts and more of very pure ether, by distillation. 3. If nitric acid be disengaged in the usual way from nitre by the addition of sulphuric acid, and the acid which comes over be received into alcohol, this last will become in part converted into ether, which may be separated by rectifying. The method is said to be attended with some danger. 4. Brugnatelli introduces into a retort one ounce of sugar, and pours over it two ounces of highly concentrated alcohol. A capacious receiver being adapted to the retort, surrounded with a wet cloth, and the junctures secured by slips of paper only, he pours through the tubulure three ounces of concentrated nitric acid. A violent action takes place, the sugar is dissolved, and ether passes over into the receiver, nearly equal in quantity to the alcohol employed. 5. In the preparation of fulminating mercury a portion of nitric ether is formed, as observed by Mr. Burkitt: and it appears, that this was known to a contemporary of Cheselden, though he seems ignorant of the fulminating powder, probably because his attention was wholly occupied by the light volatile fluid he obtained.

In certain proportions of the materials, and by due management of the process for making nitric ether, the nitric acid wholly disappears, and the residue is found to contain no nitric acid, but some vinegar and the oxalic acid.

Rectified nitric ether burns with a flame rather more luminous than that afforded by the sulphuric ether, at the same time that it gives out rather more smoke, and leaves a black trace behind: in other respects it very much resembles the sulphuric ether.

The methods of making muriatic ether consist in applying the muriatic acid in the oxigenated state to alcohol; for, in the common state of the acid, their mutual action is little or none. In Mr. Westrumb's method, it is procured from four ounces of common salt, two of powdered manganese, two of sulphuric acid, and six of alcohol, by means of distillation. The liquor, being distilled to dryness, is poured back upon the residuum, and distilled afresh. In this distillation, nearly the half which comes over is dulcified muriatic acid, and most of the other half muriatic ether, which may be separated from the rest by the addition of water. It may likewise be procured by passing the oxigenated muriatic gas into alcohol to saturation, and then distilling: or, according to Klaproth, very safely and effectually by distilling equal parts of alcohol and oxymuriat of tin: or, according to Van Mons, by distilling four parts of alcohol with one of oxymuriat of potash at a boiling heat.

Muriatic ether is very transparent and volatile, and burns with a smoke and suffocating smell.

Gehlen produced fluoric ether by adding to 10 ounces of alcohol in a retort 15 ounces of fluat of lime, previously ignited and pulverised, and ten ounces of sulphuric acid at 1·86, and distilling to dryness. During the distillation a large quantity of gas was evolved, which burnt with a beautiful blue flame, and diffused a smell resembling that of phosphuretted hidrogen. During the combustion of the gas, vapours of fluoric acid were precipitated. The product was redistilled till half had passed over. This was immiscible with water, but had an acid taste. On adding a solution of potash, a considerable quantity of silex was instantly separated, and the whole converted to a gelatinous mass. This being redistilled, yielded pure fluoric ether, much resembling the sulphuric of the specific gravity of ·72. It burned with a blue flame, and its taste was bitter, like that of almonds.

To procure acetic ether, according to Westendorff, equal parts of the strongest acetic acid and alcohol are to be mixed together, and suffered to stand for some days in a well-stopped glass vessel, until the mixture has acquired a peculiarly agreeable smell. The liquor is then to be poured into a retort with a receiver accurately luted on, and nearly the half is to be drawn off by a gentle heat. One sixteenth part of fixed alkali, dissolved in four times its weight of water, is to be added to the distilled product, and the fluid gently agitated with a circular motion, which will cause the ether to rise and float at the surface like oil, whence it may be taken off. Its quantity commonly amounts to half that of the alcohol employed. Half the original quantity of alcohol may be again added to the acetous residue once or twice more, by which means the ethereal product will be still more augmented.

Various methods are given of producing acetic ether by the decomposition of an acetous neutral salt, by the addition of a mineral acid. Thus, if an ounce of alkali saturated with vinegar be dissolved in three ounces of alcohol, and a little more of any mineral acid be added than is requisite to saturate the alkali, and the mass be then distilled, acetous ether will be obtained. Or if eight ounces of acetit of lead be gently dried to deprive it of its water of crystallization, which amounts to rather more than one fourth of its weight; and in this state be put into a glass retort, and a mixture of five ounces of sulphuric acid, and eight ounces of alcohol, be poured on it, and the whole be exposed to distillation by a very gentle heat; the first ounce that passes over will consist of dulcified acetic acid, the next ounce will be almost all ether, and the whole quantity of ether produced will be near four ounces.

Acetic ether is not nearly so volatile as the nitric or sulphuric. It burns with a blue flame like alcohol. According to Sedillot it is of excellent service as an external application in rheumatism, sciatica, and gout, half an ounce being rubbed-in every twelve hours; and internally, given in a dose of about half a drachm, is a speedier sedative than opium, and gentler in its effects.

The acid obtained by distillation from wood likewise affords an ether remarkable in its quantity, which considerably exceeds that of the alcohol made use of. Ether has been obtained too with the oxalic, sebacic, and formic acids; and with the phosphoric and benzoic, indirectly.—*Journ. de Phys.—An. de Chim.—Gehlen's Journ.—Van Mons Journ.—Crell.—Wiegleb.—Fourcroy.*

Ethiops (Martial). Iron in the form of a very subtle powder, and in the first stage of oxidation, was introduced into medicine under this name by the younger Lemery, and is thus made: Very clean iron filings are to be put into a glass vessel, and covered with water to the depth of two or three inches. In this situation they are to be frequently agitated, until a considerable portion has acquired the form of a black er, easily suspended in the water. By tation of the turbid water, and subse- repose, the black powder may be ob- separate, which is afterward to be by heat in a glass retort, and ground pon porphyry.

e ethiops appears to be produced by oncurrent action of the air and water: e latter acts very little upon iron. It ormerly supposed to possess peculiar ntages as a medicine; but there is no n to think, that the degree of calcina- in which only it differs from the other s of iron, is of much consequence to edical exhibition of this metal.

e martial ethiops is in a state so nearly aching that of the pure metal, that it the magnet, and was used by Dr. it, to make artificial loadstones, by ing it up with linseed oil.

HIOPS (MINERAL). The black sul- t of mercury.

APORATION. A chemical operation y performed by applying heat to any ound substance, in order to dispel the le parts. It differs from distillation object, which chiefly consists in pre- g the more fixed matters, while the le substances are dissipated and lost. the vessels are accordingly different, oration being commonly made in open w vessels, and distillation in an ap- us nearly closed from the external air. e degree of heat must be duly regu- in evaporation. When the fixed and volatile matters do not greatly differ ir tendency to fly off, the heat must be carefully adjusted: but in other cases less necessary.

evaporation consists in the assumption e elastic form, its rapidity will be in ortion to the degree of heat and the ution of the pressure of the atmo- e. A current of air is likewise of service s process; partly from its absorbing apours, by combining with them as rise, and partly from the convenience ding the speedy removal of these va- s when of a noxious or corrosive na-

DIOMETER. An instrument for as- ning the purity of air, or rather the ity of oxigen contained in any given of elastic fluid. Dr. Priestley's dis- y of the great readiness with which is gas combines with oxigen, and is pitated in the form of nitric acid, see (NITRIC), was the basis upon which nstructed the first instrument of this

method was very simple: a glass l, containing an ounce by measure, was with the air to be examined, which ransferred from it to a jar of an inch half diameter inverted in water; an measure of fresh nitrous gas was l to it; and the mixture was allowed to stand two minutes. If the absorption were very considerable, more nitrous gas was added, till all the oxigen appeared to be absorbed. The residual gas was then transferred into a glass tube two feet long, and one third of an inch wide, graduated to tenths and hundredths of an ounce measure: and thus the quantity of oxigen absorbed was measured by the diminution that had taken place.

Objections have been made to this mode, as slight variations of circumstances in the process are attended with material differences in the results. Thus a greater diminution takes place when atmospheric air is admitted to the nitrous put first into the tube, than when the opposite order is adopted: greater likewise if the tube be agitated the instant the airs come into contact, than if they be allowed to stand together a few seconds before shaking it. When the airs are admitted to each other without agitation, the diameter of the tube influences the result greatly. Thus Mr. Berger of Geneva found the absorption in a given quantity of atmospheric air with an equal bulk of nitrous gas, after standing twenty four hours, was in tubes of the diameter of

lines	absorption
43	1·17
22	1·05
18·5	1
5	0·70
3·5	0·68

After standing six days the absorption in the last tube was increased ·01; in the rest there was no difference.

The purity of the nitrous gas has been considered too as of consequence; and Mr. Von Humboldt, who still prefers this test, proposes that the gas should be examined, before it is used, by agitating a given quantity with a solution of sulphat of iron. The residuum, diminished by ·02 or ·03, to allow for the air escaping from the solution, is to be considered as the proportion of nitrogen in the gas examined. After the airs have been mixed, Mr. Von Humboldt analyses the residuum, by absorbing the nitrous gas, that may have been left for want of oxigen to convert it into nitric acid, by a solution of sulphat of iron; and, deducting the nitrogen in the test, as found by the process above, the remainder is the nitrogen of the air examined. When, however, the valuation is made in the shortest way, by adding nitrous gas sufficient to absorb all the oxigen at once or twice, and thus finding the quantity of oxigen by the quantity of nitrous acid formed, the presence of a little nitrogen will produce no sensible errour: nitrous oxide, indeed, would be absorbed by agitation with the water, and thus give rise to mistake;

but if the nitrous gas be prepared by means of mercury or copper, no nitrous oxide will be evolved.

Mr. Dalton too prefers nitrous gas, but making the mixture in a narrow tube, using no agitation, and transferring it into another tube as soon as the diminution appears to be over.

Mr. Davy employs the nitrous gas in a different manner. He passes it into a saturated solution of green muriat or sulphat of iron, which becomes opake and almost black when fully impregnated with the gas. The air to be tried is contained in a small graduated tube, largest at the open end, which is introduced into the solution, and then gently inclined toward the horizon, to accelerate the action, which will be complete in a few minutes, so as to have absorbed all the oxigen. He observes, that the measure must be taken as soon as this is done, otherwise the bulk of the air will be increased by a slow decomposition of the nitric acid formed.

Volta had recourse to the accession of hidrogen gas. For this purpose two measures of hidrogen are introduced into a graduated tube with three of the air to be examined, and fired by the electric spark. The diminution of bulk, observed after the vessel had returned to its original temperature, divided by three, gives the quantity of oxigen consumed.

Phosphorus and sulphuret of potash have likewise been employed in eudiometry.

A piece of phosphorus may be introduced by means of a glass rod into a tube containing the air to be examined standing over water, and suffered to remain, till it has absorbed its oxigen; which however is a slow process. Or a glass tube may be filled with mercury and inverted, and a piece of phosphorus, dried with blotting paper, introduced, which will of course rise to the top. It is there to be melted, by bringing a red-hot iron near the glass, and the air to be admitted by little at a time. At each addition the phosphorus inflames; and when the whole has been admitted, the red-hot iron may be applied again, to ensure the absorption of all the oxigen. In either of these modes $\frac{1}{40}$ of the residuum is to be deducted, for the expansion of the nitrogen by means of a little phosphorus which it affords.

Professor Hope of Edinburgh employs a very convenient eudiometer, when sulphuret of potash or any liquid is used. It consists of two bottles: one to hold the solution of sulphuret of potash, or other eudiometric liquor, about two inches in diameter, and three inches high, with a neck at the top as usual, and another to be closed with a stopple in the side near the bottom: the other rather less in diameter, about eight inches and a half long, with a neck ground to fit into that of the former. This, being filled with the air to be examined, and its mouth covered with a flat piece of glass, is to be introduced under water, and there inserted into the mouth of the other bottle. Taking them out of the water, and inclining them on one side, they are to be well shaken; occasionally loosening the stopper in a plate filled with water, so as to admit this fluid to occupy the vacuum occasioned by the absorption. Bottles of much smaller size than here mentioned, which is calculated for public exhibition, may generally be employed: and perhaps a graduated tube, ground to fit into the neck of a small phial, without projecting within it, may be preferable on many occasions, loosening it a little under water from time to time, as the absorption goes on.—*Priestley on Air.—Phil. Trans.—Journ. of Roy. Instit.—Manch. Mem.—Journ. de Phys.—An. de Chim.—Nich. Journal.*

Euphorbium. A gummy resin exsuding from a large oriental shrub, Euphorbia officin. Linn.

It is brought to us immediately from Barbary, in drops of an irregular form; some of which upon being broken are found to contain little thorns, small twigs, flowers, and other vegetable matters; others are hollow, without any thing in their cavity: the tears in general are of a pale yellow colour externally, somewhat white withinside: they easily break betwixt the fingers. Lightly applied to the tongue, they affect it with a very sharp biting taste; and, upon being held for some time in the mouth, prove vehemently acrimonious, inflaming and exulcerating the fauces, &c. Euphorbium is extremely troublesome to pulverize, the finer part of the powder, which flies off, affecting the head in a violent manner. The acrimony is so great, as to render it absolutely unfit for any internal use. It is much employed in the veterinary art as an epispastic.

Excrements. Some have extended this term to all the various secretions from the blood, however important their functions, and included under it the hair and nails, horns and hoofs: but it properly signifies only what is discharged from the body as useless by natural passages, without the excitement of disease, as the urine and fæces. However important the knowledge of the component parts of fecal matter may be to facilitate our acquaintance with the animal system, it may easily be imagined that the pursuits of the majority of chemists would be directed to departments of the science which promised effects of a less unpleasant nature. A set of experiments was made on this subject by Homberg at the beginning of the last century. This philosopher, in consequence of alchemistical information, instituted a set of operations upon the fecal matter of men fed entirely upon the bread of Gonesse and Champaigne wine. He

, that, when recent, it afforded by
ation to dryness an aqueous, clear, in-
iquor, of a disagreeable odour, which
ned no volatile alkali; but, by con-
g to distil the residue by a graduat-
e, he obtained fluid and concrete vola-
kali, a fetid oil, and a coaly residue;
nces which this imperfect method of
sis exhibits with every kind of animal
nce.

e human fecal matter, by lixiviation in

ANSION. All bodies expand by heat;
e differences are exceedingly great be-
some bodies and others. Whether
fference may depend upon, or be
cted with, any of the other known
rties of the several bodies, cannot be
ed from any experiments yet made.
substances hitherto examined, it is
, that the vegetable fibre varies its
sions lengthwise the least by change
perature; for which reason a straight-
d rod of deal wood is found to be
preferable to any other simple sub-
in the construction of pendulums
ocks. This same object, namely, the
uction of pendulums, together with
circumstances relative to geometrical
surements, have rendered it of some
tance, to ascertain the proportional
sions of metals, and some other bodies,
nge of temperature. There are two
f doing this. The first, practised by
henbroek, Ellicott, and many others,
s in the application of a train of
or levers, which magnify the motion
e increased velocity of the extreme
f the train. The other contrivance,
nsden, consists in placing two microscopes above the body, the dimensions of which are required to be ascertained; and as these instruments are fixed to a bar of cast iron constantly kept at the freezing temperature by surrounding it with melting ice, their distance does not vary from this cause. The last method, practised by General Roy, is much preferable to any other hitherto carried into effect; and it is much to be regretted, that the substances examined by the general were so few in number. He found, that the expansions of the following substances, in each foot of length, by a change of temperature of 180 degrees of Fahrenheit's thermometer, that is to say, from the freezing to the boiling points of water, were as under.

Standard brass scale, length 42·187. It expanded per foot 0·0222646 of an inch.

English plate brass rod 5 feet long, difficult from its thinness to be kept free from warping, expanded per foot 0·0227136 inch.

English plate brass in form of a trough, perfectly strong, expanded per foot 0·0227386 inch.

Steel rod 5 feet long expanded per foot 0·0137368 inch.

Cast iron prism 5 feet long expanded per foot 0·0133126 inch.

Glass tube 5 feet long expanded per foot 0·0093138 inch.

Solid glass rod 40½ inches long expanded per foot 0·0096944 inch.

The brass scale was supposed to be Hamburgh brass.

The makers of astronomical regulators availed themselves of the difference of expansion of brass and steel to make pendulums, the centres of oscillation of which remain at an invariable distance from their respective centres of suspension. Portable time-pieces are likewise made to ascertain the longitude at sea with considerable precision, by forming the rim or circular part of the balance of brass and steel soldered together, the ring of brass being outermost. The effect of two such pieces of metal being soldered together is, that they change their figure by change of temperature. For it may easily be understood, that when a rod of brass is firmly soldered to a rod of steel, and the temperature of both is raised, the greater expansion of the brass will cause that side of the compound bar to be longer than the opposite side which is steel. And this cannot take place without bending of the bar, which accordingly takes place, the brass side becoming convex. A diminution of temperature restores the original figure, and a still greater degree of diminution must of course bend it the contrary way.

The construction of time-pieces is very remotely related to the pursuits of the chemist; but there is no department of science which cannot indicate useful truths to the cultivators of other branches: this ingenious application of the differences of expansion in metals is here mentioned as a hint to the chemist, who may easily apply it in the construction of a thermometer for measuring the degrees of heat by the actual ignition of two metals rivetted, or otherwise fastened together.

Expression, or Pressure. The juices of vegetables, and the fluid parts of other soft substances, are obtained by putting them into a cloth or bag, and exposing it to the action of the press.

Extract. When decoction is carried to such a point as to afford a substance either solid or of the consistence of paste, this residual product is called an extract. When chemists speak of extract, they most commonly mean the product of aqueous decoction; but the earlier chemists frequently speak of spirituous extract.

Extracts thus prepared are mixtures of several of the materials of vegetables, whence they differ greatly according to the plants from which they are obtained; but modern chemists distinguish by the name of extract, or *extractive matter*, a peculiar substance, supposed to be one of the immediate materials of vegetables, and the same in all, when separated from any foreign admixture, except as the proportion of its constituent principles may vary. Fourcroy considers it as a kind of oxide with a triple radical, composed of carbon, hidrogen, and nitrogen, which has a tendency to absorb more oxigen than it contains, and differs from the colouring matter only in the proportion of its principles.

Eye. The humours of the eye had never been examined with any degree of accuracy till lately by Mr. Chenevix. Most of his experiments were made with the eyes of sheep, as fresh as they could be procured.

The aqueous humour is a clear, transparent liquid, with little smell or taste, and of the temperature of 60°, its specific gravity is 1·009. It consists of water, albumen, gelatine, and muriat of soda.

The crystalline contains a much larger proportion of water, and no muriat. Its specific gravity is 1·1.

The vitreous humour, when pressed through a rag to free it from its capsules, differed in nothing from the aqueous, either in its specific gravity or chemical nature.

Fourcroy mentions a phosphat as contained in these humours, but Mr. Chenevix could discover none.

The humours of the human eye gave the same products, but the specific gravity of the crystalline was only 1·079, and that of the aqueous and vitreous humours 1·0053.

The eyes of oxen differed only in the specific gravity of the parts, that of the crystalline being 1·0765, and that of the other humours 1·0088.

The specific gravity of the crystalline is not equal throughout, its density increasing from the surface to the centre.—*Phil. Trans.* 1803.

F.

Farina. See Bread.

Fat. The fat of animals is a substance of the same nature as those oils which are called fat oils in the vegetable kingdom. Its consistence is various in different animals, and in different parts of the same animal. The fat of the human species and of quadrupeds is consistent, and of a white or yellowish colour; the fat of the internal parts being usually firmer than that which is placed among the muscles. It possesses all the characters of vegetable fat oils, though the crude fat of animals appears to contain a considerable quantity of mucilage or jelly peculiar to that kingdom, which may for the most part be washed off by agitation in a large quantity of hot water.

Neumann treated the fat of the goose, the hog, the sheep, and the ox, in a glass retort, by a fire gradually raised. He obtained phlegm, an empyreumatic and brownish oil, and a brilliant coal. This analysis led him no further than to the conclusion, that there is little difference between fats. But modern experiments have shown, that they contain an acid of a peculiar nature, for an account of which see Acid (Sebacic).

Feathers. The feathers of birds much resemble horn in their nature. In the fire they melt, become brown, emit smoke with a strong smell of ammonia and empyreumatic oil, swell, inflame, and leave a light coal. Distilled in a retort they yield a fetid water, a dense and nearly concrete oil, carbonat, prussiat, and acetat of ammonia, with carburetted and sulphuretted hidrogen gas. Boiling water softens the horny matter, and at length reduces it to a jelly: the acids and alkalis soften and dissolve it likewise: and many colouring substances adhere to it, but more particularly to the plumes, whence the art of dyeing them is carried to great perfection.

Fecula. See Bread.

Fecula. The green fecula, or matter expressed from fresh vegetables, particularly the more succulent, was examined with attention by Rouelle the younger, who found it to contain gluten; and since more minutely by prof. Proust. According to him, it is concrescible at a lower temperature than albumen; and becomes elastic and horny when dry. It is precipitable by alcohol and acids. The fecula likewise contains a green resin, which is bleached and hardened by the oxigenated muriatic acid.

ient. See Fermentation.

ientation. This word was for-
sed in a very undefined and general
o denote every change undergone
ganized substances, of which the
as not apparent; such as chemists
to call by the name of spontaneous

entation has been distinguished into
ages, or more properly species: the
or spirituous, the acid or acetous, and
rid or putrefactive; which are so
rom the principal products afforded
during each of them respectively. Some add to these the saccharine, which takes place before the vinous; and the panary and colouring, which precede the putrefactive. It is ascertained almost beyond a doubt, that the vinous fermentation takes place only in such bodies as contain saccharine juices. In this the most remarkable product is that volatile, light, colourless, inflammable fluid, which mixes with water in all proportions, and is called ardent spirit, or alcohol. The acetous fermentation is distinguished by the product known by the name of vinegar, which is the least destructible of the mere vegetable acids. It does not appear, however, that fermentation is absolutely necessary for the production of this acid, which may be had by treating various organized bodies with nitric acid. In the putrid fermentation bodies appear to be reduced into very simple principles. Volatile alkali is the product, which has been remarked as the chief in this process, and is doubtless produced by the combination of hidrogen and nitrogen, which fly off in this process. It may also be had in a variety of direct chemical processes. See Ammonia.

The acetous like the vinous fermentation is confined to vegetable substances; but the putrefactive process is most eminently perceived in animal bodies. These either putrefy immediately without any other previous change, or, if the putrefaction be preceded by either of the other stages, their duration and intensity are insensible. It is considered as an established fact, that the three stages of fermentation always follow each other in the same order in such bodies as are susceptible of them all; the vinous coming first, which is followed by the acetous, and this by the putrefactive.

These spontaneous effects are greatly retarded by extreme cold, or by sudden desiccation, or by preservation of the bodies in vessels so well closed as to prevent the escape or absorption of elastic fluid. The first two of these necessarily retard the chemical processes, by depriving the parts of the requisite fluidity; and it may without difficulty be understood, that the changes of combination cannot by any means be completely made, while the communication with the open air, the great receptacle and solvent of volatile matter, and one of the chief agents in the great operations of nature, is cut off.

The three conditions for the due accomplishment of fermentation will therefore be, fluidity, or moisture; moderate heat, or a due temperature; and the access of air. It will of course be modified also by the component parts of the body itself.

As the vinous fermentation has never been found to take place where sugar was not present, it appears the most simple to consider what happens when mere sugar and water in due proportions are exposed to fermentation. If a considerable quantity of water, holding in solution about one third of its weight of sugar, be exposed to the air, at the temperature of about 70° of Fahrenheit's thermometer, after the addition of a small quantity of yeast, it soon undergoes a remarkable change. In the course of a few hours the fluid becomes turbid and frothy; bubbles of carbonic acid are disengaged, which rise and break at the surface. This disengagement becomes more and more abundant; mucilage is separated; part of which subsides to the bottom, and part, expanded into froth by the elastic fluid, forms yeast. During the course of several days these effects gradually come to their height, and diminish again; after which they proceed very slowly, but are long before they entirely cease. The fermented liquor has no longer the sweet taste it had before, but becomes brisk and lively, with a pungent spirituous flavour. Its specific gravity is likewise considerably less than before; and when exposed to distillation, it affords a light inflammable spirit miscible with water in all proportions. The quantity of alcohol which any fermented liquor will produce, is thought to follow some proportion of the change its specific gravity undergoes in fermentation; but the truth of this has not been clearly ascertained. Wine, cider, and beer, are well-known liquors of this kind.

Some vegetable juices, as those of most ripe fruits, ferment without yeast; and Seguin asserts, that all such contain a large portion of albumen; and that albumen added to saccharine matter will occasion it to ferment as well as yeast. Hence he infers, that albumen is the true ferment.

Thenard too asserts, that the ferment contained in yeast is of an animal nature, and that it is an immediate principle of vegetables.

The subject of what passes in the vinous fermentation was carefully investigated by Lavoisier. For this purpose it was necessary, accurately to determine the constituent elements of the fermentable substances; and accordingly he did not make use of the compound juices of fruits, the rigorous analysis of which is perhaps impossible, but made choice of sugar, which is easily analysed. This substance he states to be a true vegetable oxide, with a double base, composed of hidrogen and carbon, brought to the state of an oxide by means of a certain proportion of oxigen; and these three elements are combined in such a way, that a very slight force is sufficient to destroy the equilibrium of their connection. By a long train of experiments, made in various ways, and often repeated, he ascertained, that the proportions in which these ingredients exist in sugar are, nearly eight parts of hidrogen, sixty-four parts of oxigen, and twenty-eight parts of carbon, all by weight, forming one hundred parts of sugar.

Sugar must be mixed with about four times its weight of water, to render it susceptible of fermentation; and even then the equilibrium of its elements would remain undisturbed, without the assistance of some substance to give a commencement to the fermentation. Lavoisier's translator, however, remarks here, that this is not strictly true; for, especially in warm weather, all sirups are apt to run into fermentation, unless very rich of the sugar, and carefully preserved. At the same time this spontaneous fermentation is not so regular as when assisted by yeast, and is apt to become in part acetous before completing the vinous process.

The commencement of the fermentation is accomplished by means of a little yeast from beer; and when the fermentation is once excited, it continues of itself until completed. Lavoisier usually employed ten pounds of yeast, in the state of paste, for each hundred pounds of sugar, with as much water as is four times the weight of the sugar. The following is the result of his experiments, exactly as they were obtained, preserving even the fractions produced by calculation.

g thus accurately determined the nd quantity of the constituent ele- the materials submitted to ferment- e have next to examine the products from this process. For this purpose r placed the above 510 lbs. of fer- e liquor in a proper apparatus, by f which he could accurately deter- quantity and quality of gas disen- uring the fermentation, and could gh every one of the products sepa- at any period of the process he roper.

ur or two after the substances are gether, especially if they be kept perature of from 66° to 73° of Fahr. marks of fermentation commence: r turns thick and frothy; little glo- air are disengaged, which rise and the surface; the quantity of these globules quickly increases, and there is a rapid and abundant production of very pure carbonic acid, accompanied with a scum, which is the yeast separating from the mixture. After some days, less or more according to the degree of heat, the intestine motion and disengagement of gas diminish; but these do not cease entirely, nor is the fermentation completed for a considerable time. During the process 35·3458116 lbs. of dry carbonic acid are disengaged, which carry along with them 13·9140625 lbs. of water. There remains in the vessel 460·7401259 lbs. of vinous liquor, slightly acidulous. This is at first muddy, but clears of itself, and deposits a portion of yeast, When we separately analyse all these substances, which is effected by very troublesome processes, we have the results as given in the following tables:

In the calculation of these results, Lavoisier has been exact even to minuteness; not that it is possible in experiments of this nature actually to carry our accuracy so far; but as the experiments were made only with a few pounds of sugar, and as, for the sake of comparison, he reduced the results of the real experiments to the quintal, or imaginary hundred pounds, he thought it necessary to leave the fractional parts precisely as produced by calculation.

When we consider the results presented by these tables with attention, it seems easy to ascertain what occurs during fermentation. In the first place, out of the 100 lbs. of sugar employed, 4·0940755 lbs. remain, without having suffered decomposition: so that in reality we have only operated upon 95·9059245 lbs. of sugar; that is to say, upon 61·37979168 lbs. of oxigen, 7·67247396 lbs. of hidrogen, and 26·85365886 lbs. of carbon. By comparing these quantities, we find that they are fully sufficient for forming the whole of the alcohol, carbonic acid, and acetous acid, produced by the fermentation. It is not, therefore, necessary to suppose, that any water has been decomposed during the experiment, unless it is pretended, that the oxigen and hidrogen exist in the sugar already combined in that form. On the contrary, it has already been made evident, that hidrogen, oxigen, and carbon, the three constituent elements of vegetable substances, remain in a state of equilibrium, or mutual union with each other, which subsists so long as this union remains undisturbed by increased temperature, or by means of some new compound attraction; and that then only these elements combine, two and two together, to form water and carbonic acid.

The effects of the vinous fermentation upon sugar are thus reduced to the mere separation of its elements into two portions: one part is oxigenated at the expense of the other, so as to form carbonic acid, while the other part, being disoxigenated in favour of the former, is converted into the combustible substance called alcohol; therefore, if it were possible to reunite alcohol and carbonic acid together, we ought to form sugar. It is evident, that the carbon and hidrogen in the alcohol do not exist in the state of oil, but that they are combined with a portion of oxigen, which renders them miscible with water; wherefore these three substances, oxigen, hidrogen, and carbon, exist here likewise in a species of equilibrium or reciprocal combination; and in fact, when they are made to pass through a red-hot tube of glass, or porcelain, this union or equilibrium is destroyed; these elements become recombined two and two, and water and carbonic acid are formed.

Lavoisier, in his first Memoirs on the Formation of Water, had advanced, that it was decomposed in a great number of chemical experiments, and particularly during the vinous fermentation. He then supposed, that water existed ready formed in sugar; but subsequent experiments convinced him, that sugar only contains the elements proper for composing it.

He concludes his remarks upon vinous fermentation by observing, that it furnishes us with the means of analysing sugar, and every vegetable fermentable matter. We may consider the substances submitted to fermentation, and the products resulting from that operation, as forming an algebraic equation; and by successively supposing each of the elements in this equation unknown, we can calculate their values in succession, and thus verify our experiments by calculation, and our calculations by experiments, reciprocally. He adds, that he has often successfully employed this method for correcting the first results of his experiments, and directing him in the proper road for repeating them to advantage.

When it is required to preserve fermented

n the state produced by the first
fermentation, it is usual to put

matters are separated from vege-
s in the preparation of woad and
s carried much further, approaching
efactive stage.

rn discoveries have greatly eluci-
e phenomena of fermentation; but
ill remains to be accurately deter-
concerning the processes, the pro-
nd their proportions. It is not
scertained, what the yeast or ferment performs in this operation. It seems probable, that the fermentative process in considerable masses would be carried on progressively from the surface downwards; and would, perhaps, be completed in one part before it had perfectly commenced in another, if the yeast, which is already in a state of fermentation, did not cause the process to begin in every part at once. See Bread, Putrefaction, Tartar, Alcohol, Wine, Acid (Acetous), Vegetable Kingdom.

Ferrilite. The name given by Kirwan to Rowley rag.

Filtration. An operation, by means of which the greater part of a fluid is mechanically separated from such consistent particles as may be merely mixed with it. It does not differ from straining.

An apparatus fitted up for this purpose is called a filter. The form of this is various, according to the intention of the operator. A piece of tow, or wool, or cotton, stuffed into the pipe of a funnel, will prevent the passage of grosser particles, and by that means render the fluid clearer which comes through. Spunge is still more effectual. A strip of linen rag wetted and hung over the side of a vessel containing a fluid, in such a manner as that one end of the rag may be immersed in the fluid, and the other end may remain without, below the surface, will act as a syphon, and carry over the clearer portion. Linen or woollen stuffs may either be fastened over the mouths of proper vessels, or fixed to a frame, like a sieve, for the purpose of filtering. All these are more commonly used by cooks and apothecaries than by philosophical chemists, who, for the most part, use the paper called cap paper, made up without size.

As the filtration of considerable quantities of fluid could not be effected at once without breaking the filter of paper, it is found requisite to use a linen cloth, upon which the paper is applied and supported.

Precipitates and other pulverulent matters are collected more speedily by filtration than by subsidence. But there are many chemists, who disclaim the use of this method, and avail themselves of the latter only, which is certainly more accurate, and liable to no objection where the powders are such as will admit of edulcoration and drying in the open air.

Some fluids, as turbid water, may be purified by filtering through sand. A large earthen funnel, or stone bottle with the bottom beaten out, may have its neck loosely stopped with small stones, over which smaller may be placed, supporting layers of gravel increasing in fineness, and lastly covered to the depth of a few inches with fine sand, all thoroughly cleansed by washing. This apparatus is superior to a filtering stone, as it will cleanse water in large quantities, and may readily be renewed when the passage is obstructed, by taking out and washing the upper stratum of sand.

A filter for corrosive liquors may be constructed on the same principles of broken and pounded glass.

Fire. The word heat has been used with so much precision by Doctors Black, Irvine, Crawford, and others, that the word fire seems to have been rendered of little use, except to denote a mass of matter in a state of combustion, which is, indeed, its vulgar acceptation. The term has, however, been used by many eminent writers, to denote what these great philosophers call the matter of heat, now generally termed Caloric, which see.

Fish. It appears from the experiments of Neumann, that fish afford more volatile alkali by destructive distillation than the flesh of land animals does. Lobsters and other shell fish have been thought to contain a disengaged alkali; but this may with justice be doubted. With regard to their nutritious properties, the shell-fish rank next after land animals with dark coloured flesh, eels and other fish without scales perhaps next to these, and other river fish below land animals with white flesh.

Fixity. The property by which bodies resist the action of heat, so as not to rise in vapour. It is the opposite to volatility. The fixity of bodies appears to be merely relative, and depends on the temperature at which they assume the elastic state or form. Such bodies as assume this state at a low temperature will easily rise; whereas those which cannot be so dilated but at an extreme heat will remain fixed in all ordinary situations. From the analogy of a variety of facts, it does not seem probable that any substances are absolutely fixed.

Fixed bodies are, for the most part, denser than those which are more volatile. The planets nearest the sun are also found to be denser than those which are more remote, and are certainly formed of more fixed materials, as far as our experiments of heat on the solids and fluids of this globe can assure us.

Flame. Newton and others have considered flame as an ignited vapour, or red-hot smoke. This, in a certain sense, may be true, but, no doubt, contains an inaccurate comparison. Simple ignition never exceeds in intensity of light the body by contact of which it was produced. But it appears to be well ascertained, that flame always consists of volatile inflammable matter in the act of combustion and combination with the oxigen of the atmosphere. Many metallic substances are volatilized by heat, and burn with a flame by the contact of the air in this rare state. Sulphur, phosphorus, and some other bases of acids exhibit the same phenomenon. But the flames of organized substances are in general produced by the extrication and accension of hidrogen gas with more or less of charcoal. When the circumstances are not favourable to the perfect combustion of these products, a portion of the coal passes through the luminous current unburned, and forms smoke. Soot is the condensed matter of smoke.

As the artificial light of lamps and candles is afforded by the flame they exhibit, it seems a matter of considerable importance to society, to ascertain how the most luminous flame may be produced with the least consumption of combustible matter. There does not appear to be any danger of error in concluding, that the light emitted will be greatest when the matter is completely consumed in the shortest time. It is therefore necessary, that a stream of volatilized combustible matter of a proper figure, at a very elevated temperature, should pass into the atmosphere with a certain determinate velocity. If the figure of this stream should not be duly proportioned; that is to say, if it be too thick, its internal parts will not be completely burned for want of contact with the air. If its temperature be below that of ignition, it will not burn when it comes into the open air. And there is a certain velocity at which the quantity of atmospherical air which comes in contact with the vapour will be neither too great nor too small; for too much air will diminish the temperature of the stream of combustible matter so much as very considerably to impede the desired effect, and too little will render the combustion languid.

We have an example of a flame too large in the mouths of the chimneys of furnaces, where the luminous part is merely superficial, or of the thickness of about an inch or two, according to circumstances, and the internal part, though hot, will not set fire to paper passed into it through an iron tube; the same defect of air preventing the combustion of the paper, as prevented the interior fluid itself from burning. And in the lamp of Argand we see the advantage of an internal current of air, which renders the combustion perfect by the application of air on both sides of a thin flame. So likewise a small flame is whiter and more luminous than a larger; and a short snuff of a candle giving out less combustible matter in proportion to the circumambient air, the quantity of light becomes increased to eight or ten times what a long snuff would have afforded.

Flint. A semitransparent hard stone, of the siliceous order, of a grayish, black, or yellowish colour, well known for its general utility in giving fire with the steel. It is commonly found in nodules, in beds of chalk or sand, and frequently exhibits indications of its having been in a soft state. Some specimens are hollow, and internally lined with siliceous crystals. By long exposure on the surface of the ground, they gradually become white on their upper surface first, and afterward all over. This white-

a process of time, penetrates into the
ace of the flint, forming a crust some-
ne twentieth of an inch thick, which
e scraped with a knife. It has been
hat this is a conversion of flint into
eous earth; but I know of no proof
fact; and as this white matter does
pear to be affected by nitric acid, I
lined to think, that the flint is merely
red by the weather in a manner some-
nalogous to the effect of ignition and
hing in water, which renders it white
able.

es not say.

ITY. The state of bodies when
ts are very readily movable in all
s with respect to each other. Many
d curious properties arise out of
fication of matter, which form the
he mechanical science called hy-
, and are of considerable import-
hemistry. But the attention of the
s chiefly directed to the state of
s it may affect the component parts
.

body may be converted into a fluid by heat. The less the temperature at which this is effected, the more fusible the body is said to be.

All fluids, not excepting the fixed metals, appear, from various facts, to be disposed to assume the elastic form, and this the more readily the higher the temperature. When a fluid is heated to such a degree as that its elasticity is equal to the pressure of the air, its interior parts rise up with ebullition.

The capacity of a dense fluid for caloric is greater than that of the same body when solid, but less than when in the elastic state. If this were not the case, the assumption of the fluid and elastic state would be scarcely at all progressive, but effected in most cases instantly as to sense. See CALORIC.

The state of dense fluidity appears to be more favourable to chemical combination than either the solid or elastic state. In the solid state, the cohesive attraction prevents the parts from obeying their chemical tendencies; and in the elastic state, the repulsion between the parts has in a great measure the same effects. Hence it has been considered, though too hastily, as a chemical axiom, that *corpora non agunt nisi fluida*.

FLUOR. This word has been used to distinguish such bodies as are for the most part fluid in the temperature of the atmosphere. Thus, for example, the fluor acids, the fluor volatile alkali, are terms sometimes used; but in general the writers on chemistry have not adopted this word.

FLUOR SPAR. The native fluat of lime.

FLUX. A general term made use of to denote any substance or mixture added to assist the fusion of minerals. In the large way, limestone or fusible spar are used as fluxes; but in small assays, the method of the great operations is not always followed, though it would be very frequently of advantage to do so. The fluxes made use of in assays, or philosophical experiments, consist usually of alkalis, which render the earthy mixtures fusible, by converting them into glass; or else glass itself in powder.

Alkaline fluxes are either the crude flux, the white flux, or the black flux. Crude flux is a mixture of nitre and tartar, which is put into the crucible with the mineral intended to be fused. The detonation of the nitre with the inflammable matter of the tartar is of service in some operations; though generally it is attended with inconvenience on account of the swelling of the materials, which may throw them out of the vessel, if proper care be not taken either to throw in only a little of the mixture at a time, or to provide a large vessel.

White flux is formed by projecting equal parts of a mixture of nitre and tartar, by moderate portions at a time, into an ignited crucible. In the detonation which ensues, the nitric acid is decomposed, and flies off with the tartarous acid, and the remainder consists of the potash in a state of considerable purity. This has been called fixed nitre.

Black flux differs from the preceding, in the proportion of its ingredients. In this the weight of the tartar is double that of the nitre; on which account the combustion is incomplete, and a considerable portion of the tartarous acid is decomposed by the mere heat, and leaves a quantity of coal behind, on which the black colour depends. It is used where metallic ores are intended to be reduced, and effects this purpose, by combining with the oxigen of the oxide.

There is danger of loss in the treatment of sulphureous ores with alkaline fluxes: for, though much or the greater part of the sulphur may be dissipated by roasting, yet that which remains will form a sulphuret with the alkali, which is a very powerful solvent of metallic bodies. The advantage of Mr. Morveau's reducing flux seems to depend on its containing no uncombined alkali. It is made of eight parts of pulverized glass, one of calcined borax, and half a part of powder of charcoal. Care must be taken to use a glass which contains no lead. The white glasses contain in general a large proportion, and the green bottle glasses are not perhaps entirely free from it.

Forge Furnace. The forge furnace consists of a hearth, upon which a fire may be made, and urged by the action of a large pair of double bellows, the nozzle of which is inserted through a wall or parapet constructed for that purpose. It is useful for applying a considerable heat with great expedition, and is accordingly very much used by blacksmiths and other artisans. The philosophical chemist will find it very useful for fusions, reductions, and most other experiments, that require a strong heat, especially if the vessels be very small. Black lead pots, or small furnaces of every desired form, may be placed as occasions require upon the hearth; and the tube of the bellows being inserted into a hole in the bottom of the furnace, it becomes easy to urge the heat to almost any degree required.

Mr. Wedgwood found the heat of a common smith's forge (I suppose without any addition to the fire-place) to be less than that required for the fusion of cast iron, and considerably below that of his small air furnace.

A principal objection to this and every other furnace with bellows is the labour of working them.

Frankincense. See Olibanum.

Freezing Mixtures. See Tab. 2. art. Caloric.

French Berries. The fruit of the *Rhamnus infectorius*, called by the French *graines d'Avignon*. They give a pretty good yellow colour, but void of permanency. When used for dyeing the cloth as prepared in the same manner as for weld. Their colour is soluble both in water and extract. They contain a small portion of gallic acid, but neither gum nor tannin. Their decoction reduces gold, and precipitates the metallic salts.—*Berthollet*.—*Proust*.

Friesland Green. An ammoniaco-muriat of copper, the same with Brunswic green. See Copper.

Fritt. The materials of glass are first mixed together, and then exposed to calcination by a degree of heat not sufficient to melt them. The mass is then called fritt. The calcination deprives it of any accidental combustible matter it might have contained, and disposes it to fusion in the melting-pot with less effervescence than would else have taken place.

Fruits of Vegetables. In Dr. Lewis's examination of the colouring matters of vegetable fruits, he found, that the red juices of fruits did not afford a permanent dye by any treatment he used. The dark dull stain of the black cherry proved considerably durable. Sap Green is prepared from the berries of buckthorn, and Annotto is obtained from the pellicles of the seeds of an American tree. See the words.

Fuliginous. Vapours which possess the property of smoke; namely, opacity, and the disposition to apply themselves to surrounding bodies in the form of a dark-coloured powder.

Fullers Earth. See Earth (Fullers).

Fulminating and Fulmination. In a variety of chemical combinations, it happens, that one or more of the principles assume the elastic state with such rapacity, that the stroke against the displaced air produces a loud noise. This is called fulmination, or much more commonly detonation.

Fulminating gold, and fulminating powder, are the most common substances of this kind, except gunpowder. For the latter of these see the article Gunpowder. The fulminating powder is made by triturating in a warm mortar three parts by weight of nitre, two of carbonat of potash, and one of flowers of sulphur. Its effects, when fused in a ladle, and then set on fire, are very great. The whole of the melted fluid explodes with an intolerable noise; and the ladle is commonly disfigured, as if it had received a strong blow downwards. A drachm of the powder makes a report as loud as a cannon; but the noise of a few grains, or single pinch taken between the finger and thumb, is very unpleasant in a room. It has very little effect, unless first melted. A mixture of sulphuret of potash with twice its weight of nitre produces the same explosion, though in less time: whence it appears, that the alkali and sulphur of the former composition form a sulphuret; and that the explosion, in all probability, arises from the sudden extrication of sulphuretted hidrogen from the sulphuret, and

gas from the nitre, which burn the
they are formed.
solution of gold be precipitated by
ia, the product will be fulminating
Less than a grain of this, held over
ne of a candle, explodes with a very
and loud noise. This precipitate,
ted by filtration, and washed, must
d without heat, as it is liable to ex-
with no great increase of tempera-
and it must not be put into a bottle
with a glass stopple, as the friction
would expose the operator to the

ctric pile, and a spark drawn from it.
ninating mercury was discovered by
loward. A hundred grains are to be
ed with heat in an ounce and half by
re of nitric acid. The solution, when
s to be poured on two ounce measures
ohol, and heat applied till an effer-
ce is excited. As soon as the preci-
is thrown down, it must be collected
lter, that the acid may not react on
ashed, and dried by a very gentle heat.
onates with a very little heat or
n.
mixture of the hyperoxigenated muriat
tash and arsenic explodes with great violence and rapidity. A small brass cannon was split by it from top to bottom, and spread out as flat as a card. Two trains on a table, one of this mixture, and one of gunpowder, were laid in contact with each other at one end, so as to be fired at the same instant. The mixture disappeared like a flash of lightning, while the gunpowder, from the comparison, seems to burn very slowly. This mixture detonates very strongly by the stroke of a hammer, and inflames on the contact of sulphuric acid.

Three parts of this powder and one of sulphur, triturated in a metal mortar, caused numerous successive detonations, like the cracks of a whip, the reports of a pistol, or the fire of musketry, according to the rapidity and force of the pressure employed. A few centigrammes, struck with a hammer on an anvil, exploded with a noise like that of a musket, and torrents of purple light appeared round it. Thrown into concentrated sulphuric acid, it takes fire, and burns with a white flame, but without noise.

Six parts of the muriat, one of sulphur, and one of charcoal, detonate by the same means, but more strongly, and with a redder flame.

Equal parts of the muriat and antimony fulminate by the stroke, and produce only reddish sparks with the sulphuric acid.

A small proportion of zinc with the muriat fulminates by the stroke with a white flame, but is not affected by sulphuric acid.

Sulphuret of iron triturated with the muriat inflames rapidly without noise. Struck on the anvil it detonates strongly with a red flame.

The sulphurets of mercury with the muriat detonate by the stroke, but do not take fire with sulphuric acid.

Sugar, gum, or charcoal mixed with the muriat, and fixed or volatile oils, alcohol, or ether, made into a paste with it, detonate very strongly by the stroke, but not by trituration. Some of them take fire, but slowly and by degrees, in the sulphuric acid.

All these mixtures, that detonate by the stroke, explode much more loudly if previously wrapped up in double paper.—*Journ. de Phys.*—*Van Mons's Journ.*—*Phil. Trans.*—*Ann. de Chim.*

Fuming Liquor. The fuming liquors of Boyle and Libavius have been long known, and Cadet has lately added a third to the number. To prepare that of Boyle, which is a hidroguretted sulphuret of ammonia, three parts of lime fallen to powder in the air, one of muriat of ammonia, and one of flowers of sulphur, are to be mixed in a mortar, and distilled with a gentle heat. The yellow liquor, that first comes over, emits fetid fumes. It is followed by a deeper coloured fluid, that is not fuming.

The fuming liquor of Libavius is made by amalgamating tin with half its weight of mercury, triturating this amalgam with an equal weight of corrosive muriat of mercury, and distilling by a gentle heat. A colourless fluid at first passes over: after this a thick vapour is thrown out at one single jet with a sort of explosion, which condenses into a transparent liquor, that emits copious, white, heavy, acrid fumes on exposure to the air. In a closely stopped bottle no fumes from it are perceptible; but needle-shaped crystals form against the top of the bottle, so as frequently to close the aperture.

Cadet's fuming liquor is prepared by distilling equal parts of acetit of potash and arsenious acid, and receiving the product into glass bodies, kept cool by a mixture of ice and salt. The liquor produced emits a very dense, heavy, fetid, noxious vapour, and inflames spontaneously in the open air.

Furnace. See Laboratory.

Fusibility. That property by which bodies assume the fluid state. Such bodies as require a low heat for this purpose, are said to be more fusible than others which require a higher temperature to produce the same effect. Bodies vary greatly in their fusibility. No experiments have yet been made to indicate the cause of these differences. The hardness, softness, brittleness, flexibility, malleability, transparency, opacity, and, in a word, all the other obvious qualities, may, for any thing we know, be alike in two bodies, which will nevertheless differ greatly in the temperature of their fusions.—See Caloric, *Tab.* 5.

Some chemists have asserted, that fusion is simply a solution in caloric: but this opinion includes too many yet undecided questions to be hastily adopted. See Fluidity.

Fusion. The act of fusing. Also the state of a fused body.

Fustet. The wood of the *rhus cotinus*, or Venus's sumach, yields a fine orange colour, but not at all durable. It is used by the French dyers, but we believe not much in this country, with other colouring substances, particularly cochineal, to modify or heighten their effect, and in this way is more permanent. Like the French berries, its colour is soluble both in water and alcohol. Its decoction contains a small portion of gallic acid, but no gum; reduces gold; and precipitates the metallic salts.—*Berthollet.—Proust.*

Fustic, or Yellow Wood. This wood, the *morus tinctoria*, is a native of the West Indies. It affords much yellow colouring matter, which is very permanent.

A strong decoction of this wood is of a deep reddish yellow; which becomes orange on dilution. Acids render it turbid, throw down a small quantity of a greenish yellow precipitate, and leave the liquor of a pale yellow. Alkalis redissolve the precipitate, and give the liquor a deep reddish colour. Alum forms a small quantity of a yellow precipitate, and leaves the liquor transparent, but of a paler colour. Alum and tartar together produce a similar effect, but more slowly, and leave the liquor still paler. Muriat of soda heightens the colour without rendering it turbid. Sulphat of iron forms a precipitate, which grows gradually brown, and leaves the liquor brown and turbid. Sulphat of copper throws down a copious precipitate of a brownish yellow colour, and leaves the liquor slightly greenish. The precipitate with sulphat of zinc is of a greenish brown; the supernatant liquor of a reddish yellow.

The yellow given by fustic without any mordant is dull, and brownish, but stands well. The mordants employed with weld act on it in a similar manner, and by their means the colour is rendered more bright and fixed. The difference between them is, that the yellow of fustic inclines more to orange than that of weld; and, as it abounds more in colouring matter, a less quantity will suffice.

The colouring matter of fustic is soluble both in water and alcohol. The decoction contains a portion of tannin; reduces gold; and decomposes muriat of tin and the red sulphat, by means of which it dyes silk of a grayish yellow.—*Berthollet.—Proust.*

G.

GADOLINITE. By this name is distinguished the stone from Ytterby, in Sweden, in which Gadolin discovered the earth he called Yttria.

The Gadolinite is of a black colour, and its powder blackish gray. Its fracture is completely vitreous. Its specific gravity according to Hauy is 497·40. It strikes fire with steel, and is imperfectly crystallized like some kinds of garnets. It sensibly affects the magnetic needle. Exposed to the blowpipe it splits with a crackling noise into small fragments, which fly to a considerable distance in bright red sparks. What remains of the stone is of a grayish white, and does not fuse completely. It fuses with borax, and gives it a yellow colour inclining to violet. A hundred parts exposed to heat in a platina crucible assume an ochry red colour, and are reduced to 32; so that, deducting the oxigen absorbed by the iron it contains, the stone loses about 11 per cent.

It effervesces slightly with the powerful acids, and by the assistance of heat they reduce it to a thick jelly of a grayish or yellowish colour.

ccording to Vauquelin, 100 parts give ttria 35, silex 25·5, oxide of iron 25, e of manganese 2, lime 2. These leave s of 10·5, which was the smallest he in his different analyses.

ccording to Klaproth, of yttria 59·75, 21·25, black oxide of iron 17·50, alu- 0·50, water 0 50.—*An. de Chim.*—*Klap-* *Analysis*.

ALANGAL. The greater galangal is an Indian knotty root, with several cir- on the surface, of a reddish brown ur on the outside, and a yellowish white in, which greatly resembles ginger in nell, taste, and chemical composition; as ginger is the more grateful of the the galangal is scarcely ever used. It root of the *kæmpferia galanga*.

ie smaller galangal, which is knotty, marked with circular striæ like the , commonly about the size of the finger, and of a brown colour both nally and internally, is in smell stronger nore agreeable than the large, and in more pungent and hot, like pepper. is the root of the *maranta galanga*. It ins but a small proportion of oil: six- ounces afforded scarcely two scruples; gh, probably, if considerable quantities distilled at once, and the distilled water e operation employed instead of fresh r in the next, the produce upon the d would be greater. The oil is less able in smell than the galangal itself, wants its pungency, which of conse- ce remains in the extract. Very little e oil arises with alcohol: the spirit led even from a large quantity of the has scarcely any taste or smell. With d to the extracts, the water is rather pungent than the spirituous; but the r has nothing of the peculiar flavour galangal, the greater part of which ained in the latter. Sixteen ounces d with water six ounces, and after- with spirit four drachms and two les: spirit applied at first extracted an e and a half from sixteen, and water cted afterward five ounces.—*Neumann.*

LBANUM exudes from an umbelliferous , with leaves like those of anise, grow- the East Indies, but most plentifully ia and Arabia, called by Tournefort, elinum Africanum, galbaniferum, cens, anisi folio: the *bubon galbanum* his juice comes over in masses, com- of white, yellowish, brownish yel- and brown tears, unctuous to the , softening betwixt the fingers, of a sh, somewhat acrid, disagreeable taste, very strong smell, generally full of stalks, leaves, seeds, and other foreign rs.

banum contains more of a resinous gummy matter: one pound yields lcohol upward of nine ounces and a f resinous extract; but the gummy t obtained by water from the same quantity amounts only to about three ounces. The resin is hard, brittle, insipid, and inodorous: the gummy extract has somewhat of a nauseous relish, but could not be distinguished to be a preparation of galbanum. The whole smell, flavour and specific taste of this juice, reside in an essential oil, which arises in distillation both with water and spirit, and gives a strong impregnation to both: from a pound of galbanum are obtained, by distillation with water, six drachms of actual oil, besides what is retained by the water. In this respect galbanum agrees with asafœtida, and differs from ammoniacum.

The volatility of the active parts of this juice renders the common method of purifying it by solution, colature, and evaporation, very injurious to it. The smell of the galbanum is diffused, during the evaporation, over the whole house; and the inspissated matter, whatever menstruum was employed, is found to have lost the distinguishing qualities of the original juice. To prevent as much as possible this inconvenience, the solution should be made in a distilling vessel, and, after filtration, inspissated in the same, so long at least as the liquor which distils has any smell or taste; after which, the galbanum may be reduced to a due consistence by further evaporation in an open vessel, and the oil which arises in the distillation mixed with it. Galbanum may likewise be purified sufficiently for inferior purposes, as plasters, by exposing it in winter to a strong frost till it grows hard, and then pulverizing and sifting it. The woody, strawy, stony, and other foreign matters will be retained in the sieve.

Galbanum, distilled by a strong fire without addition, yields, like other resinous bodies, a large portion of empyreumatic oil, amounting to upward of eight ounces upon sixteen: it is remarkable of the oil of galbanum, that great part of it appears of a blue colour, sometimes of a deep bright blue, sometimes of only a violet blue. The matter on which the blueness depends appears to be either very volatile or very changeable: it soon escapes or changes in the air, leaving, instead of the blue, a purple colour.

GALENA, OR THE BLACK ORE OF LEAD. This, which is the commonest of all lead ores, and is frequently distinguished by the name of potter's lead ore, is of a dark bluish black colour, with a certain degree of metallic lustre. Its weight is about seven or eight times that of water; its figure usually symmetrical, being either cubical, or a variety of that figure; its texture lamellar, and its hardness variable. The component parts of galena are from fifteen to twenty-five sulphur, from sixty to eighty-five lead, and a variable quantity of silver, scarcely ever exceeding two parts in the hundred. Mineralogists assert, that the small grained galena contains the largest portion of silver; but it is not worth the extraction, if it do not contain one pound in three thousand weight. Quartz is accidentally mixed with galena; and it sometimes contains a very small portion of iron. The reduction of galena may be made by pulverization, torrefaction, and fusion, with three times its weight of black flux. The lead is obtained in a metallic button at the bottom of the crucible; and its weight, compared with that of the ore, shows its comparative richness.

The humid analysis of this ore is made by boiling the powder in diluted nitric acid, which takes up the metallic part, and leaves the sulphur, the stony matrix, and oxide of iron, undissolved. Digestion in muriatic acid will separate the iron from the residue; and caustic fixed alkali will dissolve the sulphur. The residuum, weighed before and after the application of the solvents, will show the proportion of each.

The nitric solution will contain the lead and silver: this solution may be precipitated by soda, and the precipitate washed in cold water, dried, and weighed. After weighing, it must again be digested in caustic volatile alkali, which will dissolve and take up only the oxide of silver: the residuum, being again dried and weighed, gives the proportion of the oxide of lead, of which 132 grains are equivalent to 100 in lead in its metallic state; and the difference between the weight of the precipitate, before and after the application of the volatile alkali, gives the quantity of the oxide of silver, of which 129 grains are equivalent to 100 of silver in its metallic form. See Lead.

Galena (Pseudo), an ore of zinc, known in the English mine countries by the name of black jack, or mock lead: its principal ingredients are about half its weight zinc, one third sulphur, with iron, lead, siliceous earth, water, and a small portion of arsenic.

Gall of Animals. This humor is separated in a large viscus of the lower belly, called the liver; it is afterward deposited in a bladder, or reservoir, called the gall-bladder, from which it is conveyed into the duodenum by a particular channel.

The bile is glutinous, or imperfectly fluid, like oil; of a very bitter taste; a green colour inclining to yellow; and froths by agitation, like the solution of soap.

If it be distilled on the water bath, it affords a phlegm, which is neither acid nor alkaline, but putrefies. This phlegm, according to the observation of Fourcroy, often emits a smell resembling that of musk: bile itself has the same property, according to the general observation of butchers. When the bile has given out all the water it is capable of affording upon the water-bath, the residue is a dry extract, which attracts the humidity of the air, is tenacious, pitchy, and soluble in water. By distillation in a retort, it affords ammonia, an empyreumatic oil, concrete alkali, and hidrogen gas. The coal is easily incinerated. It contains iron, muriat, phosphat, and sulphat of soda, phosphat of lime, and pure soda.

All the acids decompose bile, and disengage an oily substance, which rises to the top, and albumen.

Thenard found likewise in the bile an acrid saccharine substance, somewhat similar to certain kinds of liquorice juice. This substance is soluble in water and in alcohol, and slightly deliquescent. It is not precipitable by the common acetit of lead, but it is by the saturated acetit; and the precipitate is dissolved by the acetit of soda. It will not ferment with yeast; yields no ammonia by distillation; and is not affected by infusion of galls. Four parts of this substance combine with three of the oily matter of bile, if they be dissolved together in alcohol, evaporated, and the residuum be washed with water.

From 800 parts of ox gall Thenard obtained, water 700; oily matter 43; the peculiar substance described above 41; animal matter 4; soda 4; muriat of soda 3·2; sulphat of soda 0·8; phosphat of soda 2; phosphat of lime 1·2; oxide of iron 0·5.

The acids which act upon bile in the first passages decompose it. The greenish yellow colour of the excrements of infants at the breast, arises from a similar decomposition; and it is the resinous part which tinges them. From the action of the bile upon acids, we may deduce the effect of these remedies, when the evacuations are putrid, and the degeneration of the bile is septic. The lymph is then coagulated, and the excrements become harder. This shews the reason why the excrements of infants are so frequently clotted.

When the bile remains a long time in the first passages, as, for example, in chronical disorders, it assumes a black colour, becomes thick, acquires the consistence of an unguent, and forms a lining of several lines in thickness in the intestinal canal, according to the observation of Mr. de Fourcroy. When smeared on paper, and dried, it becomes green; diluted with water, it forms a tincture of a yellow green colour, from which a large quantity of black scales is precipitated: with alcohol it likewise forms a black tincture, and deposits that luminated brilliant salt discovered in biliary calculi by Mr. Poulletier de la Salle. This humour, which forms the atra bilis of the ancients, is nothing but the bile rendered thick; and in this case the effect of acids, and the danger of irritating substances, may be easily accounted for. This thickening of the bile clogs the viscera of the lower belly, and produces obstructions.

Many disorders are referable to the predominant character of the bile. On this subject, the interesting Memoirs of Mr. de Fourcroy may be consulted, in the collection of the Royal Society of Medicine for the years 1782 and 1783.

The use of the bile in the animal œconomy consists, no doubt, in dividing those substances which have undergone a first digestion in the stomach, and in giving efficacy and force to the motions of the intestines. When its flux is interrupted, it abounds in the blood, and the whole body becomes of a yellow tinge.

The bile or gall is an excellent vulnerary, externally applied: internally taken, it is a good stomachic, and one of the best deobstruents the art of medicine possesses. This kind of remedies deserves the preference, as being more analogous to the constitution; and bile is a proper medicine, when the digestion languishes, or the viscera of the lower belly are clogged.

Bile, like other soaps, removes spots of oil, or other greasy matter, from substances to which they are adherent.

Gall-stones. Calculous concretions are not unfrequently formed in the gall bladder, and sometimes occasion great pain in their passage through the ducts into the duodenum, before they are evacuated. Of these stones there are four different kinds.

1. The first has a white colour; and when broken, presents crystalline plates or striæ, brilliant and white like mica, and having a soft greasy feel. Sometimes its colour is yellow or greenish; and it has constantly a nucleus of inspissated bile. Its specific gravity is inferior to that of water: Gren found the specific gravity of one 0·803. When exposed to a heat considerably greater than that of boiling water, this crystallized calculus softens and melts, and crystallizes again when the temperature is lowered. It is altogether insoluble in water; but hot alcohol dissolves it with facility. Alcohol, of the temperature of 167°, dissolves $\frac{1}{20}$ of its weight of this substance; but alcohol, at the temperature of 60°, scarcely dissolves any of it. As the alcohol cools, the matter is deposited in brilliant plates resembling talc or boracic acid. It is soluble in oil of turpentine. When melted it has the appearance of oil, and exhales the smell of melted wax: when suddenly heated it evaporates altogether in a thick smoke. It is soluble in pure alkalis, and the solution has all the properties of a soap. Nitric acid also dissolves it; but it is precipitated unaltered by water.

This matter, which is evidently the same with the crystals Cadet obtained from bile, and which he considered as analogous to sugar of milk, has a strong resemblance to spermaceti. Like that substance, it is of an oily nature, and inflammable; but it differs from it in a variety of particulars. Since it is contained in bile, it is not difficult to see how it may crystallize in the gall-bladder if it happen to be more abundant than usual; and the consequence must be a gall-stone of this species. Fourcroy found a quantity of the same substance in the dried human liver.

2. The second species of biliary calculus is of a round or polygonal shape, often of a gray colour externally, and brown within. It is formed of concentric layers of a matter which seems to be inspissated bile; and there is usually a nucleus of the white crystalline matter at the centre. For the most part there are many of this species of calculus in the gall-bladder together: indeed it is frequently filled with them. The calculi belonging to this species are often light and friable, and of a brownish red colour. The gall-stones of oxen used by painters belong to this species.

3. The third species of calculi are most numerous of all. Their colour is often deep brown or green; and when broken, a number of crystals of the substance resembling spermaceti are observable mixed with inspissated bile. The calculi belonging to these three species are soluble in alkalis, in soap ley, in alcohol, and in oils.

4. Concerning the fourth species of gall-stone very little is known with accuracy. Dr. Saunders tells us, that he has met with some gall-stones insoluble both in alcohol and oil of turpentine; some of which do not flame, but become red, and consume to ashes like charcoal. Haller quotes several examples of similar calculi. Gall-stones often occur in the inferior animals, particularly in cows and hogs; but the biliary concretions of these animals have not hitherto been examined with much attention.

Soaps have been proposed as solvents for these calculi. The academy of Dijon has published the success of a mixture of essence of turpentine and ether. Fresh vegetables, which are such sovereign remedies in destroying these concretions, owe their virtue, perhaps, to the circumstance, that they develop an acid in the stomach, as we have observed in the treating of the gastric juice. —*An. de Chim.*—*Saunders on the Liver.*

Galls. These are the protuberances produced by the puncture of an insect on plants and trees of different kinds. Some of them are hard, and termed nut galls; others are soft and spongy, and called berry galls, or apple galls. The best are the nut galls of the oak, and those brought from Aleppo are preferred. These are not smooth on the surface, but tubercular, small, and heavy; and should have a blueish or blackish tinge.

Galls contain a great portion of soluble matter. Sixteen drachms by long boiling afforded Neumann fourteen of extract, and from the remainder only four grains could be extracted by alcohol. The same quantity gave twelve drachms two scruples of spirituous extract, and the residuum yielded four scruples more to water.

Deyeux investigated the properties of galls with considerable care; and more lately Mr. Davy has examined the same subject. The strongest infusion Mr. Davy could obtain at 56° F. by repeated affusion of distilled water on the best Aleppo galls broken into small pieces was of the specific gravity of 1·068. Four hundred grains of this infusion, evaporated at a heat below 200°, left 53 of solid matter, which consisted of about 0·9 tannin, and 0·1 gallic acid, united to a portion of extractive matter. One hundred grains of the solid matter left by incineration nearly 4½, which were chiefly calcareous matter, mixed with a small portion of fixed alkali.

From 500 grains of Aleppo galls Mr. Davy obtained by infusion as above 185 grains of solid matter, which on analysis appeared to consist of tannin 130; mucilage, and matter rendered insoluble by evaporation, 12; gallic acid, with a little extractive matter, 31; remainder, calcareous earth and saline matter, 12.

The fluid obtained by a last lixiviation of galls is pale green, and Mr. Davy conceives is chiefly a weak solution of gallat of lime; as acids turn it red, and alkalis restore its green colour, which is a property of all the soluble compounds of gallic acid and alkaline earths; and the ashes of galls, deprived of their soluble matter, afford a very considerable quantity of calcareous earth.—*Phil. Trans.*

The use of galls in dyeing is very extensive, and they are one of the principal ingredients in making ink. Powdered galls made into an ointment with hog's lard are a very efficacious application in piles. They are sometimes given internally as an astringent; and in the intermittents where the bark has failed. The tubercles, or knots, on the roots of young oaks, are said to possess the same properties as the nut galls, and to be produced in a similar manner.

For their acid see Acid (Gallic).

Galley. An oblong reverberatory furnace, in which a row of retorts is placed beside each other, with their necks protruding through lateral openings.

Gamboge is a concrete vegetable juice, the produce of two trees, both called by the Indians caracapulli (gambogia gutta Lin.), and is partly of a gummy and partly of a resinous nature. It is brought to us either in form of orbicular masses, or of cylindrical rolls of various sizes: and is of a dense, compact and firm texture, and of a beautiful yellow. It is chiefly brought to us from Cambaja, in the East Indies, called also Cambodja, and Cambogia; and thence it has obtained its name of cambadium, cambogium, gambogium.

It is a very rough and strong purge: it operates both by vomit and stool, and both ways with much violence, almost in the instant in which it is swallowed, but yet, as it is said, without griping. The dose is from two to four grains as a cathartic; from four to eight grains prove emetic and purgative. The roughness of its operation is diminished by giving it in a liquid form sufficiently diluted.

This gum resin is soluble both in water and in alcohol. Alkaline solutions possess a deep red colour, and pass the filter. Dr. Lewis informs us, that it gives a beautiful and durable citron yellow stain to marble, whether rubbed in substance on the hot stone, or applied, as dragon's blood sometimes is, in form of a spirituous tincture. When it is applied on cold marble, the stone is afterward to be heated to make the colour penetrate.

It is chiefly used as a pigment in water colours, but does not stand.

Gangue. The stones which fill the cavities that form the veins of metals are called the gangue or matrix of the ore; the rocks that lie over the veins are called the roof; those that lie under them the floor, and by some the hading: the matrix is almost always a finer species of stone than the surrounding rocks, though of the same genus; even the rocks themselves are finer grained as they approach the vein.

There is no matrix peculiarly appropriated to any metal; it has only been remarked, that tin is generally found among stones of the siliceous genus, and lead very frequently among those of the calcareous.

Garnet, a stone, which, when transparent and of a fine colour, is reckoned among gems. Its colour is blueish or yellowish red; its transparency often obscure, unless it be held to a strong light. The natural form of its crystals is various, and seldom regular. Its texture is granular. The specific gravity of the garnet, according to various authors, is from 3·6 to 4·4. Its hardness is nearly the same as that of the emerald, being less hard than the topaz, and more so than rock crystal.

A strong calcining heat does not deprive it of its colour. A very considerable heat is required to fuse it without addition, when it takes the form of a black slag, obedient to the magnet. Mineral alkali does not attack it so powerfully as borax or microcosmic salt.

According to the analysis of Achard, the garnet contains 48·3 of silex, 30 of alumine, 11·6 of lime, and 10 of iron. The opaque garnets scarcely give fire with steel, and afford about 20 per cent. of iron. Bergman informs us, that they contain tin, and even lead, though very rarely.

The garnet is a very common stone, frequently embodied in the masses of compound rocks. The Syrian garnet, which is of a fine red, inclining to purple, and very clear, though less brilliant than the oriental amethyst, is the most esteemed.

Gas. This term was first applied by Van Helmont, to denote the permanently elastic exhalations afforded in chemical processes. Dr. Priestley, whose extensive and successful researches into this department of natu-

ilosophy in the space of a few years
uced a revolution in the science of che-
y, used the word air as the generic
for permanently elastic fluids. Other
ical writers of gerat reputation have
ght fit to revive Van Helmont's term,
onfine the word air to the atmospheric
As this has been found convenient,
event confusion of ideas, it is now ge-
ly adopted; and we shall proceed to
an account here of these elastic fluids.

s (AMMONIACAL). This elastic fluid
first discovered by Dr. Priestley by
ng liquid ammonia, which is a solu-
of it in water, and receiving the gas
mercury. It readily occurred to him,
ver, that it might be procured more
ly by procuring it from the materials
which the liquid ammonia was obtain-
r muriat of ammonia and quicklime;

eadly properties, as it is met with in
erranean cavities, particularly the ce-
ted Grotto del Cano near Naples, oc-
ned it to be distinguished by the name
piritus lethalis. Van Helmont first gave
ame of *gas*, from a German word equi-
t to our spirit, to this vapour pro-
d from burning charcoal. He like-
called it spiritus sylvestris, and when
ng from fermented liquors spiritus vi-
s. From its existing in the inelastic
in water it was called fixed air, a name
h Black and others long retained;
y termed it mephitic air; from its great abundance in nature combined with lime in the form of chalk it has been named the cretaceous and the calcareous acid, subsequent to the discovery of its acid nature. But carbonic acid has superseded all those, since it appears to have been ascertained, that its radical is carbon. Of this, or rather of charcoal, according to the experiments of Lavoisier, it contains 28 parts by weight to 72 of oxigen. Guyton Morveau considers it as composed of 17·88 pure carbon, and 82·12 oxigen.

The basis of this gas has never been obtained separate in any other form; though it exists in the solid state in the various species of carbonats; and in the fluid in various waters. Water will absorb nearly its own bulk by agitation, and thrice its bulk by the assistance of compression, in the common temperature of the atmosphere; but it is easily expelled by heat. Heat likewise expels it from its solid combinations, as is done in making lime; but this is not so ready a way of obtaining it, as by means of another acid; for, as its affinity for the different bases is very weak, it is separated from them by any of the other acids, except the prussic; and this expels it from the metallic oxides.

Carbonic acid gas exceeds every other in specific gravity, except the sulphurous. Hence the vapour in the Grotto del Cano rises but a little above the surface; and the choak damp of miners, which is this gas, lies on the ground. Thus, too, when it is emitted from a fermenting liquor, it first fills the empty portion of the vat, displacing the lighter atmospheric air; and then flows over the sides, almost as water would do. For the same reason, if a bottle filled with it be inverted over the flame of a candle at some distance, it will descend, and extinguish it. According to the experiments of Mr. Cavendish, one part of this mixed with nine of atmospheric air renders it incapable of supporting combustion.

From the powerful attraction of carbon for oxigen, the base of this gas is not easily decomposed; but Mr. Tennant effected it by introducing phosphorus into a coated glass tube, closed at one end, and over this powdered marble. A very small aperture only being left in the other end of the tube, and a red heat applied for some minutes, phosphat of lime and charcoal were found in the tube. Dr. Pearson did the same with phosphorus and carbonat of soda.

The carbonic acid gas is likewise decomposed in part by hidrogen gas, assisted by electricity. In a glass tube eight lines in diameter De Saussure exposed a column of 4 inches in height of carbonic acid gas, and 8 inches of hidrogen gas, over mercury, to the action of the electric fluid circulating between iron conductors, for 12 hours. The gasses were at first condensed very rapidly, but by degrees more and more slowly, till in this period they were reduced to four inches. Of this, one inch was absorbed by potash, being carbonic acid gas; and the other three were nearly pure carbonic oxide, the hidrogen having formed water with the oxigen abstracted from the carbonic acid. The mercury and the conductors were but very little oxided. De Saussure had previously found, that carbonic acid and hidrogen gasses standing together over mercury for the space of a twelvemonth had decreased in volume.

Dr. Priestley had found, that carbonic acid gas, exposed to the action of the electric spark, was a little increased in bulk, and so far altered in its properties, that it was no longer entirely absorbable by lime-water, or alkalis. He likewise found the surface of the mercury oxided, as well as the iron conductors. Monge made the same experiment, and ascribed the effect to the decomposition of water contained in the gas. It appears, however, that it is owing to the absorption of a part of the oxigen by the metal, and the consequent conversion of a portion of the gas into carbonic oxide. —*Priestley.—Black.—Fourcroy.—Annal. de Chim.—Phil. Trans.—Journ. des Mines.*

Gas (Carbonic Oxide). This gas, which has been mentioned in the preceding article, was first made known by Mr. Cruickshank. Dr. Priestley had observed, that, when scales of iron mixed with charcoal, or with carbonat of barytes, were exposed to a strong heat, large quantities of a combustible gas were extricated, which he supposed to be heavy inflammable air, or carburetted hidrogen. He considered this as a strong argument against the modern theory of the formation of water; as, from the dryness of the ingredients, which were previously exposed to a red heat, and mixed and experimented upon immediately, and the quantity evolved, it could not be accounted for upon the supposition of the decomposition of water. This objection was successfully combated by Mr. Cruickshank showing that the air did not contain hidrogen, but was an oxide of carbon. It is equally procured from the oxides of other metals and charcoal; but in proportion to the facility with which these give up their oxigen, the carbon is more or less saturated with it; so that the product is a mixture of carbonic acid gas, and carbonic oxide, the proportion of the former decreasing as the process is continued.

The carbonic oxide gas, freed from carbonic acid by washing with limewater, is very little lighter than atmospheric air. It does not explode, when fired in atmospheric air, but burns with a blue lambent flame: with oxigen gas it detonates. It is noxious to animals. Water absorbs about a fifth only of its bulk. It is not absorbed by the pure alkalis, and does not precipitate limewater. If it be mixed with hidrogen gas, and passed through an ignited glass tube, its oxigen unites with the hidrogen to form water, and charcoal is deposited. De Saussure jun. however ascribes this appearance of carbonaceous matter lining the tube to the action of the hidrogen on the lead in the glass, as he produced it by hidrogen alone with a glass tube; and could not by hidrogen and carbonic oxide in a tube of porcelain.

The purest oxide of carbon is obtained by passing the carbonic acid gas through red-hot charcoal, which may be done very conveniently in the apparatus of Barruel, see Pl. III., fig. 2.; an apparatus well adapted to many processes of a similar kind.—*Nich. Journ. 4to.—Journ. de l'Ecole Polytech.—Journ. de Phys.—An. de Chim.*

Gas (Fluoric Acid). See Acid (Fluoric).

Gas (Hidrogen). As an aëriform fluid capable of taking fire, is set free in many chemical processes, it could not avoid being noticed, and from this property was commonly distinguished by the name of inflammable air; though very little more than this was known of it, till Mr. Cavendish examined it more minutely. Indeed all the inflammable compounds of hidrogen gas were confounded under this name. It was not till some time after, however, that this gentleman and Mr. Watt, unknown to each other, were led to form the opinion, that its union with oxigen constituted water, from the quantity of water deposited when it was burned in close vessels. Though this opinion was strongly contested at first, it at length prevailed, and hence this gas received its present name of hidrogen.

Hidrogen gas is generally obtained from the reverse of this process, the decomposition of water. Iron moistened with water becomes oxided, by decomposing the water; but this process is very slow. If the vapour of water be passed through a tube containing iron wire kept at a red heat, the decomposition will go on with much more celerity. But the readiest method is to employ an acid, as the sulphuric diluted with five or six times its weight of water, poured on iron filings or turnings, or on zinc in small pieces. Zinc affords it the purest, as that from iron is apt to be contaminated with carbon. Muriatic acid diluted with twice or thrice its weight of water may be employed, but it is less œconomical.

Hidrogen gas is the lightest of all ponderable substances, particularly if received over quicksilver, and freed from any humidity it may contain by exposure to any substance that attracts water strongly. When perfectly dry it is free from smell, but when it contains moisture it is slightly fetid. Though highly inflammable, it extinguishes burning bodies, if completely enveloped in it without the contact of oxigen. It is incapable of supporting life, but does not appear to possess any directly noxious quality, as it may be breathed for several respirations, or even near a minute. Fired in combination with oxigen it explodes very loudly: but if kindled as it escapes from the extremity of a capillary tube into the atmosphere, it burns calmly with a white flame, the colour of which however may be varied by different substances dissolved in the gas. It is thus the philosophical fireworks without smoke or smell are formed. If a tube of glass, metal, or any elastic material, be held over a jet of inflamed hidrogen gas, musical tones will be produced, varying in depth and strength according to the length, diameter, and material of the tube. A glass jar has a similar effect, but it must not be too wide, or so narrow as to extinguish the flame. Dr. Higgins first discovered this property.

A very high temperature is generally considered as necessary to produce the combination of hidrogen and oxigen. Biot compressed the two gasses together in the syringe of an airgun; they took fire, exploded violently, and burst the syringe: but here the temperature was sufficiently increased by the pressure. A gentleman of Orkney, however, introduced nearly equal quantities of the two gasses into a glass jar over mercury, which stood in a room without fire and with little light from the beginning of January to the end of May, when he found, that of 12 cubic inches 3½ had disappeared. The residuum was still a mixture of the two gasses.

Hidrogen gas did not appear to Dr. Priestley to be at all changed by having a growing plant confined in it for some months. Von Humboldt, however, observed some plants of the order cryptogamia growing in a mine, and consequently secluded from light, of as green a colour as they would have had growing in the open air; and hence he inferred, that the hidrogen gas there evolved had supplied the place of light.

Hidrogen combined with nitrogen forms ammonia.

The chief use of hidrogen gas is for the purpose of filling air ballons.—*Phil. Trans.*—*Journ. de Phys.*—*Nich. Journ.*—*An. de Chim.*

Gas (Hidrogen Arseniated). Scheele, dissolving tin in arsenic acid, observed the extrication of an inflammable gas, holding arsenic in solution. Proust afterward obtained it by digesting arsenious acid and zinc in diluted sulphuric acid. It may be procured likewise by treating arsenious acid, or arsenic, and iron filings, or arsenic and tin filings, with muriatic acid: but still better by treating four parts of granulated zinc, and one of arsenic, with sulphuric acid diluted with twice its weight of water.

This gas is insoluble in water; does not render limewater turbid; mixed with atmospheric air no diminution of bulk ensues, but the mixture when fixed detonates loudly, and deposits metallic arsenic; it has an alliaceous smell; it extinguishes burning bodies, and is fatal to animals; it is decomposed by oxigenated muriatic acid gas. If a lighted taper be immersed in a phial of this gas, it is instantly extinguished; but the gas burns at the mouth of the phial with a lambent white flame, which diffuses white fumes of arsenious acid. If it be inflamed in a phial with a small orifice, the flame gradually descends to the bottom of the phial, which becomes coated with crystallized metallic arsenic. Two parts of this gas with one of oxigen will explode loudly, and the products are water and arsenious acid: soap bubbles made with a mixture of these gasses explode with a blueish white flame. Equal parts of the gasses explode with a much more vivid flame, but less noise. A stream of this gas burned in a large receiver filled with oxigen emits a blue flame of uncommon splendour. According to Tromsdorff's calculation, a cubic inch of the gas contains about a quarter of a grain of arsenic. Its specific gravity is rather more than half that of atmospheric air.—*Mem. of the Acad. of Berlin.*

Gas (Hidrogen Carburetted). Previous to the year 1664 the rev. Dr. James Clayton, observing that gas issuing from fissures near a coalpit at Wigan took fire on the contact of a lighted candle, distilled some coal; and found, that first phlegm came over, then a black oil, and lastly an inflammable spirit. This he collected in bladders, and amused his friends by pricking a hole in them, and setting fire to the gas as it issued out. This is the first artificial production we know of a gas that sometimes occasions fatal explosions in coalmines, where it is termed *fire damp*.

There are several varieties of this gas, the hidrogen holding different proportions of carbon in solution, according to the process by which it is obtained.

The gas of stagnant water, which may be procured by stirring the mud at the bottom with a stick, and collecting the gas, as it rises in bubbles, in an inverted bottle, is this compound. The vapour of water passed through a tube containing ignited charcoal consists of this gas and carbonic acid, which may be separated by agitating the mixture with lime diffused in water. The vapour of ether, or of alcohol, passed through a red-hot tube of porcelain coated with clay, affords the same products. If three parts of concentrated sulphuric acid, and one of alcohol, be distilled in a glass retort with a gentle heat, a carburetted hidrogen comes over. This is distinguished by the name of olefiant gas, from its property of forming an oil on coming into contact with oxigenated muriatic acid gas. If five measures be mixed with six of the oxigenated muriatic gas, as rapid a diminution takes place as when nitrous and oxigen gasses are added to each other, and a thin film of oil forms on the surface of the water.

Mr. Henry examined these and some other varieties as well as pure hidrogen, with a particular view to the light they were capable of affording, and the following are his tabulated results.

Gas	Oxigen gas required to saturate 100 measures	Measures of carbonic acid produced
Pure hidrogen - - -	50 to 54	0
Gas from moist charcoal - -	60	35
—— —— oak - - -	54	33
—— —— dried peat - - -	68	43
—— —— coal - - -	170	100
—— —— lamp oil - - -	190	124
—— —— stagnant water - -	200	100
—— —— wax - - -	220	137
Pure olefiant gas - - -	284	179

The light evolved appeared to be in proportion to the oxigen consumed, so that the first four in the list yielded very little; but the last much exceeded all the rest. Its detonation with oxigen gas too is more violent than that of any other inflammable gas, ·03 of a cubic inch, with ·17 of oxigen gas, being sufficient to burst a strong glass tube.

About the year 1792 Mr. Murdoch made various experiments on the gas from coal, peat, and other substances, as a substitute for lamps and candles, both as fixed and as moveable lights; and in 1798 he applied it to the purpose of lighting the extensive manufactory at Soho. Light was procured by the same means several years ago at the ovens in Shropshire for preparing coak and tar on lord Dundonald's plan. And six or seven years ago a projector at Paris lighted-up his house and gardens, and proposed to light the streets of the city, in a similar way.

The varieties above enumerated differ in specific gravity, the olefiant gas being the heaviest, and that from charcoal the lightest. They differ likewise in the quantity absorbed by water, which takes up $\frac{1}{8}$ its bulk of olefiant gas, $\frac{1}{27}$ of that from stagnant pools, and still less of the others.

It was observed by Dr. Austin, that carburetted hidrogen gas may be dilated permanently to more than twice its bulk by passing the electric spark through it, and in this state it consumes more oxigen in combustion. As some nitrogen was always found after the combustion, he concluded, that he had thus decomposed carbon into hidrogen and nitrogen. Mr. Henry, who repeated the experiment, ascertained, that the expansion could not be carried beyond a certain point; that it was very trifling, if the gas were previously freed from water as much as possible; and that the admission of a drop or two of water enabled the expansion to take place as usual. Hence he inferred, that the increase was owing to an evolution of hidrogen by the decomposition of water retained in the gas: but as this would liberate a proportional quantity of oxigen, to combine with a part of the carbon, it does not appear to account for the additional portion of oxigen required to burn the expanded gas. *Phil. Trans.*—*Nich. Journ.*—*Henry.*

GAS (HIDROGEN PHOSPHURETTED). This may be procured by boiling in a retort a little phosphorus with a solution of pure potash. The phosphorus should be first melted under water in the retort, which is to be emptied when the phosphorus has congealed, and then filled with the alkaline solution. Of this a sufficient portion is to be displaced by hidrogen gas. Or one part of phosphorus, cut into very small pieces, and two of finely granulated zinc, may be put into ten parts of water, and six parts of concentrated sulphuric acid added: the gas is disengaged in small bubbles, which cover the whole surface of the fluid, and take fire on reaching the air, so as to form by their succession a well of fire.

If two parts of phosphuret of lime, broken into pieces the size of a pea, and one part of hyperoximuriat of potash, be put into an ale glass, or a Florence flask; the vessel be filled with water; and six or eight parts of concentrated sulphuric acid be poured in through a long-necked funnel reaching to the bottom; as soon as decomposition commences, flashes of fire will dart from the surface, and the bottom of the vessel will be illumined with a beautiful green light.

When phosphuretted hidrogen gas is suffered to escape into the air, as it issues from the retort, it takes fire, and a dense white smoke rises in the form of a horizontal ring, enlarging its diameter as it ascends. It detonates when mixed suddenly with oxigen, oxigenized muriatic acid, or nitrous oxide gas. By standing it loses its property of spontaneous accension, the phosphorus being deposited on the inner surface of the vessel containing it.

Phosphuretted hidrogen gas may be dissolved in about four times its bulk of distilled water, at 44° F.; and imparts to it a bitter taste, and strong unpleasant smell. This solution speedily converts the oxides of lead and mercury, and nitrat of silver into phosphurets of those metals. Nitrats of lead, mercury, and arsenic, and sulphats of copper and iron, are acted upon by it more or less slowly; but some of the phosphurets then formed are changed by standing some time into phosphats.

The ignis fatuus, or jack with a lantern, is supposed to be produced by this gas, arising from the putrefaction of animal substances in swampy places.—*Nich. Journ.*—*Ann. de Chim.*—*Henry.*

Gas (Hidrogen, sulphuretted). This gas, formerly termed *hepatic air*, may be obtained by adding dilute muriatic acid to a solution of sulphuret of potash, or of soda, which evolves it with violent effervescence; or by pouring diluted sulphuric or muriatic acid on sulphuret of iron. Sulphur and iron mixed together with a little water likewise afford it by distillation.

Sulphuretted hidrogen is particularly characterized by its offensive smell, resembling that of rotten eggs. Like the other compounds of hidrogen, it detonates if mixed with oxigen or atmospheric air, and then fired, and burns silently if inflamed as it comes into contact with them from a small aperture. If three parts of it be mingled with two of nitrous gas, the mixture burns with a yellowish green flame. Prof. Lichtenberg pouring ¼ of an ounce of nitrous acid at once into an 18 ounce bottle of sulphuretted hidrogen gas, a hissing noise took place, much red vapour was disengaged, and on his corking the bottle the mixture exploded with a loud report and a blue flame. Mr. Accum observes, that he could never succeed in this experiment with the gas procured by means of an earthy or alkaline sulphuret.

This gas is decomposed by oxymuriatic acid gas, by sulphurous acid gas, or by being kept mixed with atmospheric air, and its sulphur is precipitated. If passed through ignited charcoal it is converted into carburetted hidrogen gas. It precipitates all metallic solutions, except those of iron, nickel, cobalt, manganese, titanium, and molybdæna. It tarnishes silver, mercury, and other polished metals, and immediately blackens white paint.

This gas is absorbed by water, which at 55° takes up ·86 of its bulk, and at 85° only ·78. The solution exposed to the air becomes covered with a pellicle of sulphur; and deposits sulphur even in well corked bottles. A few drops of nitric or nitrous acid likewise precipitate the sulphur.

It is remarkable, that sulphuretted hidrogen, which contains no oxigen, consisting, according to Thenard, of 29 hidrogen and 71 sulphur, should possess the properties of an acid, reddening litmus paper, and uniting with the alkalis and all the earths, except alumine and zircon. These compounds are soluble, and most of them are susceptible of crystallization. They are at first colourless; but by exposure to the air become green, or greenish yellow, and deposit sulphur. At length, however, the solution again becomes colourless, and the base is found ultimately converted into a sulphat. Acids disengage their sulphuretted hidrogen gas. Vauquelin, having lixiviated a considerable quantity of soda manufactured in France, found after some weeks a white, transparent salt, crystallized in tetrahedral prisms, terminated by quadrangular or octangular pyramids. Its taste was acrid and intolerably bitter, and it had a slight hepatic smell. It did not precipitate any of the earthy salts, except those of alumine, zircon, and yttria. Some of the German chemists have classed it as an acid by the name of the *hydrothian*.

The waters called sulphureous, or hepatic, as those of Harrowgate, are solutions of this gas. They are recommended as alteratives in cutaneous affections; against worms; in gout and jaundice; and as deobstruents: but they are said to have been very injurious in dropsy.—*Gehlen's Journ. Nich. Journ.—Ann. de Chim.—Henry.*

Gas (Muriatic Acid). Muriatic acid exists in a separate state only in the form of gas, but its attraction for water is so strong, that it can be received and confined only over mercury. According to Kirwan, water absorbs rather more than 420 times its bulk, and is augmented by it about one third: in Dr. Thomson's experiments it took up 515 times its bulk at 60° F. It liquefies ice very rapidly, and the temperature is lowered. It has a pungent smell; is fatal to animals; and extinguishes flame, first imparting to it a greenish tinge. Its bulk is increased by a succession of electric shocks, which Mr. Henry has shown to arise from the decomposition of water, of which he infers from his experiments 60 grains hold 1·4 in solution. On its coming into contact with atmospheric air a white cloud is produced. Brisson gives its specific gravity, atmospheric air being 1000, at 1430, Henry at 1730, Kirwan at 1929. For its other properties, see Acid (Muriatic).

Gas (Muriatic Acid, Oxigenized). This gas, which is a compound of the preceding with oxigen, presents another anomaly in the theory of acidification. It was observed, that sulphuretted hidrogen resembled an acid in many of its properties, though it contained no oxigen; and we here find the radical of an acid, which with a certain proportion of oxigen ranks among the most powerful, so much weakened in its properties, as even to be denied by some a place among the acids.

This gas is not invisible, as it has a greenish yellow colour. It has a pungent, suffocating smell, and is very injurious to the lungs. It extinguishes burning bodies. A temperature of 40° F. reduces it to a liquid form. Mr. Northmore condensed nearly two pints in a receiver of the capacity of 2¼ inches, in which state it was a yellow fluid, so extremely volatile as to evaporate the instant the screw of the receiver was opened. A pint of this gas being injected upon half a pint of oxigen, the result was a thicker substance, that did not evaporate so soon, and left a yellowish mass behind. Nitrogen in the same proportion gave a still thicker substance, and of a deeper yellow. In both these experiments much of the grease of the machine was carried down. Into a receiver of 3 inches capacity a pint of carbonic acid gas was pumped, and then rather more than a pint of oxigenized muriatic acid gas: the result was of a sap green colour, but still elastic. Two pints of the gas with a pint of hidrogen was of a light yellow green, without any fluid, and highly destructive of colour.

This gas acts powerfully on various combustible bodies. If four parts of it and three of hidrogen be put into a bottle closely stopped, inverted with its mouth under water, and the stopple be taken out in this situation after they have thus stood twenty-four hours, nearly the whole of the gas will have disappeared, and the remainder will be absorbed by the water. The hidrogen may be combined at once with the oxigen of this gas by the electric spark, which causes them to detonate. Phosphorus takes fire spontaneously in oxigenized muriatic acid gas; so do perfectly dry powdered charcoal of beech wood, and almost all the metals in fine filings or very thin leaves. About a cubic inch of the gas is sufficient for a grain of metal; the bottom of the vessel should have a little sand on it, to prevent it from cracking; and the temperature should not be less than 70°. If a drachm of good ether be thrown into a three pint vessel filled with this gas, and the mouth covered with a piece of paper, a circulating white vapour will arise in a few seconds, which will soon be followed by an explosion with flame.

For the rest of its properties see Acid (Muriatic, oxigenized).—*Nich. Journ.*—*Henry.*

Gas (Nitric Acid). See Acid (Nitric).

Gas (Nitric oxide), or Nitrous Gas. We owe our first knowledge of this elastic fluid to Dr. Priesley, who called it nitrous air. It may be formed by passing ammoniacal gas through the black oxide of manganese heated red hot in an earthen tube; but it is most easily obtained by abstracting a portion of its oxigen from nitric acid. For this purpose fine copper wire, or copper filings, may be put into a retort with an equal weight of nitric acid diluted with four or five parts of water, and moderate heat applied; or diluted only with an equal quantity of water, and no heat employed. After the atmospheric air is expelled from the retort, the gas that comes over may be received in the pneumatic apparatus. Other metals might be employed for the same purpose, but mercury and copper appear to afford it in the greatest purity; and the latter is perhaps preferable, because the process goes on more regularly with it.

This gas is colourless, and somewhat heavier than atmospheric air. It is extremely deleterious, killing even insects very quickly, and destroying plants. Water deprived of air absorbs about $\frac{1}{9}$ of its bulk of this gas, without acquiring any taste from it; and a boiling heat expels it again unchanged. If the water contain air, the gas is partly decomposed, and the absorption, though in reality greater, is apparently less, from the nitrogen evolved. Water impregnated with earthy salts does not absorb so much. A solution of green sulphat or green muriat of iron however absorbs it rapidly, and becomes dark brown, and almost opake. When this is effected over mercury, the gas may be expelled unchanged by a moderate heat, or by placing the solution in a vacuum, though perhaps not the whole of it. Solutions of nitrat of iron, the sulphats of tin and of zinc, and muriat of zinc, likewise absorb it.

Nitrous gas has no acid properties. It does not redden vegetable colours, but impairs them. It extinguishes the flame of a candle, or burning sulphur, and the phosphoric light of animal substances: but lighted charcoal continues to burn in it; lighted phosphorus burns in it with great splendour, though if not previously kindled it may be melted or sublimed in it without taking fire; and Homberg's pyrophorus kindles in it spontaneously. Its most important property is its affinity for oxigen gas, on account of which it was employed by Dr. Priestley, as it still is by many, to ascertain the quantity contained in atmospheric air: See Eudiometer. When mixed with oxigen gas red fumes arise, heat is evolved, and the two gasses, if in due proportion and both pure, disappear, being converted into nitric acid.

This gas is soluble in nitric acid, and alters its properties in some measure, without however converting it into an acid in a distinct state of oxigenation as some had supposed.—*Davy.*—*Murray.*

Gas (Nitrous oxide). This is the *gaseous oxide of nitrogen* or of *azote* of some; a compound of nitrogen with a still less proportion of oxigen than the preceding gas. It is not to be obtained certainly with any purity, but by the decomposition of nitrat of ammonia. For this purpose nitric acid diluted with five or six parts of water may be saturated with carbonat of ammonia, and the solution be evaporated by a very gentle heat, adding occasionally a little of the carbonat, to supply what is carried off. The nitrat crystallizes in a fibrous mass, unless the evaporation has been carried so far as to leave it dry and compact. The latter at a heat between 275° and 300° sublimes without being decomposed: at 320° it becomes fluid, and is partly decomposed, partly sublimed: between 340° and 480° it is decomposed rapidly. The nitrous is not decomposed below 400°; but a heat above 450° decomposes it: at 600° a luminous appearance is produced in the retort, and nitric oxide, nitrous oxide, and nitrogen, mixed in variable proportions, are evolved: at 700° or 800° an explosion takes place. It is best to perform the operation over an Argand's lamp, as the heat may thus be brought to the requisite degree ily, and kept from going too far. It l be received over water, and suffered nd an hour in contact with it, to free m any nitrat of ammonia that may been sublimed, as well as from any acid nded in it. Dr. Pfaff recommends g very pure sand with the nitrat, to nt the hazard of explosion; and ob- s, that it is particularly requisite it d not be contaminated with muriatic One pound of the compact nitrat s 4·25 cubic feet of gas, and a pound e fibrous nearly five cubic feet.

his gas is heavier than the preceding, a faint smell, and is sweetish to the when respired. It dissolves in about e its bulk of water, to which it imparts ste, and from which heat expels it un- ged. Alcohol absorbs more of it than r; both the essential and fixed oils ab- still more; and heat expels it unaltered them all. It is not altered in its pro- es, or diminished in bulk, by mixture oxigen nitrogen, or hidrogen gas. the latter it detonates loudly, on the ication of a lighted candle, or the elec- spark. A candle burns in it with a ant flame and crackling noise, and the c inner flame is surrounded by a blue before it is extinguished. Phosphorus iously kindled burns in it with increas- plendour; but may be melted, or sub- d in it, or touched with a red hot wire, out taking fire: on the contact of a e at a white heat, however, it burns violence, or rather detonates. Sulphur ning with a blue flame is extinguished by but if immersed in it when in a state of ve inflammation burns vividly with a -coloured flame. Red hot charcoal s in it brilliantly: and iron wire s in it nearly as in oxigen gas, but not ong.

itrous oxide does not combine directly the alkalis. If, however, sulphit of sh, intimately mixed with a consider- e quantity of pure potash, be exposed r mercury to nitric oxide, the sulphur- acid attracts oxigen from the latter, so the sulphit is converted into a sulphat; at the same time the nitrous oxide, thus duced, combines in its nascent state with free potash. By solution, evaporation, crystallization, at a low temperature, sulphat of potash, which crystallizes first, be separated.

he nitroxid of potash, as Mr. Davy calls consists by his estimation of three parts li and one oxide. Its taste is caustic, h a peculiar pungency. It changes ve- able blues to green. Powdered charcoal gled with it, and fired, burnt with ht scintillations. Projected into zinc in on a slight inflammation was produced. phuric, nitric, or muriatic acid expelled n it nitrous oxide with a little carbonic d. Even the carbonic acid dislodges the ous oxide from its combination.

Nitroxid of soda may be formed by similar means.

The most singular property of this gas is its action on the animal system. Dr. Priestley had found, that it was fatal to animals confined in it. Mr. Davy first ventured to respire it, which he did to considerable extent. When breathed alone for a minute or two, and some have gone as far as four or five minutes, it generally produces a pleasant thrilling, particularly in the chest and extremities, frequently with an inclination to laugh, and sometimes an irresistible propensity to gesticulation and muscular exertion. The mind meanwhile is often totally abstracted from all surrounding objects. Sometimes its effects are not entirely dissipated for some hours; and it is remarkable, that, however strong they may have been, no sense of debility or languor is induced after they have subsided. On a few individuals, however, its effects have been unpleasant and depressing; in some it has produced convulsions and other nervous symptoms; and on some it has had no sensible effect. Indeed not only different persons, but the same individual, will be variously affected by it, perhaps, at different times. Similar effects have been produced on those who have tried it abroad.

In debility arising from residence in a hot climate and intense application to business, this gas has proved a complete remedy. It has given voluntary power over palsied parts while inhaled, and the subsequent application of other remedies has effected a cure. Dr. Pfaff has suggested its use in melancholia: but in some cases of this disease it has done no good, and in one harm. —*Davy.—Murray.—Henry.—Nich. Journal.—Ann. de Chim.*

Gas (Nitrogen, or azotic). Under the article air it has been observed, that about three fourths of our atmosphere consist of gas unfit to maintain combustion, or support life. This gas was obtained separate by various processes, in which the other part of atmospheric air, the oxigen, was abstracted from it by entering into combination with some substance for which it had considerable affinity. In all these processes, however, the old theory ascribed the change effected to the evolution of phlogiston from the substance by which the oxigen was in fact absorbed; and hence it was termed by Dr. Priestley *phlogisticated air*, a name for some time commonly adopted. When the existence of phlogiston was shown to be very questionable, this term, involving the assertion of that hypothesis, was rejected by many, who proposed that of *azotic gas*, as not liable to the same objection. But this term, implying its unfitness for sustaining life; a quality by no means distinctive, as it is common to the greater number of the gasses, and possessed by several in a much stronger degree; though it long maintained its ground, is now giving way to the more appropriate appellation of *nitrogen gas*. Chaptal proposed this name, from its constituting with oxigen nitric acid, a fact first ascertained by Mr. Cavendish.

Wiegleb, Goettling, and Crell, indeed, have maintained, that nitrogen gas is compounded of water and caloric. They founded the assertion on an experiment first made by Priestley, in which, when the vapour of water was passed through ignited earthen tubes, nitrogen was produced. Dr. Priestley himself, however, soon discovered, that the nitrogen came from the surrounding atmosphere, to which earthen tubes thus heated are permeable. Girtanner modified this hypothesis by asserting, that nitrogen is compounded of hidrogen and oxigen with less oxigen than forms water: but Berthollet and la Grange have shown, that his experiments were erroneous.

Nitrogen gas is a little lighter than atmospheric air. It is incapable of supporting life, or combustion, yet a small portion is absorbed in respiration. It is not inflammable: though it unites with oxigen in different proportions, forming nitrous oxide when the oxigen is only ·37, nitric oxide when it is ·56, and nitric acid when ·705. It is one of the most general elements of animal substances. With hidrogen it forms ammonia; and Fourcroy suggested, that it might possibly be the alkaligenating principle, though he confesses there are no facts in support of this conjecture: the name of *alkaligen*, therefore, which has been proposed for it, is certainly inadmissible. It dissolves small portions of phosphorus, sulphur, and carbon. According to Mr. Gimbernat, the waters at Aix la Chapelle contain sulphuretted nitrogen.

Gas (Olefiant). See Gas (Hidrogen, carburetted).

Gas (Oxigen). This gas was obtained by Dr. Priestley in 1774 from red oxide of mercury exposed to a burning lens, who observed its distinguishing properties of rendering combustion more vivid and eminently supporting life. Scheele obtained it in different modes in 1775; and in the same year Lavoisier, who had begun, as he says, to suspect the absorption of atmospheric air, or of a portion of it, in the calcination of metals, expelled it from the red oxide of mercury heated in a retort. Priestley, agreeably to his theory, called it *dephlogisticated air*; Scheele, from its peculiar property, *fire air*, a name before given it by Mayow, or *empyreal air*; Lavoisier, air eminently pure, and afterward eminently respirable, which Condorcet altered to *vital air*; a term to which perhaps there is no objection, but its intractability when wanted in compound names. Bergman's term, pure air, as well as Lavoisier's eminently pure, is not distinctive. When the French chemists commenced their complete system of reform of the chemical nomenclature, finding the bases of this gas present in every compound that possessed acid properties, and considering it as the acidifying principle, they gave it the name of *oxigen*, which it still retains, notwithstanding some anomalies with regard to this quality have since been observed. See Gas (Hidrogen, sulphuretted, and Muriatic Acid, oxigenized).

Oxigen gas forms about a fourth of our atmosphere, and its base is very abundant in nature. Water contains ·85 of it: and it exists in most vegetable and animal products, acids, salts, and oxides.

This gas may be obtained from nitrat of potash, exposed to a red heat in a coated glass or earthen retort, or in a gun barrel; from a pound of which about 1200 cubic inches may be obtained; but this is liable, particularly toward the end of the process, to a mixture of nitrogen. It may be expelled, as already observed, from the red oxide of mercury, or that of lead; and still better from the black oxide of manganese, heated red hot in a gun barrel, or exposed to a gentler heat in a retort with half its weight, or somewhat more, of strong sulphuric acid. To obtain it of the greatest purity, however, the hyperoxymuriat of potash is preferable to any other substance, rejecting the portions that first come over as being debased with the atmospheric air in the retort. Growing vegetables, exposed to the solar light, gave out oxigen gas; so do leaves laid on water in similar situations, the green matter that forms in water, and some other substances.

Oxigen gas has neither smell nor taste. It is a little heavier than atmospheric air. Under great pressure water may be made to take up about half its bulk. It is essential to the support of life: an animal will live in it a considerable time longer than in atmospheric air; but its respiration becomes hurried and laborious before the whole is consumed, and it dies, though a fresh animal of the same kind can still sustain life for a certain time in the residuary air.

Combustion is powerfully supported by oxigen gas. Any inflammable substance, previously kindled, and introduced into it, burns rapidly and vividly. If an iron or copper wire be introduced into a bottle of oxigen gas, with a bit of lighted touchwood or charcoal at the end, it will burn with a bright light, and throw out a number of sparks. The bottom of the bottle should be covered with sand, that these sparks may not crack it. Mr. Accum says, a thick piece of iron or steel, as a file, if made very sharp at the point where it is first kindled, will burn in this gas. If the wire, coiled up in a spiral like a corkscrew, as it usually is in this experiment, be moved with a jerk the instant a melted globule is about to fall, so as to throw it against the side of the glass, it will melt its way through in an instant, or, if the jerk be less violent, lodge itself in the substance of the glass. If it be performed in a bell glass, set in a plate filled with water, the globules will frequently fuse the vitreous glazing of the plate, and unite with it so as not to be separable without detaching the glaze, though it has passed through perhaps two inches of water.

Mr. Varley has made numerous experiments on the combustion of gems, on the suggestion of Mr. Francillon, who furnished them, on ignited charcoal before the blowpipe supplied with a stream of oxigen gas. A rose diamond, weighing $\frac{15}{64}$ths of a carat, was reduced in one minute 50 seconds to $\frac{4}{64}$ths. It had lost its transparency, figure, and polish; but no appearance of soot on its surface had been observed. The remaining fragment continued to draw colour as before.

Another, weighing $\frac{17}{64}$ths, was reduced in 1′ 53″ to $\frac{15}{64}$ths; at which time, falling from the charcoal, it was seen to emit a flame of a blueish pearl colour as it passed through the air. The remaining fragment had lost its figure and polish, and was studded all over with matter of a somewhat metallic brilliancy, appearing to the magnifier like plumbago.

An amethyst, weighing $\frac{17}{16}$ths of a carat, in 40″ broke into several pieces. Some of these at the expiration of 1′ 55″ were taken from the charcoal and weighed, and being exposed to the blowpipe again for 1′ 15″ were fused into one mass, which broke to pieces on cooling. The colour was gone. Another, weighing half a carat, was fused in 5′ into a globule full of bubbles and cracks, like glass thrown hot into water. A portion on one side resembled white enamel; the rest was colourless and transparent as glass.

A sapphire, weighing $\frac{11}{64}$ths of a carat, in 2′ 53″ had its angles rounded off, and lost its transparency, but nothing of its weight. It was a semitransparent whitish mass, with some traces of its original colour; partly covered and interspersed with brown scoriæ very like bronze. Seven sapphires, weighing together $\frac{48}{64}$ths of a carat, in 9′ 55″ were agglutinated together. The remainder of the stones appeared through the semitransparent whitish coat to retain somewhat of their colour. The mass was as hard, and took as good a polish, as the original stones; nor had they lost any weight.

Oriental topazes lost their colour, and became nearly opake, and of a dirtyish white colour. One lost nearly a tenth of its weight. Some pieces, that were agglutinated together in 4′ 26″, and melted into a globule in 4′ 30″ more, appeared a little heavier than before. A Brazilian topaz was perfectly fused in 3′ 26″, lost $\frac{1}{32}$ths of its weight, and was rendered white and opake.

Oriental rubies were sometimes agglutinated together, and in one instance fused into a mass. They were exposed from 6′ to 9′. What was completely fused remained of a dirty white; the stones, or parts, not fused, recovered their colour on cooling. They lost nothing in weight or hardness. A spinel ruby in 2′ 3″ assumed the appearance of a rough garnet.

A jargon, weighing $\frac{14}{64}$ths, in 2′ assumed the appearance of white enamel, without loss of weight.

Vermilions were fused in 2′ or 2′ 30″ into polished opake globules, almost black, like very dark bottle glass.

A garnet in 1′ 40″ broke into two pieces, both of which became fused. One piece was nearly black, like the vermilions; the other of a dark lead, or brown colour, and chatoyant.

An emerald in 2′ was fused into an opake white globule.

A chrysolite was fused in 2′ into a rough, opake, greenish black globule.

A jacynth was fused in 1′ 14″ into a globule resembling dark bottle glass.

An opal in 44″ was melted into a polished globule of a greenish white, almost transparent, but full of bubbles.

Crystal in 1′ 44″ melted into a transparent globule, but full of cracks and bubbles. Two pieces melted together in 5′ 19″, but on cooling flew to pieces, and partly to powder, resembling a pure white salt.

Sixteen carats of crude platina in grains were perfectly fused in a few seconds, and the globules were perfectly pure and malleable; the iron being completely oxided, and scaling from the surface when struck. In consequence of this result, the experiment of fusing platina with a blast of oxigen gas in the large way was tried, but without success: as the heat is too great to allow the process to be continued long enough to oxidate and separate all the iron. Possibly a mixture of oxigen gas and atmospheric air might answer better.

An attempt to measure the heat excited was made, but Wedgwood's pyrometer pieces were completely fused by the blast in a few seconds.

As oxigen gas appears to be a very powerful stimulus to the animal œconomy, it has been applied medicinally; and is said to have been of great service in many cases of debility, palsy, nervous affection, scrofula, rickets, and even hydrocephalus. In some cases we have witnessed its good effects, and we have heard of astonishing instances of its powers.—*Phil. Trans.*—*Journ. de Phys.*—*Annales de Chimie.*—*Nich. Journal.*—*Philos. Mag.*—*Priestley.*—*Murray.*—*Beddoes.*

GAS (SULPHUROUS ACID). When sulphur is burnt slowly a gas arises, of a suffocating pungent smell, consisting of sulphur combined with oxigen in less proportion than is requisite to form sulphuric acid. This was known to the earlier modern chemists, and Stahl examined some of its combinations. Priestley showed it was permanently elastic; Berthollet pointed out its difference from the sulphuric acid, and Fourcroy and Vauquelin completed its examination.

In the mode above mentioned it is very difficult so to regulate the combustion, as to obtain it free from sulphuric acid, which is formed when the sulphur burns with a certain degree of rapidity: so that it is commonly made by abstracting oxigen from sulphuric acid, by some other inflammable substance. The metals answer the purpose, but such as do not decompose water should be employed, otherwise more or less hidrogen will be evolved. Tin or quicksilver answers best; one part of which may be put into a retort with two of concentrated sulphuric acid, and heat applied. It should be received over mercury, as water absorbs it, taking up 33 times its bulk.

This gas is above twice as heavy as atmospheric air: it kills animals very speedily, and extinguishes burning bodies. From this latter property it has been recommended, when a chimney is on fire, to throw a spoonful or two of flowers of sulphur into the grate. It whitens and gives lustre to silk, and is useful in bleaching woollens. Fresh prepared muriat of tin decomposes it, sulphur being deposited, and the muriat oxigenized. Mr. Northmore has condensed it by pressure: and Monge did the same, with the addition of artificial cold. According to Dr. Thomson, it consists of sulphur 68 parts, oxigen 32. For its other properties and compounds, see Acid (Sulphurous).—*Annales de Chimie.*—*Nich. Journ.*—*Murray.*

TABLE *showing the absolute Weights and Specific Gravities of Gasses, and the Quantity of each absorbed by Water.*

Temperature 60° Fahr., Barometer 29·8.

Gastric Juice. That humour, which is known by the name of the gastric juice, is separated by glands placed between the membranes which line the stomach; and from these it is emitted into the stomach itself.

In order to obtain the gastric juice in a state of purity, the animals intended to furnish it are kept fasting for two days, after which the stomach is extracted. In this manner Spallanzani obtained thirty-seven ounces of this juice out of the first and second stomach of a sheep. The same naturalist caused animals to swallow thin tubes of metal, pierced with several holes, into which he had put small sponges, very clean and dry. He caused crows to swallow eight at a time, which were vomited up at the end of three hours and a half. The juice which he obtained was yellow, transparent, salt, bitter, and leaving very little sediment, when the bird was fasting. The gastric juice may likewise be procured by the vomiting which is excited by irritation during fasting. Scopoli has observed, that the most fluid part is only thrown up by irritation; and that the thicker part does not quit the stomach, but by the assistance of an emetic. Mr. Gosse, who had long accustomed himself to swallow the air, which answered the purpose of an emetic with him, availed himself of this habit to make some experiments with the gastric juice. He suspends his respiration, receives air into his mouth, and pushes it towards the pharinx with his tongue. This air, rarefied in his stomach, produces a convulsive motion, which clears it of its contents. Spallanzani has observed, that eagles spontaneously emit a considerable quantity of gastric juice, when fasting in the morning.

We are indebted to Reaumur, and the abbé Spallanzani, for very interesting experiments respecting the virtue and effects of the gastric juice in digestion They caused animals to swallow tubes of metal, perforated in various places, and filled with aliments, to examine their effects. The philosopher of Pavia used purses of thread, and bags of linen and woollen. He himself swallowed small purses filled with flesh boiled or raw, with bread masticated, and also in its original state, &c.; and likewise small cylinders of wood, five lines in length, and three in diameter, pierced with holes, and covered with cloth.

Mr. Gosse, availing himself of the facility with which he was able to vomit by means of the air, has taken all kinds of food, and examined the changes they had undergone, by returning them after intervals more or less remote from the time of deglutition.

From these various experiments it follows:

1. That the gastric juice reduces the aliments into a uniform magma, even out of the body, and in vitro; and that it acts in the same manner on the stomach after death: which proves that its effect is chemical, and almost independent of vitality. 2. That the gastric juice effects the solution of the aliments included in tubes of metal, and consequently defended from any trituration. 3. That though there is no trituration in membranous stomachs, this action powerfully assists the effect of the digestive juices in animals with a muscular stomach, such as ducks, geese, pigeons, &c. Some of these animals, bred up with sufficient care that they might not swallow stones, have nevertheless broken spheres and tubes of metal, blunted lancets, and rounded pieces of glass, which were introduced into their stomachs. Spallanzani has ascertained, that flesh, included in spheres sufficiently strong to resist the muscular action, was completely digested. 4. That gastric juice acts by its solvent power, and not as a ferment; because the ordinary and natural digestion is attended with no disengagement of air, or inflation, or heat, or, in a word, with any other of the phænomena of fermentation.

Scopoli observes very well, that nothing positive or certain can be asserted respecting the nature of the gastric juice. It is sometimes acid, and sometimes insipid. Brugnatelli has found in the gastric juice of carnivorous birds, and some others, a disengaged acid, a resin and animal substance, united with a small quantity of common salt. The gastric juice of ruminating animals contains ammonia, an extractive animal substance, and common salt. In our time the phosphoric salts have been found disengaged in the gastric juice.

It appears from the observations of Spallanzani and Gosse, that the nature of the gastric juice varies according to that of the aliments. This juice is constantly acid when the diet is vegetable. Spallanzani affirms, contrary to Brugnatelli and Carminati, that birds of prey have never afforded him an acid juice; and he affirms the same of serpents, frogs, fishes, &c.

In order to show clearly, that there is a great difference between the gastric juices of various animals, it is sufficient to observe, that the gastric juice of the kite, the falcon, &c., does not dissolve bread, though it digests flesh meat; and that the gastric juice of the turkey, the duck, &c., has no action upon flesh, but converts the hardest grain into a pulp.

Jurine, Toggia, and Carminati, have made the most successful applications of the gastric juice in the treatment of wounds.

Geanthrax. See Peat.

Gelatine, Gelly, or Jelly, an animal substance, soluble in water, but not in alcohol, capable of assuming a well-known elastic or tremulous consistence by cooling when the water is not too abundant, and liquefiable again by increasing its temperature. This last property remarkably distinguishes it from albumen, which becomes consistent by heat. It is precipitated in an insoluble form by tannin, and it is this action of tannin on gelatine that is the foundation of the art of tanning leather.

Jellies are very common in our kitchens; they may be extracted from all the parts of animals, by boiling them in water. Hot water dissolves a large quantity of this substance. Acids likewise dissolve them, as do likewise more particularly the alkalis. Jelly which has been extracted without long decoction, possesses most of the characters of vegetable mucilage; but it is seldom obtained without a mixture of albumen.

Jellies in a pure state have scarcely any smell or remarkable taste. By distillation they afford an insipid and inodorous phlegm, which easily putrefies. A stronger heat causes them to swell up, become black, and emit a fœtid odour, accompanied with white acrid fumes. An impure volatile alkali, together with empyreumatic oil, then passes over, leaving a spongy coal, not easily burned, and containing common salt and phosphat of lime.

The jelly of various animal substances is prepared for the use of sea-faring persons, under the name of portable soup. The whole art of performing this operation consists in boiling the meat, and taking the scum off, as usual, until the soup possesses the requisite flavour. It is then suffered to cool, in order that the fat may be separated. In the next place, it is mixed with five or six whites of eggs, and slightly boiled. This operation serves to clarify the liquid, by the removal of opake particles, which unite with the white of egg at the time it becomes solid by the heat, and are consequently removed along with it. The liquor is then to be strained through flannel, and evaporated on the water bath to the consistence of a very thick paste; after which it is spread rather thin upon a smooth stone, then cut into cakes, and, lastly, dried in a stove until it becomes brittle. These cakes may be kept four or five years, if defended from moisture. When intended to be used, nothing more is required to be done than to dissolve a sufficient quantity in boiling water, which by that means becomes converted into soup. See Glue.

Gems. This word is used to denote such stones as are considered by mankind as precious. These are the diamond, the ruby, the sapphire, the topaz, the chrysolite, the beryl, the emerald, the hyacinth, the amethyst, the garnet, the tourmalin, the opal; and to these may be added, rock crystal, the finer flints or pebbles, the cat's eye, the oculus mundi, or hydrophanes, the chalcedony, the moon-stone, the onyx, the carnelian, the sardonyx, agates, and the Labrador-stone; for which, consult the several articles respectively.

Geodes. A kind of ætites, the hollow of which, instead of a nodule, contains only loose earth, and is commonly lined with crystals.

Gilding. The art of covering the surfaces of bodies with gold. Manufacturers use the term improperly to denote silvering as well as gilding, and likewise the various methods of producing a golden colour without actually using gold.

The real application of gold as a covering may be performed, either by a metallic mixture after the manner of a pigment; or by friction, upon the same principle as black lead and coloured chalks are used; or by the chemical precipitation of gold from mercury, or some other fit solvent; or, lastly, by glueing or fastening extremely thin leaves of gold to the surface intended to be gilded.

The gold prepared for painting is called shell-gold or gold-powder, and may be obtained by amalgamating one part of gold with eight of quicksilver, and afterward evaporating the latter, which leaves the gold in the form of powder; or otherwise the metal may be reduced to powder by mechanical trituration. For this purpose, gold-leaf must be ground with honey or strong gum-water for a long time; and when the powder is sufficiently fine, the honey or gum may be washed off with water.

For cold gilding by friction, a fine linen rag is steeped in a saturated solution of gold, till it has entirely imbibed the liquor; this rag is then dried over a fire, and afterward burned to tinder. Now, when any thing is to be gilded, it must be previously well burnished; a piece of cork is then to be dipped, first into a solution of salt in water, and afterward into the black powder; and the piece, after it is burnished, rubbed with it.

The chemical application of gold to the surface of metals is usually called water-gilding, a term probably at first confined to such processes as demand the use of a solution of gold in aqua regia. The solution of gold may be evaporated till it is of an oily consistence, suffered to crystallize, and the crystals dissolved in water be employed instead of the acid solution. If the solution of gold in aqua regia be copiously diluted with alcohol, a piece of clean iron will be gilded by being steeped therein. Or add to the solution about three times its quantity of sulphuric ether, which will soon take up the nitro-muriat of gold, leaving the acid colourless at the bottom of the vessel, which must then be drawn off. Steel dipped into the ethereal solution for a moment, and instantly washed in clean water, will be completely and beautifully covered with gold. The surface of the steel must be well polished, and wiped very clean.

For the method called Grecian gilding, equal parts of sal ammoniac and corrosive mate are dissolved in nitric acid, and a ion of gold is made in this menstruum; this the solution is somewhat concen- d, and applied to the surface of silver, h becomes quite black; but, on being sed to a red heat, it assumes the ap- ance of gilding.

he method of gilding silver, brass, or er, by an amalgam, is as follows: Eight s of mercury, and one of gold, are in- orated together by heating them in a ible. As soon as the gold is perfectly lved, the mixture is poured into cold r, and is then ready for use.

fore the amalgam can be laid upon the ce of the metal, this last is brushed with dilute aqua fortis, in which it is vantage that some mercury may have dissolved. Some artists then wash the l in fair water, and scour it a little with and, previous to the application of the ; but others apply it to the metal while vet with the aqua fortis. But in either he amalgam must be laid on as uni- ly as possible, and spread very evenly a brass-wire brush, wetted from time ne with fair water. The piece is then pon a grate, over a charcoal fire, or in ll oven or furnace adapted to this pur- The heat drives off the mercury, and s the gold behind. Its defects are then and may be remedied by successive ications of more amalgam, and addi- l application of heat. The expert ar- however, make these additional appli- ns while the piece remains in the fur- though the practice is said to be highly us on account of the mercurial fumes. this it is rubbed with gilders' wax, may consist of four ounces of bees one ounce of verdigris, and one ounce phat of copper: then expose it to a eat, which burns off the wax; and the work is cleared with the scratch , and burnished, if necessary, with a ool. The use of the wax seems to merely in covering defects, by the on of a quantity of red oxide of cop- vhich is left behind after the burning.

gilding of iron by mere heat is per- d by cleaning and polishing its sur- nd then heating it till it has acquired colour. When this has been done, t layer of gold leaf is put on, slightly hed down, and exposed to a gentle t is usual to give three such layers, r at the most, each consisting of a leaf for common works, or two for rdinary ones. The heating is re- at each layer, and last of all the s burnished.

gilding of buttons is done in the fol- way: When the buttons, which are er, are made, they are dipped into itric acid to clean them, and then ed with a hard black stone. They n put into a nitric solution of mer- nd stirred about with a brush, till they are quite white. An amalgam of gold and mercury is then put into an earthen vessel with a small quantity of dilute nitric acid, and in this mixture the buttons are stirred, till the gold attaches to their surface. They are then heated over the fire, till the mercury begins to run, when they are thrown into a large cap made of coarse wool and goat's hair, and in this they are stirred about with a brush. The mercury is then volatilized by heating over the fire in a pan, to the loss of the article, and injury of the workmen's health; though the greater part might be recovered, with less injury to the operators. By act of parliament a gross of buttons, of an inch diameter, are required to have five grains of gold on them; but many are deficient even of this small quantity.

The gilt trinkets that are now common in the shops, are said to be made of copper coated with brass in the following manner: An amalgam of one part zinc and twelve mercury is put into muriatic acid with some argal. In this the copper, previously cleaned with nitric acid is boiled. If a little gold be added to the amalgam, the effect is improved; but this is not always done. Copper thus coated may be drawn out to the fineness of a hair.

Painting with gold upon porcelain or glass is done with the powder of gold, which remains behind after distilling the aqua regia from a solution of that metal. It is laid on with borax and gum-water, burned in, and polished. The gilding of glass is commonly effected by covering the part with a solution of borax, and applying gold leaf upon it, which is afterward fixed by burning.

The gilders of wood, and other compositions designed to supply the place of carved work, make use of two methods: the one called oil-gilding, or gilding in oil, because the gold is made to adhere by means of an oily composition; the other is sometimes called water-gilding, though seldom, but more frequently burnished gold, on account of the burnish it is capable of, which is one of the principal advantages it possesses over the other method.

Gilding in oil is performed by means of a paint sold under the name of gold size. It consists of drying oil (that is to say, linseed oil boiled upon litharge), and mixed with yellow ochre. It is said to improve in its quality by keeping. This is laid upon the work; and when it has become so dry as to adhere to the fingers without soiling them, the gold leaf is laid on, and pressed down with cotton. This method of gilding is proper for work intended to be exposed to the weather.

The method of gilding in burnished gold consists in covering the work with parchment size and whiting, thinly laid on at five or six different times. This is covered with a yellow size made of Armenian bole, a little wax, and some parchment size; but in this, as in most other compositions used in the arts, there are variations which depend on the skill or the caprice of the artists. When the size is dry, the gold is applied upon the surface previously wetted with clear water. A certain number of hours after this application, but previous to the perfect hardening of the composition, the gold may be very highly burnished with a tool of agate made for this purpose. This gilding is fit only for work within doors; for it readily comes off upon being wetted.

The edges of the leaves of books are gilded by applying a composition of one part Armenian bole, and one quarter of a part of sugarcandy, ground together with white of eggs. This is burnished while the book remains in the press, and the gold is laid on by means of a little water.

Leather is gilded either with leaf-brass or silver, but most commonly by the latter, in which case a gold coloured varnish is laid over the metal. Tin-foil may be used instead of silver-leaf for this less perfect gilding, upon such works as do not possess flexibility.

Ginger, is the produce both of the East and the West Indies. Two sorts of this root are brought to us, one internally white, the other brown: whether they are the roots of different species of the ginger plant, or of one species taken up at different ages, or in different seasons, is not certainly known. This pungent aromatic is of common use as a spice, and is observed not to heat the constitution near so much as might be expected from its strong biting taste. Its pungency resides not in its volatile but in its fixed parts: the essential oil contains the smell and distinguishing flavour of the ginger, but all the pungency is left behind in the still.

From sixteen ounces of the common brown ginger may be obtained a drachm or a little more of oil. The same quantity yielded, with alcohol, an ounce and two scruples of resinous extract, containing all the hot biting matter of the root: from the residuum, water extracted a strong mucilage, which had little or no taste, was difficultly reduced to dryness, and weighed, when exsiccated, five drachms and a half. Sixteen ounces, treated first with water, gave four ounces of extract, considerably pungent, a portion of the resinous matter being taken up by the water along with the gummy: from the residuum, alcohol extracted five scruples four grains of a very pungent resin. The indissoluble earthy matter amounts to near three fourths of the root, viz. eleven ounces six drachms and sixteen grains. Alcohol elevates in distillation some of the more subtile parts of the oil, so as to taste a little of the ginger, though not considerably.

The white ginger contains more soluble matter than the brown. From sixteen ounces of this sort were gained five ounces five drachms and a scruple of watery, and afterwards three drachms twelve grains of spirituous extract. Spirit applied at first, extracted one ounce and three drachms wanting a few grains; and water applied afterward, took up four ounces and a half: so that the indissoluble part does not amount quite to ten ounces on sixteen. The quantity of essential oil is nearly the same as in the brown sort.—*Neumann.*

Ginseng. Panax quinquefolium, Lin. A small root brought from North America, and sometimes from China; an inch or two in length, taper, finely striated, of a whitish or yellowish colour. It has a very sweet taste, accompanied with a slight bitterishness and warmth.

The Chinese are said to have a very extraordinary opinion of the virtues of this root, and to look upon it as a universal restorative in all decays, from age, intemperance or disease. The great value there set upon it has prevented its being exported thence into other countries, and its discovery in North America is but of late date; so that among us it has hitherto been very rarely made use of, although, from what can be judged of it from the taste, it seems to deserve some regard, especially as it is now procurable in plenty.

The American ginseng appears opake and white when broken; and though it produces a good price in the Chinese market, yet it is vastly less valuable than the ginseng of Chinese growth, which is nearly as transparent as horn. This property seems to have been produced by art, perhaps by long continued and gentle boiling in water.

Girasole, a name given by the Italians to the opal, which is of the flint kind, and remarkable for the mutability of its colours, according to the various directions of the light which falls on it, and the position of the eye of the observer.

Gizzard. The gizzards of poultry with white flesh have long been considered in France as medicinal. They have been recommended in obstructions of the urinary passages, complaints of the bladder, and nephritic pains; but particularly as a febrifuge. The gizzards are to be opened, cleaned from their contents, slightly washed, and strung up in the sun, or in a chimney, to dry; or between sheets of paper exposed to a gentle heat. They are then to be powdered, sifted, and kept in a bottle closely corked. The dose for adults is a drachm. This is given in intermittents, about half an hour before the fit is expected, in half a glass, or a glass, of good old white wine.

According to Bouillon Lagrange the dried gizzard contained a little acid phosphat of lime, with still less sulphat, muriat, and carbonat of potash, and carbonat of lime, and a small portion of iron. Its principal substance he considers as oxigenated

us combination with an earth; and this salt has not yet been afforded cheap enough to be used, except in assays by the blowpipe. The fluxes in glass-making are useful, not only because more fusible than the earthy matter, to which they communicate the same property, but likewise as solvents which combine with it in the dry way, and in some instances produce a compound possessing greater fusibility than belonged to any of the ingredients. See EARTH, under art. LIME.

Mr. Loysel, who was well acquainted with all the processes of the art adopted in France, and at the same time a man of science, has published a very full and able work on the subject. He observes:

Vitrification such as takes place in the large way demands two principal conditions: 1. A furnace constructed of substances capable of resisting the action of a violent and long-continued fire, and vessels capable of containing the vitrifiable matter in fusion without becoming fused themselves. 2. Substances which have the property of forming by means of fire a solid glass, suitable to the object of the manufactory.

Of the Furnaces and Crucibles.

The matter employed for the construction of the furnaces and crucibles must be of such a nature, as to take and preserve the forms required for the operations of the glass-house. Clay possesses this property in the highest degree; for which reason, though grit-stone is used in some glass-houses, and a mixture of quartz and silex with clay, for the construction of furnaces, it has nevertheless been almost generally adopted for the construction of furnaces, and exclusively for that of the vessels.

Pure clay cannot be fused by any degree of heat yet known, unless what is excited by oxigen gas; but the mixture of other earths, and particularly calcareous earth, causes it to enter into fusion, though itself alone is infusible.

The property of resisting the most extreme heat is more or less altered in clay, by the admixtures it may contain. Sand, quartz, and mica do not prevent a clay from being proper for the use of the glass-house, provided they do not too greatly diminish its ductility: but the same observation does not apply to bituminous matters, calcareous earth, gypsum, pyrites, or the metallic oxides; for these substances render it more or less fusible.

The whitest clay is generally said to be the most refractory; but whiteness is a very equivocal character, because it may consist with a large addition of calcareous earth. Now this earth is hurtful, not only because it renders the clay fusible, but because it forms pores in the crucibles by the swelling it occasions, when its carbonic acid is disengaged by the heat. A twentieth part of calcareous earth simply renders the compound less dense than clay alone, when exposed to the fire of the glass-house; but a tenth part renders it sensibly porous.

The choice of a clay in a glass manufactory is of so much the greater consequence, as a failure in this article is attended with a loss of all the expenses in fabrication.

The clay to be preferred for this use ought to possess the following qualities: 1. It must be so refractory, as not to vitrify, or even perceptibly change its figure, by the heat of the furnace. 2. It must be ductile enough to receive and retain the requisite forms.

With regard to the refractory quality Mr. Loysel proposes three proofs. In the first, after having reduced the clay into small particles, and separated such foreign matters as can be distinguished, the application of a mineral acid will show whether it effervesce It it do, there is reason to reject it; but it may be easily seen, that this proof is uncertain.

The second proof consists in working the clay into a paste with water. Of this paste, several prismatic rods and some very thin crucibles of five or six inches in diameter, and the same height, are to be made. These, after being gently dried, are to be exposed five or six days in the furnace of the glass-house. The rods must be suspended by their extremities on two supports. When these are taken out, they must be put into the annealing furnace, and cooled by insensible degrees. If the rods have not bended, if the crucibles have preserved their figure, and if no cavities be perceived upon breaking them, the clay may be judged to be good.

The third proof, which he prefers to the others, consists in judging the refractory quality of the clay by the action of an alkali upon it. For this purpose, it is mixed with different doses of fixed alkali, in crucibles of the same earth, or any other of known goodness, and a comparison is made of the proportion necessary to effect a complete vitrification with that which produces the same effect in a refractory sand exposed to the same degree of fire. Mr. Loysel has found, that if eight ounces of alkali be required to vitrify one pound of the sand of Aumont near Senlis, and ten ounces of the same alkali to produce the same effect, in a like degree of fire, upon a pound of baked clay, this clay may be employed in the construction of furnaces, and crucibles not intended to undergo a more violent heat than that of the proof, provided its firmness and tenacity be likewise sufficient.

The essay of clays, with regard to their tenacity, forms the second object. The solidity of works constructed with clay depends on the force of the cohesion of its parts. This force, when the work has been dried by degrees to a temperature of 25 or 30 degrees of Reaumur, which correspond with the 88th and 107th degrees of Fahrenheit, is so much the greater in proportion to the ductility of clay when in the state of paste; so that both these qualities may be confounded with the tenacity of the clay. But this tenacity is extremely variable. Sand diminishes it more than any other foreign admixture.

All the parts of the furnace of fusion do not require the same tenacity. The thicker parts require many cavities for the dissipation of the moisture; but the crucibles demand a compact and tenacious clay, to resist the fluxes, and oppose the pressure of the glass they are to contain. It is of importance therefore to determine the degree of tenacity suitable to each object. Of the different methods tried by Mr. Loysel, the following succeeded the best:

He forms with the clay intended to be tried, small four-sided rods, which he leaves to dry at the temperature of 25 degrees of Reaumur. He then fashions them, and reduces one of their extremities to a dimension of six lines in each of its four sides. He inserts this extremity into a cubical cavity, and at the distance of eighteen lines he places the knife edge of a balance, into the basin of which he pours sand, until a fracture takes place in that part which is only six lines thick; and from the weight of the balance, the sand, and the broken pieces, he estimates the tenacity of the clay. To avoid accidental irregularities, he repeats the experiment with several of these rods. Hence, he finds, that his constructions are solid, when the tenacity of the clay, prepared for the walls and the arched roof of the furnace of fusion of eight feet diameter, is such, as to resist about twenty-four ounces applied as here described; and for crucibles of three feet in diameter, and three inches and a half thick in the lower part, when it resists fifty-six ounces. But the degrees of tenacity, which may be usefully applied, have limits of considerable extent, and may likewise be changed according to the dimensions of the articles. Thus the resistance of a crucible may be increased by adding to its thickness.

When it is known by experience what are the thickness and tenacity of clay, suitable for vessels of a certain dimension, it is easy to determine by computation for other dimensions. Mr. Loysel has given a table for this—the thickness of the lower part of the pots, where the pressure is greatest, whence the thickness diminishes to the rim. At this part, though the pressure vanishes, it is nevertheless necessary, that a certain thickness should be given, that it may dry with regularity, and resist such occasional slight blows as the vessel is likely to receive.

For the most part it is not usual to employ native clay, because it retains moisture very obstinately, is apt to crack, and adheres strongly to the moulds. To remedy this inconvenience, its tenacity is diminished, and its porosity increased, by a mixture

of sand or of baked clay, which is
d into powder, and improperly called
t. The old crucibles, after a careful
tion of such glassy matter as may ad-
o them, are used for this purpose;
s these do not furnish a sufficient

aster of the glass work must deter-
what mixture is most suitable to his
aking, by combining these different
rties. If he use covered vessels, he
nploy a much greater proportion of
r cement in the roof of his furnace.

There are some who prefer sand to cement; but a distinction must be made as to the degree of fusibility in the clay made use of; for if the cement have more fusibility than the sand, as will happen with clays of middling quality, the sand should then undoubtedly be preferred; but with a good clay, the cement is certainly best.

Concerning the Construction of the Furnaces for Fusion.

There are three methods of constructing the furnace of fusion in a glass-house. 1. By using soft bricks. 2. By using bricks dried at the ordinary temperature of the atmosphere. And 3. By using bricks baked in the usual heat of a brick-kiln.

The soft bricks are made as follows: The clay is first dried, and the foreign matters which can be discerned are taken out, for which purpose the pieces must be broken, and examined within. If the clay contain much pyrites, the earth is mixed with water, in such a quantity, that the mass may be passed through the common sieve of the mealman. The larger pyrites remain behind, and those which come through subside to the bottom with the coarser sand. The mixture is then left to rest, the earth gradually subsides, and the water is from time to time drawn off, by cocks at different heights in the side of the vessel, until the mixture is sufficiently thick to be worked up with the sand or cement. This operation lasts between two and three months; at the end of which time, the matter, rejecting the inferior or lower part, is mixed with the sand or cement into a proper paste. If the clay do not contain pyrites, it is ground without water in a mill under a millstone of grit, then sifted and mixed with the sand or cement. Water is then added to convert the whole into a paste; or otherwise the clay purified by the first process of examination is soaked with water for four-and-twenty hours, and mixed with sand or cement.

In whatever manner the paste may have been prepared, it must be of such a consistence, that a ball of lead weighing four ounces may bury itself the depth of its diameter, when let fall out of the hand from a height not less than twenty-four inches, nor more than forty-five.

In this state the bricks would be too soft for the construction of a furnace, and would contract too much in drying. It is necessary therefore, that they be left to dry upon planks of wood. The firmer they are, the better for use, provided they do not break under the mallet of the workman, who strikes them with all his force to unite the different courses together, and to give them the figure required in the different parts of the arch-work. In this state a ball of lead of four ounces will require not less than a height of twenty-five feet, nor more than thirty-five, to bury itself half its diameter in the clay; but a consideration of importance is, that all the bricks ought to be sensibly of the same consistence, in order that the contraction of the different parts of the furnace may be as equal as possible.

This method of construction is the best which is known in the glass works. It is attended with the fewest cracks, and endures the longest. It is particularly advantageous in the manufactories of fine glass, and those wherein the vessels are uncovered. Nevertheless it is used only in great establishments. The reason is, that this construction requires more care, time, and expense than any other. It requires likewise a building, in which there are no other furnaces at work, in order that the drying may not be too hasty.

The construction with bricks dried in the air, or baked in the ordinary method, has nothing peculiar in it. This method of building ought to be reserved for glass-works where the pots are covered, or for common glass. And even in these, the first method would be found the most advantageous, if the necessary capital be not wanted.

Concerning the Fabrication of the Vessels or Crucibles.

The paste or mixture of clay and cement is prepared in the same manner as for the bricks already described, with this difference only, that it must be more consistent. A ball of lead of four ounces weight ought not to fall from a less height than sixty-five inches, nor a greater than eighty-three, to bury itself beneath the surface.

There are two methods of making pots for the glass-house. In the first, a mould of wood is made use of, lined within with a strong and well stretched cloth, and rolls of the paste are applied successively one above the other. In the second method a potter conducts his work without a mould, and joins the rolls of clay together by pressing them strongly between his hands. This second method is considered as better and more exact than the first.

The drying of the pots must be effected in the shade, in a place defended from currents of air, in a temperature between 55° and 65° of Fahrenheit. The drying must be slow, in order that the contraction may be regular. It is likewise requisite to defend them from frost and dampness. For this purpose, when the pots begin to dry, they are put into a close place, where the heat is gradually raised to 90° or 100°. They are then conveyed into the annealing furnace, where they are gradually heated to ignition; after which they are put into the melting furnace, heated less than its usual rate. The fire is successively raised to its greatest degree of heat. In large works, this diminution of the heat lasts three or four hours; but this time is not sufficient to effect a complete drying, for pots of large dimensions. These are usually left empty during the first working of the other pots.

Concerning the Heat of the Furnaces of a Glass-house.

The heat is greater the larger the quantity of air consumed. The entrance of the furnace ought to be therefore entirely free for the access of air; and the vapours of the furnace, which consist in a great measure of air unfit to maintain combustion, ought to be carried off as much as possible. Hence it follows, that the method employed in glass-works where pit-coal is the fuel, and in a few others where wood is used, deserves approbation. It consists in establishing a current of air through one or more arched passages, commonly under ground, one of the extremities abutting at the furnace, and the other being placed without the building which contains the furnace, and is commonly called the hall. By this means, several furnaces of fusion may be placed in succession in the same hall, without the combustion of the one being injurious to that of the other, as usually happens in less judicious arrangements. That disposition which approaches nearest to this is when the doors of the hall are opposite the furnaces; but the most injudicious is that which is commonly employed in glass-works where wood is burned. In this, the doors of the hall are on one side. The time required for the fusion and depuration may vary by the difference between the first and the last disposition from 18 to 34 hours.

The air ought to be heated before it arrives at the fire, that its temperature may be less remote from that wherein the combustion is effected. It ought therefore to pass through the ash-hole. Ordinarily in furnaces wherein wood is burned, the current is directed against a small dome above the ash-hole. It ought to be directed immediately into the furnace.

The interior part of the furnace cannot acquire its greatest degree of heat, but in proportion as that which is produced in the fire is deprived of the liberty of escaping during its disengagement. It is even necessary, that it should be distributed as equally as possible through the whole interior capacity of the furnace. Now this effect depends on the magnitude and position of the issues of the flame, and the interior figure of the furnace.

It is easy to ascertain by experience in each particular case the proportion which ought to exist between the entrance of the air, and the escape of the flame, by making the apertures of that escape at first larger than necessary, and then diminishing them with movable bricks disposed for this purpose, until the furnace appears to be in the greatest state of ignition.

heat is greatest in those parts where

e operations, provided that the me-
oxide do not enter into the compo-
; but if an equally quick fusion be required, with similar doses of fluxing-matter in covered as in uncovered pots, a greater heat must be applied, on account of the resistance opposed to the transmission of the heat by the cover.

Resinous woods afford more smoke than poplars, ash, &c.; and these more than birch, oak, sycamore, and beech. The last three are the best for heating the melting furnaces; as well for the purity of the flame, as the intensity of the heat.

In order to obtain the greatest quantity of flame, and the least of smoke, the same quantity of fuel must be constantly kept on the fire. It must therefore be added in small quantities, and at frequent intervals.

It has already been mentioned that Mr. Loysel, in order to determine the tenacity of different mixtures of clay and cement, and of clay and sand, made use of rods of clay, each face of which was six lines broad; that these rods were dried in the same degree of heat, and afterwards broken by weights suspended at the distance of eighteen lines from the plane of fracture. He also made experiments, to ascertain the proportions of tenacity acquired with the different degrees of heat to which the clay was exposed. With this view he prepared a great number of rods with the same clay, and in each experiment he baked at least four or five in the same degree of heat, to exclude those of which the results might be too discordant, on account of inequality or the variable porosity of the materials.

In this manner he made six experiments from 70° F. to 558°; after which having constructed a curve, the ordinates of which represent the degrees of temperature, and the abscissæ the weights necessary to break the rods, he found that his curve did not sensibly differ from the parabola; and from the equation of this curve he determines a law between the degrees of temperature and the weights necessary for the fracture.

The degrees of heat which he found immediately by the thermometer, or by the preceding rule, are as follows:

The heat of the apartments in which the unbaked pots are kept ought not to be less than 88°, and sometimes rises as high as 122°; that of the annealing furnace ought not to be higher than this, when the unbaked pots are introduced: it is gradually increased during eight days. At this period the proof of the rods indicated between 900 and 1000 degrees. The lowest heat of a great melting furnace proved to be about 8000 degrees. The most usual heat is about ten or eleven thousand degrees, and ought not to exceed fourteen or fifteen thousand degrees, because at this last temperature, pots of two feet diameter within, and three inches and a half thick, made of good clay, are broken by the pressure of twenty-five inches in depth of glass.

It may be observed that Mr. Loysel has

availed himself of a different property from that used by Wedgwood. See PYROMETER. The first has chosen the tenacity, and the second the contraction of clay, to determine the degree of heat. The second method, as the academicians observe, requires less apparatus; to which we may add, that it appears to depend less on arbitrary dimensions, and indicates minuter differences in less time. But these reporters justly question whether the one or the other method be adequate to prolong the graduation of our thermometers. The heat, at which it was possible for Mr. Loysel to make his comparative experiments, extended no farther than from 17 degrees to 234 of Reaumur; a space much too contracted to establish a progression to the extent of 14000 degrees. As to the agreement of these two methods, Wedgwood remarks, that there are three heats in the glass furnaces; a strong heat for vitrification, a low heat for settling, and a greater called the working heat. This last was found in plate glass to be 57° of his thermometer, which we may suppose to correspond with considerable latitude to the ordinary heat of Mr. Loysel just mentioned. Now Mr. Loysel's ordinary heat, reduced to the scale of Fahrenheit, is 23407°, and the working heat of Wedgwood, according to the same scale, is 8480°; a difference apparently too great to be admitted without the supposition of error in the parabolic curve of the former, the short intermediate scale of the latter, or, which is still more probable, a change in the measuring property of the clay at the higher temperatures. It must not however be overlooked, that the heats used in the glass furnaces, and elsewhere, for the same nominal purposes, were found by Wedgwood to differ extremely, though not so much as the preceding numbers do from each other.

Of the Choice of Vitrifiable Earth.

The whitest sand is the most frequently mixed with other earthy substances. To clear it of these, it is washed with agitation in clean water. The earthy parts, which are lighter than the sand, remain suspended in the water, which is decanted off, and fresh parcels added, till it comes off clear. If it contain combustible matters capable of colouring the glass, it is ignited for the purpose of burning them off. This is the method of purifying the sand for fine glass.

Of the Metallic Oxides considered as Fluxes.

Of all the metallic oxides considered as fluxes of siliceous earth, those of lead are the most used; not only because they are capable of vitrifying a larger dose of this earth, but because they are less costly, and may be employed in considerable proportions without injuring the whiteness of the glass. Minium is preferred to any other oxide of lead. If it be used with the vitrifiable earth of pulverized flints, or the white sand of Aumont near Senlis, five pounds of minium cannot completely vitrify more than two pounds of this earth in the ordinary fire of the glass-house. The glass which results is of an orange yellow, and full of veins; and specifically near five times as heavy as water. If the dose of earth be smaller, the vitrification is more speedy, and the glass is more coloured and heavy. The greater proportion of oxide of lead which enters into a composition, the less brittle the glass proves by the alternations of heat and cold. The more on the other hand the vitrifiable earth predominates, the glass will be more white, transparent, light, subject to break by sudden change of temperature, and difficult to soften by heat. The proportions of oxide of lead and sand must therefore be varied according to the object desired.

Concerning Arsenic.

The use of arsenic is avoided in glasses which contain oxide of lead, because this material favours its sublimation. The most effectual, as well as the most common method, is to mix nitre along with the vitrifiable materials. A large dose of arsenic gives a milky appearance to glass, and may even render it entirely opake. As glass is sometimes capable of being attacked by acids, it is proper to avoid arsenic in all vessels intended to contain liquors for drinking.

Arsenic mixed with coaly matter and exposed to the fire becomes violently inflamed and flies off. Advantage has been taken of this property: when it is perceived during the fusion, that the glass is coloured yellow for want of calcination, and that the mass is not sufficiently fluid, some manufacturers are in the habit of throwing pieces of arsenic into the pot. The arsenic takes away some of the colour from the glass, and by its inflammation and volatilization gives to the mass an internal movement, which facilitates its settling, and partly clears it of bubbles. But it is evident, that it is useful only as a remedy for preceding negligence. Mr. Loysel is of opinion, that arsenic may and ought to be banished from the glass-house.

Concerning Saline Fluxes.

The potash and soda employed as saline fluxes vary considerably by the quantity of earth and neutral salt they contain. For common glasses the mere ashes are frequently used. In all cases trial is made in the small way of the best proportions of the sand and the alkali.

The neutral salts which are mixed with the alkali are not only hurtful because they diminish the proportion of this last, but principally because they are incapable of combining with vitrifiable earth, and when mixed through the whole mass of the glass, they form a foreign opake matter. In this state the most active and long-continued heat would be scarcely sufficient to dissipate these salts. The most effectual remedy hitherto discovered consists in diminishing the heat of the furnace when the time of complete fusion is past. The neutral salts, being specifically lighter, rise to the surface, where they are taken off, and form what is called sandiver, salt of glass, or glass-gall; but this operation is attended with a loss of time, which is of prejudice, and some of the salt may remain in the manufacture. It is usually seen in the form of white flowers resembling flakes of snow. These kinds of glass are brittle, especially when part of the salt of glass is at the surface. It would therefore be a valuable operation, to deprive the alkalis of the neutral salts, with which they are mixed. Mr. Loysel avails himself, for the purification of potash, of its property of being much more abundantly soluble in water than the neutral salts it may contain. One hundred pounds of the saturated solution of potash contain forty-eight or fifty pounds of alkali; and this solution makes forty-eight or fifty degrees on the areometer of Baumé. If the evaporation be carried on till the solution is concentrated to the fortieth degree, the greater part of the foreign salts separates, and what remains cannot injure the glass. This method adds very little to the expense, because the best manufacturers are in the practice of dissolving their potash, to separate its impurities

During the fusion the carbonic acid is disengaged from the alkali, and produces an effervescence, which renders it necessary to increase the number of fusions; adding but small quantities of the mixture at a time, in order that the elastic fluid may be at liberty to escape. By this means the time of fusion is prolonged. The inconveniences of this effervescence are avoided by adding, as Mr. Loysel proposes, an equal weight of lime to the alkali, in the solution made for the last-mentioned purpose. This pure alkali is very deliquescent, but it may without any inconvenience be employed in the glass-works immediately after its desiccation.

Pure alkali dissolves a quantity of vitrifiable earth, which is more considerable the greater the intensity of the heat: so that the point of saturation depends on this circumstance. Whence it happens, that the glass made at different furnaces is more or less alkaline, and consequently more or less subject to decomposition. If the proportion be such, that the alkali in the glass is less than one fourth of its weight, the glass will be very solid: but if the heat made use of be so feeble, that the point of saturation cannot be obtained but by the proportion of equal parts of these two ingredients, the glass, though clear and transparent, will be of so loose a composition, as to be attacked and dissolved by mere water.

Concerning Lime.

Calcareous earth renders the glass into which it enters less subject to attract moisture, and less brittle by changes of heat and cold. Its whiteness is not perceptibly altered; but in order to avoid the effervescence produced by the disengagement of carbonic acid, the common practice is to use lime. This practice is still more advantageous, because the combustible matters of the lime stone are burned by calcination; and the water, which is one of its component parts, is dissipated. This water, together with the carbonic acid, if volatilized in the furnace of fusion, would facilitate the escape of part of the alkali.

Vegetable earth, such as is obtained by lixiviation of the ashes of vegetables, is used only for the most ordinary glass, because it alters their clear white colour. As it is fusible alone, which lime is not, it might be employed in large doses, without fear of impeding the vitrification of the sand and alkali, if there were not cause to fear the destruction of the pots, which it very speedily corrodes. This property makes it necessary to limit its proportion to one pound for every two pounds of sand, and a sufficient quantity of alkali.

The lime demands for its vitrification a greater quantity of alkali than sand does; yet the doses of sand and alkali being determined for the vitrification, a good glass may be obtained by adding a certain quantity of lime. Whence it happens, that with the same quantity of flux a larger quantity of glass is afforded, without considering the good qualities the lime communicates. Lime cannot, however, be used but with great moderation, because the glass of which it is a part vitrifies the clay of the pots, of which the preservation is an important object. From this consideration no more than ten or fifteen pounds of lime are added to one hundred pounds of alkali, and two hundred or two hundred and twenty pounds of vitrifiable earth.

There is an easy remedy against the action of the glass containing calcareous earth upon the pots. It consists in adding to the composition of the glass a sufficient quantity of clay to effect a saturation This is accordingly done in the manufacture of bottles. But as the clay used in the glass-houses always produces a green glass, it cannot be admitted in the composition of white glass.

A very remarkable effect of calcareous earth, and also of the vegetable earth, in vitrification, is the decomposition of the sulphuric salts with bases of fixed alkali, whatever may be the manner of their favouring the disengagement of the acid. Calcareous earth may be vitrified in the proportion of one part of the earth to three or four of salt, according to the degree of the fire. This property renders the use of lime and the vegetable earth very advantageous in the manufactories of common glasses, wherein the soda of kelp is used, which contains a considerable proportion of sulphat of soda.

Concerning the Substances proper to purify the Glass.

The substances most advantageously employed in the purification of glass are the oxide of arsenic, nitre, and the oxide of manganese. The first has been already mentioned.

Nitre serves as a flux by virtue of its alkaline part, and may supply the place of alkali according to the proportion it contains; but its high price prevents its being employed for this purpose. It is with a view to destroy the coaly matters contained in the mixture that it is added, and accordingly it is never used but when the materials have not been sufficiently calcined.

It is likewise with the same view that the oxide of manganese is used. We are indebted to Scheele for a knowledge of the manner in which this oxide operates. Naturally it gives a violet red colour to glass; but when deprived of part of its oxigen by the combustion of coaly matter, it loses its colour, and leaves the glass white. Hence a notion may be formed of its effects when added to glass in different proportions. If the dose be too small, it does not destroy entirely the yellow colour produced by the coal of the ingredients not sufficiently calcined; if it be too large, it communicates its own peculiar tinge.

The oxide of manganese is capable of destroying such colours only as are produced by coaly matter; but not those which arise from metallic substances, such as iron, lead, and cobalt. In these cases it produces a mixed colour from the combination of its own tinge and that of the metal already in the glass.

If it be proposed to communicate to glass the colour of the oxide of manganese, the materials must be well calcined; and arsenic must not be used, as it would attract the oxigen of the oxide. Nitre will restore the colour if destroyed. It effects this by affording oxigen.

In some cases, when it is desirable to give a slight green tinge to glass, instead of the yellow colour produced by a metallic oxide, a small quantity of the oxide of cobalt is added which gives a blue colour, and this by mixture with the yellow produces a green.

The oxide of manganese forms a glass specifically heavier than common glass; whence it arises, that the glass at the bottom of the pots in many glass-works is violet. It is undoubted, that when this happens the dose of manganese is too great. The usual method of remedying this inconvenience is to stir up the glass with an iron bar, after previously raising the fire to render it more fluid. It is thought, that the manganese is in part dissipated by that means; but it is merely distributed through the mass. A more effectual remedy is to add some combustible substance to the glass to destroy its colour; such as arsenic, charcoal, sulphur, &c.

Concerning the Calcination of the Vitrifiable Matters.

The calcination is an important preparation of the materials intended to be vitrified. Its chief effects are the dissipation of volatile substances, which ought not to enter as constituent parts of the glass, and the combustion of coaly matters, which without this operation never fail to colour the glass.

Two conditions are requisite to a perfect calcination: 1. The materials must present a large surface to the air; and 2. the heat to which they are exposed ought not to be attended with the smoke of the fuel. The first condition demands that the heat should not be so violent as to produce fusion. And moreover the heat should be gradually raised, to drive off the volatile matters, without raising along with them any part of those which are more fixed.

The sand made use of is commonly more or less white in its natural state; but it becomes still more so by calcination, and the glass is improved in consequence. The fire may be urged to the strongest degree when sand is calcined by itself; but a moderate heat is commonly used, unless when the very finest glass is intended to be made. In general the sand is subjected to no other calcination than that of the mixture of alkali, lime, &c., called the frit.

The calcination of the alkali is of the first importance. By this means the elastic fluid is driven off, which would disturb the fusion. Part of the evaporation of the salt, which takes place before it acts as a solvent to the sand, is thus prevented. And more particularly the coaly matters are burned, which it always retains notwithstanding any other previous depuration.

In the purification of alkalis all such vessels are to be avoided as might communicate colouring particles to them; such as boilers of iron. Those of lead are preferable; because, if any portions of the metal should be detached, no sensible inconvenience will arise as to the whiteness of the glass.

The heat must be more particularly attended to in the purification of the alkali, that it may be so moderate, as not to produce that liquefaction which is called the aqueous fusion, and arises from the water it contains. For this purpose the salt must be frequently turned, and not calcined in too great a quantity at a time.

calcined fixed alkali may be pre- in its concrete form in apartments ed from moisture. The same pre- is not required for the lime and sand. r the mixture of these three sub- , the mixture may be subjected to ation in the pots of the furnace of ; or it may be subjected to another tion called the operation of the frit. mixture of vitrifiable matters be not ted to this operation, the other ingre- are likewise added at this period, er they be nitre, arsenic, or oxide of nese, for purifying the glass, or such c oxides as are intended to produce . But if the mixture be fritted, no naterials are now added but the oxides are intended to possess the last state lation.

ncerning the Operation of the Frit.

operation of the frit answers two es. The first is to complete the stion of the coaly matter and the tion of volatile substances; the se- to incorporate the materials with ther by a beginning of that combina- which is perfected in the furnace of .

en a mixture of very dry concrete al- nd sand is made, and immediately ted to a heat sufficient for its vitri- on, the alkali speedily enters into ; the sand, being more heavy than luid alkali, falls to the bottom of the , and the supernatant alkali is in part rated before the whole of the sand dissolved. In this case the glass will n unvitrified sand, notwithstanding a ent or even superabundant proportion ali may have been used. This incon- ce is but too common in those works the operation of the frit is not used; is avoided by that commencement of which the sand, lime, and alkali e in this operation, and which holds ogether till the vitrification is com- .

accurate mixture of the vitrifiable s can alone produce the clearest glass, is the properest to receive the several s afforded by the metallic oxides. The therefore an operation of advantage loured glasses, as it prevents the pro- n of false or irregular tinges.

ifiable matters newly fritted destroy rrode the crucibles less than such as ot been so treated: 1. because they empt from humidity: and 2. because ali is no longer in a disengaged state. en it is proposed to augment the den- a glass by means of a metallic oxide s, such as those of lead, the glass pro- will be more uniform in its texture, ore equally the combination has effected through the whole of the Now the commencement of combi- , which is established between all the parts of the frit, prevents the oxide of lead from falling down as readily as it would otherwise do.

The operation of fritting is performed in one or more furnaces adjacent to the furnace of fusion which communicate with it, and to which the name of *arches à fritte* is given by the French; or otherwise it is done in separate furnaces. The former method is preferable, because the flame does not arrive at the frit until all the parts of the fuel have had time to be consumed; because they can more easily be kept at a steady and suitable heat without an additional expense of fuel, and because the vitrifiable matters may be immediately transferred in their white heat to the furnace of fusion. Hence the vitrification is more speedy, and the crucibles less injured, than if the materials were put in cold.

Concerning the Fusion of the Vitrifiable Matters.

It is necessary to diminish the heat of the furnace at the time of working the glass, in order that it may assume consistence enough to be wrought; but as the ingredients required to be added from time to time occasion a refrigeration, the furnace is again heated before they are introduced. The time of reheating differs in different works: but it is ordinarily one or two hours for furnaces of six or seven feet in diameter.

The cold produced by this circumstance being in proportion to the quantity added, it is clearly requisite not to add too much at a time; because too much cooling might even break the vessels. The pots are therefore filled at two, three, or four different intervals; and this is called making two, three, or four fusions, or fonts.

The second font must not succeed the first until the preceding vitrification is completed. Two methods are used to ascertain this. The first consists in observing the end of the effervescence, and the dissipation of the alkali superabundant to the vitrification; which may be known by the tranquillity of the font. The second consists in taking proof of the glass, after the cessation of the fumes arising from the evaporation of the alkali. If it be found, that the bubbles are dissipated, the second font may be made: and the same observation applies to the succeeding fonts.

The time employed in the vitrification is distinguished by the name of the time of fonding, and that employed in the dissipation of the bubbles, the settling or refining. The glass is said to be fine, or well refined, when it contains no more bubbles. If the second font were to be made before the glass of the first were well refined, the subsequent cooling would prevent the dissipation of the bubbles, at least during the whole time requisite to produce the original fluidity, and the subsequent refining would prove long and tedious. While the pots are thus supplied, the vents of the flame must necessarily be kept open, which cools the furnace also. For these reasons, it is proper to avoid either too few or too many fonts.

As soon as the glass is fine, the heat of the furnace is diminished by adding less fuel, or none at all, according to the nature of the work, whether of blown or of cast glass. By the diminution of heat, the glass becomes thicker or less fluid, and is fit for working. During the whole time of working the consistence must be the same: and for this reason, in the operation of blowing, of which the working may continue from five hours to twenty or more, according to the nature of the articles, the furnace must be kept at the same degree. But this need not be as intense as for the fonding and refining.

This last remark does not quite agree with the account given by Mr. Wedgwood of the fonding, settling, and working heats, see **Pyrometer**. But I suppose the working heat to be, as Mr. Loysel informs us, lower than the others for blown glass; and that Mr. Wedgwood's increased heat for working may be used only in the manufacture of *cast* plate glass.

There are two methods in practice of conducting the fonding, refining, and working of glass. In the first, each operation is made at the same time in all the pots; in the second, the fonding and refining are effected in one half of the pots, while the glass is worked in the others. It is easy to imagine, that the glass-works where this last practice prevails cannot have so intense a fire as the others. To supply this defect, a greater quantity of flux is used in the vitrification; and the glass, containing less earth, is tender, and subject to be decomposed. Exception must however be made with regard to those glass-works in which no other materials are used but old glass, or very fusible matters, such as lavas, basaltes, &c.

Of the Annealing of Glass.

Glasses of any considerable thickness, as for example two or three lines, if suffered to cool in the open air immediately after being formed, suffer an unequal contraction from their surface on account of the inequality of their thickness. These glasses frequently break of themselves by change of temperature. They fly or break with some noise, when an attempt is made to cut them with the diamond, or to grind them on the wheel or other tool. The annealing is a remedy for this defect. It consists in passing the glass, slowly and by insensible degrees, from the state of ignition it possesses in the furnace of fusion to the temperature of the atmosphere. For this purpose, as soon as the work is finished, and has assumed consistence enough to retain its form, it is conveyed, while still at a red heat, into a furnace which has nearly the same heat as itself. There the cooling is effected in one of the two following ways: The annealing furnace, or leer, is filled with the manufactured articles, and kept at the same heat during the whole time of working, after which it is suffered to cool slowly together with its contents: or otherwise, one or several pieces newly made are gradually passed along the annealing furnace by occasionally removing them from one end, which is hottest, to the other, where it is so low that the pieces may thence be safely transferred into the open air.

The slowness of annealing varies according to the brittleness of the kind of glass, and the thickness of the work. Thus, a glass made with flint and alkali alone is more difficult to anneal, than if it contained a metallic oxide or lime; and the first kind will always be more subject to break by alternations of heat and cold. The vessels to be annealed must be cool enough not to adhere to the support on which they are placed; for the inequality of contraction between them and the support might occasion them to break. The same accident arrives to pieces made of glasses of different dispositions to contract. The contraction of the piece to be annealed is effected more easily, the less friction it has to overcome: for which reason, when large plates of glass are to be annealed, the surface is placed on movable bodies, such as grains of sand.

Concerning the principal Defects observable in Works made of Glass.

The most considerable defects, as enumerated by Mr. Loysel, are striæ or veins, threads, tears, cords, bubbles, and knots.

The striæ or veins arise from the heterogeneous composition of the glass. It seldom happens, that glasses of any considerable magnitude are exempt from them, and the reason is not difficult to explain.

Glass produced by the solution of siliceous earth by fixed alkali, at the ordinary heat of the glass-house, possesses a specific gravity of 2·3 or 2·4, water being assumed as usual at one. Glass made with alkali and the clay commonly used weighs about 2·5. That of alkali and chalk, 2·7 or 2·8. The oxide of manganese vitrified alone weighs 3·2 or 3·3. Glasses produced by other metallic oxides are still more ponderous: that of lead, for example, weighs about 7·2 or 7·3. When the partial combinations of the ingredients of the glass are not well mixed together, but form strata of different density in the pots, they produce undulated veins in the work, similar to those observed when two liquids of very different densities are first mixed, such as water and alcohol.

As the glass in the operations of blowing is taken up nearly from the same part of the pot, and as in the casting of glass the pot is suddenly reversed and its whole contents mixed together, it is found, that blown glass is much more uniform than that which has been cast.

The name of threads is particularly given to those veins which are produced by the vitrification of clay. They are greener than those produced by calcareous earth. These threads render the glass very brittle, when they are abundant, or when any of them are of considerable size, because the contraction and dilatation of this kind of glass, from change of temperature, are very different from those of the glass of sand and flint.

Tears are the greatest defect which can be found in glass. They are the drops of glass afforded by the vitrification of the furnace of fusion. Articles in which these are found are brittle. Most of them break by the alternations of temperature, and that the more surely, the nearer the tear is to the surface. Such articles are generally thrown aside in the glass-house.

Cords are asperities on the surface of certain articles of blown glass. They are produced whenever the heat of the furnace becomes so low, that the threads of glass which fall from the pipe into the crucible cannot resume the proper degree of fluidity. When this appearance presents itself, the work is given up, till the heat of the furnace is again brought to the requisite degree.

The small bubbles abundantly diffused through certain glasses show, that the refining is imperfect. They arise from the disengagement of elastic fluid during the vitrification. This imperfection shows, either that the quantity of flux has been too small, or the fire too weak. In the first case, the glass may be used to hold liquids without fear of being attacked; in the second, the glass is tender and easily acted on by acids, if the flux were of an alkaline nature, because its proportion is too great.

Bubbles may also be produced in glass, during the working, by certain foreign matters, which are fixed, and emit aërial fluids by the heat.

Knots are of three kinds. They are either formed by grains of sand enveloped in the glass, or by the salt of glass which is found in pieces, or white flocks, or lastly by pieces detached from the crucible or the sides of the furnace.

The fused glass has the property of sticking to an iron rod or tube, by which means it is taken out, either to ascertain its state of perfection, or to blow it into such utensils as may be wanted.

The quantity to be used at once is regulated by a process somewhat resembling that of the tallow-chandlers; that is to say, the part first dipped out is suffered to cool a little, and serves as a receptacle for more glass to be taken up at a second dip, and so forth, until the quantity is sufficient. The lump of glass may be softened at pleasure, by holding it before the mouth of the furnace. The workman renders it hollow, and of a spherical form, by blowing through the tube. This sphere may be converted into a cone, a cylinder, or any other solid, the transverse section of which is a circle, by rolling it on a flat plate of iron. It may be stretched in length by swinging the tube in the air, or giving it a vibratory motion like that of a pendulum. The workmen show great dexterity in heating the glass in the various stages of the manipulation. They do this in such parts as they are desirous of extending; and on other occasions they cool certain parts of their work, by fanning the air against it. The glass, in the ignited state it possesses after it comes out of the pots, is very tough and flexible, may be cut with shears, bended with pincers, pressed into moulds, and wrought in a variety of methods dependent on these properties, of which the artists very dexterously avail themselves.

As far as observation has hitherto directed us, it appears to be a general rule, that the hardness, brittleness, elasticity, and other mechanical properties of congealed bodies, are greatly affected by the degree of rapidity with which they assume the solid state. This, which no doubt is referable to the property of crystallization, and its various modes, is remarkably seen in steel and other metals, and seems to obtain in glass. When a drop of glass is suffered to fall into water, it is found to possess the remarkable property of flying into minute pieces, the instant a small part of the tail is broken off. This, which is commonly distinguished by the name of Prince Rupert's drop, is similar to the philosophical phial, which is a small vessel of thick glass suddenly cooled by exposure to the air. Such a vessel possesses the property of flying in pieces, when the smallest piece of flint or angular pebble is let fall into it, though a leaden bullet may be dropped into it from some height without injury. Many explanations have been offered, to account for these and other similar appearances, by referring to a supposed mechanism or arrangement of the particles, or sudden confinement of the matter of heat. The immediate cause, however, appears to be derived from the fact, that the dimensions of bodies suddenly cooled remain larger, than if the refrigeration had been more gradual. Thus the specific gravity of steel hardened by sudden cooling in water is less, and its dimensions consequently greater than that of the same steel gradually cooled It is more than probable, that an effect of the same nature obtains in glass; so that the dimensions of the external and suddenly cooled surface remain larger than are suited to the accurate envelopment of the interior part, which is less slowly cooled. In most of the metals, the degree of flexibility they possess, must be sufficient to remedy this inaccuracy as it takes place; but in glass, which, though very elastic and flexible, is likewise excessively brittle, the adaptation of the parts, urged different ways by their disposition to retain their respective dimensions, and likewise to remain in contact by virtue of the cohesive attraction, can be maintained only by an elastic yielding of the whole, as far as may be, which will therefore remain in a state of tension. It is not therefore to be wondered at, that a solution of continuity of any part of the surface should destroy this equilibrium of elasticity; and that the sudden action of all the parts at once, of so brittle a material, should destroy the continuity of the whole, instead of producing an equilibrium of any other kind.

Though the facts relating to this disposition of glass too suddenly cooled are numerous and interesting to the philosopher, yet they constitute a serious evil with respect to the uses of this excellent material. The remedy of the glass-maker consists in annealing the several articles, which is done by placing them in a furnace above the furnace of fusion. The glasses are first put into the hottest part of this furnace, and gradually removed to the cooler parts at regular intervals of time. By this means the glass cools very slowly throughout, and is in a great measure free from the defects of glass which has been too hastily cooled.

It is difficult to speak with any precision concerning the materials, proportion, and management necessary to make the different kinds of glass, such as the green glass for bottles, the greenish or blueish glass for windows, the white glass for mirrors, the white flint glass for bottles, and the crystal glass used for the finer wares, called cut glass, not to mention the dense white glass made expressly for optical uses. All these are made of better quality at some manufactories than at others; and it is probable, that this superiority of produce is thus confined by the natural disposition for secrecy, which prevails among men, whose pecuniary success in a great measure depends on their monopolizing the effects of their own skill. Far be it from me to pretend to consider this proceeding as immoral. On the contrary, I very much doubt, whether any species of property can be defended under a title in any respect so strong as that which a man must hold in his own superiority of intellect and exertion. I mean simply to observe in this place, that, from the causes here mentioned, it is impossible to give a minute account of the art. The green glass is made from impure materials; the basis consisting of a ferruginous stone or sand, and the alkali being such as can be the most cheaply purchased. The colour chiefly depends on the iron; and the glass is harder, more durable, and less destructible by acids remaining in it for a long time, the less the quantity of alkali, and consequently the greater the heat. Pit coal is used as fuel in the English glass-houses. It produces a more intense heat than wood. Chaptal, in his Elements of Chemistry, mentions the successful establishment of a manufactory of opaque bottles of excessive strength and lightness, composed chiefly of basaltes; but he relates that the establishment failed, chiefly on account of the quality of the basaltes, which did not constantly prove the same, but, becoming in the latter stages of the undertaking more calcareous, produced an article of a perishable nature.

All the white glasses owe their clearness to the purity of the materials. The finest siliceous sand is fused with purified alkali. The oxides of lead act as a powerful flux, and are much used in compositions of this nature. They give density, softness, and a disposition to take a brilliant polish.

Optical writers teach us, that the refracting telescope consists of a convex lens, called the object lens, in the focus of which the image of a remote object is formed; and that this image is seen magnified and distinct by a microscope applied to it, which forms the apparatus at the other end of the telescope. It may easily be imagined, that, if the focal image be indistinct, or if there be a number of focal images occupying different parts of the field of view of the telescope, the effect will be less perfect, and the magnifying power must be less, in order that the confusion may be at all tolerable. Whenever a ray of white or compounded light is refracted out of its course, by passing into another simple medium of different density from that through which it originally passed, it is found to be separated into its component parts, which produce the sensations of various colours. This separation is made by virtue of the different properties possessed by the several rays of light, by which some are more refracted in like circumstances than others. Thus the blue is more refracted than the green and yellow, and these are more refracted than the red rays. Whence it follows, that a pencil of white light, which passed in parallel rays to a wedge or prism of glass, will come out of the prism on the other side, not only refracted in the whole, but differently refracted as to its parts; the red being less turned out of its course than any of the other rays, and the violet being the most deflected of any. And this difference of direction will be greater, the greater the mean refraction. The edges of a convex lens may be considered as wedges of the same nature, with regard to the light, as the prism here mentioned. Such a lens, refracting the red rays less than any other, will form a red image at a certain focal distance. The yellow rays, being somewhat more refracted, will afford a yellow image, at a distance less remote from the lens: and, for similar reasons, there will be formed, at still nearer distances, images of green, blue, and violet, with all

ntermediate shades of colour. The
focal image will consist of all these
s irregularly combined. It has been
ered, that the quantity of dispersion
ater in some kinds of glass than in
s, while the mean refraction or focal
n remains the same. Two prisms of
different kinds of glass, producing the
mean refraction toward contrary
on a ray of light, would not therefore
ct the colorific dispersion, though the
ould proceed onward nearly in its ori-
direction. It would be necessary, in
that this dispersion produced by the
lass should be accurately corrected by
her, that the mean refraction should
atest in that which possessed the least
in dispersing the rays of light; and,
s case, the colourless emergent ray
not proceed in its first direction. To
this doctrine to telescopes—Suppose
ex lens formed of such glass as afford-
y little colorific dispersion of the rays,
concave lens of such glass as afforded
of this effect: it will follow, that,
these two lenses possess such a figure,
the concave shall destroy the pris-
colours produced by the convex, the
of mean refraction must be in the
and consequently, that the compound
will act like a convex lens, and pro-
real colourless focal image.

e problem of constructing telescopes
shall be truly achromatic, depends,
have before observed, chiefly on the
tion to which the glasses can be
ht. The general facts respecting
for this use are, that lead, and pro-
other metallic oxides, increase the
ive power more than alkalis, and
ast more than earthy fluxes; and that
lition of alkali to glasses containing
rves greatly to diminish the mean
ion, without much affecting the di-
e power occasioned by the metal.
it might seem easy to compose such

but the practice is by no means so
Regular refraction demands, that
dium should possess a uniform den-
roughout, or, in other words, that
ts of the glass should be well com-
ogether. This however is seldom the
pecially in the dense metallic glass.
und, that the great fusibility of the
lead causes it to flow, and occupy
rstices between the particles of the
fore these are melted. So that some
right and apparently homogeneous
exhibit an infinity of small focal
of a candle, when examined by a
er, which are produced by rounded
s of sand remaining in every part of
stance. Another fault, still more
n, consists in veins of a different
from the rest, partly arising from
ct fusion, and partly from the density of the glass in the pots being greater, the lower its position.

Various have been the attempts to remedy these defects, more especially since the Board of Longitude has offered a considerable premium for this object. We do not, however, possess any ample detail of these unsuccessful experiments. It is generally understood, that it is in vain to endeavour to make this glass in small furnaces, because the heat in these is continually varying, and is either too low for the requisite fluidity, or so high as to extricate bubbles of elastic matter; whereas a steady heat is required for the purpose. Macquer and others have attempted to correct the evil by repeated fusions and pulverization of the glass, and by exposing it to long continued fires, but without success. It is said, that one of the practices in our glass-houses consists in lading the melted matter from one pot to another in the furnace. But this, on account of the heavy duty of excise, and the impolitic manner in which it is levied, cannot be done to any great extent in this country. If the glass be suffered to cool in the pots after a good fusion, its parts take a symmetrical arrangement, of the nature of crystallization, by which the light is acted upon in a manner independent of its figure, which is thought to be a great impediment to its optical use. Mr. Kier, who has had much experience in this branch of chemistry, is disposed to recommend the trial of component parts different from any which have yet been admitted into the common glasses.

Without presuming to speculate in a department of science, wherein my experience is much confined, I shall point out a few facts, which may be of use to the philosophical operator, and leave the manufacturer to his own trials. It is generally affirmed, that Mr. Dollond made his original experiments, and constructed those excellent three-foot glasses (which at present bear so high a price, and are not to be made) with one single pot of glass made at the glass-house near Wellclose Square, and that none of the same quality has since been made. But the proprietor of that glass-house has assured me, that the original receipts and practice are still followed in the making of optical glass: that the principal opticians always complain of the bad quality of the glass, but never fail to take the whole quantity he makes at their request; and that when they renew their orders, they always desire it may be exactly the same as the last. From these circumstances I think it probable, 1. That, though one pot of glass may differ from another, yet there may be as good glass obtained for optical uses now as formerly, if an optician skilled in the theory and practice, like the late Mr. Dollond, were to undertake the task of adapting the curvatures, and selecting the best lenses.

2. That Mr. Dolload's purpose as a tradesman being now answered, by the establishment of an extensive business, he has not the same motives for exertion upon powerful telescopes as actuated his father. 3. That the profits of this trade are greater, and more certain, when many hundreds of cheap perspectives are made by common workmen, than when a few extraordinary telescopes are made by the most excellent artists, superintended by the master himself; and, consequently, it is not the interest of an established house to extend the latter branch. 4. That it is not the interest of a glass manufacturer, who can gain a large and regular income by making common utensils, to employ his time in costly experiments upon optical glass, which, if brought to perfection, would afford but a moderate demand, probably no greater than he now experiences: and, therefore, that the improvement of achromatic telescopes is rather to be expected from a man of science, who may be a practical chemist, than from mere tradesmen.

I suspect the opinion to be ill founded, that those kinds of glasses are unfit for optical uses, which are veiny or clouded, or otherwise unpromising On the contrary, there are reasons to think, that the defects of glass arise from irregularities too minute and numerous to be discerned or discovered in any way, but by the actual proof of constructing a telescope. There are good glasses, which abound with the larger veins; and I possess two achromatic lenses, each of thirty inches focus, the obvious qualities of which, and excellence as object glasses, differ very much, and in opposite respects. They are each composed of a convex of crown glass, applied to a concave of flint. The one was constructed for the tube of an astronomical quadrant. It produces no colour, has no aberration from figure, and, when the eye is placed in its focus so as to receive the pencil of light from a fixed star, the whole aperture is uniformly covered with light. The other glass, though perfectly similar, was made for a pocket perspective. It produces scarcely any colour, has considerable aberration from figure, and when the eye placed in its focus receives the light of a fixed star, the whole aperture is covered with light of an irregular, curdled, or cloudy appearance. I have no doubt but the former glass was applied to the superior, and the latter to the inferior use, from their obvious qualities: but when they are examined by the true test of optical excellence, the application of a large magnifying power, the former proves dark and indistinct, while the latter exhibits the object bright and well defined, and is on the whole an excellent lens.

Mr. Reaumur was the first who made any direct experiments upon the conversion of glass into porcelain, which takes place by the evaporation or absorption of its alkali, during the continuance of a degree of heat less than is sufficient to melt it. Saline glasses are the best for this purpose; and the less salt they contain, the more readily they are converted. Instances of this effect may be observed among the rubbish of brick-kilns, where pieces of green bottles are not unfrequently subjected by accident to the requisite heat; but the direct process is as follows: A vessel of green glass is to be filled up to the top with a mixture of white sand and gypsum, and then set in a large crucible upon a quantity of the same mixture, with which the glass vessels must also be surrounded and covered over, and the whole pressed down rather hard. The crucible is then to be covered with a lid, the junctures well luted, and put into a potter's kiln, where it must remain during the whole time that the pottery is baking; after which, the glass vessel will be found transformed into a milk-white porcelain. The glass, on fracture, appears fibrous, as if it were composed merely of silken threads laid by the side of each other: it has also quite lost the smooth and shining appearance of glass, is very hard, and emits sparks of fire when struck with steel, though not so briskly as real porcelain. Lewis observed, that the above-mentioned materials have not exclusively this effect upon glass; but that powdered charcoal, soot, tobacco-pipe clay, and bone-ashes, produce the same change. It is remarkable, that the surrounding sand becomes in some measure agglutinated by this process, which, if continued for a sufficient length of time, entirely destroys the texture of the glass, and renders it pulverulent.

The ancient stained glass has been much admired, and beautiful paintings on this substance have been produced of late years. The colours are of the nature of those used in enamelling, and the glass should have no lead in its composition. Mr. Brongniart has made many experiments on this subject. The purple of Cassius, mixed with six parts of a flux composed of borax and glass made with silex and lead, produces a very beautiful violet, but liable to turn blue. Red oxide of iron, prepared by means of the nitric acid and subsequent exposure to fire, and mixed with a flux of borax, sand, and a small portion of minium, produces a fine red. Muriat of silver, oxide of zinc, white clay, and the yellow oxide of iron, mixed together without any flux, produce a yellow, light or deep according to the quantity laid on, and equal in beauty to that of the ancients. A powder remains on the surface after baking, which may easily be cleaned off. Blue is produced by oxide of cobalt, with a flux of silex, potash, and lead. To produce a green, blue must be put on one side of the glass, and yellow on the other: or a blue may be mixed with yellow oxide

on. Black is made by a mixture of

less glue.

ween two and three years ago, a Mr.
of Hull took out a patent for making
om the tail, fins, and other parts of
ale.

rs. Parmentier and Pelletier made
udicious experiments upon glue made
ones by Mr. Grenet, of which an
t is inserted in the 13th volume of
nales de Chimie, p. 192. Six pounds
ings of bone from the button-mould
were put into a copper boiler with
-four pints of water, and in that state
soak for two days without heat. At
riod the vessel was placed on a fire,
ter the expiration of one hour the
as in a state of ebullition, which was
ed for nine hours. The materials
en left to subside for a night. The
atant fluid, or glue, was by this means
ed clear. It was drawn off with a
. The quantity was fourteen pints,
o pints more were obtained by pressure from the dregs. This clear fluid was afterward concentrated by farther evaporation, then suffered to cool for half an hour, and poured into wooden moulds. In the course of the day it had acquired the consistence of a firm jelly, which was cut into cakes, and dried upon a net. Fourteen days were requisite for this purpose, in the shade, the weather being rainy and damp. The quantity of glue was fifteen ounces and four drachms, with the addition of four drachms more obtained by pressure from the dregs. The dried residue weighed four pounds three ounces, and the loss was thirteen ounces. The glue was therefore one sixth of the weight of the bones.

Ivory raspings, treated in the same manner, afforded upward of one fifth part of their weight of glue.

The dark colour of glue was found to arise from the action of the heat in the last evaporation. These intelligent chemists, adverting to the fact, that isinglass is rendered clear and white by fumigation with sulphur; but at the same time reflecting, that glue, not being composed of thin fibres, was incapable of undergoing this process, as to its interior part, determined to try the solution of sulphurous acid. They prepared a pale jelly by a short ebullition of raspings of bones in the smallest possible quantity of water. To this they added a little water charged with sulphurous acid, and mixed the fluids well together. The experiment succeeded. They proposed as a preliminary operation, to bleach the raspings by the same means, where a pale-coloured glue is required.

These commissaries found, that the glue manufactured by Mr. Grenet was equal in quality to the best made in England, or elsewhere. They could not make glue from horn.

Gluten (Vegetable). If wheat flour be made into a paste, and washed in a large quantity of water, it is separated into three distinct substances; a mucilaginous saccharine matter, which is readily dissolved in the liquor, and may be separated from it by evaporation; starch, which is suspended in the fluid, and subsides to the bottom by repose; and gluten, which remains in the hand, and is tenacious, very ductile, somewhat elastic, and of a brown gray colour. The first of these substances does not essentially differ from other saccharine mucilages. The second, namely the starch, forms a gluey fluid by boiling in water, though it is scarcely, if at all, acted upon by that fluid when cold. Its habitudes and products with the fire, or with nitric acid, are nearly the same as those of gum and of sugar. It appears to be as much more remote from the saline state than gum, as gum is more remote from that state than sugar.

The vegetable gluten, though it existed before the washing, in the pulverulent form, and has acquired its tenacity and adhesive qualities from the water it has imbibed, is nevertheless totally insoluble in this fluid. It has scarcely any taste. When dry, it is semitransparent, and resembles glue in its colour and appearance. If it be drawn out thin, when first obtained, it may be dried by exposure to the air; but if it be exposed to warmth and moisture while wet, it putrefies like an animal substance. The dried gluten applied to the flame of a candle, crackles, swells, and burns, exactly like a feather or piece of horn. It affords the same products by destructive distillation as animal matters do: is not soluble in alcohol, oils, or ether; and is acted upon by acids and alkalis, when heated. According to Rouelle, it is the same with the caseous substance of milk. See Cheese.

Tessier has made several experiments on the gluten obtainable from different sorts of wheat. He took a pound of the flour of each species, made it into a thick paste, and continued handling it a long time under a slender stream of water, or rather water falling drop by drop on it, till all the starch was washed away from the gluten; which he first weighed, and afterward dried on the cover of a saucepan full of water, kept boiling on the fire. Two sorts of wheat, one a very early kind of bearded wheat, with smooth, red ears, divergent barbs, and grains of the common colour or yellow; the other with white, smooth, beardless ears, and white grains, originally from Philadelphia, afforded each five ounces of gluten. A wheat with red, smooth, bearded, clustered (*grouppés*) ears, a variety of the *bled de miracles*, and another with white, straight bearded, elongated ears, and hard long grains, the *triticum polonicum* L., Polish wheat; afforded, one two ounces, the other two ounces and half. From a wheat with violet coloured, bearded, hairy ears, and hard grains spotted on the germ, originally from Nice and the Canary Islands, Mr. Tessier obtained only four drachms. The other sorts he tried, gave from four ounces to four ounces five drachms.

In general the flour from hard corn afforded less than that from soft. That from the hard was more friable after drying. It loses considerably by drying, so that in this state the greatest product scarcely exceeded two ounces. The diminution of weight was in the inverse ratio of the quantity obtained. By long keeping too it loses weight, so that in four years the different specimens had lost from $\frac{2}{3}$ to $\frac{7}{8}$ of their weight.

Mr. Tessier made some experiments also to try the effect of manure on the production of gluten. He divided a piece of ground, apparently of a uniform soil, into nine plots, each containing two perches, twenty-two feet square, French measure. On one he folded a flock of a hundred and forty sheep and goats about two hours. One he manured with two sacks (*sachées*) of rotten horsedung: one with the same of rotten cowdung: one with sixty-four quarts of urine: one with thirty-six quarts of bullock's blood: one with two sacks of vegetable refuse reduced to mould: one with three bushels of pigeon's dung: and one with the same quantity of dried night soil. The ninth was left without manure. On all these he sowed the same spring wheat, with white, smooth, beardless ears. The patch manured with pigeon's dung yielded the most corn: those with dried soil and urine the next: then those with bullock's blood and horsedung. Those with vegetable refuse and cowdung did not succeed so well; and that without manure produced little more than double the quantity of seed, while some yielded six times as much as was sown. With respect to the gluten, the wheat from the patch manured with urine gave six ounces from a pound of flour; that from the patch with night soil only four ounces; and each of the others five.

From the flour of barley, rye, or oats, no gluten can be extracted as from that of wheat, probably because they contain too small a quantity.

Cadet informs us, that gluten, after it has undergone the acetous fermentation, is soluble in alcohol. That when dissolved in alcohol, and reduced to the consistence of a sirup, it forms a good varnish. That pigments, particularly of the vegetable kind, mixed with at least an equal quantity of this solution, may be applied on wood, glass, or any other substance; to which they adhere strongly, drying quickly without any offensive smell; and that this painting may be washed without injury, if not rubbed too roughly. Acetous acid will furnish a varnish with gluten, but not equal in quality. Gluten with lime makes a very strong and tenacious luting.—*Journ. de l'Institut.—An. de Chim.*

Gneis. The Saxon name of a rock, consisting of mica, felt spar, and quartz, of a slaty, continuous, or fibrous texture, and not granular, as in granite.

Gold is a yellow metal, of much greater specific gravity than any other body in nature, except platina. It is soft, very tough, ductile, and malleable; unalterable and fixed, whether exposed to the atmosphere, or to the strongest heat of furnaces. The most powerful burning mirrors are said to have volatilized it; and it has been driven up in fumes, in the metallic state, by flame urged upon it by a stream of oxigen gas. The electric shock converts it into a purple oxide, as may be seen by transmitting that commotion through gold leaf between two plates of glass; or by causing the explosive spark of three or more square feet of coated glass to fall upon a gilded surface. A strong heat is required to melt it, which does not happen till after ignition. Its colour, when melted, is of a blueish green; and the same colour is exhibited by light transmitted through gold leaf.

The limits of the ductility and malleability of gold are not known, and its tenacity exceeds that of any other metal. A gold wire of one tenth of an inch diameter, requires 500lb. weight to break it.

The method of extending gold used by the gold-beaters, consists in hammering a number of thin-rolled plates between skins or animal membranes. By the weight and measure of the best wrought gold-leaf, it is found, that one grain is made to cover 56$\frac{3}{4}$ square inches; and from the specific gravity of the metal, together with this admeasurement, it follows, that the leaf itself is $\frac{1}{282000}$ part of an inch thick. This, however, is not the limit of the malleability of gold; for the gold-beaters find it necessary to add three grains of copper in the ounce to harden the gold, which otherwise would pass round the irregularities of the newest skins, and not over them; and in using the old skins, which are not so perfect and smooth, they proceed so far as to add twelve grains. The wire which is used by the lace-makers is drawn from an ingot of silver, previously gilded. In this way, from the known diameter of the wire, or breadth when flattened, and its length, together with the quantity of gold used, it is found, by computation, that the covering of gold is only $\frac{1}{12}$ part of the thickness of gold-leaf, though it still is so perfect as to exhibit no cracks when viewed by a microscope.

No acid acts readily upon gold but aqua regia and the oxigenized muriatic acid. The sulphuric acid, distilled from manganese, has some action upon it; as have likewise the pale nitric acid, and the phosphoric acid when boiling. Chromic acid added to the muriatic enables it to dissolve gold.

The small degree of concentration of which the oxigenized muriatic acid is susceptible, and the imperfect action of the latter acids, render aqua regia the most convenient solvent for this metal.

When gold is immersed in aqua regia, an effervescence takes place with the escape of air, which has not been examined; the solution tinges animal matters of a deep purple, and corrodes them. By careful evaporation, fine crystals of a topaz colour are obtained. The gold is precipitated from its solvent by a great number of substances. Lime and magnesia precipitate it in the form of a yellowish powder. Alkalis exhibit the same appearance; but an excess of alkali redissolves the precipitate. The precipitate of gold obtained from aqua regia by the addition of a fixed alkali appears to be a true oxide, and is soluble in the sulphuric, nitric, and muriatic acids; from which, however, it separates by standing, or by evaporation of the acids. Gallic acid precipitates gold of a reddish colour, very soluble in the nitric acid, to which it communicates a fine blue colour.

Ammonia precipitates the solution of gold much more readily than fixed alkalis. This precipitate, which is of a brown, yellow, or orange colour, possesses the property of detonating with a very considerable noise, when gently heated. It is known by the name of fulminating gold. The presence of ammonia is necessary to give the fulminating property to the precipitate of gold; and it will be produced by precipitating it with fixed alkali from an aqua regia previously made by adding sal ammoniac to nitric acid; or by precipitating the gold from pure aqua regia, by means of sal ammonia, instead of the ammonia alone. The fulminating gold weighs one fourth more than the gold made use of. A considerable degree of precaution is necessary in preparing this substance. It ought not to be dried but in the open air, at a distance from a fire, because a very gentle heat may cause it to explode. Several fatal accidents have arisen from its explosion, in consequence of the friction of ground stoppers in bottles containing this substance, of which a small portion remained in the neck.

Fulminating gold, when exposed by Berthollet to a very gentle heat in a copper tube, with the pneumatical apparatus of mercury, was deprived of its fulminating quality, and converted into an oxide at the same time that ammoniacal gas was disengaged. From this dangerous experiment it is ascertained, that fulminating gold consists of oxide of gold combined with ammonia. The same eminent philosopher caused fulminating gold to explode in copper vessels. Nitrogen gas was disengaged, a few drops of water appeared, and the gold was reduced to the metallic form. In this experiment he infers, that the ammonia was decomposed; that the nitrogen, suddenly assuming the elastic state, caused the explosion, while the oxigen of the oxide united with the hidrogen of the alkali, and formed the water.

This satisfactory theory was still farther confirmed by the decomposition of fulminating gold,. which takes place in consequence of the action of the concentrated sulphuric acid, of melted sulphur, fat oils, and ether; all which deprived it of its fulminating quality, by combining with its ammonia.

Sulphurets precipitate gold from its solvent, the alkali uniting with the acid, and the gold falling down combined with the sulphur; of which, however, it may be deprived by moderate heat.

Most metallic substances precipitate gold from aqua regia: lead, iron, and silver, precipitate it of a deep and dull purple colour; copper and iron throw it down in its metallic state; bismuth, zinc, and mercury, likewise precipitate it. A plate of tin, immersed in a solution of gold, affords a purple powder, called the purple powder of Cassius, which is used to paint in enamel. There are various methods of managing this process. That described by Macquer consists in dissolving tin by very small portions at a time, without heat, in an aqua regia composed of two parts of nitric and one of muriatic acid, previously weakened with water equal in weight to both the acids. The first small portion of tin must be suffered to be entirely dissolved before a second is added. This addition must be continued till the acid has acquired a yellow colour, and scarcely acts at all upon the tin last added.

On the other hand, the purest gold must be dissolved in an aqua regia composed of three parts of nitric, and one of muriatic acid. This solution may be made, as expeditiously as the operator chooses, by the assistance of the heat of a sand bath.

The solution of tin must then be largely diluted, as for example, with one hundred parts of distilled water; and a small quantity of this may then be assayed, by separating it in two parts, and diluting one of the parts still farther. Upon trial of both, by letting fall a drop of the solution of gold into each, it will be seen which affords the most beautiful purple precipitate. The whole of the solution of tin must accordingly be altered, if necessary, by adding more water. Pour into this solution, in a large glass or earthen vessel, nearly half as much of the solution of gold as it contains of solution of tin, stirring the mixture with a glass stick. In a short time the liquor will become of a beautiful red colour, which will gradually disappear on the subsidence of the precipitate. By adding a small quantity of the solution of tin, it will be seen whether the whole of the gold is precipitated. The clear liquor must then be decanted, and the precipitate washed. It consists of metallic gold and oxide of tin at a maximum in combination, and is the only known substance which has the property of communicating a purple colour to glass. This purple powder is perfectly soluble in ammonia. Nitric acid boiled on it brightens it to a tint approaching that of cinnabar.

The difficulties attending the preparation of this article appear to depend on the state of the tin. If the solution of this metal be made with heat and rapidity, it becomes too much oxided to adhere to the acid, or to precipitate the gold; and the combination of the two metals, which falls down, varies in colour according as this term is approached. These are the chief circumstances; but there is no doubt, that a complete examination of the process would indicate others worthy of notice.

Ether, naphtha, and essential oils, take gold from its solvent, and form liquors which have been called potable gold. The gold which is precipitated by evaporation of these fluids, or by the addition of sulphat of iron to the solution of gold, is of the utmost purity.

In the dry way, gold resists the action of neutral salts, more especially nitre, which deflagrates with the imperfect metals. Nitre, however, does not afford an expeditious way of purifying gold, because this metal in some measure protects and covers the alloys from its action. It is remarked, that borax, used as a flux with gold, renders it paler; and that this alteration of colour disappears by the addition of nitre or common salt. As the acid of borax forms a compound with gold, which falls to the bottom when this acid is added to the metal in solution, it is probable, that the paleness produced by borax may arise from the combination of a small portion of its acid with the gold, which might be driven off by a continuance of the heat, and united by stronger affinity with the alkali of the nitre, or of the common salt, in proportion as their acids are dissipated by heat.

Earths and alkalis do not act on gold in the dry way. Sulphur, which combines with most metals, has no effect on this. A process, called dry parting, is grounded on this property; and is more especially used in separating silver from gold, when the quantity of the latter metal is too small to answer the expense of dissolving the larger mass of silver in nitric acid. For this purpose, the mixed metal is fused, and flowers of sulphur thrown on its surface. These combine with the silver in the form of a black scoria, while the gold remains at the bottom in its metallic state. The operation of dry parting does not leave the gold in a state of purity; because the last portions of silver are defended from the action of the sulphur. But when the quantity of silver is thus diminished, the operation of parting with aqua fortis, or nitric acid, may be advantageously used.

Sulphuret of potash dissolves gold in the dry way. Equal parts of sulphur and potash are hastily fused with one fourth of a part of gold-leaf. This combination is soluble in water, with which it forms a yellowish green solution. By the addition of an acid, the gold is thrown down in combination with the sulphur, of which it may be deprived by heat.

Most metals unite with gold by fusion. With silver it forms a compound, which is paler in proportion to the quantity of silver added. It is remarkable, that a certain proportion, for example a fifth part, renders it greenish. From this circumstance, as well as from that of a considerable proportion of these metals separating from each other by fusion, in consequence of their different specific gravities, when their proportions do not greatly differ, it should seem, that their union is little more than a mere mixture without combination; for, as gold-leaf transmits the green rays of light, it will easily follow, that particles of silver, enveloped in particles of gold, will reflect a green instead of a white light.

A strong heat is necessary to combine platina with gold: it greatly alters the co-

f the gold, if its weight exceed the
eventh part of the mass. Mr. Fran-
however informs us, that six parts of
nd one of malleable platina, produce
l of a beautiful colour, great mallea-
susceptible of a fine polish, and more
rable than gold itself. It does not
affect the ductility. The Spanish
ry has prohibited the exportation of
from America, lest it should be used
lterating gold; but this does not ap-
o be a danger which need be feared,
emistry has long been in possession
eral simple and expeditious methods
ecting this fraud, which besides is
t to the sight when the quantity of
ment is considerable. It may be
oned likewise, whether the value of
would not soon equal that of gold,

is softer the larger the proportion of
ry. It softens and liquefies by heat,
ystallizes by cooling.

d unites with gold, and considerably
rs its ductility, ¼ of a grain to an
rendering it completely brittle. Cop-
enders gold less ductile, harder, more
e, and of a deeper colour. This is the
addition in coin, and other articles
in society. Tin renders it brittle in
ortion to its quantity; but it is a com-
error of chemical writers to say, that
lightest addition is sufficient for this pur-
When alloyed with tin however it will
ear a red heat. With iron it forms a
mixture, which obeys the magnet. This
is very hard, and is said to be much
ior to steel for the fabrication of
g instruments. Bismuth renders gold
e and brittle; as do likewise nickel,
anese, arsenic, and antimony. Zinc
uces the same effect; and, when equal
eight to the gold, a metal of a fine
is produced, which is said to be well
ted to form the mirrors of reflecting
opes, on account of the fine polish it
ceptible of, and its not being subject
rnish. The alloys of gold with mo-
ena are not known. It could not be
d with tungsten, on account of the in-
ility of this last substance. Mr. Hat-
gives the following order of different
ls arranged as they diminish the duc-
of gold: Bismuth, lead, antimony,
ic, zinc, cobalt, manganese, nickel, tin,
platina, copper, silver. The first
e were nearly equal in effect; and the
na was not quite pure.

r the purposes of coin Mr. Hatchett
iders an alloy of equal parts of silver
copper as to be preferred, and copper
e as preferable to silver alone.

Gold is found mostly in the metallic state, though generally alloyed with silver, copper, iron, or all three. It is found either in separate lumps, or visible grains, among the sands of rivers in many parts of Europe and elsewhere. The quantity is for the most part insufficient to pay the cost of separating it; but it is thought to be more universally diffused in sands and earths than any other metal, except iron. The greatest quantity of gold is imported into Europe from South America. Some is brought from the East Indian islands and China, and some from the coast of Africa. The principal gold mines in Europe are those of Hungary. Some sands afford gold by simple washing; the heavy metallic particles subsiding soonest: but when it is bedded in earths or stones, these substances are pounded, and boiled with one tenth of their weight of mercury together with water. The mercury, after a certain time, absorbs the gold, and may be separated by pressure through leathern bags, and subsequent distillation. Or otherwise, if the sand be heated red-hot, and quenched in water several times, for the purpose of cracking and dividing it, and the whole be then melted into glass, with twice its weight of the oxide of lead called litharge, and charcoal powder be then added, the lead will be revived in the metallic state, and will carry the gold along with it. By exposure to a proper degree of heat, with access of air, the lead may again be converted into litharge, and the gold will be left pure. This last operation is, in fact, a method of assaying sands which contain gold, rather than of obtaining it from them in the large way.

Gold is also found in certain martial pyrites in Sweden and elsewhere; from which it may be extracted by torrefaction or burning of the sulphur, and subsequent digestion in aqua regia.

To obtain gold in a state of purity, or to ascertain the quantity of alloy it may contain, it is exposed to a strong heat, together with lead, in a porous crucible. This operation is called cupellation.

After gold has passed the cupel, it may still contain either of the other perfect metals, platina or silver. The former is seldom suspected; the latter is separated by the operations called quartation and parting. For all these operations see **Assay**.

The quantity of alloy is never considered as part of the value of metals which contain either gold or silver. In estimating or expressing the fineness of gold, the whole mass spoken of is supposed to weigh twenty-four carats of twelve grains each, either real or merely proportional, like the assayer's weights; and the pure gold is called fine. Thus, if gold be said to be twenty-three-carats fine, it is to be understood that, in a mass weighing twenty-four carats, the quantity of pure gold amounts to twenty-three carats.

In such small works as cannot be assayed by scraping off a part, and cupelling it, the assayers endeavour to ascertain its quality or fineness by the touch. This is a method of comparing the colour and other properties of a minute portion of the metal, with those of certain small bars whose composition is known. These bars are called touch-needles; and they are rubbed upon the black basaltes, which, for that reason, is called the touchstone. Black flint, or pottery, will serve the same purpose. Sets of golden needles may consist of pure gold; pure gold 23½ carats with half a carat silver; 23 carats gold with one carat silver; 22½ carats gold with 1½ carat silver, and so forth, till the silver amounts to four carats, after which, the additions may proceed by whole carats. Other needles may be made in the same manner, with copper instead of silver; and other sets may have the addition, consisting either of equal parts silver and copper, or such proportions as the occasions of business require.

In foreign countries, where trinkets and small work are required to be submitted to the assay of the touch, a variety of needles are necessary; but they are not much used in England. They afford, however, a degree of information, which is more considerable than might at first be expected. The attentive assayer not only compares the colour of the stroke made upon the touchstone by the metal under examination with that produced by his needle, but will likewise attend to the sensation of roughness, dryness, smoothness, or greasiness, which the texture of the rubbed metal excites, when abraded by the stone. When two strokes, perfectly alike in colour, are made upon the stone, he may then wet them with aqua fortis, which will affect them very differently, if they be not similar compositions; or the stone itself may be made red-hot by the fire or by the blowpipe, if thin black pottery be used, in which case the phenomena of oxidation will differ according to the nature and quantity of the alloy.

Gold ores may be assayed in the moist way by pounding them very fine, weighing a determinate portion, and attempting their solution in nitric acid, which will dissolve the matrix if it consist of calcareous earth; or if it be sulphat of lime the powder may be digested in aqua regia as long as any metallic substance is taken up; after which the gold may be precipitated by an addition of sulphat of iron, which will cause it to fall down in the metallic state.

The principal use of gold is, as the medium of exchange in coin, for which it has been chosen to occupy the first place, on account of its scarcity, its great weight, and its not being subject to tarnish. The gold coins of Great Britain contain eleven parts of gold, and one of copper.

Gold is likewise used in gilding. See GILDING.

The other uses of gold, in laces, &c. are sufficiently known.

GOULARD'S EXTRACT. A saturated solution of acetat of lead. See LEAD.

GRANITE, a compound rock, consisting of quartz, feltspar, and mica, and occasionally hornblende, steatites, garnet, or basaltes. It is seen among the paving stones of London, consisting of quartz of a white colour, a reddish feltspar, and black or violet shoerl. The parts of granite are so well adapted to each other, that Mr. de Saussure concludes it to have been the product of confused crystallization.

The granite is called moorstone in English. The proportion and size of its component parts are extremely variable, as well as their colour. The quartz, feltspar, and mica, constitute the hardest sort of granite, the most anciently known. That into which the shoerl enters is more subject to decomposition. The granite never has any particular texture or regular form, but consists of enormous shapeless masses, of great hardness.

In the finer granites, the quartz is transparent; in others, generally white or gray, violet or brown. The feltspar, white, yellow, red, green, or black, is generally the most copious ingredient. The mica is also gray, brown, yellow, green, red, violet, or black, and is commonly least copious. The shoerl is generally black, and abounds in the granites that contain it.

Hence the colour of granites chiefly depends on that of the spar or shoerl. The red granites consist commonly of white quartz, red feltspar, and gray mica. The gray, of white quartz, gray or violet feltspar, and black mica. The black commonly contain shoerl instead of feltspar; and the green commonly contain green quartz.

The globular granite of Casica is composed of crystals of hornblende, feltspar, quartz, and mica; in which are immersed spheroids, an inch and a half or two inches in diameter, composed of concentric alternate coats of quartz and hornblende.

If granite be exposed to flame urged by a blowpipe, its different concretions separate from each other. In a crucible, Mr. Gerhard found the feltspar of a piece of granite melted into a transparent glass; under it the mica lay in the form of a black slag, and the quartz remained unaltered. But when all three were powdered and mixed, it melted somewhat better; yet still the quartz may be distinguished by the help of a lens. This well explains why small white grains are frequently found in lavas. The experiments of Messrs. d'Arcet and Saussure perfectly coincide on this subject.

The mixture of mica prevents the silex or quartz from cracking or splitting: and

e its infusibility and advantageous .use
rnaces.

he granitone, mentioned by Ferber, in
Letters from Italy, is a stone composed
eltspar and mica. A substance of this
, which moulders by being long ex-
d to the air, is found in Findland: it
id to contain sometimes saltpetre, and
etimes common salt. It is there called
kivi.

RANULATION. The method of dividing
llic substances into grains or small
icles, in order to facilitate their combi-
n with other substances, and some-
s for the purpose of readily subdividing
by weight.

the entire metals cannot be pulverised,
use not sufficiently brittle, and as the
anical subdivision of their parts is at-
d with considerable labour and diffi-
, recourse is generally had to fusion;
he subdivision is made at the instant of
elation. This is done either by pouring
nelted metal into water, or by agitating
a box until the moment of congelation,
hich instant the whole becomes con-
d into a powder. These different pro-
s are preferable the one to the other,
ding to the nature of the metallic sub-
e. Thus gold, silver, copper, or iron,
ot be granulated by agitation; not only
use the great heat required for their
n would be productive of inconve-
ce, but likewise because they possess a
t degree of tenacity, when heated al-
to melting. Lead, tin, and brass, on
contrary, are very brittle when heated,
are therefore best granulated in this

rious contrivances are used to prevent
er, and insure success, in the several
factories that require granulation.
er is granulated for making brass, by
ng it through a perforated ladle into
ered vessel of water with a moveable
bottom. A compound metal, consist-
hiefly of lead, is poured into water
gh a perforated vessel of another
for making small shot, in which the
t above the surface of the fluid is said
uire particular adjustment. But in a
anufactory of this kind, we understand
he height is very great, being upward
hundred feet.

AVITY, a term used by physical
s to denote the cause, by which all
move toward each other, unless pre-
l by some other force or obstacle. Its
on the motions of the celestial bodies
plained by astronomical writers. The
familiar effect, and that which con-
y obtrudes itself on our notice, is the
t of bodies, or their tendency toward
ntre of the earth. Though the phe-
a arising from the weight of bodies
he basis of a separate science, called
nics, yet they are of great consequence to the chemist. It has not been ascertained, or rendered probable, that gravity is a secondary property of matter; that is to say, that it flows from any of the other known original properties. Sir Isaac Newton, however, was of opinion, that our reasonings on the subject might be simplified, by supposing it to depend on a prodigiously elastic and rare fluid, by him called ether, and assumed to possess an increasing degree of condensation, in parts of space more and more remote from the various masses of matter. According to this doctrine, a falling body moves, because it is pressed toward the rarer parts of this extended fluid. We shall leave this theory to its merits, as being neither very perspicuous, nor much related to our subject. Bergman and others have considered the chemical and cohesive attractions to be one and the same with the attraction of gravity; but modified in its laws, by variations in the masses, densities, and distances of the particles of bodies. Many difficulties appear at first sight to offer themselves against this supposition. But in truth it cannot be examined at first sight; and requires to be submitted to the rigour of mathematical investigation. I do not know that any attempt of this nature has been made. See ATTRACTION.

GRAVITY (SPECIFIC). Boyle is among the first of our philosophers, who suggested the advantage, that chemistry and mineralogy might derive from an attention to the specific gravities of bodies. Much advantage may indeed be derived from this property in the general determination of the classes of minerals, and the purity of some metallic bodies; and it is very probable, that an attention to the specific gravities, capacities for heat, fusibilities, volatilities, laws of crystallization, elasticity, hardness, tenacity, malleability, and some other obvious specific properties of bodies, may produce a more intimate acquaintance with the mutual actions of their particles, than any we have hitherto acquired.

Annexed to this article is a table of specific gravities. In compiling this, I had Brisson's table at the end of Lavoisier's Traité Elémentaire de Chimie, and Muschenbroek's large table in his Cours de Physique, before me. Some few specific gravities are from other authors, or from experiment. It appeared useless to carry it to more than four places of figures, as the temperatures were not noted; and the various specimens of the same substance often differ in the third figure. These assertions may be thought to require proof: for which reason I shall observe, that, by experiment, I find that the fifth figure changes in water at every three degrees of Fahrenheit's thermometer; that lead, tin, and probably all other metals, though cast out of the same fusion, will vary in their specific gravities in the third figure, from circumstances not yet determined, but most likely from the cooling, as is seen in the hardening of steel; that salts, and other artificial preparations, retain more or less of the solvent they were separated from, according to the temperature at which the crystallization was effected; and that all parts of organized substances not only differ according to the place of their production, their age, and other circumstances, but likewise from their dryness, moisture, and manner of preservation.

The specific gravity of solids is determined by weighing them first in air, and then in water. The loss of weight, arising from the action of the water, is equal to that of a mass of the fluid possessing the same dimensions as the solid itself. Whence it is easy to construct a general table of specific gravities, by reducing the proportion of the absolute weight to the loss sustained by immersion, into terms of which that expressing water shall be unity. If the solid be so light as to float upon water, it is convenient to attach to it a heavier body sufficient to cause it to sink, but the weight of which in water must be added in computing the loss. The specific gravity of fluids is ascertained by weighing a known body immersed in them. For the loss by immersion will accurately show the weight of the same bulk of the fluid; and, consequently, the proportion of these several quantities to the loss the same solid sustained in water, being reduced as in the other case to the common standard of unity, will exhibit the specific gravity. Other methods are likewise used in experiments with fluids. Thus equal bulks of different fluids may be weighed by filling a small bottle with a ground stopper with each respectively, and from their several weights the weight of the bottle and stopper must be deducted. Or otherwise, the instrument called the hydrometer may be used. See HYDROMETER. This possesses the advantage of portability, speed, and a degree of accuracy not easily obtained by the use of ordinary balances.

or the specific gravities of different ds of elastic fluids, see the table at the of the article Gas.

Great Work. A process for converting ransmuting metallic substances into gold. emistry possesses no facts tending to w, that any of the metals are convertible o each other; neither do we know of y, which evince the absurdity of suppo- g such a conversion to be possible. The hemists were doubtless misled, either by desire of profit, or by the effect of a delusive phenomena, or specious gene- reasonings, adapted to the infant state chemistry. These hopes, these facts, and se reasonings, have not yet entirely lost eir force with the ignorant. But the ongest terms are insufficient to describe deplore the situation of those, who may ect their exertions to a pursuit so much culated to agitate and distress the mind, d possessing so little probability of success, the great work of the alchemists.

Gritt-stone. A stone consisting of nd agglutinated together. Its properties fer according to the fineness or coarseness its grain, and the firmness of its texture. me kinds are pounded, to convert them ain into sand; others are used for build- g, others for grinding edge tools, and hers for filtering water.

Growan. A Cornish mine term used to note a compound stone, consisting of hite clay mixed with mica, quartz, and of particular texture.

Guaiacum. A resinous substance exud- g from incisions in a tree, the wood of hich is known by the name of *lignum vitæ*. xternally it is of a green hue, tinged with d; but when powdered is gray. This owder changes to a green when acted upon by air and light. The powder has a pleasant balsamic smell and not much taste, though when swallowed it excites a burning sensation in the throat. When heated it melts, and diffuses a pungent aromatic smell. Its specific gravity is 1·2289. Exposed to distillation, 100 grains afforded acidulated water 5·5; thick brown oil, becoming turbid on cooling, 24·5; thin empyreumatic oil, 30; coal, 30·5; mixed gasses, consisting chiefly of carbonic acid and carburetted hidrogen, 9. The coal yielded 3 grains of lime.

From the action of different solvents, Mr. Brandé observes, it differs from resins in affording a portion of vegetable extract; by being converted into a more perfect resin by the addition of oxigen, which may be imparted to it by nitric acid not used in too large proportion; by yielding oxalic acid; and by the quantity of charcoal and lime obtained from it.

One hundred grains of guaiacum give out about nine to water, and about ninety-five to alcohol. Ether does not dissolve so much as alcohol. It is soluble in alkalis, and their carbonats. Two ounces of a saturated solution of caustic potash took up 65 grains; the same quantity of liquid ammonia 25 grains.

Formerly guaiacum was much commended in siphilis and other complaints; at present it is used chiefly in rheumatism, dissolved in liquid ammonia.—*Phil. Trans.*

Guano. A substance found on many of the small islands in the South Sea, which are the resort of numerous flocks of birds, particularly of the ardea and phœnicopteros genus. It is dug from beds 50 or 60 feet thick, and used as a valuable manure in Peru, chiefly for Indian corn. It is of a dirty yellow colour, nearly insipid to the taste, but has a powerful smell partaking of castor and valerian. According to the analysis of Fourcroy and Vauquelin, about one fourth of it is uric acid partly saturated with ammonia and lime. It contains likewise oxalic acid, partly saturated with ammonia and potash; phosphoric acid combined with the same bases and with lime; small quantities of sulphat and muriat of potash and ammonia; a small portion of fat matter; and sand, partly quartzose, partly ferruginous.—*An. de Chim.*

GUHR. A loose calcareous earth found in the clefts or cavities of rocks, mostly of a white colour, but sometimes red or yellow, from a mixture of clay or ochre.

GUM. The mucilage of vegetables. It is usually transparent, more or less brittle when dry, though difficultly pulverable; of an insipid, or slightly saccharine taste; soluble in, or capable of combining with water in all proportions, to which it gives a gluey adhesive consistence in proportion as its quantity is greater. It is separable, or coagulates by the action of weak acids; insoluble in alcohol, or in oil; and capable of the acid fermentation, when diluted with water. The destructive action of fire causes it to emit much carbonic acid, and converts it into coal without exhibiting any flame. Distillation affords water, acid, a small quantity of oil, a small quantity of ammonia, and much coal.

These are the leading properties of gums, rightly so called; but the inaccurate custom of former times applied the term gum to all concrete vegetable juices, so that in common we hear of gum copal, gum sahdarach, and other gums, which are either pure resins, or mixtures of resins with the vegetable mucilage.

The principal gums are, 1. The common gums, obtained from the plum, the peach, the cherry-tree, &c.—2. Gum Arabic, which flows naturally from the acacia in Egypt, Arabia, and elsewhere. This forms a clear transparent mucilage with water.—3. Gum Seneca, or Senegal. It does not greatly differ from gum Arabic: the pieces are larger and clearer; and it seems to communicate a higher degree of the adhesive quality to water. It is much used by calico-printers and others. The first sort of gums are frequently sold by this name, but may be known by their darker colour.—4. Gum Adragant or Tragacanth. It is obtained from a small plant of the same name growing in Syria, and other eastern parts. It comes to us in small white contorted pieces resembling worms. It is usually dearer than other gums, and forms a thicker jelly with water.

Mr. Willis has found, that the root of the common blue bell, hyacinthus non scriptus, dried and powdered, affords a mucilage possessing all the qualities of that from gum arabic. The roots of the vernal squill, white lily, and orchis, equally yield mucilage. Lord Dundonald has extracted a mucilage also from lichens. See LICHEN.

Gums treated with nitric acid afford the acid of sugar.

GUM (ELASTIC). See CAOUTCHOUC.

GUM RESIN. Vegetable juices consisting of a mixture of gum and resin, or essential oil. These parts do not appear to be in a state of combination, for no menstruum completely dissolves the whole. If water be applied, by the assistance of trituration, the gummy matter is completely dissolved; and the resin, being suspended in a state of minute division, exhibits the emulsive form. Alcohol in like manner takes up the resinous matter; and the gum, for similar reasons, gives opacity to the fluid.

Macquer observes, that, since the gum resins consist of principles not truly combined with each other, the compound must be opake; and he therefore lays it down as a rule, that all transparent vegetable concretes are either pure gums, or pure resins.

The principal gum resins are frankincense, scammony, assafœtida, aloes, gum ammoniac, and gamboge.

GUNPOWDER. This well-known powder is composed of seventy-five parts, by weight, of nitre, sixteen of charcoal, and nine of sulphur, intimately blended together by long pounding in wooden mortars, with a small quantity of water. This proportion of the materials is the most effectual. But the variations of strength in different samples of gunpowder are generally occasioned by the more or less intimate division and mixture of the parts. The reason of this may be easily deduced from the consideration, that nitre does not detonate until in contact with inflammable matter; whence the whole detonation will be more speedy, the more numerous the surfaces of contact. The same cause demands, that the ingredients should be very pure, because the mixture of foreign matter not only diminishes the quantity of effective ingredients which it represents, but likewise prevents the contacts by its interposition.

The nitre of the third boiling is usually chosen for making gunpowder, and the charcoal of light woods is preferred to that of those which are heavier, most probably because this last, being harder, is less pulverable. An improvement in the method of making the charcoal has lately been adopted, which consists in putting the wood, cut into pieces about nine inches long, into an iron cylinder laid horizontally, closed at one end, and furnished with small pipes at the other, that the pyroligneous acid and carburetted hidrogen may escape, and thus exposed to the heat of a fire made underneath. It is said, this charcoal improves the strength of gunpowder so much, that only two thirds of the old charge of gunpowder for ordnance are now used in our navy. The requisite pounding of the materials is performed in the large way by a

in which wooden mortars are dis-
in rows, and in each of which a pestle
ved by the arbor of a water-wheel:
ecessary to moisten the mixture from
o time with water, which serves to
nt its being dissipated in the pulveru-
orm, and likewise obviates the danger
plosion from the heat occasioned by
lows. Twelve hours pounding is in
al required to complete the mixture;
hen this is done, the gunpowder is in
ade, and only requires to be dried to
r it fit for use.

ferent modes of trying gunpowder
been adopted. A ready one is, to lay
three small heaps on separate pieces
ting paper, and fire one with a red
ire. If the flame ascend quickly, with
l report, leaving the paper free from
specks, and not burnt into holes;
the same time the other heaps be
ed by the sparks, the powder is well
and the ingredients are good.

re are experiments which seem to
that gunpowder is stronger in the fine
able form, than when granulated.
ppears to be true with regard to gun-
er originally made, or pounded till it
es that form; but it may be doubted,
er it have any foundation in general,
eed that the greater strength depends
upon this form. The granulation of
owder is performed by placing the
while in the form of a stiff paste, in a
sieve, covering it with a board, and
ing the whole: by this means it is cut
mall grains or parts, which, when of
isite dryness, may be rendered smooth
ssy by rolling them in a cylindrical
or cask. Gunpowder in this form
fire more speedily than if it be after-
reduced to powder, as may be easily
nted for from the circumstance, that
flammation is more speedily propagated through the interstices of the grains. But the process of granulation does itself, in all probability, weaken the gunpowder, in the same manner as it is weakened by suffering it to become damp; for, in this last case, the nitre, which is the only soluble ingredient, suffers a partial solution in the water, and a separation in crystals of greater or less magnitude; and accordingly the surfaces of contact are rendered less numerous.

The detonation of gunpowder has been always an interesting problem in chemistry. Numerous theories have been offered, to account for this striking fact. But it is now very well settled, that the nitric acid is decomposed by the heat of ignition; that its oxigen combines with the charcoal, and forms carbonic acid, while the nitrogen, or other component part, with steam from the water of crystallization, becomes disengaged in the elastic form. Berthollet found, that the elastic product, afforded by the detonation of gunpowder, consisted of two parts nitrogen gas, and one carbonic acid gas. The sudden extrication and expansion of these airs are the cause of the effects of gunpowder.

The muriat afforded by combining the oxigenized muriatic acid and potash, affords gunpowder of much greater strength than the common nitre, but too dangerous for use. For the method of making this salt, see ACID (MURIATIC, OXIGENIZED).

GYPSEOUS EARTH, OR GYPSUM. A combination of lime with sulphuric acid. As this salt requires about five hundred times its weight of water to dissolve it, the earlier chemists reckon it among the earths. But as its component parts and properties are now well known, gypsum is at present considered as a salt by chemists. See ACID (SULPHURIC).

H.

R. Mr. Vauquelin boiled hairs in wa-
for several days without being able
olve them; yet the water contained a
uantity of animal matter. He effected
olution, however, without any alte-
in Papin's digester, by regulating
gree of heat. In this operation, if the
carried beyond a certain point, the
ill be wholly or partly decomposed;
own by the ammonia, carbonic acid,
npyreumatic fetid oil, which is found
solution, to which the oil imparts a
ellow colour. He likewise dissolved
water, containing merely 4 per cent.
stic potash.

n numerous experiments Mr. Vau-
infers, that black hair is formed of
ifferent substances, namely:
an animal matter, which constitutes the greater part; 2. A white concrete oil in small quantity; 3. Another oil of a grayish green colour, more abundant than the former; 4. Iron, the state of which in the hair is uncertain; 5. A few particles of oxide of manganese; 6. Phosphat of lime; 7. Carbonat of lime, in very small quantity; 8. Silex, in a conspicuous quantity; 9. Lastly, a considerably quantity of sulphur.

The same experiments show, that red hair differs from black only in containing a red oil instead of a blackish green oil: and that white hair differs from both these only in the oil being nearly colourless, and in containing phosphat of magnesia, which is not found in them.

From this knowledge of the nature of the constituent principles of hair, Mr. Vauquelin thinks we may account for the various colours that distinguish it. According to him, the black colour will be owing to a black and as it were bituminous oil, and perhaps likewise to a combination of sulphur with iron. Carroty and flaxen hair will be occasioned by the presence of a red or yellow oil, which when deepest, and mixed with a small quantity of brown oil, produces the dark red hair. Lastly, white hair is owing to the absence of the black oil and sulphuretted iron. He believes, that in the carroty and flaxen, as well as in the white, there is always an excess of sulphur; since, on the application of white metallic oxides to them, such as those of mercury, lead, bismuth, &c., they grow black very speedily. The manner in which this substance acts on metallic bodies leads him to suspect, that it is combined with hidrogen.

Mr. Vauquelin attempts next to explain the whiteness produced suddenly in the hair of persons struck with profound grief or great terror. We must suppose, he says, that in these critical moments, when nature undergoes a revolution, and the natural functions are in consequence suspended or changed, some agent is developed in the animal œconomy, which, passing into the hair, decomposes the colouring matter. But what agent can produce this effect? The acids alone appear capable of it; at least this is certain, black hair immersed some time in them, particularly in the oxigenized muriatic, whitens very evidently.

The rapid production of an acid in the animal œconomy does not appear to him impossible, considering that a fit of anger in men, as well as in inferior animals, is sufficient to change the nature of certain of their fluids, and render them venomous; and seeing that the galvanic fluid frequently occasions the formation of an acid or an alkali, according to circumstances, both in animal and vegetable substances. As to the whiteness produced gradually by age, he ascribes this to a deficient secretion of colouring matter.

In hair, exclusive of the animal matter that forms its basis, and which is the same in all, there is a colouring matter, that may be separated from it, and the hue of which varies according to the kind of hair of which it constitutes the distinction. To this fatty substance Mr. Vauquelin attributes the suppleness, elasticity, and unalterability, which exist in hair: to this substance too is owing no doubt the property it has of burning so rapidly, and that of forming soap abundantly with alkalis.

After having treated of the colouring matters of hair, he endeavours to characterize the animal matter, that forms its substance, and this appears to him to be mucus.

This humour, which is secreted in the nostrils, mouth, œsophagus, trachea, stomach, bladder, and all the cavities of the body in general, imparts to water a considerable viscosity, and the property of frothing greatly on agitation. In certain species of coryza it may be drawn out into threads like the substance of silk, or the web of the spider; retains its transparency and flexibility after desiccation; and Mr. Vauquelin has no doubt, that it would perfectly resemble hair, if it contained a little oil.

The epidermis, nails, horns, wool, and hair of beasts in general, are formed of the same animal mucus, and equally include in their composition a certain quantity of oil, which imparts to them the suppleness and elasticity they are known to possess.

Mr. Vauquelin has begun an examination of the humour of the *plica polonica*, with which he was furnished by Mr. Alibert, physician to St. Lewis's Hospital; and from what he has done, he is led to believe, that it is of the same nature as the substance of the hair, but secreted in greater quantity than the formation of the hair requires.—*An. de Chim.*

HARDNESS may be defined as that property of bodies by which they resist indentation. It differs from tenacity, which is the opposite quality to frangibility, whereas hardness is the opposite quality to softness, or the disposition which the parts of a solid body possess of easily yielding without fracture. Chemists and others usually ascertain the comparative hardness of bodies by rubbing the one against the other; any angular prominence of a harder body being capable of scratching or making a mark upon the surface of a softer. This is not a bad method, though it may be rendered uncertain by the greater or less brittleness of the respective bodies. Thus hardened steel will scratch glass, and will in return be scratched by glass; the brittleness of the glass causing it to yield under the steel, which is more tenacious, though softer. On this principle likewise it is, that the keenest edge tools, and those best calculated to cut hard bodies, are not hardened to the highest temper the steel is capable of, but to such a degree only as to retain much tenacity with a moderate hardness.

The mechanical philosophers, at the beginning of the present century, accounted for the hardness of bodies, by supposing their particles to be of such a form as to apply to each other with large surfaces of contact. This doctrine seems in some measure to be true, when applied to the crystals of bodies on their assumption of the solid form. Sugar-candy, or the more slowly formed crystals of sugar, are harder (or perhaps less brittle) than loaf sugar, in which the same small crystals are more confusedly applied to each other: calcareous spar is harder than chalk, &c. But how far this doctrine may apply to the hardness arising from the hasty crystallization of steel and other bodies by immersion in water, remains to be settled by future researches.

. Kirwan, in his Mineralogy, has ex-d the hardness of the different species ones, as ascertained by Mr. Quist, by npression made on each other. In the ving table the stones, which stand first, ole to scratch or cut the succeeding, not vice versa; and such stones, the ness of which does not exceed 11, may ratched by steel. The first column es the hardness, and the second the fic gravity.

AT. The sensations expressed in com-anguage by the words heat and cold-re of too simple a nature to require or nit of definition. These words, how-are not always used to denote the same ; but are indiscriminately applied to the sensation itself, and to that causes it. Thus, we say, that we lves are hot or cold; and that the fire which heats or cools us, is likewise cold, though the sensations we expe- are certainly very different things that which enables bodies to excite

It may also be remarked, that, in nbiguous manner of speaking, there is er cause of uncertainty, that arises the use of a variable standard of com-n. Every one knows, that the esti-n of heat or coldness differs in various ns, because each forms his judgment his own sensations; and the same body ppear hot to one person, and cold to er, or to the same person at different ; though the variation is not in the body itself, but in the state of the person in whom these sensations are excited. Hence it appears necessary, in order to avoid error in the pursuit of inquiries concerning heat, that the sense of the words made use of should be accurately defined, and that some fixed standard of comparison be made use of instead of the human body, which, though fixed enough for the common affairs of life, is certainly not enough so for the purposes of science.

The word heat, in a philosophical sense, is used to denote the cause of the power which bodies possess of exciting the sensations of heat or coldness.

The word temperature denotes the state of the body with respect to that power. So that a body which excites a more intense sensation of heat or coldness than another body is said to possess a higher or lower temperature.

It has not yet been determined in what heat itself, or the cause of temperature, consists. Two opinions have long divided the scientific world. One is, that heat consists of a peculiar motion or vibration of the parts of bodies, so that the temperature is higher, the stronger the vibration. The other is, that heat is a substance or fluid, the greater or less quantity of which produces a higher or lower temperature. The decision of this great question is highly deserving of the attention of philosophers. But it will not be necessary to consider its merits in our first steps of investigation, because the doubts respecting it will not impede our reasoning concerning such phenomena as are well known. For since effects are proportioned to their causes, we may speak of the quantities of heat in bodies, without deciding whether they be quantities of motion or quantities of matter; the relation of these quantities to each other, and not their peculiar nature, being the chief object of our research.

That heat is actually matter, however, which was an opinion held by some in very ancient times, is now pretty generally maintained; and it is as generally distinguished by the name CALORIC. To that article, therefore, we refer, for what is at present known on the subject: the facts being the same, whether we understand by it a peculiar substance, or a power of producing certain effects.

HEDERÆ (GUM). Lemery says, that this gum exsudes from incisions made in the hedera arborea, or tree ivy, whence it is collected by the peasants in Italy, Provence, and Languedoc. The account is confirmed by Pomet; but Neumann, from unsuccessful inquiries made on his own travels, is disposed to consider the account as doubtful, though he learned, that it was the produce of Sicily and the kingdom of Naples.

This gum resin, when genuine, is of a bright transparent reddish brown colour, deeper than the hyacinth, and approaching to the garnet; when reduced to powder, of a saffron yellow, and of an agreeable aromatic taste and smell. From an ounce of this, Neumann obtained five drachms and a half of resinous extract by solution in alcohol, and of the residue water took up half a drachm, and left two drachms of insoluble residue. When water was applied first to another ounce, it took up two drachms of gummy matter, and of the residue alcohol dissolved three drachms two scruples, and left two drachms and half a scruple undissolved. By distillation with alcohol, the fluid came over with a slight taste of the gum resin. Water distilled from the hederæ was considerably impregnated both with the taste and smell, and brought over a small quantity of essential oil, less hot to the taste than other oils of that class.

Heliotropium, Turnsole. See Archil.

A beautiful siliceous stone likewise, imported lately from Egypt, has been sold under the name of heliotropium. It is of a fine apple-green colour: semitransparent when its thickness does not exceed half an inch: spec. grav. 2·708: sufficiently hard to strike fire with steel, but capable of being scratched by the point of a good penknife. Its fracture is even and sharp.

By Mr. Accum's analysis 500 grains give silex 365; alumine 20·25; oxide of iron 29·25; lime 56·5; water 24.—*Nich. Journ.*

Hellebore. Two ounces of the root of white hellebore yielded with water nine drachms and one scruple of gummy extract; and the same quantity of root yielded with alcohol seven drachms of resinous extract. The powder of this root is a violent sternutatory. It is sometimes mixed in external applications for destroying cutaneous insects. Internally it operates with great violence both upward and downward, but on account of its acrimony is now never given.

From six ounces of the roots of black hellebore, six drachms and one scruple were extracted by alcohol; and from the same quantity of root, six drachms and two grains were extracted by water. Borrichius relates, that the distilled water of the entire plant possesses emetic and purgative virtues. The root is a stimulating cathartic. —*Neumann.*

Hepar. The combination of sulphur with an alkali was formerly denominated Hepar Sulphuris, or Liver of Sulphur, from its brown-red colour. Chemists have applied the term *hepar* in a general way to all combinations of alkali or earth with sulphur or with phosphorus.

Hepatic Air. See Gas (Hidrogen, Sulphuretted).

Hidrargillite. This fossil was found many years ago, in a quarry near Barnstaple, by Dr. Wavell. It is commonly in small hemispherical groups of crystals, white, sometimes with a tinge of gray, green, or yellow. Its texture is loose, but its small fragments are hard enough to scratch agate. Spec. grav. about 2·7. Some specimens are semitransparent. Its component parts, as analysed by Mr. Davy, are alumine ·70, lime ·014, water ·262. The loss ·024 Mr. Davy thinks should be added to the water. There was a very small quantity of acid in the water, which Mr. Davy afterward found to be the fluoric, in such a state of combination in the stone as not to be rendered sensible by the sulphuric acid.—*Phil. Trans.*—*Nich. Journal.*

Hidrat. This term has been employed by some to express a chemical combination of water, not in the state of moisture, with some other substance.

Hidrocarburet. See Gas (Hidrogen, Carburetted).

Hidrogen. The base of the air formerly called inflammable, which, united with oxigen, composes water. See Gas (Hidrogen).

Hidrogenation. A term implying the act of combining hidrogen with any other substance. It has lately been maintained by some, that metals are susceptible of hidrogenation, as well as of oxigenation, and in different degrees. This is deduced from facts observed in metals exposed to the action of the galvanic pile. The doctrine of Ritter on this subject is, that positive galvanism, and positive electricity, disengage oxigen from water; and negative electricity, or negative galvanism, disengages from it hidrogen. And the negative pole of the galvanic pile disposes metals to combine with the hidrogen of water, as the positive pole does with its oxigen. Silver hidrogenated at a maximum is converted into a gas. If a little vessel of iron or platina filled with mercury be placed in contact with the negative pole, and the surface touched with the positive conductor, a point or circle of a powder very different from the black oxide of mercury is produced.

Hidroguretted Sulphuret. Supersulphuretted hidrogen combined with a base. See Sulphur.

Homberg's Phosphorus. The combination of lime and muriatic acid, which remains after distilling the volatile alkali from sal ammoniac, has usually an overproportion of lime. If it be urged by a violent heat it fuses; and when cold it has the property of emitting a phosphoric light, when struck with any hard body. It is called Homberg's phosphorus, from the name of the first observer of the fact.

Honey. Honey is contained in a peculiar organ of plants, called the nectary, which is commonly attached to some of the parts of fructification. It serves as food for most insects which have a proboscis. It appears to consist of sugar, mucilage, and water. The sugar sometimes separates in crystals. Alcohol too separates crystals from it, particularly from that which has a

ulous appearance; but these, according
Proust, are less sweet than common
r.

oney is supposed to have undergone no
ation in the body of the bee, as it re-
the odour, and not unfrequently the
ities, of the plants it was gathered from;
at it is sometimes deleterious, in the less
vated parts of North America, where
onous shrubs abound. Dioscorides and
y mention the same fact.

hirty-six ounces of honey, diluted with
quarts of warm water, and fermented
a little yeast, yielded on distillation a
of watery spirit, which by rectification
reduced to eight ounces.

oofs of Animals. The hoofs of ani-
are composed of a substance nearly of
ame nature as Horn; which see. They
ot applied to any use, but to afford
onia and animal coal, in the prepara-
of the prussiat of potash, and in the
hardening of iron.

ops. It is universally taken for granted,
hops render beer less liable to change
become sour. Neumann affirms the
thing, and that they sensibly increase
pirituosity. It is well known, that the
atic bitter of the hop is an agreeable
probably a wholesome addition to beer:
the rest remains yet to be proved by
eriment.

orn. Among the consistent parts of
nals, we observe a resemblance in the
eral properties of such as appear to be
sted of sensation, namely, the bones,
ns, hoofs, hair or wool, and epidermis.
e bony substances are very hard, and
ear to consist of much phosphat of lime,
ther with about one sixth of their weight
roper jelly or glue, soluble in hot water
ell as cold. Ivory, which is softer, con-
about one fourth of its weight of glue.
tshorn, which approaches as much to
nature of bone as horn in its obvious
erties, affords about one fifth, and skin
ears to afford most of all. Horn affords

s to the gelatine in it being combined
a considerable portion of oxigen. This
tance differs from bone in its remark-
elastic flexibility, and the softness it
ires by a moderate heat.

acquer asserts, that horn may be en-
y converted into jelly, by treatment
water, in Papin's digester. What hap-
in this process requires to be examined.
mann found, that twenty-five grains of
xtract, of a brownish colour and saline
, were obtained by boiling half an
ce of cow's horn in water. When treated
e dry way, horn affords the same pro-
s nearly as other animal matters, namely,
queous alkaline liquor, concrete vola-
alkali, and a fetid oil, which, by re-
ed rectifications, becomes more and
e limpid and clear.

Tortoiseshell and whalebone appear to be nearly of the same nature as horn.

Hornblende, or Hornstone. This forms the tenth species of the argillaceous genus of Kirwan's System of Mineralogy. Its general characters, beside a partial solubility in acids, without effervescence, and a hardness never sufficient to strike fire with steel, are, 1. a specific gravity, never less than 2·66, and in many specimens as high as 3·88; 2. a strong earthy smell, when breathed upon, or wetted with hot water; 3. a toughness when pounded in a mortar, resembling that of mica, or horn, from which property it obtained its name; 4. its affording a greenish gray powder, when pulverized; 5. fusibility without addition, as it is said, though Mr. Kirwan could not fuse it with the blowpipe. It is frequently mixed with pyrites. Of this species the author reckons three varieties.

Hours (Mineralogical). The direction of veins, with respect to the meridian, is in the language of miners denoted by hours. The circle of the horizon is divided into twice twelve hours. The north and south directions are denoted by twelve, and consequently the east and west by six o'clock.

Hyacinth. A stone of an orange red, nearly as hard as rock crystal: specific gravity from 3·687 to 4·62. It refracts the rays of light double. It is fusible with oxigen gas, and loses its colour in the fire. It is now classed with the jargon of Ceylon, as a species of the genus zircon, from the earth of this name being its basis. When it is of a pure bright flame colour, jewellers distinguish it by the epithet of la belle: when it is of a fine deep red, they call it rubicelle, and class it with the rubies. The andreolite was ranked among the hyacinths by Bergman, and called cruciform white hyacinth by Romé de Lisle. The sommite too has been termed a white hyacinth. But neither of these stones contains zircon.

According to Klaproth 100 parts give zircon 70; silex 25; oxide of iron 0·5: according to Vauquelin, zircon 64·5: silex 32; oxide of iron 2. The hyacinth of Expailli gave 1·5 more of zircon, and 1 less of silex. Bergman's analysis of the hyacinth gave alumine 40; silex 25; lime 20; and oxide of iron 13.

Hydrogen, &c. See Hidrogen, &c.

Hydromel. A fermented liquor made of honey and water. It is more commonly known by the name of Mead.

Hydrometer. The best method of weighing equal quantities of corrosive volatile fluids, to determine their specific gravities, appears to consist in inclosing them in a bottle with a conical stopper, in the side of which stopper a fine mark is cut with a file. The fluid being poured into the bottle, it is easy to put in the stopper, because the redundant fluid escapes through the notch, or mark, and may be carefully wiped off. Equal bulks of water, and other fluids, are by this means weighed to a great degree of accuracy, care being taken to keep the temperature as equal as possible, by avoiding any contact of the bottle with the hand, or otherwise. The bottle itself shows with much precision, by a rise or fall of the liquid in the notch of the stopper, whether any such change have taken place. See GRAVITY (SPECIFIC).

But as the operation of weighing requires considerable attention and steadiness, and also a good balance, the floating instrument called the hydrometer has always been esteemed by philosophers, as well as men of business. It consists of a hollow ball, either of metal or glass, capable of floating in any known liquid: from the one side of the ball proceeds a stem, which terminates in a weight, and from the side diametrically opposite proceeds another stem, most commonly of an equal thickness throughout. The weight is so proportioned, that the instrument may float with the last mentioned stem upright. In the less accurate hydrometers this stem is graduated, and serves to show the density of the fluid, by the depth to which it sinks; as the heavier fluids will buoy up the instrument more than such as are lighter. In this way, however, it is clear, that the stem must be comparatively thick, in order to possess any extensive range. For the weight of vitriolic ether is not equal to three fourths of the same bulk of water; and therefore such an hydrometer, intended to exhibit the comparative densities of these fluids, must have its stem equal in bulk to more than one fourth of the whole instrument. If this bulk be given chiefly in thickness, the smaller differences of density will not be perceptible, and it cannot, with any convenience, be given in length.

To remedy this imperfection, various contrivances have been proposed for the most part grounded on the consideration, that a change in the ballast, or weight employed to sink the ball, would so far change the instrument, that the same short range of graduations on a slender stem, which were employed to exhibit the densities of ardent spirit, might be employed in experiments upon water. Some have adjusted weights to be screwed upon the lower stem; and others, with more neatness and accuracy, have adjusted them to be slipped upon the extremity of the upper stem. But the method of Fahrenheit appears to be on all accounts the simplest and most accurate.

The hydrometer of Fahrenheit consists of a hollow ball, with a counterpoise below, and a very slender stem above, terminating in a small dish. The middle, or half length of the stem, is distinguished by a fine line across. In this instrument every division of the stem is rejected, and it is immersed in all experiments to the middle of the stem, by placing proper weights in the little dish above. Then as the part immersed is constantly of the same magnitude, and the whole weight of the hydrometer is known; this last weight added to the weights in the dish, will be equal to the weight of fluid displaced by the instrument, as all writers on hydrostatics prove. And accordingly the specific gravities for the common form of the tables will be had by the proportion:

As the whole weight of the hydrometer and its load, when adjusted in distilled water,
Is to the number 1,000, &c.
So is the whole weight when adjusted in any other fluid
To the number expressing its specific gravity.

In order to show the degree of accuracy an instrument of this kind is capable of, it may in the first place be observed, that the greatest impediment to its sensibility arises from the attraction or repulsion between the surface of the fluid and that of the stem. If the instrument be carefully wiped with a soft clean linen cloth, the metallic surface will be equally disposed to attract or repel the fluid. So that if it possess a tendency to descend, there will be a cavity surrounding the stem; or if, on the contrary, its tendency be to rise, the fluid will stand round the stem in a small protuberance. The operator must assist this tendency, by applying the pincers, with which he takes up his weights, to the rim of the dish. It is very easy to know when the surface of the fluid is truly flat, by observing the reflected image of the window, or any other fit object seen near the stem in the fluid. In this way the adjustment of the weights in the dish may, without difficulty, be brought to the fiftieth part of a grain. If, therefore, the instrument displace 1000 grains of water, the result will be very true to four places of figures, or even to five. This will be as exact as most scales are capable of affording.

Some writers have spoken of the adjustment of an hydrometer of this kind, so that it shall at some certain temperature displace 1000 grains of water, as if this were a great difficulty. It is true, indeed, that the performance of a piece of workmanship of this nature would require both skill and judgment on the part of the artist: but it is by no means necessary. Nothing more is required on the part of the workman, than that the hydrometer shall be light enough to float in ether, and capable of sustaining at least one third of its own weight in the dish, without oversetting in a denser fluid. This last requisite is obtained by giving a due length to the stem beneath, to which the counterpoise is attached. With such an instrument, whatever may be its weight, or uantity of water it displaces, the che- may proceed to make his experiments, deduce his specific gravities by the pro- ion before laid down. Or to save oc- nal computation, he may once for all e a table of the specific gravities, cor- onding to every number of the load in lish, from one grain up to the whole ber of grains, so that by looking for oad in one column, he may always find pecific gravity in the column opposite. l this method very ready and conveni- n practice: but, if it be preferred, the hts may be adjusted to the hydrometer, to show the specific gravity, without utation or reference. For this purpose ydrometer must be properly counter- d in distilled water, at the assumed ard temperature; suppose 60°, and the e weight of the instrument and its load l 1·000, &c. Then the weight of the ment and its load must be separately mined in grains and parts, or other hts, by a good pair of scales. And as vhole weight of the instrument and its is proportioned to the weight of the ment alone; so will be the number , &c. to a fourth term expressing the ht of the instrument in such parts as the whole 1·000, &c. Make an actual f decimal weights (see Balance, § 16, of which 1·000, &c., shall be equal to hydrometer and its load. And it is , that, whatever may be the load in weights, if it be added to the number ting the weight of the instrument, the will denote the specific gravity of the , wherein the instrument floats with load.

following the above easy method it be found, that every hydrometer, esoever made, must give the same re- The subject is indeed in itself suffi- y simple, and would require scarcely liscussion, if it had not happened, that philosophers, for want of requisite tion, have made their experiments with ometers graduated on the stem by no n rule by which operators at a di- e from each other might compare their iments. The hydrometers, or *pese- rs* of Baumé, though in reality com- le with each other, are subject in part e defect, that their results, having no endent numerical measure, require nation to those who do not know the ments. Thus, for example, when a ist acquaints us, that a fluid indicated grees of the *pese-liqueur* of Baumé, we t usefully apply this result, unless we some rule to deduce the correspondent ic gravity: whereas we should not been in any respect at a loss, if the r had mentioned the specific gravity As a considerable number of French ophers refer to this instrument, it will use to explain its principles.

. Baumé appears to have directed his ion chiefly to the acquisition of a means of making hydrometers with a graduated stem, which should correspond in their results, notwithstanding any differences in their balls or stems. There is little doubt but he was led into the method he adopted, by reflecting on that by which thermometers are usually graduated (see Thermometer). As thermometers are graduated, independent of each other, by commencing with an interval between two stationary points of temperature, so Mr. Baumé adopted two determinate densities for the sake of marking an interval on the stem of his hydrometer. These densities were those of pure water, and of water containing $\frac{15}{85}$ parts of its weight of pure dry common salt in solution. The temperature was 10 degrees of Reaumur above freezing, or 54·5° of Fahrenheit. His instrument for salts was so balanced, as nearly to sink in pure water. When it was plunged in this saline solution, the stem arose in part above the surface. The elevated portion was assumed to be 15 degrees, and he divided the rest of the stem with a pair of compasses into similar degrees.

It is unnecessary to inquire in this place, whether this interval be constant, or how far it may be varied by any difference in the purity, and more especially the degree of dryness, of the salt. Neither will it be requisite to inquire how far the principle of measuring specific gravities by degrees representing equal increments, or decrements, in the bulks of fluids, of equal weight but different specific gravities, may be of value, or the contrary. It does not seem probable, that Baumé's instrument will ever become of general use; for which reason nothing further need be ascertained, than the specific gravities corresponding with its degrees, in order that such experiments as have this element among their data may be easily understood by chemical readers.

Mr. Baumé, in his Elemens de Pharmacie, has given a table of the degrees of his hydrometer for spirits, indicated by different mixtures of alcohol and pure water, where, he says, the spirit made use of gave 37 degrees at the freezing point of water; and in a column of the table he states the bulk of this spirit, compared with that of an equal weight of water, as $35\frac{5}{8}$ to 30. The last proportion answers to a specific gravity of 0·842, very nearly. A mixture of two parts, by weight, of this spirit, with thirty of pure water, gave twelve degrees of the hydrometer at the freezing point. This mixture, therefore, contained $6\frac{1}{2}$ parts of Blagden's standard to 100 water; and, by Gilpin's excellent tables, its specific gravity must have been 0·9915. By the same tables, these specific gravities of 0·842 and 0·9915 would, at 10° Reaumur, or 55° Fahr., have fallen to 0·832 and 0·9905. Here then are two specific gravities of spirit corresponding with the degrees 12 and 37, whence the following table is constructed.

Baumé's Hydrometer for Spirits.

Temperature 55° Fahrenheit, or 10° Reaumur.

Deg.	Sp. Grav.	Deg.	Sp. Grav.	Deg.	Sp. Grav.	Deg.	Sp. Grav.	Deg.	Sp. Grav.
10	1·000	17	·949	23	·909	29	·874	35	·842

14	·970	21	·922	27	·886	33	·852	39	·822
15	·963	22	·915	28	·880	34	·847	40	·817
16	·955								

With regard to the hydrometer for salts, the learned author of the first part of the Encyclopédie, Guyton-de-Morveau, who by no means considers this an accurate instrument, affirms, that the sixty-sixth degree corresponds nearly with a specific gravity of 1·848; and as this number lies near the extreme of the scale, I shall use it to deduce the rest.

Baumé's Hydrometer for Salts.

Temperature 55° Fahrenheit, or 10° Reaumur.

Deg.	Sp. Grav.	Deg.	Sp. Grav.	Deg.	Sp. Grav.	Deg.	Sp. Grav.	Deg.	Sp. Grav.

3	1·020	18	1·140	33	1·295	48	1·500	63	1·779
6	1·040	21	1·170	36	1·333	51	1·547	66	1·848
9	1·064	24	1·200	39	1·373	54	1·594	69	1·920
12	1·089	27	1·230	42	1·414	57	1·659	72	2·000

It may not be amiss to add, however, that in the Philosophical Magazine, Mr. Bingley, the assay-master of the mint, has given the following numbers as the specific gravity of nitric acid found to answer to the degrees of an areometer of Baumé by actual trial; temperature about 60° Fahr. But his appears to have been a different instrument, as it was graduated only from 0 to 50°.

Deg.	Sp. Grav.	Deg.	Sp. Grav.	Deg.	Sp. Grav.	Deg.	Sp. Grav.	Deg.	Sp. Grav.

There are a variety of hydrometers used for determining the strength of ardent spirit. See ALCOHOL.

HYDROPHANES. This stone, which is also called oculus mundi, and lapis mutabilis, was formerly of great value. Its distinguishing characteristic is that of becoming transparent by immersion in water. Bergman has written a distinct treatise upon it.

The hydrophanes is either of a whitish brown, yellowish green, milky gray, or yellow colour, and opake. Some specimens give fire with steel. Its specific gravity is about 2·048, and it is easily cut and polished. Without addition, it is infusible; but the flame of the blowpipe changes it into a brown brittle substance. Neither acids nor alkalis have any action upon it in the humid way. Wiegleb and baron Racknitz say it is so soft in the mine, as to receive impressions from hard bodies.

Three of these stones are to be seen in the British Museum in London. The largest is about the size of a cherry-stone, but of an oval form. It is opake, and in colour resembling the common yellow pea. It may be scratched, though not without difficulty, with a knife, but it seems to leave a trace upon common glass. The nitric acid does not cause any ebullition when applied to it.

When it has lain in water some hours it becomes transparent, and of a yellow amber colour. This change begins soon after the immersion, and at one end, in the form of a small spot (but in a small one of the same kind the beginning is round the edges), which increases by slow degrees, till the whole stone has become uniformly clear throughout. When taken out of the water, it loses its transparency, first at one end, and then gradually over the remainder. This change happens in less time than is required to produce the transparency, as might indeed be naturally expected. For the stone cannot become transparent, until ater has soaked through its whole nce; but it becomes opake, as soon ertain thickness from the surface is ried.

ere is no doubt but this phenomenon duced in the same way as oil or water rs paper transparent. It depends on a al principle, which is well explained r Isaac Newton, in his Optics, viz., all porous bodies may be rendered arent, by filling their pores with some matter of nearly the same density. this last case the light passes through ery little impediment or deviation; as it was before subject to reflection efraction at all the surfaces of the r particles, and therefore became ab- and lost. That the hydrophanes s moisture, and emits air, which is a f much less density, is evident from ight it acquires, and the small bubbles cover its surface during the time it es transparency.

se facts evidently show that the effect rom a coarse porosity in the structure stone. It is a general circumstance, ose siliceous stones, which resemble mmon flint in breaking smoothl and y, are frequently surrounded by a ng of coarser material. Bergman these coarser parts were extruded by ntraction of the more homogeneous r, during the gradual transition from ft to the hard state. It is not easy to any notion of a mechanical action of ind; and it seems more probable, that arseness, or rather porosity, of these al crusts may have arisen from the of water, air, or other agents, which a long course of time may have car- some of the parts to a certain depth, e cracked, split, or destroyed the ity to a certain depth, as is seen upon face of broken flints, and other stones d to the weather. These crusts must rily differ in texture, density, and ss; and accordingly it cannot be ex- , that the requisites of the hydro- should be very frequently met with. roper pieces, which are generally nded with such as are useless, cannot inguished by their external appear- but such as do not adhere to the may be rejected. Immersion in water ay will determine their quality, be- uch as require a longer time to be- ransparent are of no value.

ugh it is probable, that the crusts of varieties of siliceous stones may yield drophanous stone, yet experience that it is chiefly to be sought for those of a loose texture, such as opals alcedonies. The opal gives admit- o water, but wants the opacity re- to make the experiment striking. If ndered opake by fire, which must be autiously and gradually applied, it becomes the hydrophanes. Too sudden heat causes it to fly in pieces.

Bergman found the same component parts in the opal and the hydrophanes. He reduced the stone to a very fine powder, and separated 100 grains of the most subtile particles by elutriation. He formed this into a ball, with three times as much mineral alkali, and a little water, and exposed it for an hour and half in an iron vessel to a fire gradually raised, but not to such a degree as to melt the mass. If this last event should happen, which it is difficult to prevent, the fluid becomes loaded with iron, and is so troublesome to analyse, that it is better to repeat the process as at first, but with more care. After a certain time the ball splits again into a powder, by the dissipation of part of the alkali. In this powder the siliceous earth was combined with alkali, and the other earths were rendered much more accessible to acid menstruums, from which the silex might have defended them. By digestion of the powder in muriatic acid he found, that sixteen parts of alumine were taken up, and eighty-four parts of silex remained untouched. There was not the smallest appearance of any lime. Klaproth found in Saxon hydrophanes silex 93·125, and alumine only 1·625, in the hundred parts: the remaining 5·25 he considers as volatile inflammable matter and water.

The value of the hydrophanes is estimated by its bulk, the quickness of the change, and the beauty of its colour. Of two equally penetrable, the larger must be longer in becoming transparent; but the effect may be increased by giving them a flat thin figure. The colour is derived from iron. Hot water produces the effect more speedily than cold. If frequent repetition of the experiment should render the stone less disposed to become transparent on immersion, it will most probably have arisen from calcareous deposition; in which case it may be cleared by immersion in acids. Alkalis, or acids, penetrate this stone, and render it transparent; the concentrated sulphuric acid renders it permanently so, by attracting water from the atmosphere. But the opacity may be restored by immersing it in a hot alkaline liquor. Nitric acid highly concentrated oxides the iron, and alters the colour of this stone, by that means producing various shades of yellow. Bergman thinks, that acids, by dissolving part of the alumine, may improve the quality of such stones as admit the water too slowly.

This stone probably received the name of oculus mundi, from an internal spark, or luminous spot, which changes its position according to the direction of the incident light. Bergman has made the most accurate remarks on this phenomenon, and finds, that it proceeds from the caustic curves and focal image, by refraction from the usual rounded form of the stone, and rendered visible by the semiopacity of the material through which the light passes.

Though this mutability is chiefly found in stones of the siliceous order, yet as it depends upon the mechanism or construction, rather than the component parts, it may naturally be expected to be met with in the other orders. The requisites are, that transparent particles should be so joined, or agglutinated together, as to leave innumerable minute interstices capable of admitting water. This construction is sometimes met with among the steatites. It may easily be understood how this may be rendered transparent, as more than half its weight consists of siliceous particles, frequently pellucid. But the hydrophanous steatites, being loaded with magnesia, seldom acquire the same degree of transparency as those which almost entirely consist of siliceous earth, which are likewise harder, though less beautiful and various in their colours. Dr. Bruckmann, quoted by Bergman, mentions red, white, green, and gray steatites possessed of this property. He directs, that they should be first boiled in an alkaline lixivium, and then in vinegar.

If the hydrophanes be made completely dry, and then steeped in melted wax, or spermaceti, it acquires the property of being rendered transparent by heat. Some years ago a dealer abroad sold such stones as natural curiosities by the name of *pyrophanes*.

Hypericum Perforatum. St. John's wort. Mr. Baunach says, that the tops and flowers of this plant give out a blood red colour to water and alcohol, and a fine bright crimson to vinegar. With the stronger acids it affords a yellow colouring matter. Alum with a little potash is the proper mordant for it: and a bath of water sufficiently impregnated with the juice of this plant, in which there is a due quantity of the mordant, will give a bright yellow to linen, woollen, silk, or cotton. If a larger quantity of the mordant be used, the tint will approach toward green: and the addition of solution of tin will give a rose, cherry, or crimson hue, with a fine lustre. The shade produced, and durability of the colour, depend chiefly on the heat of the bath, the time the stuff is kept in it, and the mordant employed.

If the expressed juice be dried in an oven, powdered, and rubbed with a little turpentine, it may be readily dissolved, either in essential or fat oils. With linseed oil, and a little oil of turpentine, it makes a fine red varnish.

The oil of St. John's wort, made by macerating the flowers in olive oil, was formerly used externally: and the plant itself has been recommended in hysteria.—*Ann. de Chim.*

I.

ICE. Water in the solid state. Mairan observed, that water, in freezing, has a tendency to form angles of sixty degrees, and to form stars with six rays. Romé de Lisle calculates, that the primitive form of ice is an equilateral eight-sided figure. Hassenfratz has observed, that water, when it freezes under favourable circumstances, always assumes a hexahedral prismatic form. This fact is not inconsistent with the deduction of R. de Lisle.

The specific gravity of ice being considerably less than water, it always floats at the surface, where it is most commonly formed, in consequence of the superior coldness of the atmosphere. It may nevertheless be formed at the bottom or side of any vessel, if the temperature be more effectually diminished in those parts than elsewhere, as by a freezing mixture. Ice is sometimes formed at the bottom of running waters, which Hales explains by remarking, that the superior parts of stagnant waters, as also of the earth, are colder in frosty weather than the inferior; but in running waters the uppermost parts are mixed with the lower, and all are cooled nearly alike; and as the water at the surface flows *quicker* than that below, the water at the bottom freezes soonest. There seems to be something defective in this explanation; for, as far as we know, agitation can impede freezing or crystallization in no other way, than by mixing the warmer parts of the fluid with the colder. But there is no doubt of the fact, from the concurring testimony of fishermen and other inhabitants near rivers, who are well acquainted with ground ice; beside which, Mr. Pott made an experiment in frosty weather with two similar tubs, into each of which were thrown nails, iron wire covered with flannel, hair, &c. A current of water was made to pass through one of them, and in the other was placed water with no current. Ice was formed on the nails and other substances at the bottom of the former, but none at the surface. And in the latter the surface was congealed, but there was no ice at the bottom. I am inclined to think, that the formation of ground ice depends on the springs, which issue from the earth at a more elevated temperature than the freezing point; namely, at the medium tempe-

ure of the climate. Suppose a spring to
e from the earth at the temperature of
, into a freezing atmosphere, it naturally
ows, and experience shows, that the
am must run over a certain extent of
und before it can be cooled as low as
, and become congealed. And if other
ngs flow into it from distances nearer
ir own sources, the distance of the place
ongelation from the first source may be
more augmented. When the original
am has increased to the size of a river,
effect of the additional springs will be
fined to the surface. Hales is mistaken
upposing, that the water at the surface
s quickest, for all hydrostatical writers
e the contrary. Suppose now the water
cooled as low as 32°, or lower, at a
ain part of the river. It will there begin
reeze, and the larger masses will be ac-
ulated where the crystallization is least
rbed, namely, at the edges. But the
equent accessary streams will flow on
surface of this, because warmer, and
equently lighter; and as the lower part
river runs the swiftest, it will follow
the stream, in the act of congelation,
llow on beneath the upper and warmer
am, and deposit ice upon the stones at
ottom, while none appears at the sur-
. If this explanation be true, it will be
d, 1. That wherever ground ice is
d, there will be ice at the surface, high-
p the stream; and, 2. the river has re-
ed a supply from some warmer springs
ome place intermediate between the
es where the ice is formed at the surface,
where it is formed at the bottom.

e expansive force of water, when it is
erted into ice, is greater than any
gth in the texture of bodies which has
opposed to it. Boyle and Hales made
experiment with pistol-barrels and
shells, which were bursten by the
nsion. Other philosophers have since
ted these experiments with similar re-

e freezing point of water is the 32° on
enheit's scale. See Caloric, Ther-
eter, Water.

land Spar. A substance, which has
ly engaged the attention of philoso-
s, under this name, or the name of
nd crystal. Bartholin, Huyghens,
on, Beccaria, and others of later date,
made experiments on its remarkable
erty of separating the rays of light in
a manner as to exhibit two images of
ject seen through it. It is the trans-
t specimen of common calcareous
and usually contains about 54 parts
35 carbonic acid, and the rest water.
ecific gravity is about 2·7. Priestley's
s, and the authors referred to by him,
be consulted, for an account of as
of the laws of this unusual refraction
et known. Magellan says, that Mr.
ond, professor of natural philosophy

at Milan, has observed, that glass has the same effect, whenever a number of parallel lines have been cut on its surface with a diamond, at the distance of the five hundredth or thousandth of an inch asunder; and that he (M.) had seen one of the pieces of glass, which produced this effect. Hence it should seem, as if the effect were produced either by inequalities at the surface, or fissures in the mass itself.

Ichthyocolla. Fish-glue, or *Isinglass*; which see.

Ignis Fatuus. A luminous appearance or flame, frequently seen in the night in different country places, and called in England *Jack with a lantern*, or *Will with the wisp*. It sometimes appears in the form of a flame dancing or undulating above the lower plants of the field; in other instances it has the appearance of an extensive luminous exhalation; sometimes it is seen to have a considerably rapid progressive motion; and other observations show, that it may have a stationary appearance, and definite form. Philosophers are not agreed as to its cause; but it appears probable that these meteors near the surface of the earth may not all be of the same nature. It seems with us to be mostly occasioned by the extrication of phosphorus from rotting leaves and other vegetable matters, which may be carried up in the first state of combustion by the summer heat, and rendered visible at night. Whether the hidrogen gas extricated from marshes may produce an appearance of this kind, is doubtful, unless it be phosphuretted. It is probable, that the motionless ignes fatui of Italy which are seen nightly on the same spot, are produced by the slow combustion of sulphur, emitted through clefts and apertures in the soil of that volcanic country.

Illumination. See Light.

Incineration. The combustion of vegetable or animal substances, for the purpose of obtaining their ashes or fixed residue.

Incombustible Cloth. See Asbestos.

Incrustation. When the external part of any mineral is of a different texture and appearance from the internal part, the former is called the incrustation.

Indigo. A blue colouring matter extracted from a plant called Anil, or the Indigo Plant.

In the preparation of this drug the herb is put into a vat or cistern, called the steeping trough, and there covered with water. The matter begins to ferment sooner or later, according to the warmth of the weather and the maturity of the plant; sometimes in six or eight hours, and sometimes in not less than twenty. The liquor grows hot, throws up a plentiful froth, thickens by degrees, and acquires a blue colour inclining to violet. At this time, without touching the herb, the liquor impregnated with its tincture is let out by cocks in the bottom into another vat placed for that purpose, so as to be commanded by the first. Mr. Quatremere says, that hidrogen gas is disengaged during this fermentation.

In the second vat, called the beating vat, the liquor is strongly and incessantly beaten with a kind of buckets fastened to poles, till the colouring matter is united into a body. Lewis, from Labat, says, that much nicety is required to hit the point, at which the colour is disposed to subside, because it is again taken up, if the beating be too long continued; and that the manufacturers accordingly make frequent observations on small quantities of the liquid taken out in a cup. But this does not agree with the assertion of Mr. le Blond, who affirms, that the effect of beating is to dissipate a quantity of carbonic acid, by which the blue fecula is suspended; that this method is insufficient to throw down the whole; but that the addition of lime water completely accomplishes it. It is said by Labat, that lime-water, or lime, is sometimes used in the beating; and he conjectures, that the hardness or flintiness of some indigo may be caused by this practice.

As soon as it is judged, from the blue colour of the liquid, that the beating is sufficient, it is left at rest for two hours; after which the clear liquor is drawn off by cocks in the side of the vat, and the blue part is discharged by another cock into a third vat, where it is suffered to settle for some time longer; then conveyed in a half fluid state into bags of cloth, to strain off more of its moisture; and lastly, exposed to the air in the shade in shallow wooden boxes, till it is thoroughly dry.

The indigo thus produced differs in its quality, not only according to that of the plant, but likewise the care taken in manufacturing it. Its colouring part appears nevertheless to be always the same, and its variations depend only on the admixture of foreign matter, and the consistence it acquires in drying.

Berthollet speaks of the indigo from Guatimala, as the best of any. It is so light as to swim on the surface of water, instead of sinking to the bottom, as all the other kinds do. Another kind is called coppery indigo, because its surface acquires a copper colour when rubbed with a hard body: there are other kinds of less purity, such as that from Carolina.

Bergman examined this drug in his usual masterly way: he found, that one ninth part of the indigo was taken up by boiling it in water. The parts dissolved were partly mucilaginous, partly astringent, and partly saponaceous. The solution of alum, and of sulphat of iron as well as of copper, precipitate the astringent portion.

Mr. Quatremere likewise separated the soluble part of indigo by means of water. He pretends, that the quantity thus taken up is more in proportion, as the indigo is of inferior quality; and affirms, that the indigo thus purified is equal to the best. Berthollet remarks upon this method of purifying, that, though doubtless advantageous, it is not perfectly effectual, because it leaves the earthy insoluble parts, which, though not detrimental to the colour, must certainly affect the proportion of colouring matter.

Powder of indigo, digested in pure alcohol, afforded a tincture, first yellow, then red, and lastly brown. By several repetitions of this process it lost one twenty-seventh part of its weight. Water being added to the alcohol, threw down a brownish resinous matter.

Ether had nearly the same action on indigo as the alcohol; but oils, whether fixed or volatile, affected it very little.

Bergman mixed one part of well pulverized indigo with eight parts of colourless sulphuric acid, of the specific gravity of 1·900, in a glass vessel slightly closed. The acid very quickly acted upon the indigo, and excited much heat. After a digestion of twenty-four hours the solution was effected; but the mixture was opake and black. By the addition of water it became more transparent, exhibiting in succession all the shades of blue, according to the quantity of water added. At least twenty pounds of water were required to render the smallest drop of the solution imperceptible in a cylindric glass of seven inches diameter.

If the sulphuric acid be first diluted in the water, it attacks only the earthy principle which is mixed with the indigo, and some of the mucilaginous parts.

The fixed alkalis saturated with carbonic acid separate a very fine blue powder from the solution of indigo, which is deposited very slowly. Bergman distinguishes this by the name of precipitated indigo. It is also obtained by pouring the solution drop by drop into alcohol, or into the saturate solutions of alum, of sulphat of soda, or of other salts containing the sulphuric acid. But the liquid always remains a little coloured.

The concentrated nitric acid attacks indigo with so much activity, as to set it on fire; but if the acid be properly diluted, it acts with less violence. The colour of the indigo becomes ferruginous, and the residue, which has the appearance of amber, amounts to no more than one third of the weight of the indigo. Fixed alkali precipitates from the acid a small quantity of oxide of iron, mixed with lime and barytes. But if too much alkali be added, part of the precipitate is redissolved, and the colour of the fluid is rendered deeper than before.

Haussman, in a very interesting dissertation, in the Journal de Physique for March 1788, has given a more connected set of observations on the changes produced

igo by the nitric acid. When the
of the indigo he had exposed to the
of this acid had appeared to be
yed, he found in the vessel a coagu-
which, after all the nitric acid had
carried off by washing, formed a
viscid mass of the appearance of
resin. It was soluble in pure alcohol,
indigo is not; and was not soluble
ter, but when the quantity was great.
more soluble in hot water than cold,
vas considerably bitter. The water
had been used in the lotions afforded
aporation small crystals, which exhi-
several of the properties of the acids
ar and of sorrel, but which were not
ely determined by the author. Brug-
says, that indigo distilled with four
of nitric acid leaves half an ounce of
the alcoholic tincture of which gives
tiful and durable yellow to linen or
and likewise to the skin.

muriatic acid by digestion, and even
upon indigo, takes up the earthy
, the iron, and a little of the extrac-
atter, which gives it a brown colour,
no respect attacks the blue colour.
indigo be precipitated from the sul-
acid, the muriatic will very readily
p a certain quantity, and acquires a
blue colour. Other acids, such as the
c, acetic, and phosphoric, have the
habitudes with indigo as the muriatic.
uric acid too much diluted to be ca-
of dissolving indigo, or nitric acid
from the same cause is too weak to
on it, takes up only the earthy and
tive parts, which are foreign to the
ing matter.

oxigenized muriatic acid has scarcely
fect upon indigo in substance; but
roys the colour of indigo in a state of
n. Berthollet applied it to the so-
in sulphuric acid. By the admixture
oxigenized muriatic acid the blue
was entirely destroyed, and the fluid
e of a yellow brown. He evaporated
this state, and obtained by gradual
tion a viscid blackish matter, which
ed to be of the same nature as that
d to Mr. Haussman by the nitric

effect of the oxigenized muriatic
considered by Berthollet, as afford-
ood method of ascertaining the pro-
nal quantities of colouring matter in
fferent kinds of indigo. For this
e he takes equal weights of each
ly powdered, puts them into se-
matrasses, with eight times their
of concentrated sulphuric acid.
are to be kept for twenty-four hours
at between 100° and 120° of Fahren-
or which purpose a dunghill, or the
d of a hothouse, may be employed.
olution is then diluted with an equal
y of water filtered, and the residue
on the filters collected, separately ground in a glass mortar, again digested with a little sulphuric acid, diluted with equal quantities of water, and each added to its corresponding liquor. And lastly, to each solution is added so much oxigenized muriatic acid as is necessary to discharge the colour, or rather to bring them all to the same shade of yellow, The goodness of each kind of indigo is proportionate to the quantity of oxigenized acid employed to destroy the colour.

Pure or caustic fixed alkali dissolves some matters foreign to the colouring matter of the indigo, but acts very little on the colouring particles. Pure volatile alkali has nearly the same effect. Precipitated indigo is speedily dissolved in the cold in the alkalis, whether fixed or volatile, if pure or caustic. The blue colour is gradually changed to a green, and at last destroyed. But mild alkalis do not alter the colour. Lime water has little action upon indigo; but it dissolves it when precipitated, and affects the colour nearly in the same manner as caustic alkalis do.

Indigo exposed to the action of fire in an open crucible, or under a muffle, smokes, swells up, ignites, and sometimes takes fire with a white flame. One hundred parts of indigo leave thirty-three or thirty-four parts of ashes. These do not afford fixed alkali when lixiviated with distilled water. Muriatic acid dissolves the greater part of the ashes with a slight effervescence. The insoluble remainder is about one eleventh part, and has the characters of siliceous earth.

From this muriatic solution prussiat of potash throws down from thirty to thirty-two grains of the blue precipitate, which represents five or six of iron in the ounce. The ashes likewise contain lime and barytes, beside the iron and silex.

Indigo detonates strongly with nitre. By destructive distillation it affords carbonic acid gas, a liquor containing a little ammonia and an oil resembling the empyreumatic oil of tobacco, and very soluble in alcohol.

Bergman concludes from his analysis, that one hundred parts of good indigo contain of mucilaginous matter separable by water 12, resinous matter soluble in alcohol 6, earthy matter taken up by the acetous acid, which does not attack the iron, here in the state of oxide, 22, oxide of iron taken up by the muriatic acid 13.

There remained forty-seven parts, which are the colouring matter, nearly in a state of purity, and afforded by distillation, carbonic acid 2, alkaline liquor 8, empyreumatic oil 9, coal 23.

The coal, when burned in the open air, afforded four parts of earth, of which nearly half was oxide of iron, and the rest silex in a very subtle powder.

From these results Bergman concludes, that indigo is a substance analogous to

Prussian blue, and the colouring matter of ink; and that its colour, like theirs, is owing to iron. Upon this deduction Berthollet remarks, with regard to Bergman's inference respecting the iron, that by an error in estimating the value of the Prussian blue, this great chemist has stated the quantity of this metal about four times too large; that the iron taken up by muriatic acid is extraneous to the pure indigo, as well as the earths, and the mucilage and resin taken up by water and alcohol. So that, on an accurate consideration of the facts, there does not appear to be more than one thirtieth part of iron in a combined state. He observes, that it is at present well known, that the products of destructive distillation, such as oil, carbonic acid, and volatile alkali, do not previously exist in bodies, but are afforded by new combinations of the principles which formed the body acted upon. And accordingly he concludes, that indigo contains a considerable quantity of hidrogen, a small quantity of nitrogen, a very small portion of iron, and particularly a larger quantity of coal than is obtained from any other known vegetable substance. It does not appear, whether the siliceous earth be merely an admixture, or whether it enter into the combination of the colouring matter.

From the great quantity of coal and hidrogen he accounts for the combustibility of this substance, its detonation with nitre, and the effects of the nitric and muriatic acids upon it. The fixity of its colour is also, in conformity to other observations of Berthollet, deduced from the quantity of coal, which is but slowly consumed by the action of oxigen from the atmosphere. From a mature consideration of the process of the manufactory, this intelligent author deduces, that the indigo exists in the plant in a resinous state; that the kind of putrefaction it undergoes is of the nature of combustion, during which, part of its hidrogen is burned, and part flies off; and that the utility of the process of beating is grounded on the facility it affords for the absorption of oxigen. If the beating be continued too long, the indigo is rendered black, and becomes what is called burnt indigo.

The solubility of indigo in alkalis appears to be produced by the abstraction of part of the oxigen it had absorbed. This appears to be well established from the experiment of Bergman, wherein equal weights of sulphat of iron and indigo, and double the weight of lime, are mixed together in water, and produce a solution of the indigo in the lime-water. But if the iron of the sulphat be previously oxided to a higher degree, by boiling it in much water for several hours, and subsequent evaporation, the solution will not be effected, because the precipitated iron is no longer disposed to absorb oxigen, as the experiments of Priestley show the common precipitate from sulphat of iron to be. Or again, if indigo be added to a solution of caustic fixed alkali, and orpiment be added (which consists of arsenic and sulphur), the indigo is soon dissolved, and takes a green colour. If the arsenic corresponding with the orpiment be only added, the bath will never be fit for the dyer; but if the quantity of sulphur it ought to contain be added, the appearances of solution will speedily be had.

Mr. Haussman proved by a direct experiment, that the solution of orpiment mixed with indigo is disposed to absorb oxigen. For having placed this solution, which is known in the dye-houses by the name of printing blue, in contact with oxigen gas, seven-eighths of the air were absorbed, and the remainder was nitrogen. The blue solution was entirely spoiled. The indigo was regenerated. Some of the alkali formed sulphat of potash with the acid; a portion of the alkali remained pure and uncombined; and the arsenic, instead of being in the metallic state as it is in the orpiment, was combined with it in the form of oxide, or probably acidified.

It follows therefore, that indigo contains oxigen in its natural state; that in this state it will not unite with lime or alkalis; but that substances capable of depriving it of part of its oxigen render it soluble in lime or alkalis; and lastly, that the natural state of the indigo is restored by the contact of oxigen which it absorbs. In this last way it is that the blue dye is effected. The piece comes out of the vat of the same colour as the solution: viz. green; but becomes blue by exposure to the air. The alkali, or lime, is carried off by the washing, and the indigo remains combined with the stuff by this means dyed.

The action of acids, even the sulphuric, upon indigo, appears to affect it in the way of combustion; by which it is so far altered, as not to adhere so strongly to wool or silk as when in its natural state. For other interesting particulars, consult the Memoir of Mr. Haussman before cited, and compare with the theories of Bergman and Berthollet.—*Lewis.—Berthollet.—Journ. de Phys.—Ann. de Chim.*

Infernal Stone. Lapis infernalis. A name frequently given to the combination of silver with the nitric acid, which is fused into little sticks to be used as a caustic.

Inflammable Air. See Gas (Hidrogen).

Inflammable Principle. See Phlogiston.

Inflammation of Oils. See Acid (Nitric).

Infusion. The process of infusion differs from maceration in the menstruum being poured hot, generally boiling, on the substance to be infused; and from digestion in the heat not being kept up by artificial means. It is by no means unfrequent, however, that we see the term in-sometimes indeed with the incon- pithet *cold* prefixed, used improper- ad of maceration. It is likewise em- by chemists, to denote a quantity of oaded with as much of the principles substance, not totally soluble, as it e up in the usual temperature of the here.

Every liquor or pigment used for or printing, is distinguished by the f ink. Common practice knows only nd red.

lack ink there are three principal 1. Indian ink, 2. printers' ink, and, ng ink.

Indian ink is used in China for writ- h a brush, and for painting upon the ible paper of Chinese manufacture. ertained as well from experiment as formation, that the cakes of this ink de of lamp black and size, or animal th the addition of perfumes or other ces not essential to its quality as an is used in Europe for designs in nd white, in which it possesses the ge of affording various depths of according to its state of dilution with The coarse lampblack of the shops ot answer the purpose; but the fine om the flame of a lamp or candle, d by holding a plate over it, mixed lean size from shreds of parchment e-leather not dyed, will make an ink to that imported.

general composition of printers' ink known, but the particulars of the s by which ink of the best quality is re kept secret by the few manufac- of this article. It is probable, that nand is not sufficient to afford induce- for men of research to make many nents on this object, and it is not un- that much may depend on minute stances in the management.

d printers' ink is a black paint, and uniform in its composition, of black colour, and possesses a singular le to adhere to paper thoroughly im- ted with moisture. It is remarkable, is composition adheres uniformly to ted sheep-skin cover of the printers'- which a common oil paint would not at it quits the wet ball to adhere to e of the dry metallic type, and this so ly as to leave a new skin bare where pe touches it; and that much the part of the ink afterward leaves the adhere to the moistened paper, but ot if the paper be dry. If the ink possess these requisites, it will not well, but will clog the face of the and give an imperfect impression.

consistence and tenacity of the oil in mposition are greatly increased, and asiness diminished, by means of fire. d oil or nut oil is made choice of for e. The nut oil is supposed to be the nd is accordingly preferred for the black ink, though the darker colour it acquires from the fire renders it less fit for the red. It is said, that the other expressed oils cannot be sufficiently freed from their unctuous quality; whence the ink made with them dries exceeding slowly, is apt to come off and smear the paper in the beating and pressing it undergoes in the hands of the bookbinder, or sinks into the substance of the paper beyond the mark of the type, and stains it yellow.

Ten or twelve gallons of the oil are set over the fire in an iron pot, capable of holding at least half as much more; for the oil swells up greatly, and its boiling over into the fire would be very dangerous. When it boils it is kept stirring with an iron ladle; and if it do not itself take fire, it is kindled with a piece of flaming paper or wood; for simple boiling, without the actual accension of the oil, does not communicate a sufficient degree of the drying quality required. The oil is suffered to burn for half an hour or more, and the flame being then extinguished by covering the vessel close, the boiling is afterward continued with a gentle heat, till the oil appears of a proper consistence; in which state it is called varnish. It is necessary to have two kinds of this varnish, a thicker and a thinner, from the greater or less boiling, to be occasionally mixed together, as different purposes may require; that which answers well in hot weather being too thick in cold, and large characters not requiring so stiff an ink as small ones.

The thickest varnish when cold may be drawn into threads like weak glue; by which criterion the workmen judge of the due boiling, small quantities being from time to time taken out and dropped upon a tile for this purpose. It is very viscid and tenacious, like the soft resinous juices, or thick turpentine. Neither water nor alcohol dissolves it; but it readily enough mingles with fresh oil, and unites with mucilages into a mass diffusible in water in an emulsive form. Boiling with caustic alkali produces a soapy compound. It is by washing with hot soaplees and a brush that the printers clean their types. The oil loses from one tenth to one eighth of its weight by the boiling into the thick varnish. This loss seems to differ in different samples of the same kind of oil. Dr. Lewis found that fish oil lost three fourths of its weight by this treatment, before it acquired the thickness produced in linseed oil.

The workmen are accustomed to add in the preparation of ten or twelve gallons of oil, as soon as the burning is over, a pound or two of dry crusts of bread, and a dozen or two of onions, by which they suppose the greasiness to be more effectually destroyed. Dr. Lewis, with much appearance of justice, doubts the advantage of such additions, and that more especially, as he prepared the varnish seemingly of a good quality by the fire alone. There are other additions of more evident effect, namely, turpentine or litharge, both which are occasionally used. The turpentine is boiled first by itself to a state nearly of resin, and the oil being taken from the fire, the hot fluid turpentine is poured in, and the boiling then continued to the proper point. This is somewhat difficult to attain, because the mixture is more disposed to grow too thick if overboiled; and is full of little hard grains, probably of resin, if not sufficiently boiled. It is affirmed, that varnish containing either turpentine or litharge, particularly the latter, is more adhesive than other varnish, and presents a great difficulty in cleaning the types, which soon become clogged. Very old oil requires neither of these additions. New oil can hardly be brought into a proper state for drying, so as not to set off, without the use of turpentine.

Lamp black is the common material to give the black colour, of which two ounces and a half are sufficient for sixteen ounces of the varnish. Vermilion is a good red. They are ground together on a stone with a muller, in the same manner as oil paints.

The ink used by copper-plate printers differs in the oil, which is not so much boiled as to acquire the adhesive quality. This would render it less disposed to enter the cavities of the engraving, and more difficult either to be spread or wiped off. The black is likewise of a different kind. Instead of lamp black, or sublimed charcoal, the Frankfort black is used, which is a residual or denser charcoal, said to be made from vine-twigs. This is softer and less gritty than the ivory or other blacks prepared among us, and no doubt contains more coal than any animal residue, as all these abound with phosphat of lime. It is said, that lamp black gives always a degree of toughness to the ink, which the Frankfort black does not; but the goodness of the colour seems to be the leading inducement for the use of the latter. A pale or brown black can be much more easily endured in a book, than in the impression of an engraving.

We have no good explanation of what happens with regard to the chemical effect of boiling and burning upon the oil for printers' use.

Common ink for writing is made by adding an infusion or decoction of the nut gall to sulphat of iron, dissolved in water. A very fine black precipitate is thrown down, the speedy subsidence of which is prevented by the addition of a proper quantity of gum arabic. This is usually accounted for by the superior affinity of the gallic acid, which, combining with the iron, takes it from the sulphuric, and falls down. But it appears as if this were not the simple state of the facts; for the sulphuric acid in ink is not so far disengaged as to act speedily upon fresh iron, or give other manifestations of its presence in an uncombined state. According to Deyeux, the iron in ink is partly in the state of a gallat, partly in that of a carburetted oxide.

Mr. Ribaucourt paid particular attention to the process for making black ink, and from his experiments he draws the following inferences: That logwood is a useful ingredient in ink, because its colouring matter is disposed to unite with the oxide of iron, and renders it not only of a very dark colour, but less capable of change from the action of acids, or of the air. Sulphat of copper in a certain proportion gives depth and firmness to the colour of the ink. Gum arabic, or any other pure gum, is of service, by retarding the precipitation of the feculæ; by preventing the ink from spreading or sinking into the paper; and by affording it a kind of compact varnish, or defence from the air, when dry. Sugar appears to have some bad qualities, but is of use in giving a degree of fluidity to the ink, which permits the dose of gum to be enlarged beyond what the ink would bear without it. Water is the best solvent.

Lewis had supposed, that the defects of ink arise chiefly from a want of colouring matter. But the theory, grounded on the facts discovered by Mr. Ribaucourt, requires, that none of the principles should be in excess. If there be a want of the gallic acid, part of the sulphat will not be decomposed; if, on the contrary, there be too much, the sulphat will take as much as it can decompose, and the remainder will be nearly in the state of the decoction of galls, subject to change by becoming mouldy, or to undergo an alteration after writing, which destroys its legibility much more completely than the change undergone by ink containing too small a proportion of the galls.

It is doubtful whether the principles of the galls be well extracted by maceration; and it is certain, that inks made in this way flow pale from the pen, and are not of so deep a black as those wherein strong boiling is recurred to.

From all the foregoing considerations, Mr. R. gives these directions for the composition of good ink:

Take eight ounces of Aleppo galls (in coarse powder); four ounces of logwood (in thin chips); four ounces of sulphat of iron; three ounces of gum arabic (in powder); one ounce of sulphat of copper, and one ounce of sugar candy. Boil the galls and logwood together in twelve pounds of water for one hour, or till half the liquid has evaporated. Strain the decoction through a hair sieve, or linen cloth, and then add the other ingredients. Stir the mixture till the whole is dissolved, more especially the gum; after which leave it to subside for twenty-four hours. Then decant the ink, and preserve it in bottles of glass or stone ware, well corked.

 recommend, that the sulphat of
ould be calcined to whiteness. Mr.
eaux jun., an ink manufacturer in
elds, has given the following in the
phical Magazine as the result of
xperience: Boil 4 ounces of log-

many occasions it is of importance to
an ink indestructible by any pro-
at will not equally destroy the ma-
on which it is applied. Mr. Close
ecommended for this purpose 25
of copal in powder dissolved in 200
of oil of lavender, by the assistance
tle heat, and then mixed with 2½
of lamp black and ½ a grain of indigo; or 120 grains of oil of lavender, 17 grains of copal, and 60 grains of vermilion. A little oil of lavender, or of turpentine, may be added, if the ink be found too thick. Mr. Sheldrake suggests, that a mixture of genuine asphaltum dissolved in oil of turpentine, amber varnish, and lamp black, would be still superior.

When writing with common ink has been effaced by means of oxigenized muriatic acid, the vapour of sulphuret of ammonia, or immersion in water impregnated with this sulphuret, will render it again legible. Or if the paper that contained the writing be put into a weak solution of prussiat of potash, and when it is thoroughly wet a little sulphuric acid be added to the liquor, so as to render it slightly acidulous, the same purpose will be answered.

Mr. Haussman has given some compositions for marking pieces of cotton or linen, previous to their being bleached, which are capable of resisting every operation in the processes both of bleaching and dyeing, and consequently might be employed in marking linen for domestic purposes. One of these consists of asphaltum dissolved in about four parts of oil of turpentine, and with this is to be mixed lamp black, or black lead in fine powder, so as to make an ink of a proper consistence for printing with types. Another, the blackish sulphat left after expelling oxigen gas from oxide of manganese with a moderate heat being dissolved and filtered, the dark gray pasty oxide left on the filter is to be mixed with a very little solution of gum tragacanth, and the cloth marked with this is to be dipped in a solution of potash or soda, mild or caustic, in about ten parts of water.

Among the amusing experiments of the art of chemistry, the exhibition of sympathetic inks holds a distinguished place. With these the writing is invisible, until some reagent gives it opacity. We shall here mention a few out of the great number, that a slight acquaintance with chemistry may suggest to the student. 1. If a weak infusion of galls be used, the writing will be invisible till the paper be moistened with a weak solution of sulphat of iron. It then becomes black, because these ingredients form ink. 2. If paper be soaked in a weak infusion of galls, and dried, a pen dipped in the solution of sulphat of iron will write black on that paper, but colourless on any other paper. 3. The diluted solutions of gold, silver, or mercury, remain colourless upon the paper, till exposed to the sun's light, which gives a dark colour to the oxides, and renders them visible. 4. Most of the acids or saline solutions being diluted, and used to write with, become visible by heating before the fire, which concentrates them, and assists their action on the paper. 5. Diluted prussiat of potash affords blue letters when wetted with the solution of sulphat of iron. 6. The solution of cobalt in aqua regia, when diluted, affords an ink which becomes green when held to the fire, but disappears again when suffered to cool. This has been used in fanciful drawings of trees, the green leaves of which appear when warm, and vanish again by cold. This effect has not been explained. If the heat be continued too long after the letters appear, it renders them permanent. 7. If oxide of cobalt be dissolved in acetous acid, and a little nitre added, the solution will exhibit a pale rose colour when heated, which disappears on cooling. 8. A solution of equal parts of sulphat of copper and muriat of ammonia gives a yellow colour when heated, that disappears when cold.

Sympathetic inks have been proposed as the instruments of secret correspondence. But they are of little use in this respect, because the properties change by a few days remaining on the paper; most of them have more or less of a tinge when thoroughly dry; and none of them resist the test of heating the paper till it begins to be scorched.—*Lewis's Phil. Com. of Arts.—Ann. de Chim.—Nich. Journ.—Phil. Mag.*

Insects. Various important products are obtained from insects. The chief are, 1. Cantharides. 2. Millepedes. 3. Cochineal. 4. Kermes. 5. Lac. 6. Silk. 7. Wax. For all which the several titles may be consulted.

Instruments (Chemical). See Balance, Thermometer, Laboratory.

Intermedium, or **Medium**. When two chemical principles, which are not disposed to unite, are made to enter into a triple compound, by the addition of a third, this last is frequently called the medium, or intermedium. Thus fat oils are made to unite with water by the intermedium of a pure alkali, which converts the oil into soap.

Iridium. Mr. Tennant, on examining the black powder left after dissolving platina, which from its appearance had been supposed to consist chiefly of plumbago, found it contained two distinct metals never before noticed, which he has named iridium and osmium. The former of these was observed soon after by Descostils, and by Vauquelin.

To analyse the black powder, Mr. Tennant put it into a silver crucible with a large proportion of pure dry soda, and kept it in a red heat for some time. The alkali being then dissolved in water; it had acquired a deep orange or brownish yellow colour, but much of the powder remained undissolved. This digested in muriatic acid gave a dark blue solution, which afterward became of a dusky olive green, and finally, by continuing the heat, of a deep red. The residuum being treated as before with alkali, and so on alternately, the whole appeared capable of solution. As some silex continued to be taken up by the alkali, till the whole of the metal was dissolved, it seems to have been chemically combined with it. The alkaline solution contains oxide of osmium, with a small proportion of iridium, which separates spontaneously in dark-coloured thin flakes by keeping it some weeks.

The acid solution contains likewise both the metals, but chiefly iridium. By slow evaporation it affords an imperfectly crystallized mass; which, being dried on blotting-paper, and dissolved in water, gives by evaporation distinct octaedral crystals. These crystals, dissolved in water, produce a deep red solution inclining to orange. Infusion of galls occasions no precipitate, but instantly renders the solution almost colourless. Muriat of tin, carbonat of soda, and prussiat of potash, produce nearly the same effect. Ammonia precipitates the oxide, but, possibly from being in excess, retains a part in solution, acquiring a purple colour. The fixed alkalis precipitate the greater part of the oxide, but retain a part in solution, this becoming yellow. All the metals that Mr. Tennant tried, except gold and platina, produced a dark or black precipitate from the muriatic solution, and left it colourless.

The iridium may be obtained pure, by exposing the octaedral crystals to heat, which expels the oxigen and muriatic acid. It was white, and could not be melted by any heat Mr. Tennant could employ. It did not combine with sulphur, or with arsenic. Lead unites with it easily, but is separated by cupellation, leaving the iridium on the cupel as a coarse black powder. Copper forms with it a very malleable alloy, which, after cupellation with the addition of lead, leaves a small proportion of the iridium, but much less than in the preceding instance. Silver forms with it a perfectly malleable compound, the surface of which is tarnished merely by cupellation; yet the iridium appears to be diffused through it in fine powder only. Gold remains malleable, and little altered in colour, though alloyed with a considerable proportion; nor is it separable either by cupellation or quartation. If the gold or silver be dissolved, the iridium is left as a black powder.

The French chemists observed, that this new metal gave a red colour to the triple salt of platina and sal ammoniac, was not altered by muriat of tin, and was precipitated of a dark brown by caustic alkali. Vauquelin added, that it was precipitated by galls, and by prussiat of potash; but Mr. Tennant ascribes this to some impurity.

Mr. Tennant gave it the name of iridium from the striking variety of colours it affords while dissolving in muriatic acid.

Wollaston has observed, that among
ins of crude platina there are some

ed.

n iron is exposed to the action of
ter, it acquires weight by gradual
on, and hidrogen gas escapes: this is
a very low operation. But if the steam of water be made to pass through a red-hot gun barrel or through an ignited copper or glass tube, containing iron wire, the iron becomes converted into an oxide, while hidrogen gas passes out at the other end of the barrel. The action of air, assisted by heat, converts iron into a black oxide, containing ·25 of oxigen. By the action of stronger heat this becomes a reddish brown oxide, containing ·48 of oxigen. The yellow rust, formed when iron is long exposed to damp air, is not a simple oxide, as it contains a portion of carbonic acid. According to Mr. Chenevix, there are four stages of oxidation of iron: the first, or minimum, white; the 2d green; the 3d black; the 4th, or maximum, red. Thenard admits only three, the white, green, and red.

The concentrated sulphuric acid scarcely acts on iron, unless it is boiling. When the acid is distilled to dryness from this metal, the retort is found to contain sublimed flowers of sulphur, and a white and reddish mass, partly soluble in water, which is sulphat of iron more or less decomposed: the product which comes over is sulphurous acid, fluid and aëriform. If the sulphuric acid be diluted with two or three parts of water, it dissolves iron readily, without the assistance of any other heat than is produced by the act of combination. During this solution, hidrogen gas escapes in large quantities. If heat be applied, the acid proceeds to dissolve more iron, and deposits a white saline mass, or pale sulphat of iron.

The green sulphat of iron is much more soluble in hot than cold water; and therefore crystallizes by cooling, as well as by evaporation. The crystals are efflorescent, and fall into a white powder by exposure to a dry air, the iron becoming more oxided than before. A solution of sulphat of iron, exposed to the air, imbibes its oxigen; and a portion of the iron, becoming too much oxided to adhere to the acid, falls to the bottom in the form of ochre. The solution, as well as the crystals it affords by evaporation, are thus rendered paler than before.

Sulphat of iron is not made in the direct way, because it can be obtained at less charge from the decomposition of martial pyrites. It exists in two states, one containing oxide of iron with ·27 of oxigen, which is of a pale green, not altered by gallic acid, and giving a white precipitate with prussiat of potash. The other, in which the iron is combined with ·48 of oxigen, is red, not crystallizable, and gives a black precipitate with gallic acid, and a blue with prussiat of potash. In the common sulphat these two are mixed in various proportions.

Sulphat of iron is decomposed by alkalis and by lime. Caustic fixed alkali precipi-tes the iron in deep green flocks, which are dissolved by the addition of more alkali, and form a red tincture. The mild alkali does not redissolve the precipitate it throws down, which is of a greenish white colour. Distillation separates the acid from sulphat of iron, and leaves the brown oxide of iron, called colcothar.

Vegetable astringent matters, such as nut-galls, the husks of nuts, logwood, tea, &c., which contain the gallic acid, precipitate a fine black fecula from sulphat of iron, which remains suspended for a considerable time in the fluid, by the addition of gum arabic. This fluid is well known by the name of ink. See INK.

The beautiful pigment, well known in the arts by the name of Prussian blue, is likewise a precipitate afforded by sulphat of iron.

If two parts of alum, and one of sulphat of iron, be dissolved in 8 or 10 parts of boiling water, and a solution of prussiat of potash be added as long as any effervescence and precipitation are produced, the precipitate, thoroughly washed by affusion of boiling water, will have a green colour. This is owing to yellow oxide of iron thrown down with the prussiat, which must be dissolved by adding muriatic acid. The deep blue powder, insoluble in this acid, is then to be washed and dried for use. According to prof. Proust, the iron in Prussian blue contains ·48 of oxigen, and is obtainable only from a superoxigenated sulphat; the precipitate from a pure alkaline prussiat and sulphat of iron with a minimum of oxigen being white, and containing only ·27 of oxigen. This may explain a fact observed by a French colourman, who, having mixed some Prussian blue and white lead with nut oil, and set it by for some time covered with water, found the surface only blue, and all the rest white. On pouring it out on his stone, and beginning to grind it afresh, with intention to add more Prussian blue, he found the colour gradually returning of itself. Here it might be supposed the oxide of the prussiat had parted with oxigen to the oil, or the oxide of lead, or both, thus becoming white; except that on the surface, which was supplied with oxigen from the superincumbent water; and that it recovered its colour by attracting oxigen from the air. But on this supposition it would seem, that light must contain oxigen, since the colour of this paint, spread on wood or paper, returned by exposure to light in vacuo as well as in the open air. The colour of Prussian blue is affected by the contact of iron. Mr. Gill, finding a knife with which he was mixing some Chinese blue acquire a green tinge, spread a little of it, and afterward a little Prussian blue, sufficiently diluted, on the blade of a knife, and with a camel hair pencil took off enough to form a tint on paper, and thus continued, till he had taken off in the first instance 36, and in the second 86, without adding any fresh colour. These tints differed in regular gradation from greenish blue to green, olive green, yellowish green, yellow, and so on to a buff.

Concentrated nitric acid acts very strongly upon iron filings, much nitrous gas being disengaged at the same time. The solution is of a reddish brown, and deposits the oxide of iron after a certain time; more especially if the vessel be left exposed to the air. A diluted nitric acid affords a more permanent solution of iron, of a greenish colour, or sometimes of a yellow colour. Neither of the solutions affords crystals; but both deposit the oxide of iron by boiling, at the same time that the fluid assumes a gelatinous appearance. This magma, by distillation, affords fuming nitrous acid, much nitrous gas, and some nitrogen, a red oxide being left behind.

If potash be added to the nitric solution of iron, a brown precipitate falls down; of which a small quantity is redissolved by the alkali. Carbonat of potash separates a yellowish oxide, which soon becomes of a beautiful orange red colour. If the mixture be agitated during the effervescence, the precipitate is redissolved in much greater quantity than by the pure potash; doubtless by the medium of the carbonic acid. This solution is known by the name of Stahl's martial alkaline tincture, and is of a fine red colour, which however is impaired by time. Pure ammonia separates a deep green and almost black precipitate from the nitric solution of iron. The carbonat of ammonia redissolves the iron, which it separates from the acid; and forms an alkaline tincture of a more lively colour than that of Stahl.

Diluted muriatic acid rapidly dissolves iron, at the same time that a large quantity of hidrogen is disengaged, and the mixture becomes hot. In this, as well as in the sulphuric solution of iron, the same quantity of alkali is said to be required to saturate the acid as before the solution; whence it is inferred, that the acid is not decomposed, but that the oxidation is effected by the oxigen of the water; whence also it appears to follow, that the hidrogen must be afforded from the decomposed water, and not from the metal.

The muriatic solution of iron is of a yellowish green colour, and is much more permanent than the solutions of that metal in the sulphuric or nitric acid; though, like all the other solutions of iron, it deposits its metal by exposure to the air. By evaporation it assumes the consistence of sirup; in which, needle-formed and deliquescent crystals appear. Some chemists affirm, that the acid quits the iron by distillation, though much more difficultly than either the nitric or sulphuric acid; in fact, a porn of the iron rises at first with the acid, toward the end of the operation, iron is sublimed in the state of black de.

The muriatic solution of iron is decomed by lime and by alkalis; but the preitates are more easily reduced to the callic state than those afforded by other ls. Alkaline sulphurets, sulphuretted rogen, and astringents, decompose this, vell as the other solutions of iron; and prussiat of potash throws down a very blue precipitate. If iron filings be urated with muriat of ammonia, moistng the mixture; then drying, powdering, again triturating; and lastly subliming h a heat quickly raised; yellow or nge coloured flowers will rise, consistof a mixture of muriat of ammonia h more or less muriat of iron. These, ch were called *flowers of steel*, and still re improperly *ens veneris*, were oncemuch emed; but are now little used, as they nauseous in solution, and cannot very veniently be given in any other form.

Carbonic acid, dissolved in water, comes with a considerable quantity of iron, roportion to its mass. Vinegar scarcelissolves it, unless by the assistance of air.

hosphoric acid unites with iron, but y slowly. The union is best effected by ing an alkaline phosphat to a solution one of the salts of iron, when it will down in a white precipitate. A saated phosphat of iron has been found ve in France, semitransparent, of a red wn colour, and foliated texture. A blue phosphat of iron, lamellated, fragile, of the specific gravity of 2·6, ught from the Isle of France, and anad by Laugier, Fourcroy, and Vauquegave iron 41·25, phosphoric acid 19·25, er 31·25, alumine 5, and ferruginous 1·25, in 100 parts. A similar phosphat been found in Brazil. This acid is nd combined with iron in the bog ores, being at first taken for a peculiar metal called *siderite* by Bergman.

iquid fluoric acid attacks iron with ence; the solution is not crystallizable, thickens to a jelly, which may be rened solid by continuing the heat. The may be expelled by heating it strongly, ing a fine red oxide.

orat of iron may be obtained by precitting a solution of the sulphat with tral borat of soda.

rsenic acid likewise unites with iron. s arseniat is found native in Cornwall, pretty large cubic crystals, tolerably sparent, of a dark green colour with ownish tinge; sometimes yellowish, or brown yellow, like resin. The count Bournon found likewise a cupreous arat of iron, in minute rhomboidal crystals faint sky blue colour and uncommon liancy. Specific gravity 3·4. The green and red sulphats of iron may be decomposed by arseniat of ammonia, and afford arseniat of iron in the two different states.

Chromat of iron is said to have been found abundantly in the department of Var in France, and to form a beautiful green for enamelling or colouring pastes. Its analysis by Vauquelin and Tassaert gave chromic acid 43, oxide of iron 34·7, alumine 20·3, silex 2, in 100 parts.

In the dry way, this metal does not combine with earths, unless it be previously oxided; in which case it assists their fusion, and imparts a green colour to the glass. It appears to combine with alkalis by fusion. Nitre detonates strongly with it, and becomes alkalized.

Sulphur combines very readily with iron, in the dry and even in the humid way, though neither of these substances is scarcely at all soluble in water. A mixture of iron filings and flowers of sulphur being moistened, or made into a paste, with water, becomes hot, swells, adheres together, breaks, and emits watery vapours of an hepatic smell. If the mixture be considerable in quantity, as for example, one hundred pounds, it takes fire in twenty or thirty hours, as soon as the aqueous vapours cease.

By fusion with iron sulphur produces a compound of the same nature as the pyrites, and exhibiting the same radiated structure when broken. If a bar of iron be heated to whiteness, and then touched with a roll of sulphur, the two substances combine, and drop down together in a fluid state. It is necessary that this experiment should be made in a place where there is a current of air to carry off the fumes; and the melted matter, which may be received in a vessel of water, is of the same nature as that produced by fusion in the common way, excepting that a greater quantity of sulphur is fused by the contact of the bar of iron. The experiment of combining iron and sulphur together by fusion has not been made with an attention to the volatile products, if any be extricated. As neither of these substances contains water, and both are supposed to be simple bodies, the experiment might, perhaps, afford an interesting result. According to Proust the native sulphuret, or pyrites, contains 47·36 per cent. of sulphur, the artificial sulphuret but 37·5. Mr. Hatchett however has found, that the magnetical pyrites contains the same proportion as the artificial sulphuret.

Phosphorus may be combined with iron by adding it cut into small pieces to fine iron wire heated moderately red in a crucible: or by fusing six parts of iron clippings, with six of glacial phosphoric acid, and one of charcoal powder. This phosphuret is magnetic; and Mr. Hatchett remarks, that iron, which in its soft or pure state cannot retain magnetism, is enabled to do so when hardened by carbon, sulphur, or phosphorus, unless the dose be so great as to destroy the magnetic property, as in most of the natural pyrites and plumbago.

The combination of carbon with iron is of all the most important, and under the names of Cast Iron and Steel will be considered in the latter part of the present article. We shall just observe here, that according to Mr. Mushet of the Calder Iron-works, who has investigated the subject very extensively in the large way, soft cast steel capable of welding contains $\frac{1}{120}$ of carbon, common cast steel $\frac{1}{100}$, cast steel of a harder kind $\frac{1}{90}$, steel too hard for drawing $\frac{1}{50}$, white cast iron $\frac{1}{25}$, mettled cast iron $\frac{1}{20}$, black cast iron $\frac{1}{15}$. He conceives, however, that in steel the carbon is more intimately united with the iron. When iron is saturated with carbon it becomes what is commonly called plumbago.

Iron unites with gold, silver, and platina. When heated to a white heat, and plunged in mercury, it becomes covered with a coating of that metal. Long trituration of mercurial amalgams likewise causes a coating to adhere to the ends of iron pestles; small steel springs, kept plunged beneath the surface of mercury in certain barometers, become brittle in process of time; and the direct combination of iron and mercury in the form of an amalgam may be obtained, according to Vogel, by triturating the filings with twice their weight of alum, then adding an equal weight or more of mercury, and continuing the friction, with a very small quantity of water, till the union is completed. Mr. A. Aikin unites an amalgam of zinc and mercury with iron filings, and then adds muriat of iron, when a decomposition takes place, the muriatic acid combining with the zinc, and the amalgam of iron and mercury assuming the metallic lustre by kneading, assisted with heat. Iron and tin very readily unite together, as is seen in the art of tinning iron vessels, and in the fabrication of those useful plates of iron, coated with tin, which are generally distinguished by the simple name of tin alone. The chief art of applying these coatings of tin consists in defending the metals from oxidation by the access of air. After the iron plates are scraped, or rendered very clean by scouring with an acid, they are wetted with a solution of sal ammoniac, and plunged into a vessel containing melted tin, the surface of which is covered with pitch or tallow, to preserve it from oxidation. The tin adheres to, and intimately combines with the iron to a certain depth, which renders the tinned plates less disposed to harden by hammering, than before; as well as much less disposed to alter, by the united action of air and moisture. The process for tinning iron vessels does not essentially differ from that which has already been described for copper vessels. Iron does not unite easily with bismuth, at least in the direct way. This alloy is brittle, and attractable by the magnet even with three fourths of bismuth. As nickel cannot be purified from iron without the greatest difficulty, it may be presumed that these substances would readily unite, if the extreme infusibility of both did not present an obstacle to the chemical operator. Arsenic forms a brittle substance in its combination with iron. Cobalt forms a hard mixture with iron, which is not easily broken. The inflammability and volatility of zinc present an obstacle to its combination with iron. It is not improbable, however, but that clean iron filings would unite with zinc, if that metal were kept in contact with them for a certain time, in a heat not sufficient to cause it to rise; for it has been found, that zinc may be used in the operation of coating iron in the same manner as tin. Antimony unites with iron, and forms a hard brittle combination, which yields in a slight degree to the hammer. The sulphuret of antimony is decomposed by virtue of the greater affinity of the iron to the sulphur. For this purpose, five ounces of the points of nails from the farriers may be made red hot in a crucible, one pound of pulverized ore of antimony must then be thrown into the crucible, and the heat quickly raised to fuse the whole. When the fusion is perfect, an ounce of nitre in powder may be thrown in, to facilitate the separation of the scoriæ. After the mass is cooled, the antimony is found separate at the bottom of the crucible, while the iron remains in combination with the sulphur and alkali. If the proportion of the iron be considerably greater than five ounces to the pound of ore, the antimony will be alloyed with iron. Manganese is almost always united with iron in the native state. Tungsten forms a brittle, whitish-brown, hard alloy, of a compact texture, when fused with white crude iron. The habitudes of iron with molybdena are not known.

Iron is the most diffused, and the most abundant, of metallic substances. Few mineral bodies or stones are without an admixture of this metal. Sands, clays, and the waters of rivers, springs, rain, or snow, are scarcely ever perfectly free from it. The parts of animal and vegetable substances likewise afford iron in the residues they leave after incineration. It has been found native, in large masses, in Siberia, and in the internal parts of South America. This metal however in its native state is scarce: most iron is found in the state of oxide, in ochres, bog ores, and other friable earthy substances, of a red, brown, yellow, or black colour. The hematites, or blood stones are likewise ores with oxide of iron: these are either of a red colour, or blue, yellow, or brown. An iron ore is likewise found, of a blue colour, and powdery appearance. This useful metal is so abundant, that whole mountains are composed of iron

e; whereas other metals usually run in
l veins. Beside these ores of iron, which
either nearly pure, or else mixed with
is, as in spars, jasper, boles, basaltes,
iron is mineralized with sulphur, as
e pyrites; or with arsenic. The coally
ores contain bitumen. The magnet,
adstone, is an iron ore, the constitution
hich has not yet been accurately exa-
d. Iron is also found in combination
the sulphuric acid, either dissolved in
r, or in the form of sulphat.

ed ore, and placed in a crucible, lined
mixture of a little clay and pounded
al, with a cover luted on, is to be
urged with the strong heat of a smith's forge for half an hour. The weight of the ore, in this experiment, should not exceed 60 grains. Other processes for determining the contents, or metallic product, of iron ores, are instituted by performing the same operations in the small, as are intended to be used in the large way.

In the large iron-works, it is usual to roast or calcine the ores of iron, previous to their fusion; as well for the purpose of expelling sulphureous or arsenical parts, as to render them more easily broken into fragments of a convenient size for melting. The mineral is melted or run down, in large furnaces, from 16 to 30 feet high; and variously shaped, either conical or elliptical, according to the opinion of the iron-master. Near the bottom of the furnace is an aperture for the insertion of the pipe of large bellows, worked by water or steam, or of other machines for producing a current of air; and there are also holes at proper parts of the edifice, to be occasionally opened, to permit the scoriæ and the metal to flow out, as the process may require. Charcoal or coke, with lighted brushwood, is first thrown in; and when the whole inside of the furnace has acquired a strong ignition, the ore is thrown in by small quantities at a time, with more of the fuel, and commonly a portion of limestone, as a flux: the ore gradually subsides into the hottest part of the furnace, where it becomes fused; the earthy part being converted into a kind of glass; while the metallic part is reduced by the coal, and falls through the vitreous matter to the lowest place. The quantity of fuel, the additions, and the heat, must be regulated, in order to obtain iron of any desired quality; and this quality must likewise, in the first product, be necessarily different, according to the nature of the parts which compose the ore.

The iron which is obtained from the smelting furnaces is not pure; and may be distinguished into three states: white crude iron, which is brilliant in its fracture, and exhibits a crystallized texture, more brittle than the other kinds, not at all malleable, and so hard as perfectly to withstand the file: gray crude iron, which exhibits a granulated and dull texture when broken; this substance is not so hard and brittle as the former, and is used in the fabrication of artillery and other articles which require to be bored, turned or repaired: and black cast iron, which is till rougher in its fracture; its parts adhere together less perfectly than those of the gray crude iron: this is usually fused again with the white crude iron.

Whenever crude iron, especially the gray sort, is fused again in contact with air, it emits sparkles, loses weight, and becomes less brittle. In order to convert it into malleable iron, it is placed on a hearth, in the midst of charcoal, urged by the wind of two pair of bellows. As soon as it becomes fused, a workman continually stirs it with a long iron instrument. During the course of several hours it becomes gradually less fusible, and assumes the consistence of paste. In this state it is carried to a large hammer, the repeated blows of which drive out all the parts that still partake of the nature of crude iron so much as to retain the fluid state. By repeated heating and hammering, more of the fusible iron is forced out; and the remainder, being malleable, is formed into a bar or other form for sale. Crude iron loses upwards of one fourth of its weight in the process of refining; sometimes indeed one half.

Purified or bar iron is soft, ductile, flexible, malleable, and possesses all the qualities, which have been enumerated under this article as belonging exclusively to iron. When a bar of iron is broken, its texture appears fibrous; a property which depends upon the mechanical action of the hammer, while the metal is cold. Ignition destroys this fibrous texture, and renders the iron more uniform throughout; but hammering restores it.

If the purest malleable iron be bedded in pounded charcoal, in a covered crucible, and kept for a certain number of hours in a strong red heat (which time must be longer or shorter, according to the greater or less thickness of the bars of iron), it is found, that by this operation, which is called cementation, the iron has gained a small addition of weight, amounting to about the hundred-and-fiftieth, or the two-hundredth part; and is remarkably changed in its properties. It is much more brittle and fusible than before. Its surface is commonly blistered when it comes out of the crucible; and it requires to be forged, to bring its parts together into a firm and continuous state. This cemented iron is called steel. It may be welded like bar iron, if it have not been fused, or over-cemented; but its most useful and advantageous property is that of becoming extremely hard when ignited and plunged into cold water. The hardness produced is greater in proportion as the steel is hotter, and the water colder. The colours which appear on the surface of steel slowly heated are yellowish white, yellow, gold colour, purple, violet, deep blue, yellowish white; after which the ignition takes place. These signs direct the artist in tempering or reducing the hardness of steel to any determinate standard. If steel be too hard, it will not be proper for tools which are intended to have a fine edge, because it will be so brittle, that the edge will soon become notched; if it be too soft, it is evident, that the edge will bend or turn. Some artists ignite their tools, and plunge them into cold water: after which, they brighten the surface of the steel upon a stone: the tool being then laid upon charcoal, or upon the surface of melted lead, or placed in the flame of a candle, gradually acquires the desired colour; at which instant they plunge it into water. If a hard temper be desired, the piece is dipped again, and stirred about in the cold water as soon as the yellow tinge appears. If the purple appear before the dipping, the temper will be fit for gravers, and tools used in working upon metals; if dipped while blue, it will be proper for springs, and for instruments used in the cutting of soft substances, such as cork, leather, and the like; but if the last pale colour be waited for, the hardness of the steel will scarcely exceed that of iron. When soft steel is heated to any one of these colours, and then plunged into water, it does not acquire nearly so great a degree of hardness, as if previously made quite hard, and then reduced by tempering. The degree of ignition required to harden steel is different in the different kinds. The best kinds require only a low red heat. The harder the steel, the more coarse and granulated its fracture will be; and as this is not completely remedied by the subsequent tempering, it is adviseable to employ the least heat capable of affording the requisite hardness. It is a circumstance worthy of remark, that steel has a less specific gravity when hardened, than when soft; but there are no circumstances, upon which a probable connection between these two properties, namely, the increased hardness and the diminished specific gravity, can be made out.

The usual time required for the cementation of steel is from six to ten hours. If the cementation be continued too long, the steel becomes porous, brittle, of a darker fracture, more fusible, and incapable of being forged or welded. On the contrary, steel cemented with earthy infusible powders is gradually reduced to the state of forged iron again. Simple ignition produces the same effect; but is attended with oxidation of the surface. The texture of steel is rendered more uniform by fusing it before it is made into bars: this is called cast steel; and is rather more difficultly wrought than common steel, because it is more fusible, and is dispersed under the hammer if heated to a white heat.

The English steel made by cementation, and afterward fused, and sold under the name of cast-steel, in bars, plates, and other forms, possesses great reputation for its uniformity of texture, and other good qualities. I have been informed by various authorities, of which the respectability and connections are calculated to produce the most absolute confidence, that all the prime steels of England are made from Swedish iron, known in this country by the name of steel-iron, of

different marks, the first of which
tes the best quality, and the third the
; and that the whole produce of this
f iron is monopolized, under a con-
with Sweden, by two commercial
s, one in London, and the other at
ngham, the names of which were
oned to me. Hence it seems probable,
e useful art of steel-making might be
promoted by examining this material,
certaining chemically, as well as me-
ally, what may be the cause of its
ority. By chemical examination, I
the determination of its component

of it.

conversion of iron into steel, either
sion, viz. the direct change of crude
nto steel, or by cementation of bar-
present many objects of interesting
y. From various experiments of
an it appeared, that good crude iron,
or a certain time in a state of fusion,
such additions as appeared calculated
oduce little other effect than that
ending the metal from oxidation, be-
converted into steel with loss of
t. These facts are conformable to
general theory of Vandermonde,
e, and Berthollet: for, according to
researches, it should follow that part
carbon in the crude iron was dissi-
, and the remainder proved to be
n proportion as constitutes steel. The
chemist cemented crude iron with
ago, or carbonat of iron, and found
he metal had lost no weight. Mor-
repeated the experiment with gray
iron. The loss of weight was little,
. The metal exhibited the black
by the application of nitric acid, as
usually does, but it did not harden by
on and plunging in water. Hence I
de, that it was scarcely altered: for
irons also exhibit the black spot, and
t by common management acquire
rdness of steel.

m the experiments of the three excel-
hemists last mentioned, it appears,
he gray crude iron consists princi-
of iron, with as much carbon as it can
ve in the strong heat of the smelting
ce. They have shown also, that it de-
part of this addition when cooled in
ct with an iron bar immersed in the
This separation must be general in
rdinary or gradual way of cooling,
ce the gray colour must arise from the
hite colour of the iron mixed with
ack of the carbon. And this gray
r is also in a degree perceived, when
lose-grained steel is broken. These

circumstances lead me to conclude, that hard steel may in a certain respect differ from that which is softer by the intimate combination of a larger proportion of carburet. This accounts for the whiter and more metallic aspect of hardened steel, than of such as is soft. For the former contains less of disengaged carburet. Hence also we may account for the greater hardness of steel which has been made quite hard, and then let down by tempering to a certain colour, than of steel merely heated to that colour, and plunged in water. For in the first method of hardening, a sufficient degree of heat is given to produce combination between part of the disengaged carburet and the iron, which in the latter does not take place. If the carburet be merely sufficient to saturate all the iron at a moderate degree of ignition, the hardness will be considerable; but the steel will be easily degraded to the state of iron by frequent ignition. Such steel in its hard state will be very uniform in its texture, not excessively hard in its temper, but disposed to take a very fine firm edge, which will not easily be broken or injured by violence. These are accurately the properties of the English cast steel, which is of so uniform a nature, as to be distinguished by its conchoidal or glassy fracture. When the dose of carbon in steel is greater, it will bear a greater heat without degradation, insomuch, that it may be welded like iron. Its hardness will also be capable of a higher degree; and if this degree produced by a stronger ignition be not given, the edge of the tool will never become fine and smooth; and even at this higher degree, with all the advantage of subsequent tempering, it will be less smooth than that of the cast steel, and more disposed to break. Steel of this kind is better adapted for the construction of hammers, vices, hatchets, leather-cutters' knives, and other instruments wherein the edge is either stout, or sudden blows unnecessary, or the construction demands frequent heating and welding.

By pursuing this train of reflection, it will follow, that, since crude iron differs from steel only in the superabundance of carbon, it ought to be capable of extreme hardness, if ignited to that degree, which is requisite to combine the greater part of this carbon with the iron, and then suddenly cooled. This is accordingly found to be the case. If the gray crude iron, commonly distinguished by our founders by the name of soft metal, be heated to a white heat, and then plunged into water, it becomes very hard, much whiter, denser, and more metallic in its appearance; and will bear a pretty good edge fit for gravers, for the use of turners in iron or steel. In these tools the angle of the planes which form the edge is about 45°. The hardness of this kind of iron is not considerably diminished but by ignition continued for a length of time, which is a fact also conformable to what happens in steel. For the cast steel will be softened nearly as much by annealing to the straw colour, as the harder steels are by annealing to a purple or full blue.

Some of our artists have taken advantage of this property of soft crude iron in the fabrication of axles and collars for wheelwork; for this material is easily filed and turned in its soft state, and may afterward be hardened so as to endure a much longer time of wear.

The founders who cast wheels and other articles of mechanism are occasionally embarrassed by this property. For, as the metal is poured into their moulds of moistened sand, the evaporation of the water carries off a great portion of the heat, and cools the iron so speedily, as to render it extremely hard, white, and close in its texture. This is most remarkable in such portions of the metal, as have the greatest distance to run from the git or aperture of reception. For these come in contact successively with a larger portion of the sand, and are therefore more suddenly cooled. I have seen the teeth of cog-wheels altogether in this state, while the rim and other parts of the wheel remained soft. The obvious remedy for this defect is to increase the number of gits, and to have the sand as dry as possible or convenient. In other articles this property has been applied to advantage, particularly in the steel rollers for large laminating mills, which Messrs. Vandermonde, Monge, and Berthollet have supposed to be an over-cemented steel. They are made by casting the gray crude iron in moistened sand, the contact of which gives the hard steel temper to the outside surface, for the depth of more than half an inch. I have no doubt, but that the iron-masters pay considerable attention to the quality of the iron, and perhaps to the degree of heat and moisture of the sand in this operation, in order that the hardness may be such as to yield to the turning tool; and I likewise understand, that a considerable number crack longitudinally in the cooling, a loss which in all probability arises from the difference of contraction between the hard and soft parts.

In the experiments of Rinman, a bar of cast iron being placed over the fire of a smelting furnace was almost fused. It was observed in breaking it, that the side nearest the fire had become soft iron to the depth of one sixteenth of an inch; that the rest was steel, excepting the upper part exposed to the air, which remained in the state of crude iron.

I must refer to the Encyclopédie for a considerable enumeration of experiments relative to the cementation of iron with various metals, and also to such as relate to the return of steel to the state of iron. It appears in general, as might be expected, that iron by a sufficient continued heat in closed vessels, in contact with coally matter, becomes steel; but that if such matter be not present, the effect does not take place; and even the state of steel, if possessed by the iron, that is to say, its power of hardening by moderate ignition, goes off.

A variety of facts concerning the hardening and softening of steel are collected by Guyton-Morveau, the most interesting of which I shall here subjoin. According to Reaumur, that part of the steel which was hottest at the time of immersion in the water will be the hardest; whence it has been thought a fair conclusion, that the hardness of steel is the greater, the stronger the ignition, and the more speedy the cooling. Nevertheless, the celebrated Rinman deduces a very different consequence; namely, that the steel which is naturally the hardest is that which requires the least heat, and that the best temper for each kind of steel is that produced by the lowest degree of heat suitable to that peculiar kind. Hence, various methods have been proposed to ascertain the degree of heat most advantageous to any particular sample of steel. They are all reducible to that of igniting one end of a bar to a white heat, and plunging it into water. The hardness of the several parts may then be ascertained by examination.

It appears to me, that the considerations on which the first-mentioned general rule is founded, are rather of a complicated nature. If it be true, as conjectured above, that the hardness of steel depends principally on the intimate combination of its carbon; it will follow, that the utmost hardness any steel is capable of will be produced by a degree of heat sufficient to effect this purpose, and that any superior degree will only degrade the quality of the steel; and consequently, that the general rule will apply only to heats inferior to this maximum. It may also happen, when the mass of water is not considerable, though I doubt the fact when the quantity is large, that the heating of the water, and the production of hidrogen, may so far modify the rate of cooling, as even to render it less sudden than might have happened with an inferior degree of ignition. Lavoisier has remarked, that the conversion of iron into the hard brittle oxide, when water is decomposed, may perhaps be of the same nature as the hardening of steel. There is another fact, which is of great consequence, and may perhaps afford the principal ground for Rinman's apparent exception to the general rule concerning the hardening of steel. Hardness is that property of bodies by which they resist indentation, and rather break than bend, or suffer contusion. It is the opposite to softness. Tenacity, which

ry frequently confounded with hard-
is not the property by which they re-
ndentation, but separation of their
. It is the opposite to friability or
eness. Now that steel, in common
age, is said to be the hardest, which
s most eminently the properties of
ness and tenacity. But the effect of
and sudden cooling is directly opposite
ese two respects. Soft steel is the most
ious, but the least hard. The opera-
of hardening diminishes its tenacity,
ncreases its hardness progressively to
aximum of heat the steel is formed to
There will be no difficulty then in
iving, that the best state of steel, re-
to any particular use, will be at some
e degree between the softest and
est qualities. Thus for springs, much
ity and moderate hardness are re-
d. For chissels and similar tools,
operate by a blow, a greater hard-
nay be admitted. Razors, knives, and
tools as effect the intended purpose
gradual stroke, will be still more
ble the harder they are; but even in
the tenacity must not be too much di-
hed, otherwise the edge will be liable
reak. They must all be capable of
g the edge turned or bended on one
n the operation of whetting. Files
rhaps of all tools such as require the
est hardness; but in these, it is far
being the utmost the steel is capa-
of receiving. It is found, that the
ty of steel is considerably increased
ntinued hammering to a certain point.
he whole effect of this hammering is
off by strong ignition. Good steel by
ning at a white heat may be rendered
ttle, that it will break full as easily as

ble softness is required.

man affirms, that steel does not har-
when cooled in a close cylinder, or
n a vessel purged of air. Not having
rk in my possession, I find some dif-
in conceiving how the experiment
be made, so as to obviate all objec-
relative to loss of time, unless the
ng glass and receiver of an air-pump
used. Reaumur also found, that a
piece of steel introduced red-hot into a tube of glass full of mercury, which was immediately set upright so as to form an ordinary barometer with the vacuum at the top, continued as soft as if it had been cooled in the open air. Do these facts warrant the strange conclusion, that the mere pressure of the atmosphere is concerned in the hardening of steel? It seems, nevertheless, that no other effect of the air could be transmitted to the steel so instantaneously through a body of water. When we reflect on the effectual modifications which the smallest agitation, or even the presence of light, have upon the arrangement of the parts of solid bodies in crystallization, we shall have less cause for wonder if these facts should be confirmed.

Iron may be hardened to a certain degree by ignition and plunging in water, but this effect is confined to the surface; except, as it very often happens, the iron contains veins of steel. These are no small impediments to the filing and working this material. It sometimes likewise may happen, that the iron may have undergone a process of the nature of case-hardening from the fuel. I have been informed by a workman, that ignited iron, suddenly plunged into the soft leather of a shoe, becomes very hard on its surface, which must arise from an instantaneous effect of this kind.

The increase of dimensions acquired by steel in hardening is such, that in general such pieces of work as are finished soft will not fit their places when hardened. Rinman found, that bars of steel six inches long, six lines wide, and half an inch thick, were lengthened at least one line after hardening by a whitish red heat, which is about one seventieth of the linear dimensions; and supposing the dilatation to be proportional, Guyton-Morveau computes the bulks to be as 48 to 49. But the cubes of 72 lines and 73 lines are in proportion more nearly as 47 to 50. Various kinds of steel at different hardness must no doubt greatly differ in this respect. The specific gravities, as given by Brisson, p. 366, art. Gravity (Specific), afford a much less ratio. Rinman found by his experiments on two different kinds of fine cemented steel, the specific gravity of which was 7·991, that one after hardening gave only 7·553, and the other 7·708. These numbers agree sufficiently near with the experiment of the six-inch bar. Yet he once found Styrian steel augmented in density by hardening in the ratio of 7·822 to 7·782. Morveau found, with pieces of steel 28 lines long, that the increase of length by hardening was about the 350th part.

The fineness of grain in hard steel, as exhibited in its fracture, is various according to the quality of the metal, and the temper it has received. The harder the steel the coarser the grain. But in like circumstances, fine steel has the closest grain, and is ever the most uniform in its appearance. Workmen avail themselves much of this indication. In general a neat curve lined fracture, and even gray texture, denote good steel; and the appearance of threads, cracks, or brilliant specks, denotes the contrary. But the management of the forging and other circumstances of manufacturing will modify these indications; and the steel that is good for some purposes may be less suited to others.

The fluid into which ignited steel is plunged is of great consequence. All the facts seem reducible to these general conclusions. The hardness will be greater, 1. The hotter the steel is made, provided it be not decomposed: 2. The more considerably its temperature is lowered in the cooling: 3 The shorter the time of cooling: and 4. The more favourable the fire or the cooling material may be to the steel-making process. But the most useful combination of hardness and tenacity will be at a medium temperature in each kind of steel.

With regard to the first particular, little need be said, but that the decomposition of steel in heating will be prevented, and its surface somewhat improved, if it be bedded in charcoal, or the cementing compound, during the application of the heat. The second and third, namely the quantity and suddenness of cooling, require an attention to the doctrine of Caloric, as explained under that article. The cooling will be more sudden and effectual the greater the quantity of heat absorbed in the same time. There are three circumstances which favour this effect, namely, a very low temperature of the body to which the hot steel is applied; that it shall be a good conductor of heat; or that it shall assume either the fluid or elastic state, which always demand a supply of heat for their maintenance. Thus it is found, that steel is more effectually hardened in cold than in warm water, and at like temperatures more effectually in mercury than in water. It may also be remarked, that these two fluids cool the steel by different energies. The water is partly converted into vapour, which carries off the heat, and leaves the fluid much less altered in temperature than mercury, which acts by its conducting property. This last fluid, not having evaporated in the process, is found to have acquired a much more elevated temperature by the immersion. Oil is found to harden the surface of steel much more than its internal part, so that it resists the file, but is much less easily broken by the hammer. This effect arises from its imperfect conducting quality, and the elevated temperature it demands to be converted into the vaporous state; to which we may also add, that a stratum of coal is formed round the steel from the burned oil, which still more effectually prevents the transmission of the heat. A remarkable instance of this nature presented itself to my observation in hardening a small piece of steel two inches long, and a quarter of an inch diameter. At the time of ignition, the water nearest at hand had been used with soap. The steel made very little noise when plunged into the water, and remained hot for a considerable time; but when taken out was found to be scarcely at all hardened. It was covered with coally matter; which being cleared off, and the process repeated with clean water, it became perfectly hard. The heat in both cases was a low red heat, proper for cast steel, which is not intended to be afterwards annealed. I have very little doubt, but that alcohol and the essential oil of turpentine, which are good conductors of heat and very volatile, would render steel very hard, if their inflammability, and the little necessity there is for using them, were not an impediment to their application. Various artists avail themselves of different substances for the immersion of ignited steel. Some use urine, others water charged with common salt, nitre, or sal ammoniac. Tallow and oil are used for such works as are not required to be brittle, though very hard, the reason of which has just been mentioned; but tallow differs from oil in the heat which becomes latent for its fusion; and accordingly, solid tallow is an excellent material for hardening drills and other small articles. It has been found by Reaumur, that saline liquids produce rather more hardness than common water; and in particular, that aqua fortis possesses this property in an eminent degree, probably from its conducting power: the makers of files cover them with the grounds of beer and common salt, which assist their hardening, and keep the surface from scorifying. The mucilage of the beer supplies a coally matter; and the fused salt seems not only to form a varnish in the fire and defend the steel, but may also produce cold, by its sudden solution in the water at the time of immersion. Very small articles heated in a candle are found to be hardened perfectly by suddenly whirling them in the cold air; and thin bars or plates of steel, such as the magnetic needle of a compass, acquire a good degree of hardness by being ignited, then laid on a plate of cold lead, and suddenly covered with another plate. These would be unequally hardened, and bend, if plunged in water.

The *blueing* of steel appears to affect its elasticity in a manner not easily explained. This operation consists in exposing steel, the surface of which has been first brightened, to the regulated heat of a plate of metal, or a charcoal fire, or the flame of a lamp, till the surface has acquired a blue colour. Now, if this blue coal be removed by grinding, the elasticity is completely destroyed, d may be restored by blueing the steel ain. Rubbing with sand or emery-paper, azing, or burnishing, equally impairs the asticity in proportion as it destroys the ue coat. Sawmakers first harden their ates in the usual way, in which state they e brittle and warped: they then soften em by *blazing*, which consists in smearing e plate with oil or grease, and heating it l thick vapours are emitted, and burn off ith a blaze; and after this they may be mmered flat: lastly, they blue them on hot iron; which renders them stiff and astic without altering their flatness.

The Damascus swordblades have long een celebrated for their excellence, but it not known how they are made. Mr. oddart took six small bars of good alleable iron, and the same number of eer steel; laid them alternately on each her; welded them together; forged them to a stout flat plate, which was twisted irally into a cylinder, hammered flat, and gain welded; hammered this flat, doubled throughout its length, inserted in the fold slip of good steel to form the edge, and y another welding heat consolidated the hole into one mass. This being forged to proper shape, cracked in different places n being cooled in water after heating: but Ir. Stoddart conceives, that by using more ieces, repeating the twisting, and not uenching in water, the process would ucceed.

Mr. Duhamel, in the Encyclopédie, gives n ample account of the methods of making eel by the ancient way of fusion from the re, and the more modern way of cemen- ation. We have treated concisely of both lready, and in this place shall only add a ew of the facts noted by this author con- erning cementation. The English, who eservedly possess the greatest reputation n this work, have found, that every species f iron is convertible into steel by cemen- ation; but that good steel is not to be nade except from iron of the best quality, vhich possesses a certain stiffness and hard- ess as well as malleability. Swedish iron, s we have before remarked, is the best for his purpose. Mr. Duhamel tried a great umber of the irons of France, Sweden, and pain. He found the second to be the best; ut he likewise obtained excellent steel, su- erior to those of Styria and Carinthia, vhich are the best German steels, by using ertain iron made in France. But this iron vas selected without fault, and, in some in- tances, the loup or piece at the smelting urnace was fused and forged a second ime; a process which, though attended vith loss of weight and additional expense, e recommends as absolutely necessary for naking steel iron from ores of indifferent uality. The white spathose iron ores af- orded him the best iron for the purpose f cementation; and these also are the ores, vhich afford the best steel by fusion in, Styria, Carinthia, and Tyrol. He informs us, that the English use no other cement than mere charcoal, which he also finds perfectly adequate to the purpose; and moreover, that the quality of the steel is not affected by the different kinds of charcoal made use of. He remarks nevertheless, that it may be adviseable to add from one fourth to one third of wood-ashes, especially where the iron is not of so good a quality as to afford steel possessing tenacity or body, as well as hardness. These ashes, which he used with success, prevent the steel-making process from being effected as rapidly as it would otherwise be, and give the steel pliability without diminishing its hardness. It is remarked, that in the case of this management, the blisters on the surface of the steel are smaller and more numerous. He likewise tried sea-salt. Fifty pounds of salt are sufficient for a furnace of steel of twelve thousand weight. The salt is pulverised, and sprinkled on the bars of iron when put into the furnace. He found, that this ingredient likewise contributes to give body to the steel. In the arrangement of the bars in the furnace, the cement is laid one inch thick at the bottom, and half an inch thick between each layer of iron. Our author affirms, that the process would succeed equally well, if the thickness were a little more than a quarter of an inch. The thickness of the bars of iron is indifferent, but there ought not to be a great difference in this respect between bars cemented at the same time. The common thickness is a little more than half an inch. It is not adviseable, that they should be very broad in proportion to the thickness, as this figure is found to produce flaws and cracks in the direction of the length of the bar. The bars may be square, or their breadth may conveniently be somewhat more than twice their thickness. The fire for cementation must be of considerable intensity, and kept up until the conversion has perfectly taken place, which is ascertained by proof bars, so disposed as to be taken out from time to time. The cementation is finished on the sixth day; that is to say, it commonly lasts five times four-and-twenty hours. And accordingly, the workmen take one of the proofs out on the fifth day, which is forged, hardened, and examined by the fracture. If it break short, and show no indications of iron, the fire of the furnace is suffered to go out. But if it contain iron, the fire is kept up for twelve or twenty-four hours, accordingly as the quantity of fibrous iron may have proved greater or less in the first proof. A second proof bar taken out at the proper time serves to direct them in the same manner with regard to their operations. By this management, the cementation is continued somewhat beyond the time requisite for the entire conversion. For there is less inconvenience attending a slight degree of excess in the cementation, than would result from a portion of iron remaining in the steel. The charcoal after cementation is as black, and apparently in the same state, as it was before. Mr. Duhamel moistened it, and applied it to the same use a second time. It answered the purpose, but so much more slowly, that he objects to the use of it in manufactories. From this, as well as other circumstances attending the steel-making process, it seems advantageous, at least with regard to expedition, that the coals should contain volatile matter. And hence the superior advantages of animal coal, such as the coal of leather, or the hoofs and horns of animals, imperfectly burned, which are used in case-hardening, though they may be less applicable to the longer process of steel-making for various reasons.

Mr. Duhamel advises to have two tilting hammers; one of the weight of one hundred and fifty pounds, and the other half that weight; the first, for the purpose of forging large work, and the latter small bars for cutlers. He recommends another small hammer of about twelve pounds for forging bars still smaller, to make gravers, small files, and the like. The steel must not be heated beyond the degree of cherry red for forging. The tilting hammers should give at least three hundred strokes in a minute.

On this head, I must make a reflection, which perhaps may be of value to the manufacturer, though experience certainly affords the only means of determining the utility of proposed alterations in the implements or utensils. When a hammer strikes with a certain momentum, the change of figure produced by the blow will be greater, the more of velocity and the less of mass possessed by the hammer. It seems therefore, in the application of mechanic force, that in most cases the expenditure would prove more profitable, if an extreme velocity were given to a small weight, the face of the hammer remaining the same, than if a larger weight were moved proportionally slower. And so likewise, it should appear, that more work would be done by a certain number of swift blows, than by twice the number with only half the swiftness. When the usual number of strokes is three hundred in a minute, or five in a second, the velocity cannot be considerable, even when assisted by a back spring, or other contrivance. It would therefore at least be worth trying in situations where the power is limited, as in the case of a small stream of water, or steam engine, whether the weights and velocities of the hammers may not be altered with profit. An ingenious mechanic would find no difficulty in contriving a simple apparatus, by which these correspondent alterations might be made at pleasure, accordingly as the nature of the work or other circumstances might demand.

The cast steel of England is made by a process, which the manufacturers keep a secret. Mr. Duhamel gives the following account of it: A crucible about ten inches high, and seven in diameter, is filled with ends and fragments of the crude steel of the manufactories, and the filings or fragments of steel works. Magellan affirms, that they buy up broken tools at Sheffield or elsewhere for this purpose. They add a flux, the component parts of which are carefully concealed It is probable, however, that the success does not much depend upon this flux, which, from the quality of the cast steel itself, may be presumed to be of the nature of a steel cement. This crucible is placed in a wind furnace, like that of the founders, but smaller, because intended to contain one pot only. It is likewise surmounted by a cover and chimney to increase the draught of air. The furnace is entirely filled with coke or charred pit-coal. Five hours are required for the perfect fusion of the steel. It is then poured into long square, or octagonal moulds, each composed of two pieces of cast iron fitted together. The ingots when taken out of the moulds have the appearance of cast iron. It is then forged in the same manner as other steel, but with less heat and more precaution; because more liable to break.

This cast steel is almost twice as dear as other good steel. Mr. Duhamel says, that it is not proper for all kinds of work, particularly those which require much tenacity, as well as hardness to resist violent blows and strains; but it is good for razors, knives, and all toys and small work which require an exquisite polish. It does not seem, however, that the tenacity of this steel is inferior to that of the best of the other kinds, and its uniformity of texture is for many works an invaluable advantage. It is daily more and more used in England, but must necessarily be excluded from many works of considerable size, on account of the facility with which it is degraded in the fire, and the difficulty of welding it, which cannot be done in the common way. I have been informed, that the faces of anvils and broad hammers, for the use of silver-smiths and other artists, have been made of cast steel and welded to iron by a particular management, which consisted in substituting between the iron and the steel another kind of steel in the form of filings, or a thin plate. The steel plate intended for the face was made as hot as could be done with safety, and the iron being at the same time brought to the welding heat, was applied to the steel, and quickly united by hammering.

When we consider the operations by which crude iron is brought into the malleable state, then converted into steel, and afterward into a fusible metal, which is not malleable; we may perceive that steel, making is a kind of inversion of the process of refining iron, as practised in the first instance. When the oxide of iron is mixed in the smelting furnace with combustible matter and glass, it will either be completely or partially revived, according to the management of the process. Much of the coal will however be so enveloped with the vitreous matter as to remain unburned: and the reduced iron, with which it may be in contact, will be in the same situation as forged iron in the cementing pot; that is to say, it will be in contact with coal at a very elevated temperature, and defended from the air. From the great infusibility of iron, it may reasonably be concluded, that the reduced metal does not flow into the bottom of the furnace, until the charcoal has converted it into a fusible matter similar to steel, by the same action which takes place in cementation, whatever that action may be. Hence it must follow, that the various specimens of crude or cast iron will differ in their qualities, as well on account of the degree of cementation they have undergone, as the degree of reduction which has taken place among the metallic parts, which are carried down, and form the whole mass. Since the coal, in the process of cementation, communicates or adds weight to the iron; and since crude iron, as well as steel, exhibits sparkles, and is more easily burned than other iron; it may therefore be concluded, that in the process of refining, that part of the inflammable substance which had united with the metal is burned, and leaves the iron much less fusible than before. Stirring the mass multiplies the contacts of the air with the burned substances; these surfaces of contact will therefore successively afford thin coats of infusible metal. In this manner it is found, that, if a large piece of crude iron be exposed to heat in a wind furnace, the external part will be deprived of its fusibility during the time required to produce a strong heat in the whole mass; and the internal part will be melted, and run out, leaving the shell behind. Iron, which is of the consistence of paste, may therefore be considered, like any other paste, as a mixture of a fluid with a solid. It will be easily understood, that the forging will bring the parts of difficult fusion together, and extrude the less refined and fluid parts: it will also be evident, that this operation is not likely to drive out the whole of the fusible matter. When the iron has arrived at that state, wherein the quantity of fibre or tough iron is sufficient to answer the mechanical purposes to which it is intended to be applied, the artist will consider it as sufficiently refined; and the residue of fusible iron contained in the bar answers, in all probability, the valuable purpose of connecting these infusible masses together. Thus we find, that forged iron appears as if covered with a varnish, when urged to a white heat; we find that this varnish is more abundant in steel; and that iron and steel may be respectively welded together by application in this state; an effect which it would be very difficult to account for, in this most infusible of metals, if it were not for such an admixture. But cast steel, steel overcemented, and crude iron, appear to be in the state of all other metals, platina excepted. They cannot be welded, because welding implies a partial fusion; or an effect similar to the glueing or uniting of solids by the application of a fluid, which afterward becomes consistent. And as platina possesses this valuable property, it seems reasonable to infer, that it must also consist of two metallic substances of different degrees of fusibility; a supposition that appears to be confirmed by the discoveries of Dr. Wollaston and Mr. Tennant.

Crude iron, and steel of a uniform texture, consist therefore of a fusible combination of iron with the combustible substance of the coal, or something which is imparted from it; the crude iron differing from the steel simply in being overdosed with carbon, and less pure, on account of the admixture of metallic oxide, which can scarcely, perhaps, be avoided in the large process. It appears therefore, that crude iron must pass through the state of steel, before it can become forged iron; and consequently, that the fabrication of steel from this last is a circuitous process, which can only be repaid by the absence of those unreduced parts, which may exist in the crude iron. At some forges, however, where the ore, the flux, the fuel, and the management, are adapted to each other, the produce affords steel, when duly refined. At other manufactories, the crude iron is either refined, or converted into steel, by running it into thin plates, which are stratified with charcoal, and burned in a close furnace. In this way the metal is refined by degrees, without undergoing fusion; and if the heat be raised to that of cementation, the iron will not only be reduced, but converted into steel. In the forges of Carinthia the gray crude iron is also converted either into soft iron, or steel, according to the management of a somewhat similar process. The iron is fused in a large melting-pot; and a small quantity of water, being thrown upon the surface of the metal, causes a thin plate to congeal, which is taken off; and by continuing the operation, the greatest part of the fused iron becomes converted into plates. To produce steel, these plates are again fused, and kept a long time in an elevated heat; at the same time that the metal is defended from the contact of the air by a sufficient quantity of the vitreous slag. To produce soft iron, the plates are exposed to a continued roasting, while the air is constantly renewed by means of two pair of bellows. The extensive surface of the plates renders it unnecessary to use that agitation, or stirring, which is required when fused crude iron is refined. In these processes it is evident, that the same matter in the crude iron, which it obtained in the smelting furnace, is employed, and supplies the place of the charcoal used in forming steel by cementation; and, on the other hand, that this substance, which prevented the crude iron from being soft, tough, and infusible, is burned away, together with a portion of the iron itself, while the remainder is left in a much purer state.

These are facts observed at the furnaces. But the observations and inquiries of the chemist must be carried farther, in order to determine what it is that iron gains or loses at the time of its conversion into its various states. It is found, that crude iron approaches towards the soft state, not only by heating with exposure to the air, which burns the combustible addition, but likewise by fusion, without the free access of air. In this case, when the fusion has been complete, and the cooling gradual, it is found that a black substance is thrown up to its surface, which is more abundant the grayer or blacker the iron; and the same black substance is observed to coat the ladles of forged iron, which are used to take out the metal, and pour it into moulds for casting shot, and other articles. It appears therefore, that the heated iron, like other heated fluids, is capable of holding a larger quantity of matter in solution than when cold; and that a portion of this black substance separates during the cooling, whether by the gradual effect of surrounding bodies, or by the contact of the ladle, in the same manner as various salts are separated, in part, from water, by a diminution of temperature. From chemical analysis, as well as from its obvious characters, this black substance is found to be plumbago, or the materials used to make pencils, and commonly known by the name of black lead, which is nothing but a carburet of iron.

The presence of this black matter is likewise exhibited by dissolving steel, or crude iron, in acids, in which plumbago is insoluble, and therefore remains behind in the form of a powder. Hence likewise is deduced the cause of the black spot which remains upon steel, or crude iron, after its surface has been corroded by acids; for this spot consists of the plumbago, which remains after the iron has disappeared by solution.

Solution in the sulphuric or muriatic acid not only exhibits the plumbago contained in iron, but likewise possesses the advantage of showing the state of its reduction by the quantity of hidrogen gas which is disengaged: for the quantity of this gas, in like circumstances, is proportional to that of the iron which is converted into oxide. There are considerable differences between the various products of the smelting furnace in these respects; but it is found, that the white crude iron affords the least quantity of hidrogen in proportion to its bulk, and leaves a moderate portion of plumbago; the gray crude iron affords more hidrogen, and more plumbago than the white; and the softest bar iron affords most hidrogen of any, and little or no plumbago. The quantities of hidrogen gas, at a medium, by ounce measures, were 62, afforded by 100 grains of the white crude iron; 71 by the gray crude iron; and 77 by the malleable iron.

Hence it may be inferred, that, in the white crude iron, the processes of reduction and cementation are both carried to a less extent than in the gray crude iron, which is produced by means of a stronger heat, excited with a larger quantity of fuel: and that the reduction of gray crude iron is still less perfect than that of the soft bar iron; though this last, by the refining in an open vessel, is so far from being more cemented, that it scarcely contains any plumbago at all.

It must be admitted, however, that the solution in acids serves only to support these general conclusions, in conjunction with the facts observed in the dry processes; but cannot accurately show the quantities either of hidrogen or plumbago afforded by the several kinds of iron. For the plumbago, as it becomes disengaged, floats on the top of the sulphuric acid; where it gradually disappears, though insoluble in that acid. It must therefore be taken up by the hidrogen gas, and it is found that the volume of this air is diminished by the absorption. Hence there is a double source of inaccuracy from the loss of plumbago, and the contraction of the hidrogen gas.

On the whole then, since iron contains plumbago in a state of combination, of which it may be deprived by heat with access of oxigen, which converts its carbon into the carbonic acid; and since it recovers the plumbago by cementation with charcoal; there can be no question, but that this substance is originally afforded by the fuel. It appears also, that the reduction of the metallic oxide takes place first at a lower temperature; and that the combination of the carbon follows at a greater heat. Whence, in the refining of iron, the carbon is first burned, and the iron remains reduced; and in the cementation of bar iron, the metal is converted into steel, with blisters on its surface; which most probably arise from carbonic acid, formed by the oxigen of some portions of unreduced oxide uniting with the acidifiable base from the charcoal. And, lastly, as iron holds this acidifiable base, or carbon, in solution, so likewise it may not be separable from this metallic solvent, without carrying a portion with it; in the same manner as salts, which crystallize in water, always take up part of the solvent in the formation of their crystals.

It would require many volumes to enumerate the leading uses of iron. This most valuable of metals is applied to so many, and such important uses, that we cannot look round us without seeing its effects. When we contemplate the innumerable effects of human industry, and ask ourselves the simple question, Could this have been done without iron? there is not a single instance, which will not immediately show its value.

Iron is one of the principal ingredients for dyeing black. The stuff is first prepared with a bath of galls and logwood, then with a similar bath to which verdegris is added, and lastly dyed in a similar bath with the addition of sulphat of iron. If it be wished, that the colour should be particularly fine, the stuff should previously be dyed of a deep blue: otherwise a brown may be first given with the green husks of walnuts. Silk however must not be previously blued with indigo, and sumach may be substituted instead of galls. Leather, prepared by tanning with oak bark, is blackened by a solution of sulphat of iron.

Cotton has a very strong affinity for oxide of iron, so that, if it be immersed in a solution of any salt of iron, it assumes a chamois colour, more or less deep according to the strength of the solution. The action of the air on the oxide of iron deepens the colour; and if the shade were at first deep, the texture of the stuff is liable to be corroded by it. To prevent this, the cotton should be immersed in the solution cold, carefully wrung, and immediately plunged into a ley of potash mixed with a solution of alum. After having lain in this four or five hours, it is to be wrung, washed, and dried.

Mr. Brewer, to give a nankin colour, prepares his cotton yarn by boiling it five hours in a mixture of water made grass green with sheep's dung and a solution of white soap; twice more, an hour each time, with half the quantity of soap; and a fourth time in a ley of pot or pearl ashes, one pound to twenty of yarn, another hour. He then passes it through iron liquor, to every gallon of which half a pound of red chalk, or ruddle, in powder is added; the liquor being poured off clear, after it has stood four hours to settle; and immerses it in an alkaline lixivium. When of the proper colour, for which this operation may be repeated if necessary, he dries it, as after each of the former processes; and then puts it into a warm lixivium, in which it is brought to a scald. It is afterward to be soaked an hour in water made almost as sour as lemon juice with sulphuric acid, and then washed and wrung twice. Lastly, it is to be boiled slowly an hour in a solution of white soap, one pound to ten of yarn.

The ancients appear to have had the art of preparing a blue enamel from iron. Mr. Klaproth analysed a piece of antique glass of a sapphire blue colour, transparent only on the edges, two hundred grains of which gave the following products: silex 163 grains; oxide of iron 19; alumine 3; oxide of copper 1; lime 0·5. The loss was 13·5.

Iron is very liable to be oxided, or contract rust. Conté informs us, that if fat oil varnish be mixed with half, or at most four fifths of its weight of oil of turpentine, and this be applied lightly and evenly with a sponge to iron or steel, and left to dry where it is not exposed to dust, the metal will retain its lustre, without any danger of rusting. In order to prevent gunbarrels from rusting they are frequently browned. This is done by rubbing it over when finished with aqua fortis or spirit of salt diluted with water, and laying it by for a week or two till a complete coat of rust is formed. A little oil is then applied, and the surface, being rubbed dry, is polished by means of a hard brush and a little bees-wax.

The yellow spots called iron moulds, which are frequently occasioned by washing ink spots with soap, may in general be removed by lemonjuice, or the oxalic or tartarous acids; or by muriatic acid diluted with five or six parts of water, but this must be washed off in a minute or two. Inkspots may readily be removed by the same means. If the iron mould have remained so long, that the iron is very highly oxided, so as to be insoluble in the acid, a solution of an alkaline sulphuret may be applied, and, after this has been well washed off, the acid will remove the stain.—*An. de Chim.*—*Crell's Annals.*—*Bergman.*—*Magellan.*—*Des Mortiers on Decoloration of Pruss. Blue.*—*Phil. Mag.*—*Bullet. des Sciences.*—*Phil. Trans.*—*Van Mons Journ.*—*Nich. Journ.*—*Fourcroy.*—*Henry.*

Iserine. An ore of titanium, found near the source of the Iser, on the borders of Bohemia, in small, obtuse angular grains, of an iron black, inclining to brown, much resembling iron sand: and in pebbles with a rough, glimmering surface; of a conchoidal fracture; and shining internally with a semimetallic lustre.—*Irish Trans.*

Isinglass. This substance, though well known in the arts, has been greatly mistaken, not only with regard to the manner of its fabrication, but as to the effects it produces. It is almost wholly gelatine: 100 grains of good dry isinglass containing rather more than 98 of matter soluble in water.

The principal consumption of isinglass is in fining liquors of the fermented kind. It appears to do this merely by the mechanical effect of its organization, which forms a kind of strainer, or fine net-work, and carries the gross impurities before it as it subsides. Glue is unfit for this purpose, because it wants the peculiar structure. Isinglass itself, if converted into glue by boiling ment, and is infusible in the fire. Mr. Saussure seems to have extracted iron from it.

It is sometimes of a whitish milky colour, from China; but mostly of a greenish, or deep green colour, from America, or of a gray, yellowish and olive colour. The jade is vulgarly denominated lapis nephriticus, from being supposed to cure nephritic pains by external application to the loins.

The semitransparency, hardness, and specific gravity are the characters by which the lapis nephriticus may be distinguished from other stones.

Jalap is the root of a species of convolvulus, with leaves like those of ivy, but not so thick, and beautiful red flowers, which have this remarkable property, that they open in the night, and shut again on the least appearance of the sun; whence the plant is called by the French *Belle de nuit*, The beauty or fair one of the night: in rainy or cloudy days the flowers open a little, but fall off the sooner, as if daylight were injurious to them. The jalap plant is a native of the province Chalapa or Xalapa, in New Spain, whence its name is derived, and written, according to the pronunciation of different languages, *Jalapa* or *Jalapium*, *Gialappa*, *Chalapa*, *Xalapa*, *Zalopa*, &c. The roots raised in Europe have been found much weaker than the American.

Jalap is brought over in thin slices; of which the best are compact and hard, so as not to be broken by the fingers; ponderous, of a dark brown colour, of a glossy resinous appearance, or at least furnished with resinous streaks and circles; easily inflammable, of no smell, or a faint unpleasant one, and of a slightly acrid taste. The fine dust, which flies off in powdering them, provokes sneezing. Those which are thoroughly resinous are not liable to be worm-eaten, the worms preying chiefly upon the gummy or mucilaginous parts, and not touching the resin, or at least not till these are consumed: hence we may suppose the worm-eaten roots to have been originally of a bad kind, produced in moist soils or rainy seasons, &c.; and hence the worm-eaten may be employed for extracting the resin equally with any other, the resin being equal in goodness, though less in quantity.

From sixteen ounces of good jalap root, Neumann obtained, by alcohol, five ounces and four scruples of resinous extract; and afterward by water, two ounces and a half of a gummy one: on applying water at first, he gained four ounces and a half of gummy extract, together with six drachms of a resinous matter, which fell to the bottom in evaporating the decoction; the remainder yielded, with spirit, three ounces of resin: the indissoluble part amounted in the first case to eight ounces three drachms, in the latter to seven ounces six drachms. By precipitating a spirituous tincture of the root with water, he gained, from a pound, four ounces of pure resin.

The inferior sorts of jalap yield less resinous and more gummy extract; such must have been that employed by Boulduc, who obtained, from sixteen ounces, only two ounces five drachms and a scruple of resinous extract; but upwards of eight ounces and a half of a gummy one.

It has been remarked, that jalap possesses a notable degree of fermentative power; exciting this action in gross, sweet, vegetable juices, such as melasses, and at the same time impregnating them with its purgative quality. I am informed, however, that this is by no means the case, but that it is used to check the rapid progress of fermentation in the manufacture of melasses' spirits, for which purpose it is strewed over the surface of the liquor. It is a late discovery, that common resin will do as well. This effect requires explanation. Perhaps the resin may combine with part of the alcohol, at the instant of its extrication. If this be true, it seems likely that so much of the spirit may be prevented from rising in distillation, and more loss may be sustained by this practice than might have followed from the activity of the fermentation.

Japan Earth. See Catechu.

Jargon. A hard gem brought from the East Indies in the form of thin plates, which appear to be split from pebbles. They are of different colours, white, black, yellow, and brown, about as hard as the sapphire. As they have a great resemblance to the diamond, they are substituted instead of it in jewellers' work, sometimes fraudulently. It is probable that the great specific gravity of this stone, which is from 4·416 to 4·615, may be attended with an extraordinary degree of refractive power, on which the brilliancy of precious stones depends. See Diamond.

Bomare says, that the jargon is found in Brasil, but Romé de l'Isle informs us that it comes from Ceylon, and that its form consists of two tetrahedral pyramids of equal sides, separated by a short quadrangular prism. Mr. D'Arcet exposed it to a violent heat in a porcelain test. Its surface was a little vitrified, and it stuck to the vessel; the blowpipe with oxigen gas destroys its transparency, without diminishing its weight, and gives it the appearance of white enamel.

It was in this stone Mr. Klaproth discovered the new earth, called from the French name of this stone zircon, of which it contains ·69, with ·265 of silex, and ·005 of oxide of iron.

Jaspachates. See Jade.

Jasper. *Jaspis.* (The Diaspro of the Italians.)

All opaque flints are called by this name, the texture of which resembles dry clay, and which have no other known quality, whereby they may be distinguished from other flints, except that they may be more easily melted in the fire; and this quality, perhaps, may proceed from the mixture of iron. It often breaks with conchoidal surfaces; is capable of a fine polish; its colour is generally reddish, or green, or striped; but it is also found blue, gray, or whitish; its specific gravity is from 2·58 to 2·778, or more, when it contains more iron.

Jasper is infusible alone with the blowpipe; with the mineral alkali it is only partially soluble, separating itself with effervescence into small particles; but it melts with *borax* or *microcosmic salt*, without any effervescence. Wedgwood found that the action of fire increases its hardness.

According to Bergman, in his Sciagraphia, it is composed of *siliceous earth*, united to alumine very full of iron. The mineral acids have no action upon jasper in a short time, but at the end of some months it is found corroded, if immersed in them. De la Metherie's analysis of the Egyptian pebble, which is a variety of jasper, gave silex ·54, alumine ·30, oxide of iron ·16.

Mr. Daubenton mentions 15 varieties of jasper. 1. The *green*, from Bohemia, Silesia, Siberia, and the shores of the Caspian sea. This seems to be the *pavonium* of Aldrovandus. 2. The *red*, or the *diaspro rosso* of the Italians, which is neither so common, nor in such great masses, as the green. 3. The *yellow*, from Freyberg and Rochlitz; it is sometimes of a lemon colour, and looks as if composed of silky filaments. This is called the *silk jasper*. 4. *Brown*, from Dalecarlia, in Finland and Sweden. 5. The *violet*, from Siberia. 6. The *black*, from Sweden, Saxony, and Finland. This is the *paragone antico* of the Italians. 7. The *bluish gray*, which is very rare. 8. The *milky white*, of which Pliny speaks; it is found in Dalecarlia. 9. The *variegated* with *green*, *red*, and *yellow* clouds. 10. The *blood stone*, which is green with red specks, from Egypt, and was supposed to stop the blood. 11. The *veined*, with various colours. When these veins have the resemblance of letters, it is then called *jaspe grammatique* by the French. Some of this kind are found near Rochelle in France, and called *polygrammatiques* by the curious in these trifling accidental qualities. 12. That which has various coloured zones. 13. That called *fiorito* by the Italians, which has its various colours promiscuously, without any order. 14. When the jasper has a great number of colours together, it is then (very improperly) called universal. 15. Lastly, when the jasper is found to contain some portions of agate, it is then called *agatized jasper*.

Jelly. See Gelatin.

Jesuits Bark. See Cinchona.

Jet. *Gagas*, *Succinum nigrum*, Lat. *Jet*, *Jayet*, French.

The *jet*, the *lapis obsidianus*, and the *fossil wood*, penetrated by mineral inflammable matter, are often confounded together, on account of their black glossy colour. But the lapis obsidianus is a volcanic glass, and jet is a compact bitumen. Jet is much harder than asphaltum, always black, susceptible of a good polish, and glossy in its fracture, which is conchoidal; its specific gravity is about 1·104, or according to Brisson 1·259; it melts in a moderately strong heat, with a disagreeable smell; when burnt, it leaves a gray earthy ochrous residuum; it is partly soluble in alcohol. By friction it becomes slightly electric.

It is found in *England*, *Scotland*, *France*, *Italy*, *Germany*, *&c.* Wallerius, Bomare, and others assert, that it floats on water; a circumstance which, if true, must indicate a specific gravity less than 1·000.

The use of this fossil consists in the manufacture of small toys. It is also said to be an ingredient in some varnishes.

Jews Pitch. See Asphaltum.

Juices of Plants. The juices of several plants are expressed to obtain their essential salts, and for several medicinal purposes, with intention either to be used without further preparation, or to be made into sirups and extracts.

The general method of extracting these juices is, by pounding the plant in a marble mortar, and then by putting it into a press. Thus is obtained a muddy and green liquor, which generally requires to be clarified, as we shall soon observe.

The juices of all plants are not extracted with equal ease. Some plants, even when fresh, contain so little juice, that water must be added while they are pounded, otherwise scarcely any juice would be obtained by expression. Other plants, which contain a considerable quantity of juice, furnish by expression but a small quantity of it, because they contain also much mucilage; which renders the juice so viscid, that it cannot flow. Water must also be added to these plants to obtain their juice.

The juices thus obtained from vegetables by a mechanical method are not, properly speaking, one of their principles, but rather a collection of all the proximate principles of plants, which are soluble in water; such as the saponaceous extractive matter, the mucilage, the odoriferous principle, all the saline and saccharine substances; all which are dissolved in the water of the vegetation of the plants. Beside all these matters, the juice contains some part of the resinous substance, and the green colouring matter. These two latter substances, not being soluble in water, are only interposed between the parts of the other principles which are dissolved in the juice, and consequently disturb its transparency. They nevertheless adhere together in a certain degree, and so strongly in most juices, that they cannot be separated by filtration alone.

When therefore these juices are to be clarified, some previous preparations must be used, by which the filtration may be facilitated. Juices which are acid, and not very mucilaginous, are spontaneously clarified by rest and gentle heat. The juices of most antiscorbutic plants, abounding in saline volatile principles, may be disposed to filtration merely by immersion in boiling water; and as they may be contained in closed bottles while they are thus heated in a water bath, their saline volatile part, in which their medicinal qualities chiefly consist, may thus be preserved. Fermentation is also an effectual method of clarifying juices, which are susceptible of it; for all liquors, which have fermented, clarify spontaneously after fermentation. But this method is not used to clarify juices, because many of them are susceptible only of an imperfect fermentation, and because the qualities of most of them are injured by this process.

The method of clarification most generally used, and indispensably necessary for those juices which contain much mucilage, is by boiling with the white of an egg. This matter, which has the property of coagulating in boiling water, and of uniting with mucilage, does accordingly, when added to the juice of plants, unite with and coagulate their mucilage, and separates it from the juice in form of scum, together with the greater part of the resinous and earthy matters, which disturb its transparency. And as any of these resinous matters, which may remain in the liquor after this boiling with the white of eggs, are no longer retained by the mucilage, they may easily be separated by filtration. See **Filtration**.

The juices, especially before they are clarified, contain almost all the same principles as the plant itself, because, in the operation by which they are extracted, no decomposition happens, but every thing remains, as to its nature, in the same state as in the plant. The principles contained in the juice are only separated from the grosser, oily, earthy, resinous and woody parts, which compose the solid matter that remains under the press. These juices, when well prepared, have therefore exactly the same medicinal qualities as the plants from which they are obtained. They must evidently differ from each other, as to the nature and proportions of the principles with which they are impregnated, as much as the plants from which they are extracted differ from each other in these respects.

K.

KALI is a maritime plant, from the ashes of which a considerable quantity of soda is obtained by lixiviation. See **Soda**. Henckel informs us, that by boiling the plant in water, and by evaporating the decoction, he obtained a considerable quantity of sea salt.

Kannel Coal. See **Cannel Coal**.

Kaolin. The Chinese name of an earth used as one of the two ingredients of the oriental porcelain. Some of this earth was brought from China, and examined by Reaumur. He found that it was infusible, and supposed it to be a talky earth; but Macquer supposed it to contain clay, because it forms a tenacious paste with the other ingredient called petuntse, which has no tenacity. Bomare found, that it was a compound of clay, calcareous earth, mica, and small quartz crystals. He says, that he has found a similar earth upon a stratum of granite, and conjectures that it may be a decomposed granite.

As porcelain is now manufactured in various parts of Europe, some mineralogists have applied the term kaolin to the porcelain clay.

Karabe, or **Carabe**. See **Amber**.

Karat. The fineness of gold is commonly noted by karats. Pure gold being considered to be divided into twenty-four equal parts, or karats; it is then said to be twenty-four karats fine. If the quantity of pure gold in any mass be less than this, that quantity only is noted in expressing the fineness. Thus, for example, if two parts out of the twenty-four be copper or other base metal, the gold is said to be twenty-two karats fine. This is the standard of British coin. See **Assay**.

The karat is a real weight used by jewellers, divided by us into four grains: but these grains are less than the grains of troy weight; four grains troy being equal to five of these subdivisions of the karat, according to David Jefferys. See **Diamond**.

Kedria Terrestris. Barbadoes tar. See **Bitumen**.

Keffekil. The *meerschaum* of the Germans, *spuma maris*. A stone of a white or yellow colour, soapy feel, and moderate hardness, which increases in the fire. It is the substance of which the large Turkey pipes are made. It is found in Crim Tartary, in Canada, in Flanders, and elsewhere. The Tartars use it instead of soap, as do likewise the country people in the barony of Hierges, in Austrian Flanders. Wiegleb found it to consist of equal parts of magnesia and silex, whence it seems to operate as a fullers-earth. See **Earth** (**Fullers**). What Wiegleb analysed had been manufactured into a pipe. Klaproth analysed it in its crude state. A whitish variety, of the specific gravity of 1·6, afforded him from 100 parts, silex 50·5; magnesia 17·25; lime 0·5; water 25; carbonic acid 5. A gray sort gave silex 41; magnesia

25; lime 5; water and carbonic acid 39. a third he found the proportion of silex ch less, and of magnesia as much greater. could not expel the whole of the carnic acid in the humid way.

Kermes (*coccus ilicis*, Lin.) is an insect nd in many parts of Asia, and the south Europe. It was known to the ancients the name of *coccum scarlatinum*, *coccus hicus*, *coccus infectorius*, *granum tincton*. That which came from Galatia and menia was preferred; but at present it is hered chiefly in Languedoc, Spain, and tugal.

he kermes lives on a small kind of oak *rcus coccifera*, Lin.). The females grow and at length remain motionless; when are nearly the size and shape of a pea, of a reddish brown colour. On acnt of their figure, they were a long taken for the seeds of the tree on ch they live; whence they were called *s of kermes*. They also bore the name ermilion.

the living insect be bruised, it gives a red colour. Its smell is somewhat sant; its taste a little bitter, rough, pungent. When dry it imparts this smell taste to water, and also to alcohol, to which it gives a deep red colour. This ur is retained by the extracts made from e infusions.

o dye spun worsted with kermes, it is boiled half an hour in water with bran; two hours, in a fresh bath, with one of Roman alum, and one tenth of tarto which *sour water* is commonly added; which it is taken out, tied up in a bag, and carried to a cool place, re it is left some days. To obtain a full ur, as much kermes as equals three hs, or even the whole of the weight e wool, is put into a warm bath, and vool is put in at the first boiling. As is more dense than wool, either spun the fleece, it requires one fourth less e salts in the boiling, and of kermes e bath. Less proportions of kermes produce lighter and paler colours. If vant a succession of shades, we must, ual, begin with the deepest.

ellot directs a small handful of cot or e wool to be thrown into the boiler in h the kermes is, and to let it boil a ent before the wool to be dyed is put This will absorb a kind of black dregs, he wool afterwards dipped will take a r colour. Before the wool that is just is taken to the river, it may be dipped bath of water a little warm, in which ll quantity of soap has been dissolved: is way the colour will acquire more tness, though it will be rendered a rosy, that is, will have a crimson cast.

using kermes and tartar, without , and with as much solution of tin as quired for a scarlet with cochineal, e obtained a very lively cinnamon colour in a single bath. Cloth steeped in a solution of sulphat of potash took with kermes a pretty fine and permanent agate gray: in a solution of sulphat of iron and tartar a fine gray: in a solution of tartar and sulphat of copper, an orange colour: and the same with nitrat of copper. Solution of bismuth, added drop by drop to a kermes bath, produced a violet. All acids convert it to a cinnamon colour, which inclines more or less to red, according as the acids are weak, and their quantity small. Alkalis render its colour dull and rosy.

The colour that kermes imparts to wool has much less bloom than the scarlet made with cochineal; whence the latter has generally been preferred, since the art of heightening its colour by means of solution of tin has been known.—*Berthollet.*

Formerly it was used in medicine as a cordial and mild astringent, and gave its name to a confection.

Kermes Mineral. See Antimony.

Killas. This stone is chiefly found in Cornwall; its colour is pale gray or greenish gray; its texture either lamellar or coarsely granular: the lamellar is softer and less martial than the roof schistus: its specific gravity from 2·63 to 2·666.

Kirwan found a hundred grains of the lamellar sort to contain about 60 of silex, 25 of alumine, 9 of magnesia, and 6 of iron. The greenish sort contains more iron, and gives a greenish colour to the nitric acid.

Kingdoms. Naturalists and chemists divide all natural bodies into three great classes, called kingdoms, namely, the mineral, the vegetable, and the animal kingdoms. The utility of these divisions appears to be in a great measure confined to the natural history of the various subjects examined by the chemist. The distinctive criterions of their respective principles are difficult, and perhaps impossible to be ascertained, excepting in bodies of no great simplicity; for none of the principles of organized bodies exhibit their peculiar characters when resolved by putrefaction or otherwise into their simplest parts. See Animal Kingdom, Vegetable Kingdom, Mineral Kingdom, and Analysis.

Kino. A few years ago this was introduced into our shops and medical practice by the name of a gum; but Dr. Duncan has shown that it is an extract. It was first brought from Gambia, but what we have now comes chiefly from Jamaica, and is an extract of the seaside grape, *coccoloba uvifera*: the finest however is made from different species of *eucalyptus*, particularly the *resinifera*, or brown gum tree of Botany Bay.

Vauquelin too found it was not a gum, and analysed probably the latter sort. By distillation it yielded first an aqueous fluid; then a light and nearly colourless oil, which grew heavier and darker; a small quantity of carbonic acid, and a large quantity of carburetted hidrogen. The aqueous fluid has an acrid taste, and contains ammonia. 100 parts left 42·5 of a very bulky coal, which by incineration left 3·6 of ashes, consisting chiefly of lime, silex, alumine, and oxide of iron. It is little soluble in cold water, but more in hot. Its decoction grows turbid on cooling. Alkalis precipitate it: so does gelatine, and ferruginous salts; but the precipitate with the latter is green, like those with infusions of cinchona and rhubarb. Wool and cotton boiled in a solution of kino, and then dipped in a bath of sulphat of iron, appeared of a bottle green, which was changed by washing and drying to a blackish brown, that proved very durable. Hot alcohol dissolves about three fourths of its weight; and the remainder, which has lost its bitterness and astringency, and tastes rather mucilaginous and sweet, dissolves easily in hot water, and gives it a deep red colour. This is precipitable by alcohol, but neither by glue, nor by any metallic solution. Sulphuric acid diminishes the action of water on kino.—*Edinb. Disp.*—*Ann. de Chim.*—*Nich. Journ.*

Kolmord Marble. A white calcareous stone of a scaly texture, interspersed with spots of steatites, or soap rock, either green or black.

Koumiss. A vinous preparation of Milk, which see.

Kupfer Nickel. See Nickel.

Kuteera. A gum somewhat resembling tragacanth, but not of so glutinous a nature, lately imported from Hindostan. In water it slowly softens to a pulp: but if first powdered, and then boiled a quarter of an hour, it dissolves completely, a teaspoonful giving three pints of water a thin sirupy consistence. The natives mix it with other gums to make varnishes, and use it much in some diseases of horses.—*Trans. of Soc. of Arts.*

L.

LABDANUM. A resin of a species of cistus in Candia, of a blackish colour. The country people collect it by means of a staff, at the end of which are fastened many leather thongs, which they gently strike on the trees. They form it into cylindrical pieces, which are called labdanum in tortis. It is greatly adulterated by the addition of black sand, and has been given as an astringent, but is chiefly used in cephalic and stomachic plasters and perfumes.

Laboratory. A place properly fitted up for the performance of chemical operations. The several laboratories intended for the preparation of articles of the materia medica, or the arts, in the large way, have their respective accommodations and contrivances, the description of which would occupy several volumes. The philosophical chemist, whose operations afford products chiefly of value for the results they exhibit, naturally endeavours, as well for the advantage of time, as expense, to perform all his operations on as small a scale as possible. It was once thought to be indispensably necessary, that a philosophical chemist should be provided with a regular laboratory, or room fitted up with furnaces and other apparatus, on a considerably extensive scale. This is no doubt of great utility and advantage; but the researches of Bergman, Morveau, and other eminent chemists, have shown, that many, if not most of the chemical operations, may be performed with the blowpipe, or by very small glass vessels, and a lamp, with greater speed, perspicuity, facility, and cheapness, than where larger quantities of the materials are used. But as the proportional quantities of products, and the indications afforded by experiment for conducting manufacturing processes, are more accurately deduced from considerable quantities, I shall in this article give the excellent sketch of a laboratory, as I find it in Macquer's Dictionary, with such additions or improvements as have since been made.

As chemistry is a science founded entirely on experiment, we cannot hope to understand it well, without making such experiments as verify most of the known fundamental operations, and also such as reasoning, analogy, and the spirit of inquiry, never fail to suggest to those, whose taste and suitable talents lead them to this essential part of experimental philosophy. Besides, when a person himself observes, and operates, he must perceive, even in the most common operations, a great variety of small facts, which must necessarily be known, but which are not mentioned either in books or in memoirs, because they are too numerous, and would appear too minute. Lastly, there are many qualities in the several agents, of which no just notion can be given by writing, and which are perfectly well known as soon as they have been once made to strike our senses.

A chemical laboratory necessarily occasions certain expenses, but not so much as is generally believed, when the operator knows how to manage his utensils, and to employ only the proper quantity of the several substances upon which he operates; and lastly, when he chooses the least expensive methods of attaining his purposes.

Many people think, that a laboratory level with the ground is most convenient, for the sake of water, pounding, washing, &c. It certainly has these advantages; but

o subject to very great inconvenience
oisture.

stant moisture, though not very con-
le and sensible in many respects, is a
great inconvenience in a chemical
tory. In such a place, most saline
s become moist in time, and the in-
ons fall off, or are effaced; the bel-
ot; the metals rust; the furnaces
er, and every thing almost spoils. A
tory, therefore, is more advanta-
placed above than below the
, that it may be as dry as possible.
must have free access to it; and it
ven be so constructed, that, by means
or more opposite openings, a current
nay be admitted, to carry off any
s vapours or dust.

ne laboratory a chimney ought to
structed, so high that a person may
tand under it, and as extensive as is
e; that is, from one wall to another.
nnel of this chimney ought to be as
s is possible, and sufficiently con-
to make a good draught. As char-
ly is burnt under this chimney, no
ollected in it; and therefore it need
so wide as to allow a chimney-
to pass up into it.

er this chimney may be constructed
ick furnaces, particularly a melting
, a furnace for distilling with an
, and one or two ovens like those in
. The rest of the space ought to
up with stands of different heights,
foot to a foot and a half, on which
furnaces of all kinds are to be
These furnaces are the most con-
from the facility of disposing them
ure; and they are the only furnaces
are necessary in a small laboratory.

e pair of bellows of moderate size
o be placed as commodiously under
nney, or as near as the place will
hese bellows are sometimes mount-

onvenient when the bellows are not
an eighteen or twenty inches long.
ellows ought to have a pipe di-
oward the hearth where the forge
placed.

necessary furnaces are, the simple
for distilling with a copper alem-
amp furnace; two reverberatory
of different sizes, for distilling with
an air or melting furnace, an essay
and a forge furnace.

r the chimney, at a convenient
must be a row of hooks driven into
and side walls; upon which are to
small shovels; iron pans; tongs;
crooked, and circular pincers;
iron rods, and other utensils for dis-
he fuel and managing the crucibles.

e walls of the laboratory ought to
ned shelves of different breadths and
, or these shelves may be suspended

by hooks. The shelves are to contain glass vessels, and the products of operations, and ought to be in as great a number as is possible. In a laboratory where many experiments are made, there cannot be too many shelves.

The most convenient place for a stone or leaden cistern to contain water is a corner of the laboratory, and under it a sink ought to be placed with a pipe, by which the water poured into it may discharge itself. As the vessels are always cleaned under this cistern, cloths and bottle brushes ought to be hung upon hooks fastened in the walls near it.

In the middle of the laboratory a large table is to be placed, on which mixtures are to be made, preparations for operations, solutions, precipitations, small filtrations; in a word, whatever does not require fire, excepting that of a lamp.

In convenient parts of the laboratory are to be placed blocks of wood upon mats; one of which is to support a middle-sized iron mortar; another to support a middle-sized marble, or rather hard stone mortar; a third to support an anvil. Near the mortars are to be hung searces of different sizes and fineness; and near the anvil a hammer, files, rasps, small pincers, scissars, sheers, and other small utensils, necessary to give metals a form proper for the several operations.

Two movable trestles ought to be in a laboratory, which may serve to support a large filter mounted upon a frame, when it is required. This apparatus is removed occasionally to the most convenient place.

Charcoal is an important article in a laboratory, and it therefore must be placed within reach; but as the black dust which flies about it whenever it is stirred is apt to soil every thing in the laboratory, it had better be in some place near the laboratory, together with some furze, which is very convenient for kindling fires quickly. This place serves, at the same time, for containing bulky things, which are not often wanted; such as furnaces, bricks, tiles, clay, fire-clay, quick-lime, sand, and many other things necessary for chemical operations.

Lastly, a middle-sized table, with solid feet, ought to be enumerated among the large movables of a laboratory, the use of which is to support a porphyry, or levigating stone, or rather a very hard and dense grit-stone, together with a muller made of the same kind of stone.

The other small movables or utensils of a laboratory are, small hand mortars of iron, glass, agate, and Wedgwood's ware, and their pestles; earthen, stone, metal, and glass vessels, of different kinds, funnels, and measures

Some white writing paper, and some unsized paper for filters; a large number of clean straws, eight or ten inches long, for stirring mixtures in glasses, and for supporting paper filters placed in glass funnels.

Glass tubes for stirring and mixing corrosive liquors; spatulas of wood, ivory, metal, and glass.

Thin pasteboards, and horns, very convenient for collecting matters bruised with water upon the levigating stone, or in mortars: corks of all sizes; bladders and linen strips for luting vessels.

A good portable pair of bellows; a good steel for striking fire; a glue pot, with its little brush; lastly, a great many boxes of various sizes, for containing most of the above-mentioned things, and which are to be placed upon the shelves.

Beside these things, some substances are so necessary in most chemical operations, that they may be considered as instruments requisite for the practice of this science. These substances are:

All metals and semimetals, which ought to be very pure.

Sulphuric acid, some of which ought to be concentrated and rectified, and also some of that sort commonly sold by druggists.

Aqua fortis, such as is commonly sold, and is cheap; also nitric acid moderately strong, but very pure: the same acid very pure, concentrated, and smoking.

Common muriatic acid; some of the same acid very pure, very strong, and smoking. All these acids ought to be kept in glass bottles, and closed with glass stoppers.

Some distilled vinegar, which may be kept in an ordinary bottle; some acetic acid, which ought to be kept in a bottle with a glass stopper; some cream of tartar, in an earthen or glass vessel, or in a box.

Common fixed vegetable alkali, very dry, such as potash, which must be kept in a well closed bottle. The same alkali in a liquid state.

Very pure subcarbonat of potash, some dry, and some liquid.

A solution of subcarbonat of soda. The same alkali dry and very pure; that is, well formed crystals of soda.

The two fixed alkalis liquid, and rendered caustic by quick lime. Alkalis, particularly those which are caustic, ought to be kept in bottles with glass stoppers. Some prussiat of potash.

Some dry sulphuret of potash kept in a well closed bottle. The same liquid. Some common sulphur.

Carbonat of ammonia, some solid, and some liquid, kept in a bottle with a glass stopper.

Very pure caustic ammonia, as strong as is possible. Some of this may be kept of less strength.

Lime water, and quick-lime, in well closed bottles.

The purest and highest rectified alcohol.

Good sulphuric ether.

Rectified essential oil of turpentine; oil of olives; soap.

Galls; sirup of violets; tincture of litmus, or litmus rags; fine blue paper; river or distilled rain-water.

Beside these substances, most of which are solvents, certain neutral salts ought to be had, which are frequently used in chemical operations, or are difficultly prepared. These are:

Sulphat of potash; alum, and calcined alum: sulphats of iron and copper; nitre; decrepitated common salt; some of the same salt very pure, dissolved in distilled water; purified sal-ammoniac; calcined borax; boracic acid.

A pure solution of silver in nitric acid; a solution of mercury in the same acid; muriat of antimony. All these to be kept in bottles with glass stoppers. Corrosive sublimate.

Ceruss; litharge; minium; sand washed and ground; white marble; washed chalk; glass of lead; glass of borax.

A person provided with the above-mentioned instruments and substances may at once perform any chemical experiment. He may indeed occasionally want several neutral salts, which have not been named; but all these salts with bases of earths, metals, or alkalis, may be easily and instantly prepared, as most of them do not require distillation or sublimation. They may nevertheless, if they be not too numerous, be all previously prepared and kept ready for any occasion.

The general observations of Macquer upon the conducting of chemical processes are truly valuable and judicious. Method, order, and cleanliness, are essentially necessary in a chemical laboratory. Every vessel and utensil ought to be well cleansed as often as it is used, and put again into its place: labels ought to be put upon all the substances. These cares, which seem to be trifling, are however very fatiguing and tedious; but they are also very important, though frequently little observed. When a person is keenly engaged, experiments succeed each other quickly; some seem nearly to decide the matter, and others suggest new ideas: he cannot but proceed to them immediately, and he is led from one to another: he thinks he shall easily know again the products of the first experiments, and therefore he does not take time to put them in order: he prosecutes with eagerness the experiments which he has last thought of; and in the mean time, the vessels employed, the glasses and bottles filled, so accumulate, that he cannot any longer distinguish them; or at least, he is uncertain concerning many of his former products. This evil is increased, if a new series of operations succeed, and occupy all the laboratory; or if he be obliged to quit it some time: every thing then goes into nfusion. Thence it frequently happens, t he loses the fruits of much labour, and t he must throw away almost all the pro- cts of his experiments.

The only method of avoiding these in- nveniences is to employ the cares and at- ntions above mentioned. It is indeed dis- reeable, to stop continually in the middle the most interesting researches, and to ploy time that appears very precious and nsiderable in cleaning vessels, arranging m, fastening labels on them, &c. These ployments are capable of cooling or re- ding the progress of genius, and are te- us and disgustful; but they are never- less necessary. Those persons, whose une enables them to have an assistant rator, on whose exactness and intelli- ce they can depend, avoid many of e disagreeable circumstances; but they ht nevertheless to attend to the execu- of these things. We cannot depend much on ourselves in these matters, ever minute, on account of their con- ences. This becomes even indispensa- when the experiments are to be kept et, at least for a time; which is often essary in chemistry.

When new researches and inquiries are le, the mixtures, results, and products ll the operations ought to be kept a g time, distinctly labelled and registered; these things, when kept some time, fre- ntly present phenomena, that were not ll suspected. Many fine discoveries in nistry have been made in this manner; many have certainly been lost by owing away too hastily, or neglecting products.

cannot be too much recommended to nical operators, to be exceedingly upon r guard against imposing and deceitful riments, which frequently present nselves in practice. A circumstance ingly unimportant, or not easily per- ible, is frequently sufficient to give the earance of a great discovery, by means ertain effects, which, nevertheless, are d to proceed from some other cause. nical experiments depend on so many ssary things, that all of them can sel- be attended to, particularly when the ect is new: hence we frequently find, very different results proceed from the e experiments, and at different times. therefore must not decide after the first ess; but the experiment must be re- ed several times, and even varied, till oubt can remain.

nce chemistry offers many views for the rovement of many important arts; as it ents prospects of many useful and pro- le discoveries; those who apply their urs in this way ought to be exceedingly mspect, not to be led into a useless ex- e of money and time. Those researches h have some analogy with the philosopher's stone, from the hopes of wealth which they suggest, are also attended with similar danger. In a certain set of experiments some one is generally of an imposing appearance, although in reality it is nothing more. Chemistry is full of these half successes, which serve only to deceive the unwary, to multiply the number of trials, and to lead to great expense before the fruitlessness of the search is discovered. By these reflections we do not intend to divert from all such researches those, whose taste and talents render them fit for them; on the contrary, we acknowledge, that the improvement of the arts, and the discovery of new objects of manufacture and commerce, are undoubtedly the finest and most interesting part of chemistry, and which make that science truly valuable; for without these ends what would chemistry be but a science purely theoretical, and capable of employing only some abstract and speculative minds, but useless to society? We acknowledge also, that the successes in this kind of chemical inquiry are not rare; and that their authors have sometimes acquired fortunes, so much the more honourable as being the fruits of their talents and industry. But we repeat, that, in these researches, the more dazzling and near any success appears, the more circumspection, and even distrust is necessary. See ANALYSIS, ATTRACTION, BALANCE.

The plates annexed, with the following explanations of them, will give the student an idea of a large variety of the most useful and necessary articles of a chemical apparatus.

Plate II, fig. 1. Crucibles or pots, made either of earth, black lead, forged iron, or platina. They are used for roasting, calcination, and fusion.

Fig. 2. Cucurbits, matrasses, or bodies, which are glass, earthen, or metallic vessels, usually of the shape of an egg, and open at top. They serve the purposes of digestion, evaporation, &c.

Fig. 3. Retorts are globular vessels of earthen ware, glass, or metal, with a neck bended on one side. Some retorts have another neck or opening at their upper part, through which they may be charged, and the opening may be afterwards closed with a stopple. These are called tubulated retorts. A Welter's tube of safety may be inserted in this opening, instead of a stopple. See Pl. VII, fig. 1, *b* and *e*.

Receivers are vessels, usually of glass, of a spherical form, with a straight neck, into which the neck of the retort is usually inserted. When any proper substance is put into a retort, and heated, its volatile parts pass over into the receiver, where they are condensed. See fig. 5, and Pl. V, fig. 2, *k*.

Fig. 4. The alembic is used for distillation, when the products are too volatile to admit of the use of the last-mentioned apparatus,

The alembic consists of a body *a*, to which is adapted a head *b*. The head is of a conical figure, and has its external circumference or base depressed lower than its neck, so that the vapours which rise, and are condensed against its sides, run down into the circular channel formed by its depressed part, from whence they are conveyed by the nose or beak *c*, into the receiver *d*. This instrument is less simple than the retort, which certainly may be used for the most volatile products, if care be taken to apply a gentle heat on such occasions. But the alembic has its conveniences. In particular, the residues of distillations may be easily cleared out of the body *a*, and in experiments of sublimation, the head is very convenient to receive the dry products, while the more volatile and elastic parts pass over into the receiver.

Fig. 6. Represents the large stills used in the distillation of ardent spirits. *a* represents the body, and *b* the head, as before. Instead of using a refrigeratory or receiver, the spirit is made to pass through a spiral pipe called the worm, which is immersed in a tub of cold water *d*. During its passage it is condensed, and comes out at the lower extremity, *e*, of the pipe, in a fluid form.

The manner in which the excise laws for Scotland were framed rendering it advantageous to the distillers in that country to have stills of small capacity, which they could work very quickly, their ingenuity was excited to contrive the means of effecting this. It was obvious, that a shallow still, with a broad bottom completely exposed to a strong heat, would best answer the purpose: and this was brought to such perfection, that a still of the capacity of 40 gallons in the body, and 3 in the head, charged with 16 gallons of wash, could be worked 480 times in 24 hours. Fig. 7. is a vertical section of this still. *a*, the bottom, joined to *b*. the shoulder, with solder, or rivets, or screws and lute. *c*, the turned-up edge of the bottom, against which, and on a level with *a*, the brick-work of the coping of the flue rests, preventing the flame from getting up to touch *c*. *d*, the discharge pipe. *e e*, the body of the still. *f*, section of the central steam escape pipe. *g*, section of one of the lateral steam escape pipes; *h*, outside view of another. *i i i i*, inferior apertures of lateral steam pipes; *k k k k*, their superior apertures. *l l*, bottom scraper, or agitator, which may either be made to apply close to the bottom, or to drag chains; *m*, the upright shaft of this engine, as it is called; *n*, the horizontal wheel with its supporters; *o*, its vertical wheel; *p*, its handle and shaft; *n*, support of the shaft; *r*, froth and ebullition jet-breaker, resting on the cross bar *s*; *t*, its upright shaft; *u*, its cup-mouthed collar, filled with wool and grease, and held down by a plate and screws. *v*, general steam escape pipe, or head. The charge pipe, and the sight hole, for the man who charges it to see when it is sufficiently full, are not seen in this view.

The best construction of a furnace has not been well ascertained from experience. There are facts which show, that a fire made on a grate near the bottom of a chimney, of equal width throughout, and open both above and below, will produce a more intense heat than any other furnace. What may be the limits for the height of the chimney is not ascertained from any precise trials; but thirty times its diameter would not probably be too high. It seems to be an advantage to contract the diameter of a chimney, so as to make it smaller than that of the fireplace, when no other air is to go up the chimney than what has passed through the fire; and there is no prospect of advantage to be derived from widening it.

Pl. V, fig. 3. exhibits the wind or air furnace for melting. *a* is the ash-hole, *f* an opening for the air. *c* is the fire-place, containing a covered crucible, standing on a support of baked earth, which rests on the grate. *d* is the passage into *e*, the chimney. At *d* a shallow crucible or cupel may be placed in the current of the flame, and at *x* is an earthen or stone cover, to be occasionally taken off for the purpose of supplying the fire with fuel.

Fig. 2 is a reverberatory furnace. *a a* the ash-pit and fireplace. *b b* body of the furnace. *c c* dome, or reverberating roof of the furnace. *d d* chimney. *e e* door of the ash-pit. *f f* door of the fireplace. *g g* handles of the body. *h* aperture to admit the head of the retort. *i i* handles of the dome. *k* receiver. *l l* stand of the receiver. *m m* retort, represented in the body by dotted lines.

Another reverberatory furnace, a little differing in figure, may be seen in Pl. I, fig. 2.

Mr. Chenevix has constructed a wind furnace, which is in some respects to be preferred to the usual form. The sides, instead of being perpendicular, are inverted, so that the hollow space is pyramidical. At the bottom the opening is 13 inches square, and at the top but 8. The perpendicular height is 17 inches. This form appears to unite the following advantages: 1st. A great surface is exposed to the air; which, having an easy entrance, rushes through the fuel with great rapidity. 2d, The inclined sides act in some measure as reverberating surfaces: and 3d, The fuel falls of itself, and is always in close contact with the crucible, placed near the grate. The late Dr. Kennedy of Edinburgh, whose opinion on this subject claims the greatest weight, found that the strongest heat in our common wind furnaces was within 2 or 3 inches of the grate. This, therefore, is the most advantageous position for the crucible, and still more so when we can keep it surrounded with fuel. It is inconvenient, and dangerous for the crucible, to stir the fire often to make the fuel fall, and the pyramidical form renders this unnecessary. It is also more easy to

id a sudden bend in the chimney, by the
per part of the furnace advancing as in
construction. In Pl. V, fig. 1, *a* is a
te; *c* and *c* are two bricks, which can be
in at pleasure to diminish the capacity;
another grate, which can be placed
on the bricks *c* and *c* for smaller pur-
es; *d* and *d* are bricks, which can be
ced upon the grate *b* to diminish the up-
capacity, so that in fact there are four
ferent sizes in the same furnace. The
cks should all be ground down to the
pe of the furnace, and fit in with tolerable
uracy. They are totally independent of
pyramidical form of the furnace.

Mr. Aikin's portable blast furnace is com-
sed of three parts, all made out of the
nmon thin black lead melting pots, sold
London for the use of the goldsmiths.
e lower piece *c*, fig. 6, is the bottom of one
these pots, cut off so low as only to leave a
vity of about an inch deep, and ground
ooth above and below. The outside di-
eter, over the top, is five inches and a
f. The middle piece, or fireplace *a*, is a
ger portion of a similar pot, with a cavity
out six inches deep, and measuring seven
hes and a half over the top, outside dia-
ter, and perforated with six blast holes
the bottom. These two pots are all that
essentially necessary to the furnace for
ost operations; but when it is wished to
ap up fuel above the top of a crucible
ntained, and especially to protect the
es from the intolerable glare of the fire
hen in full height, an upper pot *b* is ad-
d, of the same dimensions as the middle
e, and with a large opening in the side,
to allow the exit of the smoke and flame,
has also an iron stem, with a wooden han-
(an old chisel answers the purpose very
ll) for removing it occasionally. The bel-
vs, which are double (*d*), are firmly fixed,
a little contrivance which will take off and
, to a heavy stool, as represented in the
ite; and their handle should be lengthened
as to make them work easier to the hand.
increase their force on particular occa-
ns, a plate of lead may be firmly tied on
wood of the upper flap. The nozzle is
ceived into a hole in the pot *c*, which con-
cts the blast into its cavity. Hence the
passes into the fireplace *a*, through six
les of the size of a large gimlet, drilled at
ual distances through the bottom of the
t, and all converging in an inward direc-
on, so that, if prolonged, they would meet
out the centre of the upper part of the
e. No luting is necessary in using this
rnace, so that it may be set up and taken
wn immediately. Coak, or common cin-
rs, taken from the fire when the coal
ases to blaze, sifted from the dust, and
oken into very small pieces, forms the
st fuel for higher heats. The fire may
kindled at first by a few lighted cinders,
d a small quantity of wood charcoal. The
at which this little furnace will afford is so intense, that its power was at first discovered accidentally by the fusion of a thick piece of cast iron. The utmost heat procured by it was 167° of Wedgwood's pyrometer, when a Hessian crucible was actually sinking down in a state of porcelaneous fusion. A steady heat of 155° or 160° may be depended on, if the fire be properly managed, and the bellows worked with vigour.

The process of cupellation may be exhibited in a lecture, or performed at other times, by means of this furnace. The method consists in causing a portion of the blast to be diverted from the fuel, and to pass through a crucible in which the cupel is placed. This arrangement supplies air; and the whole may be seen by a sloping tube, run through the cover of the crucible.

Charcoal is the material most commonly used in furnaces. It produces an intense heat without smoke, but it is consumed very fast. Coke or charred pit coal produces a very strong and lasting heat. Neither of these produces a strong heat at a distance from the fire. Where the action of flame is required, wood or coal must be burned. Several inconveniences attend the use of coal, as its fuliginous fumes, and its aptitude to stop the passage of air by becoming fused. It is used however in the reverberatory furnaces of glass-houses, and is the best material where vessels are to be supplied with a great quantity of heat at no great intensity, such as in distilleries, &c.

Frequently however the flame of an Argand lamp may be employed very conveniently for chemical purposes. Pl. VI, fig. 2, is a representation of a lamp furnace, as it is perhaps not very properly called, as improved by Mr. Accum. It consists of a brass rod screwed to a foot of the same metal, loaded with lead. On this rod, which may be unscrewed in the middle for rendering it more portable, slide three brass sockets with straight arms, terminating in brass rings of different diameters. The largest measures four inches and a half. These rings serve for supporting glass alembics, retorts, Florence-flasks, evaporating basins, gas-bottles, &c.; for performing distillations, digestions, solutions, evaporations, saline fusions, concentrations, analyses with the pneumatic apparatus, &c. If the vessels require not to be exposed to the naked fire, a copper sand-bath may be interposed, which is to be previously placed in the ring. By means of a thumb-screw acting on the rod of the lamp, each of the brass-rings may be set at different heights, or turned aside, according to the pleasure of the operator. Below these rings is a fountain-lamp on Argand's plan, having a metallic valve within, to prevent the oil from running out while the reservoir is put into its place. This lamp also slides on the main brass rod by means of a socket and thumb-screw. It is therefore easy to bring it nearer, or to move it further, at pleasure, from the vessel, which may remain fixed; a circumstance which, independent of the elevation and depression of the wicks of the lamp, affords the advantage of heating the vessels by degrees after they are duly placed, as well as of augmenting or diminishing the heat instantly; or for maintaining it for several hours at a certain degree, without in the least disturbing the apparatus suspended over it. It may therefore be used for producing the very gentle heat necessary for the rectification of ethers, or the strong heat requisite for distilling mercury. The chief improvement of this lamp consists in its power of affording an intense heat by the addition of a second cylinder, added to that of the common lamp of Argand. This additional cylinder incloses a wick of one inch and a half in diameter, and it is by this ingenious contrivance, which was first suggested by Mr. Webster, that a double flame is caused, and more than three times the heat of an Argand's lamp of the largest size is produced.

Every effect of the most violent heat of furnaces may be produced by the flame of a candle or lamp, urged upon a small particle of any substance, by the blowpipe. This instrument is sold by the ironmongers, and consists merely of a brass pipe about one eighth of an inch diameter at one end, and the other tapering to a much less size, with a very small perforation for the wind to escape. The smaller end is bended on one side. For philosophical or other nice purposes the blowpipe is provided with a bowl or enlargement, *a* (Pl. V, fig. 5), in which the vapours of the breath are condensed and detained, and also with three or four small nozzles, *b*, with different apertures, to be slipped on the smaller extremity. These are of use when larger or smaller flames are to be occasionally used, because a larger flame requires a large aperture, in order that the air may effectually urge it upon the matter under examination.

There is an artifice in the blowing through this pipe, which is more difficult to describe than to acquire. The effect intended to be produced is a continual stream of air for many minutes, if necessary, without ceasing. This is done by applying the tongue to the roof of the mouth, so as to interrupt the communication between the mouth and the passage of the nostrils; by which means the operator is at liberty to breathe through the nostrils, at the same time that by the muscles of the lips he forces a continual stream of air from the anterior part of the mouth through the blowpipe. When the mouth begins to be empty, it is replenished by the lungs in an instant, while the tongue is withdrawn from the roof of the mouth, and replaced again in the same manner as in pronouncing the monosyllable tut. In this way the stream may be continued for a long time without any fatigue, if the flame be not urged too impetuously, and even in this case no other fatigue is felt than that of the muscles of the lips.

A wax candle of a moderate size, but thicker wick than they are usually made with, is the most convenient for occasional experiments; but a tallow candle will do very well. The candle should be snuffed rather short, and the wick turned on one side toward the object, so that a part of it should lie horizontally. The stream of air must be blown along this horizontal part, as near as may be without striking the wick. If the flame be ragged and irregular, it is a proof, that the hole is not round or smooth; and if the flame have a cavity through it, the aperture of the pipe is too large. When the hole is of a proper figure and duly proportioned, the flame consists of a neat luminous blue cone, surrounded by another flame of a more faint and indistinct appearance. The strongest heat is at the point of the inner flame.

The body intended to be acted on by the blowpipe ought not to exceed the size of a pepper-corn. It may be laid upon a piece of close-grained, well-burned charcoal; unless it be of such a nature as to sink into the pores of this substance, or to have its properties affected by its inflammable quality. Such bodies may be placed in a small spoon made of pure gold or silver, or platina.

Many advantages may be derived from the use of this simple and valuable instrument. Its smallness, which renders it suitable to the pocket, is no inconsiderable recommendation. The most expensive materials, and the minutest specimens of bodies, may be used in these experiments; and the whole process, instead of being carried on in an opake vessel, is under the eye of the observer from beginning to end. It is true, that very little can be determined in this way concerning the quantities of products; but, in most cases, a knowledge of the contents of any substance is a great acquisition, which is thus obtained in a very short time, and will at all events serve to show the best and least expensive way of conducting processes with the same matters in the larger way.

The blowpipe has deservedly of late years been considered as an essential instrument in a chemical laboratory, and several attempts have been made to facilitate its use by the addition of bellows, or some other equivalent instruments. These are doubtless very convenient, though they render it less portable for mineralogical researches. It will not, here, be necessary to enter into any description of a pair of double bellows fixed under a table, and communicating with a blowpipe which passes through the table. Smaller bellows, of a portable size for the pocket, have been made for the same purpose. The ingenious chemist will find no great difficulty in adapting a bladder to the blow pipe, which, under the pressure of a board, may produce a constant stream

air, and may be replenished, as it be-
nes empty, by blowing into it with bel-
s, or the mouth, at another aperture fur-
hed with a valve opening inwards.

The chief advantage these contrivances
e over the common blowpipe is, that
y may be filled with oxigen gas, which
reases the activity of combustion to an
onishing degree. The vapour from al-
ol has likewise been employed, and an
enious contrivance for this purpose by
. Hooke is represented, Pl. V, fig. 4. *a* is
ollow sphere for containing alcohol, rest-
upon a shoulder in the ring *o*. If the
tom be made flat instead of spherical,
action of the flame will then be greater.

For the various habitudes of bodies when
mined by the blowpipe, see Blowpipe.

Little need be said concerning the man-
of making experiments with fluid bodies
he common temperature of the atmo-
ere. Basins, cups, phials, matrasses, and
er similar vessels, form the whole appa-
us required for the purpose of containing
matters intended to be put together;
l no other precaution or instruction is
uired, than to use a vessel of such mate-
s as shall not be corroded or acted upon
its contents, and of sufficient capacity to
nit of any sudden expansion or frothing
he fluid, if expected. This vessel must
placed in a current of air, if noxious
es arise, in order that these may be
wn from the operator.

The method of making experiments with
manently elastic fluids, or gasses, though
ple, is not so obvious. We live immersed
n atmosphere not greatly differing in
sity from these fluids, which for this
on are not sufficiently ponderous to be
ained in open vessels by their weight.
eir remarkable levity, however, affords
nethod of confining them by means of
er denser fluids. Dr. Priestley, whose
ours have so far exceeded those of his
decessors and contemporaries, both in
ent and importance, that he may with
ice be styled the father of this important
nch of natural philosophy, used the fol-
ing apparatus.

Pl. VI, fig. 1, *a* represents a wooden vessel or tub; *k*, *k*, *k*, is a shelf fixed in the tub. When this apparatus is used, the tub is to be filled with water to such a height, as to rise about one inch above the upper surface of the shelf. *b*, *g*, *f*, are glass jars inverted with their mouths downward, which rest upon the shelf. If these, or any other vessels open only at one end, be plunged under the water, and inverted after they are filled, they will remain full, notwithstanding their being raised out of the water, provided their mouths be kept immersed: for in this case, the water is sustained by the pressure of the atmosphere, in the same manner as the mercury in the barometer. It may without difficulty be imagined, that if common air, or any other fluid resembling common air in lightness and elasticity, be suffered to enter these vessels, it will rise to the upper part, and the surface of the water will subside. If a bottle, a cup, or any other vessel, in that state which is usually called empty, though really full of air, be plunged into the water with its mouth downwards, scarce any water will enter, because its entrance is opposed by the elasticity of the included air; but if the vessel be turned up, it immediately fills, and the air rises in one or more bubbles to the surface. Suppose this operation to be performed under one of the jars which are filled with water, the air will ascend as before; but, instead of escaping, it will be detained in the upper part of the jar. In this manner, therefore, we see, that air may be emptied out of one vessel into another by an inverted pouring, in which the air is made to ascend from the lower vessel *i* to the upper *g*, in which the experiments are performed, by the action of the weightier fluid, exactly similar to the common pouring of denser fluids, detained in the bottoms of open vessels, by the simple action of gravity. When the receiving vessel has a narrow neck, the air may be poured through a glass funnel, *h*.

c (*ibid.*) is a glass body or bottle, the bottom of which is blown very thin, that it may support the heat of a candle suddenly applied, without cracking. In its neck is fitted, by grinding, a tube *d*, curved neatly in the form of the letter *s*. This kind of vessel is very useful in various chemical operations, for which it will be convenient to have them of several sizes. In the figure, the body *c* is represented as containing a fluid, in the act of combining with a substance that gives out air, which passes through the tube into the jar *b*, under the mouth of which the other extremity of the tube is placed. At *e* is a small retort of glass or earthenware, the neck of which being plunged in the water, beneath the jar *f*, is supposed to emit the elastic fluid, extricated from the contents of the retort, which is received in the jar.

When any thing, as a gallipot, is to be supported at a considerable height within a jar, it is convenient to have such wire stands as are represented fig. 3. These answer better than any other, because they take up but little room, and are easily bent to any figure or height.

In order to expel air from solid substances by means of heat, a gun-barrel, with the touch-hole screwed up and riveted, may be used instead of an iron retort. The subject may be placed in the chamber of the barrel, and the rest of the bore may be filled with dry sand, that has been well burned, to expel whatever air it might have contained. The stem of a tobacco-pipe, or a small glass tube, being luted in the orifice of the barrel, the other extremity must be put into the fire, that the heat may expel the air from its contents. This air will of course pass through the tube, and may be received under an inverted vessel, in the usual manner.

But the most accurate method of procuring air from several substances by means of heat, is to put them, if they will bear it, into phials full of quicksilver, with the mouths inverted in the same, and then throw the focus of a burning lens or mirror upon them. For this purpose, their bottoms should be round and very thin, that they may not be liable to fly with the sudden application of heat. The body *c* Pl. VI, fig. 1, answers this purpose very well.

Many kinds of air combine with water, and therefore require to be treated in an apparatus, in which quicksilver is made use of. This fluid being very ponderous, and of considerable price, it is an object of convenience, as well as œconomy, that the trough and vessels should be smaller than when water is used. See Pl. VII, fig. 1, *f f*.

When trial is to be made of any kind of air, whether it be fit for maintaining combustion, the air may be put into a long narrow glass vessel, the mouth of which, being carefully covered, may be turned upward. A bit of wax candle being then fastened to the end of a wire, which is bent so that the flame of the candle may be uppermost, is to be let down into the vessel, which must be kept covered till the instant of plunging the lighted candle into the air.

Where the change of dimensions, which follows from the mixture of several kinds of air, is to be ascertained, a graduated narrow cylindrical vessel may be made use of. The graduations may be made by pouring in successive equal measures of water into this vessel, and marking its surface at each addition. The measure may be afterward used for the different kinds of air, and the change of dimensions will be shown by the rise or fall of the mercury or water in the graduated vessel. The purity of common air being determinable by the diminution produced by the addition of nitric oxide gas, these tubes have been called eudiometer tubes.

Some substances, more especially powders, cannot conveniently be put into a phial, or passed through a fluid. When air is to be extricated from, or added to these, there is no better method, than to place them on a stand under the receiver of the air-pump, and exhaust the common air, instead of excluding it by water or mercury. This process requires a good air-pump, and careful management, otherwise the common air will not be well excluded.

It is frequently an interesting object, to pass the electric spark through different kinds of air, either alone or mixed together. In this case a metallic wire may be fastened in the upper end of a tube, and the sparks or shock may be passed through this wire to the mercury or water used to confine the air. If there be reason to apprehend, that an expansion in the air may remove the mercury or water beyond the striking distance, another wire may be thrust up to receive the electricity, or two wires may be cemented into opposite holes in the sides of an hermetically sealed tube. Holes may be made in glass, for this and other chemical uses, by a drill of copper or soft iron, with emery and water; and where this instrument is wanting, a small round file with water will cut a notch in small vessels, such as phials or tubes, though with some danger of breaking them. In some electrical experiments of the kind here mentioned, there is reason to expect a fallacious result from the wires being burned by the explosion or spark. For this reason, the electricity may be made to pass through the legs of a syphon, containing the air which is under consideration in the upper part of its curvature. One of the vessels, in which the legs of the syphon rest, must therefore be insulated; and if any watery fluid be used to confine the air, it is generally supposed that no combustion takes place.

It is sometimes desirable to impregnate water for medicinal purposes with some gas, as the carbonic acid, and for this the apparatus of Dr. Nooth is very effectual and convenient. It consists of three glass vessels, Pl. VI, fig. 4. The lower vessel *c* contains the effervescent materials; it has a small orifice at *d*, stopped with a ground stopper, at which an additional supply of either acid or water, or chalk, may be occasionally introduced. The middle vessel *b* is open, both above and below. Its inferior neck is fitted by grinding into the neck *h* of the lower vessel. In the former is a glass valve, formed by two pieces of tube, and a plano-convex lens, which is movable, between them, as represented in fig. 5. This valve opens upwards, and suffers the air to pass; but the water cannot return through the tubes, partly because the orifice is capillary, and partly because the flat side of the lens covers the hole. The middle vessel is furnished with a cock *e*, to draw off its contents. The upper vessel *a* is fitted, by grinding, into the upper neck of the middle vessel, ts inferior part consists of a tube that passes lmost as low as the centre of the middle essel. Its upper orifice is closed by a round stopper *f*. When this apparatus is o be used, the effervescent materials are put nto the lower vessel, the middle vessel is lled with pure water, and put into its lace; and the upper vessel is stopped, and kewise put in its place. The consequence , that the carbonic acid gas, passing hrough the valve at *h*, ascends into the up-er part of the middle vessel *b*, where by s elasticity it reacts on the water, and orces part up the tube into the vessel *a*; art of the common air, in this last, being ompressed, and the rest escaping by the topper, which is made of a conical figure, hat it may be easily raised. As more car-onic acid is extricated, more water rises, ill at length the water in the middle vessel alls below the lower orifice of the tube. he gas then passes through the tube into he upper vessel, and expels more of the ommon air by raising the stopper. In this tuation the water in both vessels being in ontact with a body of carbonic acid gas, it ecomes strongly impregnated with this gas, fter a certain time. This effect may be astened by taking off the middle and upper essels together, and agitating them.

The valve is the most defective part of his apparatus; for the capillary tube does ot admit the air through, unless there is a onsiderable quantity condensed in the low-r vessel; and the condensation has in some nstances burst the vessel.

Modern discoveries respecting bodies in he aëriform state have produced several ca-ital improvements in the vessels used for istillation. It was common with the ear-est chemists, to make a small hole in the pper part of their retorts, that the elastic apours might escape, which would other-ise have burst the vessels. By this means ney lost a very considerable part of their roducts. Sometimes too it is requisite, to btain separately the condensable fluid that omes over, and the gasses that are and are ot soluble in water. For this purpose a se-es of receivers, more or less in number as ne case may require, is generally employ-d, as in Pl. VII, fig. 1, which represents hat is called Woulfe's apparatus, though fact its original inventor was Glauber, ith some subsequent improvements. The apour that issues from the retort being ondensed in the receiver *a*, the gas passes on rough a bent tube into the bottle *c*, which half filled with water. The gas not ab-rbed by this water passes through a simi-r bent tube to *d*, and so on to more, if it e thought necessary; while the gas that is ot absorbable by water, or condensable, at s exit from the last bottle is conveyed by recurved tube into a jar *g*, standing in a ercurial trough *f*, *f*.

It often happens in chemical processes, om the irregularity of the heat, or other circumstances, that the condensation is more rapid in proportion to the supply of vapour at some period of the same operation than in others; which would endanger the fluid's being forced backward, by the pressure of the atmosphere, into the receiver, or even into the retort. To prevent this, Mr. Woulfe's bottles had a central neck, beside the two here delineated, for the insertion of a tube of safety, the lower extremity of which opened underneath the water, and the upper communicated with the atmosphere, so as to supply air in case of sudden absorption. See Pl. VII, fig. 3, *h*. Instead of this, however, a curved Welter's tube is now generally used, as more convenient. Into this tube water is poured, till the ball *b*, or *e*, fig. 1, is half full: when absorption takes place, the water rises in the ball till none remains in the tube, and then the air rushes in: on the other hand no gas can escape, as it has to overcome the pressure of a high column of water in the perpendicular tube.

Another contrivance to prevent retrograde pressure is that of Mr. Pepys. This consists in placing over the first receiver a glass vessel, the neck of which is ground into it, and furnished with a glass valve, similar to that in Nooth's apparatus, so that whenever sudden condensation takes place in the receiver, its effect is merely to occasion a vacuum there.

An ingenious modification of Woulfe's apparatus is that of Mr. Knight, Pl. VI, fig. 6. *a a a* represent three vessels, each ground into the mouth of that below it. *b b b* glass tubes, the middles of which are ground into the neck of their respective vessels, the upper extremity standing above the surface of the liquor in the vessel, and the lower extremity reaching nearly to the bottom of the vessel beneath. *e* a Welter's tube to prevent absorption. *f* an adapter ground to fit the receiver; to which any retort may be joined and luted before it is put into its place. *c* a tube for conveying the gas into a pneumatic trough. The foot of the lowest vessel, *d*, slides in between two grooves in a square wooden foot, to secure the apparatus from oversetting. A stopple fitted to the upper vessel, instead of the adapter *f*, converts it into a Nooth's apparatus, the materials being put into the vessel *a*, and in this case it has the advantage of not having a valve liable to be out of order.

A very simple and commodious form of a Woulfe's apparatus is given by the late Dr. W. Hamilton, at the end of his translation of Berthollet on Dyeing: see Pl. VII, fig. 3. *a* is the retort, the neck of which is ground into and passed through the thick collar *b*, represented separately at b, with its ground stopple a, which may be put in when the neck of the retort is withdrawn. The collar *b* is ground into the wide neck of the receiver c, the narrow neck of which is ground into the wide neck of d. *d*, *e*, *f*, and *g*, are connected in a similar manner; and into the small necks of *d*, *e*, and *f*, are ground the tubes *i*, *k*, and *l*, so curved, that their lower extremities nearly reach the bottom of the receiver into which they open. From the last receiver proceeds the recurved tube *m*, opening under an inverted cup *n*, a hole in the bottom of which conveys the gas issuing from it into one of the bottles placed in the movable frame *p*, which has a heavy leaden foot to keep it steady in the centre of a flat pan of water, in which the mouths of the bottles are immersed. In the receiver *d* is a tube of safety *h*. The receivers are placed on a stand a little inclined, and kept steady by slips of wood hollowed out to fit their curvatures, as represented at *s s*. This apparatus requires no lute; has no bent tubes that are difficult to adjust, and liable to break; and the retort may be removed at any stage of the process, either to find the weight it has lost, or for any other purpose, the receiver being meanwhile closed with the stopple. Similar advantages attend Mr. Knight's.

When it is required to pass an aëriform fluid through a redhot substance, such an apparatus as that of Barruel, Pl. I, fig. 2, may be employed. In this three gunbarrels, *b*, *c*, *d*, are placed horizontally in a reverberatory furnace *a*, about two inches distance from each other. From the extremity of the central barrel *c* a bent tube *k* conveys the gas to the jar *m*, in the pneumatic trough *l*. The other extremity of *c* is connected with *d* by the curved tube *i*; *d* with *b* by the curved tube *h*; and the other end of *b* with the bottle *f* by the tube *e*. When this apparatus is employed for obtaining carbonic oxide, the part of each barrel exposed to the fire being filled with charcoal pressed lightly in, but not rammed hard; carbonat of lime diluted with a very little water being poured into the bottle *f*; and the junctures being all well luted, the fire is to be kindled. As soon as the barrels are redhot, sulphuric acid is to be poured into the funnel *g*, and the carbonic acid gas expelled, traversing three portions of redhot charcoal, will completely saturate itself with it before it reaches the receiver *m*.

Pl. VII, fig. 2, represents the different parts of the apparatus required for measuring the quantity of elastic fluid given out during the action of an acid on calcareous soils. The bottle for containing the soil is represented at *a*; *b* the bottle containing the acid, furnished with a stop cock; *c* the tube connected with a flaccid bladder *d*; *f* a graduated measure; *e* the bottle for containing the bladder. When this instrument is used, a given quantity of soil is introduced into *a*; *b* is filled with muriatic acid, diluted with an equal quantity of water; and the stop-cock, being closed, is connected with the upper orifice of *a*, which is ground to receive it. The tube *c* is introduced into the lower orifice of *a*, and the bladder connected with it placed in its flaccid state in *e*, which is filled with water. The graduated measure is placed under the tube of *e*. When the stopcock of *b* is turned, the acid flows into *a*, and acts upon the soil; the elastic fluid generated passes through *c* into the bladder, and displaces a quantity of water in *e* equal to it in bulk, and this water flows through the tube into the graduated measure; the water in which gives, by its volume, the indication of the proportion of carbonic acid disengaged from the soil; for every ounce measure of which, two grains of carbonat of lime may be estimated.

Labrador Stone. A beautiful stone from the coast of Labrador. Its colour is commonly of a light, or of a deep gray, frequently blackish; but when held in certain positions to the light, it exhibits varieties of beautiful internal colours, chiefly consisting of shades of blue and green, seldom yellow, in some parts of a copper red, and violet. These colours have for the most part a flaky or spotted appearance, but sometimes they lie in stripes.

These stones are found of an angular form in pieces of considerable magnitude, their specific gravity is 2·755, their fracture is laminated; the broken parts are rhomboidal, and semitransparent. In other respects this stone agrees with the feldt spar, but is softer.

Lac Is a substance well known in Europe, under the different appellations of stick-lac, shell-lac, and seed-lac. The first is the lac in its natural state, incrusting small branches or twigs. Seed-lac is the stick-lac separated from the twigs, appearing in a granulated form, and probably deprived of part of its colouring matter by boiling. Shell-lac is the substance which has undergone a simple purification, as mentioned below. Beside these we sometimes meet with a fourth, called lump-lac, which is the seed-lac melted and formed into cakes.

Lac is the product of the coccus lacca, which deposits its eggs on the branches of a tree called Bihar, in Assam, a country bordering on Thibet, and elsewhere in India. It appears designed to answer the purpose of defending the eggs from injury, and affording food for the maggot in a more advanced state. It is formed into cells, finished with as much art and regularity as a honeycomb, but differently arranged; and the inhabitants collect it twice a year, in the months of February and August. For the purification, it is broken into small pieces, and put into a canvass bag of about four feet long, and not above six inches in circumference. Two of these bags are in constant use, and each of them held by two men. The bag is placed over a fire, and frequently turned, till the lac is liquid enough to pass through its pores; when it is taken off the fire, and twisted in different directions by the men who hold it, at the same time dragging it along the convex part of a plantain tree prepared for this purpose; and while

s is doing, the other bag is heating, to be
ated in the same way. The mucilaginous
l smooth surface of the plantain tree pre-
nts its adhering; and the degree of pres-
e regulates the thickness of the coating
ac, at the same time that the fineness of
bag determines its clearness and trans-
rency.

Analysed by Mr. Hatchett, stick-lac gave
a hundred parts, resin 68, colouring ex-
ct 10. wax 6, gluten 5·5, extraneous
ostances 6·5: seed-lac, resin 88·5, colour-
; extract 2·5, wax 4·5, gluten 2: shell-
, resin 90·9, colouring extract 0·5, wax 4,
ten 2·8. The gluten greatly resembles
t of wheat, if it be not precisely the
ne; and the wax is analogous to that of
e myrica cerifera.

In India lac is fashioned into rings, beads,
l other trinkets: sealing-wax, varnishes,
d lakes for painters, are made from it: it
nuch used as a red dye, and wool tinged
h it is employed as a fucus by the ladies:
l the resinous part, melted and mixed
th about thrice its weight of finely pow-
red sand, forms polishing stones. The
idaries mix powder of corundum with it
a similar manner.

The colouring matter is soluble in water;
t 1 part of borax to 5 of lac renders the
hole soluble by digestion in water nearly
a boiling heat. This solution is equal
many purposes to spirit varnish, and is
excellent vehicle for watercolours, as
hen once dried water has no effect on
Lixivium of potash, soda, and carbonat
soda, likewise dissolve it. So does nitric
d, if digested upon it in sufficient quan-
y 48 hours.

The colouring matter of the lac loses con-
erably of its beauty by keeping any
gth of time; but when extracted fresh,
d precipitated as a lake, it is less liable to
ury. Mr. Stephens, a surgeon in Bengal,
at home a great deal prepared in this way,
hich afforded a good scarlet to cloth pre-
ously yellowed with quercitron: but it
ould probably have been better, if, instead
precipitating with alum, he had em-
oyed a solution of tin, or merely evapo-
ed the decoction to dryness.

Lac is the basis of the best sealing wax.—
il. Trans.—Trans. of Soc. of Arts.

LAC (WHITE). Under the article ACID
ACCIC), we have already noticed a sub-
nce resembling bees-wax, and, from the
nner of its production by a species of
ccus, called by Dr. Anderson white lac.
chief properties, not there mentioned,
: when purified by fusion and straining
rough cloth, by which it loses about two-
ths of its weight, it adheres so firmly to
od, paper, tin, and other substances, as
answer the purpose of a good cement:
cannot be bleached by exposure to the
n, or to oxigenized muriatic acid: by
iling with charcoal in water it is absorb-
: with potash it combines very imperfectly, but with ammonia it forms a soap: made into candles it burns with smoke and smell: sulphuric acid turns it black: boiling nitric acid dissolves it, but by cooling, or by pouring the hot solution into water, it separates of a whiter colour: oil of turpentine dissolves one fifth of its weight, by the aid of heat, without appearing to alter it: ether at 80° dissolves one tenth of its weight with some slight change: alcohol takes up about one twentieth: it does not afford a good varnish.

By destructive distillation the products were one fourth butyraceous oil, one half thin oil, and the rest minute quantities of acid, water, and coaly and saline matter, with carbonic acid gas, hidrogen, and azot. —*Phil. Trans. for* 1794, *Part* II.

LACQUER. See VARNISH.

LAKES. This term is used to denote a species of colours formed by precipitating colouring matter with some earth or oxide. The principal lakes are, Carmine, Florence-lake, and lake from Madder.

For the preparation of *Carmine*, four ounces of finely pulverized cochineal are to be poured into four or six quarts of rain or distilled water, that has been previously boiled in a pewter kettle, and boiled with it for the space of six minutes longer; (some advise to add, during the boiling, two drachms of pulverized crystals of tartar.) Eight scruples of Roman alum in powder are then to be added, and the whole kept upon the fire one minute longer. As soon as the gross powder has subsided to the bottom, and the decoction is become clear, the latter is to be carefully decanted into large cylindrical glasses covered over, and kept undisturbed, till a fine powder is observed to have settled at the bottom. The superincumbent liquor is then to be poured off from this powder, and the powder gradually dried. From the decanted liquor, which is still much coloured, the rest of the colouring matter may be separated by means of the solution of tin, when it yields a carmine little inferior to the other.

For the preparation of *Florentine* lake, the sediment of cochineal, that remained in the kettle, may be boiled with the requisite quantity of water, and the red liquor likewise, that remained after the preparation of the carmine, mixed with it, and the whole precipitated with the solution of tin. The red precipitate must be frequently edulcorated with water. Exclusively of this, two ounces of fresh cochineal, and one of crystals of tartar, are to be boiled with a sufficient quantity of water, poured off clear, and precipitated with the solution of tin, and the precipitate washed. At the same time two pounds of alum are also to be dissolved in water, precipitated with a lixivium of pot-ash, and the white earth repeatedly washed with boiling water. Finally, both precipitates are to be mixed together in their liquid state, put upon a filter, and dried. For the preparation of a *cheaper* sort, instead of cochineal, one pound of Brazil wood may be employed in the preceding manner.

The red extracted from shreds of scarlet cloth by boiling them in a lixivium of a pound of pearl ashes to two quarts of water, being precipitated by a solution of a pound and half of cuttlefish bone in a pound of aqua fortis, is said to make a very fine carmine. If 1½ lb. of the bone be not sufficient to saturate the aqua fortis, more must be added, till it excites no effervescence. If the lake appear too purple, a little alum may be added to the solution.

For the following process for making a *lake from madder*, the Society of Arts voted sir H. C. Englefield their gold medal. Enclose two ounces troy of the finest Dutch crop madder in a bag of fine and strong calico, large enough to hold three or four times as much. Put it into a large marble or porcelain mortar, and pour on it a pint of clear soft water cold. Press the bag in every direction, and pound and rub it about with a pestle, as much as can be done without tearing it, and when the water is loaded with colour, pour it off. Repeat this process till the water comes off but slightly tinged, for which about five pints will be sufficient. Heat all the liquor in an earthen or silver vessel, till it is near boiling, and then pour it into a large basin, into which a troy ounce of alum dissolved in a pint of boiling soft water has been previously put. Stir the mixture together, and while stirring pour in gently about an ounce and half of a saturated solution of subcarbonat of potash. Let it stand till cold to settle; pour off the clear yellow liquor; add to the precipitate a quart of boiling soft water, stirring it well; and when cold separate by filtration the lake, which should weigh half an ounce. If less alum be employed, the colour will be somewhat deeper: with less than three fourths of an ounce the whole of the colouring matter will not unite with the alumine. Fresh madder root is equal, if not superior, to the dry.

Almost all vegetable colouring matters may be precipitated into lakes, more or less beautiful, by means of alum, or oxide of tin; but Guyton-Morveau asserts, that the oxide of tungsten is superior to any other base. If this oxide were boiled in vinegar, so as to give it a blue colour, the tints of the lake were heightened. From the fermented juice of the succotrine aloe he obtained a fine purple-red with this oxide.

Lamp. See Light.

Lampblack. When the parts of organized substances which are of an inflammable nature are burning under circumstances wherein a complete combustion does not take place, part of the coaly matter is carried up through the flame, and forms soot. Common soot contains other matters beside charcoal: but the soot of oily substances is considerably pure. The finest lampblack is actually produced by collecting the smoke from a lamp with a long wick, which supplies more oil than can be perfectly consumed, or by suffering the flame to play against a metalline cover, which impedes the combustion not only by conducting off part of the heat, but by obstructing the current of air. Lampblack, however, is prepared in a much cheaper way, for the demands of trade. The dregs which remain after the eliquation of pitch, or else small pieces of fir-wood, are burned in furnaces of a peculiar construction, the smoke of which is made to pass through a long horizontal flue, terminating in a close boarded chamber. The roof of this chamber is made of coarse cloth, through which the current of air escapes, while the soot remains behind.

Lapis Hepaticus. A stone of a white, gray, yellow, brown, or black colour; it is generally compact, but not so hard as to give fire with steel; of a texture either equable or laminar, scaly or sparry, and which takes a polish as alabaster.

It does not effervesce with acids. When calcined, it is partially reduced to a sort of plaster of Paris. It emits a smell of sulphuretted hidrogen, at least when rubbed. According to Bergman, 100 parts of it afford 38 of sulphat of barytes, 33 of silex, 22 of alum, 7 of gypsum, and 5 of mineral oil. The increase proceeds from the water of crystallization.

Lapis Infernalis. See Infernal Stone.

Lapis Lazuli. The colour of this stone is a beautiful opake blue, which varies a little in intensity, and is generally sprinkled over with yellow, bright, pyritaceous specks or streaks: it obstinately retains its colour in a strong heat, but in that of an enameller's furnace it changes to gray: it is of an equable or very fine granular texture, and takes a beautiful polish; its specific gravity is 3·054. If powdered and not calcined, it effervesces very slightly with acids; but if calcined, it does not effervesce, but becomes gelatinous. In a strong fire it melts without addition into a whitish glass.

Klaproth gives the following as the analysis of 100 parts of this stone. Silex 46, alumine 14·5, carbonat of lime 28, sulphat of lime 6·5, oxide of iron 3, water 2. According to Guyton-Morveau, however, the colouring matter is a blue sulphuret of iron, mixed in some specimens with nothing but silex and sulphat of lime, to which in others barytes is added, and in others alumine and carbonat of lime.

The fine blue colour called Ultramarine, which see, is prepared from this stone.—*Klaproth's Analyses.—An. de Chim.*

Lapis Lydius. A variety of the trap of the Swedes; its colour is black, and it is well known by the name of the touch-stone. The black basaltes, from which this stone

carcely differs in its component parts, is
sed for the same purpose. See ASSAY.

LAPIS NEPHRITICUS. See JADE.

LAPIS OLLARIS. A stone of the magne-
an genus, of a greenish or yellowish gray,
ometimes speckled with red It is easily
rought and turned, so that pots and mor-
ars are often made of it. Spec. grav. from
·769 to 3·023.

LAPIS SPECULARIS. A name given to the
ansparent sulphat of lime.

LAPIS SUILLUS. See LAPIS HEPATICUS.

LAVA. See VOLCANIC PRODUCTS.

LAUDANUM. See OPIUM.

LAZULI, (LAPIS.) See LAPIS LAZULI.

LEAD. Is a white metal, of a conside-
ably blue tinge, very soft and flexible, not
ery tenacious, and consequently incapable
being drawn into fine wire, though it is
sily extended into thin plates under the
ammer. Its weight is very considerabie,
eing rather greater than that of silver.
ong before ignition it melts; and then
egins to be oxided, if oxigen be present.
a strong heat it boils, and emits fumes;
uring which time, if exposed to the air,
oxidation proceeds with considerable ra-
dity. If melted lead be poured into a
ox previously rubbed with chalk to pre-
ent its action on the wood, and be conti-
ually agitated, it will concrete into sepa-
te grains, of considerable use in various
echanical operations, particularly that of
eighing. Lead is brittle at the time of
ngelation. In this state it may be broken
pieces with a hammer, and the crystal-
zation of its internal parts will exhibit an
rangement in parallel lines.

This metal, during the progress of heat,
st becomes converted into a dusky pow-
r, which by a continuation of the heat
comes white, yellow, and afterward of a
ight red, inclining to orange colour,
lled *minium*, or red lead. The process
quires considerable management with re-
rd to the heat, and access of the air, in
e making of red lead. Many days are
quired for this purpose. See MINIUM.
the heat be too great or rapid, the lead
comes converted into a flaky substance,
lled litharge; and a still greater heat con-
rts it into a clear, transparent, yellow
ass, which powerfully dissolves and cor-
des metallic oxides or earths; and on this
count it usually finds its way through the
ucibles in a short time. It acts more dif-
ultly on argillaceous than on siliceous
rths; whence it is found, that vessels
ade of clay mixed with broken pottery
e preferable to those that are composed of
y and sand. The oxide of lead is a prin-
pal ingredient in most of the modern
e white glasses. It is more particularly
lculated to form the dense glass used to
rrect the aberration arising from colour
those telescopes, which are known by
e name of achromatic; because it com-
unicates the property of separating the coloured rays from each other in greater angles than obtained in alkaline glasses at equal angles of mean refraction. See ACHROMATIC, also GLASS. The imperfection which most considerably affects this kind of glass is, that its density is seldom uniform throughout. The irregularities show themselves in the form of veins, which greatly disturb the regular refraction.

According to Dr. Thomson, there are three distinct oxides of lead: the yellow; or *massicot*, which is at the first stage of oxidation, and contains 9 5 per cent. of oxigen; the red, which contains 12 per cent.; and the brown, which contains about 20. The last, which Scheele discovered, may be made by pouring dilute nitric acid on red lead, which dissolves part, and leaves the rest in the state of brown oxide: or by passing a current of oxigenized muriatic gas through water in which red lead is suspended. The ashes of lead, or dusky powder that first appears in its oxidation, consist of the yellow oxide and lead in powder: white lead is the yellow oxide combined with some acid, commonly the carbonic; and litharge is a subcarbonat of lead, consisting of about 93 parts yellow oxide, and 4 carbonic acid, with 3 of oxide of antimony.

Lead is not much altered by exposure to air or water, though the brightness of its surface, when cut or scraped, very soon goes off. It is probable that a thin stratum of oxide is formed on the surface, which defends the rest of the metal from corrosion.

Most of the acids attack lead. The sulphuric does not act upon it, unless it be concentrated and boiling. Sulphurous acid gas escapes during this process, and the acid is decomposed. When the distillation is carried on to dryness, a saline white mass remains, a small portion of which is soluble in water, and is the sulphat of lead: it affords crystals. The residue of the white mass is an insoluble sulphat of lead. Descotils says, that, if sulphat of lead be treated with pretty strong muriatic acid, it may be totally dissolved by heat, and on cooling crystals of muriat of lead will fall down, particularly if a little cold water be added. This muriat is soluble in water, and may be almost entirely decomposed again by sulphuric acid.

Nitric acid acts strongly on lead, and converts it into a white powder, if the acid be concentrated; but if it be more diluted, the powder is dissolved, and forms a nitrat of lead which is crystallizable, and does not afford a precipitate by cooling. It detonates on ignited coals. Lime and alkalis decompose the nitric solution of lead. The sulphuric acid added to this solution combines with the metallic oxide, and falls down. The muriatic acid in the same manner carries down the lead, and forms a combination called plumbum corneum, which is more soluble in water than the horn silver. When nitrat of lead has an excess of acid, its colour is yellow.

Muriatic acid acts directly on lead by heat, oxiding it and dissolving part of its oxide. The muriat of lead is crystallizable. If oxigenized muriatic acid gas be passed into a nitric solution of lead, small brilliant cubes of oxymuriat will be formed by slowly evaporating the liquor to two thirds, and cooling. These detonate violently when struck, if a small bit of phosphorus be added.

The acetous acid dissolves lead and its oxides; though probably the access of air may be necessary to the solution of the metal itself in this acid. *White lead*, or *ceruse*, is made by rolling leaden plates spirally up, so as to leave the space of about an inch between each coil, and placing them vertically in earthen pots, at the bottom of which is some good vinegar. The pots are to be covered, and exposed for a length of time to a gentle heat in a sand bath, or by bedding them in dung. The vapour of the vinegar, assisted by the tendency of the lead to combine with the oxigen which is present, corrodes the lead, and converts the external portion into a white substance which comes off in flakes, when the lead is uncoiled. The plates are thus treated repeatedly until they are corroded through. Ceruse is the only white used in oil paintings. Commonly it is adulterated with a mixture of chalk in the shops. It may be dissolved without difficulty in the acetous acid, and affords a crystallizable salt, called *sugar of lead* from its sweet taste. This, like all the preparations of lead, is a deadly poison. According to Dr. Bostock, the common sugar of lead is a superacetat; and the water of acetated litharge, or Goulard's extract, made by boiling litharge in vinegar, a neutral acetat, in which there is little more than half the quantity of acid to a given quantity of oxide. The power of the neutral salt, he adds, as a coagulator of mucus, is much superior. Thenard observes, that the neutral acetat is less soluble, less saccharine in its taste, crystallizes in laminæ, and is slightly efflorescent. If a bit of zinc be suspended by brass or iron wire, or a thread, in a mixture of water and the superacetat of lead, the lead will be revived, and form an arbor Saturni, as the zinc abstracts its oxigen.

Sulphurets precipitate lead from its solutions, the sulphur falling down in combination with the lead. Sulphuretted hidrogen does the same. Pure alkaline solutions dissolve a small portion of lead, and corrode a considerable quantity; the solution is said to give a black colour to the hair.

Oils dissolve the oxides of lead, and become thick and consistent; in which state they are used as the basis of plasters, cements for water works, paints, &c.

In the dry way, lead alone is oxided and vitrified. When fused with fixed alkaline salts, it is converted into a dark-coloured scoria, partly soluble in water. The neutral salts in general are not acted upon by lead. Nitre oxides this metal when treated with it, though scarcely any commotion or apparent flame is produced by its action. Sulphur readily dissolves it in the dry way, and produces a brittle compound, of a deep gray colour and brilliant appearance, which is much less fusible than lead itself; a property which is common to all the combinations of sulphur with the more fusible metals.

The phosphoric acid, exposed to heat together with charcoal and lead, becomes converted into phosphorus, which combines with the metal. This combination does not greatly differ from ordinary lead; it is malleable, and easily cut with a knife; but it loses its brilliancy more speedily than pure lead; and when fused upon charcoal with the blowpipe, the phosphorus burns, and leaves the lead behind.

Lead decomposes sal ammoniac by the assistance of heat; its oxides unite with the muriatic acid of that salt in the cold, and disengage its volatile alkali. When volatile alkali is obtained by distilling sal ammoniac with the oxides of lead, the residue consists of plumbum corneum.

Litharge fused with common salt decomposes it; the lead unites with the muriatic acid, and forms a yellow compound, at present used in this country as a pigment, for which an exclusive privilege has been granted. The alkali either floats at top, or is volatilized by the heat, if strongly urged. The same decomposition takes place in the humid way, if common salt be macerated with litharge; and the solution will contain caustic alkali.

Lead unites with most of the metals. Gold and silver are dissolved by it in a slight red heat. Both these metals are said to be rendered brittle by a small admixture of lead, though lead itself is rendered more ductile by a small quantity of them. Platina forms a brittle compound with lead; mercury amalgamates with it; but the lead is separated from the mercury by agitation, in the form of an impalpable black powder, oxigen being at the same time absorbed. The presence of oxigen is indispensably necessary in this process. Copper and lead do not unite but with a strong heat. If lead be heated so as to boil and smoke, it soon dissolves pieces of copper thrown into it; the mixture when cold is brittle. The union of these two metals is remarkably slight; for, upon exposing the mass to a heat no greater than that in which lead melts, the lead almost entirely runs off by itself. This process, which is peculiar to lead with copper, is called eliquation. The coarser sorts of lead, which owe their brittleness and granulated texture to an admixture of copper, throw it up to the surface on being melted by a small heat. Iron does not unite with lead, as long as both substances retain their metallic form. Tin unites very easily with this metal, and forms a compound, which is much more fusible than lead by itself, and is for this reason used as a solder for lead. Two parts of lead and one of tin form an alloy more fusible than either metal alone: this is the solder of the plumbers. Bismuth combines readily with lead, and affords a metal of a fine close grain, but very brittle. A mixture of eight parts bismuth, five lead, and three tin, will melt in a heat which is not sufficient to cause water to boil. Antimony forms a brittle alloy with lead. Nickel, cobalt, manganese, and zinc, do not unite with lead by fusion.

All the oxides of lead are very easily revived. Minium, when exposed to a strong heat, gives out part of the oxigen it absorbed during its oxidation; but, like the other oxides of this metal, it requires the addition of some combustible substance for its complete revival. A familiar instance of this revival is seen by exposing common red wafers to the flame of a candle. These wafers are coloured with minium, which is revived by the heat and the carbon of the wafer, so that it falls down in metallic globules.

Lead is found native, though seldom;
nd also in the form of an oxide called na-
ive ceruse, or lead ochre, or lead spar of
arious colours, red, brown, yellow, green,
lueish, and black. These ores, when
reed as much as possible from earthy mat-
er, may be dissolved in diluted nitric acid.
Oxide of iron is usually thrown down from
he solution by boiling. If the lead be then
recipitated by the subcarbonat of soda,
nd weighed, 132 grains of the dry preci-
itate will correspond with 100 grains of
ead in the metallic state. If the precipi-
ate be suspected to contain copper, it may
e separated by digesting in ammonia. If
be supposed to contain silver and copper,
he precipitate may again be dissolved in
itric acid, and separated by the addition
f muriatic acid; which, combining with
he metal, produces luna cornea, and plum-
um corneum; and the latter of these,
eing soluble in 30 times its weight of boil-
g water, may be washed off, while the
lver remains undissolved; or the silver, if
one in the precipitate, may be taken up
y ammonia, which will leave the oxide of
ad of the same value with regard to
eight as the foregoing. A native minium
as been found lately in Hesse by Mr.
nithson. Lead is also found mineralized
y the sulphuric and the phosphoric acids:
is last is generally of a greenish colour,
ising from a mixture of iron. When un-
ixed with iron it is sometimes brown,
metimes lemon-coloured, and more rarely
ayish white. The sulphat of lead is soluble in about 18 times its weight of water. One hundred and forty-three grains of the dried salt represent 100 grains of lead. The phosphoric lead ore may be dissolved in nitric acid by means of heat, except a few particles of iron, which remain at the bottom. By the addition of sulphuric acid, the lead is thrown down in the form of white flakes of sulphat, which when washed and dried discover the quantity of lead they contain, by the same allowance of 143 grains of the salt to 100 grains of metallic lead. The remaining solution being evaporated to dryness, affords phosphoric acid. The yellow lead ore of Carinthia consists of 2 parts of yellow oxide of lead, and rather more than one of oxide of molybdena. The red lead ore of Siberia has lately been found to be chromat of lead; and oxide of chrome is united with oxide of lead in a green ore.

Lead is abundantly found in combination with sulphur, in the form of heavy, shining, black, or blueish lead-coloured cubical masses, the corners of which are usually truncated; its texture is laminated, and its hardness variable. This is called galena, or potters lead ore. Most lead ores contain more or less of silver. When antimony enters into its composition, the texture is radiated or filamentous. There are also lead pyrites, which contain a considerable proportion of iron and sulphur.

If sulphuretted lead be boiled in nitric or muriatic acid of a moderate strength, the sulphur may be obtained pure, and collected in a filter. When iron or stony particles are contained among the undissolved part, the sulphur may be separated by digestion in a solution of caustic fixed alkali, which converts it into a sulphuret, and leaves the other insoluble matters behind. If the first solution be made with nitric acid, it may contain silver and lead, which, after the precipitation by mild mineral alkali, may be separated by the volatile alkali, as mentioned in the humid analysis of the calciform ores: when the muriatic acid is used for the solution of the ore, a large quantity of plumbum corneum separates, for want of a sufficient quantity of water to dissolve it. This requisite quantity of water must be added to dissolve the salt, before the precipitate is made by the fixed alkali.

All the ores of lead, except the phosphoric, are reducible to the metallic state, by dissipating their volatile contents by the blowpipe on a piece of charcoal. In the large way, they are revived by fusion with charcoal.

The ores of this metal are abundantly found in the mine counties of England, and in various other parts of the globe. Its uses are numerous, and scarcely need be mentioned. Its oxides have been already mentioned as of great use, as pigments, and in the manufacture of glass. Lead is cast into thin sheets for covering buildings, making water-pipes, and various other uses; and this is rolled between two cylinders of iron, to give it the requisite uniformity and thinness. Lead is thought, and with some reason, to be not perfectly innocent even for water pipes, and much less for any other kind of vessels. The workmen in any of the preparations of lead are generally subject to a peculiar colic, and paralytic disorders; which most probably arise from the internal use of the metal: for it is a fact, that these workmen are not sufficiently cautious in washing their hands, or removing such particles of lead, or its preparations, as may casually intermix with their food.

Leather. The skins of animals prepared by maceration in lime-water, and afterward with astringent substances. See Tanning.

Leaves of Plants. Lewis found that the green colour of the leaves of plants is extracted by alcohol, and by oils. The spirituous tinctures are generally of a fine deep green, even when the leaves are dull coloured, yellowish, or hoary. These colours are seldom lasting in the liquor. Alkalis heighten both the tinctures and the green juices. Acids weaken, destroy, and change it to a brownish. Lime-water improves both the colour and durability. By means of lime, not inelegant green lakes are procurable from the leaves of acanthus, lily of the valley, and several other plants.

Few plants communicate any part of their green colour to water, and perhaps none that give a green of any considerable intensity. It is said, however, that the leaves of some plants give a green dye to woollen, without the addition of any other colouring matter; particularly those of the wild chervil, or cow-weed, the common rag-wort and devil's bit. Lewis gives the process from Linnæus as practised by the peasants in Sweden with the last. It consists in boiling the leaves with their woollen yarn for a short time, and leaving the whole together for a night, after which the yarn is taken out, hung in the steam of the liquid, and again made to boil over the fire. It is then wrung, the leaves are taken out of the liquor, a little fresh water added, and the wool frequently dipped therein till sufficiently dyed.

Many kinds of leaves afford a yellow dye to woollens previously boiled with alum and tartar, weld in particular, which see. Indigo and woad afford blue. Lewis tried, without success, to obtain blues by macerating the leaves of other plants in water.

Lees, (Soap). See Potash. Also Soap.

Lemnian Earth, See Earth, (Fullers.)

Lemons. See Acid, (Citric).

Lepidolite. A stone first brought into notice by the name of *lilalite*, and considered as a species of gypsum, and afterward classed as a zeolite by Born. It is of a violet colour, or purple, in the mass, separable into laminæ, which have the lustre of mother of pearl. It is capable of some polish, though soft enough to be scratched with the nail. Spec. grav. 2·816. It fuses into a dense white glass. Analysed by Klaproth, 100 parts gave silex 54·5, alumine 38·25, potash 4, oxides of manganese and iron 0·75.—*Klaproth's Analyses.*

Leucite. A fossil often occurring in the lavas and other mingled masses of rocks in Italy, remarkable for its determinate specific fissure, which consists of low double octahedral pyramids, flatly sharpened off to four terminating surfaces, so as to form a roundish crystal bounded by 24 trapeziums. It has been called white garnet, vesuvian garnet, and garnet-shaped schorl. Mr. Klaproth analysed several, most of them of the size of a nutmeg or upward, and of the spec. grav. of 2·455. They gave silex 53·75, alumine 24·63, potash 21·35. This was the first stone in which potash was discovered. —*Klaproth's Analyses.*

Levigation. The mechanical process of grinding the parts of bodies to a fine paste, by rubbing the flat face of a stone called the muller upon a table or slab called the stone. Some fluid is always added in this process. The advantage of levigation with a stone and muller, beyond that of triturating in a mortar, is, that the materials can more easily be scraped together, and subjected to the action of the muller, than in the other case to that of the pestle; and, from the flatness of the two surfaces, they cannot elude the pressure.

Lichen, Liverwort. Several species of this genus are useful in the arts, particularly dyeing, or as food or medicine. Under the word Archil we have already noticed one. To wool, previously prepared with a bath of lycopodium complanatum, l. clavatum, or l. alpinum, the lichen Westringii is said to give a fine orange, superior to that of annotta. The lichen cinereus does the same. The chlorinus gives a bright yellow, and the vulpinus a lemon colour. Brasil gives to wool thus dyed with the l. Westringii a very deep blue black; to that with the chlorinus a fine green black, or raven's wing colour; and to that with the vulpinus a blueish green. The lichen parellus, from which archil has been said by some to be prepared, affords only a blue, which is so fugitive as to be useless.

Lord Dundonald has lately taken out a patent for the use of lichen as a substitute for gum. Lichens that grow on trees and shrubs afford this gum, and apparently different species of them. The lichen is scalded two or three times with boiling water, to remove the outer skin and resinous matter, washed in cold water, and then left ten or twelve hours on a stone or brick floor; after which the gum is extracted by boiling some hours in water, with about half or three quarters of an ounce of alkali to each pound of lichen. According to the report, 1lb. of dry lichen will do as much work in calico-printing as 1¾lb. of gum Senegal; and the difference of price makes a saving of 45*l.* on each table or press in war time, and half that in peace.

The lichen islandicus has been much recommended in consumptions. It is certainly nutritious, and according to prof. Proust, after its bitter principle is extracted by cold or hot water, a quarter of an hour's boiling makes it a very agreeable vegetable for the table. If after this boiling it be dried, it will keep any length of time, and may be made fit for the table instantly by pouring boiling water on it; or even by steeping in cold water, either fresh or salt. Its decoction in milk or whey makes a very nutritious jelly. It consists of 64 parts fleshy or pulpy substance, 3 bitter matter, and 33 gummy matter soluble in hot water but not in cold.—*Bullet. des Sciences.—Phil. Mag.—Journ. de Phys.*

Light. Philosophers are not agreed as to the independent existence of light, or the cause by which we see; that is to say, whether light be a body, or a property. If light be a body, it must consist of particles of extreme minuteness, projected with a very great degree of velocity from luminous bodies; if on the other hand light be nohing more than a modification or property, t must subsist in some other matter universally diffused through every part of known space. The philosophers who mainain this last opinion consider the universe o be occupied by a fluid of extreme rarity and elasticity, permeating all bodies; the undulations of which, transmitted in all diections from the luminous body, or exiting cause, produce the sensation and other effects of light. Though much ingenious reasoning has been employed on his subject, we have not obtained possession of any decisive facts; but each hypothesis may without inconsistency be applied to very natural appearance hitherto observed. t is difficult, however, to speak of these acts, without considering light accordiug o one or the other of these suppositions. This is not the place for discussing their espective merits. I shall therefore assume he hypothesis, which admits of the independent existence of light, not only because t is more generally admitted and known, ut because it appears best calculated to xplain some of the appearances, more esecially the various refrangibility of the ays of light.

It is observed, that whenever light passes hrough a space occupied by a medium of niform density, it describes a right line. These lines, or rather prisms, are called the ays of light. They rebound, or are reected by bodies against which they strike, t is sufficiently ascertained, that this reflecion is caused by a repulsive power in the ody itself, exerted at a considerable ditance; so that the light is driven back without coming into contact with the matter which repels it. When light is made to pass near a body in such a direction, or under such circumstances, as that it may come nearer the limit of repulsion, it is attracted, and alters its course by deviating towards the attracting body. If the body possess a very narrow surface, such for example as the edge of a knife, this deviation in the ray of light may be measured by attending to the course of the ray after it has passed the body. But if the surface be broader, the attractive power usually causes the light to pass into the body, where it is absorbed and lost, if the body be opaque, or passes through, if the body be transparent. The change produced in the course of a ray of light, by the attraction of a body into which the light does not enter, is called inflection; but when the light does enter the body, this change is called refraction. It is found, that the light of the sun from which we derive the sensation of whiteness is composed of an admixture of rays possessing the property of exciting sensations of every possible colour, each according to its respective nature. The attractive and repulsive powers of bodies differ in their intensities with regard to these several rays, and accordingly they are separated from each other by reflection, refraction, or inflection. A like separation is also made in the rays of light by the thickness or distance between the two surfaces of the medium through which they pass. It is more particularly observable in thin plates of glass, or water blown into bubbles, and the like. The colours of bodies depend on a power possessed by them of reflecting some of the rays of light, and absorbing others, and this power in all probability depends upon the principles here sketched out.

The velocity of light is so extremely great, that in all common experiments it appears to be instantaneous. Astronomers have nevertheless found, that its progress across the regions occupied by the solar system requires so much time, that in computing the eclipses of Jupiter's moons they are under the necessity of making an allowance for the greater or less distance of that planet, which occasions the time of any eclipse to be later when seen from a greater distance than from a less. Other observations upon the fixed stars show, that there is a sensible proportion between the velocity of light, and that of the earth in its annual orbit. From these acute investigations it is deduced, that light passes from the sun to the earth in little more than eight minutes, which gives a velocity of about 167000 geographical miles in one second.

Optical writers may be consulted for a great number of curious and useful deductions made from these principles, and applied to the doctrine of vision, the nature of colours, the construction of mirrors, telescopes, and other instruments, not immediately within the province of chemistry.

Light comes to our eyes under five different circumstances. 1. It is emitted from bodies in a rapid state of combustion: or, 2. from other bodies at an elevated temperature, which are then said to be ignited. 3. It also comes to us by reflection; or 4, refraction: and 5, there are very few bodies which being exposed to a strong light, and afterward taken into the dark, do not remain luminous for a considerable time. Hence it seems, that we experimentally know of no other source of light, than combustion; and from this fact it is, that many writers have considered fire, heat, and light, to be the same thing. But these objects differ in various remarkable particulars. The heat of a fire is by no means proportional to the light it gives. The light will pass through transparent bodies swiftly, and without impediment, but the heat remains attached to the body, and is not transmitted in any other way, than it would have passed through an opaque substance, viz. by raising the temperature of the body itself. Heat, with access of oxigen, causes bodies to be burned, and to lose their combustible property. Light in many instances produces a contrary effect. The effect of light in chemical experiments is so considerable, that the operator ought to be constantly aware of the influence it may have upon his products. It appears to be particularly active in disengaging oxigen from its combinations; but whether by uniting with the air, or otherwise, has not been explained. Every chemist knows that pure pale nitric acid cannot be preserved but in bottles quite full, or in the dark. For the light expels oxigen from the acid, if there be any space into which it can escape, and leaves the residue yellow and fuming, in consequence of the redundant portion of the basis of the acid. Mere heat is so far from effecting this, that it restores the purity of the acid by expelling the redundancy. So likewise the black oxide of manganese, which contains nitrogen and oxigen, emits the former at a low heat, but does not give out the latter until light is present by the ignition of the vessels. Light appears to be the great agent in the production of combustible matter on the surface of the globe. It extricates oxigen from the leaves and other parts of vegetables, most probably by decomposing their aqueous part, and leaves the combustible matter, or hidrogen, which enters into the composition of mucilages, oils, and resins, the most inflammable of which are the products of such climates as possess the greatest intensity of solar light. The consequences of a want of light in vegetation are remarkably shown in the properties and chemical products of plants of the same kind, reared in the open day, or in the dark. The tendency of plants growing in a room, which turn themselves toward the aperture that admits the light, or even toward the thinnest side of a wooden box wherein they are included, is a striking effect, and has been ascribed to a degree of sensibility in these organized beings. But the evaporation of camphor and of water, the vegetation and crystallization of salts, and of metallic substances, which are considerably modified by light, and incline themselves toward the place of its emission, seem to be instances of the same kind. The metallic oxides, and the salts produced by the oxigenized muriatic acid, undergo a change by the action of light, rendering them nearer the state of combustibility than before.

Various experiments have been made by Dr. Herschel, Sir H. C. Englefield, Dr. Wollaston, and Mr. Ritter of Jena, on the heating and chemical effects of light, when separated by the prism into the several coloured rays. It appears from these, that the heat is totally independent of the rays; and that the effect produced on the thermometer varies from one extremity of the spectrum to the other, that of the red being greatest, and so on diminishing in degree to the other extremity of the spectrum, though not in any regular ratio; so that the calorific rays, like the luminous, are separable by the prism into rays of different intensity. In these experiments it was observable, that the greatest heat was produced so far beyond the red as to be quite out of visible light. On the contrary, the disoxigenating effects of light appear to follow the opposite order. Thus the white muriat of silver is blackened most, just beyond the confines of the violet ray; and if previously a little blackened, according to Ritter, the whiteness is partly restored beyond the confine of the red ray: phosphorus too is kindled in the vicinity of the red ray, and extinguished in the vicinity of the violet. Guaiacum is rendered green in the red rays, and its yellow is restored in the violet; this Dr. Wollaston considers as a proof, that the effect of the invisible rays on the violet side is improperly termed disoxidating. Thus it appears, that the solar light consists of three different orders of rays, one producing colour, a second producing heat, and a third chemical effects the reverse of those occasioned by heat: and that the action of the last two differs in its intensity in proportion to the refraction it undergoes, but in an opposite order. Mr. Ritter is said to have separated the rays of the third order completely from those that produce colour.

Whence comes the light afforded by ignited bodies; whether it have been previously imbibed by them; whether the commencement of ignition be distinctive of the same temperature in all bodies; whether the great planetary sources of light be bodies in a state of combustion, or merely luminous upon principles very different from

y which our experiments can point out;
hether the momentum of the particles
light, or their disposition for chemical
ombination, be the most effectual in the
hanges produced by its agency;—these, and
umerous other interesting questions, must
e left for future research and investiga-
on.

The production of light by inflammation
an object of great importance to society
large, as well as to the chemist. It ap-
ears to arise immediately from the strong
nition of a body while rapidly decom-
osing. Most solid bodies in combustion
e kept, partly from a want of the access
air, and partly from the vicinity of con-
ucting bodies, at a low degree of ignition.
ut when vapours rapidly escape into the
r, it may, and does frequently happen,
at the combustion, instead of being car-
ed on merely at the surface of the mass,
enetrates to a considerable depth within,
nd from this, as well as from the imper-
ct conducting power of the surrounding
r, a white heat, or very strong ignition, is
roduced. The effect of lamps and can-
es depends upon these considerations. A
ombustible fluid, most commonly of the
ature of fat oil, is put in a situation to be
osorbed between the filaments of cotton,
nen, fine wire, or asbestos. The extremity
this fibrous substance, called the wick, is
en considerably heated. The oil evapo-
tes, and its vapour takes fire. In this si-
ation the wick, being enveloped with
ame, is kept at such a temperature, that
e oil continually boils, is evaporated,
urns, and by these means keeps up a con-
ant flame. Much of the perfection of
is experiment depends on the nature,
uantities, and figure of the materials made
e of. If the wick be too large, it will sup-
y a greater quantity of the fluid than can
e well decomposed. Its evaporation will
erefore diminish the temperature, and
onsequently the light, and afford a fuligi-
ous column, which will pass through the
entre of the flame, and fly off in the form
smoke. The magnitude of the wick may,
om time to time, in candles, be reduced, as
length, by snuffing; but this operation
ill not remedy the evils, which arise from
o great a diameter. If the oil be not suf-
ciently combustible, the ignition will be
ut moderate, and the flame yellow; and
e same effect will be produced, if the air
e not sufficiently pure and abundant. An
xperiment to this effect may be made by
cluding the flame of a small candle or
mp in a glass tube of about one inch in
ameter, standing on the surface of a ta-
e. The air which passes between the
ass and the table, will be sufficient to
aintain a very bright flame; but if a me-
llic covering, perforated with a hole of
oout a quarter of an inch diameter, be laid
oon the upper orifice of the tube, the com-
ustion will be so far impeded, that the
flame will be perceptibly yellower. The hole may then be more or less closed at pleasure by sliding a small piece of metal, for example a shilling, over it. The consequence will be, that the flame will become more and more yellow, will at length emit smoke, and if the hole be entirely closed, extinction will follow.

The smell arising from the volatile parts, which pass off not well consumed from a lamp or candle, must be different according to the nature of those parts. This depends chiefly on the oil, but in some measure upon the wick. When a candle with a cotton wick is blown out, the smell is considerably more offensive, than if the wick be of linen, or of rush; but less offensive than if the supply of the combustion had been oil. Whenever a candle or lamp is removed, the combustion is in some measure impeded by the stream of cold air, against which it strikes. Smoke is accordingly emitted from its anterior side, and the peculiar smell is perceived. From this imperfection, lamps are much less adapted to be carried from place to place than candles.

From the necessity of the access of air, there will be more light produced from a lamp with a number of small wicks, than with one large one, or from a number of small candles, than the same quantity of tallow used to make a single large one. In the lamp of Argand, the wick consists of a web of cloth in the form of a pipe or tube, the longitudinal fibres of which are thicker than the circular ones. This is passed by a suitable contrivance into a cylindrical cavity, which contains the oil; and there are other precautions in the construction of the apparatus, by which the oil is regularly supplied, the access of air is duly permitted, as well within as without the circle formed by the upper edge of this cylindrical wick, and this edge can be raised or lowered at pleasure. Hence the possessor has it in his power to regulate the surface of the wick, so that the greatest flame consistent with perfect combustion may be produced; and the steadiness of the flame is secured by a glass shade or tube, which surrounds it, and in a certain degree accelerates the current of air.

In the illumination by candles, where the fused matter is contained in a cup or cavity of the matter not yet fused, it is of some consequence, whether the substance be fusible at a high or low temperature. The difference between wax and tallow candles arises from this property. Wax being less fusible will admit of a thinner wick, and needs no snuffing; but in a tallow candle it is absolutely necessary to have a large wick, capable of taking up the tallow as it melts.

The difference of effect in illumination between a thick and a thin wick cannot be better shown, than by remarking the appearances produced by both. When a candle with a thick wick is first lighted, and the wick snuffed short, the flame is perfect and luminous, unless its diameter be very great; in which last case, there is an opake part in the middle, where the combustion is impeded for want of air. As the wick becomes longer, the space between its upper extremity and the apex of the flame is diminished; and consequently the oil, which issues from that extremity, having a less space of ignition to pass through, is less completely burned, and passes off partly in smoke. This evil continues to increase, until at length the upper extremity of the wick projects beyond the flame, and forms a support for an accumulation of soot, which is afforded by the imperfect combustion. A candle in this situation affords scarcely one tenth of the light, which the due combustion of its materials would produce; and tallow candles, on this account, require continual snuffing. But on the contrary, if we consider the wax-candle, we find, that as its wick lengthens, the light indeed becomes less, and the cup becomes filled with melted wax. The wick however, being thin and flexible, does not long occupy its place in the centre of the flame; neither does it, when there, enlarge the diameter of the flame, so as to prevent the access of air to its internal part. When its length is too great for the vertical position, it bends on one side; and its extremity, coming into contact with the air, is burned to ashes, excepting such a portion as is defended by the continual afflux of melted wax, which is volatilized and completely burned by the surrounding flame. We see therefore, that the difficult fusibility of wax renders it practicable to burn a large quantity of fluid by means of a small wick; and that this small wick, by turning on one side in consequence of its flexibility, performs the operation of snuffing upon itself, in a much more accurate manner than it can ever be performed mechanically. Mr. Walker has suggested an ingenious contrivance to effect this in tallow candles. It consists in placing the candle in such a position, as to be inclined in an angle of about 30° from the perpendicular; by which means the wick will come out at the side of the flame when it is long enough to require snuffing, and there burn to ashes. The light thus produced remaining nearly equable at all times, must be less injurious to the eye.

Mr. Henry made some experiments on the light afforded by the combustion of different gasses, and found, that it was apparently in the ratio of the oxigen that entered into combination with the hidrogen they contained. Thus 100 parts of pure hidrogen gas required from 50 to 54 of oxigen: 100 of gas from oak 42: from moist charcoal, and from dried peat, each 50: from lamp oil 136: from coal 140: from wax 166: pure olifiant gas 210. Tallow is nearly on a par with oil. The production of light from the first four was so trifling, that they did not appear applicable to economical purposes.—*Phil. Trans.*—*Journ. de Phys.*—*Journ. of the Roy. Ins.*—*Nick. Journ.*

Lime. See Earths; also Cement.

Linen Fossil. The fibrous amianthus. See Asbestos.

Linseed. See Oil.

Liquefaction. A chemical term not much used. In some instances it is synonymous with the word fusion, in others with the word deliquescence, and in others again with the word solution. It may easily be imagined, therefore, that accurate writers will use these terms respectively, because more definite.

Liquid Amber. A resinous juice, which flows from a large tree (Liquidambar styraciflua Lin.) growing in Virginia, Mexico, and other provinces in America. This juice is at first about the consistence of turpentine, but by long keeping hardens into a resin: it is of a yellow colour inclining to red, of a warm taste, and a fragrant smell, not unlike that of storax heightened with a little ambergris. It was formerly of great use as a perfume, but is at present a stranger to the shops.

Liquor of Flints. The preparation of this liquor consists in uniting, by fusion, powdered flints or sand with a sufficient quantity of fixed alkali, so that a compound results from it, in which the properties of the alkali prevail, and particularly a total solubility in water. For this purpose, one part of ground flints or sand is to be well mixed with three or four parts of fixed alkali. The mixture is to be put into a crucible, which ought to be very large, in proportion to the quantity of matter. The crucible is then to be placed in a forge or good melting furnace, and gradually heated. When this mixture has acquired a certain heat, a considerable boiling and swelling are observable, occasioned by the action of these two matters upon each other. To prevent the matter in this state from flowing over the crucible, this ought to be large, and the fire gradually raised. A part only of the mixture may be put into the crucible at once; and when its effervescence is over, the rest may be added at different times, taking care that each portion to be added be previously heated, to prevent explosion from any moisture which it might contain, when mixed with red-hot melted matter. When the effervescence of all the mixture is over, it is to be kept in a good fusion during a quarter of an hour, and is then to be poured upon a greased stone or plate of iron. The matter when cold is brittle, and seems vitrified. It is even transparent like glass, when the quantity of alkali is only double or nearly double the quantity of flints. It quickly and strongly attracts moisture from the air, and is entirely soluble in water, except a very small portion of earthy matter. But a similar earth is also separated from considerably pure fixed alkali, during its solution in water.

The filtrated solution is at first clear, and limpid; but it afterward becomes turbid, and forms an earthy sediment, like that formed by solutions of fixed alkali, only the former seems more copious. This liquor has all the properties of liquid fixed alkali. All these properties of alkaline salts, and particularly its total solubility in water, are caused by the quantity of fixed alkali which enters into this kind of vitrified matter. As compound bodies partake always of the properties of their component principles, and as the properties of the principle which predominates in the composition of any body do also predominate in that body, we may perceive why the properties of the fixed alkali in the present combination should be more sensible than those of the earthy matter, or flints. The alkali communicates to the earthy matter some of its strong disposition to unite with water. The flints are really kept dissolved in water, and by this experiment they are consequently reduced into a liquor, and hence it has been called the liquor of flints. If any acid be added to the liquor of flints, so as to saturate the alkali, the flint which was kept dissolved in water by means of this alkali will be now precipitated in the state of a fine earth. Macquer mentions a singular fact from Pott, that the earthy precipitate will be entirely taken up, if a redundancy of acid be added: but this is contrary to the results of experiment by Bergman, Klaproth, and other eminent chemists; though an inquiry into the cause that seems to have misled Pott, Baumé, and others, certainly deserves to be investigated. The liquor has been said to increase the quantity of gold precipitated by it from solution.

Glasses which contain too much alkaline salt in their composition, or which have not sustained a fire long or strong enough to unite the earth intimately with the fixed alkali, are partly soluble in acids, have sometimes even an alkaline taste, tarnish, and moisten in the air.

Liquor of Libavius. See Tin.

Liquorice. The saccharine extract from liquorice is prepared by strong decoction in water. It is prepared in the large way in Spain and some parts of Germany. That of our own growth is considered by some as superior. It is chiefly cultivated near Pontefract, in Yorkshire; and its extract is met with in the shops under the name of Pomfret cakes. The black colour arises from coal produced by the empyreuma toward the end of the process. Neumann found, that of one ounce of the Spanish extract water dissolved seven drachms two scruples, leaving a residue from which spirit extracted nothing. Alcohol, first applied, dissolved four drachms two scruples out of an ounce, which consisted of nearly the whole of the sugar; for though water took up three drachms of the remainder, it was nearly tasteless.

Lithanthrax. Pit coal, or stone coal: a black, solid, compact, brittle, inflammable substance, of a moderate hardness, laminated texture, more or less shining, but in few specimens capable of a good polish. See Coal.

Litharge. A subcarbonate of lead in an imperfect state of vitrification. When silver is refined by cupellation with lead, this latter metal, which is scorified, and causes the scorification of the imperfect metals alloyed with the silver, is transformed into a matter composed of small semitransparent shining plates, resembling mica; which is litharge. Litharge is more or less white or red, according to the metals with which the silver was alloyed. The white is called litharge of silver, and the red has been improperly called litharge of gold.

Litharge may be easily revided into lead; accordingly much of that which is produced by refining in the large way is reduced, by being melted upon burning coals. The part of it which is least altered by mixture with other metals is thus reduced, and by this method good and saleable lead is obtained. The rest of the litharge of these refineries is sold and used for various purposes. Potters use much of it for glazing their ware. It is employed for the preparation of some plasters, and other external remedies; and also in painting, to render linseed oil drying. Lastly, it is added in the composition of some glasses, for it is very fusible, and assists the fusion of other substances. It has in general the same properties as the other oxides of lead. All the litharge which is commonly sold comes from refineries. The quantity formed there is more than sufficient for the demand. See Lead.

Lithology. The systematical arrangement of stones.

Lithomarga. See Earth, (Fullers).

Litmus. See Archil.

Liver of Antimony. See Antimony.

Liver of Arsenic. See Arsenic.

Liver of Sulphur. See Sulphurets.

Liver Stone. See Lapis Hepaticus.

Lixivial. Those salts are called lixivial, which have been extracted by lixiviation, and these chiefly are fixed alkalis; which are therefore called lixivial salts.

Lixiviation. The application of water to the fixed residues of bodies, for the purpose of extracting the saline part.

Lixivium. A solution of residual salts, obtained by lixiviation.

Loadstone. An iron ore, the constitution of which has not yet been properly examined. It is of a dark or black lead colour, generally of considerable hardness, weight, and closeness of texture. It is supposed to contain much iron in the metallic state, or nearly so. It attracts iron or steel filings, by which criterion it is easily known.

Loam. A natural mixture of clay and sand. The coloured clays and loams participate of iron; hence many of these melt in a strong fire, without any addition: both clay itself, and mixtures of it with crystalline earths, being brought into fusion by ferruginous oxides, though the fusible mixtures of clay and calcareous earths are by the same ingredient prevented from melting. The bricks made from some loams, particularly the Windsor, are, when moderately burnt, remarkably free, so as to be easily rubbed smooth, cut, sawed, grooved, &c. Hence their use in building furnaces, &c. They bear a considerably strong fire, but have been frequently melted in a vehement one.

Lodestone. A name given by the Cornish miners to stones likewise called tinstone. They consist chiefly of stones or sand of different kinds, through which oxide of tin is invisibly disseminated. They are heavy, and of various colours, but blue, gray, black, and brown are the commonest.

Logwood. India, Jamaica*, or Campeachy wood has received those names from the places where it grows most plentifully. It is very common at Jamaica, and on the eastern shore of the bay of Campeachy; and is found also at St. Croix, Martinico, and Granada.

The tree is called by Linnæus Hæmatoxylum campechianum. It grows very high and large in a good soil: the bark is thin, smooth, and of a bright gray, or sometimes yellowish: the trunk is straight and prickly: the leaves somewhat resemble those of the bay-tree in appearance, and also in their aromatic qualities, whence the tree has been called aromatic bay, or Indian bay: its seeds have been improperly called clove seeds, from their flavour, and in England are known by the name of Jamaica pepper, or all-spice.

Logwood is so heavy as to sink in water, hard, compact, of a fine grain, capable of being polished, and scarcely susceptible of decay. Its predominant colour is red, tinged with orange, yellow, and black.

For use, its juice as it is commonly called may be extracted by decoction with water. It yields its colour both to spirituous and watery menstrua. Alcohol extracts it more readily and copiously than water. The colour of its dyes is a fine red, inclining a little to violet or purple, which is principally observable in its watery decoction. This, left to itself, becomes in time yellowish, and at length black. Acids turn it yellow: alkalis deepen its colour, and give it a purple or violet hue. Sulphuric, nitric, and muriatic acids produce in it a small quantity of a precipitate, which is some time in separating, and its colour, with the sulphuric acid, is a dark red; with the nitric, feuillemort; with the muriatic, a lighter red. The supernatant liquor is transparent, of a deep red colour with the sulphuric and muriatic acids, and yellowish with the nitric. The oxalic acid forms a light marron precipitate; the liquor remaining transparent, and of a yellowish red. The acetous acid acts nearly in the same manner, except that the colour of the precipitate is a little deeper. Tartar gives the same precipitate as vinegar, but the liquor remains turbid, and more inclined to yellow. Fixed alkali occasions no precipitate, but changes the decoction to a deep violet, which afterward becomes nearly brown. Alum produces a pretty copious precipitate, of a lightish violet colour; the liquor remaining violet, and nearly transparent. Alum and tartar occasion a dark red precipitate in tolerable quantity; the liquor remaining transparent, and of a yellowish red. Sulphat of iron gives it instantly a blueish black colour, like that of ink; a pretty copious precipitate of the same colour is produced, and the liquor remains turbid a long while; but if it be sufficiently diluted, and especially if there be a small excess of the sulphat, all the black matter is at length deposited. Sulphat of copper produces a very copious precipitate, of a browner and less bright black than the preceding: the liquor remains transparent, and of a very deep brownish or yellowish red. Sugar of lead instantly occasions a black precipitate, with a slight reddish tinge; the liquor remaining transparent, and of the colour of very pale beer. Lastly, tin dissolved in aqua regia forms immediately a precipitate of a very fine violet or purple, almost prune de Monsieur: the supernatant liquor is very clear, and perfectly colourless.

Stuffs would take only a slight and fading colour from decoction of logwood, if they were not previously prepared with alum and tartar. A little alum is added also to the bath. By these means they acquire a pretty good violet.

A blue colour may be obtained from logwood, by mixing verdegris with the bath, and dipping the cloth till it has acquired the proper shade.

The great consumption of logwood is for blacks, to which it gives a lustre and velvety cast, and for grays of certain shades. It is also of very extensive use for different compound colours, which it would be diffi-

---

* In England, the name of Jamaica wood is commonly applied to the better species of mahogany, the inferior kind being brought from Honduras.—*Hamilton.*

cult to obtain of equal beauty and variety, by means of drugs affording a more permanent dye.

Juice of logwood is frequently mixed with that of brasil, to render colours deeper; their proportion being varied according to the shade desired.

Logwood is used for dyeing silk violet. For this the silk must be scoured, alumed, and washed; because without aluming it would take only a reddish tinge, that would not stand wetting. To dye silk thus, it must be turned in a cold decoction of logwood, till it has acquired the proper colour: if the decoction were used hot, the colour would be in stripes and uneven.

Bergman has already observed, that a fine violet might be produced from logwood, by impregnating the silk with solution of tin. In fact, we may thus obtain, particularly by mixing logwood and brasil in various proportions, a great number of fine shades, more or less inclined to red, from lilac to violet.

If decoction of logwood be substituted for that of brasil in the process communicated by Mr. Brown, a fine violet colour will be obtained; and if the two be mixed, we shall have shades of puce colour, and prune de Monsieur, more or less inclining to red. See Brazil Wood.

The remarks made on brasil are also applicable to logwood, the colouring matter of which exhibits similar properties.—*Berthollet.*

Lorication. The same with Coating, which see.

Ludus Helmontii. An indurated marle, composed of various pieces of a whitish brown colour, separated into a great number of polygonous compartments, the boundaries of which are formed of matter of a lighter colour than the rest. According to Bomare, the ludus stellatus Helmontii, found in the county of Kent, is covered with a kind of striated selenite, resembling the zeolite. It is for the most part of a globose figure, seldom flat, but often convex on the outside. And sometimes with a concave surface.

Lumachella. A conglutinated, calcareous stone, composed of shells and coral, united together by a cement of the same nature. When they have many colours, they are called marbles, and employed as such. In the island of Gottland there is found one of this kind of one colour only, which on that account is not called marble.

Luna. The alchymist's term for silver.

Luna Cornea. Muriat of silver. See Silver.

Lunar Caustic. Nitrat of silver, fused in a low heat. See Silver.

Lute. In many chemical operations, the vessels must be covered with something to preserve them from the violence of the fire, from being broken or melted, and also to close exactly their joinings to each other, to retain the substances which they contain, when they are volatile and reduced to vapour. For this purpose several matters are employed, called in general lutes.

The lutes with which glass and earthen ware retorts are covered ought to be composed of nearly equal parts of coarse sand and refractory clay. These matters are to be well mixed with water, and a little hair, or cut tow, so as to form a liquid paste, with which the vessels are to be covered, layer upon layer, till it is of the required thickness. See Coating.

The sand mixed with the clay is necessary in this lute, to prevent the cracks which are occasioned by the contracting of clay during its drying, which it always does when it is pure. The hair serves also to bind the parts of the lute, and to keep it applied to the vessel: for, notwithstanding the sand which is introduced into it, some cracks are always formed, which would occasion pieces of it to fall off. This lute is applicable to the junctures of vessels requiring much heat, but it must be quite dry before they are used.

Mr. Willis has recommended as a coating for earthen retorts a solution of borax in 8 parts of boiling water brought to the thickness of cream with slaked lime; which when dry is to be covered with a thin paste of slaked lime and linseed oil.

The lutes with which the joinings of vessels are closed, are of different kinds, according to the nature of the operations to be made, and of the substances to be distilled in these vessels.

When vapours of watery liquors, and such as are not corrosive, are to be contained, it is sufficient to surround the joining of the receiver to the nose of the alembic, or of the retort, with slips of paper or of linen, covered with flower-paste. In such cases also slips of wet bladder are very conveniently used.

Almond powder, mixed with water or mucilage to the consistence of a stiff paste, makes a good lute.

When more penetrating and dissolving vapours are to be contained, a lute is to be employed of quick-lime slaked in the air, and beaten into a liquid paste with whites of eggs. This paste is to be spread upon linen slips, which are to be applied exactly to the joining of the vessels. This lute is very convenient, easily dries, becomes solid, and sufficiently firm. The whites of eggs with their yolks, and about half their weight of powdered chalk, or lime, thoroughly slaked in the air, applied in this manner, is sufficient, according to prof. Paysse for the oxigenized muriatic acid. Of this lute vessels may be formed hard enough to bear polishing on the wheel.

Gluten and lime make a strong lute.

Lastly, when saline, acid, and corrosive vapours are to be contained, we must then have recourse to the lute called fat lute.

This lute is made by forming into a paste some dried clay finely powdered, sifted through a silken searce, and moistened with water, and then by beating this paste well in a mortar with boiled linseed oil, that is, oil which has been rendered drying by litharge dissolved in it, and fit for the use of painters. This lute easily takes and retains the form given to it. It is generally rolled into cylinders of a convenient size. These are to be applied, by flattening them, to the joinings of the vessels, which ought to be perfectly dry, because the least moisture would prevent the lute from adhering. When the joinings are well closed with this fat lute, the whole is to be covered with slips of linen spread with lute of lime and whites of eggs. These slips are to be fastened with pack-thread. The second lute is necessary to keep on the fat lute, because this latter remains soft, and does not become solid enough to stick on alone.

Fine porcelain clay, mixed with a solution of borax, is well adapted to iron vessels, the part received into an aperture being smeared with it.

LYCOPODIUM. The fine dust of lycopodium, or clubmoss, is called by some, on account of its great inflammability, vegetable sulphur. The dust is properly the seeds of the plant. There are sundry other vegetables, as polypodies, ferns, coniferous trees, &c., the seeds of which are like a yellow, impalpable farina, so subtle as to be blown away by the least motion of air: it is this dust which has given rise to some reports of showers of brimstone.

The dust of lycopodium, diffused or strewed in the air, takes fire from a candle, and burns off like a flash of lightning. It is used in the London theatres. A quantity laid together upon burning coals does not flame, but smokes away with a fetid smell: burned in a red-hot crucible, it leaves a very small proportion of a light cobweb-like matter. It does not, as some report, take fire from flint and steel, nor explode like gunpowder; nor does it seem to detonate more violently with nitre than other inflammable matters do. Olearius relates, that the Russians employ much of it in fire-works, but does not inform us in what manner.

There is a curious experiment of taking a shilling from the bottom of a vessel of water without wetting the hand. It is said to be done by strewing a small quantity of the dust of lycopodium on the surface of the water, which it so strongly repels, as to form a covering for the hand, and defend it from the contact of the water. If a handkerchief be strewed over with this dust, water may be tied up in it.

Neumann examined this substance. It appears to contain a resinous matter, and an oily one of the expressible kind, intimately combined together, so as to be both extracted, at least in part, by alcohol: on inspissating the tincture, the oil separated, remained permanently fluid, and would not unite again even with the resinous extract: it is remarkable, that alcohol would no longer touch this resin any more than the oil. The quantity thus extracted from an ounce of the powder amounted only to a drachm: water did not take up near so much; it was with great difficulty he obtained by water eight grains of extract from an ounce. Both the water and spirit arose in distillation unchanged.

By destructive distillation in an open fire, he gained a large proportion of empyreumatic oil, no less than two ounces and a half from four: this was preceded, not by an acid liquor, which most vegetables yield on the same treatment, but by an alkaline one: the black coal remaining in the bottom of the distilling vessel weighed five drachms.

Some of the species of lycopodium are good dyes. Wool or silk boiled in a decoction of the l. complanatum, or l. clavatum, and then immersed in a weak infusion of brasil, acquires a good and very fast blue. All acids however redden it; but the colour is again restored by alkalis. By increasing the quantity of brasil the colour may be brought to a puce. The l. annotinum treated in the same way produces grays; as do the l. selago, and selaginoides, more or less inclining to blue or violet.

All the species appear to be good mordants. The bark of the young shoots of plumtrees affords by their means a fine carmelite, and that of the populus dilatata a permanent yellow. See also LICHEN.

M.

MACE, one of the exterior coverings of the nutmeg, is at first of a purplish red colour, which changes before it arrives among us to an orange yellow, and by long keeping grows paler and paler. Mace is a warm aromatic, like the nutmeg, accompanied with a degree of bitterishness; and like that spice also contains both an essential and expressible oil.

From sixteen ounces of mace, Neumann obtained with alcohol four ounces and a half of extract, which retained some of the expressible, and the more ponderous part of the essential oil, the lighter arising towards the end of the inspissation, and impregnating the distilled spirit: from the residuum were obtained two ounces and a half of gummy extract, with five drachms f essential oil, which arose during the In- pissation, and sunk to the bottom of the stilled water. Water applied first ex- acted four ounces and a half: the resi- uum gave with alcohol three ounces of an ly extract, eight ounces and a half re- aining undissolved. The watery extract as an unpleasant somewhat saline taste, hich that of nutmegs has nothing of. On xpression, mace yields au oil less consistent han that of nutmegs, which is usually sold r it. The genuine is commonly brought rom the East Indies in glass or porcelain essels.

Maceration. The steeping of a body a cold liquor. It does not differ from Di- **estion**, excepting that the term is never sed when the temperature of the mass is aised beyond that of the surrounding air. is obvious, that maceration, or digestion ithout heat, must be used in all requisite ases wherein the fugitive nature of some of he component parts of the subject of exa- nination, or its disposition to become hanged by heat, renders the process of di- estion, assisted by heat, unfavourable to he intended analysis.

Madder, a substance very extensively mployed in dyeing, is the root of the rubia inctorum.

Although madder will grow both in a tiff clayey soil, and in sand, it succeeds etter in a moderately rich, soft, and some- vhat sandy soil: it is cultivated in many of he provinces of France, in Alsace, Nor- nandy, and Provence: the best of Euro- ean growth is that which comes from Zealand.

There are various methods of cultivating nd preparing madder, and many treatises ave been written on the subject: that of Mr. Duhamel may be consulted, but more articularly that of Mr. le Pileur d'Apli- gny, published at the end of his Art of Dyeing Threads and Cotton Stuffs.

The madder prepared for dyeing is di- tinguished into different sorts: that obtain- ed from the principal roots is called crop madder; the non crop is that which is produced from the stalks, which by being ouried in the earth are transformed into roots, and are called layers: each of these kinds is sub-divided into fine, bale, bunch, and short, or mull.

When the madder roots are gathered, he layers are separated from them, to form he non crop; and such of the fibres of the roots as do not exceed a certain degree of hickness are added, as are also those roots which are too thick, and which contain a great deal of heart or ligneous part: the best roots are about the thickness of a goose quill, or at most of the little finger; they are semi-transparent, and of a reddish colour; they have a strong smell, and the bark is smooth.

When the madder is gathered and picked, it must be dried, in order to render it fit for grinding and being preserved: in warm climates it is dried in the open air; in Holland, by means of stoves, which sometimes communicate too great a degree of heat, and change its colour by an admixture of fuliginous particles. Hellot ascribes the superiority of the madder which comes from the Levant to the circumstance of its having been dried in the open air.

After the root has been dried, it must be shaken in a sack, or lightly beaten on a wooden hurdle, after which it must be sifted or winnowed. In this way the earth is separated from it, and the billon is removed, a name by which the small roots and their bark are distinguished. After this, nothing remains but to reduce it to powder, which may be done by a vertical millstone, or by pestles, or even by a common snuff-mill.

All the parts of the madder cannot be powdered with equal facility; the outer bark and ligneous parts are more easily pounded than the parenchymatous parts. Advantage is taken of this circumstance in order to separate those parts, as they do not all give the same colour; the outer bark, as well as the wood within, affords a yellowish colour, which spoils the red we wish to obtain. This separation established the distinction of madder into robée, mirobée, and courte. After the first operation of the mill, the madder is passed through a sieve, with a cover fitted to it, by which means what is called the short madder, which is intended for tan and modoré colours, is obtained; the remainder is again ground and sifted, and thus the mi-robée is obtained; and a third operation affords the robée. The madder thus powdered is to be preserved in a dry place, well packed in casks, where from its natural unctuosity it concretes into lumps.

Mr. Beckmann agrees with Mr. Hellot in opinion, that the heat of stoves injures the colour of madder, and that it would be better to dry it in the air only, the effect of which might be promoted by various means. He finds that common ovens, immediately after the bread is taken out, may be used instead of the Dutch stoves, when artificial heat is to be employed. Mr. d'Ambourney has made some interesting experiments upon madder; he thinks, that the fresh root may be used in dyeing with as much advantage as the powdered. He observed that four pounds of the fresh are equal to one of the dried, although in the drying seven-eighths of its weight are lost; the expense of stoving, packing, and sifting is saved; and it is only necessary to take care, that the roots be thoroughly washed in a current of water as soon as they are taken out of the ground; they are afterward cut into pieces, and bruised by the vertical mill. In dyeing with the fresh roots, on account of the quantity of water they contain, we must take care not to put too much water into the bath. Mr. Beckmann subscribes to Mr. d'Ambourney's opinion, though he has constantly made one observation, which seems to contradict it, that madder is more fit for dyeing, after having been preserved for two or three years, than when fresh.

In the neighbourhood of Smyrna, and in the island of Cyprus, a kind of madder is cultivated, which affords a more lively red than that raised in Europe; on which account it is employed in the preparation of the Adrianople red. In the countries where it grows it is called chioeborza, and hazala, but it is commonly known by the name lizari. It is now cultivated in Provence, and Mr. Beckmann has raised it with great success at Gottingen.

The red colouring matter of madder may be dissolved in alcohol, and on evaporation, a residuum of a deep red is left. Fixed alkali forms in this solution a violet, the sulphuric acid a fawn-coloured, and the sulphat of potash a fine red precipitate. Precipitates of various shades may be obtained by alum, nitre, chalk, sugar of lead, and the muriat of tin,

When madder is macerated in several portions of cold water successively, the last receives only a fawn colour, which appears entirely different from the peculiar colouring particles of this substance, and resembles that which is extracted from woods and other roots: this fawn-coloured substance does not perhaps belong to the pulp, but is peculiar to the ligneous and cortical parts.

After Berthollet had by repeated boiling exhausted the madder of such colouring parts as are soluble in water, it still retained a deep colour, and alkali extracted from it much colouring substance: the residuum which still remained coloured was very inconsiderable; so that the pulp appears to be entirely composed of colouring matter, a large part of which is not soluble in simple water.

Oxigenized muriatic acid, employed in sufficient quantity to change an infusion of madder from a red to a yellow colour, produces a small quantity of a very pale yellow precipitate; and the supernatant liquor is transparent, retaining a greenish yellow colour, more or less deep according to the quantity and strength of the oxigenized muriatic acid.

The quantity of this liquor required to destroy the colour of a decoction of madder, is double what is necessary to destroy that of a decoction of an equal weight of brasil wood; which proves, that the colouring particles of madder are much better calculated to resist the influence of the air, than those of brasil wood. They would be easily changed, however, if not rendered fixed by mordants. On this subject, Berthollet relates some experiments made by the celebrated Mr. Watt upon the best Zealand madder, and communicated to him.

A. This madder is of a brownish orange colour, and of the consistence of a coarse powder, possessing a slight degree of cohesion; it attracts moisture, in which case it loses its properties, so as to become unfit for the purposes of dyeing.

B. With water it affords an infusion of a brownish orange colour; its colour cannot be extracted without a copious addition of water. Margraff directs three quarts of water for two ounces of madder. Its colouring particles may be extracted either by hot or cold water; to the latter it appears to give a more beautiful colour; its decoction is brownish.

C. When an infusion or decoction of this drug is slowly evaporated in an open vessel, a pellicle is formed on the surface, which gradually falls to the bottom; after which fresh pellicles are successively formed until the evaporation is finished.

D. The extract thus prepared is of a dark brown; it partly dissolves in water, to which it communicates a lightish brown colour.

E. The infusion set to digest for some days in an open vessel, which should be of such a height that the liquor reduced to the form of vapour may fall back again, deposits dark brown pellicles. The liquor remains of a brownish colour, and the pellicles are soluble in water, but with difficulty.

F. Alum forms in the infusion B, a deep brownish red precipitate, composed of pellicles, and the supernatant liquor is of a yellow colour inclining to brown.

G. Fixed alkalis precipitate from this last liquor a lake of a blood red colour, which has greater or less intensity, according to the quantity of alum that has been dissolved in it. In this way, a blood red lake may be obtained; but we cannot, by any means hitherto known, give it the brightness of cochineal lake: in oil it is transparent, but in water it is opake and without beauty.—See LAKE.

H. If a superabundant quantity of alkali be employed, the precipitate is redissolved, and the liquor becomes red.

I. The lake precipitated by potash is of a more beautiful colour than that by soda.

K. Calcareous earth precipitates a more dark and brown coloured lake than alkalis, particularly if it form lime water.

L. If a few drops of alkali be added to the water employed in making the infusion B, the infusion extracts many colouring particles of a deep red bordering on brown. 1st. Alum precipitates a deep brown lake from this infusion 2dly. Acids added in small quantity change it to a yellowish colour, and in greater quantity render it a brown yellow, but they precipitate nothing from it. 3dly. This infusion evaporated to dryness forms a gummy extract, which easily dissolves in water.

M. If the infusion B be made with water very slightly acidulated with a mineral acid, it is yellowish. 1st. This liquor by long digestion becomes of a greenish brown, and the yellow appears to be destroyed. 2dly. The addition of an alkali restores the red colour; and the infusion then affords, on evaporation, an extract, which readily dissolves in water.

N. If carbonat of magnesia be added to the water used for the infusion B, the infusion is of a clear blood red, and on evaporation forms a blood red extract, which readily dissolves in water. 1st. A solution of this extract, which is employed as a red ink, when exposed to the light of the sun becomes yellow. 2dly. Alum precipitates from this infusion a small quantity of an ill-coloured lake. 3dly. Alkalis give it a redder and more fixed colour.

O. If the infusion be made with a solution of alum, it is of an orange yellow. This infusion precipitated by an alkali affords a lake resembling that of F, but its colour is not so good.

P. A solution of sugar of lead added to the infusion B forms a brownish red precipitate. 1st. A solution of mercury in the nitric acid, gives a purple brown precipitate. 2dly. A solution of sulphat of iron, a fine bright brown precipitate. 3dly. A solution of sulphat of zinc has not been tried. 4thly. A solution of sulphat of manganese, a purple brown precipitate. 5thly. A solution of iron in aqua regia has not been tried.

Q. The infusion B being mixed while hot with the infusion of cochineal, a brownish red precipitate, bordering on a deep purple, was formed, of difficult solubility in water; by continuing the digestion, a greater quantity of this precipitate appeared. 1st. A pattern soaked in the preparation which the linen-printers use, having been dyed in this mixture, took a brownish red colour; and after having been boiled in a solution of soap, the colour appeared pretty good. 2dly. The solution of soap became very red, but communicated a very indifferent colour to paper.

Wool would receive from madder, as has been already stated, only a perishable colour, if its colouring particles were not fixed by a base, which occasions them to combine with the stuff more intimately, and which in some measure defends them from the destructive influence of the air. For this purpose, the woollen stuffs are first boiled for two or three hours with alum and tartar, after which they are left to drain; they are then slightly wrung and put into a linen bag, and carried into a cool place, where they are suffered to remain for some days.

The quantities of alum and tartar, as well as their proportions, vary much in different manufactories. Hellot recommends five ounces of alum and one ounce of tartar to each pound of wool; if the proportion of tartar be increased to a certain degree, instead of a red, a deep and durable cinnamon colour is produced, because, as we have seen, acids have a tendency to give a yellow tinge to the colouring particles of madder. Mr. Poerner somewhat diminishes the proportion of tartar: he directs, that it should be only one seventh of the alum. Schaeffer, on the contrary, directs, that the quantity of tartar should be double that of the alum; but Berthollet found, that, by employing one half tartar, the colour sensibly bordered more on the cinnamon, than when the proportion was only one fourth of the alum.

In dyeing with madder, the bath must not be permitted to boil, because that degree of heat would dissolve the fawn-coloured particles, which are less soluble than the red, and the colour would be different from that which we wish to obtain.

When the water is at a degree of heat which the hand can bear, Hellot directs us to throw in half a pound of the best crop madder for each pound of wool to be dyed, and to stir it well before the wool is put in, which must remain for an hour without boiling; but in order to be more certain of the dye, it may be boiled for four or five minutes toward the end of the operation. Mr. Beckmann advises the addition of a little alkali to the madder bath; Berthollet approves this plan in the dyeing of thread and cottons.

By this process reds are obtained, which are never so beautiful as those produced even by kermes, much less those from lake and cochineal; but as they cost but little, they are used for common low-priced stuffs. The madder reds are sometimes rosed with archil and brasil wood, in order to render them more beautiful and more velvety; but the brightness given them in this way is not lasting.

The quantity of madder which Mr. Poerner employs is only one third of the weight of the wool, and Schaeffer advises only one fourth. Mr. Poerner says, that having added to the alum and tartar a quantity of solution of tin of equal weight with the tartar, and, after two hours boiling, having let the cloth remain in the bath that had been left to cool for three or four days, he dyed it in the usual way, and obtained a pleasing red. He describes another process, in which, after having prepared the cloth by the common boiling, he dyed it in a bath but slightly heated with a larger quantity of madder, tartar, and solution of tin; he let the cloth remain twenty-four hours in the bath, and after it had become cold, he put it into another bath made with madder only, and there left it for twenty-four hours: in this way he obtained a pleasing red, somewhat clearer than the common red, and bordering a little on a yellow. According to Schaeffer, by boiling wool with a solution of tin, the quantity of which he does not mention, with one fourth of alum, and by dyeing with one fourth of madder, an orange red is obtained.

Bergman says, that if, without boiling the wool, it be dyed with one part of a solution of tin, and two parts of madder, it acquires a cherry colour, which when exposed to the air acquires a deeper tinge.

If wool be boiled for two hours with one fourth of sulphat of iron, then washed, and afterward put into cold water with one fourth of madder, and then boiled for an hour, a coffee colour is produced. Bergmann adds, that, if the wool have not been soaked, and if it be dyed with one part of sulphat of iron and two of madder, the brown obtained borders upon a red.

According to these chemists, by employing sulphat of copper as a mordant, we obtain from madder a clear brown bordering on yellow. A colour of the same kind will be produced, by dyeing the wool simply soaked in hot water, with one part of sulphat of copper and two of madder: if equal parts of these two substances be used, the yellow will be somewhat more obscure, bordering on a green; in both these cases, the colour does not become darker by exposure to the air.

Berthollet employed a solution of tin in various ways, both in the preparation and in the maddering of cloth. He used different solutions of tin, and found that the tint was always more yellow or fawn-coloured, though sometimes brighter than that obtained by the common process.

Madder does not afford a colour sufficiently bright for dyeing silk; but de la Folie has given us a process for employing it for this purpose.

Half a pound of alum is to be dissolved in each quart of hot water, to which two ounces of potash are to be added: after the effervescence has ceased, and the liquor has begun to grow clear, the silk must be soaked in it for two hours; it is then to be washed, and put into a madder bath. Silk dyed in this way becomes more beautiful by the soap proof. Schaeffer gives us a somewhat different process; the silk is to be alumed in a solution of four ounces of alum with six drachms of chalk for each pound of scoured silk; when a sediment is formed, the solution is to be decanted; and after having become quite cold, the silk is to be put into it, and to be left eighteen hours: it is then to be taken out and dried, after which it is to be dyed with an equal weight of madder, when it takes a pretty good, but rather dark red. Mr. Guhliche also describes a process for dyeing silk with madder: for one pound of silk he orders a bath of four ounces of alum, and one ounce of a solution of tin; the liquor is to be left to settle, when it is to be decanted, and the silk carefully soaked in it, and left for twelve hours; and after this preparation, it is to be immersed in a bath containing half a pound of madder softened by boiling with an infusion of galls in white wine; this bath is to be kept moderately hot for an hour, after which it is to be made to boil for two minutes. When taken from the bath, the silk is to be washed in a stream of water, and dried in the sun. Mr. Guhliche compares the colour thus obtained, which is very permanent, to the Turkey red. If the galls be left out, the colour is clearer. A great degree of brightness may be communicated to the first of these, by afterward passing it through a bath of brasil wood, to which one ounce of solution of tin has been added: the colour thus obtained, he says, is very beautiful and durable.

Madder is used for dyeing linen and cotton red, and even for giving them many other colours by means of different admixtures; it is the most useful of all the colouring substances employed in this kind of dyeing. It is proper to enter into a somewhat minute detail of the different means by which this kind of dye may be rendered more certain, more beautiful and varied. Thread does not so easily take a colour from madder as cotton, but the processes which succeed best for the one are likewise preferable for the other.

The madder red of cotton is distinguished into two kinds: one is called simple madder red; the other, which is much brighter, is called Turkey or Adrianople red, because it comes from the Levant, and has seldom been equalled in brightness or durability by our artists.

Madder reds likewise differ very much in brightness and permanency according to the processes employed. We are indebted to Mr. Vogler for some very interesting experiments on this subject. He first considers the mordants, and afterwards the preparation of the madder bath.

The first mordant he tried, consisted of a solution of three drachms of Roman alum in fourteen ounces of water. Thread and cottons boiled for some minutes in this solution, and afterward passed through the different madder baths, which will be hereafter described, took a slight poppy-coloured red. Our author observed in this, and many other experiments, that Roman alum was much better than common alum, and gave greater brightness to the colours. He always used yellowish thread and cotton, which he first leyed, then washed and dried.

The above proportion of alum appeared to him the best; yet, though he repeated the aluming three times, he was not able to give the thread and cotton a good colour. The addition of the smallest quantity of any kind of acid rendered it paler; the addition of arsenic produced no effect; sheep- and cow-dung, and album grecum, added to the mordant, as also urine employed instead of water to dissolve the alum, contributed somewhat, but not much, to strengthen the colour. Common salt and sal ammoniac had more effect, but these salts rendered the colour more dull; lime-water acted very much in the same way. The substances which had the best effect were gum arabic, starch, fenugreek seed, and, above all, glue. The author says he has attempted to impregnate thread and cotton with fish-oil, hogs' lard, and olive oil, but without success. The gastric juice and the serous part of the blood of animals act like the glue.

The thread and cotton may be soaked alternately in a solution of glue and a solution of alum, or the glue may be dissolved with the alum, in the proportion of from one drachm and a half to four drachms, with the quantity of alum directed: It is necessary to choose fine glue. This substance used with alum produces a more saturated colour, but without alum the red is dusky.

The muriat and nitrat of alumine not only produce a more intense and durable red than the sulphat, but the tint is pleasanter, more especially when the nitrat is employed. In general, muriats render the colour darker, more saturated, and more durable. Corrosive muriat of mercury produces the same effect.

Having dissolved in a strong lie of potash as much powdered white arsenic as it would take up with the assistance of heat, and mixed this solution, which had been diluted with two parts of water, with a saturated solution of alum, the mixture became turbid, and of the consistence of jelly; it recovered its transparency on adding gradually a solution of alum.

Thread and cotton soaked for twelve hours in this mordant, when washed and dried, received from madder a beautiful well saturated colour. Thread and cotton, which had been for six hours in aqua regia, and afterward washed and dried, took from madder a more beautiful and durable colour than that which dyers obtain from annotta; some bad madder, by means of this mordant, afforded a yellowish brown, of an agreeable shade.

This colour may be changed into a poppy coloured red, which may be compared with the most beautiful colours of this hue, obtained from brasil wood and cochineal, by first soaking the stuff in a solution of alum and common salt, and boiling it a second time with madder.

Mr. Vogler macerated for a night three drachms of potash with an equal quantity of common madder in a pound of water; he then applied a boiling heat, and put into it some thread and some cotton, and after half a quarter of an hour's boiling, he took it out, rinsed and dried it, then soaked it in a solution of alum and common salt, after which he passed it through a solution of glue, and at last dipped it in a madder bath: it took a fine full red.

If to the preparation of madder and potash annotta be added, the thread and cotton take in this bath a beautiful orange colour: it is thus that the dyers in many places prepare that colour, but it is not so durable as that above described.

If instead of potash Roman alum be employed, a colour is obtained which is at first weak, though more lively than the potash, and on going on with the process a fine full red is obtained.

By giving a weak madder colour to thread and cotton that have been alumed, by afterward soaking them in a solution of alum and salt, impregnating them with glue, and dyeing them a second time in the madder bath, they take a beautiful very lively red.

The red of thread and cotton coloured by two madderings was very much weakened by the nitric, sulphuric, and muriatic acids diluted with two parts of water, and became more or less pale and yellow. The action of the nitric acid was the most powerful, and that of the muriatic the weakest; this last turned the colour brown. The vegetable acids have a much weaker action; a solution of alum powerfully dissolved the colour, rendered it clearer, and at the same time brighter; potash and lime-water have the property of extracting much of its colour, and changing it to a deep red.

Galls dispose thread and cotton to receive the madder colour. Mr. Vogler's preparation for galling consisted of five drachms of black galls, kept for twenty-four hours in a pound of water, which was then boiled for ten minutes, and sometimes he added six drachms of common salt. The galled thread and cotton, after having received the mordants of alum and salt, took with the madder a perfectly saturated colour, but which was of a dark red. Thread and cotton successively impregnated with a solution of tin and glue, steeped in an infusion of cochineal and galls, washed and dried, and afterward impregnated with the alum and salt mordant, and last of all dyed in a madder bath, received an uncommonly beautiful colour, which was very bright and considerably durable. The mordant of alum and corrosive muriat of mercury, and that of alum and salt, gave a somewhat deeper colour.

Mr. Vogler was equally successful, when instead of galls he used several other vegetable astringents, such as the ground bark of the alder and oak, the powdered bark of walnut-tree root, flowers and bark of pomegranate, the leaves, bark, and tops of the sumach. He made many experiments with metallic and earthy salts, all of which, except the aluminous and the solution of tin, appeared to him to be but little adapted, or entirely hurtful in the dyeing of red: the principal results were as follow:

The solution of nitrat of lead, employed as a mordant, produced a very loaded dirty red inclining to brown. In general, solutions of lead, used as mordants for thread and cotton, dispose them abundantly to receive colours from all vegetable colouring substances, but they have always a dark and dirty appearance These mordants may be employed for brown or black colours; the bad brown just mentioned, for instance, will change to a perfect brown of a very beautiful shade, if passed through a mordant of alum and salt, and boiled a second time with madder. Mr. Vogler obtained a very fine black, by galling thread and cotton impregnated with salt of lead, and then putting them into a solution of sulphat of copper, and boiling them in a bath of logwood.

Cobalt dissolved in aqua regia produced a very pleasant colour nearly resembling a very saturated violet. A solution of sulphat of copper gave a bad lilac. Verdegris dissolved in vinegar produced the same effect.

The nitrat of copper produced a much more beautiful and saturated colour,

Thread and cotton, that have received the mordant of sulphat of copper or iron, take in the madder bath a dirty dull violet colour.

Mr. Vogler having added the alkaline solution of arsenic above mentioned to a moderately saturated solution of sulphat of copper or iron, produced a turbid mixture, which effervesced; and he rendered it transparent by adding sulphat of iron. Thread and cotton impregnated with this preparation received a beautiful saturated puce colour, which penetrated them deeply.

The nitrat and muriat of iron produced a better effect than the sulphat and acetat of the same metal. They afforded a beautiful well-saturated violet colour. The alkaline solution of arsenic mixed with earthy and metallic salts generally renders them better mordants for all colours. This likewise renders the effect of the mordants into which it enters more lasting; so that the stuff impregnated with it many years before may be dyed without disadvantage; a circumstance we do not remark respecting any other mordant, excepting a solution of tin. Sulphat of zinc afforded a weaker violet than sulphat of copper. Sulphat and nitrat of lime produced no effect. Sulphat of manganese discovered some though but little action. Mr. Vogler remarks, that it is always necessary to rinse the cotton and thread when they come out of a mordant; if this precaution be neglected, a weak colour only is frequently obtained, where a strong one was expected; because the particles of the mordant, dispersing through the bath, combine with the colouring particles, and are precipitated with them: this precaution is especially necessary, when we dye with substances which do not contain much colouring matter.

Mr. Vogler prepares the madder-bath in different ways. He put three drachms of madder into sixteen or eighteen ounces of water; he macerated it for twenty-four hours, then boiled it for a quarter of an hour, introduced the thread and cotton, and boiled them for half a quarter of an hour; he afterward washed them in two or three waters, and then dried them in the shade: he remarks, that the colour of the stuff is taken away and destroyed by long boiling.

Fresh urine substituted for water affords more lasting colours; but in summer it is apt to become very soon putrid, so as to render the infusion incapable of giving the dye.

One drachm of sheep's dung, or of album grecum, produced the same effect as the urine.

Three drachms of common salt, or one drachm of sal ammoniac, produced a fuller but less bright colour. Sulphat and nitrat of potash had no effect.

Three drachms of white sugar afforded a more beautiful and saturated colour; on the addition of four drachms of long pepper, it was found to have become more capable of resisting the nitric acid.

One drachm or one and a half of starch or gum arabic thrown into the bath just as it begins to boil, and before the cotton is put in, gives a finer and more saturated colour; one drachm of fenugreek seed produced very nearly the same effect.

If in the beginning of the digestion four drachms of Spanish pepper be added, we obtain from the liquor colours that are more durable than the preceding, especially if we afterward add three drachms of common salt.

From one ounce to one ounce and a half of glue, in the state of jelly, thrown into the liquor as the ebullition commences, affords a particularly beautiful full colour; and the addition of three drachms of common salt not only renders the colour more lasting, but preserves the infusion from becoming putrid.

The most beautiful colour of all, however, is obtained by mixing four drachms of oxgall with the decoction; but at the same time it must be observed, that this colour is more easily destroyed by the nitric acid than any other.

All the madder baths, except those prepared with urine, glue, and animal dung, may be preserved for a long time without losing their power. Mr. Vogler kept some till they became mouldy and fetid, and yet they dyed very well; nay, he observes, that they produced more durable colours, or, at least, colours which resisted the action of the nitric acid more powerfully.

On putting from thirty-six to forty grains of crystals of tartar into the bath just as the linen was thrown in, the colour produced was found capable of resisting the nitric acid. The sulphuric, nitric, and muriatic acids, in very small quantity, produced the same effect; in too large a quantity, they weakened the colour and rendered it pale. One drachm and a half of powdered alum made the colour finer, but not more durable; twenty-four drachms of corrosive muriat of mercury rendered it more obscure, but more permanent. White arsenic employed in different proportions never occasioned the least change, though dyers frequently use it as well as orpiment, with a view of making the colour more durable.

In Mr. Vogler's experiments, cotton always took the colour better than thread; the difference, however, was not very great, when he employed linen or hempen cloth that had been a little worn, and that had become soft to the touch, and when its texture was loose and the thread slightly twisted.

The red in printed stuffs is likewise produced by madder, but it must be fixed by a mordant. Mr. Wilson describes that which is used for this purpose, as follows: In four pounds of hot water (some employ lime water), three pounds of powdered alum, and one pound of sugar of lead, are to be dissolved; this solution is put into a vessel sufficiently large to allow of the effervescence which takes place, and two ounces of powdered chalk, two ounces of potash, and two ounces of corrosive muriat of mercury, are to be added. This mixture must be well stirred, and suffered to settle; the clear liquor must then be decanted, or, which is better, filtered.

With this liquor, coloured with the decoction of brasil wood, and thickened with gum, they print, and pass the stuff through hot water in which cows' dung has been diffused, in order to take away the starch or gum used to give consistence to the mordant; they then carefully wash it, and put it into a madder bath. All the stuff becomes coloured; but that which has not been fixed by the mordant is destroyed, by alternately boiling with bran, and exposure on the grass.

Mr. Oberkamf uses the same ingredients for the mordant, except that he does not put into it any muriat of mercury. We have seen by Mr. Vogler's experiments, that this metallic salt rendered the colour of the madder more durable, and at the same time deeper.

The reader may here recollect, that alum is decomposed by sugar of lead, and that there results from the decomposition an acetit of alumine, while the lead combined with the sulphuric acid forms an insoluble salt, which remains in the sediment. The alkali and the chalk serve to take up the superabundant acid, which would weaken the colour of the madder, and give it a yellow tinge.

Mr. Wilson directs the use of this mordant, which is known by the name of printers' mordant, and which is the same which Mr. Watt refers to in the experiments above mentioned, relative to the dyeing cotton red: according to his process, it must be galled, dried, impregnated with the mordant, diluted with hot water, dried a second time, maddered, washed, and dried again.
