The essential difference between the cyclone and the anticyclone is the fact that the latter is usually conterminous with a single air mass. One important characteristic of the anticyclone, found in classifying the air masses according to their source regions, is the homogenizing influence of the quasi-permanent subtropical anticyclones upon the migratory cold anticyclones, which are absorbed into these warm subtropical highs. The success of weather prognosis depends, to a large extent, upon the somewhat orderly behavior of the cyclone. The maximum extent of time in which detailed weather prognosis is possible is determined partly by the time of evolution of the cyclone. The weather immediately associated with the anticyclone is not so hazardous as the cyclonic weather; and, partly for this reason, anticyclones are not known so well as cyclones. Anticyclones with divergent motion are nevertheless primarily instrumental in the transformation of the solar radiative energy received by the atmosphere into the kinetic energy of its motion relative to the earth. They are sources, then, for the conversion of geopotential energy or internal heat energy into horizontal kinetic energy [75]. From them the processes of advection and work by pressure forces are continually and rapidly transferring this kinetic energy to cyclonic areas, that is, to the centers of major weather activity.

Local Modifications of Air Currents, Air Masses, and Fronts. Whenever possible, the forecaster should apply the foregoing models while working out the prognostic maps. Sometimes, however, their application must be introduced between the preparation of the prognostic map and the formulation of the forecast. This introduction may be particularly necessary because of important (thermal and orographic) local modifications to the idealized, normal evolution of the lower-tropospheric models. These disturbances are particularly important to the area forecaster; but they often operate on a scale so large that, if ignored by the regional forecaster, they would introduce grave errors into the general forecast.

When an air mass moves over a colder (warmer) surface, its stability (instability) is increased. An air mass becomes stable in winter (unstable in summer) by motion from sea to land; for motion from land to sea the reverse is true. The stability is increased (decreased) for an air mass moving poleward (equatorward) over an isothermal portion of the surface of the earth. The air-mass stability (instability) of a stationary continental anticyclone increases from day to day in fall and winter (spring and summer). Especially near the ground, the properties of warm and cold air masses show a marked diurnal variation, because they depend mainly on the vertical lapse rate of temperature. At night (in the afternoon), a warm (cold) air mass will have all its properties accentuated and a cold (warm) air mass will, in the lowest layer, temporarily acquire the properties of a warm (cold) air mass: uniform wind, poor visibility, stratiform clouds, even drizzle occasionally in the case of a warm air mass; gusty wind, improved visibility, cumuliform clouds and showers in the case of a cold air mass. Over sea the effects will be the opposite, although much less marked.

Moreover, periodic wind systems are often created owing to differences in the diurnal temperature variation over land and sea, and over mountain and plain these wind systems may become both intensive and extensive enough to influence even the general forecast. The more stable a moving air mass, the more it tends to converge horizontally about an obstacle such as an elevated part of a continent bordering a plain or a lowland bordering the sea. To the low-pressure side of a stable warm air-mass current, the forecaster should thus predict an extraordinary intensification of the wind at the "corner" of the obstacle—the *corner effect*—and of the "coastal" convergence and precipitation at

the windward coast. Orographic showers or rain may thus be superimposed upon the idealized precipitation areas of the models. Leeward of the mountain range, on the other hand, the foehn effect may lead to a dissolution of the idealized precipitation and cloud areas of the models. Mountain chains in general obstruct the rapid motion of all fronts; the hindrance is greater the higher the obstruction and the less the vertical extent of the front itself. But a swiftly moving cold front will flow over a low obstruction without especial deformation.

Frontolysis, Cyclolysis, and Anticyclolysis. When the cold air lies to the right of the general flow, frontolysis occurs in the lower portion of the front. A front which is traveling normal to the general flow aloft is very subject to frontolysis. A front dissipates as it departs from a deep pressure trough.

As a consequence of the convective mixing of the two air masses below and above a frontal surface, the thermodynamic effect generally will tend to smooth and delete any weak fronts rather than to create new ones. A *medium-* or *high-speed cold front* (mostly found in the interior of an already existing cyclone) will generally be a katafront in the upper layers (see Fig. 2). It will then be subject to frontolysis, tending to make the frontal surface diffuse and thus dynamically ineffective (even if the effect of friction upon the motion tends to increase its slope and thereby presumably the horizontal shear). A *medium-* or *high-speed warm front* is generally an anafront, but the friction will tend to diminish its slope markedly, at least in the lowest kilometer of the atmosphere and thus, according to synoptic experience, also reduce the horizontal shear.

After occlusion, the deepening of the cyclone ceases and its filling commences, provided that a false warm sector does not occur. The existing pressure gradient weakens and the cyclone fills more or less rapidly when it possesses supergeostrophic, divergent flow (Hesselberg [40] and Guilbert [36]). In particular a cyclone with marked supergeostrophic wind on its forward side fills during the following 12–24 hr. With weak upper flow around its periphery, a cyclone will fill. If an upper low reaches to the surface without especial tilting of the axis, the surface low sometimes fills.

A young anticyclone weakens when approached by a cold front, particularly with weak upper flow around its periphery. The degeneration of the stable anticyclone, unfortunately, can seldom be anticipated in advance. This fact is especially regrettable, for seldom is a reliable forecast more insistently demanded than during the prolonged periods of abnormal weather due to the blocking action of the mature anticyclone. The anticyclolysis and the movement of such an anticyclone is generally desultory. Sometimes the weather regime of the blocking anticyclone appears to be at last giving way, as the anticyclone starts to move and dissolve, only to be renewed again as it restrengthens and meanders back to its original position. In fact, in closing this section on surface map prognosis, we mention that another weather forecasting deficiency on which much future study is needed concerns our lack of knowledge about anticyclone development.

THE PROGNOSIS OF THE UPPER-AIR MAPS

The upper-air prognosis of the pressure field proceeds in the same way as the analysis. By the layer method, we first prognosticate the partial relative hypsography of a mandatory surface, then graphically add it to the prognostic absolute hypsography of the adjacent and lower mandatory surface. By the layer method the forecaster builds upward one prognosticated mandatory layer on top of another, beginning with the prognostic surface map as the base. This method not only requires that the prognostic absolute hypsographies of all mandatory surfaces for a given time be mutually consistent and hydrostatically interrelated, but also provides a means of developing the baric prognosis upward from the more reliable prognosis of the surface map to the less predictable future state aloft. The main attention is directed toward prognosticating the pressure field at sea level and the relative hypsographies of each mandatory surface. The upper-air prognosis of the pressure field is then based solely upon *predicting locally* the rate of change in the partial relative height. *Upper-air prognosis is thus concerned with extrapolating the relative hypsography on the basis of an estimate of its future over-all rate of change.*

The Geometrical Extrapolation of the Relative Hypsography. Closed centers of both low and high values in the relative hypsography, so-called *thermal lows* and *thermal highs*, respectively, and formerly termed "cold-air drops" (*Kaltlufttropfen*) and "warm-air drops," are often observed to occur in the partial and total relative hypsographies of higher level constant-pressure maps. These thermal lows are important *conservative* features of the constant-pressure maps. The same holds for the thermal highs. In prognosticating the relative hypsographies of the constant-pressure maps, therefore, attention should be given to preserving the real continuity in time of these models. *Stage three*, then, in the order of our prognostic operations is the *geometrical extrapolation of these thermal lows and highs.*

A series of actual surface and upper-air maps showing the typical features of the thermal centers are shown in Fig. 6, which is taken from a paper by Schwerdtfeger [73]. Following the cold front, the thermal low *C* in the 500/1000-mb hypsography moves (southeast) for 2½ days with remarkable regularity and little change in size and value—536 gpDm to 540 gpDm (geopotential decameters). As a second example we may refer to the 2½-day movement of the 500/1000-mb low in Fig. 8*b*, the innermost closed 516 gpDm isohypse of which remained about the same size during that period. It has been generally observed that this low moves not with the velocity of the air in which it exists but roughly with the horizontal velocity of the cold-front surface underneath it. Although the island of cold air in a moving upper low-pressure center

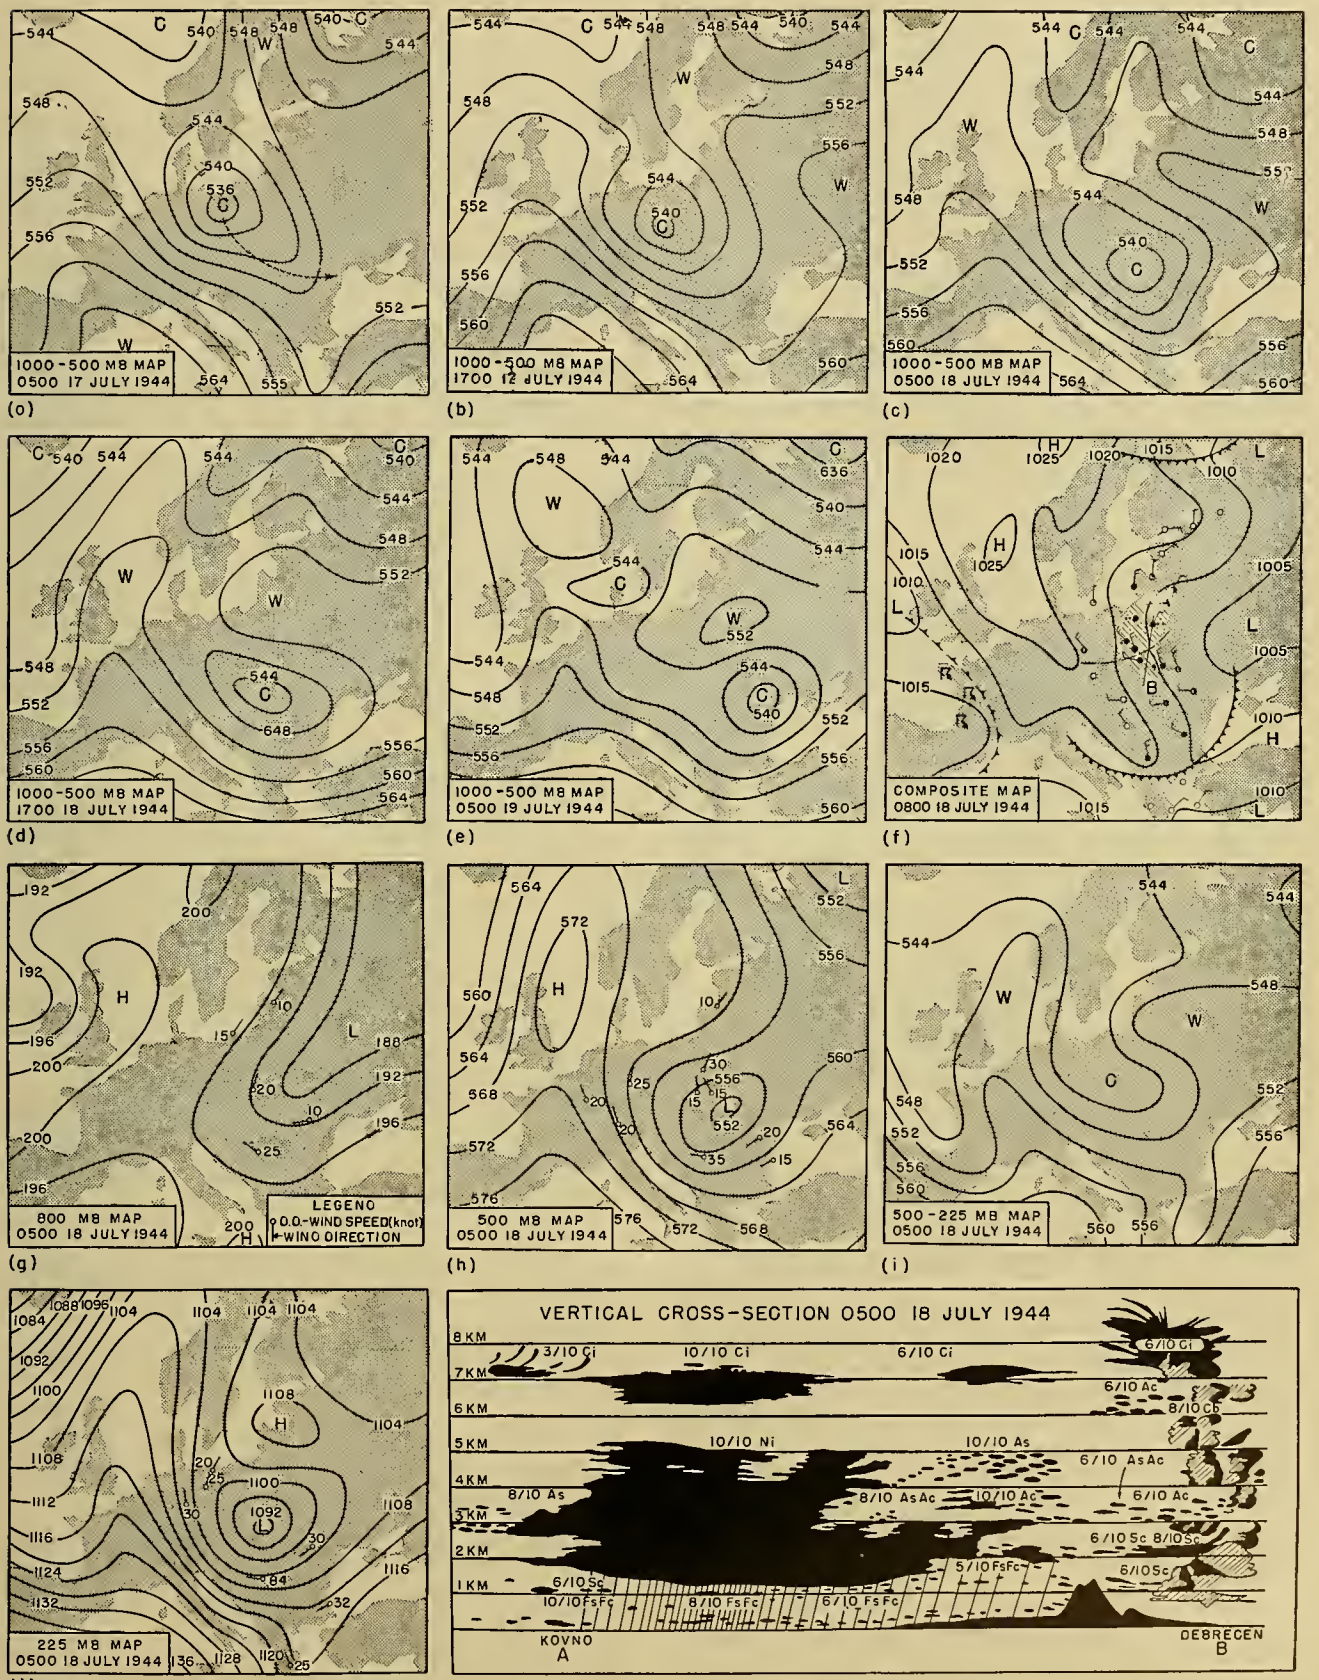

FIG. 6.—The thermal low. Units are geopotential decameters on the upper-level charts and millibars on the composite map.

would be advectively advanced to the right of the upper low (see Fig. 7), the anterior ascent of air in the low and posterior descent alone could maintain a concentric system of relative and absolute isohypses,

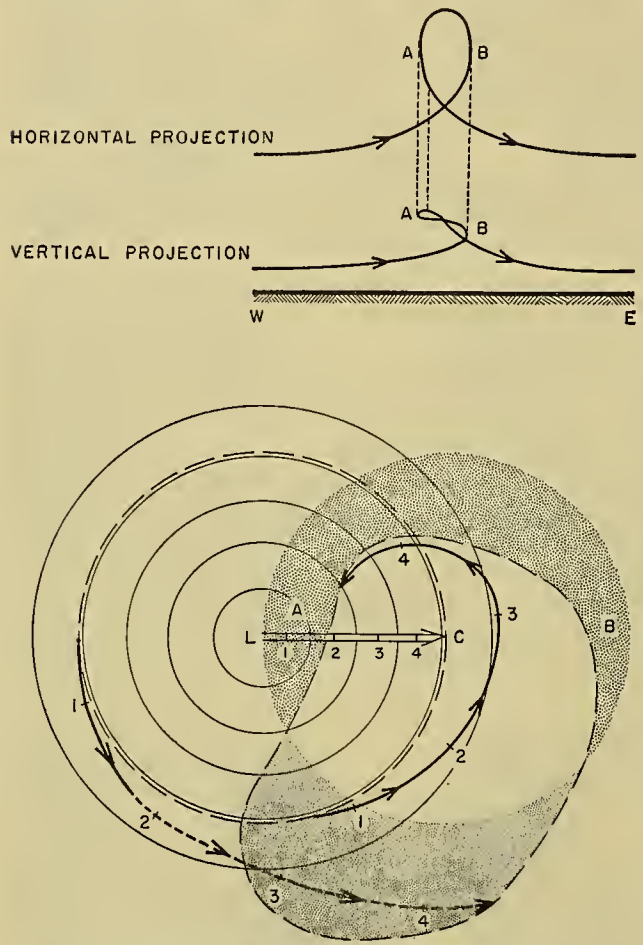

FIG. 7.—Three-dimensional motion in a nondeveloping upper low concentric with its island of cold air. In the lower part, the continuous concentric circles are the absolute isohypses of an upper low at, say, t_0. The dashed circle congruent with an absolute isohypse is a relative isohypse, also for t_0, of an upper island of cold air. The double-stroked arrow is the subsequent displacement of the nondeveloping cold low from L to C, while the two curved single-stroked arrows give the resulting trajectories of two selected points on the relative isohypse, according to the field of gradient motion of the propagating cold low. When continuous, the single-stroked arrows also indicate upward motion; when dashed, downward motion (*cf.* upper part of figure). The displacements and trajectories during four successive 6-hourly periods are indicated by the numbers (1, 2, 3, and 4) along all three arrows. With C as its center, the circle indicated by the shaded areas is the position of the relative isohypse at $t_0 + 24^h$. The eccentric, dashed closed curve is the advected position of the relative isohypse also at $t_0 + 24^h$. The shaded areas therefore indicate the nonadvective displacement of the relative isohypse—light-shaded for nonadvective increase in relative height, dark-shaded for nonadvective decrease. The letters A and B are references to the upper part of the figure.

(even disregarding the contributing diabatic effects). The thermal low thus appears as a sort of cold-air source region, mainly in the middle tropopause just above the cold-front surface. Most important in upper-air map prognosis, this conservatism of the cold-air islands allows for their geometrical extrapolation. In fact, the forecaster, at least in the beginning, devotes considerable attention to the thermal lows, treating the prediction of them as a mainstay around which the map prognosis can be built.

The Prognosis of the Relative Hypsography by Advective-Adiabatic Extrapolation. Local changes in the relative height may be considered as being associated mainly with the isobaric transport—into the locality—of an air column with a height different from that of the initial column. As a semi-Lagrangian method of predicting this advective change in the relative height, *the relative isohypses for t_0 are considered as conservative mean-isentropes of their mandatory layer embedded in its isobaric flow; and, as the fourth prognostic stage, they are displaced passively with the estimated future flow of the same layer, for the period, say, from t_0 to $t_0 + 24^h$.* The transport of the relative isohypses should include not only that part of the advection which is due to the gradient wind at either boundary surface of their mandatory layer, but also the advection by the gradient wind shear between these boundary surfaces. (The advection effect of the gradient wind shear is zero only if, along the vertical, the horizontal gradient of the virtual temperature maintains the same direction throughout the layer.)

The most accurate procedure, therefore, is to transport the relative isohypses according to the vector mean of the gradient flow at the boundary surfaces of their mandatory layer. This vector mean is determined approximately by the mean absolute hypsography of the bounding surfaces, obtained by the graphical addition of the two absolute hypsographies with only every second possible line being drawn. Since the mean absolute isohypses form a greater angle of intersection with the relative isohypses than do the absolute isohypses of either bounding surface, the mean absolute hypsography is more useful than either of the absolute hypsographies for estimating the transport of the relative isohypses due to gradient advection.

On a hitherto unused map (printed on vellum tracing paper), superimposed on the constant-pressure map for t_0, a rough draft of the prognostic relative hypsography for $t_0 + 24^h$ is, in this way, completed for each mandatory layer under the preliminary assumptions that advection is perfectly isobaric and that the field of horizontal motion at t_0 is constant during the prognostic period. But, after having first found the prognostic absolute hypsographies for $t_0 + 24^h$, we may then apply—as a correction to stage four—an average field of motion during the 24-hr prognostic period and arrive at better-advected positions of the prognostic relative isohypses. A method of successive approximations can thus be introduced for finding the varying field of horizontal motion during the 24-hr prognostic period, thereby improving the advective-adiabatic extrapolation of the relative hypsography.

We shall now proceed to consider the nonadvective and diabatic extrapolations of the relative hypsography. This prognostic operation takes into account the changes occurring in the quasi-conservative aspects of relative height and neglected in stage four. These

nonadvective changes in the relative height are due to (1) vertical motion, and (2) condensation or evaporation and radiative heating or cooling of the air.

The Local Change in the Relative Height Associated with Transisobaric Motion. Also associated with the local changes in the relative height is another atmospheric process known as *the transisobaric displacement of the air*. This is a somewhat less important process than the isobaric advection and involves the conservation of entropy. Although in reality both effects occur simultaneously with various degrees of relative intensity, for the sake of convenience in the operations of prognosis they are considered separately.

The greatest convective temperature changes are produced by the vertical advection of pressure, whereas only generally small convective changes in the temperature are caused by the relative local pressure change and by the horizontal advective pressure change. For example, a modest and frequently observed value of the vertical motion is 1 km per 12 hr, corresponding to an *individual* pressure change of about 23 mb per 3 hr for $p = 700$ mb and $T = 0$C. This rate of pressure change in turn corresponds to a convective isobaric change in temperature of 1.3C per 3 hr. In extreme instances the isobaric temperature change resulting from transisobaric displacement may be as large as 4C. On the other hand, at 3 km the pressure tendency seldom exceeds 3 mb per 3 hr, corresponding to a temperature change of only 0.18C per 3 hr at 700 mb and 0C. Extreme limits of cross-isobaric velocity component and pressure gradient are 5 m sec^{-1} (about 10 knots) and 6×10^{-5} cb m^{-1} (about 1 mb in 10 miles), respectively; such ageostrophic flow leads to a pressure change of 3 mb per 3 hr, corresponding to a temperature change of 0.18C per 3 hr at 700 mb and 0C.

The "convective" variation in the thickness of a mandatory layer is found by differentiating the statical equation with respect to time and ascribing the total convective changes in the temperature to the vertical advective pressure changes alone. In this differential equation, the pressure variable is eliminated by means of the statical equation, and the lapse rate of potential temperature is then introduced. Integrating this equation by using appropriate mean values for the mandatory layer, we obtain $-\Phi(\theta_2 - \theta_1)/\bar{\theta}$, where θ and θ_2 are values of the potential temperature at the lower and upper boundary surfaces, respectively, of the mandatory layer, and $\bar{\theta}$ is the mean potential temperature of the layer.

Since θ always increases upward in a deep layer, *unsaturated adiabatic descent* relative to a mandatory layer *increases* the partial relative height of the upper boundary surface. In a total layer of the lower troposphere, this motion is generally connected with subsidence which, after some time, makes the upward increase of θ even larger and thereby tends to produce an especially large rate of local increase in the total relative height. (In Fig. 8*a*, for example, it is seen that there is a pronounced center of nonadvective increase in the 500/1000-mb height over the south-central United States, where the northwesterly flow is descending from the Plateau Region.) However, the initial descent is soon hindered more and more by the increasing upward ascendent of θ, which, as a second-order contribution, dampens and somewhat reduces this otherwise large rate of local increase in the total relative height. Over inactive fronts the subsidence produces an increase in the relative height. (In Fig. 8*a*, for example, the cold front and occlusion in eastern United States are *inactive*, as evinced by the precipitation and altostratus-nimbostratus cloud system. It is seen that there is a ridge of nonadvective increase in the 500/1000-mb height to the rear of this front, the region traversed by this front during the past 24 hr.) At a cold front this effect partly reduces the generally larger relative-height decrease due to the advection of colder air, while at a warm front, it augments the relative-height increase due to the advection of warmer air. Consequently the spacing of the relative isohypses would be smaller for warm fronts than for inactive cold fronts.

On the other hand, *unsaturated adiabatic ascent* relative to a mandatory layer is accompanied by a *decrease* in its relative height. In a total mandatory layer of the lower troposphere, this motion is generally connected with vertical stretching, whereby the upward increase of θ through the mandatory layer is appreciably reduced, so that the associated rate of local decrease in the relative height will be smaller than the increase in the case of descent. (In Fig. 8*a*, for example, it is seen that there is a tongue of nonadvective decrease in the 500/1000-mb hypsography along the western seaboard of British Columbia and Washington where there is forced ascent of the westerly flow in crossing the Coast Mountains and the Cascade Range.) However, the initial ascent of air through a mandatory layer is abetted by the consequent reduction in the upward increase of θ between the boundary surfaces of the layer, so that, as a second-order contribution, this decreasing vertical ascendent of θ partly increases the otherwise small rate of local decrease in the relative height.

The *lifting* of *saturated* and *conditionally stable air* (or, more generally, of all saturated air *below its level of free convection*), such as in most cases of warm air-mass or warm-front precipitation, also produces a decrease in the relative height. (In Fig. 8*a*, for example, it is seen that there is a pattern of nonadvective decrease in the 500/1000-mb hypsography along the eastern seaboard of the United States and in southern Quebec, where a saturated and conditionally stable, warm air mass is being lifted in its poleward ascent over quasi-stationary warm-front surfaces. Over the corresponding (active) warm-front surface this relative-height decrease partly compensates for the larger relative-height increase due to the advection of warmer air. On the other hand, above the level of free convection, the relative-height increase due to the ascent of the conditionally unstable, *saturated* air over a cold-front surface would reduce the large relative-height decrease due to advection; above some warm-front surfaces the same effect would add to the height in-

crease due to advection. In most instances of saturated ascent, the initial lapse rate departs only slightly from the saturated indifferent one. In such cases even large upward vertical velocities have negligible effects upon the relative-height change.

The Local Changes in the Relative Height Associated with the Diabatic Processes. The local change in the relative height can be regarded as due in part also to a variation in the entropy of the air particles within the isobaric layer. Mainly because of evaporation, the latent heat being supplied by the air, and also by direct cooling, falling rain produces an appreciable diabatic decrease of the relative height in the lower layers. For example, the 850/1000-mb height is reduced about 20 gpm (geopotential meters) during the first four hours of a typical warm-front rainfall; after that (as the layer approaches a saturated state) no appreciable reduction takes place. Of course, in the adjacent lower layer of a temperature inversion the direct warming from falling precipitation partly reduces the larger relative-height decrease due to the evaporation. (In Fig. 8*a*, for example, it can be seen that the nonadvective decrease in the 500/1000-mb height corresponds roughly to the areas of precipitation and of the altostratus-nimbostratus cloud system.)

Diabatic changes in the relative height may also be brought about by the contact of the air mass of the total mandatory layers with warmer or colder ground or sea surface. Owing to increased turbulence by heating from below, a warm earth surface affects the relative height of a deeper layer than does a cold surface. The increase in the relative height is also particularly large for the 1000–700-mb layer in the cold air mass of polar outbreaks. (In Fig. 8*a*, for example, where the northwesterly flow of the cold air passes from the snow-covered Great Plains to the snow-free south-central states, a crescent-shaped center of nonadvective increase is found in the 500/1000-mb hypsography; the opposite considerations apply to the southerly flow of warm air as it passes from snow-free southeastern United States to snow-covered New England and Quebec.) Yet, even the ordinary turbulence in winds around 15 knots produces a decrease in the relative height for as much as the lowest hundred meters of a warm air mass. Even so, this decrease is still relatively large compared with the decrease by radiative cooling of that layer, the last atmospheric process of importance to be considered for relative-height change.

The relative-height decrease due to the net radiative cooling of the cloudless atmosphere is greater in summer, at low latitudes with warm humid air, and for low altitudes than in winter, at high latitudes with cold dry air, and for high levels. For example, the summertime radiative decrease in the 700/1000-mb height of a cloudless atmosphere is very roughly 5–10 gpm per day in a typical tropical air mass. Although according to estimates of Elsasser [24] the net rate of radiative cooling decreases steadily from 2 km to 5 km, later investigations by Penner [57] in an arctic region show that this rate is a maximum in the 600-mb to 500-mb layer.

The Prognosis of the Relative Hypsography by Nonadvective and Diabatic Extrapolation. These changes occurring in the quasi-conservative aspects of relative height are described by the nonadvective relative allohypsography, the allo-entropic centers of which are mainly due to (1) transisobaric lifting or sinking and to (2) condensation or evaporation (the latter especially in connection with precipitation) if the period is 24 hr. For periods shorter than 24 hr they will often be due mainly to (3) radiative heating or cooling of the air, which appreciably modifies this pattern, especially over high plateau areas such as western North America.

Further subdivision of the change in the relative height according to its component processes is not feasibly incorporated into the daily prognosis. In the practical method for calculating the transisobaric displacement of the air, the necessary assumption that the entire nonadvective change in relative height is adiabatic prevents us from separating the nonadvective relative allohypsography into, say, its "convective," "precipitative," and "radiative" relative allohypsographies. (Godske *et al* [33] have shown how the comparative intensities in these diabatic processes can be determined.) The results of Godske's method can then be introduced into stage five (see below).

The foregoing considerations of the nonadvective changes in the relative height, substantiated by synoptic experience, can be generalized into a *synoptic upper-air model*, which relates the nonadvective relative allohypsography to the corresponding relative hypsography. For example, the center R of nonadvective increase in Fig. 8*a* is just behind the equatorward portions of the troughs in the 500/1000-mb hypsography in Fig. 8*b*. The ridges in the relative hypsography (see Fig. 8*b*) and its centers of nonadvective decrease, F in Fig. 8*a*, are similarly related. *Generally speaking, these centers of nonadvective increase and decrease in the relative hypsography for the period* $t_0 - (t_0 - 24^h)$ *appear respectively at, or just behind, the equatorward portion of the trough and the poleward part of the crest in the relative hypsography for* t_0.

Important, then, in preparing the way for the prognosis is the analysis of the nonadvective relative allohypsography for the past 24-hr period, the zero isopleth of which, when traced onto the relative hypsography for t_0, can be applied as the starting place of prognosis by advective-adiabatic extrapolation. At the position of this isopleth, the relative isohypses have a past 24-hr displacement due just to their isobaric advective transport according to the past 24-hr flow of their layer. As the starting point for the fourth prognostic stage, already introduced, we may proceed, then, to advect adiabatically, during the 24-hr prognostic period, those portions of the relative isohypses for t_0 which are in the vicinity of this isopleth. The prognostic positions so obtained constitute a tentative, fixed framework for the prognosis by nonadvective and diabatic extrapolation.

Thus, as *stage five* in the order of prognostic operations, *we now complete the layer prognosis by supple-*

menting the advective-adiabatic extrapolation of the layer isentropes with physical considerations regarding the nonadvective and diabatic contributions to their future displacement. We choose an appropriately idealized prognostic pattern of the nonadvective relative allohypsography for $(t_0 + 24^h) - t_0$. Whereas the advective-adiabatic extrapolation in stage four is mainly mechanical in its application, this prognosis, on the other hand, brings into play the creativeness and intuitiveness of the forecaster and depends largely upon his experienced insight in perceiving and anticipating the nonadvective (and diabatic) processes in the atmosphere and in evaluating their effect upon relative-height change. The rational separation of the prognosis into its mechanical and nonmechanical operations (*viz.*, stages four and five), in addition to concentrating the forecaster's efforts in a routine way on these more or less intangible processes and the asso-

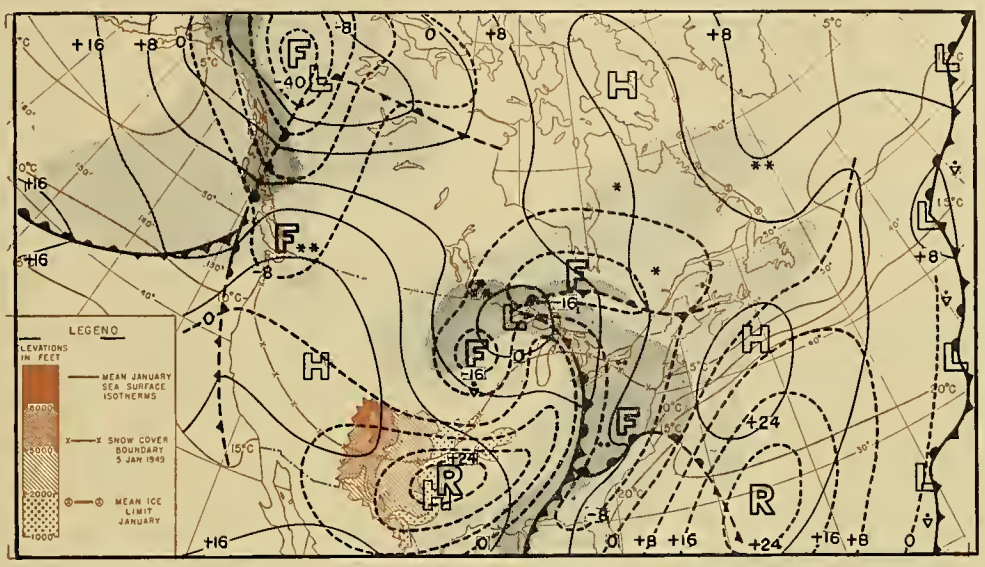

FIG. 8*a*

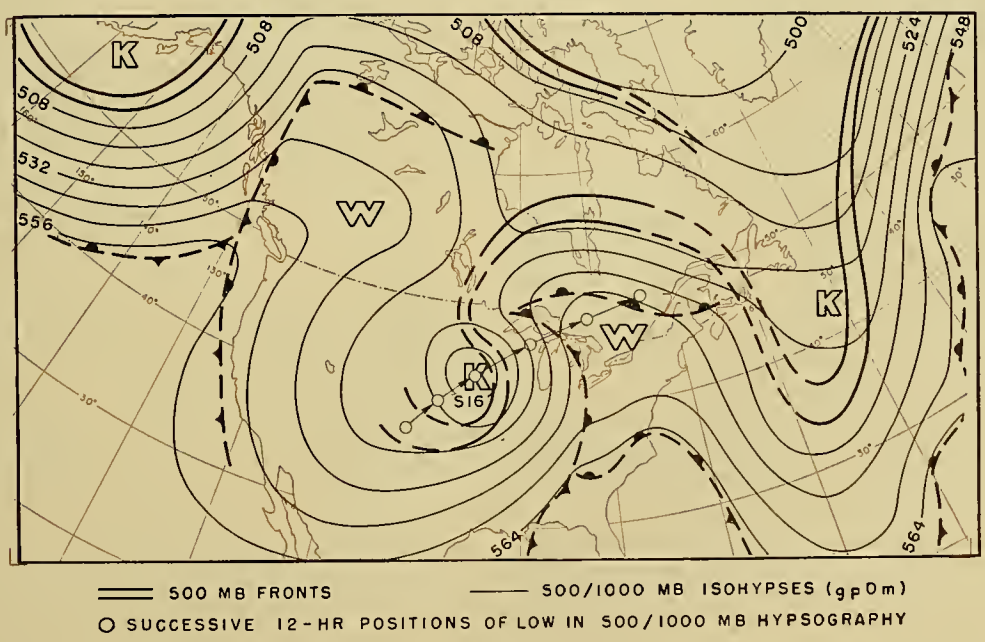

FIG. 8*b*

FIG. 8.—Maps for 1500 GMT, January 5, 1949, showing the relation of the nonadvective 500/1000-mb allohypsography for the past 24 hr to (*a*) the 1000-mb and 500/1000-mb hypsographies, (*b*) the areas of precipitation and altostratus-nimbostratus, (*c*) the extent of snow cover, (*d*) the sea surface temperature, and (*e*) the pertinent orography. This allohypsography has been based on streamline maps at 6-hr intervals, and instantaneous values of the *isobarically geostrophic advective change in the relative height* computed from the statical-kinematical tendency equation. (See [33], equation 11·61(1).)

ciated physical extrapolations, also provides for the acquisition of forecasting experience concerning such processes and extrapolations. Later verification will indicate the extent to which the nonadvective, diabatic processes have been correctly anticipated in the 24-hr prognosis: this verification is automatically accomplished at $t_0 + 24^h$, at which time is made the actual nonadvective relative allohypsography for the period from t_0 to $t_0 + 24^h$.

The final 24-hr prognosis of the relative hypsography is now obtained simply by adding graphically the prognosis of the advective relative hypsography for $t_0 + 24^h$, which has been just obtained by stage four, and the prognostic pattern of the nonadvective relative allohypsography for the period $(t_0 + 24^h) - t_0$.

With the completion of stages four and five, we can now proceed to utilize the temperature field for the prognosis of the surface map in a way not possible before the development of synoptic aerology, owing to the unrepresentativeness of the surface air-temperature observations. *As stage six, then, we exploit the prognostic relative hypsography for obtaining the prognosis of the surface map.* For example, as shown in Fig. 8*b*, frontal waves on the surface map should be associated with a warm tongue, or ridge, in the relative hypsography. An open frontal wave should be fitted to a broad and flat tongue (*e.g.*, Florida). A large spread between the prognostic relative isohypses describes a homogeneous air mass, which should be associated with the warm sector of an open wave (*e.g.*, Lake Ontario). The packing of the prognostic relative isohypses must occur in the frontal strip (*e.g.*, Gulf of Alaska, Mississippi Basin, Atlantic Ocean). An occluded frontal disturbance should be chosen for a narrow ridge with large amplitude in the prognostic relative hypsography (*e.g.*, the west coast).

Stage seven is the prognosis of the absolute hypsography, obtained by a simple routine procedure. The 24-hr prognosis of the relative hypsography is superimposed upon the prognostic surface map, upon which is now placed a hitherto unused transparent map overlay. By graphically adding these two prognoses, the prognostic absolute hypsography is drawn on the overlay.

Prognosis Beyond Thirty-Six Hours, Based on Extrapolation of Individual Upper Long Waves. The importance of the latitudinal variation of the Coriolis parameter for the explanation of the large-scale motions has been incorporated by Rossby [68] into a barotropic, approximately nondivergent, wave model. This physical model became a very simple instrument for the extended-period extrapolation of the baroclinic long waves in the upper westerlies. This extrapolation is based upon parameters determined at the "equivalent barotropic level." At this level it is then assumed that the extrapolation is governed primarily by the quasi-conservation of the vertical component of absolute vorticity. In spite of this somewhat unrealistic assumption, the simple prognostic rules developed from the application of this autobarotropic model have achieved partial success in predicting the propagation speed of the individual long waves in the upper westerlies and, to a lesser extent, their development. (This partial success initiated the use of such a model in making the mathematico-physical prognosis discussed in this volume by Charney on pp. 470–482 and by Fjørtoft on pp. 454–463.) In this subsection we very briefly consider the application of these rules, particularly those which have been rather well substantiated by synoptic experience.

Let us first consider the individual 500-mb maps, selected because they are, according to Charney [16, p. 147] approximately at the level of nondivergence. In the 500-mb westerlies one often finds *long waves* consisting of slowly moving cold troughs and warm ridges. Being often obscured on the surface map, they represent a family of *major waves* quite distinct from the rapidly moving *minor waves* or warm troughs and cold ridges which have their greatest amplitudes at the lowest level of the atmosphere and diminish with height.

The eastward velocity of propagation of the long waves is computed by means of Rossby's wave formula in the form

$$c = 2\Omega a \cos^3 \bar{\phi} \frac{L_s'^2 - L'^2}{(360)^2}, \tag{2}$$

where L' is the observed angular wave-length (expressed in degrees), and L'_s is the theoretical angular length which a wave should have in the atmospheric situation under consideration in order to be stationary. (The earth's parameters are represented by the usual notation, *viz.*, angular speed Ω, radius a, and mean latitude $\bar{\phi}$ of the waves.) Rossby's wave formula in the form

$$c = v_{x,5} - \frac{2\Omega a L'^2 \cos^3 \bar{\phi}}{(360)^2} \tag{3}$$

shows that, on the 500-mb map, a change in c can occur from a change in L' or from a change in ϕ (the latitudinal position of the maximum zonal wind) or $v_{x,5}$ (the geostrophic west-wind component), that is, in L'_s according to (2). In practice, the hemispheric chain of maximum westerlies is divided up into three parts, approximately 120° of longitude in length, such that waves within each part are roughly at the same latitude. Then $v_{x,5}$, which is measured at various latitudes across the maximum westerlies, and ϕ are space-averaged along each 120°-length of the maximum westerlies. To facilitate the application of equations (2) and (3), Byers has designed a nomogram [17] into which L', $v_{x,5}$, and $\bar{\phi}$ can be entered for finding c.

The short-range (*e.g.*, 48-hr) variations in these averaged values $v'_{x,5}$ and $\bar{\phi}$ of the maximum zonal windstream over its 120°-length are so small that they cause no significant change in L'_s, which is a function only of $v'_{x,5}$ and $\bar{\phi}$. A forecast of persistence for L'_s is therefore usually a good forecast. Hence, c varies primarily according to L'. However, it is generally difficult to predict the future changes in L', so that the forecaster must be content with using just the instantaneous t_0-value of c, over a third of the hemisphere, for the prognostic extrapolation of the long waves. The extent

to which he can predict the acceleration of propagation of the long waves depends on how well he can predict the changes in their wave length.

In an intense westerly jet stream (and also in the cases with waves of large amplitude), representative values of $v_{x,5}$ cannot be determined; the evaluation of c by Byers' nomogram should therefore not be attempted for such waves. The motion of the long waves in a narrow jet stream can be determined instead by averaging the speed profile from several cross sections, each eight degrees of latitude in width, and centered at the maximum speed of the jet stream. Next, α_i, the average direction, measured from the east-west axis (east = 0), of the isohypses at their inflection points, and ϕ_i, the corresponding average latitude are found directly from the 500-mb map. Then, the constant absolute vorticity path is evaluated; the wave length of this constant absolute vorticity path is equal to L'_s, the stationary-wave length. Therefore, for $L'/L'_s < 1$, the long wave under consideration will progress eastward during the prognostic period; and for $L'/L'_s = 1$, the wave will be quasi-stationary. When $L'/L'_s > 1$, L' will soon decrease; the decrease occurs first as a retrogression of the long waves and then as an increase in their wave number n.

The westward movement of the long waves is seldom a real phenomenon, but only an apparent, discontinuous one. It results from the fact that the major trough is transformed into a vanishing minor trough accelerating eastward simultaneously as a new major trough forms westward of the former position of the old major trough. After the retrogression, the final position of the major trough is at the distance of L'_s from the next major trough to the west. In the hemispheric chain of long waves, successive retrogressions of the major troughs generally occur downstream at short intervals of time.

At the end of this retrogression cycle, a new major trough often forms as an adjustment of L' in response to a change in L'_s, this adjustment appearing as an increase in n. It has been generally observed that an increase in a hemispheric chain of previously retrograding long waves leads to progression.

If the considerations outlined above could lead to a prognosis, three to six days in advance, of the major waves in the upper westerlies, it would establish the basic framework, so to speak, of the predicted future atmospheric state. But many assumptions still are involved in passing over from this more or less abstract prediction ("analysis-prognostic process") to the more detailed forecasting of the various weather constituents ("prognosis-forecast process"). These mental operations do, however, fall naturally into three straightforward parts: conjecturing qualitatively the most probable future (1) development of the minor waves in the upper westerlies, (2) sea-level paths of the cyclones, (3) anomaly patterns of precipitation and ground-surface temperature for the forecast period, or large intervals thereof, rather than for certain days, or particular times of the period.

Fultz [30] has suggested a certain life cycle for the minor waves in their conjunction with the major waves. These minor waves are associated with the cyclones. According to Klein [48] two of the prevailing sea-level paths of the cyclones converge in a region of confluence in the major wave. In this region, heavy precipitation is generally observed. In fact, from his investigation and from the experiences of others, Klein [48] has developed a schematic model of the precipitation anomaly pattern probably associated with a major wave. The ground-surface temperature anomaly pattern associated with the major wave has been studied by several investigators, whose results are reported by Bundgaard [33, Fig. 18·61·2].

THE PREDICTION OF VARIOUS WEATHER CONSTITUENTS

Introduction. The prediction of the interrelated weather constituents—temperature, cloud, precipitation—is naturally a composite process and should therefore be based mainly on the synoptic system of weather maps, actual and prognostic. But the map-made predictions of the weather cannot express the details of the local effects, since the map systems are intended to describe only in a coarse way the atmospheric state for the future—or even for the present. However, such effects can sometimes be applied locally for predicting an explicit weather constituent. In the first subsection we shall mention briefly and in a general way how objective techniques can be developed by methods of statistico-graphical integration. We then illustrate in a few words how temperature, cloudiness, precipitation, wind, etc., can be predicted by objective methods as well as by various physico-empirical considerations and synoptic rules of experience.

The Objective Method. The method of graphical integration provides a graphical solution of the form:

$$W = f(X_1, X_2, \cdots, X_i, \cdots, X_n), \qquad (4)$$

where W is the value of the weather constituent, (*e.g.*, rainfall, temperature) which is to be predicted and X_i are variables, measured at the initial time, which are believed to be related to W at some later period. The X_i are combined in successive pairs, each set of two variables being plotted on a scatter diagram with the X_i as coordinates and the values of the dependent variate, W, indicated beside each plotted point (see Fig. 9). Here, the small frequency charts represent the distribution of W in a small area on the graph. The data are analyzed by constructing $\overline{W}_i$-isograms of $a, b, \cdots, n$.

Each pair of X_i is analyzed in this manner, resulting in an equation of the form:

$$W = F(\overline{W}_1, \overline{W}_2, \cdots, \overline{W}_i, \cdots, \overline{W}_{n/2}), \qquad (5)$$

where each of the $\overline{W}_i$ is now a function of two X_i. The number of the new, $\overline{W}_i$-variables in (5) is about half the number of original X_i-variables in (4). This process is repeated, now using pairs of $\overline{W}_i$ as coordinate variables and, as before, analyzing each scatter diagram by considering the distribution of W itself. Obviously

this process may be continued until only one variable, W_f, is left on the right-hand side of (5).

The final variable W_f thus derived is a function of all of the original X_i. It has been obtained by a process which permits the distribution of the central tendency of the data to specify the form of the functional relationship, *thereby eliminating the major disadvantage of mathematical regression techniques, discriminant functions and the like, which require prior knowledge of, or assumptions regarding, the nature of the relationship between the independent variables and the dependent variate.* (Present mathematical regression techniques can treat only those relationships between variables of the

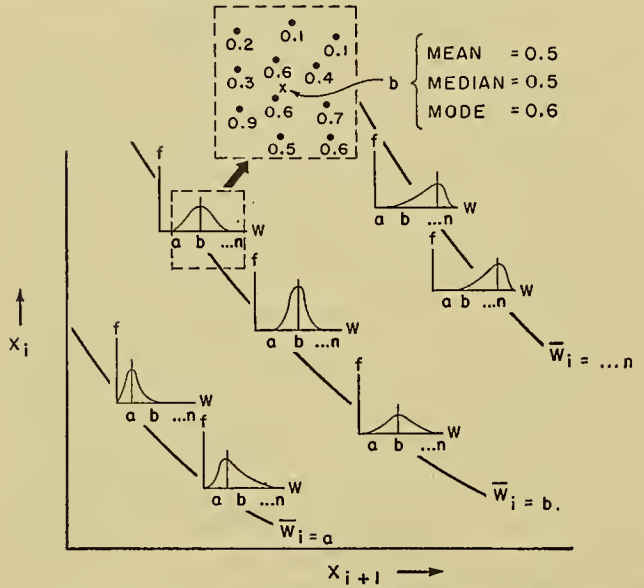

FIG. 9.—Schematic analysis of the scatter diagram. The dashed inset square at the top is an example of a small area of the diagram containing, for the purposes of this illustration, eleven values of a weather element W, say, rainfall amounts. For these eleven values of W, some measure $\overline{W}_i$ of their central tendency (*e.g.*, the mean), represented in this instance by the quantity $\overline{W}_i = b$, is entered at ×, the geometrical center of this small area. After such values of $\overline{W}_i$ have been entered over the entire chart, $\overline{W}_i$-isograms of these quantities, $a, b, \ldots n$, are drawn.

form $y = b_1x_1 + b_2x_2 + \cdots + b_nx_n$ or relations which can be transformed to that form. This permits the use of polynomial regression and sometimes exponential regression.) Practical application of the graphical integration process will be illustrated in the subsection on precipitation.

Temperature. The temperature ${}_gT$ at some point P on the ground can be predicted by starting from, say, the prognostic 700/1000-mb hypsography and by applying the indirect aerological methods as presented by Godske and others [33]. Relabelled (according to Table 17·50·1 in [33]), the prognostic 700/1000-mb isohypses give directly the ground temperature ${}_gT_s$ to which the predicted 700/1000-mb heights are reduced on the basis of the saturation-adiabatic lapse rate. Temperature corrections indicative of the *effective* 700/1000-mb lapse rate are added to ${}_gT_s$ by systematically considering at P the air-mass type (using Table 17·50·2 in [33]) and the pattern of the prognostic sea-level isobars (using Fig. 17·50·2 in [33]). Finally, additional corrections are applied to account for frontal surfaces, if any, predicted to be over P (using equation 17·50(1) in [33]) and anticipated ground inversions, if any, over P (using Fig. 17·50·1 in [33]). For predicting the rapid temperature changes occurring at frontal passages—one must take into account certain unrepresentative influences, such as the existence of cold-air films at the ground, pseudo fronts in advance of the real front,[9] local wind systems such as the land and sea breezes and foehn winds,[10] evaporation cooling in falling precipitation, and the predictable cloud distribution in space and time.

The local, diurnal, temperature minimum can be predicted quantitatively by means of formulas and nomograms which relate empirically the sunset observations of temperature, humidity, and wind at the place of prediction and at auxiliary stations some distance upwind to the heat loss during the ensuing night for synoptic situations in which no new air masses are to be expected. Such numerical methods have been developed by Kammermann [45], Dufour [21], Kessler and Kaempfert [46], Brunt [13], and Jacobs [44]. Geiger [31] has presented many detailed considerations for forecasting the night frosts, a problem still remaining after the minimum temperature has been predicted.

Speculating on the ways in which the total solar radiation received at the ground is dissipated, Gold [35], Neiburger [55], and Bundgaard [33] have presented quantitative methods for predicting locally the daily temperature maximum. These methods are applicable if, for at least the approximate half-day period from one hour after sunrise to the time of temperature maximum (normally 1300–1500 LMT), clear skies and no air-mass replacement are forecast locally. Under these conditions, then, the locality remains well within a homogeneous, extensive, and slowly moving air mass during this period, so that local advective changes are negligible.

General Hydrometeors. Extrapolated frontal positions at once indicate the future position of the areas of nimbostratus rain and altostratus cloud. The future location of drizzle and low stratiform cloud will extend through such parts of the extrapolated air masses where there will be cooling from below, showers and low cumuliform cloud where warming from below is anticipated. Using the predicted map changes of (1) surface temperature, (2) vertical motion, (3) upper-air humidity, and (4) upper-air stability, the regional forecaster can issue general predictions about nonfrontal hydrometeors: stratiform cloud—with or without drizzle, cumuliform cloud—with or without showers, thunderstorm, and hail. The change (3) enables us to decide whether or not the processes leading to hydrometeors, once started by a thermal influence (1) or a kinematical impulse (2), will culminate in the condensation phe-

9. Consult "The Instability Line" by J. R. Fulks, pp. 647–652 in this Compendium.

10. Consult "Local Winds" by F. Defant, pp. 655–672 in this Compendium.

nomena, while (4) enables us to predict the type of precipitation. The future location of precipitation due to upper-tropospheric instability will be found in the forward half of the extrapolated islands of cold air aloft (see Figs. 7 and 8). Upper-tropospheric instability usually occurs above a cold air mass within a nonfrontal trough in the rear of a cyclone on the surface map. At sea, where the cold air mass already contains convective clouds, the presence of upper tropospheric instability will give the clouds there maximum vertical growth. The same development may be found over land if the initial humidity supply and the heating from below are sufficient. When the low-level instability is missing, the upper-tropospheric instability can be seen to produce castellatus from layers or stripes of medium cloud. Showers and thunderstorms from such cloud systems are rather independent of the time of day or night and can be followed from map to map. On the other hand, in the rear half of the upper island of cold air, both the warm advection and the descent of the air contribute to the suppression of the unstable character of whatever cloudiness and precipitation there may be in that area. The forecaster should also take into account the orographic strengthening of ascending cloud masses due to the nature of the terrain and other more indirect orographic effects, such as foehn effects.

There is a tendency towards formation of cloud and precipitation in the entrance regions, whereas there is a tendency towards dissolution of hydrometeors in the exit regions. There is a tendency towards formation of hydrometeors in the areas where the isohypses are cyclonically curved and a tendency towards dissolution of them in regions of anticyclonic curvature. In poleward-moving air extending through a deep layer over the earth, cloudiness and precipitation may be expected in areas where the prognostic isohypses of the lower mandatory surfaces are either straight or cyclonically curved. This effect will be especially marked within tropical air, owing to its great relative and specific humidity already before its lifting and stretching. In an equatorward flow of similar vertical extent, cloudiness and precipitation are likely to occur only where the prognostic isohypses have pronounced cyclonic curvature.

The centers of nonadvective decrease of relative height correspond to regions where the air of the corresponding layer either is ascending or is losing entropy by radiation or precipitation. In both instances cloudiness and precipitation must be expected to be associated with these centers (see Fig. 8*a*). A detailed prediction of the air-mass hydrometeors, of great practical importance, must, however, be left to the area and local forecasters.

Warm Air-Mass Hydrometeors. Detailed predictions of warm air-mass hydrometeors—fog, stratus, and drizzle—cannot be based completely on the prognostic map system, since local effects are also important. Warm air-mass fogs, excluding the steam and frontal fogs, are abetted by the cooling of the air particles near the ground sufficiently below the dew point (Petterssen [59]) and are hindered by turbulence-producing wind. Upslope fogs may be predicted locally by applying a prognosticated lifting condensation level to the large-scale orographic ascent of the air which occurs with certain wind directions. For predicting local sea and coastal fogs, a problem more difficult than the regional problem of predicting tropical air fogs, the local forecaster must be familiar with the local changes in the sea temperature and wind as well as the local aerological observations, which are necessary to clarify the difference between the situation in which fog occurs and that in which the fog is lifted by turbulence so that stratus cloud appears. Valid for clear skies and slight winds (below 5.5 mph), Taylor's empirical diagram [77] for forecasting radiation fog at Kew Observatory has as its abscissa the evening temperature and as the ordinate the dew-point deficit. For the local prediction of advection-radiation fogs, George [32] constructed similar but more complete empirical diagrams which also take into consideration clouds, wind speed, wind direction, and air trajectories. Predicting the morning-time dissipation of fog and stratus by synoptic-local methods should take into consideration its linear relation to cloud thickness [83], in addition to other fog-dissolving influences such as wind speed and snow cover.

Cold Air-Mass Hydrometeors. Cumuliform clouds, cold-front and orographic showers, and showers superimposed upon a warm-front rain can all be predicted in a general way by the regional forecaster on the basis of his prognostic upper-air maps showing the conditional and potential lability of the air, its humidity, and the position of its ice nuclei. In fact, such shower areas also form a typical part of the cyclone models for the surface map. In nighttime and during winter, continental air acquires cold air-mass properties over sea, while in the afternoon and during summer, at the time of maximum ground heating, all air masses and especially maritime air acquire cold air-mass properties over land. For the diagnosis and prognosis of the early cumulus stage, we may mention that Beers [8] has applied a practical method of evaluating for each individual layer its circulational acceleration, a value which may also be interpreted as the geopotential difference of the ascending column from the descending one.

For very short-range forecasting (6-12 hr) of thunderstorms, Brooks [12] has found a correlation between thunderstorm occurrence and the direction of the lower tropospheric winds (ground to 1½ km), but no evident relationship between the speed of these winds and thunderstorm occurrence. However, strong winds above 3 km tend to inhibit thunderstorm activity. Brancato [11] states that large thunderstorms move with the 11,000-ft winds, while (small) nonfrontal storms seem to be steered by the 5000-ft winds. Humphreys [43] formulates the relation differently; he states that the thunderstorms move with the strata containing most of the cumulonimbi. But these conclusions are rendered indecisive by the report of Byers [15] that the thunderstorms move to the right of the winds aloft.

The formation of hail is favored by high humidity and strong upward motions which slow the fall of the hailstone and increase the equivalent cloud thickness

traversed by it. Hail starts rather suddenly and usually lasts from a few minutes to less than half an hour; it is mostly followed by rain, these two phases being partly superimposed. It falls along narrow streaks a few kilometers wide. The foregoing considerations show

for predicting the amount of winter rainfall occurring in Los Angeles during the 30-hr period beginning at $t_0 + 6^h$.

Figure 10 shows the results of the complete graphical integration process using the six variables listed in

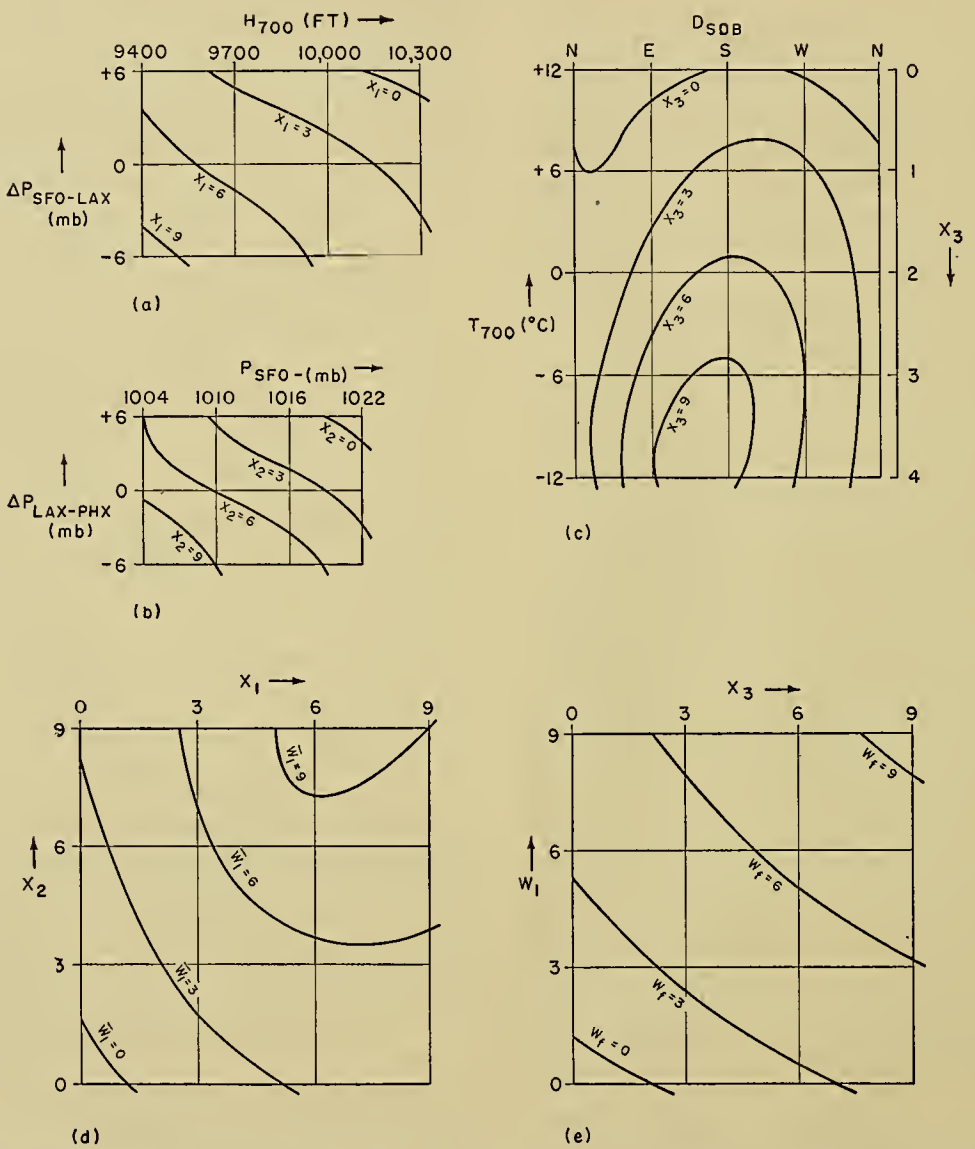

FIG. 10.—A nomogram for making an objective forecast of rainfall at Los Angeles. The rectangular coordinates of the scatter diagrams represent t_0-values of the six predictors listed in Table II. The solid curves are isograms of rainfall amount, adjusted to a scale of 0 to 10, during the 30-hr period following $t_0 + 6^h$. In part (*c*), the variable D_{SDB} loses its sensitivity as an indicator of the true wind field at low wind speeds, and thus was not used for speeds less than seven knots. These cases were plotted against T_{700} along the vertical axis to the right of the scatter diagram and analyzed separately to determine X_3. The solid curves in part (*e*) define a variable W_f, which is used in computing rainfall probabilities as given in Table III.

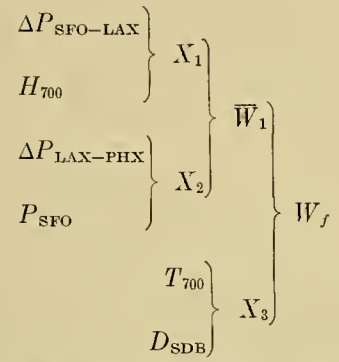
that the individual shower prediction will, at best, be possible only some few hours in advance for very small districts and with the assistance of *rareps* from specially trained observers, who reside within these districts in places with free horizon.

Amount of Precipitation. The application of objective techniques introduced in the first subsection can now be illustrated by Thompson's objective method [79]

Table II. The analysis of each part of this figure was carried out by first constructing isograms of rainfall amounts on parts *a–c* of Fig. 10 and then adjusting the isogram values to a scale 0 to 10. This latter device provides a uniform system of coordinates on all succeeding scatter diagrams *d–e* of Fig. 10, an operation which somewhat simplifies their use by the forecaster. The order in which the variables were combined is

illustrated schematically below:



A complete discussion of the physical reasoning involved in the selection of these variables has been given by Thompson.

TABLE II. PREDICTORS USED FOR OBJECTIVELY PREDICTING THE RAINFALL AMOUNT AT LOS ANGELES

Predictor	Abbreviation symbol for predictor	Part of Fig. 10 in which predictor is used
1. The sea-level pressure difference, San Francisco (SFO) minus Los Angeles (LAX)	$\Delta P_{SFO-LAX}$	*a*
2. The 700-mb height at Oakland	H_{700}	*a*
3. The sea-level pressure difference, Los Angeles minus Phoenix (PHX)	$\Delta P_{LAX-PHX}$	*b*
4. The sea-level pressure at San Francisco	P_{SFO}	*b*
5. The 700-mb temperature at Santa Maria	T_{700}	*c*
6. The surface wind direction at Sandberg (SDB)	D_{SDB}	*c*

The parameter W_f from Fig. 10*e* is used as the forecast criterion. Corresponding to each integral value of this criterion, the percentage frequency of rainfall is listed in Table III. This frequency is tabulated for

TABLE III. RELATION BETWEEN W_f AND THE PROBABILITY THAT RAIN WILL OCCUR IN THE INDICATED CATEGORIES
(*Abbreviated from Thompson* [79].)

W_f	No rain	0.01–4.00 mm	4.01–12.50 mm	12.51–38.00 mm	38.01 mm or more
0	100	—	—		
3	88	9	3	—	
4.1	*69*	*23*	*8*	—	—
6	28	36	28	6	2
6.6	*24*	*26*	*36*	*11*	*3*
9	—	—	25	55	20

each of five rainfall intervals, namely, no rain, 0.01–4.00 mm, 4.01–12.50 mm, etc. For example, suppose that by applying Fig. 10 the value of the forecast criterion has been found to be 4.1. Then, according to Table III, there are eight chances out of every hundred that the occurrence of rainfall will exceed 4 mm. If on the other hand $W_f = 6.6$, then the probability is $36 + 11 + 3 = 50$ per cent, or the chances are even that the rainfall will be greater than 4 mm. Finally we mention that objective methods for predicting precipitation also have been applied at Atlanta by Beebe [7] and at Washington, D. C. by Rapp [65].

Wind. The prognostic upper-air maps give a general picture of the future distribution of geostrophic and gradient winds aloft. The extent to which the wind deviates vectorially from the geostrophic wind has been investigated by Houghton and Austin [42], Machta [51], Bannon [6], Durst and Gilbert [22], Emmons [25], and Godson [34]. They found that, on the whole, the magnitude of this deviation is from about one-fourth to one-third of the wind speed. With increasing speed, this ratio first decreases and then increases. The minimum value of this ratio occurs with winds around sixty knots. At 700 mb the geostrophic speed is, on the whole, as accurate as the gradient speed. However the gradient wind-speed becomes more accurate than the geostrophic wind-speed whenever

$$KV_G^2 < 10^{-3} \text{ m sec}^{-2},$$

for example, at troughs with strong pressure gradients.

The geostrophic angular deviation of fast winds (for example, at 300 mb) is negligible. In this case, the absolute isohypses (or the absolute prohypses of the prognostic maps) may be considered as streamlines. For slow winds (*e.g.*, on the 700-mb map), there may be, under certain circumstances, appreciable differences in the direction of the absolute isohypses and streamlines. We shall now (1) indicate where on the constant-pressure map the forecaster should expect large, geostrophic angular deviations of the wind to occur, as well as (2) make some remarks on the nature of these deviations. In making an accurate upper-winds forecast from the prognostic constant-pressure maps, he must take (1) and (2) into account.

The normal equation for horizontal frictionless motion may be written as $V = a \cos \beta \, V_G$. (In this expression, $V = |\mathbf{V}|$ is the wind speed; $V_G = |\mathbf{V}_G|$ is the geostrophic wind speed; $a = f/(f + d\psi/dt)$, ψ being the wind direction, f the Coriolis parameter; and the angle β of geostrophic deviation is measured counterclockwise from $\mathbf{V}_G$ to $\mathbf{V}$.) For sufficiently small angles of geostrophic deviation the normal equation may be written approximately as $V = aV_G$. Assuming a constant, $\dot{V} = a\dot{V}_G$. But $\dot{V}_G \approx \partial V_G/\partial t + aV_G(\partial V_G/\partial s_G + \beta \partial V_G/\partial n_G)$. (In this differentiation $\sin\beta$ has been replaced by β, and the value of $\cos\beta$ has been taken as unity.) For this expression, s_G is measured in the direction of the geostrophic wind, and n_G normal to it. Thus, $\dot{V} = a\partial V_G/\partial t + a^2 V_G(\partial V_G/\partial s_G + \beta \partial V_G/\partial n_G)$. Introducing the tangential equation of horizontal motion $\dot{V} = f \sin \beta V_G \approx f\beta V_G$ for the left member and solving for β, we have finally

$$\beta = \frac{a\left(\frac{1}{V_G}\frac{\partial V_G}{\partial t} + a\frac{\partial V_G}{\partial s_G}\right)}{f - a^2\left(\frac{\partial V_G}{\partial n_G}\right)}.$$

This equation shows, first of all, that convergence or divergence in space and time of the absolute isohypses tends to produce positive or negative angles of geostrophic deviation, respectively. In other words, in regions of confluence (difluence), the air flows across the absolute isohypses toward lower (higher) height. Moreover, this equation shows that the angle of geostrophic deviation will be amplified or suppressed according as the horizontal geostrophic shear is anticyclonic or cyclonic, respectively. It can also be seen that, in the case of anticyclonic geostrophic shear at a constant-pressure surface, anticyclonic curvature of the path tends to magnify the horizontal shear effect and is therefore also conducive to relatively large angles of geostrophic deviation. (For anticyclonic curvature, the value of a is greater than one.) Relatively large deflection of the streamlines across the absolute isohypses (or prohypses in the case of prognostic maps) can therefore be expected in regions of anticyclonic horizontal geostrophic shear and where the curvature of the path is anticyclonic. Such conditions may be found in the right half of the confluent and difluent regions. On the other hand, the conditions for a relatively small angle of geostrophic deviation are (1) that the horizontal shear of the geostrophic wind be cyclonic or only slightly anticyclonic and (2) that, if the horizontal shear is anticyclonic, the curvature of the path be cyclonic or only slightly anticyclonic. (For cyclonic curvature, the value of a is less than one.) These conditions are found in the left half of the confluent and difluent regions. Analytic examples showing large geostrophic angular deviations of wind have been found by Gustafson [37, Figs. 1–3] (*cf.* also Petterssen [61, Fig. 2].)

The prediction of wind for a mandatory surface is thus comparatively simple once the pressure field is forecast; the prediction for intermediary pressures is achieved by interpolation between two mandatory surfaces. To forecast locally the wind *speed* aloft, say 12 hr in advance, the regional forecaster can, often with good results, extrapolate the quasi-conservative configuration of the isotachs. The crescent-shaped centers of maximum speed usually have their long axis of symmetry along the absolute isohypses. They move generally in the direction of the geostrophic wind. Their future direction of propagation is thus given by the prognostic absolute isohypses and their displacement by purely formal extrapolation. These efforts have revealed certain deficiencies, however, in the current techniques of observing the upper winds, especially at high levels with very large speeds. In the United States, these deficiencies are expected to be remedied with the introduction in the near future of an improved radar wind-finding instrument known as the AN/CPS-10. Finally, we mention that if no system of upper-air maps is available for predicting upper winds, we may apply indirect aerology, for instance, the method employed by Kibel [47], already introduced by Exner [27].

Closely connected with the prediction of wind is the problem of forecasting atmospheric turbulence. Since the amount of horizontal (vertical) shear of the actual wind is far higher (the same) for turbulent layers than (as) for normal ones, the forecaster should be on the lookout for pronounced clear-air turbulence in the regions adjacent to, but not within, the jet stream. The maximum speed of the wind gusts at the ground associated with thunderstorms can be forecast by the formula: C (in knots) $= 11\sqrt{\Delta\theta} + 15$, where $\Delta\theta$ is the difference (centigrade degrees) between the lowest wet-bulb potential temperature of the sounding and the wet-bulb potential temperature of the rising air above the condensation level [11].

Excessively strong winds occur in a small-scale model, the tornado (horizontal extent below one km), whose prediction is connected with the peculiar difficulty that it completely escapes detection on the synoptic map. For a long time to come, it will be generally impossible to forecast the time and position of occurrence of individual tornadoes. The forecaster must be content to predict only the general conditions favorable to tornado formation and then to forecast in a rather vague way that a number of tornadoes are likely to occur at scattered points in a region (say, 200 km square) and during a certain time period (of about one to two hours). These general conditions, shown in

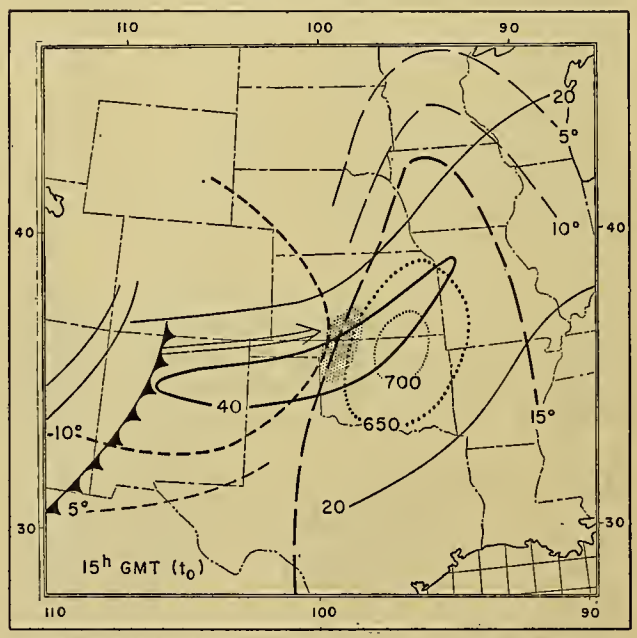


FIG. 11.—Characteristic features of the weather maps (at t_0) for the subsequent development of tornadoes in the shaded region at about $t_0 + 12^h$. The isohumes connect points of equal dew point; isotachs, points of equal wind speed.

Fig. 11 as they appear on the weather maps, are[11] [28, 74]:

1. A conditionally unstable, deep tongue of unusually dry air (namely, a 700-mb dew point of −10C

11. Consult "Tornadoes and Related Phenomena" by E. M. Brooks, pp. 673–680 in this Compendium.

or less) is superimposed on a horizontally narrow wedge of abnormally humid air at the ground (a dew point of +15C or more at the surface of the earth) which is possibly both conditionally and potentially unstable (hence, for the humid layer, a level of free convection at 650 mb, or lower).

2. Heading obliquely to the axis of the humid wedge, there must be a very narrow band of strong westerlies aloft (>35 knots at 600 mb).

3. The accurate analysis of forerunning upper cold fronts is also an important prerequisite for tornado forecasting. Forced lifting of the lower wedge of humid air must take place—usually as a result of the invading cold front to which the forerunning upper cold front or cold quasi-front is associated.

only in that part of a deep, subfreezing water cloud where supersaturation with respect to ice also occurred.

As shown by Godske and others [33], supersaturation with respect to ice exists whenever $T > -8D$, where the temperature T and the dew-point deficit D are expressed in degrees centigrade. On an aerological diagram, the icing layer is determined by the subfreezing cloud area enclosed by the temperature ascent-curve on the left and the $-8D$ curve[12] on the right, as shown in Fig. 12. Moreover, the intensity of the icing is indicated by the size of this enclosed area. The cloud type and precipitation, both observed at the surface of the earth, will show the degree of colloidal-thermodynamic instability and hence the type of icing—rime or glaze. In particular, whenever the ascent curves of tempera-

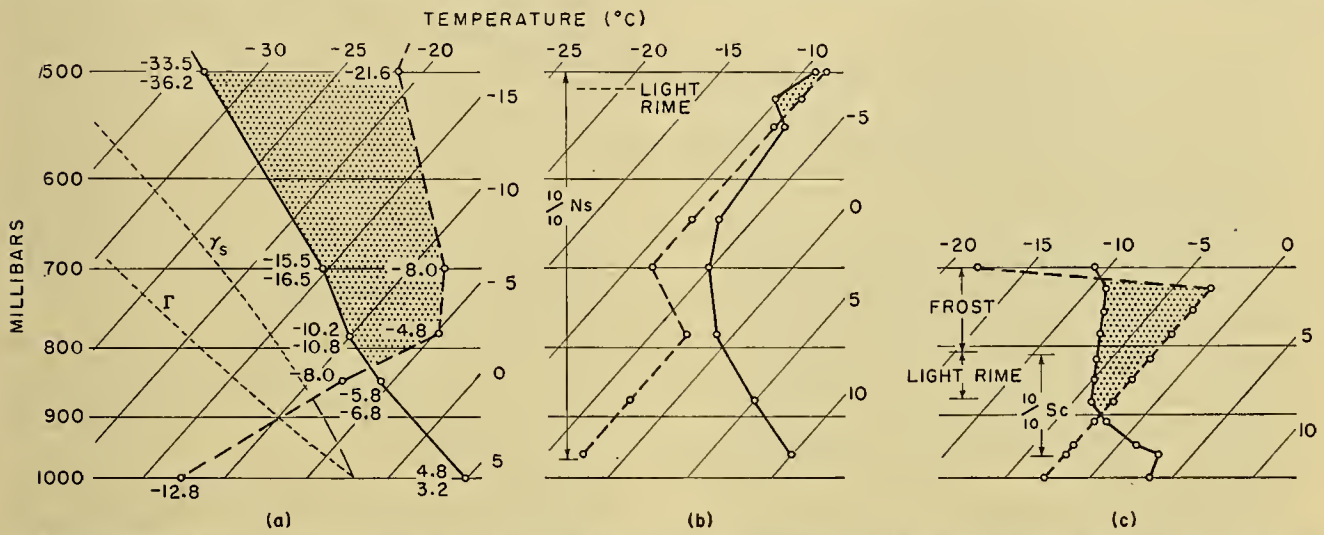

FIG. 12.—Three sets of ascent curves for temperature (solid) and—8D (dashed), plotted on a skew T, log p-diagram. (*a*) Radiosonde observations for 0300 GMT, April 25, 1949, Yakutat, Alaska. Image points labelled with values of temperature in degrees centigrade (upper left) and dew point; the —8D curve labelled with corresponding values of —8D. (*b*) Aircraft ascent for 1400 GMT, February 20, 1949, at 41.2°N, 56.2°W, with the observed icing and clouds plotted to the left. (*c*) Aircraft ascent for 1700 GMT, February 7, 1949, at 40.1°N, 46.6°W, with the observed icing and clouds plotted to the left.

An empirical rule for forecasting the movement of an individual tornado has been given by both Showalter [74] and Willett [82], namely that a tornado moves roughly with the direction and speed of the mT stratum just beneath the inversion. Others state simply that the tornado travels roughly parallel to the path of the accompanying cyclone.

The Prediction of Aircraft Icing. For icing on aircraft in flight, the subfreezing cloud containing water in the liquid phase must be supersaturated with respect to ice. Although supercooled cloud droplets occur in air subsaturated with respect to (a plane surface of) water, sublimation starts only after the moist air attains saturation equilibrium with respect to ice. In a layer subsaturated with respect to ice, the physically unstable, supercooled fog droplets, upon striking the leading edges of the aircraft, are induced mechanically to congeal as light rime ice which almost instantly evaporates into the air streaming very rapidly over the rime-forming surface of the aircraft. For example, the two aircraft soundings in Figs. 12*b* and 12*c* report icing

ture and dew point coincide, the $-8D$ curve must necessarily coincide with the 0C isotherm on the diagram. In the case where the ascent curves of temperature and dew point coincide in a subfreezing layer, the air would be saturated with respect to water, supersaturated with respect to ice. Only light rime icing would occur in the altostratus-nimbostratus cloud system of this layer; but moderate rime icing would be encountered in cumulonimbus virga which is located in this layer. Severe clear icing—for the same sounding as above—would occur in the stratocumulus virga, cumulus virga—particularly when transforming to cumulonimbus—and stratus. Whenever, on the other hand, the ascent curves of temperature and dewpoint do not coincide but the temperature curve lies to the left of the $-8D$ curve in a subfreezing layer, this

12. For most practical purposes, the dew-point ascent curve, which is frequently plotted on the aerological diagrams, could be replaced by the $-8D$ curve, since the latter, together with the 0C isotherm, may be used in place of the ascent curves of temperature and dew point for showing the vertical variation of the dew-point deficit

layer is supersaturated with respect to ice and probably subsaturated with respect to the cloud droplets. Only light rime icing will be experienced by aircraft entering this layer, if the clouds reported in them are altostratus, altocumulus cumulogenitus, or altocumulus virga; only light hoar frost will be sublimed on the aircraft, if the clouds in such a layer are reported as cirrus, cirrocumulus, cirrostratus, or cirrus nothus. In cloudless regions of this layer, no supercooled droplets will be present, but hoarfrost will also form on the aircraft through direct sublimation of the water vapor. Finally, in the case where the temperature curve lies to the right of the $-8D$ curve in a subfreezing layer, this layer is subsaturated with respect to both ice and plane water surface, so that no icing should be forecast here.

OBJECTIVE WEATHER FORECASTING

By R. A. ALLEN

U. S. Weather Bureau, Washington, D. C.

and E. M. VERNON

U. S. Weather Bureau, San Bruno, Calif.

It is the purpose of this paper to outline the breadth of the field of study which may be called "objective weather forecasting," to describe in a general way some of the recent developments in this field, and to indicate the deficiencies and unanswered questions which have arisen in such work.

THE FORECASTING PROBLEM

Definition of Objective Weather Forecasting. In the history of weather forecasting, attempts have often been made to devise numerical and objective methods for producing the forecast. Thus Besson [2] in 1904 and Taylor [24] and Rolf [20] in 1917 produced graphical devices for representing lag relationships between selected weather variables. These studies, in common with others made in later years [4, 12, 14, 15, 27], have attempted to provide an equation or a graphical device of some form which would be useful in applying a particular relationship or combination of relationships to the problem of making a forecast. The distinction between an objective forecasting procedure and a procedure which depends on subjective judgments and subjective experience has not been sharply defined, nor is it intended in this paper to advocate a rigid definition. The purpose of this review will be served by defining an objective forecasting system as any method of deriving a forecast which does not depend for its accuracy upon the forecasting experience or the subjective judgment of the meteorologist using it. Strictly speaking, an objective system is one which can produce one and only one forecast from a specific set of data. From the practical standpoint it appears reasonable to include as objective, however, those forecasts which require meteorological training insofar as such training is standardized and is itself based upon a study of well-founded physical principles and atmospheric models which are commonly recognized from the facts of observation. It would be throwing away information of demonstrated value in forecasting if, for example, an objective forecasting system were not permitted to make use of isobaric patterns on analyzed maps because of the objection that they are arrived at subjectively. The test of whether a system is objective is whether different meteorologists using the system independently arrive at the same forecast from a given set of maps and data.

Goals of Objective Forecasting Investigations. The obvious ultimate goal of forecasting investigations is to enable the forecaster to increase the accuracy of forecasts made routinely. Contributions toward this end may be made in several ways. The forecaster may study the physical characteristics of the atmosphere, especially the dynamic relationships which have been derived on the basis of simplifying assumptions. Such study may enable him, in the course of analyzing given situations, to recognize processes in the real atmosphere which have been described analytically, and in such cases he will know better what to expect of the atmosphere in the immediate future. The success of this method of attack depends on the skill of the theoretical meteorologist in describing the real atmosphere when he sets up a model and makes simplifying assumptions, and on the skill of the forecaster in diagnosing the present sequence of events in the atmosphere, selecting the theoretical processes which are most nearly applicable, and judging what modifications are necessary in individual instances.

On the other hand, the forecaster may search for empirical relationships between observable characteristics of the atmosphere, and with little or no reference to the physical validity of the relationships, make use of them in forecasting. Many forecasters gain a high degree of skill after many years of experience because of this second factor, but skill obtained in this way is difficult to transfer from place to place or from individual to individual. It appears certain, furthermore, that some forecasters base forecasts in large part on hypothetical relationships that have neither a physical nor a statistical basis and that cannot even be expressed in objective or quantitative terms. In such a case, it is impossible to discover from data whether or not these relationships exist in the atmosphere.

Ideas for testing and possible incorporation into an objective system can come from several sources: by testing new theoretical concepts for their possible contribution to forecasting practice and providing objective ways to use the results; and by testing, combining, and systematizing the use of rules and principles which have been discovered or are already used by experienced forecasters.

The goal of objective forecasting is simply to eliminate as many as possible of the subjective elements which enter into the *application to forecasting* of the results of such studies. Objective forecasting is not so much concerned with the source of hypothetical relationships as it is with the practical value of the ideas and the extent to which they contribute to the accuracy of forecasts.

Objective forecasting studies and research projects which aim to develop objective methods or objective aids to forecasting are characterized by the use of historical data to demonstrate the reliability of forecasting rela-

tionships, and by the expression of the forecast itself in quantitative terms or at least in unequivocal terms. Fear has sometimes been expressed by forecasters that a result of the development of objective forecasting methods will be to supplant experienced forecasters by mechanical methods. It should be obvious, however, that the greater the reduction in the number of subjective and uncertain decisions required in the process of preparing the forecast, the more time will be available to the forecaster either for studying the effect of new and untried variables and the value of new principles, or for interpreting the forecast for the exceedingly diverse uses to which it is applied by the public.

From the standpoint of discovering and understanding relationships which hold in the atmosphere, forecasting investigations have been relatively ineffective because of their stress on lag relationships, and it seems clear that only a complete physical explanation of the atmosphere together with complete observational data will make it possible to produce perfect weather forecasts. Practically, however, uncertainties exist which make the maximum attainable accuracy something less than perfection [22]. The forecasting problem is thus, in essence, one of estimating what is likely to occur with any given state of the atmosphere and its environment. More precisely, the problem is to state the probability that any specified weather event will occur within any specified time interval.

The statistical or probability aspect of weather forecasting was recognized as early as 1902 by Dines [7], who pointed out the impossibility of knowing exactly what weather is going to occur and suggested that the laws of chance should be applied. Hallenbeck [9] in 1920 found an encouraging response from the public when he attempted the use of numerical probability statements as part of his agricultural forecasts. It seems to have been only recently, however, that this objective has been recognized by a large group of meteorologists and that attempts have been made to apply the methods of mathematical statistics or to develop new methods suitable for the estimation of forecast probabilities [5, 25]. Since the public generally has demanded categorical forecasts, attempts to express the "chances" of a weather event occurring have usually been frowned upon by forecasters. Nearly every decision the forecaster is called upon to make, however, involves weighing the chance as indicated by one set of factors against the chance as indicated by one or more other sets. Objective forecasting studies have not often provided final, conclusive evidence of the chance of occurrence of the weather event in question, but such studies have reduced the uncertainty to quantitative and understandable terms, and it is one purpose of such studies to determine the actual frequency with which any sequence of events which it may be desired to specify can be expected to occur.

Limitations of Objective Forecasting. Some of the objective forecasting methods which have been developed [1, 8, 17] have demonstrated a rather clear superiority to forecasts made by conventional methods under routine operational conditions. The question then arises, why have forecasters generally not seized wholeheartedly the opportunities offered by these methods of investigation for improving their own forecasts? There are a number of reasons, based partly upon misunderstanding of the methods and accomplishments of objective forecasting, but based more largely on the limitations of objective forecasting under the present organization of forecasting services.

One criticism often made is that objective methods do not take account of all of the pertinent variables nor of all the characteristics of the weather situation which help in judging the weather to come. This deficiency is certainly true of most, if not all, of the systems which have been published, but it is less a criticism of objective forecasting as such than it is an admission that items are used in forecasting which the forecaster cannot express objectively or quantitatively. The extent to which present forecasting knowledge is real knowledge as distinct from lore may be judged in part by the extent to which forecasters have been able to incorporate it into objective systems or have been able to write it down in a form which can readily be taught to students of forecasting. It is one of the goals of objective forecasting studies to collect and systematize this knowledge so it will be available for study and subsequent use by any forecaster, but major problems are encountered at this point. Even a relatively inexperienced forecaster has an ability to find in a given weather situation features which appear to be significant for the forecast, but which are extremely difficult to express in any objective way. Methods must be devised to take into account these more tenuous concepts and features of the atmosphere and to separate the real relationships from the fictitious.

The time required to work out a forecast by objective techniques is a limitation on the use of such techniques in many offices. The organization of forecasting services is generally centralized to reduce the work of plotting and analyzing the numerous maps and charts required for forecasting and to make it possible to utilize the best forecasters to cover the widest possible area. This generally results in the forecaster's being faced with tight schedules and gives him a totally inadequate amount of time to spend in actual preparation of the forecast. In spite of the success of simplified objective methods in equalling the accuracy of conventional forecasting procedures, it is suspected that forecasts which are improved to any great extent over present levels of accuracy will be produced, for the most part, only by methods which require a longer time to apply and which, therefore, cannot conveniently be used by forecasters at present.

One characteristic requirement of present-day forecasts which are issued to the public is that a definite bias must frequently be introduced into the forecast, or in other words, the forecaster must not state exactly what he thinks is most likely to happen. For example, the bare mention of rainfall in a public forecast will often be construed by the public as a forecast of rain no matter how the forecaster qualifies the statement. If the occurrence or nonoccurrence of rain is an un-

usually important matter because of previous extremely wet weather or extremely dry weather or because of an approaching national holiday, the forecaster will have to reach a decision not alone on the basis of the probability of occurrence of rain but in large measure on the anticipated public reaction to a rain (or no-rain) forecast. This type of situation is well typified in Gulf and Atlantic coastal areas when a hurricane is approaching. An objective forecasting system obviously cannot take into account these nonmeteorological factors. However, progress toward a rational solution from the standpoint of meteorology has been made by expressing the objective forecast in terms of the probability of occurrence of the specified event.

Another serious deficiency of objective forecasting systems which have been developed thus far is that the selected weather element is forecast only for individual times and places. Aviation forecasts in particular must usually cover a route of hundreds or perhaps thousands of miles, and forecasts generally must portray the expected weather trends through time intervals up to several days. These requirements impose a severe limitation on the extent to which objective forecasts have been applicable, although some progress has been made in solving this problem. New developments in the field of air traffic control suggest that probability forecasts may eventually be required for essentially all aviation purposes.

TYPES OF OBJECTIVE FORECASTS

A review of the literature on forecasting suggests three different methods of approach to the development of systems of objective forecasting. Although it is the purpose of this paper to discuss only one of these approaches, the other two are mentioned briefly in order to indicate in what way they offer the possibility of improved forecasts.

Numerical Calculation. The method of numerical calculation which was first attempted by Richardson [19] has recently become of practical importance through the work of Charney and Eliassen [6] and the development of high-speed electronic computers. This method of producing a forecast, based solely on the solution of simplified equations of the atmosphere, showed little promise of practical value so long as hand computation was required to obtain the solution. The value of the equations of motion for applied forecasting was limited to their ability to suggest variables which might then be found, empirically, to be of forecasting significance. The possibility now exists, however, that a prediction of the contour pattern at an upper level can be completed by a high-speed computer in time to be of use in preparing the weather forecast. This development requires careful consideration by those engaged in research on objective forecasting to insure that the information in such prognostic contour charts can be fully incorporated in objective techniques for preparing the weather forecast. Relatively little work has been done on the use of prognostic charts, and few forecasting systems can be evaluated in a way that would show the increase in accuracy to be had with a perfect prognostic chart or that give any hint of the possibility of using information from a prognostic chart in preparing the forecast. Studies of this kind have been made by Mook and Price [13] and by Klein [11].

Statistical Methods. Although all forecasting except that done by numerical calculation is in reality based on the statistical processing of data, there are differences in the extent to which a logical foundation of meteorological and physical principles is built up prior to the application of statistics. One possibility is to use statistical methods exclusively in the search for variables, retaining for prediction purposes only those variables which have a statistically significant relation to the element being forecast. In the field of long-range forecasting particularly, this approach has been appealing and to some extent perhaps necessary because of the absence of enough knowledge of the causes of long-term fluctuations in the general circulation to provide a useful mathematical-physical foundation. Among those leading in such studies have been Walker and Bliss (for a critique and bibliography of Walker's work up to 1936, see [16]).

More recently in the field of short-range forecasting, the statistical approach has been investigated at some length by Schumann [21] and Wadsworth [28]. Meteorologists have criticized this type of study on the basis that the statistical selection of variables for prediction without resort to prior meteorological knowledge is basically unsound [23], and this has led in some cases to rather sharp differences of opinion between meteorologists and statisticians. Sutcliffe, for example, takes the extreme view that meteorologists, by developing a physical foundation for all relationships used in forecasting, should drive statisticians out of meteorology. On the other hand, Professor Norbert Wiener discusses this question in an unpublished note [29], in which he points out that in meteorology the role of dynamics is to suggest what quantities one should expect to find interrelated, and that the role of statistics is to verify the correctness of the dynamics. Although this may be a somewhat oversimplified statement of the situation, it seems clear that any meteorological hypothesis which is claimed to be of use in forecasting must be tested statistically before its value will have been demonstrated, even though it may express a theoretical relationship based on what seem to be reasonable assumptions. Conversely, of course, relationships which are derived solely from empirical considerations, even though supported by a large number of cases, cannot be safely adopted as real (*i.e.*, practically certain to exist in future data) unless they can be shown to have a rational physical basis.

To the extent that the goal of a study is to increase the accuracy of forecasts, the proof of success will rest in the verification of the forecasts, and this is largely a statistical matter. In order that the interplay between the physical and statistical approaches can be effective, somewhat greater recognition needs to be given to the place of modern statistical methods in meteorology. At the same time, it must be recognized that statistical tools, for example, correlation or regression, can easily

be misinterpreted if the user is unfamiliar with their purpose or if he tends to rush into a statistical treatment without first considering the meteorology of the situation [10, 18].

A report by Wadsworth [28] illustrates some of the recent work in statistical forecasting; but this subject is to receive a more complete treatment elsewhere.[1]

Combined Deductive-Empirical Methods. The method of numerical calculation has the disadvantage that it is difficult (*i.e.*, it requires a large number of calculations) to permit actual atmospheric data to determine the coefficients of the forecasting equations used, and the equations which are presently available do not forecast the final weather elements. Other theoretical approaches to forecasting often are of little immediate value to forecasters because the application of the new concepts and new principles which result is not a straightforward procedure. The forecaster finds that he must expend considerable effort in applying the new principles to a variety of cases in order to learn what modifications to make and the conditions under which they apply. This situation appears to result in a gap between the development of new dynamic techniques and their application to routine forecasting practice.

On the other hand, statistical methods often depend too largely on empirical results and do not make adequate use of ideas which result from theoretical deductions. A new forecasting technique is required which will neither neglect the indications of theory nor require subjective interpretations and projections of weather maps and charts in order to arrive at a forecast. The methods of approach which have been under recent development in the United States will be described briefly in the following section. In this discussion, a distinction will be made between the terms "forecast method" and "forecast aid." The term "forecast method" will imply that the objective system produces a final forecast, and that in actual practice the forecaster should seldom if ever modify this forecast, no matter what he may feel about its chances for success. The term "forecast aid," on the other hand, will be used in the sense of a tool or an indication which the forecaster must consider and weigh subjectively with other available indications.

METHODS OF DERIVING OBJECTIVE FORECASTING AIDS

Specification of the Problem. A distinguishing characteristic of work which has been done on objective methods of forecasting is that the forecasting problem is attacked a little at a time. A problem is defined objectively by specifying a single weather element to be forecast, a single point or a specified set of points for which the forecast is to be made, and a single time or a time period to be covered by the forecast. The practical value of the result of the study depends in large part on the extent to which the specification of the problem meets practical forecasting requirements. The local forecast for a given city usually requires, for example, that the occurrence or nonoccurrence of precipitation be forecast by 12-hr periods or perhaps even by shorter periods. Thus an objective method which forecasts precipitation occurrence for a 24-hr period does not entirely meet the usual requirements, although it may nevertheless be of value in preparing a shorter-term forecast, and may be useful as a preliminary study. Limitation of the work to a single problem in this way is necessary in order that the weather element being forecast can be measured or objectively specified in some way. It imposes no limitation on the kinds of forecast problems that can be investigated, for the preparation of any type of forecast that can be objectively verified, such as area or route forecasts, cold-wave warnings, or the deepening of lows, can be studied by objective procedures.

Developing Hypotheses for Testing. The crux of the problem of increasing the accuracy of forecasts is that of discovering new and more exact relationships between observed parameters of the atmosphere and subsequent weather. The efficient application of such relationships to practical forecasting is the goal of objective forecasting, but without an underlying model of the atmosphere and its processes, based on the best available physical facts and theories, no amount of systematizing and testing will produce the desired results.

Numerous sources of ideas are available. In maximum-temperature forecasting, for example, equations are available for computing the effect of insolation on the maximum temperature [14] and, in theory, other effects can be evaluated. In practice, the most serious disturbing factors seem to be those for which quantitative data are scarce, such as albedo and outgoing long-wave radiation, or those which in turn depend on a forecast, such as cloud cover and temperature advection.

Recent developments in dynamic meteorology have provided new concepts which have not been adequately tested. Relationships involving wave length, zonal wind, and wave propagation in the upper air, and the various theories subsequently developed which have contributed to the understanding of large-scale phenomena in the atmosphere, need to be stated in ways that are amenable to objective evaluation in connection with short-range forecasting. This is the purpose of work begun recently at the University of Chicago, and a report on tropical cyclone forecasting [3] illustrates the method of attack. Such a report is only the beginning, however, and a large amount of work remains before the results can be objectively applied in forecasting.

A number of papers have been published within the last few years which describe forecasting studies wherein the ideas seem to have been only those suggested by a superficial study of the physical processes which are involved. A more logical approach has been initiated by the Honolulu office of the U. S. Weather Bureau, which, as a preliminary step in developing objective methods of rainfall forecasting, has prepared a lengthy report on the physical causes of rainfall on the Hawaiian Islands,

1. Consult "Application of Statistical Methods to Weather Forecasting" by G. P. Wadsworth, pp. 849–855 in this Compendium.

incorporating the ideas of all the forecasters as to basic causes or simultaneous relationships [26]. A study such as this is a major project in itself and is practicable only for a forecasting staff whose members are highly cooperative and willing to put aside work on other study projects to collaborate on an intensive study of a single weather element. The resulting report, aside from the immediate value which it may have for conventional forecasting techniques, furnishes a sound background of ideas for testing and development.

Another source of hypotheses which has not been sufficiently exploited is the "case study" approach. The preparation of "case books" consisting of detailed analyses of a number of individual weather situations such as cases of heavy snow at a city or in an area, or cold-wave cases, has sometimes been suggested as a useful aid for forecasting. Case studies alone may suggest *necessary* criteria, but further testing is necessary in order to establish sufficient criteria.

Testing Procedures. Although objective forecasting procedures are distinguished from conventional forecasting techniques chiefly by the fact that they are based on objectively expressed and tested ideas rather than on subjective and untested judgment, very little has been written about the testing procedures which are applicable. The reason for this appears to be the lack of any standard set of procedures which are sufficiently generalized that they can be advocated for use on all forecasting problems. A number of papers on objective forecasting have been published, most of them in the *Monthly Weather Review* since 1948, representing nearly as many different methods of procedure as there are papers. Other projects now under way will undoubtedly present improvements from the standpoint of more accurately representing the complex division of different weather types with which a forecaster must deal.

Brier [5] first presented a method of combining any number of meteorological variables by means of scatter diagrams to produce a weather forecast. The forecast can be expressed either in terms of the probability of occurrence of an event, or as a forecast of the magnitude of the weather element. The use of scatter diagrams in the search for forecasting relationships was not new, but Brier's study appears to be the first to combine a large number of variables into a simple forecasting procedure by this method. The use of scatter diagrams has since been widely adopted, and it has been a useful substitute for more rigorous methods of testing.

The statistical methods of correlation and regression are suitable for expressing forecasting relationships and testing the validity of those relationships if the assumptions which underlie their use are valid. Thus the relationship between temperature and predictors such as normal temperature, temperature of the approaching air mass, expected turbulence, and expected cloudiness may be expressed by a multiple regression equation. This is possible even if the relationships are nonlinear, provided the form of the relationship is known so that a transformation to a linear form can be made. If a long record of observations were available so that the present climatic era could be randomly sampled, valid tests of significance of the relationships could also be made.

For practical purposes, although rigorous statistical methods are useful in guiding the selection and processing of data, it is not often possible to make valid tests of significance, and the forecaster must depend upon an independent data sample to indicate the reliability of the forecasting relationship being tested. In investigations such as these, observational data may indicate how selected atmospheric events are interrelated, and thus stimulate the conception of new hypothetical relationships, or they may be used as evidence of the truth or falsity of a priori, objectively expressed hypotheses. In selecting data for testing purposes, the investigator must adopt the role of impartial umpire; otherwise he is likely to select or reject cases according to whether they do or do not support the relationship under test.

RECOMMENDATIONS FOR FUTURE RESEARCH

The development and use of objective forecasting methods encounters various unsolved problems such as inadequate data and insufficient time for the forecaster to work through the procedure. However, the basic problems which are encountered in common with any other method of forecasting are a lack of understanding of the physical processes in the atmosphere and an inability to apply to practical problems such knowledge as now exists. Most of the research in objective forecasting has been done by meteorologists whose primary interest is in forecasting and who feel the need for more systematic tools. Further progress could be expedited if a closer working relationship could be established between theoreticians and forecasters having an interest in the development of objective methods. As pointed out above, qualitative descriptions of how a forecaster can use the results of basic research are useful as a source of ideas, but assumptions must be made before the new parameters can be measured from observational data or from analyzed maps and expressed quantitatively, and the theoretician can best say which assumptions are most in accord with the theory.

Many of the objective forecasting methods developed in recent years make use of variables derived directly from station observations. The result is that changes in station location or the discontinuance of a station may invalidate a method until it can be tested by using a substitute variable. Claims have sometimes been made that the methods are more accurate when station data rather than values interpolated from analyzed maps are used. This subject needs more investigation, for if the claims are valid, it follows that administrators should be more slow to move or to discontinue stations, and further that much of the emphasis on centralized, accurate analysis is misplaced. The success of some of the objective methods which use station data is so great that this point cannot be lightly dismissed.

Graphical techniques such as the scatter-diagram technique used in searching for and testing relationships are unsatisfactory in spite of their success, because

of the considerable amount of subjectivity that may appear in the graphical analysis. More rigorous methods are needed, although it must be noted that difficulties seem to arise only when scatter diagrams are analyzed with too few data, or when there is no rational physical model underlying the selection of variables and the pattern of isograms drawn on the scatter diagram.

In spite of these difficulties, the methods illustrated in recent literature have had a rather astonishing success in producing useful forecasts, and it can be recommended that more forecasters attempt such investigations of their own local forecasting problems.

GENERAL ASPECTS OF EXTENDED-RANGE FORECASTING

By JEROME NAMIAS

U. S. Weather Bureau, Washington, D. C.

Absolute definition of the term "extended-range forecasting" is not possible and probably will not be for many years. As understood today it vaguely refers to those predictions which go beyond the limit imposed by ordinary standardized forecast techniques. The latter forecasts, disseminated by meteorological services the world over, generally cover periods of 24, 36, or at most 48 hr. With this in mind, "extended-range forecasting" presumably embraces any atmospheric prediction involving any time period beyond 48 hr and up to the geological epochs including the ice ages. The field of extended-range forecasting thereby becomes most inviting to people both within and without professional meteorology, particularly in view of the tremendous potentialities it offers in the direction of improving the lot of man.

Considering the extent and complexities of the problems posed by the vast spectrum of long-range weather forecasts, meteorologists have made small and slow progress. This spectrum may be divided arbitrarily into the broad bands: medium range (covering periods from three or four days to a week), monthly, seasonal, annual, decennial, centurial, and so on to millennial.

In spite of the fact that many workers have spent arduous years attempting to find solutions applicable to these periods, no system has evolved which even remotely approaches reliability. Unfortunately, the same comment can be made in regard to the short-range forecasts covering as little as 24 hr in advance. This sad state of affairs reflects the lack of basic knowledge of the workings of the atmosphere and points up the need for periods of stocktaking as exemplified by this Compendium.

But if objectives appear distant, it does not mean that progress has not been made. Indeed, medium-range forecasts covering periods from a few days to a week are already proving economically valuable in many countries. Forecasts of general weather conditions for periods a month in advance have shown promise. There are even some optimistic meteorologists who believe that seasonal, annual, or even decennial forecasts of some degree of reliability may be possible in the not-too-distant future. For the most part, this optimism cannot be traced to statistically significant results in the prediction of weather phenomena. If we look at the problem through the harshly revealing magnifying glass of statistics, it appears that, of the spectrum of extended-range forecasts cited, only the medium-range and perhaps monthly forecasts have demonstrated some degree of skill. The term skill is used here in its rigid statistical sense, that is, that the predictions are correct more often than are predictions made from many years of climatic records, or that forecasts must in the long run show a higher proportion of successes than the climatic probability of occurrence of the event being forecast.

The use of this yardstick makes it possible to restrict this article to only those two forms of extended-range forecasting, medium range and monthly, which in the knowledge of the author have met this criterion over a period sufficiently long to be considered significant. It must be admitted that this manner of selection may be somewhat unfair to those who claim ability to forecast for decades, centuries, and longer, for adequate meteorological records are as yet unavailable to verify these predictions.

THE MEDIUM-RANGE FORECAST PROBLEM

The historical development of modern short-range weather forecasting has been essentially inductive in nature. A multitude of observations taken at small space and time intervals are organized into an analysis designed to give physical meaning to the observations. This analysis is then compared with earlier analyses, generally in order to ascertain changes in circulation and weather over larger intervals of time and space, and by this method, essentially kinematic, a prediction is made possible. To the extent that the weather is determined by features of the weather map of roughly the dimensions of the cyclone and the anticyclone, the forecasts are successful. But the day-to-day movement of cyclones and anticyclones is often of roughly the same order of magnitude as their dimensions (their diameters). This rapid motion of weather systems, often coupled with erratic path, speed, and development, points up the difficulty of attempting to make forecasts for more than a day or two by using standard forecast methods which still rely, for the greatest part, on methods of interpolation and extrapolation.

Perhaps the first real forward step in crystallizing the problem of extended-range forecasting came with the discovery of the great "centers of action"—a term first applied by L. Teisserenc de Bort. These centers are brought to light by the statistical averaging of daily pressure maps during one month (or season) for many years. But if the averaging is carried out only for one month of one year (or even for only one week), one also obtains clear-cut large-scale features of the general circulation usually many times the size of ordinary migratory cyclones and anticyclones of the weather map. Since the time of Teisserenc de Bort (1855–1913) it has been recognized that it is the position and intensity of these centers of action that govern, or at least are associated with, the longer-period characteristics of the weather. The use of "govern" has been and still is objectionable to that diminishing group of meteorologists who view the centers of action only as a statistical average of randomly behaving cyclones and anticy-

clones which for certain periods happen to find some favorite life history and path.

In later years fresh emphasis on the importance of the centers of action in governing general weather conditions for long periods was afforded by Baur, whose work forms the basis for another article on extended-range forecasting elsewhere in this volume.[1] Baur recognized certain broad-scale (macroscopic) features of the general circulation which were effective in "steering" the individual cyclones and anticyclones along fairly well determined paths. He referred to these as *Grosswetterlagen*, a term now known the world over as denoting the broadscale weather situation as distinct from the day-to-day snapshot of the weather map. Moreover, it was Baur who was largely instrumental in associating the large-scale weather situation observed at the surface with the flow patterns in the middle and high troposphere and in ascribing to this latter flow pattern the property of steering. Contemporaneously, the Russian meteorologist, V. P. B. Multanovsky, had also discovered rather indirectly the large-scale weather situation in "natural periods." During these periods cyclones and anticyclones tend to follow in much the same tracks as their predecessors, that is, a series of cyclones (or anticyclones) during a natural period appear to move within a restricted region.

The work of these two investigators was certainly not unique in the meteorological world, for there may be found in the literature of the past half century considerable evidence that many weather forecasters had been toying with these ideas. But Multanovsky and, particularly, Baur became the most persistent advocates of the large-scale approach.

Despite the fact that the concept of *Grosswetterlagen* enjoyed increasing attention prior to World War II, no one had succeeded in developing a technique for predicting the strange and different large-scale weather situations which unquestionably showed up in the form of the natural periods of Multanovsky, in the steering patterns of Baur, or in the multitudinous systems of map typing proposed by various groups throughout the world.

Indeed it was not until the late 1930's that a physical theory of the evolution of different forms and positions of the great centers of action was proposed. This appeared in two papers: one by C.-G. Rossby and collaborators, "Relations between Variations in the Intensity of the Zonal Circulation and the Displacement of the Semi-Permanent Centers of Action" [17], and another by J. Bjerknes, "The Theory of Extratropical Cyclone Formation" [3]. From these epoch-making papers and considerable subsequent work, particularly by the American school of meteorologists, it has become increasingly clear that while earlier investigators were correct in stressing the broad-scale aspects of long-range forecasting, *the problem probably involves an even larger scale than they had assumed*, perhaps world-wide interactions. The recognition of the global nature of the problem arose essentially from two facts which in the past ten years have been documented with considerable empirical evidence: (1) that the behavior of any center of action depends upon that of others in the same hemisphere, regardless of how remote; and (2) that the speed of propagation of planetary wave energy from one system to another often takes place at a rate appreciably greater than the actual speed of the air particles in any observable atmospheric layer. The credit for the first discovery belongs largely to Rossby as indicated in his 1939 article [17] and in subsequent papers. To him also belongs much of the credit for proposing on theoretical grounds the second atmospheric characteristic of "dispersion," although this had been discovered earlier in forecasting practice by the author [14].

To the knowledge of the present writer there exists only one method of attack, to be described later, which utilizes directly these two concepts through the medium of hemispheric surface and upper-level charts. This method, first practiced in the United States, is now gaining ground in certain European countries, and during the past twelve years hundreds of related papers have appeared, some of which are summarized elsewhere in this Compendium (*e.g.*, see articles dealing with the general circulation).

Yet it must not be assumed that this vast research has led to amazing success in the prognostication of weather for long periods. To be sure, prediction is the ultimate goal here just as it is in all sciences. The point is that these global methods for the first time enable us to explain on a rational physical basis the evolution of large-scale weather types (*Grosswetterlagen*). The degree to which this "explanation" can be expressed in quantitative terms will determine the predictive skill of the method.

Once the two phenomena, hemispheric teleconnection of the centers of action and the dispersive character of planetary atmospheric waves, are recognized as facts, it becomes obvious that any system of extended-range forecasting based solely upon the data for a limited area of the hemisphere is bound to have imperfections. The degree of imperfection will presumably increase as the area considered in preparing the prediction is diminished. For this reason certain forecasting methods to be described and compared suffer inherent difficulties which place upon their maximum possible degree of skill a ceiling which is well removed from perfection. Among the methods to which these restrictions particularly apply are those involving symmetry points, singularities, regional weather types, and trends (kinematics).

The foregoing paragraph is not meant to indicate that these methods are of no value. Indeed, in our present imperfect state of knowledge of extended-range forecasting these tools, used judiciously, can assist materially in obtaining forecasts of some degree of skill. But these tools in themselves, without consideration of interhemispheric reactions, can hardly be expected to raise forecasting skill to a satisfactory level.

METHODS OF MEDIUM-RANGE FORECASTING

Statistical Methods. Inasmuch as the physics of large-scale weather phenomena has been so imperfectly understood during the past half century, it seems natural that purely statistical approaches to the problem would be taken. These approaches have been many and varied. Some of them have been conducted with indiscriminate use of the correlation technique in the pious hope that the atmosphere would "speak for itself" and thus relieve man of the apparently superhuman task of working out its physical behavior. For the most part such hopes have been consistently thwarted by an atmosphere which apparently resists such crude forms of regimentation represented by the strait-jacket technique of simple lag correlation.

Other statistical, or chiefly statistical, techniques which possess some background of physical reasoning have enjoyed more success. Among the most widely known and practiced of these, and those to which we shall refer, are methods involving trends, singularities, symmetry points, weather types, and weather analogues. A brief (though necessarily incomplete) description of each of these methods will be given, followed by an attempt to evaluate and compare the various methods.

Longer-period trends seem to infiltrate many systems of extended-range forecasting. In their simplest form, it is the purpose of these methods to estimate the rate of change of a state of the general circulation, regionally or for several regions, and from this rate and the initial state to extrapolate the circulation for desired periods of time. Precisely this sort of thing forms the basis of perhaps 80 per cent of short-range forecasts that are issued today. The problem has been rendered more tractable in short-range than in extended-range forecasting by kinematic methods applied by Petterssen [16] and others, and more recently by the simple expedient of preparing synoptic charts every three or six hours. In this manner the tendencies are easily deduced and from these and from the continuity, extrapolations are easily made.

In extended-range forecasting, however, one is faced with the questions, first, What *is* the initial state of the large-scale circulation? and second, What is the tendency interval desired? Various methods have been proposed for determining the initial large-scale state of the circulation. All of these essentially involve some form of smoothing, the effect of which is to damp out the smaller-scale and presumably secondary irregularities of the circulation, chiefly migratory cyclones and anticyclones, and thereby bring into focus the great centers of action. Thus the Russian school plots composite charts on which are indicated singular features of the surface pressure distribution, particularly cyclones, anticyclones, ridges, troughs, etc., for certain "natural periods" during which the locations and tracks of these features are similar [15]. The areas persistently occupied or invaded by anticyclones or cyclones thereby become clear, and the composite chart gives a good clue to the dominating centers of action. In the U. S. Weather Bureau the smoothing is achieved by the procedure of averaging over intervals of time. In this manner five-day (or other period) means are prepared by averaging the pressures (or temperatures) interpolated from a grid of latitude and longitude intersections from twice-daily Northern Hemisphere charts at sea level and aloft. When isolines are drawn to these values, smooth patterns appear which usually leave no question as to the position and intensity of the centers of action. Other methods of smoothing are also possible and it may be that a simple arithmetic mean is not the best for the purposes of extended-range forecasting. Further research along these lines would appear to be desirable.

Of late some have advocated that a sufficient degree of smoothing for ordinary medium-range forecasting work is achieved by merely resorting to charts for higher elevations, perhaps 10 to 13 km. While it cannot be denied that these charts appear simpler in form than those in the lowest layers of the troposphere (except at low latitudes), there is some question as to what extent the greater simplicity arises from fewer and less accurate data which give freer rein to the analyst's imagination. Besides, the slow evolution so characteristic of means taken over longer time intervals is easily lost when each snapshot of the circulation at any level is inspected from day to day.

Having decided upon the initial state of the general circulation, the *Grosswetterlagen*, the next problem in the estimation of trends is to find the necessary "tendency interval" and methods of determining the tendency quantitatively. Here one rough method is to compare the last available daily chart with its preceding sequence, again using some integrating device like the mean or composite chart. The reason why such a method has some success in determining the trend of the large-scale features of the circulation is that there is appreciable serial correlation in meteorological data such as pressure. As a result, today's chart will bear a maximum resemblance to the mean chart whose period centers on the current day—provided the period of averaging is not too large. Thus the comparison of daily charts with mean charts may throw light on the larger-scale trends. Because of its subjective nature, this procedure is often not satisfactory and for this reason a more quantitative method of evaluating trends has been developed in the U. S. Weather Bureau. Inasmuch as this method is closely related to other statistical methods to be compared, and perhaps clarifies these methods, it will be described in some detail.

If we wish to treat the slow evolution of large-scale circulation patterns which, for example, appear at the 700-mb level, it would be helpful to be able to construct a tendency field to serve the same function as does the 3-hr tendency field of daily charts. The choice of a tendency interval, while somewhat arbitrary, must be small compared to the length of the period over which the means are taken and should preferably be centered around the mean. In the case of five-day means, for example, a tendency interval of two days might be a good choice. What is desired for each location, then, is the slope of a hypsogram representing a running five-

day mean of the 700-mb surface. The two-day tendency would then be the slope of the hypsogram from one day preceding to one day following the mean on the day the tendency was desired.

The use of the persistence correlation (or the short-range, 24-hr prognosis) makes it possible to estimate the values of the predictors for the tendency interval. The statistical method of doing this, described in more detail elsewhere [11], involves the computation of regression equations which express unknown (subsequent) values as a function of the last-known quantities and the normal values for the particular time and place. The basis of these computations rests in the observed approximately exponential behavior of the autocorrelation coefficient for pressure (and other continuous meteorological elements) as expressed by the equation:

$$r_n = r_1^n,$$

where r_1 is the simple linear one-day lag autocorrelation coefficient for the departure from normal of pressure, and n refers to the number of days between values being correlated. While r_1 varies with season, elevation, and geographical location, its value at mid-troposphere levels is surprisingly uniform (around 0.7). This uniformity makes tendency computations by this method practicable in routine forecasting procedure.

These height tendencies are computed for a desired grid of points, and from them a field of isallohypses (corresponding to isallobars) may be constructed. From the tendencies and mean contour fields it is possible to make kinematic computations of the movement and development of the principal singular features of the mean maps such as troughs, ridges, centers, and so on, for desired periods of time.

In short, the particular method just described, called the trend method, utilizes both the persistence of pressure and its tendency to be restored to certain normal values which vary from place to place and from month to month. It makes use of these two factors together with the past performance characteristics of the atmosphere in an attempt to evaluate longer-period trends of large-scale circulation features and results in tendency fields which apply to moving and developing centers of action. The use of climatological normals and extremes as a qualitative guide in projecting thickness patterns for extended-range forecasting work has recently been started by Sutcliffe and his colleagues in England [20]. It appears that the trend technique just described might be applied with advantage to thickness patterns as well as to contour patterns.

Another statistical method using a related technique is currently being used by German meteorologists. This method, credited to Baur, involves correlation tables. The ultimate purpose is to arrive at a forecast of the pressure distribution three days in advance. The method relies upon multiple correlations computed from a number of variables, important among which are the current day's pressure, pressure tendencies for different time periods, and the cloudiness. Tables giving the expected three-day changes in pressure are worked out for several stations in Europe. The grid of stations permits the construction of a prognostic chart of three-day isallobars. An attempt is then made to decide subjectively how the prognostic changes might come about from the initial state.

Clearly, this method has some features in common with the trend method of the U. S. Weather Bureau, described previously. The latest daily pressure and certain pressure tendencies used in the formulation of regression equations undoubtedly enter, though not necessarily explicitly, into both methods. But in the use of the multiple correlation technique it is of some importance to evaluate the contribution of each of the participating terms to the final correlation. To the knowledge of the present author, no figures on this point are available, and it seems quite possible, if not probable, that some of the terms used are not contributing to the goodness of the final correlation. The trend method, utilizing only autocorrelation and the normal restoring force, suffers from no such ambiguity. The contributions of its components are known through many statistical works [22]. Besides, the computed tendencies can be applied in an objective manner to the initial large-scale pressure patterns as reflected in the mean states.

Still another allied statistical procedure used in extended-range forecasting is the method of singularities. The primary contention of this method is that certain characteristic circulations and weather tend to recur in certain areas at almost the same time of the year, year in and year out. One might in this connection refer to the many papers of Schmauss (see, for example, [19]) which have appeared in German meteorological publications, and a summarization of some allied work by Brooks [4]. In the practical use of this method in the French Meteorological Service, normal curves of sea-level pressure for periods of five days are computed for a number of stations in Europe and the eastern Atlantic. In spite of the long periods of record from which they are constructed, these curves show certain irregular convolutions which are superimposed upon gradual seasonal trends. It is the contention of the followers of the school of singularities that many of these irregularities are genuine and would not be smoothed out by adding more years of record to the data. Hundreds of papers have appeared in the literature of the past twenty years in which attempts were made to endow these singularities with statistical significance. The arguments pro and con are still reverberating in the meteorological world, and in all probability it is safe to say that the last word on singularities has not been said nor will be for many years to come.

Returning to the practical use of the method, at least as the author saw it practiced in France, a plot is made of the observed five-day mean pressures for the past several months. This plot is made on a tissue and then superimposed on a normal curve with the same time scale. An approximate match is chosen chiefly by the positions of troughs and ridges in the curves, little consideration being given to amplitude or general mean level. In other words, parallelism is used as the principal indicator of singularity, and a slight sliding of the time scale generally becomes necessary to find the singu-

larities. Once the singularities have been determined, individual five-day mean curves are extrapolated more or less parallel to the normal curves (but the amplitudes may be suppressed or exaggerated according to the seasonal behavior relative to the normal). This procedure is followed for several points in Europe and the eastern Atlantic and results in the preparation of a five-day mean prognostic pressure-change chart which serves as an extended-range forecasting aid.

The similarity of this method to the trend method lies in the fact that it, too, makes some use of persistence and the normal. Persistence is incorporated by drawing and keeping the extrapolated five-day mean curves at the same general level (departure from normal) at which they have been operating. To the extent that singularities are real, the method also introduces the normal and its rate of change. It is difficult to compare trend and singularities methods as to efficacy, especially since one of them (singularities) is to a considerable extent subjective. At least it can be said that the trend method, aside from its greater objectivity, arrives at a method for predicting an orderly evolution of an existing large-scale state with a minimum of questionable basic assumptions.

Another statistical procedure—one concerning which considerable controversy has arisen—involves the concept of symmetry points. The strongest advocate of this method has been Weickmann who, along with his associates, has published many papers dealing with this subject (see, for example, [24, 25]). During World War II, investigations of the symmetry-point technique were made in Britain (*e.g.*, Walker [23] and the following discussion by C. E. P. Brooks, N. Carruthers, and others) and in the United States by Haurwitz [6]. Both of these groups could find little in the way of prognostic significance in the symmetry-point method. Their methods of testing undoubtedly involved the best available statistical procedures, and it would indeed be difficult to dispute the findings of these distinguished investigators who, while admitting the existence of symmetry points in meteorological data, could find no method of detecting them in advance. Presumably, if the faith of the users of this method is still unshattered, it is to be concluded that its use involves certain subjective elements which are as yet impossible to express quantitatively in a form suitable for testing.

In order to pursue this interesting topic further, it will be helpful to describe briefly the practical procedure currently being used by Weickmann's assistants working at Bad Kissingen. First, they work not with isolated points but with areas roughly 500-km square. The mean pressures of about ten stations in many such areas are plotted day-by-day in graphs. The graphs are then copied on transparent paper. By turning over the paper one obtains a mirror image and with the help of the original graphs tries to locate by inspection a point of symmetry. Cases of "inverted" symmetry, where the tissue must be folded along a horizontal line, are also sought. By working in this manner for several areas and then copying off portions of the observed curve as it would be reflected to produce the symmetry, an extrapolation of the pressure distribution into the future may be made.

Everyone must agree, along with Haurwitz, Brooks, and Carruthers, that symmetry points do exist in meteorological data. However, Baur [2], in a statistical study, claimed the existence of such symmetry can be entirely accounted for by the serial correlation (persistence) present in day-to-day pressures. To what extent symmetry points contain more information than a series of almost random data in which persistence operates is indeed a formidable question for its proponents.

On the other hand, no synoptic meteorologist who possesses the most fragmentary appreciation of art can deny that the flow patterns observed in mid-troposphere evolve in a manner suggestive of a vast attempt on the part of the atmosphere to arrange itself into symmetrical patterns. The currently popular concepts of the conservation of the total absolute vorticity about the vertical may be looked upon as nature's attempt to achieve symmetry. This attempt repeatedly shows up in the manner in which an upstream circulation subsequently becomes reflected some distance downstream in a manner suggestive of folding the zonal flow pattern along a meridian. The frequent failure of the atmosphere to achieve this symmetry in space is due to ever-present forces which work to destroy and change one portion of the pattern before there has been time for it to be reflected downstream.

The tendency toward symmetry described above applies to symmetry in space, whereas Weickmann's ideas are supposed to apply in time. Insofar as longitudinally symmetric patterns move steadily eastward or westward in an unchanging manner, they will produce symmetry of barograms. It may be that the method propounded by Weickmann is an attempt to capture the tendency toward spatial symmetry. If so, it would seem that it contains a germ of the truth, but this germ would be difficult to isolate in order to make diagnoses and prognoses.

Weather Type and Analogue Methods. The concepts of weather types and analogues probably arose very early in the history of meteorology. As with all systems of classification, the type method is designed to set up a certain partition of weather map sequences so that the differences between weather maps of one type are small compared to the differences between maps of different types. The work of Multanovsky [15] many years ago had indicated that the duration of a given type was not constant from year to year, and he referred to the particular length of operation of one sequence as the "natural period." But other typing systems have attempted to restrict the life history of a weather type to a certain number of days, it then being necessary for the type to change (or repeat) after this time interval. One such typing method is described at length elsewhere in this Compendium by one of the foremost exponents of the weather-type approach, R. D. Elliott.[2]

2. Consult "Extended-Range Forecasting by Weather Types" by R. D. Elliott, pp. 834–840.

The indefatigable work of Baur on the subject of types must also be mentioned, for he has probably done more work of this sort as it applies to European weather than anyone else [1]. For his types he has tabulated the seasonal frequency of occurrence, associated weather, and other statistics which are generally worked up by various typing schools.

Since both Baur and Elliott have articles describing their methods in this Compendium, we shall make only a few remarks on this general subject.

In the first place, the question of uniqueness of classification arises. Will two equally trained meteorologists give the same type designation to an observed sequence of maps, and furthermore, will they agree as to the dates of its beginning and termination? For the most prominent regional types it appears that there can be fairly good general agreement. However, there seem to be numerous "borderline" or transitional cases where there is disagreement. The dates of inception and termination of a type seem to be difficult to define. In the minds of some meteorologists, these difficulties have raised the question as to whether discrete types, with the necessary discontinuities between types, exist, or whether there is a more or less gradual transition between circulations. The final answer to this problem cannot yet be given. On the one hand the supporters of the type approach emphasize those periods in which a very rapid change of the circulation takes place and completely alters the weather regime in a short period of time, while its detractors point to many periods where the evolution of the general regional circulation is of a gradual nature for many weeks. Unquestionably the truth is composed of both these viewpoints.

When we come to the question of prognosis the lines become more sharply drawn. The exponents of weather types maintain that there exist methods of predicting the subsequent type. Statistical studies of the probability of one type following another and the relationship of subsequent types to the position and orientation of some center of action have been carried on for the purpose of prediction. Perhaps the safest method of prediction, though limited, is that used by the Multanovsky school—to wait until the first one or two days of a type have elapsed. By that time the type has been identified and one issues a forecast only for the remainder of the natural period during which the type exists. In the opinion of the present author, the weakest phase of the entire weather-type approach is the lack of any reliable methods of predicting what will be the coming type. This statement does not involve denial of the utility of weather types in diagnosis, or particularly in pedagogy, but it questions their utility for purposes of prognosis. This question was raised in the introduction to this article where the inadequacies of a regional approach, contrasted to a hemispherical approach, were cited.

The analogue method appears to crop up more or less periodically in the history of synoptic meteorology, showing perhaps a tendency to reach maximum popularity at the times of greatest stress (wartime). Wadsworth [22] was one of the principal exponents of this approach during World War II. The basic theory underlying it is entirely logical: If two maps or weather situations are found which are identical, then so are their physical properties, and therefore the subsequent evolution will be identical. Assuming no discontinuities in extraterrestrial influences, no one can take serious issue with this concept. The problem then resolves into one of finding the proper analogue in the archives of weather maps.

The proponents of the analogue method cite several advantages of its usage:

1. It is objective and does not rely upon complex and subtle reasoning inherent in physical methods which are far from perfected.
2. It is relatively fast in operation and forecasts can be turned out rapidly (indeed, analogues can now be selected by punch-card machinery).
3. Analogues automatically contain the climatological peculiarities of every location for which a forecast is required.

These three arguments are indeed potent and unquestionably have a strong appeal, particularly to administrative officials. To counter these arguments the opponents of the analogue technique point out the following:

For the analogue to be successful for a period of a few days or more the agreement between current and historical maps must be three-fold: (1) spatially similar for large areas covering a large portion of the hemisphere, (2) similar in the third dimension, and (3) similar in evolution. The necessity of considering large areas is a direct consequence of the rapid dispersion of planetary atmospheric waves indicated earlier. The other two considerations are obvious.

When these restrictions are placed upon the selection of an analogue it becomes virtually impossible to find a good one in the relatively limited archives of available weather maps. The very necessity of considering the upper-air flow patterns greatly shortens the available historical record. To this objection the proponents of the analogue method offer the rebuttal that it is possible to estimate with sufficient accuracy the appearance of the upper-air flow patterns from surface maps. They also maintain that while no analogies are ever complete, the discrepancies can be evaluated subjectively and allowance can be made for differences.

From the long-range view perhaps the most damaging blow to the analogue technique is that it is at best a substitute for understanding—and without understanding it is unlikely that meteorology can elevate itself above the low plateau of skill obtainable by analogue methods. Moreover, there is no evidence that this plateau is any higher than that of other more physical methods.

Physical Methods in the Circulation Prognosis. With the increase in upper-air data brought about largely by the progress in aviation there has come a better understanding of the general circulation. Of course the complete solution of the general circulation problem contains the key to long-range weather forecasting. Progress along these lines is described elsewhere in this

Compendium.[3,4] We shall refer to such studies only inasmuch as they have current and direct application.

The first milestone in the new aerological era was the increase of knowledge of the interrelationship between upper-level and sea-level circulations. Perhaps no one school of thought can be given principal credit for the discoveries, for many groups working along similar lines were converging to the truth. In this development, the centers of action observed at sea level became interrelated with the long waves in the middle and upper westerlies.

A clue that the movement and development of these upper waves might be predicted by physical methods was given by Rossby [17], who showed that such large-scale waves, when treated on the basis of conservation of the vertical component of total absolute vorticity, seemed to fit into a reasonable theory. This theory resulted in the now classical frequency equation from which is given the eastward speed c of a long wave in the upper tropospheric westerlies as a function of the zonal wind speed U, the wave length L, and the northward variation of the Coriolis parameter β:

$$c = U - \beta L^2/4\pi^2. \tag{1}$$

From this expression it develops that the stationary wave length L_s (*i.e.*, when $c = 0$) is a function only of U:

$$L_s = 2\pi\sqrt{U/\beta}. \tag{2}$$

In the practical application of this formula one is confronted first with the question of how the proper values of zonal speed U and the wave length L are to be computed. A great deal of work on these and other questions of application has been done at the U. S. Weather Bureau, and some of the more important results are described elsewhere in this Compendium.[4] These results, and indeed this entire article, should be considered a part of this treatment of extended-range forecasting. The principal results of these studies which relate primarily to the 700-mb level indicate that:

1. Zonal wind speeds for use in equation (1) are best obtained by computing the geostrophic wind in mid-troposphere averaged over large areas (perhaps of the order of 100° to 180° of longitude) for the latitude bands in which the waves are found. There may be, and usually are, two or more out-of-phase wave trains present in different latitude bands.

2. It is difficult to identify the primary long waves on a daily map because of the irregularities (small cyclone waves) embedded in the flow. The identification, as pointed out earlier, may be accomplished by some form of smoothing such as averaging over intervals of time, considering high tropospheric flow, or considering the patterns of isotherms associated with the contours. In the latter case those troughs and ridges in which isotherms and contours are definitely in phase are generally the primary long waves.

3. Equation (1) may then be applied by choosing a trough or ridge whose subsequent motion is desired and scaling off its distance from the next primary ridge or trough upstream.

When this is done for many cases it becomes clear that while there is reasonably good positive correlation between computed and observed values of c for periods up to three or four days, the computed motions generally give eastward speeds which are too small. For this reason empirical corrections must be developed for different areas and seasons as described elsewhere.[4] From such a coordination of theoretical and empirical data one may construct graphs (for different areas and seasons) which are useful in predicting the motion of long waves.

Another less restrictive method of using the vorticity principle in extended-range forecasting consists of constructing (on daily or mean charts) inertia trajectories based on the conservation of the vertical component of the total absolute vorticity. Here again, empirical, areal, and seasonal modifications are necessary for optimum success.

Both of the methods described above suffer from limitations imposed by the many assumptions underlying the development of the simplified vorticity equations. Among the most serious of these are perhaps the assumptions of no divergence, no solenoids, and no change in speed of air particles. It is indeed surprising that in spite of these and other restrictive assumptions, the waves behave in such good accordance with the theoretical-empirical formula. Part of this agreement must be ascribed to the quasi-barotropic nature of the atmosphere, and to fields of divergence which are normally operative in a fairly consistent manner within a given season over a given area.

However, the use of empirically derived wave-length formulas and constant vorticity trajectories leave numerous forecasting problems unsolved. One of the principal of these involves the development of new troughs and the disappearance of old ones. Wave-length expressions generally fail to distinguish between retrogression (westward motion of the long waves) and the possible development of a new trough which may increase the hemispheric wave number, thereby taking up the slack indicated by a wave length greater than the stationary wave length. On the other hand, computed vorticity trajectories may suggest a new trough development in an area currently occupied by a ridge or a flat westerly flow.

The problem of trough formation is closely allied with the process of "development" which has recently received considerable attention from British meteorologists, particularly Sutcliffe [20]. This approach makes considerable use of hemispheric thickness patterns for the layer 1000–500 mb. Naturally, these charts are similar to contour charts and thus bring to light the major long waves in the westerlies. Sutcliffe and his group attempt to apply wave-length concepts to them, at least qualitatively. But in addition, Sutcliffe has developed certain criteria for the deepening and filling of systems, formation of secondary disturbances, etc.,

3. Consult "The Physical Basis for the General Circulation" by V. P. Starr, pp. 541–550.

4. Consult "Observational Studies of General Circulation Patterns" by J. Namias and P. F. Clapp, pp. 551–567.

based upon the field of thermal vorticity indicated by the thickness lines. Further synoptic studies are being carried on by the British group to lend support to these criteria, and it seems possible that the vexing problems of trough development or disappearance may find partial solution in this work.

In the practical routine of extended-range forecasting in the U. S. Weather Bureau, the thermal field of the upper air is given careful consideration—not only in the thickness patterns themselves but also in charts showing departures from normal of both the thickness patterns and the temperatures at 700 mb. These thermal fields are also used as adjuncts in determining deepening or filling of individual long-wave systems.

These purely physical methods of prognosis are naturally far from perfected. For this reason it is necessary to use them in conjunction with the kinematic procedures described earlier. Just as with short-range forecasting, the evaluation of time derivatives becomes important. In a sense, to the extent that the tendencies are accurate, the kinematic methods represent an integration of physical processes. The arbitrary division into physical and kinematical tools is made only because it is possible to make partially successful extended-range forecasts with these kinematic methods even though the user has no idea of the physical processes involved.

Experience indicates that the highest skills are obtained by judicious combination of physical and kinematical tools. A specific example of such coordination may clarify this point. Let us say that there are two pronounced troughs in the upper-level westerlies whose wave length is about equal to the stationary wave length, but that the tendency fields suggest strongly that the troughs are spreading apart—perhaps the western one is retrograding while the eastern one is progressing eastward. Kinematic displacement computations would therefore suggest the incipience of a new trough, and the forecaster would be alerted to examine other evidence for further clues, such as computed vorticity paths, thermal fields, and cyclogenetic characteristics of the latest weather map.

The methods described above are meant to apply primarily to the construction of five-day (or longer-period) prognostic mean upper-level charts. From such upper-level prognoses the associated mean sea-level charts may be prepared by methods of differential analysis.

In the past ten years it has become increasingly clear to the author that *the most successful extended-range forecasting procedures must involve not only the current state (daily or mean) of the atmosphere, but also its manner and rate of evolution.* Methods of extended-range forecasting which do not incorporate in some manner the evolution must be very limited in scope and success.

Here we come to one of the principal dilemmas of the modern weather forecaster. How can he coordinate the tremendous mass of data in space and time necessary to incorporate evolution in a three-dimensional, globally interactive atmosphere? Yet he must do this to arrive at a regional prognosis which is internally consistent with other hemispheric features. The principal hope for the solution of this apparently superhuman task seems to lie in the development of new electronic high-speed computing machines from which may emerge at least a first approximation to the prediction.

THE RELATIONSHIP BETWEEN CIRCULATION AND WEATHER

The methods of prediction described above aim at forecasting features of the atmospheric circulation generally represented by pressure patterns at one or more levels. The tacit assumption is made that weather forecasts are by-products of the circulation prognosis. Precisely this assumption underlies the preparation and transmission of short-range prognoses as practiced around the world. While this assumption is to a considerable extent justified, controlled experiments indicate that even if forecasters were provided with perfect prognostic charts (analyses rather than prognoses) they would be unable to make perfect forecasts. In fact, in many situations forecasts of weather from such charts, whether a short- or long-range (mean) prognosis, leave much to be desired. For this reason it would appear that a disproportionate amount of research may be currently placed on improving circulation prognoses while very little is being done to interpret circulations in terms of associated weather.

This problem, equally important in longer-range work, appears to have received more attention than it has in short-range forecasting. For example, Baur [1] has made extensive statistical studies of the weather regimes associated with various large-scale circulation patterns over Europe, and similar studies for America have been carried on at the California Institute of Technology [5]. One of the most systematic studies relating pressure patterns to weather phenomena has been in progress for several years at the U. S. Weather Bureau. Here an attempt has been made to associate temperature anomalies and total precipitation observed over five-day and monthly periods to mean pressure patterns at sea level and, more especially, at 700 mb. The essence of the most promising methods for finding these relationships appears to lie primarily in the large-scale contour patterns of the lower troposphere.

Studies for different seasons and for many points over the United States indicate that regardless of how mean maps are made up (that is, the sequence and distribution of day-to-day patterns within the period), they determine to a large extent the average temperature and precipitation anomalies[5] for the period considered. This statement often comes as a surprise to many meteorologists in spite of the fact that it seems to have been recognized almost a century ago by the pioneers who discovered and studied the great centers of action. In part, the physical reality of the mean as it relates to average weather is due to the fact that events in time are serially correlated. Not only this persistence but

5. The term "anomaly," as used in this article, refers to departure from a long-term average over time and has nothing to do with the departures from means computed for latitude circles.

also a persistent recurrence of certain circulation types gives a decided character to both mean pressure patterns and associated weather phenomena. This relationship is rather fortunate in practical extended-range forecasting since it frees the forecaster from the seemingly hopeless task of giving a play-by-play description of the detail of the weather in order to make a statement of average conditions anticipated. Likewise the use of means makes it unnecessary to break up the period, if long, into a sequence of discrete types.

One rather simple technique of translating circulation patterns into weather anomalies consists of constructing isolines of departure from normal of the pressure or height. From the components of flow relative to normal, in conjunction with the distribution of normal surface isotherms or normal thickness charts of the lower troposphere, one can readily decide if a circulation is apt to bring warm or cold air to a locality and also get a rough measure of the degree of abnormality. Statistical refinements of this method as practiced in America and developed by Martin [9, 10] attempt to determine for various places and for different months the key regions where the anomaly of the contour pattern to a large extent governs the temperature anomaly. These studies bring into sharp focus the distant controls operating on apparently local weather. For example, for most stations in the eastern United States it turns out that surface temperature anomalies in winter are remarkably dependent upon the anomaly of 700-mb heights near southeastern Alaska! When the mid-tropospheric ridge in this area is strong (high positive anomaly) it sets in motion vast outbreaks of polar Canadian air which pour into eastern United States and produce low temperatures there. When the ridge is absent, a series of frontal waves move across the United States–Canadian border and a westerly flow of mild maritime Pacific air leads to warm weather over the east. These and other factors are now considered objectively so that it is possible to construct in a mechanical fashion the temperature anomaly anticipated with a given 700-mb pattern.

The relationship of precipitation to mean circulation is more difficult. Even here, however, a reasonable degree of success may be achieved by relating to the observed precipitation such factors as location and orientation of major trough and ridge systems of the mid-troposphere, anomalous components of wind, and curvature of isobars [7]. While a strictly objective method of doing this is obviously the goal, it appears to be difficult to design a system as effective as the objective temperature method.

When it comes to giving a day-by-day weather forecast beyond two or three days in advance, the current state of knowledge is indeed unsatisfactory. Most of the skill of extended-range forecasts appears to rest in the ability to predict general characteristics of a period and perhaps broad trends. The strain imposed by the requirement of a running description of detailed weather in temperate latitudes for, let us say, a week is much too great for all systems of extended-range forecasting developed so far. Consequently, the degree of skill when verified on a day-by-day basis falls off rapidly after two or three days. However, there is some encouragement in the fact that even on the sixth day some forecasts have demonstrated slightly greater success than climatological probabilities. But such forecasts can hardly be used to plan a picnic.

Despite this low level of skill an attempt is generally made to specify day-to-day conditions through the medium of the prognostic chart. In the U. S. Weather Bureau, prognostic charts for six days in advance are prepared—not with the belief that they possess striking accuracy, but rather with a view of expressing the anticipated general lines of air-mass, frontal, cyclonic, and anticyclonic activity. The prognoses elucidate further the anticipated mean state of the circulation and serve as a guide to general trends in temperature, rainfall, wind, etc. The charts are drawn by considering the mean prognosis and its steering influence, and are naturally constructed so as to be logically continuous with the short-range (*i.e.*, 30-hr) prognosis. Obviously, a healthy, vivid imagination and a firm hand on the part of the forecaster are helpful.

A more objective method of preparing such day-to-day prognoses for periods of a week or so in advance is supplied by the analogue method, for here, once the analogous period is decided upon, one can substitute (perhaps with small modification) observed maps for prognostic maps. The advantage of greater objectivity, while desirable and appealing, is unfortunately largely offset by inability to find in the archives of maps proper analogues, not only before the events, but many times even after the period is over.

Within the past few years the prognosis of mid-troposphere flow patterns for 48 or 72 hr in advance has become increasingly popular and these charts offer a starting point for a more extended prognosis. The methods for constructing these prognoses are for the most part those briefly discussed under physical methods, and involve discriminating use of vorticity principles, thermal fields, warm and cold advection, and kinematic (generally pressure-change) methods. As in the mean-map technique, there appears to be no especial reason why the forecast must be made in steps of 24-hr intervals. It would appear that synoptic meteorologists have too long considered the unit of 24 hr as mandatory in the preparation of a series of charts. The theory underlying modern extended-range forecast techniques is that the forecaster strikes out for a general state expected to be observed well ahead of 24 hr and then proceeds to determine how this general state will evolve. Experienced forecasters of all countries who have tried the step-by-step or extrapolation method of extended-range forecasting have long ago recognized that this method breaks down after about 48 hr. Probably the reason for this breakdown lies in the inability of man's brain to cope with the increasing complexity of atmospheric interactions. If and when electronic machines are used to grind out a reasonably good 24-hr mid-troposphere prognosis, meteorologists will have a good way of determining how far the step-by-step method of long-range prognosis can proceed.

THE EXTENSION OF FORECASTS TO LONGER PERIODS

The basis of the preparation of most medium-range forecasts is essentially synoptic in nature, although there is a substantially greater infiltration of statistical treatment than in short-range forecasting. As longer periods are considered, there appears to be greater and greater reliance upon statistical techniques at the expense of synoptic techniques. Yet the possible extension of synoptic techniques to forecasting problems for periods longer than a week has been explored very little. In view of the fact that some statistically significant success has been achieved in applying synoptic methods to monthly mean maps (described below) it would appear that meteorologists, particularly dynamic meteorologists, might be able to make rewarding contributions by directing some of their efforts to this problem.

As stated earlier, this article is concerned only with those long-range forecasting methods which can demonstrate skill in the rigid statistical sense over reasonably long periods of time. This means consistently predicting occurrences with greater success than the climatic probabilities. This criterion, while harsh, is after all the only rigid means of differentiating between a successfully operating forecasting method and a theory. When the field of long-range forecasting methods is scanned through this revealing eyepiece, there appears surprisingly little that can be discussed. In part, this reflects the unavailability of rigid statistical verifications of forecasts, but more probably it indicates the overwhelming complexity of the long-range forecast problem.

Public claims of success in long-range forecasting should be backed by statistically sound verification. It is high time that professional societies bring the spotlight upon those whose claims cannot be substantiated. Meteorology, no less than medicine, can ill afford to harbor quacks. This is not meant to detract from the painstaking work of those who have spent years, if not decades, in the quest for forecasting tools. Their work must be judged on other grounds than its immediate application to forecasting problems.

Before closing this article the author feels compelled to dwell a bit further on the question of the extension of synoptic-statistical techniques to longer-range forecasting. In 1942 he began an experiment in the preparation of thirty-day forecasts, the aim of which was to explore the possibility of extending mean circulation methods then used in five-day forecasting to monthly periods. Of course, it was soon recognized that the normal state of the circulation and its rate of change become increasingly important in such work. In essence the problem was found to be similar to the shorter (five-day) problem. At the start two highly pertinent questions arose:

1. Do the thirty-day mean circulation patterns determine the average weather conditions (anomalies) for the month? The answer is an unqualified yes. The scientific basis for this answer has been briefly discussed and is expanded upon elsewhere [7, 10, 13].

2. Is there a rational continuity to the great centers of action when treated on a thirty-day mean basis? Here again, experience gained during the last decade, in part reported on in the literature [8, 12, 13], indicates that there is a rational continuity when thirty-day charts are studied carefully with the aid of kinematical and physical techniques. This continuity is discussed twice monthly in a routine fashion by workers in the Extended Forecast Section of the U. S. Weather Bureau with as much conviction as are the movements of cyclones and anticyclones at daily map discussions.

The detailed method for projecting the centers of action into the future of the next thirty days is naturally too involved to be discussed here, but its basis may be briefly stated this way:

1. The past and current rate of evolution of mid-tropospheric flow patterns is assessed with the aid of the tendency method described earlier. These methods automatically introduce the effect of normals changing with time.

2. After kinematic displacements of the major features of the patterns (ridges, troughs, and centers) are made, it must be decided if these kinematic displacements are in harmony with vorticity (thus wave-length) principles. In other words, within certain speeds of the mid-troposphere westerlies the atmosphere prefers a certain spacing between ridges and troughs. If kinematically computed displacements introduce no severe contradictions into these physically harmonious upper-air patterns, the forecast is relatively straightforward. If contradictions arise—as is often the case—certain large-scale features, whose immediate behavior is more clearly outlined in their profiles and tendency fields, must be chosen as anchor points and the adjacent portions of the forecast molded into harmony with these.

Meteorologists can, and usually do, immediately raise embarrassing questions regarding this technique. In the first place, what reasons are there for applying physical reasoning (vorticity principles), designed essentially for instantaneous daily maps, to maps covering periods as long as thirty days? No satisfactory answer to this question can be given at present. However, it should be emphasized that the thirty-day mean is not composed of randomly distributed data. The daily circulations of which it is composed are themselves serially correlated and, moreover, during one month there are generally repetitive circulation types. Thus in a given area a circulation, which on a daily map introduces a certain field of vorticity attempting to modify its surroundings, recurs again and again during the month to perform a similar modifying function. Is it surprising, then, that when the mean chart is considered from a vorticity standpoint it, too, seems to behave as a physical entity? Another consideration involves an analogy to the statistical theory of turbulence. Here the equations of motion for laminar flow can be applied to an average fluid flow on which are superimposed random eddies, provided certain frictional stress terms are added. In the work with thirty-day means, these additional terms are, of course, not evaluated or known, but their omission may not be as serious as at first thought. It should be pointed out that they are

also omitted in working with daily charts which, in reality, are also mean charts, but for brief time intervals.

But these arguments can be of little avail until definite solutions, theoretical or empirical, are found. Ultimately empiricism and theory must converge to truth. It seems probable that in long-range forecasting, as in hydrodynamics, the most rewarding line of attack will be a happy combination of theory and empiricism.

By way of stimulating dynamic meteorologists to study the problem of evolution of mean states of the general circulation over periods as long as a month, the author desires to point out some indicative results of a statistical verification of thirty-day forecasts made twice monthly during the past five years and summarized by seasons.

1. The average correlation coefficients between forecast and observed patterns of *anomalies* of the mean monthly 700-mb contours have been positive during 19 out of 20 seasons over North America.

2. The forecasts of monthly temperature anomaly over the United States (verified at 100 points) have been superior to climatological probability forecasts for 19 out of 20 seasons.

3. The forecasts of total monthly precipitation over the United States (verified at 100 points) have been superior to climatological probability forecasts during 17 out of 20 seasons.

THE COURSE AHEAD

Viewed pessimistically, the present status of extended-range weather forecasting may appear to be hopelessly distant from perfection. It is in part this attitude which leads to the quest for stop-gap solutions. From the optimistic viewpoint, it appears that during the last decade notable advances have been made in understanding as well as in forecasting the general circulation and its weather. These advances lie principally in interrelations between the great centers of action and have been made largely through study of mid-tropospheric patterns. This progress holds out the hope that forecast skill may be on the lower branch of an exponentially increasing curve which may subsequently turn into an asymptotic approach to perfection.

Indeed, the problem of extended-range forecasting may be looked upon as the ultimate test of a complete theory of the general circulation. For this reason remarks made elsewhere in this Compendium pertaining to the avenues of improvement of knowledge of the general circulation are directly applicable to the subject of improvement in extended-range forecasting.

In addition to completing basic studies, meteorologists the world over would do well to improve the position of extended-range forecasting by consolidating their gains of the past score of years. Along this line, it would be desirable for those engaged in forecasting practice or research to make a greater effort to study and apply methods developed in other countries and to relate them to locally practiced techniques. This is a plea for greater international collaboration.

Another less basic but highly practical problem is a better method of representation of the tremendous wealth of data apparently necessary to make long-range forecasts. Similar questions involving time and space derivatives also arise in short-range forecasting.

Perhaps a healthier state of cooperation more conducive to progress could be developed between the so-called dynamic meteorologists and the practicing forecasters and empirical researchers. The ultimate goal of these groups is essentially the same—prediction, or understanding which leads to prediction. For this reason it is hard to reconcile attitudes of some dynamic meteorologists that application (*i.e.*, forecasting) is not their concern and that empirical, including statistical, knowledge is of little relevance if it does not fit certain classical concepts. Likewise, it is equally difficult to understand the philosophy of that group of practicing forecasters who look upon all theoretical work as completely removed from everyday problems of weather forecasting.

Given a prevailingly peaceful state of world affairs permitting international collaboration, the outlook for long-range weather forecasting appears bright. In the opinion of the author, an incurable optimist, not only an increase in accuracy but also in the time range of general forecasts is probable. Forecasts for at least a season in advance and possibly a decade are within the grasp of the present generation.

EXTENDED-RANGE WEATHER FORECASTING*

By FRANZ BAUR

University of Frankfurt am Main

SCIENTIFIC BASES OF EXTENDED-RANGE WEATHER FORECASTING

The Basic Problems of Macrometeorology. *The First Basic Problem.* Macrometeorology forms the scientific basis for extended-range forecasting. The first basic problem of this new branch of meteorology is whether or not a real *Grosswetter* exists at all. In other words, can the observed longer periods of persistent cold or warm, dry or wet weather be attributed to some major variable influences, or are they merely the consequence of the so-called "persistence tendency" in connection with random developments and the annual variation of meteorological elements? Among the older school of meteorologists, there are, at least in Europe, those who are convinced that *Grosswetter* takes its course according to the principle: "small causes, large effects." They try, for instance, to explain the development of a severe winter by the fact that clearing takes place at the beginning of the winter after the first widespread snowstorm, thus causing the temperature to drop considerably. Hence the cold air is "maintained" so that with the next upgliding of warm air, a new snowfall will occur and thus the wintry cold will gradually be amplified.

Their reasoning is as follows: If it had "accidentally" been just two degrees warmer on that first day of winter, there would have been rain instead of snow. Thus the radiative heat loss during the following night would not have been so great. Less cold air would have formed and, finally, the winter would have been less severe. However, the following reasoning can likewise be applied to this case: During every winter in the temperate zone, there will be one case of clearing after a snowstorm. Whether the winter following a snowfall with subsequent clearing will, in the long run, turn out to be severe or mild depends on whether the probability of the occurrence of cold days is larger or smaller than normal as a consequence of governing influences. If there should be a severe cold wave, there are nevertheless sufficient possibilities for the cold to recede after some time, when there exist no governing influences that would cause a tendency toward new cold outbreaks and thus a greater probability of cold days.

The winter of 1876–77 in central Europe is an excellent example, showing that even after very severe winter days mild weather can recur even before the end of the winter season. The month of December 1876 started with especially mild weather; the departure of the temperature from a well-established average was +4.9C for the first half of December in Berlin. Then cooling, snowfall, and clearing occurred, and the daily mean temperature for December 24 dropped to −15.8C (corresponding to a departure from normal of −16C), and it remained below −10C until December 27. However, the daily mean temperature of December 30 was again 6.4C above normal, the month of January was 3.5C above normal, and the month of February was 2.2C above normal.

Such isolated examples, however, are not sufficient to enable one to decide whether *Grosswetter*, in the sense mentioned above, exists in reality. Rather, it is necessary to establish statistically from extensive observational data whether or not the fundamental probabilities of the occurrence of the meteorological phenomena that determine weather are (aside from the annual trend) constant or subject to variations.

Lexis' theorem [36] serves as the method of finding fluctuations of the fundamental probability. If the probability p of the occurrence of a phenomenon during an arbitrary number n of test series (each consisting of s independent trials) remains constant, the resulting distribution of the frequencies $m_1, m_2, \ldots m_n$ of the occurrence of the phenomenon in s trials is a so-called "Bernoulli distribution," whose standard deviation is $\sigma_B = \sqrt{sp(1-p)}$. If, however, the probability of the occurrence of the phenomenon remains constant from test to test within a series, but varies *from series to series*, then the observed standard deviation σ_h is larger than σ_B. In this case, the quotient $Q_1 = \sigma_h/\sigma_B$, known as *Lexis' ratio*, is greater than unity. If, however, the probability p varies *from test to test*, whereas $p_0 = (p_1 + p_2 + \ldots + p_s)/s$ remains constant from series to series, then $Q_1 < 1$. Lexis' ratio, therefore, is a criterion for determining whether or not the fundamental probability is subject to variations.

In its original form, however, Lexis' theory cannot be applied to meteorological observations, since in these —owing to their persistence tendency—the condition of the independence of consecutive terms is not fulfilled. Baur [12], therefore, introduced a new criterion, the "divergence coefficient of the second kind" which is defined by the quotient $D_1 = \sigma_h/\sigma_M$, where Markoff's standard deviation σ_M is used instead of Bernoulli's. By σ_M we mean the standard deviation of the distribution $w_n(x)$, where $w_n(x)$ designates the probability with which the phenomenon having the (constant) fundamental probability p will occur x times among the first n observations of a Markoff alternating chain (*i.e.*, an alternating series where each term depends on the preceding term). If the fundamental probability remains unchanged from series to series and from test to test, the mathematical expectation of D_1 again equals unity. If, however, the fundamental probability varies from series to series, but remains unchanged from test to test, then $D_1 > 1$.

* Translated from the original German.

Instead of counting the frequency of the occurrence in each series consisting of s tests, it is possible to determine the frequency of the occurrence in the first n tests, in the second n tests, etc., of all series, thus obtaining the standard deviation σ_H, as well as $Q_2 = \sigma_H/\sigma_B$ and $D_2 = \sigma_H/\sigma_M$, from the resulting distribution. If the probability p of the occurrence of a phenomenon varies systematically from test to test such that, for instance, the probability p of the third and tenth tests in each series is larger than that of the other tests, which would, meteorologically, correspond to an existence of true "singularities" according to Schmauss [50], then $Q_1/Q_2 = D_1/D_2 < 1$.

A study has been undertaken [20, pp. 924–928] involving nineteen series of meteorological observations of various elements, made at different locations (in different countries of the temperate zone) and during different seasons. Observations from January 1 to February 19 and from July 1 to August 19 for the fifty years from 1888 to 1937 (where $s = n = 50$) were used. The results showed that $D_1 > 1$ for all these series without exception (D is considerably greater than 1 in most cases) and Q_1/Q_2 was much larger than 1, the maximum of this ratio being 3.46. Two theorems follow unequivocally:

First Empirical Theorem: *A* Grosswetter *exists, in which there are governing complexes comprising variable conditions; because of these complexes, the probabilities of the occurrence of certain indices that characterize the weather for longer periods vary from year to year.*

Second Empirical Theorem: *These fluctuations of the weather-forming probabilities are, apart from the large annual trend, much more significant for the weather character than are the calendar probabilities.*

The first of these two theorems, that concerning the existence of *Grosswetter*, forms the logical foundation for the exploration of the problem of extended-range weather forecasting. If there were no governing complexes comprising variable conditions, and the *Grosswetter* evolved by chance and by a persistence tendency, then a reliable extended-range weather forecast would be impossible for all time, and a detailed study of this problem would be senseless.

The Second Basic Problem of Macrometeorology. Statistical evidence has been obtained that the fundamental probabilities of the meteorological elements change from year to year, and that there must be governing complexes comprising variable conditions which produce these variations of the fundamental probabilities. This evidence leads to the second problem: What are these governing complexes? Are they of terrestrial or extraterrestrial origin?

Whereas we shall see the various terrestrial influences on *Grosswetter*, we shall find that these influences are not sufficient to explain the large fluctuations of the probabilities of the occurrence of the indices that characterize the weather for longer periods of time. Therefore, we must look outside the earth for the governing complexes comprising variable conditions. This is now only an assumption. Evidence of the correctness of this assumption is found in the section on cosmic influences (p. 819).

Terrestrial Influences on *Grosswetter*. *Volcanic Eruptions.* The investigations by Abbot and Fowle [2], Humphreys [34], and Ångström [4] have shown conclusively that after violent volcanic eruptions the atmospheric transparency for solar radiation is decreased over wide regions. After the Katmai eruption in 1912, the direct solar radiation reaching the earth's surface was reduced by more than 10 per cent for several months. Furthermore, there is no doubt that, as a consequence of the decrease of insolation, the mean temperature for large regions is decreased by 0.5–1.0 centigrade degrees; and by as much as 2–3 centigrade degrees after especially violent eruptions.

According to Defant [31], the atmospheric circulation over the North Atlantic is disturbed through violent volcanic eruptions to an oscillation with a period of approximately 3½ yr, with a decrease of the meridional pressure gradient after the eruption, and an increase in the following two years. The disturbance, however, is rapidly damped.

These and similar examples cannot be considered the basis for extended-range forecasting. At best, they serve as a warning against the application of statistical results obtained in years without eruptions to a year during which there will be an eruption. At any rate, major volcanic eruptions that influence the general weather are too rare to provide an explanation for the fluctuations of the fundamental probabilities of the weather elements, mentioned in the opening section.

Ocean Currents and Ice Conditions. The number of investigations that have been made regarding the relationship between *Grosswetter* and preceding anomalies[1] of ocean currents and ice conditions is so great that it is impossible to mention all of them here. Most of these investigations were made in Europe; the reason for this is that the Gulf Stream, owing to the orientation of the west coast of Europe (from southwest to northeast), is much more important for the climate of western Europe than is the Kuroshio for North America. Furthermore, it is evident that the occurrence of ice in the North Atlantic plays an important role in the climate of Europe, since a large portion of the ocean ice of the north polar basin melts in the summer and is transported into the North Atlantic through the region between the northeastern tip of Greenland and Spitsbergen, as well as through the Davis Strait. By contrast, according to Schott [51], no ice passes from the polar basin through the Bering Strait into the Pacific Ocean.

It was initially hoped that a study of the influences of temperature and velocity anomalies in the Gulf Stream on European weather, as well as of the occurrence of ice near Iceland, might yield clues for extended-range weather forecasting. However, these hopes were not fulfilled. This statement is corroborated by the follow-

1. The term "anomaly," as used in this article, refers to departure from a long-term average over time and has nothing to do with departures from means computed for latitude circles.

ing examples: According to Pettersson [43], the temperature variations of the Gulf Stream are faithfully reflected in the simultaneous variations of the air temperature on the west coast of Scandinavia. Furthermore, Meinardus [38] showed that, during the years 1862–97, in 92 per cent of the cases the mean temperature for February and March in Berlin changed, relative to the preceding year, in the same direction as the mean temperature for the previous November, December, and January in Kristiansund had changed relative to the preceding year. This result seemed, indeed, useful for prognostic purposes and was mentioned to that effect in textbooks for several decades. However, a new investigation [11] showed that the correlation coefficient between these quantities was +0.73 for the period 1862–90, but was only −0.30 for the subsequent period 1891–1920.

For many years J. W. Sandström was of the opinion that a warm Gulf Stream would bring a mild winter to northern Europe. In the year 1939, however, the Gulf Stream temperatures reached a record height, but northern and central Europe experienced the coldest winter in 110 years.

A relationship between ice conditions and the general weather, particularly in northern Russia, has been shown by Wiese in several papers [56]. Undoubtedly, ice conditions and ocean currents are interrelated with the general atmospheric circulation in many ways. However, these interrelations exist mainly in the form of simultaneous correlations. The significant correlation coefficients between ice conditions and meteorological elements in subsequent time intervals, that were computed from long series of observations, were, at best, of the magnitude $|r| = 0.5$. Thus, the ocean currents and the ice conditions are never decisive, but only of contributory significance.

Motions of the Pole. The quasi-periodical displacements of the rotational axis of the earth which have been found by observations of polar motion are composed of a period of approximately 434 days (Chandler's period), caused by the unequal mass distribution of the solid terrestrial body, and of an irregular annual period caused by the air-mass displacements in the course of the seasons. The displacements of the rotational axis cause, in turn, changes in the centrifugal force and thereby a transport of air masses. These displacements of the earth's axis, however, are only very small. On the average, the amplitude of the oscillation amounts to 0.2–0.3 seconds of arc, 0.5 seconds of arc at the most. Thus, the pole deviates only about 9 m from its mean position. It has recently been found that over a forty-year period, a high pressure over northern Sweden was followed 434 days later by another high pressure with a relative frequency of 59 per cent [17, pp. 72–73]. Although this frequency, which was derived from 382 cases, exceeds the limit of chance, it is nevertheless much too small to be considered of practical importance for extended-range weather forecasting.

The Problem of Rhythms. *Pressure Waves.* The question regarding the existence of periods other than the well-known daily and annual periods of weather phenomena is of great importance to extended-range weather forecasting. It was hoped, above all, that periods or waves in the fluctuations of atmospheric pressure would be found, which, when extrapolated, would permit the computation of the future pressure trend for a given location. By using this process for several stations, one would be able to calculate the development of pressure patterns, at least for a limited number of days in advance. When V. Bjerknes and his co-workers [28, 30] showed that waves, subsequently developing into cyclones, can form along surfaces of discontinuity in the troposphere, a mathematical-physical basis was established for the problem of atmospheric pressure waves. Others, Exner [33, pp. 383–388] for instance, consider the thermal contrast of continents and oceans as a cause of the formation of forced oscillations. At any rate, regardless of the explanation offered for the formation of pressure waves, they can exist for a longer period of time only if they coincide approximately with the free oscillations of the atmosphere. Progress has also been made in the exploration of free atmospheric oscillations during the last two decades. While V. Bjerknes [30] neglected the vertical acceleration (quasi-static method) and considered the earth's surface as plane, Wünsche [58] treated the free oscillations of a compressible medium as a spatial problem in polar coordinates, and thus neglected neither speed nor acceleration in a vertical direction. However, his computations were still based on the assumption that the oscillations occur as isothermal changes of state in an isothermal atmosphere. This assumption naturally has an influence on the lengths of the resulting periods.

The short-period waves to which the cyclones owe their formation are of no importance for extended-range forecasting. It would be erroneous to attempt computation of the pressure distribution for the next two days from extrapolation of these short-period waves, since this can be achieved more easily by the methods of synoptic analysis. The assumption of J. Bjerknes and H. Solberg [29] that the rhythm of pressure changes is the result of four cyclone families circulating with more or less constant velocity around the pole has been disproven by observational facts. As regards the longer waves, there is still no convincing proof of their existence. During World War II, more than one thousand analyses of rhythms were made at the *Forschungsinstitut für langfristige Witterungsvorhersage* in Bad Homburg, Germany. Subsequent extrapolation of those resultant waves that were recognized as quasi-persistent on the basis of mathematical criteria, permitted prediction of the direction (sign) of atmospheric pressure changes to a definite date. These predictions were accurate more frequently than would have been possible by chance. However, the relative frequency of correct forecasts remained below 75 per cent and is therefore inadequate for practical purposes. If we determine how often in such analyses the individual trial waves prove to be quasi-persistent, we find frequency maxima for European stations at 7 and 8, 12 and 13, 20, 22 and 24, as well as 30 and 33

days. However, even the more than one thousand analyses are not sufficient to permit the definite statement that the frequency of a single wave exceeds the maximum limit of chance [20, pp. 933–934].

Periods of Several Years. Of the many oscillations with periods of several years that have been claimed in the past, only a small number have proved to be "probably real." They are a 2.2-yr period, a 3- to 3½-yr period, and an approximately 7-yr period. All these periods, however, are nonpersistent, in other words, they cease intermittently. With respect to temperature and pressure, the 3- to 3½-yr period is most marked in the region of the Malayan Archipelago and northern Australia. This period is probably a "free oscillation" (in a broader sense) between a tropical low-pressure area (India-northern Australia) and a subtropical high (South Pacific anticyclone near Easter Island), caused by the lagging of the temperature anomalies with respect to the pressure anomalies as a consequence of the inertia of the participating ocean currents. According to Berlage [25], this oscillation is propagated from the Malayan region over both hemispheres to the subpolar pressure troughs. The cause for the excitation of the Indian-Pacific oscillation has not yet been determined.

The oscillations with periods of 2.2 yr and 7 yr are probably free oscillations of the atmospheric circulation over the North Atlantic. These oscillations are similar to the 3-yr period found in the Malayan region. Whereas the 2.2-yr fluctuation is restricted to the North Atlantic and Europe, the 7-yr period has a world-wide distribution [20, pp. 937–940].

The 3-yr fluctuation in the Malayan region occurs so clearly at times that it can be obtained directly from the curve of the semiannual pressure averages. However, on the whole, these fluctuations of several years' period have such a small amplitude that they can be extracted from the observations only by means of mathematical processes (*e.g.*, periodogram analysis).

From periodogram analyses, a widespread 5- to 5½-yr oscillation has been found [17, pp. 93–96]. In reality, however, this oscillation has a variable period which only on the average amounts to 5½ yr and is identical with the double oscillation of the large-scale weather during a sunspot cycle (see section on cosmic influences).

Periodic Fluctuations of Climate. Rhythmic fluctuations of the meteorological elements having a period of more than 30 yr are called "climatic periods." For many decades, the existence of a 35-yr period was presented in all meteorological textbooks, and was known as the "Brückner cycle." This period is a classic example of the deceptions to which one may succumb by determining periods with primitive research methods and without adequate statistical tests for significance. It is to Wagner's credit that he proved [54] that the 35-yr period does not exist as a natural phenomenon, but was introduced by the methods of computation and smoothing used by Brückner.

For the demonstration of still longer periods, the data available today are insufficient.

Correlations between Consecutive Weather Anomalies. *Persistence and Repetition Tendencies.* The persistence tendency of the weather is caused by the fact that, for physical reasons, certain weather anomalies (*e.g.*, very high pressure or cold air) extending over wide regions, cannot disappear from one day to the next. However, this persistence tendency in its proper sense extends over a period of only a few days. When a certain anomaly in ten-day or monthly averages is found to be generally followed by one of the same sign more frequently than by one of opposite sign, it exhibits, fundamentally, not a persistence tendency but rather a repetition tendency, that is, the tendency of a situation which has existed for several days to be reinstated after a brief interruption. Important as the repetition tendency may be for the explanation of some phenomena, its importance must not be overrated. In the temperate zone, the repetition tendency is subject to strong local and seasonal differences. The dependence of the repetition tendency on the seasons is shown in Fig. 1.

Statistical determination of the local and seasonal differences of persistence and repetition tendencies and their physical explanation are indirectly of importance for extended-range weather forecasting. In the past, the persistence tendency of certain weather elements, such as pressure or temperature, was usually investigated by counting the frequency of sequences of the same sign or by computing correlation coefficients. Instead, the persistence and repetition tendencies of *Grosswetterlagen* should be subject to investigations in which statistics and synoptics supplement each other.

During certain parts of the year and in some regions, the probability of weather changes is, under certain premises, greater than is the persistence tendency during other seasons. As can be seen from Fig. 1*a*, such a tendency toward a major change in the synoptic situation exists in Europe in the last third of June. Connected with this tendency is the fact that for fourteen years (of the 102-yr period 1848–1949), in which the temperature of the first half of June in Berlin was more than 2C above normal, the following midsummer (July and August) was for the most part abnormally cool in central Europe, and that in thirteen (93 per cent) of these years the precipitation was more than 15 mm above normal (Table I). Since the fundamental probability of a positive precipitation departure of more than 15 mm in midsummer is 38 per cent, the maximal chance limit of the relative frequency of such midsummers for a random choice of 14 cases is 81 per cent if, as is customary, the limit of the range of chance is so chosen that the probability of exceeding this limit is $\epsilon = 0.0027$. The observed relative frequency of 93 per cent of wet midsummers is, therefore, significantly above chance.

On the other hand, when the temperature during the first half of July is 2C above normal in central Europe, there follows in about three-fourths of the cases a warm and dry late summer (August and September). This varying repetition tendency can probably be explained physically as follows: In June, when the subtropical high-pressure belt over the North Atlantic

lies still farther to the south, and the daily insolation is still increasing, an overheating of central Europe causes an irreversible pressure fall over the continent and a corresponding pressure rise over the North Atlantic. In July, however, when the Azores High is farther to the north and the daily insolation is decreasing, the pressure fall caused by overheating is no longer irreversible and, during the following August and September, it is possible for high-pressure cells to split off repeatedly from the Azores High and to migrate toward central Europe.

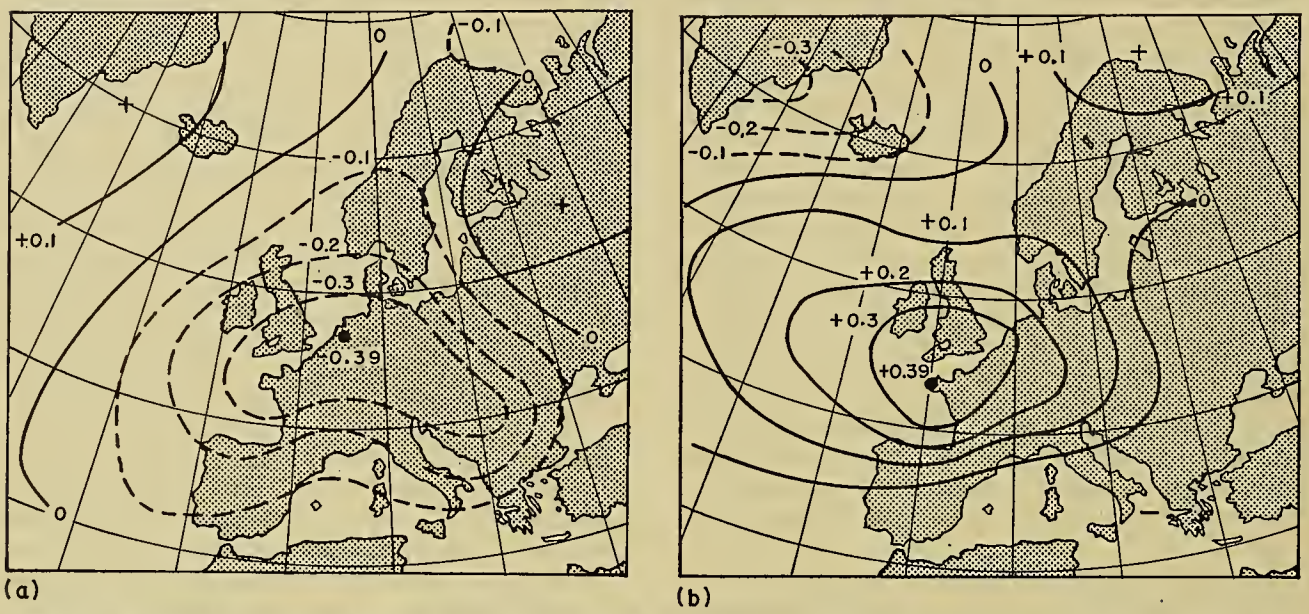

FIG. 1.—Isopleths of the correlation coefficients between the mean barometric pressure of the preceding 10-day period for various places in Europe and the mean barometric pressure at Potsdam for the following 10-day period for the years 1893–1932 (number of cases $N = 40 \times 10 = 400$), (*a*) when the ten preceding 10-day periods end on the days between June 15 and June 24, (*b*) when the ten preceding 10-day periods end on the days between July 26 and August 4.

TABLE I. LARGE POSITIVE TEMPERATURE ANOMALIES IN BERLIN IN JUNE AND SUBSEQUENT PRECIPITATION AND TEMPERATURE ANOMALIES IN CENTRAL EUROPE

Year	Temperature departure in Berlin for June 1–15 (cent. deg.)	Precipitation departure in central Europe for the following midsummer (average of 16 stations) (mm)	Temperature departure in central Europe for the following midsummer (cent. deg.)
1855	+3.1	+34	−0.1
1858	+4.5	+43	−0.2
1866	+3.0	+26	−1.5
1877	+3.3	+42	+0.4
1889	+6.5	+16	−0.9
1896	+3.3	+25	−0.7
1897	+2.1	+22	0.0
1910	+5.2	+44	−1.3
1915	+3.4	+17	−1.4
1917	+2.7	+16	+0.2
1930	+3.1	+60	−0.6
1937	+4.1	−16	+0.2
1940	+2.8	+43	−1.5
1948	+3.9	+45	−0.4

Also of importance for the physical explanation is the fact that in many cases a repetition or change tendency exists only for anomalies of one sign. During the period 1848–1947 for instance, when the temperature in the first half of December in central Europe was more than 3C above normal, the following midwinter (January and February) was too warm in all 13 cases. However, if the first half of December was below normal by just as many degrees, the following midwinter was too cold in only 4 out of 14 cases; in 10 cases, the midwinter was warmer than normal.

The considerations of this section can be summarized as follows:

THIRD EMPIRICAL THEOREM: *The repetition tendency of weather anomalies varies with the seasons and, as a rule, is not the same for positive and negative anomalies.*

Correlations between Successive Weather Anomalies in Distant Regions. A large part of the nonsimultaneous correlations of weather anomalies in distant regions can be traced to the persistence tendency of the general atmospheric circulation, as has been shown by Schell [46]. However, these correlations are, for the larger part, significant only in the tropics and subtropics and in the Southern Hemisphere. In the temperate zone of the Northern Hemisphere only a few exceed the limit of chance. Here, those correlations that point toward a *change* of the circulation are more important; in this respect, the "general circulation" is less important as a rule than the "special large-scale circulations" into which the general circulation of the Northern Hemisphere resolves (see p. 825).

Particularly, the atmospheric circulation over the North Atlantic is, to a great extent, a closed system that follows certain rules of its own (see p. 817). Generally, the pressure gradient between the Azores and Iceland determines the strength of the zonal circulation over the North Atlantic Ocean. According to Baur [7], however, the preceding zonal pressure gra-

dients as well as the temperature difference between the eastern and western parts of the circulation system are decisive for the mean pressure changes that are observed over the Azores and Iceland during periods of approximately a month's duration. Thus, from these pressure gradients and temperature contrasts, at least for the spring, the change of the pressure difference between the Azores and Iceland can be computed from one month to the next with an error of approximately six-tenths of the standard deviation. These correlations are presented in Table II, in which the correlation coefficients that exceed the upper limit of chance are italicized.

Cosmic Influences on *Grosswetter.* *Unimportance of Moon and Planets.* No one has ever proved in a single case to date that during or after a given arrangement of the moon or the planets any weather phenomenon occurred more frequently or less frequently than would have been expected from chance. On the contrary, proof has been established from extensive data and by means of statistical criteria [14; 17, pp. 93–96] that certain coincidences claimed by "astro-meteorologists" lie well within the range of chance.

The influence of the moon upon the atmosphere is restricted to producing atmospheric tides, which represent diurnal pressure variations that amount to only $\frac{1}{1000}$ of the changes associated with weather developments. Likewise, there is no notable influence of the planets on terrestrial weather. The hypothesis by See, according to which the planets are supposed to influence the sun's activity by their power of attraction upon a hypothetical stream of matter directed toward the sun, is no longer tenable. According to Waldmeier [55], each sunspot cycle, from one sunspot minimum to the next, represents a separate phenomenon that can be caused only by processes in the sun's interior (eruption hypothesis).

Relationships between Grosswetter *and Sunspot Cycles.* Köppen was the first to show the existence of an average period of eleven years in the air temperature. However, according to more recent investigations [3; 5; 17, pp. 97–105], no significant parallelism or antiparallelism of any one meteorological element to the variation of sunspots exists in the temperate zone, and even in the tropics the relationship is generally quite poor. There is a better-than-chance correlation only between the fluctuations of the level of Lake Victoria in East Africa and sunspots, but even this correlation is not persistent. The correlation coefficients between the annual means of relative sunspot numbers and the annual means of the water level of Lake Victoria (mean of maximum and minimum readings at Kisumu according to *World Weather Records*) are:

+ 0.87 for 1899–1924,
+ 0.07 for 1925–1943,
+ 0.58 for 1899–1943.

The utilization of these weak correlations for prognostic purposes does not seem feasible. However, several investigations [9, 18, 19] have revealed that over the whole earth, particularly in both temperate zones, a double, sometimes a triple, fluctuation of nearly all meteorological elements occurs within a sunspot cycle. The world-wide distribution of this fluctuation is shown by the curves of Fig. 2. The bottom curve represents the dependence of the departure of the mean annual temperatures in Apia, Samoa, and Colombo, Ceylon, on the year's position in the sunspot cycle. This curve shows that a single oscillation prevails in the tropics, but that even here a double oscillation is superposed. The temperature maximum does not coincide with the sunspot minimum, as would be the case with pure antiparallelism, but occurs two years before. Summarizing all phenomena, we find that about 2–2½ yr before the sunspot extremes, the general (zonal) atmospheric circulation is increased. The subtropical high-pressure belts are stronger and displaced poleward in midsummer, at least in the North Atlantic and European region. Moreover, the pressure difference between winter and summer over the Asiatic continent is diminished, and central Europe has dry midsummers as a rule. In years of sunspot extremes (*i.e.*, minima as well as maxima) and shortly before and afterward, the following phenomena are observed: The planetary circulation is weakened, the mean pressure in the high-pressure belts is lowered, the difference between winter and summer pressure in Asia is increased, and the

frequency of severe winters in central Europe, as well as in central and eastern North America, is increased.

Figure 3 shows that in central Europe, during the period 1755–1949, winters with a negative temperature departure of more than 1.8C occurred particularly around the time of sunspot maxima and minima. In central Europe, during the intervals between 0.5 yr before and 1.0 yr after a sunspot maximum, nine out

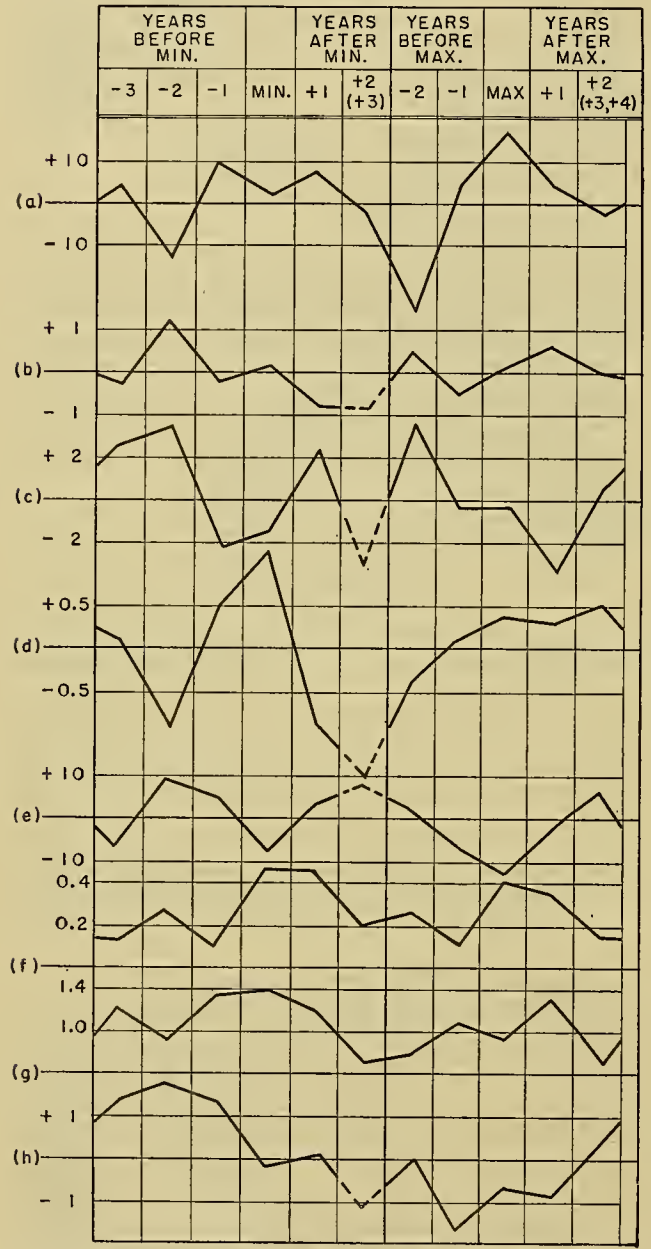

Fig. 2.—The average course of some meteorological elements during a sunspot cycle. (The dashed portion of some curves indicates that these cases, because of the relative brevity of the interval, are based on only few years of observations.) (*a*) Departure of precipitation (in mm) in central Europe during the midsummers, 1803–1943; (*b*) pressure departure (in mm *Hg*) in Berlin for the midsummers, 1875–1944; (*c*) departure of the pressure difference (in mm *Hg*) between the Azores and Iceland for the winters, 1866–1940; (*d*) departure of the difference between winter and summer pressures (in mm *Hg*) for ½ (Barnaul + Irkutsk) + ½ (Lahore + Karachi) for 1881 to 1940; (*e*) departure of the mean annual pressure for ½ (Capetown + Adelaide) (in 1/1000 in.) for 1865 to 1940; (*f*) yearly number of severe winter months (| departure | $>1.6\ \sigma$) in central Europe, 1752–1947; (*g*) yearly number of cold winter months (| departure | >4.5F) for Chicago + St. Louis, 1847–1946, (*h*) departure of the mean annual temperature in $\frac{1}{10}$C for ½ (Apia + Colombo), 1890–1945.

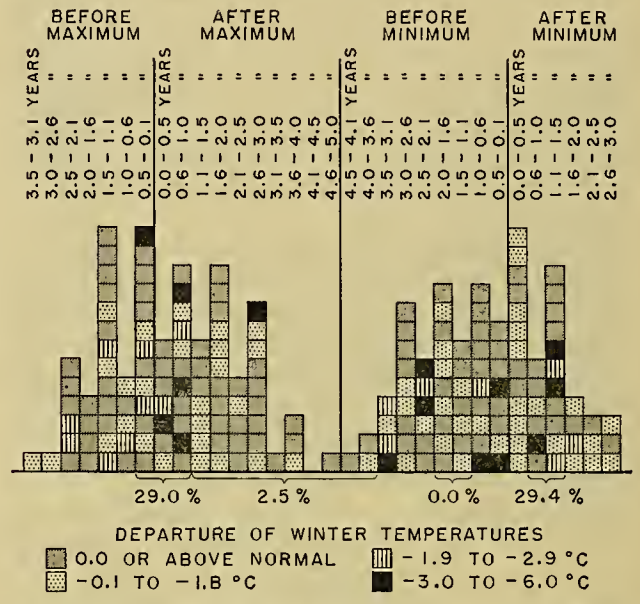

Fig. 3.—The position of the winter (January) with respect to the nearest sunspot extreme and the temperature characteristics of the winter in central Europe for the period 1755–1949 (for lack of space the individual years have not been identified). The frequencies below the abscissa refer to winters with negative temperature departures of more than 1.8C.

of thirty-one winters (29 per cent) were too cold by more than 1.8C, whereas only one such winter (2.5 per cent) occurred in the intervals from 1.1 yr after a sunspot maximum to 3.6 yr before a minimum. The probability that this difference in the relative frequencies is due to chance (assuming a constant fundamental probability) amounts to 0.0018 (computed according to R. A. Fisher's *H*-method). This probability is below the residual probability of the usual limits of the chance range. Thus a physical relationship must be assumed to exist here.

It has been shown in a similar manner that the relative frequencies of various *Grosswetter* phenomena in different seasons and in different parts of the world exhibit fluctuations within the solar cycle, a fact incompatible with the assumption of a constant fundamental probability. For this reason, there can no longer be any doubt that the *Grosswetter is dependent on the solar cycle* [18; 19; 20, pp. 962–966]. It must be emphasized, however, that this dependency does not appear in the primitive form of a linear relationship with sunspots.

Relationships between Grosswetter *and Variations in Solar Radiation.* It seems surprising, at first, that precipitation and temperature in the tropics show mainly a single oscillation within a solar cycle, whereas in the temperate zones, a double or higher multiple oscillation can be observed. This can, however, be easily explained if we consider that, on the one hand, the sun can exert an influence upon the weather only by way of radiation and that, on the other hand, the sun's radia-

tion is an extraordinarily complex phenomenon. Those parts of the sun's radiation which emanate from the sun's corona and the uppermost chromosphere fluctuate with the sunspots, that is, on the average, with an eleven-year period. These radiations (corpuscular rays and electromagnetic waves) are, however, with one exception, absorbed in the ionosphere and hence, according to our present ideas, are of no influence upon the weather. Only the ultrashort electromagnetic waves with a wave length $\lambda < 15$ m penetrate to the earth's surface. Since, according to Kiepenheuer [35], ultrashort waves act upon colloidal processes, it is possible that the single fluctuation of precipitation in the tropics is caused by a solar influence on the condensation and sublimation of the water vapor, whereas the temperature fluctuation is secondarily produced by cloudiness and precipitation. In agreement with this assumption is the fact that the correlation of sunspots with temperature is of opposite sign and of less significance than is the correlation of sunspots with the amount of precipitation or with the water level of large inland lakes.

The radiation emanating from the photosphere, that is, the heat radiation, shows—as has been demonstrated several times [7, 9, 26]—no single oscillation in or out of phase with the sunspots. However, when the different mean annual trends in the time intervals 1919–23 and 1924–30 are eliminated [9], the curve of the solar constant for the period from July 1918 to February 1937 shows minimum values at about the time of sunspot extremes, and maximum values 1½ to 2½ yr before the sunspot extremes [19; 20, pp. 967–968]. These fluctuations agree quite well with the double oscillation of the meteorological elements as presented in the preceding section. However, it must be conceded that the double fluctuation in the most recently revised monthly means of the solar constant no longer appears so clearly [1].

An increase in the total energy radiated from the sun would mean an increase in the heat supply, particularly for low latitudes during winter. The temperature difference between the tropics and the polar region would thereby be increased, resulting in an increase of the general circulation of the atmosphere and a consequent increase of the pressure gradient between the subtropics and the subpolar low-pressure belt. The reality of the fluctuations of the solar constant is corroborated by the fact that during midwinter (January and February) in the period 1919–37, a strong positive correlation existed between the mean solar constant and the simultaneous mean values of the pressure differences between Valencia (Ireland) and Spitsbergen and between Rome (Italy) and Haparanda (Sweden) [17, pp. 97–105]. These correlation coefficients were +0.69 and +0.65, respectively, both of which exceed the maximum chance value.

The objection has been raised that the variations of the solar constant are too small to cause fluctuations of the general atmospheric circulation. However, according to the Stefan-Boltzmann law, a variation of an amplitude of 1 per cent of the solar constant (assuming incoming and outgoing radiation to be equal) causes a temperature change (temperature departure) of 0.7C which refers to the entire earth's surface. It is therefore quite possible that, owing to the inequalities of insolation (as a function of the geographical latitude) and the different heat capacities of land and ocean, the temperature change caused by a one per cent change of insolation may amount to considerably more than 0.7C in some regions.

Results of recent investigations [35, 37] suggest that the fluctuations of the atmospheric circulation within a sunspot cycle are caused not so much by the changes of the entire heat radiation as by the fluctuations of the sun's radiation in the ultraviolet. This idea is supported by the fact that the difference between the areas of the sun's faculae F and those of sunspots L, both relative to their long-established mean values F_0 and L_0, undergoes the same double fluctuation within a solar cycle as does the atmospheric circulation [19]; this is shown in Fig. 4. Radiation emanating from the

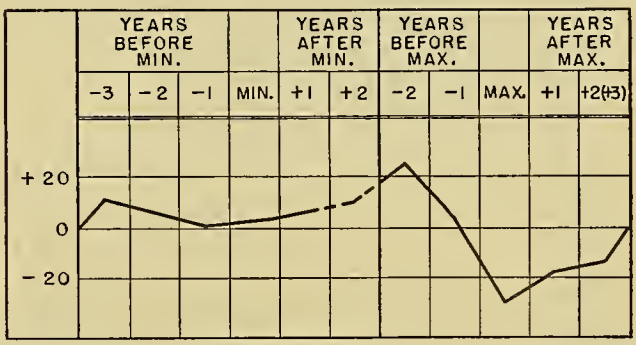

FIG. 4.—The mean course of the difference between the equivalent annual means of the areas of sun faculae (F) and sunspots (L), $100(F/F_0 - L/L_0)$, for the sunspot cycle, from 1875 to 1940.

faculae is known to be particularly rich in ultraviolet. This relationship can be explained as follows: In the upper mixing layer above the stratospheric inversion layer, temperature differences are set up by differences in the absorption of ultraviolet radiation. These temperature differences are connected with pressure differences of the same sign in a manner similar to that found in the middle troposphere. If this assumption holds true, an increased ultraviolet radiation results in an increased pressure gradient from the equator toward the pole in the upper-air layers, because—disregarding the time around the summer solstice (see p. 824)—the ultraviolet radiation as well as the total radiation affects primarily the lower latitudes. Because of the increase of the pressure gradient aloft, the planetary (zonal) circulation increases, and the poleward border of the subtropical high-pressure belt is displaced toward the pole.

Solution of the Second Basic Problem. It follows from the discussion in the foregoing sections that weather-governing complexes, the existence of which has been proven (first empirical theorem), are not to be found in terrestrial processes. The terrestrial processes are either too rare (strong volcanic eruptions) or too weak (motions of the pole) to influence the course of the weather. There are, indeed, purely terrestrial regulatory

phenomena such as the alternation between meridional and zonal circulation in the Northern Hemisphere (see p. 827) and the southern oscillation in the Southern Hemisphere. However, these regulatory phenomena merely shape the macrometeorological events and cannot be regarded as governing complexes of conditions. If they alone were decisive, obvious periods should occur in the course of the weather, whereas in reality one must search for such periods by means of "methods for the discovery of hidden periodicities." The solution of the second fundamental problem is given by the empirical facts briefly sketched in the two preceding paragraphs from which the following conclusions can be derived:

Fourth Empirical Theorem: *The fluctuations in the solar radiation represent complexes of conditions that govern the course of the large-scale weather.*

for the latitudes 50°N, 60°N, and 70°N, where R is the mean radius of the earth, ϕ is the latitude, and $|\Delta p|_\lambda$ is the pressure difference from one extreme value to the next along a latitude circle. The mean zonal air motion (eastward *and* westward) is expressed by the mean of the meridional pressure gradients at sea level from 40°N to 75°N, averaged over all meridians,

$$M_{40-75} = \frac{1}{n}\sum_{1}^{n}\frac{\Sigma\,|\Delta p|_\phi}{L},$$

where L is the length of the meridional distance between 40°N and 75°N, $|\Delta p|_\phi$ is the pressure difference from one extreme value to the next along the meridian between 40°N and 75°N, and n is the number of meridians for which $|\Delta p|_\phi$ is computed [22]. It should be noted that the mean gradients were first determined for each single day and the monthly means computed

Table III. Monthly Means of the Daily Zonal and Meridional Pressure Gradients in the Northern Hemisphere

Mean (50°N–70°N)								9.5				

* Numbers in parentheses are uncertain.

Therefore, an intensive promotion of solar physics is one of the prime prerequisites for progress in long-range weather forecasting.

Morphology of the *Grosswetter.* *Forms of the General Atmospheric Circulation.* Twenty years ago it was recognized that it is erroneous to consider the west-east circulation as the essential feature of the "general atmospheric circulation" in the temperate zone [8; 33, pp. 215–218]. Without the meridional movements there would not be the exchange between the warm subtropical and cold polar air masses that is the most important effect of the general circulation in the temperate zone. The quantitative equivalence of zonal and meridional circulation in the lower troposphere is shown in Table III. Here, the mean meridional air motion (poleward *and* equatorward) is expressed by the mean of the zonal pressure gradients at sea level,

$$Z(\phi) = \frac{\Sigma\,|\Delta p|_\lambda}{2R\pi\cos\phi},$$

from them afterwards. Comparison shows that the differences between the mean zonal and the mean meridional gradients by months are much less pronounced than the seasonal trend of both these indices.

Sometimes, however, large differences between these indices occur *on individual days.* Thus the mean zonal gradient at 60°N amounted to only 8.5 mb per 1000 km on January 11, 1949 but, on the same day, the average of all meridional gradients from 50°N to 65°N was 15.0 mb per 1000 km. The mean gradient for meridians with west-east zonal circulation only, between 50°N and 65°N, (that is, two-thirds of all meridians on that particular day) was 17.5 mb per 1000 km. Table IV shows the pronounced daily fluctuations of the circulation in addition to the seasonal trend. On some winter days, values are observed that almost equal the summer normals and on many summer days the gradients correspond closely to the mean values of winter.

The recently available daily circumpolar 500-mb con-

tour charts show that a remarkable meridional circulation extends also to the upper troposphere of the middle latitudes. Even at the 5- and 10-km levels, there is, only in exceptional cases and then at the most as far south as 55°N, an uninterrupted west-east circulation around the pole (Fig. 5). In most cases, the isobars at the 5-km level seem to "meander" (Fig. 6), the poleward convexities representing warm ridges, the poleward concavities representing cold troughs [52, 53].

* The principal maxima are in boldface; the principal minima are in italics.

The sinuosities of the isobars are called waves by some meteorologists. One can, however, argue that this designation is misleading because it is suggestive of progressive waves. Experience has taught us that the ridges and troughs at the 5-km level are, in general, rather stationary with respect to their geographical longitude (as in Figs. 7 and 8). Zonal movements occur principally when two pressure ridges on either side of a trough join on the poleward side of the trough thereby cutting off a low-pressure cell, or when two troughs on both sides of a wedge join on its equatorward side thus cutting off a high-pressure cell. In some cases there may be longer zonal movements of individual pressure centers in the upper troposphere. An impressive example of such a case is the high-pressure cell at the 5-km level that within five days (November 24–29, 1949) moved from 70°N and 172°W to 78°N and 55°W along an unusual path. This is also an example of the fact that relatively warm anticyclones in the upper troposphere can occur at rather high latitudes even during the winter season. (Regarding zonal displacements of wedges and troughs, see p. 830.)

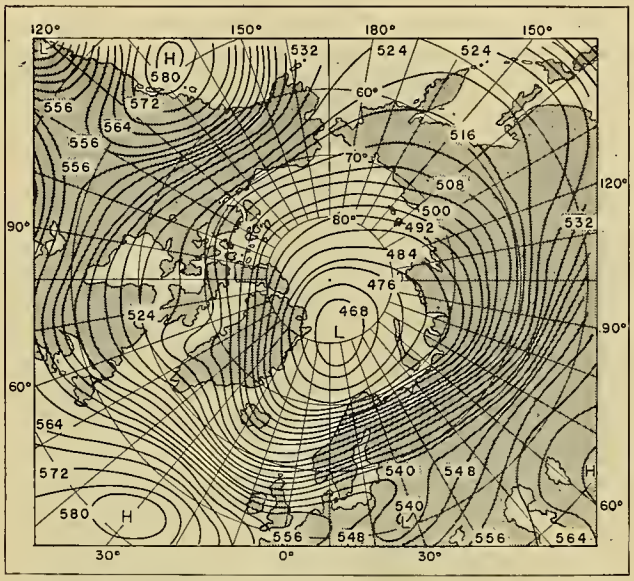

FIG. 5.—Contours of the 500-mb surface (in tens of dynamic meters) for January 11, 1949 at 0200 GMT. Example of a circumpolar zonal circulation.

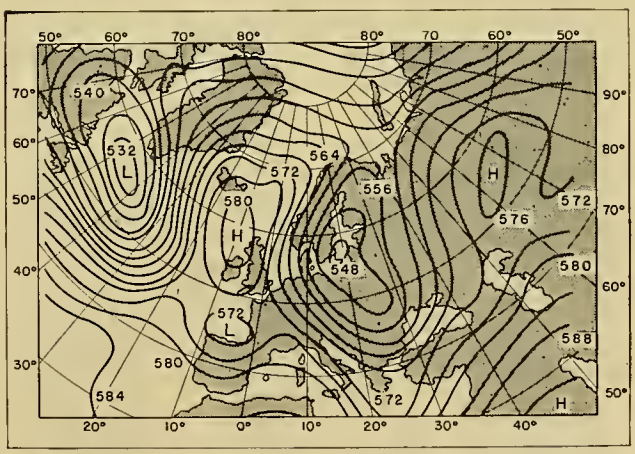

FIG. 6.—Contours of the 500-mb surface (in tens of dynamic meters) for June 23, 1949 at 0200 GMT. Example of a circulation in the form of elongated meridional circulation cells (*Zirkulationsstreifen*).

The centers of high- and low-pressure cells at the 5-km level for the period from June 21 to July 5, 1949 are shown in Fig. 7. In each of the regions marked I and III there is a moving low-pressure center (the one of region III splits at times). Regions II and IV each contain a high-pressure center and show, in particular, the small zonal displacement. On June 27 and 28, a stronger zonal movement occurred. to the northeast for region

II, and to the northwest for region IV, thus producing a new high-pressure cell in region V, which, according to the investigations of Palmén and Rossby [53], remained there until July 6.

Fig. 7.—Centers of anticyclones (●), ridges (○), and cyclones (+) at the 5-km level from June 21 to July 5, 1949.

Assuming that the meridional heat transport is the main effect of the general circulation, we can distinguish the following principal forms of the general circulation [8; 17, pp. 49–55].

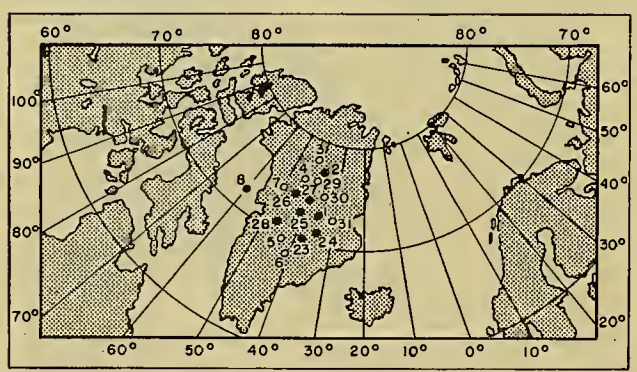

Fig. 8.—Centers of anticyclones (●) and ridges (○) at the 5-km level from July 23 to August 8, 1949.

1. *An unordered heat exchange.* This occurs in west-east-travelling highs and lows of the lower troposphere with isobars running approximately from west to east at the 5-km level (zonal circulation). In this case, the southern portion of the troposphere (in the Northern Hemisphere) is warm, the northern portion is cold. As long as the flow equilibrium between warm and cold air remains undisturbed, a "frontal zone" ascending poleward exists in the troposphere with a strong meridional temperature gradient [47, 52, 53]. Above this frontal zone, the isobars of the upper troposphere are crowded in a comparatively narrow belt, so that the west-east current reaches very high speeds (jet stream). The maximum of this zonal movement is found where the tropopause slopes down most strongly toward the pole. This form of circulation (Fig. 5) rarely develops as an upper circumpolar low as far south as the 55th parallel, as is so in the case illustrated in Fig. 5, and, according to our present experience, it usually develops in only one or two quadrants, and never in the entire temperate zone around the whole hemisphere. Even in the rare case represented in Fig. 5, the jet stream does not run uninterruptedly around the entire hemisphere, but parts of it are dissipated by divergent currents.

2. *The meridional circulation strips.* An ample heat exchange is effected in these strips; quasi-stationary warm tropospheric anticyclones that reach up to the stratosphere and are displaced far poleward alternate with cold tropospheric troughs that reach far equatorward and likewise extend to high altitudes (Fig. 6).

Whereas these two principal forms occur during all seasons, the two following secondary forms occur only in certain seasons:

3. *The winter anticylcone in the lower troposphere* [52]. Below the circumpolar low at high altitudes there often exists during the winter an anticyclonic circulation system in the lower troposphere over the interior of the Arctic. When these arctic air masses penetrate to the south, additional cooling occurs through radiation over the continent, and wide regions of stationary cold anticyclones are thus formed. The frontal zone between these cold air masses and warm air to the south, and the resulting westward drift, are displaced far toward the equator. In Europe this displacement extends to the Mediterranean area, in North America to the northern edge of the Gulf of Mexico.

4. *The arctic anticyclone of the stratosphere in midsummer.* According to Baur and Philipps [23], the total insolation during the summer solstice is strongest at the pole, and thus the ultraviolet radiation is most likely also to be a maximum there. For this reason, in the upper stratosphere a pressure gradient from the pole to the equator exists during this short season, in strong contrast to midwinter conditions.

Figure 9 shows the average topography of the 41-mb surface (at approximately 22-km height) as it exists, according to Scherhag [47], in July over the Northern Hemisphere. In the Arctic this high pressure extends in some years to the earth's surface, as in Europe from June 5 to June 13, 1947 (Fig. 10) before the extremely dry summer.

Fifth Empirical Theorem: *On the average for all meridians and over long periods of time, the zonal and meridional components of the atmospheric circulation in the lower troposphere are nearly equal in middle latitudes of the Northern Hemisphere.*

Sixth Empirical Theorem: *In the lower and middle troposphere on both hemispheres, there are always long*

zones, extending over many meridians, in which warm subtropical air borders on cold polar air (polar front). In the upper troposphere above these zones, there is always a narrow belt with extremely strong westerly winds (jet stream), which reach their maximum velocity at the tropopause level. However, neither the polar front nor the jet stream runs uninterruptedly around the entire Northern Hemiphere.

Seventh Empirical Theorem: *A zonal circulation exists only on rare occasions over all meridians of the middle latitudes. In most cases, regions with a prevailing zonal circulation and regions with a prevailing meridional circulation exist simultaneously.*

Types of Grosswetter. Since in middle latitudes of the Northern Hemisphere the character of the circulation is seldom uniform over the entire hemisphere, it is necessary to consider a division into separate circulation cells, which Seilkopf refers to as "special circulations" [52]. Furthermore, it is necessary to define an observational unit which lies between the daily weather situation of a smaller region and the world weather situation over the Northern Hemisphere or even the entire earth. This unit is the *Grosswetterlage*. Because of the existence of two continents (one of which has a large longitudinal extent) and two oceans on the Northern Hemisphere, there usually exist four or five troughs and the same number of ridges in the Northern Hemisphere. Therefore, the most suitable regional delineation of *Grosswetterlagen* results from a division of the total circulation of the Northern Hemisphere into five (partly overlapping) special circulation regions [17, pp. 58–62]:

North America	(160°W–60°W)
North Atlantic	(70°W–0°)
Europe	(30°W–45°E)
Asia	(45°E–150°E)
North Pacific	(150°E–135°W).

At some future time it might perhaps be useful to combine the overlapping North Atlantic and the European regions into a single circulation region.

The temporal limits of a *Grosswetterlage* result from the following definition [13]: A *Grosswetterlage* is the mean pressure distribution (at sea level) for a time interval during which the position of the stationary (steering) cyclones and anticyclones and the steering within a special circulation region remain essentially unchanged. Here "steering" means the direction of propagation of 24-hr isallobars. The reference to the pressure distribution at sea level is necessary in order to enable one to apply this definition to observations of earlier years when there were no daily aerological observations. On the other hand, by requiring constancy of the steering, the pressure distribution in the middle troposphere (5-km level) is indirectly taken into consideration.

The mean pressure distribution during an arbitrary five-day period cannot be considered as a *Grosswetterlage*. Rather, it is possible that by such an arbitrary formation of means, two different *Grosswetterlagen* might cancel each other.

Baur [17; 20, pp. 920–923] established 17 types of *Grosswetterlagen* for the circulation region of Europe—25 types, if finer subdivisions are included. For the circulation region of the North Atlantic he introduced 16 types of *Grosswetterlagen*. The 25 European *Grosswetter* types can be grouped into the following divisions:

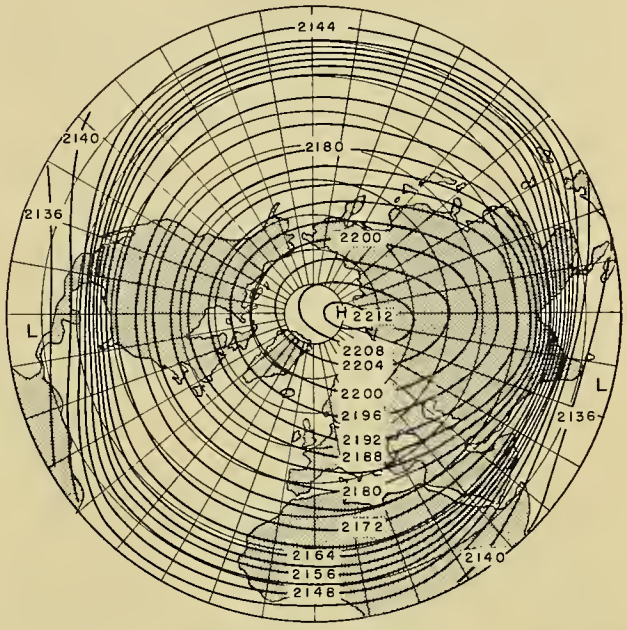

Fig. 9.—Average topography of the 41-mb surface for July in the Northern Hemisphere. (*After Scherhag* [47]).

1. A high in the northwest region (between Greenland and Scandinavia).

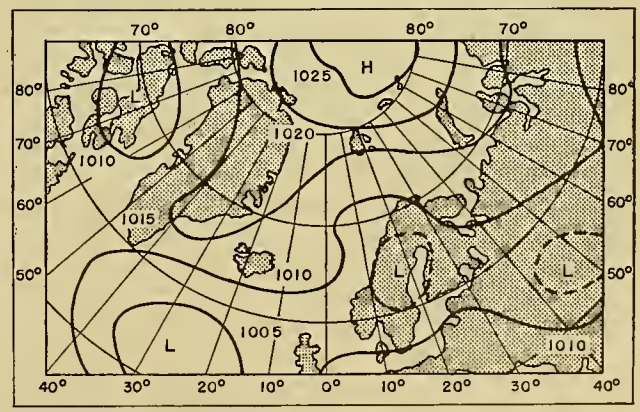

Fig. 10.—Mean pressure distribution (in mb) at sea level in the north polar region for June 4–12, 1947.

2. A high in the west and southwest (between the Azores and England).
3. A continental high.
4. A high in the southeast and south.
5. Westerly cyclonic flow.
6. Central cyclonic situations.

The 16 types of the North Atlantic *Grosswetterlagen* are grouped into zonal, meridional, and mixed situa-

tions. (For further details, see [13; 17; 20, pp. 920–923].) For the North American circulation region, Krick and Elliott have established a system of weather types.[2]

Considering the pressure distribution at the 5-km level, we can classify the *Grosswetterlagen* in all special circulation regions of the temperate zone in the Northern Hemisphere according to the following seven fundamental types based on the circulation:

1. Three types with zonal circulation:
   - I. High pressure in the south; low pressure in the north; westerlies and jet stream reach farther south than normally.
   - II. High pressure in the south; low pressure in the north; northern boundary of high pressure either in normal or more northerly position; westerlies and jet stream far to the north.
   - III. High pressure in the north; low pressure in the south.
2. Four types with meridional circulation:
   - IV. Subtropical meridional flow; high pressure in the east; low pressure in the west.
   - V. Polar meridional flow; high pressure in the west; low pressure in the east.
   - VI. Meridional ridge.
   - VII. Meridional trough.

These seven types occur in all special circulation regions of the temperate zone in the Northern Hemisphere, but with different frequencies.

Schematic illustrations of the pressure distribution and air flow in the middle troposphere occurring with these seven types are shown in [21].

Annual Variation of Grosswetterlagen. *Frequency Maxima above Chance Limit* (*Weather Key-Days*). The establishment of types of *Grosswetterlagen* and the determination of the corresponding weather represent only the first steps toward rational macrometeorological research. Further steps must include the following: (1) determination of the seasonal trend of *Grosswetter* types, (2) investigation to determine whether certain *Grosswetterlagen* occur at certain times of the year more frequently than according to chance, (3) determination of the persistence and repetition tendency of individual *Grosswetter* types and their dependence on the seasons and on the general atmospheric circulation, and (4) investigation of the frequency and the circumstances of transition from one *Grosswetterlage* to another. There are many problems to be solved which require the closest coordination of theory, synoptics, and statistics based on the probability theory. A clear-cut solution of these problems is of incomparably greater value for extended-range forecasting, particularly for medium-range forecasting, than are the many harmonic and rhythm analyses still undertaken at several institutes.

The determination of the annual course of the relative frequency of European *Grosswetter* types in a 63-yr period showed [16] that in Europe one or more types of *Grosswetterlagen* occur in 22 intervals of several days each during the year with so high a relative frequency that it cannot be explained as chance fluctuation of a uniform distribution over the entire year. The number 22 represents only the present state of our knowledge; it is possible that this number will be increased with the further increase of observational data. As an example, Fig. 11 gives a portion of the annual course of

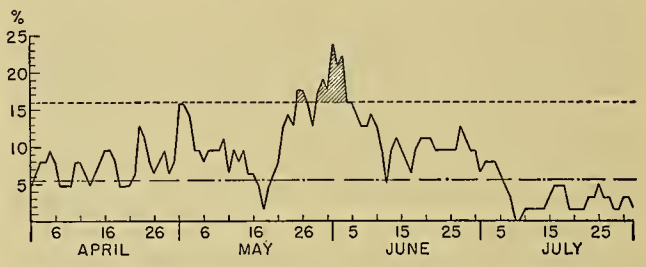

FIG. 11.—Seasonal variation of the relative frequency of the *HN*-situation from April 1 to August 1 for the period 1881–1943. The dash-dot line represents the annual mean value of the relative frequency of the *HN*-situation among the other *Grosswetterlagen*, the dashed line represents the upper limit of the range of chance of this relative frequency, where the range of chance is defined in the usual manner as the range which contains 99.730 per cent of all values.

the relative frequency of the "*HN*-situation," a *Grosswetterlage* which is characterized by a "steering high" or "central high" over the northeastern Atlantic Ocean between 30°W to 5°E and 58°N to 75°N. As can be seen from this figure, the relative frequency of occurrence on May 25 and 26, as well as on May 29 to June 3, exceeds the maximum chance limit. In such a sector of better-than-chance occurrence, the day of the greatest relative frequency is called a "weather key-day."

The general physical explanation of the annual course of the relative frequency of the European *Grosswetter* types by means of the annual course of insolation and the general circulation of the atmosphere is given elsewhere [17; 20, pp. 920–923].

It must be emphasized, however, that the relative frequency of a given *Grosswetter* type, at least in Europe, never reaches 50 per cent on any day of the year, and, even when several similar *Grosswetter* types are combined into one group, it never exceeds 70 per cent (see second empirical theorem).

EIGHTH EMPIRICAL THEOREM: *The occurrence of certain* Grosswetter *types is connected with the annual course of the general atmospheric circulation in such a manner that during certain parts of the year certain types occur more frequently than according to chance. However, they do not occur so frequently that, without the aid of other indications, an extended-range forecast could be based on them.*

Weather Key-Days and Weather Development. The weather key-days indicate, so to speak, the rhythm of the normal seasonal trend of the atmospheric circulation in the special circulation region under consideration. The term "rhythm," however, is not to be interpreted as a periodic or quasi-periodic process, but its meaning in this connection is only a defined dependence upon time. The basic cause of this rhythm is the annual course of the incoming and outgoing

2. Consult "Extended-Range Forecasting by Weather Types" by R. D. Elliott, pp. 834–840 in this Compendium.

radiation. The irregularity of the rhythm probably has its cause in the irregular distribution of land and water and in the variation of the period of the possible free oscillations. This latter variability results from the continuous change of temperature in the course of the year. The occurrence or nonoccurrence of the atmospheric phenomena pertaining to the weather key-days of the year is therefore the expression of the circulation character of the season or year in question. It is therefore probable that the weather on weather key-days is connected with the later weather development.

In fact, in Europe series of better-than-chance connections have been found between characteristic weather anomalies occurring around weather key-days and the subsequent or later meteorological situation [15; 17, p. 133]. For example, September 29 is a weather key-day for Europe. On this day, as well as on the preceding and the following day, certain European anticyclonic situations within the period from 1881 to 1943 reach a better-than-chance frequency [16]. From September 23 to October 1, central Europe has in 65 per cent of all years a so-called *Altweibersommer* with little cloudiness, infrequent precipitation, and relatively high midday temperatures. Weather of this character occurs in high-pressure regions, stretching from west to east, with a zonal circulation over northern Europe, as well as in the region of high pressure with the center over eastern Europe accompanied by a meridional circulation. In the latter case, the pressure at Moscow is considerably above normal. As is shown in Table V,

Table V. Pressure Anomalies During the European "Altweibersommer" and Temperature Character of the Subsequent Winter

(Example of an unequivocal, significant relation)

Year	Pressure departure (in mb)			Temperature departure of the subsequent winter in central Europe (cent. deg.)
	Sept. 21 to 30		Sept. 1 to 30	
	Moscow	Berlin	Moscow	
1884	+5.3	+3.7	+3.5	+0.9
1901	+8.3	+2.4	+4.7	+1.4
1902	+2.3	+9.3	+0.9	+0.7
1904	+16.7	+1.5	+8.8	+1.1
1909	+5.6	+2.0	+5.5	+2.2
1912	+7.2	+9.7	+2.8	+1.5
1913	+4.8	+6.0	+1.3	+0.8
1920	+12.3	+5.1	+3.2	+2.4
1926	+4.3	+1.1	+0.1	+1.6
1929	+6.3	+5.9	+1.3	+2.0
1937	+3.7	+2.3	+0.9	+1.2
1938	+12.4	+3.9	+5.9	+1.2
1947	+5.7	+0.4	+1.2	+2.2

in all the years of the period from 1881 to 1948 during which the mean pressure between September 21 and September 30 at Moscow was 2.0 mb above normal and, furthermore, the mean pressure departure was positive for Berlin from September 21 to 30 and for Moscow from September 1 to 30, the average temperature of the subsequent winter in central Europe was, without exception, greater than 0.6C above normal. Since the basic probability of such winters is 41.8 per cent, the upper limit of the scope of chance, within which the relative frequency can fluctuate by chance alone (if one defines the chance limit as on p. 817) lies at 86.5 per cent for $n = 13$. We can therefore conclude from the 13 cases (100 per cent) of mild winters shown in Table V that a physical relationship exists between the given pressure anomalies in September and the temperature character of the following winter in central Europe. This relationship is founded on the laws followed by the change between meridional and zonal circulation in the North Atlantic and European circulation regions.

Ninth Empirical Theorem: *Unequivocal relationships which lie outside the scope of chance exist between the weather anomalies about the time of the weather key-days and the subsequent* Grosswetter.

The Change between Meridional and Zonal Circulation. The persistence of each of the seven types of special circulation, described on page 826 is limited. For example, if with low pressure over the North Atlantic and high pressure over Europe and North America, subtropical meridional flow (Type IV) prevails for a relatively long period over western Europe and polar meridional flow (Type V) over eastern North America, then over western Europe and the eastern Atlantic, warm subtropical air is continuously transported toward the polar regions, while over eastern North America and the western Atlantic, cold polar air is transported toward the subtropical regions. Thereby the temperature contrast between subtropical and polar regions is diminished and with it the fundamental cause of the meridional circulation, so that eventually a zonal circulation replaces the meridional circulation. On the other hand, in the absence of a meridional exchange the temperature difference between subtropical and polar regions is re-established by the radiation difference between these two regions. With purely zonal circulation the temperature contrast between low and high latitudes eventually becomes so great that it forces the establishment of a meridional circulation. This re-establishment of a meridional circulation is explained as follows: The increase in the meridional temperature gradient causes a strong concentration of isotherms connected with a strengthening of the jet stream aloft. The large-scale lateral mixing processes (and frictional forces) on both sides of the vigorous westerly flow cause the formation of cyclonic vortices on the equatorial side and of anticyclonic vortices on the polar side of the band of west winds [44, 53]. Thus pressure troughs and ridges are formed, and a meridional circulation is again started.

In this manner, a continuous change between increased and diminished, and between predominantly zonal and predominantly meridional circulation, takes place. However, this change in circulation types does not occur in the same manner over the entire temperate zone of the Northern Hemisphere and, in general, not simultaneously either. This follows from the fact that, aside from the very rare case of a zonal circulation over all meridians, one and the same circulation type never exists in all special circulation regions (see seventh empirical theorem). The significant correlation coefficients in Table II confirm the fact that

circulation changes within limited regions—of the size of perhaps a continent or an ocean—actually exist and are caused to a large extent, though not exclusively, by the distribution of pressure and temperature within these regions and those immediately adjacent to them.

CRITIQUE OF THE METHODS OF EXTENDED-RANGE FORECASTING

Medium-Range Forecasts. It is useful to distinguish between medium-range forecasts (for two to five days) and extended-range forecasts (for six to ten days, for months, or for seasons). The methods of synoptic meteorology play a decisive role in medium-range forecasts. This is possible today, since weather maps of the entire Northern Hemisphere are available every day owing to the improvement of the communication system. However, it is necessary to supplement synoptics by meaningful statistics, partly to enlarge and consolidate our experience, and partly to create objective bases which could be of direct aid to forecasting. The application of rhythm analyses and symmetry points is of little use for the medium-range forecast, since the shorter pressure waves are mostly nonpersistent [20, pp. 933–934]. These methods are therefore discussed in the section on long-range forecasting.

Analogue Methods. An aid for the medium-range forecast can be found in the study of the subsequent development of past cases with both similar pressure distributions and similar preceding *Grosswetter* developments. It is to be noted, however, that such subsequent developments have a definite seasonal trend with frequency maxima in certain rather narrowly limited portions of the year, just as have the types of *Grosswetterlagen* and the repetition tendency. Therefore, only those days of previous years should be used for comparison whose date is not more than five days removed from the day in question. As a consequence of this restriction, really useful and significantly similar cases can be found only on rare occasions. This method can be used regularly only when weather map series for 150 yr are available.

Combination of Synoptics and Statistics. The only hopeful method of obtaining reliable medium-range weather forecasts is the combination of synoptics and statistics. By synoptics we mean here not only the chartwise representation and analysis of weather and *Grosswetterlagen*, but also the thorough consideration of subsequent developments from a physical viewpoint. For this purpose, it is necessary to develop the present synoptics, from which forecasts can be made only up to 36 hr in advance, to *Grosswetter* synoptics. Such *Grosswetter* synoptics deal with the physical aspects of the sequence of *Grosswetterlagen*, the forms of transition from one type to another, and the mutual influence of *Grosswetterlagen* in neighboring circulation regions. With such *Grosswetter* synoptics, the preceding development which has led to a certain *Grosswetterlage* must be taken into account to a much greater extent than has been the case with daily synoptics.

The multitude of the phenomena and problems that must be taken into account make it absolutely necessary that statistics be used as a broad empirical basis. What a theoretically designed experiment is to the physicist, clear statistics are to the *Grosswetter* investigator. Investigations of special situations which are favored in the usual synoptics give results which only appear to be proofs and have no value in promoting knowledge of macrometeorology. Such investigations can be compared to experiments in physics in which uncontrollable secondary effects are not eliminated. Clean-cut statistics must be preceded by definite physical or theoretical formulations of the problems; these statistics must comprise all available observations pertaining to the problem and they must be compared with suitable control samples to show whether or not the correlations are statistically significant. Such investigations can serve a double purpose: furthering our knowledge in a manner similar to a well-designed experiment as well as serving as a basis for forecasting, provided their results are unequivocal and significant (with a significance level of 0.27 per cent).

Forecasting the Sea-Level Pressure Distribution for Two to Three Days. The combination of synoptics and statistics makes it possible today to predict in many cases the approximate pressure distribution for the second and third day in those regions for which the necessary data are available. Scherhag [49] has shown how to determine the sea-level pressure distribution for the following day from the movement and intensity change of 3-hr and 24-hr isallobars, from the direction of the isopleths of geopotential, and finally from the divergence and convergence of the isopleths on the 500- and 225-mb charts. Furthermore, one can compute approximately the change in thickness of the layer between the 500- and 1000-mb surfaces from the surface pressure distribution; by adding the prognostic thickness chart to the prognostic surface pressure chart, the prognostic 500-mb chart for the following day can be obtained. In turn, from this 500-mb chart a forecast of the surface pressure distribution can be obtained for the second consecutive day. Finally, a prognostic chart of the surface pressure for the third consecutive day can be obtained by repeating this procedure with a consideration of the "steering" of the isallobaric maxima and minima in the upper troposphere by means of the 96-mb chart [17, p. 126]. Of course, the forecast becomes more uncertain with each successive day because of the propagation of errors. For this reason, it is necessary to supplement the prognosis statistically.

If we transform the hydrodynamic equation of motion so that it includes surface friction, and add to it the equation of continuity, the first law of thermodynamics, and the equation of state, a system of equations is obtained from which the following equation for the pressure change can be derived, as shown in [24]:

$$\frac{\partial p}{\partial t} = \frac{p}{RT}\left[\frac{\kappa}{1-\kappa}\frac{dq}{dt} + \left(gv_z - \frac{RT}{1-\kappa}\frac{\partial v_z}{\partial z}\right) + v\left(\frac{dv}{dt} + cv\right)\right] - \frac{p}{1-\kappa}\,\mathrm{div}_2\,\mathbf{v},$$

where the symbol $\mathrm{div}_2\,\mathbf{v}$ stands for the *horizontal* divergence of the velocity $\mathbf{v}$, $\kappa = R/c_p = 0.2884$, dq/dt is

the amount of heat received per unit time by a unit mass of a moving particle, c is a constant depending on external friction, and the other symbols have their customary meanings.

The replacement of the terms on the right-hand side of this equation by quantities which can be statistically interpreted—for these quantities the reader is referred to the original report [10]—leads to the following variables which are used as headings in a table of multiple correlations:

X_1 = pressure in mb reduced to sea level, on the clue day (day of forecast) at 1400 (4 classes),
X_2 = 24-hr temperature change in centigrade degrees from the previous day at 1400 to the clue day at 1400 (4 classes),
X_3 = 24-hr pressure change in mb from the previous day at 1400 to the clue day at 1400 (4 classes),
X_4 = cloudiness in tenths at 1400 on the clue day (4 classes),
X_5 = 7-hr pressure change in mb from 0700 to 1400 on the clue day (5 classes).

In Table VI, a section from a multiple-correlation table is given whose headings include these five variables. The numbers in the blocks are the 48-hr pressure changes from 1400 of the day of the forecast to 1400 two days later, as well as the date of the clue day (in parentheses). All observations refer to Potsdam (near Berlin). The table is based on observations from June 21 to August 9 of the years 1893–1937. Of the 1280 blocks of the table, 698 are covered with a total of 2250 entries. The boldface numbers of the table represent the mathematical expectation of the 48-hr pressure changes, in mb. Of course, in practice, only those squares are to be used that are most likely to lead to an unequivocal result, as is the case with the blocks of Table VI, marked by a black star. If one block contains a pressure change whose sign is different from all the other values of that block, this possibility could be excluded if the weather situation on the day in question (for instance July 12, 1928, in Table VI) were entirely different from that on the day of the forecast. For such comparisons, the method of similar (or, in this example, opposite) cases can be applied even at the present time.

The same table can be used for several climatically coherent places. However, different tables must be computed for different climatic regions and different seasons. The tables can be supplemented by the meridional and zonal pressure gradients or other physically important quantities. This, however, is possible only if observations over a longer period at several climatically similar stations can be combined in one table, such that the number of blocks, which increases with every new variable, can be filled with sufficient observations.

On days when sufficiently reliable results cannot be obtained from a multiple-correlation table, it is better not to draw prognostic pressure charts for the second and third consecutive days.

Mean-Circulation Methods of Forecasting. A judicious combination of synoptics and statistics is represented in the American investigations which can be classed under the name of "mean-circulation methods of extended forecasting" [32, 40, 41, 45, 53, 57]. With respect to the nature and results of these methods, the reader is referred to the article by Namias in this Compendium.[3] Only a few critical remarks will be made in

3. Consult "General Aspects of Extended-Range Forecasting" by J. Namias, pp. 802–813.

order to include these valuable investigations in the total structure of macrometeorology.

The most important aspect of these investigations is the world-wide point of view of the general circulation, on which they are based. This is *Grosswetter* synoptics in the true sense of the term. This method of consideration, comprising the entire Northern Hemisphere, is also applied in Rossby's formula [45]:

$$c = U - \frac{\beta L^2}{4\pi^2},$$

where c is the eastward velocity of the perturbation (trough or ridge), L is the wave length, U is the zonal velocity of the westerlies, and β is the rate of change of the Coriolis parameter with latitude. This formula (as derived from simplifying assumptions) is of such fundamental importance for the mean circulation methods that it is necessary to conduct rigorous statistical investigations to determine the extent to which it is confirmed by observation, and the conditions under which systematic deviations occur which can be eliminated by computation.

Clapp [41] made such an investigation using five-day mean 10,000-ft charts covering the period from January 1941 to April 1943. He computed the correlation coefficients between the observed displacements (for half a week and for a full week) of troughs and ridges at 45°N and those computed from Rossby's formula. Clapp used as a representative value of U, the zonal westerlies, the mean west to east geostrophic wind between 40°N and 50°N over the entire range of longitudes from about 130°W to 30°W, known as the 10,000-ft index I_3. He furthermore defined the wave length L as twice the difference in longitude between a given trough and the ridge to the west of it. Eliminating cases of new trough development, Clapp obtained the following correlation coefficients r in N cases:

	Full week		Half week	
	r	N	r	N
Winter	*0.66*	37	*0.67*	36
Spring	0.44	35	*0.51*	35
Summer	0.35	29	0.42	29
Fall	0.42	35	*0.63*	35

For the displacements during a full week the correlation is better than chance (with a significance level of 0.27 per cent) only in winter; however, for displacements during half a week, three of the four correlation coefficients are significant. We can conclude from this, that the Rossby formula, in spite of the simplifications made in its derivation, furnished an approximation of actual conditions. However, the correlations are too small to permit predictions of the displacement of troughs and ridges on the basis of this formula. For this reason, Namias [40] employed additional criteria and methods for the forecasting of circulation patterns.

According to Rossby's formula, a westward displacement (retrogression) of a trough or a ridge occurs when the wave length, that is, the distance between troughs, exceeds a certain value depending on the season and the geographical latitude; in other words, when an increased zonal circulation exists. This result is in apparent contradiction with the concept prevailing among central European investigators, according to which a westward displacement of steering centers, particularly high-pressure centers, at the 5-km level is to be expected for physical reasons, notably when a pronounced meridional circulation prevails on both sides of the steering center [47]. Nevertheless, both concepts are mutually consistent. It is entirely possible that a strong meridional circulation on both sides of a ridge at high altitudes is associated with a large distance between pressure ridges (Fig. 12*a*), whereas for a shorter

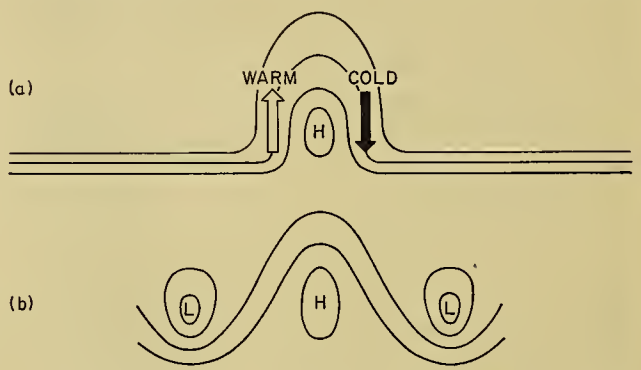

FIG. 12.—Schematic representation of the 500-mb contour lines with (*a*) alternating strong zonal and strong meridional circulation on both sides of a ridge, and large distance between ridges, and (*b*) prevailing meridional circulation, but not so concentrated locally and not so strong as in (*a*) and small distance between ridges.

distance the strong meridional circulation will, perhaps, occur less frequently or not at all (Fig. 12*b*). Further investigations are needed to establish the relative frequency with which a strong meridional circulation on both sides of a steering center in the upper troposphere is associated with an intensified zonal circulation at a relatively large distance from this steering center.

Observation of the large-scale meridional and zonal temperature contrasts is of great importance for the theory as well as for the practice of extended-range forecasting. Namias [39] has called attention to the very high correlation between the meridional temperature difference (35°N–55°N) and the west-east component of the wind speed at the 3-km level. Scherhag [48] has shown by a selected example that, even for monthly means, a strong negative pressure anomaly near Iceland corresponds to a strong meridional temperature gradient over the Great Lakes region of North America. Both these results are in agreement with the high correlation obtained by Baur [6] of the monthly mean temperature difference between New England and eastern Greenland with the simultaneous monthly mean pressure difference between the Azores and Iceland, for nearly all months of the year. For January, the correlation coefficient for the mean monthly temperature difference between New Haven and ½ (Jacobshavn + Upernivik) and the simultaneous mean monthly pressure difference between Ponta Delgada and Stykkisholm amounts to +0.61. However, this

correlation of the monthly means can be interpreted contrariwise: When the pressure over Iceland is very low, western Greenland lies within a cold northern flow, whereas to the west of the above-normal Azores High, warm air flows from the south to the north. In turn, with a strong air-mass exchange between high and low latitudes the temperature difference will diminish. The general circulation shows, after a certain duration of intensified air movement, "fatigue phenomena" which finally lead to a change in the circulation pattern (see Table II and [7]).

In order to develop circulation methods so that they can be used as a basis for reliable extended forecasts; a transition is necessary from the statistics of averages, now predominantly in use, to statistics of selected cases which take into account especially the physical processes, and the special characteristics of the particular case. Examples of "selective statistics" are contained in Tables I and V, which, to some extent, form parts of a multiple-correlation table. Table VI also forms part of "selective statistics."

Long-Range Forecasting. Forecasts for more than five days are not possible on a synoptic basis. The multitude of all possible developments no longer permits consideration of the development in all physical details. Here, statistics must be employed if we are to make statements about the future. However, two prerequisites must be fulfilled: (1) the choice of statistical methods must be guided by a physical formulation of the problems and by physical considerations, and (2) long-range forecasts should be given, at least publicly, only if better-than-chance statistical relationships are obtained that ensure the success of the forecast with a probability of over 92 per cent. It must be borne in mind that the damage which might result from an incorrect forecast is greater the longer the time interval for which the forecast is made. Therefore all demands for regular issues of monthly and seasonal forecasts must be declined in the present state of our knowledge. In order to be on the safe side, it is advisable to issue long-range weather forecasts only if at least two arguments are available that fulfill the above-mentioned prerequisites and lead to the same expected weather character without contradiction by any other statistical argument.

Extrapolation of Periods. The extrapolation of periods is more helpful for long-range forecasts than for medium-range forecasts. Tests of over a thousand harmonic analyses at the *Forschungsinstitut für langfristige Witterungsvorhersage* over a number of years have shown, however, that the percentage of correct forecasts is too small for these extrapolations to be used as a basis for long-range forecasts. Even the use of rigorous mathematical criteria permits only the decision as to whether the period has been persistent to date, but it does not yield any clues to its future behavior. Rhythm analyses cannot be used as the basis for any meteorological forecasts as long as we have no physical, statistically sound criteria that would indicate the continuation of the period with an expectancy of over 92 per cent during the forecast period.

Symmetry Points. There are even stronger objections against the use of so-called symmetry points for the pressure curve. In the first place, it was shown that even in a model sample based on chance and persistence tendency only, symmetry points occur with the same degree of approximation as they do for the actual pressure curve [20, pp. 924–926 and 934–936]. In the second place, the existence of a symmetry point can be detected with some degree of certainty only if about 20 days have elapsed. In the third place, even from a very good symmetry during 20–25 days, no sufficiently reliable conclusion can be drawn as to whether and how long the reflected curve of the pressure or any other weather element will persist. As an example, the symmetry point for the pressure curve of Potsdam on December 26, 1932, may be cited. The correlation coefficient of corresponding days from the first to the 25th day before and after the symmetry point was $+0.75$; from the 26th to the 50th day it was -0.46.

Regression Equations. It is necessary that regression equations which are to be used for long-range forecasts yield a multiple correlation coefficient greater than 0.80, since only then will the standard error of estimate of the correlation be less than $\frac{6}{10}$ of the standard deviation. Furthermore, the basic single correlations must be stable, that is, they must be approximately the same for subdivisions of the total period.

Multiple Correlation Tables. Since most of the *Grosswetter* correlations are not linear, it is very rare that multiple-correlation coefficients are obtained for sufficiently long periods which are larger than 0.80. Selective statistics again appear much more promising in this case, since fundamentally they yield parts of multiple correlation tables. As long as their computation is guided by a physical approach to the problem, unequivocal, better-than-chance results can be used as an empirical basis for the further development of the theory as well as a basis for long-range forecasts.

EXTENDED-RANGE FORECASTING BY WEATHER TYPES

By ROBERT D. ELLIOTT

North American Weather Consultants

INTRODUCTION

During the last two decades there has been a considerable development in the field of extended-range forecasting, that is, forecasts for up to a week in advance. While it is known that a modest success in forecasting general weather trends for as much as seven days in advance has been achieved by several groups using techniques of their own development, no particular method has gained the widespread acceptance in meteorological circles enjoyed by the frontal and air-mass analysis techniques of short-range forecasting. However, most of the extended-range forecasting methods have a number of points in common and these will be discussed briefly.

Meteorologists engaged in effective extended-range forecasting must become accustomed to dealing with certain forms of representation which summarize the circulation characteristics of a given region over a finite period of time. This may take the form of fixed-time-interval mean charts such as the overlapping five-day mean maps used by the Extended Forecast Section of the U. S. Weather Bureau [20], or more variable and "natural" period representations such as composite maps [21], weather types [3], or steering patterns [26]. In each case the representation involves, basically, the concept of mean circulation patterns at the surface and/or aloft, covering a fixed or variable time interval of several days or more. Even a pure analogue selection technique must involve considerations of this nature in order to be successful. One-map "thumbprint" selection schemes have not proved successful in extended-period forecasting, and exhaustive statistical tests by Darling [6] show that persistence is the principal factor taken into account by this method.

Ordinarily, the time interval is chosen in such a manner that the local circulation patterns of simple migratory and transitory cyclones and anticyclones are smoothed out, thus delineating the more basic quasi-stationary and broad-scale features of the circulation pattern which are responsible for the longer-period weather characteristics in a given region. The mean patterns thus revealed are characterized by large-scale cyclones and anticyclones at the surface and by an undulatory pattern aloft having longer wave lengths than those observed on daily upper-level charts. The movements and changes in form of these patterns are on the whole slower than those of the individual migratory systems making up the mean, which at least partly compensates for the difficulty of having to forecast so far in advance. In this country, methods for forecasting these movements and changes in form are based upon statistical weather-type prediction schemes [8], the application of the conservation of vorticity principle [20], and a number of other techniques which will be considered later.

Once the extended-period mean or type pattern is forecast, the anomalies[1] for the weather elements for the time interval in question can be predicted. Considerable statistical work has been done relating temperature and precipitation anomalies for an extended period with the weather types [3] and with the mean isobaric pattern at upper levels [17, 20]. In general, extended-period surface temperature anomalies are negative behind mean troughs aloft and positive ahead, with precipitation and cloudiness at a maximum just ahead of the mean trough.

The problem of preparing daily prognostic charts for up to seven days in advance is considerably more difficult. It is of course obvious that the sum of the daily prognostic charts should correspond to the extended-period prognostic representation; however, there are a great variety of ways in which this pattern may be made up. A prognostic extended-period upper-level chart may be used as a "steering" pattern to fix in a general way the paths of migratory cyclones and anticyclones, the individual systems being extrapolated forward from forecast day with due consideration being given to the predicted strength of the flow aloft. In one technique this is supplemented by various prognostic zonal and meridional indices [20]. Another technique [4] resorts to the use of analogues selected from the archives of weather charts in which the mean flow pattern matches the predicted pattern. Still another method is to use "ideal" weather types [3] giving the characteristic daily surface charts for each day of the weather types as determined through statistical study of past cases.

The foregoing paragraphs very briefly outline the features which most extended-range forecasting techniques have in common. These may be summarized as follows:

1. A method for concise representation of circulation characteristics during an extended period.
2. A method for forecasting movement and changes in form of circulation features delineated in 1, thus permitting the preparation of a prognostic representation.
3. A method for forecasting extended-period anomalies of the weather elements from information provided by 2.
4. A method for preparing daily prognostic charts and forecasts for daily weather elements from 2.

1. The term "anomaly," as used in this article, refers to departure from a long-term average over time and has nothing to do with the departures from means computed for latitude circles.

Although some investigators who are inclined toward statistical analysis advocate the elimination of one or more of the intermediate steps by going directly from the representation scheme to the forecast of the weather elements themselves, in the opinion of the author our present knowledge concerning weather processes is so limited that the use of the intermediate steps is required in order that the forecaster can grasp more readily the physical significance of the processes involved.

A general discussion of the California Institute of Technology weather-type technique is presented in the following section.

THE WEATHER-TYPE APPROACH

Various sorts of weather types had been developed for different areas in the past [2, 14, 23]. Often the earlier attempts at typing were based upon single typical synoptic charts and therefore did not truly take into account weather processes occurring during an extended period. After some preliminary investigation during the late thirties [10, 18] a six-day North American weather-type scheme was developed wherein the type itself embraced a sequence of days characterized by certain locations and orientations of the semipermanent elements of circulation such as the Pacific anticyclone, the Aleutian cyclone, the trajectories of polar outbreaks, and cyclone paths. Empirical evidence was discovered which indicated that the mean period between the passages of cyclone families past a given point was about three days and that about two-thirds of the time the type characteristics associated with the passage of a given family occurred also in either the preceding or the following cyclone family. Because of this, the types were arranged so as to have a lifetime in any given sector or region of six days plus or minus one day. The instances where the type characteristic was not maintained during the passage of two successive cyclone families were handled by the introduction of the so-called "complex" types in which the first three days had the characteristics of one type and the last three those of another. Considerable work was done on these types over a period of several years, resulting in the development of a weather-type catalogue covering the period 1921–42 [22] and a set of "ideal" types [3] showing the most probable location of frontal systems and centers on successive days of each type, along with other statistical information on the weather element anomalies associated with these "ideal" types.

Although these types proved of value, continued study indicated a number of shortcomings, the most important of which seemed to be that forcing the types into a six-day lifetime seemed somewhat arbitrary. Therefore, during World War II, in response to a request from the Army Air Force, which was interested in extended-range forecasting techniques and had contracted with the California Institute of Technology for continued research on the subject, new three-day types [4] were developed wherein the life of the type corresponded to the passage of a single cyclone family across a region. This averaged three days, with considerable variation. The three-day weather types included all the essential and well-tested features of the older six-day types plus a number of refinements found necessary as a result of experience in their application. They were developed for each of four synoptic regions consisting of sectors of forty-five degrees of longitude extending along the belt of westerlies from 135°E through 180° to 45°W and a fifth region extending from 45°W to 45°E. Some twenty to thirty different types were determined for each region and a catalogue of weather types for forty-six years was prepared [4, 5, 15].

It was early recognized that the large-scale and persistent distortions of the upper-level pattern controlled and determined the weather types in each region. With an increasing file of adequate upper-level charts it has been possible to establish in a reliable fashion the upper-air patterns associated with each weather type [19]. Because this file does not extend far back historically, it has not been possible to employ upper-air type characteristics in cataloguing, except in recent years.

It had early been noted that the weather types for each region could be divided into two distinctive categories and that types in the same category often occurred simultaneously in neighboring regions. These two categories were the meridional and zonal flow types. Meridional flow types are characterized in the mean by upper-level crests and troughs of large amplitude which tend to steer the surface migratory systems along paths far to the north or south of normal, depending upon their location. Most of the large polar outbreaks which penetrate to southerly latitudes occur in this category. Elsewhere, unseasonably warm weather is experienced. Meridional flow patterns are particularly interesting because of the conspicuous anomalies of temperature associated with them. An interesting example may be cited in this connection: during the entire month of January, 1949, in North America there existed an extremely strong and persistent trough aloft in western United States with a persistent crest in eastern United States. As a result, temperatures were far below normal in the West and above normal in the East.

Zonal flow types are characterized by zonal flow aloft. Variations in the strength and latitude of the belt of westerlies lead to variations within this category.

It is beyond the scope of this article to present the details of weather types as delineated by daily or "ideal" charts. However, a set of schematic diagrams representing the major features of the mean flow pattern occurring with a number of the more important wintertime weather types of the North American area is shown in Fig. 1. The types are arranged in two columns; in the left-hand column are meridional flow types, in the right-hand column zonal flow types. In addition, the position of each type in its column is determined by the degree to which it displays the characteristics of the category. In the case of the meridional flow types, the more the principal mean trough over North America is shifted westward, the stronger the meridional flow character of the type. In the extreme of this category the trough is off the west

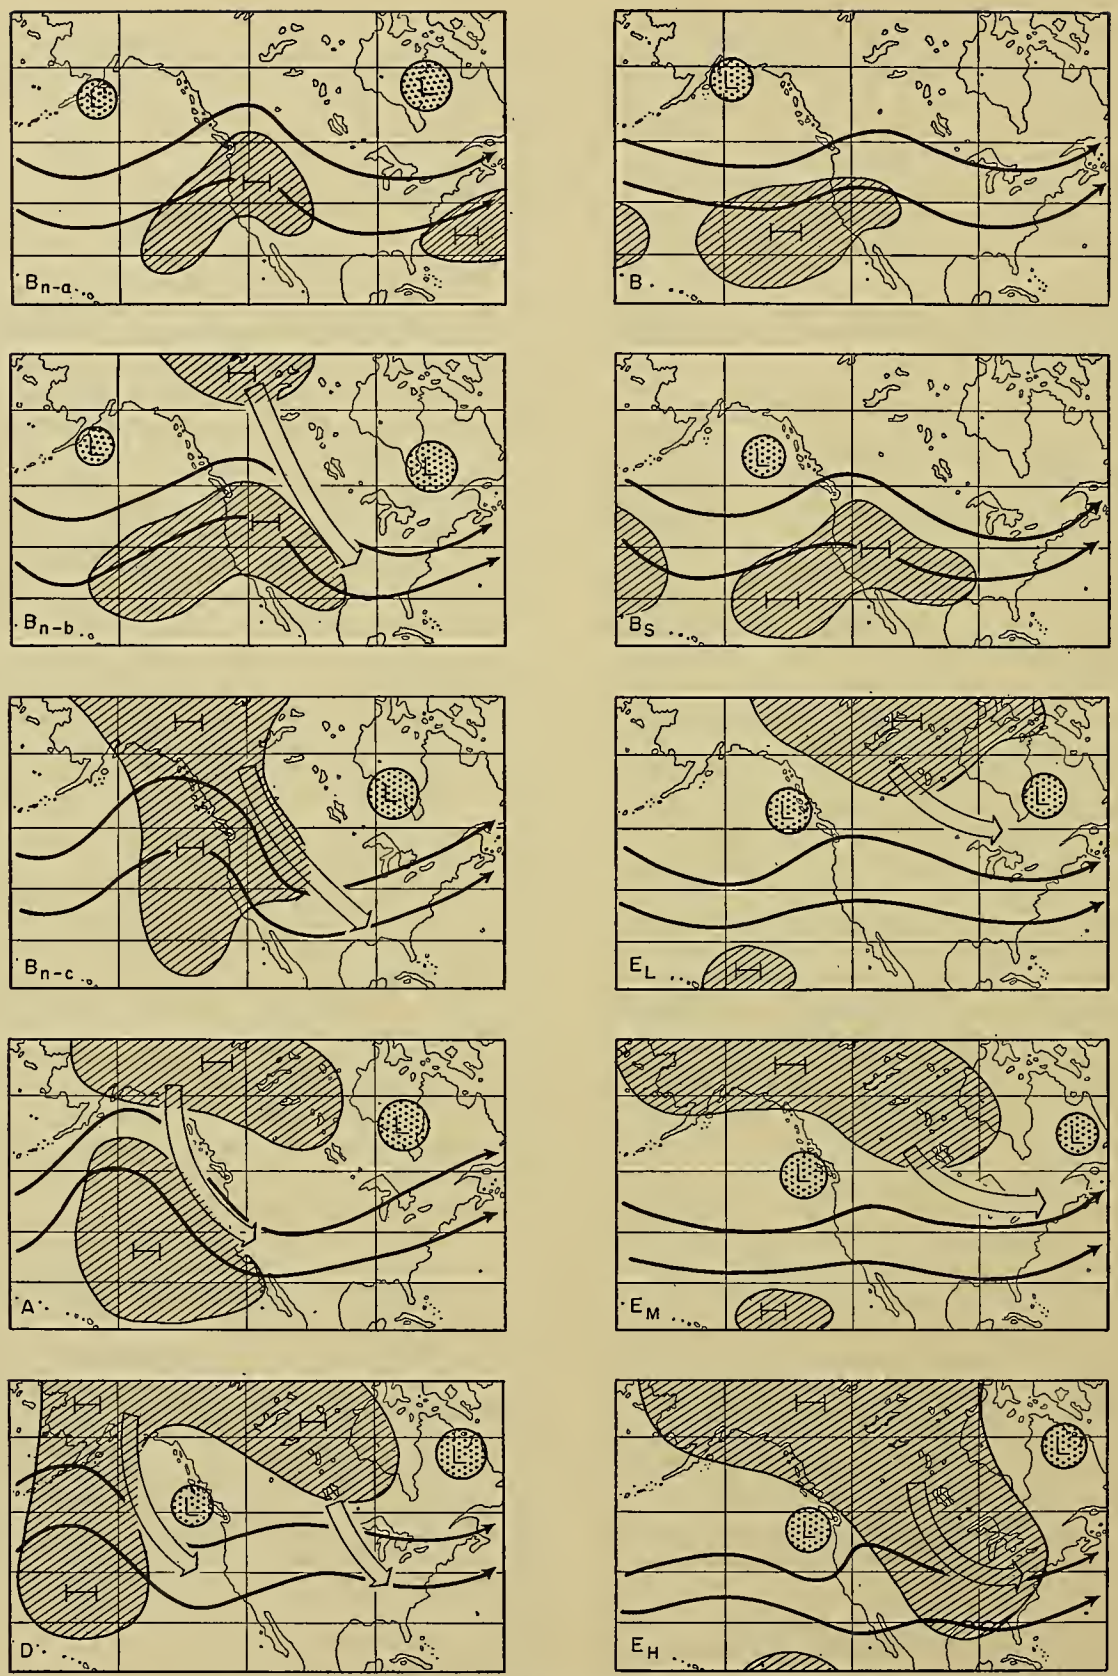

FIG. 1.—Schematic diagrams of weather types. Heavy lines with arrows at ends indicate upper-level mean flow. Hatched areas are regions of persistent subtropical or polar high pressure at the surface. Stippled areas are quasi-stationary low-pressure centers. Open arrows indicate the paths of polar outbreaks.

coast of North America. The depth of the trough as a rule increases with the westward shift. With the zonal flow types, the farther southward the westerlies are shifted over a broad sector, the stronger the zonal flow character of the type. In the extremes of this last category the southward shift occurs over a sector 90° (or more) wide and is accompanied by the formation of extensive polar anticyclones to the north of the principal storm path. This storm path is unusually far south.

In the meridional category, the *Bn-a* type has a definite upper-level trough at about 90°W and a crest over the Great Basin (eastern Washington, Idaho, eastern Oregon, Utah, Nevada, and northern Arizona). Because only minor polar outbreaks occur in this type and because of the presence of a large dynamic anticyclone over the Great Basin which deflects Pacific storms northward, the United States and southern Canada experience relatively warm dry weather. As one proceeds to the *Bn-b* type, it is found that whereas conditions to the west of the Rockies are nearly identical with those for *Bn-a*, in the East a polar outbreak occurs as indicated on the diagram. This tends to make the eastern trough aloft deeper than in the case of *Bn-a* and produces below-normal temperatures east of the Rocky Mountains. In the case of *Bn-c* type, the meridional character of the flow becomes quite marked with a well-developed trough aloft at about 100°W. Frequently a strong dynamic cyclone remains trapped for several days in the southern Great Basin. The polar outbreak, instead of being confined to the area east of the Rocky Mountains as in the case of *Bn-b*, flows westward through mountain passes as well as southward along the eastern front of the Rockies and produces much-below-normal temperatures throughout most of western United States. Ahead of the mean upper-level trough, surface temperatures are considerably above normal, and precipitation is likely to be excessive near the mean trough. It is interesting to note that the Great Basin anticyclone, present in the two preceding types, is now weaker and appears to be merged to the west with the Pacific anticyclone, which has shifted northward. A further westward shift of the mean upper-level trough position is exhibited in type *A*. Here the Basin anticyclone has disappeared from the scene as a semipermanent feature of the circulation at the surface. The eastern lobe of the Pacific anticyclone has moved unusually far north and the polar outbreak associated with this type consists of a mass outflow of cold air moving southward along the Pacific Coast, then southeastward into the Great Basin. In contrast to polar outbreaks over the land areas of North America, this outbreak is characterized by cyclonically curved isobars at the surface. Surface temperatures are below normal along the Pacific Coast and in the Great Basin but are above normal in the East. Because of the interaction of tropical and polar air masses in an area north of normal in the East, precipitation is excessive in the Mississippi and Ohio Valleys. This type and the closely related *Bn-c* type were responsible for the abnormally cold weather in the West and warm weather in the East during the winter of 1948–49 and also during January, 1937. Type *D* represents the most extreme of the meridional flow types. In this case the principal trough lies entirely off the West Coast with an unusually intense, northward-displaced Pacific anticyclone, which is merged with the cold anticyclone over Alaska. The principal outbreak of cold air is so far west that a second minor outbreak occurs downstream in eastern North America.

There exists a somewhat infrequent, yet important additional meridional flow type not shown in Fig. 1. This is the *C* type which resembles the *Bn-a* type except that there is a low-latitude trough aloft just off the southern California coastline. In this way the westerlies are split into two branches, the northernmost branch moving along a crest at about 125°W and the southern branch moving along a trough at this same longitude. The two streams converge downstream. For this reason there are essentially two storm tracks, a northern and a southern track. Very heavy precipitation occurs along the southern track in southern California, Arizona, and New Mexico.

The first of the zonal flow types, *B*, is characterized by a northerly storm track with a belt of well-developed subtropical anticyclones to the south. As a result, relatively dry and warm weather prevails over most of the United States and the southern Prairie Provinces of Canada. In the second zonal flow type, *Bs*, the upper-level westerlies are farther south in the East but in the West they are as far north as in type *B*, thus tending to accentuate the western crest. Although the Great Basin anticyclone is actually more persistent in the case of type *Bs*, it is considered to be more zonal than *B* because the westerlies are farther south on the average over a broad sector and are definitely stronger as reflected by the greater rapidity of movement of migratory systems along the principal storm path. Types E_L, E_M, and E_H are each in turn characterized by a more extensively developed polar anticyclone and a more southerly shift in the westerlies aloft and consequently in the storm tracks. The great masses of cold polar air associated with these types seldom move southward in any form of organized polar outbreak such as occurs with the meridional flow types but merely linger north of the mean frontal zone accentuating the air-mass contrast across the front and leading to excessive precipitation along the mean frontal zone itself. In the extreme E_H type the cold air occupies most of the United States and entirely blocks the eastward progress of Pacific storms beyond the Rocky Mountains.

GENERAL CIRCULATION CONSIDERATIONS

A recent study [13] of broad-scale and long-period weather processes occurring in connection with certain abnormal meridional flow patterns has supplied information providing more justification for the weather-type treatment thus far discussed. Among other things,

this study was aimed at ascertaining the significance of mean flow representations not only with respect to the mean pattern itself but also with respect to the smaller-scale and more transitory disturbances going to make up the mean flow. This involved the application of the turbulence principles of fluid mechanics to the circulation of the westerlies. Similar investigations [9, 24] have been undertaken in the past, but no attempt had been made to apply this concept through a more-or-less statistical treatment of a long record of weather data such as the forty-year Northern Hemisphere series [28]. In this treatment the smoothed-out fluctuations, the migratory and transient cyclonic and anticyclonic systems, were treated as turbulent eddies having the property of being able to transport heat and momentum across large horizontal sheets of the atmosphere. This analysis indicated that the very large amounts of heat picked up from the oceans off the east coasts of the continents [16] are removed from the westerlies downstream through lateral turbulent diffusion so that equilibrium is maintained. In addition it showed that in years when the north-south thermal gradient is in excess of normal, the lateral mixing in the westerlies is excessive, and the cross-westerly heat transport is also excessive. In connection with excessive lateral mixing there occurred an excess of meridional flow types.

The detailed analysis of the eddy motion in the westerlies indicated the existence of a spectrum of eddy periods with a mean of about six days in the heart of the westerlies and slightly higher values on either side. The most frequent value was three days, corresponding to the mean period in the passage of cyclone families as used in weather typing. The longer-period eddies even showed a tendency towards durations which were multiples of the three-day period.

Eddies of very long duration were associated with larger-than-average distortions from the normal flow pattern, with respect to both wave length and amplitude. In many cases these large eddies appeared on the surface charts as quasi-stationary anticyclones in the middle latitudes, with trapped cyclones to the south of them. In the study these were referred to as "blocking highs" because of their action in blocking the normal eastward progress of migratory systems. In cases where such large blocking eddies exist it becomes hardly proper to treat them as eddies in the time and space scales generally involved in the extended-range circulation representation schemes. The smaller and more frequent short-period eddies characterizing true migratory cyclone and anticyclone activity are steered around or completely blocked by these eddies. Therefore the large eddies merely serve to introduce large-scale distortions of the normal westerly flow on extended-range charts. In effect, these eddies tend to lengthen the closed path of the westerlies around the hemisphere and there is thus provided a longer perimeter along which the smaller eddies can act to transport heat and momentum across the westerlies. This situation corresponds to that existing in the meridional flow category discussed above. These types must then be those for which the cross-westerly heat transport is at a maximum, and the zonal category corresponds to the case where the girdle of westerly winds has a minimum length, at least in the regions where zonal types are in existence, and therefore represents a state of minimum cross-westerly heat transport.

It is often apparent that there is a certain time lag between the development of meridional flow types in various regions of the Northern Hemisphere. This observation coupled with the known quasi-periodic alternation between zonal and meridional flow types within one type region suggests that under ordinary circumstances the zonal flow types are incapable of providing the required cross-westerly heat transport needed to balance global radiational effects, whereas the meridional flow patterns are more than adequate for this purpose. Since there is no dynamically stable intermediate stage, an alternation between the two circulation types results. At times the alternation seems to be in phase throughout the Northern Hemisphere but at other times this is not true. In view of the rapid dispersion of energy indicated by recent theoretical investigations [25], one might expect the in-phase condition to predominate but there is some evidence of slower modes of energy propagation in the atmosphere. Regardless of this, in any given region the action suggested is analogous to that of a relaxation oscillator, the potential, as represented by the north-south thermal gradient, building up to critical levels from time to time and then relaxing as the flow of the westerlies breaks down into meridional flow patterns. A study by Schwerdtfeger [27] indicated that in a source region for polar outbreaks the polar air may be built up to critical strength from a stage of complete exhaustion through radiation processes within a period of some three weeks. Observation indicates, however, that the pulse period of outbreaks in North America is more on the order of a week (corresponding to rather large-sized eddies) with a longer-period fluctuation in the strength of the pulses on the order of a month. The latter would correspond to the oscillation in question but such pulsations are far from systematic and hence it seems that other events, such as perhaps variations in extraterrestrial radiation, may play an important role.

The effect of the irregular geographic distribution of oceans and continents, although complicating matters, should not in itself account for the lack of regular periodicity.

INTERACTION ON A HEMISPHERIC BASIS

As was pointed out above, the most difficult step in extended-period forecasting is that involving the prediction of the movement and changes in form of the systems appearing on the extended-period representations. In the weather-type method this amounts to the forecasting of the next weather type or types. This usually involves directly or indirectly the study of large-scale and long-period weather processes on a hemisphere-wide basis. Some of these general processes which can be used in connection with extended-period forecasting by the use of weather types were set down

by the author during World War II [11]. Since then, additional work has been done upon them [1, 13]. In line with the character of this article, a few very general remarks will be included covering this approach.

At times, particularly during meridional flow periods, certain systematic movements are apparent. Curiously enough, such motions frequently exhibit a westward displacement or retrogression, not so much of the individual broad-scale crests and troughs aloft but of the amplitude or energy of the disturbance. Thus, following the development of a trough and crest pair, the next major trough or crest-trough pair upstream will increase in amplitude. The rate of the propagation is some seven degrees of longitude per day in winter [1]. Sometimes this upstream effect appears to be propagated mainly through the action of the subtropical easterlies; at other times the polar easterlies appear to be the controlling factor. Other evidence [13] indicates that systematic distortions of the westerlies develop slowly over a period of two or more weeks both upstream and downstream from a major disturbance such as a blocking high. Recent theoretical studies [25, 29] of energy propagation indicate the possibility of a number of modes of energy dispersion and clearly indicate the possibility of interaction on a hemisphere-wide basis. This confirms much recently obtained synoptic evidence of the dependence of North American weather developments on events occurring elsewhere in the Northern Hemisphere.

Considerations of the type just mentioned have been handled statistically through the use of the data appearing in the forty-six-year weather-type catalogue. Naturally the first and simplest statistical aid to be developed from the catalogue was merely the determination of the seasonal expectancies of the various types. Next came the expectancies for various types in one region following a given type. Later, the North American types were arranged in a certain order depending upon such items as the latitude of the Pacific anticyclone, strength and location of polar outbreaks, and natural statistical relationship, and numbers were assigned in accordance with this order. Then type-prediction regression formulas were developed [8] whereby future types could be predicted on the basis of the past sequence of types in one region. Success was limited. It is believed that the greatest shortcoming of these earlier regression formulas lay in their disregard of present and past types in other zones. More recently the type data for the five zones have been punched on International Business Machine sorting cards [1], and prediction schemes based upon present and past types in each of the five zones will be developed.

The use of the type catalogue in analogue selection is of course obvious. It is highly efficient in this respect but selections must be made with extreme care in order to avoid the above-mentioned shortcomings of "thumbprint" analogues. In a theoretical study [8] of "thumbprint" analogue prediction schemes it has been shown that the weakness of this system compared to a generalized prediction scheme lies in the fact that it is not possible to consider direct and cross matches between analogue elements with different time lags. The analogue scheme thus assumes that weather is a one-dimensional function of time.

In statistical investigations using the type catalogue it has been found necessary to consider processes of much greater duration than those covered in the usual extended-period considerations. Some rather interesting results have been found in studies of seasonal characteristics. An unpublished study shows that in a normal season the extreme meridional flow types occur frequently in the autumn but that, as winter approaches, the frequency of their occurrence drops off

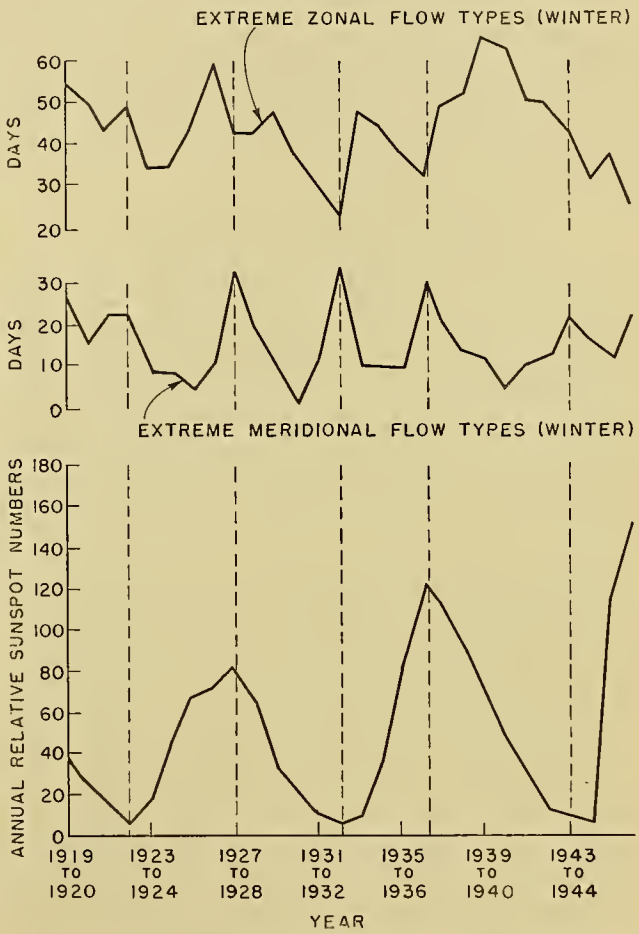

FIG. 2.—Curves showing the frequency of meridional (middle curve) and zonal (upper curve) flow types during the winter seasons 1919–20 through 1943–44. The lower curve gives the annual relative sunspot numbers during the same period.

rapidly and the extreme zonal flow types (E) increase in frequency. Again, in the spring the frequency of the meridional flow types increases and the zonal flow type decreases. Apparently, cross-westerly heat transport and general lateral mixing are greatest in the spring and the autumn. In certain years there is a distinct tendency for the extreme meridional flow types to continue with high frequencies on into the winter season. Since winter meridional flow types exhibit stronger abnormalities than those of autumn and spring, this leads to quite exceptional weather (*viz.*, January, 1937 and 1949) and for this reason the phenomenon was studied in detail. The effect can best be

demonstrated by graphing the number of days of occurrence of extreme meridional flow types (*D*, *A*, *Bn-c*) in the winter season (December, January, and February) for each year. This appears as the middle curve in Fig. 2. The curve for the extreme zonal flow types (*E*L, *E*M, *E*H) is the top curve in the figure. These curves show quasi-periodic variations with a period of five or six years and an appreciable amplitude. The two curves are out of phase.

The period is suggestive of half the sunspot cycle, and the curve of sunspot annual relative numbers is shown at the bottom for comparison. The sunspot curve is based upon the annual value corresponding to the year of the January and February portion of the plotted winter-season type characteristics and hence is in effect somewhat lagged in phase from the top two curves. The correspondence between the peaks in the extreme meridional flow types and the sunspot maxima and minima is striking.

PROSPECTS FOR THE FUTURE

With regard to prospects for the improvement of techniques for extended-range forecasting, it is the author's opinion that two fields of investigation offer the most attraction. One of these is the study of the long-period interaction between broad-scale circulation features in different parts of the Northern Hemisphere and, for that matter, over the whole world. This, it would appear, involves the modes of energy dispersion. A joint theoretical and synoptic attack is in order.

The other field involves a thorough study of the radiational properties of the earth and its atmosphere and the study of the effects of variations in solar output upon atmospheric motions. The example of a general relationship between solar activity and weather-type frequencies presented above is just one of many such relationships developed from studies of weather types. The works of Abbot, Clayton, and many others provide evidence favoring a real relationship. Meteorological events, seemingly inexplicable from the viewpoint of a closed system consisting of the atmosphere and the earth, are continually occurring and require a systematic investigation of extra-terrestrial effects.

VERIFICATION OF WEATHER FORECASTS

By GLENN W. BRIER and ROGER A. ALLEN

U. S. Weather Bureau, Washington, D. C.

INTRODUCTION

Verification of weather forecasts has been a controversial subject for more than sixty years and has affected nearly the entire field of meteorology. This paper will discuss some of the important reasons for this controversy and attempt to show that much of the existing confusion disappears when a careful analysis is made of the objectives of forecasting and verification. A number of verification systems that have been used will be described, but it is beyond the scope of this paper to make a complete survey of verification practices or of the literature on the subject. For the latter purpose the reader is referred to articles by Bleeker [1], Muller [6], and the U. S. Weather Bureau [10], which contain extensive bibliographies.

Definition of the Problem. Verification is usually understood to mean the entire process of comparing the predicted weather with the actual weather, utilizing the data so obtained to produce one or more indices or scores and then interpreting these scores by comparing them with some standard depending upon the purpose to be served by the verification. In the discussion which follows, it will be assumed that both forecasts and observations have been expressed objectively so that no element of judgment enters into the comparison of forecast with observation, and it will be assumed further that errors of observation are unimportant. These assumptions are discussed in a subsequent section. The selection and interpretation of an index or score which will meet the objectives of the verification study usually constitute the most difficult part of the problem since, as will be shown, practical considerations often require that the score fulfill a number of requirements and furnish information on a number of different characteristics of the forecasts. Selection of arbitrary scores intended to measure a number of parameters usually leads to difficulty in the last step, interpreting the score.

PURPOSES OF VERIFICATION

One of the earliest purposes of forecast verification was to justify the existence of the newly organized national weather services, and thus the question of verification immediately became a football to be kicked around by the supporters and opponents of the national weather services. Some, such as Klein [5], claimed that the official synoptic forecasts had little or no practical value and produced verification figures intended to prove their point. Others, for instance Schmauss [7], claimed that the weather forecasts could not be subjected to rigorous statistical tests or that the tests that had been performed had no meaning. Today the value of the national weather services is so widely accepted that this particular purpose of verification no longer is of much importance. However, the effects of this controversy still show their influence by often preventing a realistic attempt to solve some of the problems of forecast verification since some meteorologists object a priori to any scoring system that does not produce high enough figures to make the forecasts appear favorable in the eyes of the public or government appropriating bodies.

Economic Purposes of Verification. Since the sole purpose of practical forecasting is economy of life, labor, and dollars, it would seem that one of the chief purposes of verification is to determine the economic value of the forecasts which have been made. But such an evaluation, especially for the whole economy, is difficult or impossible since the uses and users of forecasts are so diverse and ramified. Forecasts that may have considerable value for one user may have little or no utility for another user or may actually have a negative value if their accuracy is low. The measurement of the economic value of the forecast is thus a separate project for each user, and this is usually impracticable or impossible because the individual has neither the essential economic data nor the facilities to make such an evaluation. Thus a farmer may feel that an accurate weather forecast enabled him to make some saving in seed cost and planting labor, but he may be unable to estimate the cost of his own labor, and the total saving might depend upon the value of the harvested crop which is, of course, unknown until harvest time. Sometimes such economic evaluation of the forecasts is possible, the necessary data being found in the cost accounting and financial structure of the particular business [2]. However, since evaluation in economic terms is usually impossible, it is most often desirable to determine the reliability of weather forecasts by measuring their approach to the truth and expressing the result in terms of some arbitrary scale such as errors in degrees Fahrenheit or per cent of hits. The user of the forecast can then interpret the information in terms of his operations. Thus an electric power company may want to know when thunderstorms are forecast for a given area and what the likelihood is that the forecast will be correct, or, on the other hand, what per cent of observed thunderstorms in an area will be correctly forecast.

Administrative Purposes of Verification. One of the most useful purposes of verification is to determine the relative ability of different forecasters. In a weather organization the relative ranks of forecasters may be desired for a number of reasons, such as selecting promising personnel for further training in forecasting, selecting able men for difficult or specialized forecasting

assignments, selecting research personnel, or rating the efficiency of the forecaster. The verification scheme adopted may apply only to the regular official forecasts made by the individual or to a special practice-forecast program. Such a program may involve people not assigned to regular forecasting and thus provide a basis for discovering hidden talent. In the classroom a practice-forecast verification program is used to measure the progress of student forecasters and can assist the professor in vocational guidance. A student showing low forecasting ability but high mathematical ability might be encouraged to go into theoretical meteorology rather than into practical forecasting. Numerous other examples of administrative purposes of verification could be given.

Verification procedures, when applied to the official forecasts of a weather station, can make a valuable contribution to the control of the quality of the output of the station. In industry it has been found that scientific sampling procedures are necessary to maintain uniformity in the manufacturing process. If the forecasts made at a particular station over a period of time appear to fall below the standards of accuracy that have previously been attained, administrative action to investigate the reasons for the falling standards might be desirable. There is also a further advantage that the mere existence of a checking scheme, even if imperfect, tends to keep the forecasters more alert and interested in maintaining the accuracy of forecasts.

Scientific Purposes of Verification. One of the goals of scientific meteorology is to be able to predict precisely the state of the atmosphere at any time in the future. This goal is a difficult one to attain, but considerable progress has been made in the past several decades in understanding the physics of the atmosphere. Sometimes the question is raised as to whether there has been any increase in the accuracy of weather forecasts over a period of time. The question asked may be quite general, such as whether temperature or precipitation forecasts made by meteorologists in general are more accurate than they were fifty years ago. Sometimes the question may be directed at a specific group of forecasters using special methods on an experimental basis. In both these cases verification statistics can be used to provide information on the trend in forecast accuracy, although the technical difficulties in obtaining accurate statistics may be great. When some new advance in meteorological theory which bears on forecasting is proposed, it may be possible to compare the verification scores of experimental forecasts made using the supposed advance with forecasts made without the new theory. In this case verification is equivalent to testing the validity of a scientific hypothesis.

Another scientific purpose of forecast verification is the analysis of the forecast errors to determine their nature and possible cause. This is, in the opinion of some, the most important and most fruitful objective of verification since it is more susceptible of scientific treatment than some of the other purposes. A search may be made for indicators of forecasting difficulty which will help to locate the synoptic situations under which forecasts are most likely to be wrong. It is commonly thought, for example, that situations where weather changes are taking place rapidly are more difficult to forecast than other situations, but it should be noted in passing that the literature does not reveal any precise studies to support this view. Likewise, although this is a widespread belief, it remains to be shown by verification figures that the forecasting accuracy for some element such as precipitation occurrence is lower for cases in which deepening or filling of a low is poorly forecast than for cases in which the deepening or filling is accurately forecast. Such verification as this can be used to discover the weaknesses of forecasting systems in order to decide where research emphasis is needed.

FUNDAMENTAL CRITERIA TO BE SATISFIED

Terminology of Forecasts. One essential for satisfactory verification is objectivity, which requires that the forecasts be explicitly stated, either numerically or categorically, thus permitting no element of judgment to enter the *comparison* of forecast with subsequent observation. But the relation between the forecaster and the public, which depends upon the forecaster's terminology, is usually subjective in nature, since even objective terms and the actual weather are interpreted subjectively by many individuals. Bleeker [1] discusses this point clearly. If every forecast is accompanied by a definition of the terms used, the forecaster sometimes objects on the basis that it hinders his freedom to express himself adequately. At this point it is easy to raise questions about the psychology of forecasters and of the public and many arguments in forecast verification revolve around this point. Although these are practical and very important problems to those attempting to serve the public with weather information, they are in essence outside the field of forecast verification and the goals of verification would be reached much sooner if this were more generally recognized. Only those forecasts which are expressed in objective terms can be satisfactorily verified *as forecasts*. The extent to which public forecasts satisfy the public is a different question which can be answered, it appears, only by public opinion polls; and the answer generally will contain little information about the agreement of forecast and actual weather.

Meteorologists themselves sometimes advocate subjective verification, particularly in the case of prognostic charts which attempt to portray the pattern of some weather element (such as pressure) rather than to specify the weather at individual points. In some cases this has led to the use of boards of experts who compare the prognostic charts with observed charts. The difficulty in objective comparison arises because of the unsatisfactory state of knowledge as to what are the important parameters of the prognostic pattern; or in other words, the forecaster is unable to specify objectively just what he is trying to represent with a prognostic chart. In effect, the forecaster is trying to verify something which cannot be observed, hence this situation does not meet the definition of verification.

An extreme view denying the need for objectivity is that expressed by Hazen [3], who says,

> ... to make a proper verification of a weather forecast, and one that shall be rigidly applicable to every case ..., it should be done by ... one thoroughly acquainted with the average conditions and he should verify from the map on which the prediction was based and not from subsequent maps. If the verification is from a subsequent map, care should be taken to consider what abnormal conditions have occurred which could not have been anticipated.

Selection of Purposes of Verification. Before any satisfactory verification scheme is adopted it is necessary to determine the primary purpose or purposes to be served by the verification This may appear to be obvious, but the history of the forecast verification controversy during the past half-century makes it clear that this fundamental point has been forgotten again and again. A scheme that is adequate for one purpose may be unsatisfactory for another, just as an automobile is suited for travel over the highway but is quite inefficient for flying through the air. Unfortunately, much time has been wasted and much confusion has resulted from attempts to devise a verification method or single score that will serve all purposes. The very nature of weather forecasts and verifications and the way they are used make one single or absolute standard of evaluation impossible. A set of forecasts has many different characteristics. Some of the forecasts are correct, and knowledge of the percentage which are correct may serve some purposes. Usually the weather occurrences in one part of the range will seem to be more important than those in other parts of the range, and this must be considered in specifying the purpose of the verification. Thus if the set of forecasts are forecasts of temperature in a citrus grove, the characteristic which is most important may be the percentage of forecasts of temperature below freezing which were actually followed by temperature below freezing, and the percentage of forecasts which were correct may be unimportant. The situation is in important respects analogous to measuring an object, for instance a table. The table has length, breadth, height, smoothness of the top, hardness of the top, number of legs, etc. A measure of any such characteristic is of no value unless a way of using the measurement has first been established.

In general, if each purpose of verification is exactly specified in advance, in the form of a hypothesis, not only will it be much easier to select verification scores to satisfy each purpose, but there will be no doubt as to what action is indicated by any numerical value which the verification score may have. It will often be desirable to select the purpose and the score in such a way that the result will either support or reject an a priori hypothesis.

Specifications of a Scale of Goodness. Another essential criterion for satisfactory verification is that the verification scheme should influence the forecaster in no undesirable way. One of the greatest arguments raised against forecast verification is that forecasts which may be the "best" according to the accepted system of arbitrary scores may not be the most useful forecasts. Resolving this difficulty becomes a question of how to define "best." That there is no unique answer to this question can be seen by considering the following example in which it is desired to verify some forecasts of minimum temperature. Suppose that on some particular occasion the probability of occurrence during the subsequent night of the various integral degrees of minimum temperature is actually known by a forecaster to be as follows:

Minimum temperature (°F)	31	32	33	34	35	36	37
Probability of occurrence	.05	.10	.15	.25	.30	.10	.05

If the forecaster is required to state a single temperature figure in his forecast for verification purposes, what figure should he state on this particular occasion so as to maximize his score? There are a number of answers. If the verification scheme counts as hits only the occasions when the forecasts are exactly right, he should forecast 35F, since this value has the greatest probability of occurrence. If he is being verified on the basis of mean absolute error, he should say 34F, the median of the frequency distribution, since this will minimize the sum of the absolute deviations. If he is to be verified on the basis of the square or root-mean-square of the error, he should forecast 34.15F, which is the mean value of the frequency distribution. Any number of such arbitrary scoring systems could be devised and they will all influence the forecaster, at least to some extent, or in effect actually do part of the forecasting. The verification scheme may lead the forecaster to forecast something other than what he thinks will occur, for it is often easier to analyze the effect of different possible forecasts on the verification score than it is to analyze the weather situation. Some schemes are worse than others in this respect, but it is impossible to devise a set of scores that is free of this defect. There is one possible exception to this which will be discussed in the section on verification of probability statements.

VERIFICATION METHODS AND SCORES

It has been stated above that, in general, different verification statistics will be required for each different purpose. The discussion of various verification statistics in the following paragraphs can therefore only hint at the use which might be made of each of the scores, since so few types of scores appear ever to have been of real value.

Contingency-Table Summaries. When forecasts are made in categorical classes a useful summary of the forecast and observed weather can be presented in the form of a contingency table. Such a table does not constitute a verification method in itself, but provides the basis from which a number of useful pertinent scores or indices can easily be obtained An example is given in Table I where precipitation was forecast in three classes, heavy, moderate, or light, for thirty

occasions. One of the greatest advances in forecast verification was made when the limits of the various classes were chosen in such a way that each category had an equal probability of occurrence, based on the past climatological record. Thus there is no incentive for a forecaster to choose one class in preference to another because of purely probability (climatological) considerations. This principle, with slight modification, has been used in the verification of the Extended Forecasts of the U. S. Weather Bureau [11], and during the last war the Army Air Forces [8] devised a scheme in which thirty classes (called *trentiles*) were used, each class representing $\frac{1}{30}$ of the frequency distribution based on past records of the particular element being verified.

Table I. Contingency Table for Precipitation Forecasts

Observed precipitation	Forecast precipitation			
	Heavy	Moderate	Light	Total
Heavy	5	2	1	8
Moderate	8	4	1	13
Light	2	2	5	9
Total	15	8	7	30

From this table a number of interesting verification statistics can be obtained. A comparison of the margins reveals whether the various categories were forecast with the same frequency as they occurred. Thus it is noted that, although heavy precipitation was forecast 15 times, it occurred only 8 times, the opposite tendency being shown for moderate precipitation. This may be only a sampling difference, or it may be great enough to cause the forecaster to reject the hypothesis that he is able to distinguish the relative frequencies of the various classes. The relative frequency of occurrences of the various classes can also be compared with that expected on the basis of climatology.

Percentage Correct. From the contingency table a frequency distribution of errors can easily be obtained. In the example given, 14 forecasts are exactly right, 13 forecasts are wrong by one class, and 3 forecasts are wrong by two classes. A commonly used score is the per cent right, in this case $\frac{14}{30} = 47$ per cent. More useful information is provided by constructing two other tables, Tables II and III. The extent to which subsequent observations confirm the prediction when a certain event is forecast is shown by Table II. The term *post agreement* has been suggested for this attribute of the forecasts [9] and the term *prefigurance* for the extent to which the forecasts give advance notice of the occurrence of a certain event (illustrated by Table III). Thus it is seen that forecasts of heavy precipitation were followed by the occurrence of heavy precipitation 33 per cent of the time while occurrences of heavy precipitation were correctly indicated in advance 62 per cent of the time.

Table II. Per Cent of Time Each Forecast Event Occurred for a Particular Category

Observed class	Forecast class		
	Heavy	Moderate	Light
Heavy	33	25	14
Moderate	53	50	14
Light	14	25	72
Total	100	100	100

Table III. Per Cent of Time Each Observed Category Was Correctly Forecast

Observed class	Forecast class			
	Heavy	Moderate	Light	Total
Heavy	62	25	13	100
Moderate	61	31	8	100
Light	22	22	56	100

For some economic uses these two scores are probably the most important verification figures. In planning an operation which is influenced in an important way by heavy rain, for example the operation of a series of flood-control dams, it is potentially of value to know both the percentage of heavy-rain forecasts which are likely to be correct, that is, the reliance to be placed on a heavy-rain forecast, and the percentage of heavy-rain occurrences which are likely to be correctly forecast.

Skill Score. The information contained in the contingency table is often combined into a single index (S), called a *skill score* and apparently first proposed by Heidke [4]. It is defined by

$$S = \frac{R - E}{T - E},$$

where R is the number of correct forecasts, T is the total number of forecasts, and E is the number expected to be correct based on some standard such as chance, persistence, or climatology. This score has a value of unity when all forecasts are correct and has a value of zero when the number correct is equal to the expected number correct. It will be discussed at greater length in the section on comparison with control forecasts.

Average Error, Root-Mean-Square-Error, Etc. When the values of the forecast element are expressed on a continuous numerical scale, as temperature usually is, it is often desirable to express a verification score in terms of an average absolute error or a root-mean-square-error (*RMSE*). If in a series of N forecasts F_i represents the i-th forecast and O_i the corresponding observation, the average absolute error $\bar{e}$ is given by the formula

$$\bar{e} = \frac{\sum |F_i - O_i|}{N}$$

and the *RMSE* by

$$RMSE = \sqrt{\frac{\sum (F_i - O_i)^2}{N}}.$$

One disadvantage of using either of these scores is that it gives the "cautious" forecaster an opportunity to

hedge by playing the middle of the range. Thus a forecaster may feel that the minimum temperature during the night will be near 40F if the cloud cover remains but will be near 30F if the skies clear. If he is being verified on the basis of the *RMSE*, he might tend to choose 35F in cases of doubt even though he may be quite sure that the temperature will not be close to 35F.

These scores can also be used to verify prognostic pressure-patterns by comparing the forecast and observed pressures or pressure gradients at a number of sample stations or points on the map.

Correlations. The correlation coefficient is a statistic which measures association between two sets of values, such as forecast and observed temperatures. One simple formula for the coefficient is

$$r = \frac{N\sum F_i O_i - (\sum F_i)(\sum O_i)}{\sqrt{N\sum F_i^2 - (\sum F_i)^2}\cdot\sqrt{N\sum O_i^2 - (\sum O_i)^2}}.$$

When used as a verification score it has the advantage of being relatively free from the fault of influencing the forecaster in an undesirable way. However, it is insensitive to any bias or error in scale that a forecaster may have. Thus the centigrade and Fahrenheit scales are perfectly correlated, but a person would not use one scale to verify forecasts made using the other scale. The correlation coefficient is also difficult to interpret for the purpose of making operating decisions and is subject to abuse of interpretation, such as attaching too much significance to the value of a coefficient obtained from a small sample. It is influenced by trends that exist in both series so it is usually desirable to compute it by using departures from normal.

Verification of Probability Statements. There appears to be one situation where it is possible to devise a verification scheme that cannot influence the forecaster in any undesirable way. This is the case when the forecasts are expressed in terms of probability statements. Suppose that on each of N occasions an event can occur in only one of r possible classes and on one such occasion i, $f_{i1}, f_{i2}, \ldots, f_{ir}$ represent the forecast probabilities that the event will occur in classes $1, 2, \ldots, r$, respectively. If the r classes are chosen to be mutually exclusive and exhaustive, $\sum_{j=1}^{r} f_{ij} = 1$ for each and every $i = 1, 2, \ldots, N$.

A score P can be defined by

$$P = \frac{1}{N}\sum_{j=1}^{r}\sum_{i=1}^{N}(f_{ij} - E_{ij})^2,$$

where E_{ij} takes the value 1 or 0 according to whether the event occurred in class j or not. For perfect forecasting this score will have a value of zero and for the worst possible forecasting a value of 2. Perfect forecasting is defined as "correctly forecasting the event to occur with a probability of unity or 100 per cent confidence." The worst possible forecast is defined as "stating a probability of unity or certainty for an event that did not materialize" (and also, of course, "stating a probability of zero for the event that did materialize"). It can be shown that if $p_1, p_2, p_3, \ldots, p_r$ are the respective climatological probabilities of classes 1, 2, $3, \ldots, r$ then in the absence of any forecasting skill the best values to choose for f_{ij} will be p_j for all N occasions. This will minimize the score P for constant values of $f_{1j} = f_{2j} = \ldots f_{Nj}$ and the expected value of the score will be

$$E(P) = 1 - \sum_{j=1}^{r} p_j^2.$$

To illustrate the procedure consider the following table of ten actual forecasts of "rain" or "no rain" in which a probability or confidence statement was made for each forecast.

TABLE IV. EXAMPLE OF FORECASTS STATED IN TERMS OF PROBABILITY

Occasion	Rain		No rain	
	Forecast probability	Observed	Forecast probability	Observed
1	0.7	0	0.3	1
2	0.9	1	0.1	0
3	0.8	1	0.2	0
4	0.4	1	0.6	0
5	0.2	0	0.8	1
6	0.0	0	1.0	1
7	0.0	0	1.0	1
8	0.0	0	1.0	1
9	0.0	0	1.0	1
10	0.1	0	0.9	1

In the table, unity is placed in the "rain" column if rain occurs. If the event is "no rain," unity is placed in the "no rain" column. The score P is therefore

$$P = \tfrac{1}{10}\{0.7^2 + 0.7^2 + 0.1^2 + 0.1^2 + 0.2^2 + 0.2^2 + \ldots 0.1^2 + 0.1^2\} = 0.19.$$

Since rain occurred $\frac{3}{10}$ of the time, the minimum (or best) score that could have been obtained by making the same forecast every day would be

$$P_{\min} = 1 - (0.3^2 + 0.7^2) = 0.42.$$

Thus the forecaster is encouraged to minimize his score by getting the forecasts exactly right and stating a probability of unity. If he cannot forecast perfectly, he is encouraged to state unbiased estimates of the probability of each possible event. On the other hand, with complete absence of knowledge or forecasting skill he is encouraged to predict the climatological probabilities and not just forecast the most frequent class.

TABLE V. VERIFICATION OF A SERIES OF 85 FORECASTS EXPRESSED IN TERMS OF THE PROBABILITY OF RAIN

Forecast probability of rain	Observed proportion of rain cases
0.00–0.19	0.07
0.20–0.39	0.10
0.40–0.59	0.29
0.60–0.79	0.40
0.80–1.00	0.50

When a series of forecasts has been made using probability statements, a study can also be made to determine whether the forecast probabilities are related to the relative frequency at which the events occur. An example of this type of comparison is shown in Table V (based on a more extended series of such forecasts) which suggests a relationship between the forecast and the observed probabilities, but which indicates that the forecaster should modify or adjust his scale to improve the forecasts.

Arbitrary Scores for Special Purposes. An infinite number of scores can be devised for verification purposes, but it is beyond the scope of this paper to discuss many of them in detail. In particular cases, such as verifying the forecasts of cloud heights or visibilities, it may seem desirable to express errors in terms of per cent and compute a score such as

$$e_p = \frac{1}{N}\sum_{i=1}^{N}\frac{|F_i - O_i|}{O_i},$$

where F_i is the forecast value and O_i is the observed value.

In other instances, verification of selected cases in which either forecast or observation was of particular importance may be required, or it may be desired to transform the forecasts into forecasts of change before verifying them. It is common, for example, to want to verify only cases when low visibility either is forecast or occurs, since high values are much less critical for airplane operations. It may be desired to verify only the cases when ceiling changes across the critical value, either in the forecast or in the occurrence. With more intensive study of the decisions which are made on the basis of such forecasts and of the consequences of right or wrong decisions, it would be possible to devise verification scores based on the relative values of different forecasts, but as it is, practically all such specialized verification systems are arbitrary. This is not intended to discourage the use of such scores, but it should be emphasized that conclusions as to the relative *values* of two sets of forecasts will always be uncertain so long as the value of any individual forecast cannot be estimated. Innumerable other scores to be used for some special purpose could be mentioned.

CONTROL FORECASTS FOR COMPARISON

Chance or Random Forecasts, Persistence, Climatology. Up to this point most of the discussion has been concerned with methods of comparing the forecast weather with the actual weather and obtaining some indices or scores. The final phase of the verification procedure is the interpretation of these scores, which is usually performed by comparing them with some standard. It has long been recognized that a figure such as the percentage of correct forecasts is often meaningless, since the same figure might be obtained by chance or by some scheme of forecasting requiring no meteorological knowledge.

It has been suggested that forecast scores be compared with scores obtained using various "blind" forecasts such as random forecasts, persistence forecasts, or climatological forecasts. Many arguments have arisen over the proper choice (if any) of the blind forecasts to use as a standard. There is no correct answer, of course, since the choice depends not only upon the use that is made of the forecasts but upon the purpose of the verification.

To illustrate these comparisons, let us return now to the skill score defined in the earlier section. The expected number of forecasts correct E_R, based on chance or random forecasts for the data in Table I, is computed by the following formula:

$$E_R = \frac{\sum R_i C_i}{T},$$

where R_i is the total of the i-th row and C_i is the total for the i-th column. In the example given, this is

$$\frac{8 \times 15 + 13 \times 8 + 9 \times 7}{30} = 9.6,$$

so the skill score based upon the margins of the contingency table is

$$S_R = \frac{14 - 9.6}{30 - 9.6} = 0.22.$$

If, in this same example, persistence forecasts had been made by predicting a continuation of the preceding precipitation, the expected number right would have been 12, so the skill score would be

$$S_p = \frac{14 - 12}{30 - 12} = 0.11.$$

If the climatological frequencies of heavy, moderate, and light precipitation were P_H, P_M, and P_L, respectively, the expected number right E_c is given by the formula

$$E_c = P_H(F_H) + P_M(F_M) + P_L(F_L),$$

and

$$E_c = \tfrac{1}{3}(30) = 10$$

in the example, since the three classes were defined as equally likely.

Generally, any score which may be devised can be computed for a set of control forecasts as well as for the actual forecasts, and a comparison can be made.

Adjustment for Difficulty. When the purpose of verification is to compare a number of forecasters, a practical difficulty often encountered is that the forecasts are not comparable because they were made at different times and under different conditions. It is known that different synoptic situations present varying degrees of difficulty and it is invalid to make comparisons between forecasters working at different times unless some attempt is made to take account of this source of variation. This can be partly accomplished by finding parameters dependent on the synoptic situation that are related to the errors in the forecasts.

For example, it might be found that there is a high correlation between the verification scores for visibility forecasts made by an individual and the scores obtained by a visibility forecast based simply on persistence. By

means of a regression analysis the scores S made by a number of forecasters can then be adjusted to equivalent "persistence" values before making comparisons by use of the formula

$$S_A = S + b\,(S_p - \bar{S}_p),$$

where S_A is the adjusted score, S the unadjusted score, S_p the persistence score corresponding to S, $\bar{S}_p$ the mean persistence score, and b the average within regression of forecast score on persistence score. This procedure can be generalized to take account of two or more parameters measuring difficulty.

Forecast-Reversal Test. A useful and simple procedure that can often be used to advantage might be called the "forecast-reversal" test. Suppose that a long-range forecaster claims he can pick out a year in advance the days of the month upon which rain will fall, provided a "tolerance" in timing of one day in either direction is allowed. On this basis some arbitrary verification is proposed which appears to give a relatively good score when applied to some actual forecasts. In the forecast-reversal test the same arbitrary verification procedure would be used, but the forecasts would be reversed with "rain" days being called "no-rain" days and vice versa. If approximately the same verification score were obtained on the reversed forecasts, one would be led to suspect either that the forecasts had no merit or that the verification scheme had no merit, or both. If this procedure were more generally used, especially for long-range forecasts, probably fewer claims would be made by long-range forecasters. It would also probably result in the selection of more sound verification schemes for use in determining the accuracy of such forecasts.

PITFALLS OF VERIFICATION

There are many pitfalls of verification to entrap both the novice and the expert. One of the greatest dangers lies in attempts to compare the relative abilities of forecasters on the basis of forecasts which are not comparable because of differences of location, season, time of day, length of forecast interval, etc. The reason for this is that the degree of forecasting difficulty varies so much from one circumstance to another that a very large sample of forecasts is needed to assure that the average weather has been approximately the same in the two sets of forecasts being compared. Even if the forecasts being compared are for the same event, there may be other factors to be considered, such as whether equal map facilities were available to each forecaster.

Interpretation is made even more difficult when scores on two or more forecast weather elements are arbitrarily combined to form a single index to be used for comparison purposes. It *may* be true, for example, that there is some particular use of a forecast for which an error of 2° in temperature is equivalent to an error of 0.25 in. in a precipitation forecast, but it is *certain* that this (or any other) arbitrary weighting is not true in general Those who must make a selection between forecasters based on verification scores may demand a single index to represent the verification of all forecasts made by each man, but since a logical combination of scores is in general impossible, it would be far better to consider each score separately. As pointed out in the section on Selection of Purposes of Verification, if it is decided ahead of time just what measures of accuracy are needed and what will be done with each, the need for combining scores could be largely eliminated.

Another practice that may lead to difficulty is the use of overlapping classes for verification purposes. Thus rules may be set up stating that a ceiling forecast of 200 ft will verify if the observation is between 100 and 400 ft, and that a forecast of 400 ft will verify if the observation is between 200 and 800 ft. Although such rules may seem reasonable they tend to encourage forecasters to hedge by choosing the classes having the widest range. Also, the choice of rather wide tolerances in verification limits tends to give rather high and uniform percentage scores to all forecasters, thus failing to discriminate between the better and poorer forecasters. Since the use of a contingency table for comparing forecasts and observations presents the data in one of the most useful forms, the practice of using overlapping classes is to be discouraged because such verification cannot be displayed in this way.

FUTURE RESEARCH

The preceding discussion has emphasized that verification is less difficult than has been thought and that the lack of recognition in the past of the various and diverse objectives of verification has been the real obstacle to progress. One of the most promising fields of study in this connection is that of setting up realistic problems to be solved and selecting scores which would furnish the desired information. Such studies might profitably be conducted in collaboration with administrators who need to select or rank forecasters; with economists or business advisors who need to know the effect of weather on operations and who are in the best position to determine what characteristic of the forecasts is related to profit and loss factors, or with meteorologists who know what characteristic of the forecast is useful for verifying scientific hypotheses. This appears to be a field of study in which private meteorologists should play a very important role, for their knowledge of the real uses which can be made of weather forecasts should be invaluable in specifying the questions which need to be answered by verification. On the scientific side of verification, the relation of forecast error to measures of forecast "difficulty" needs further investigation. If measures relating the synoptic conditions to forecast errors can be found, it would not only assist in the comparison of forecasts made at different times, but would also provide information as to where applied meteorological research is most needed and might contribute to fundamental knowledge of atmospheric processes.

Investigations regarding the effect of verification systems on the forecaster are needed since very little concrete evidence on this point is available. In this connection the use of probability statements in forecasting needs to be explored in more detail, for if such

statements can be verified without influencing the forecaster in any undesirable way, an important objection to verification is removed. Furthermore, forecasts expressed in this manner might very well be more useful at the same time. As was stated in the section defining the verification process, it has been assumed that errors of observation are unimportant in practical verification. This is not always the case, and further investigation of the effect of such errors is needed. Most weather forecasting is so far from perfect that forecasting errors far overshadow observational errors, but exceptions may be found, for example in visibility forecasting and perhaps in other cases.

There are many other unsolved problems in verification, but on careful analysis it appears that most of them are meteorological in nature. As long as our knowledge of the physics of the atmosphere remains so incomplete this state of affairs will be reflected in the verification problem.

APPLICATION OF STATISTICAL METHODS TO WEATHER FORECASTING

By GEORGE P. WADSWORTH

Massachusetts Institute of Technology

It must seem very odd to the layman and to the scientist who is not connected with the field of meteorology that so little practical progress has been made during the last decade in the all-important problem of weather forecasting. This defect is particularly conspicuous when such phenomenal advances have been made in the field of nuclear physics and thermodynamics. However, it is necessary to spend only a moderate amount of time examining observational data of the meteorological elements to understand that the problem is much more difficult in many of its aspects than those considered in most allied fields. If we regard the atmosphere as a dynamic model, it soon becomes apparent that the whole process behaves as a complicated mechanism in which past and present values do not determine the future as in most linear processes, but they themselves have an effect upon the system which in turn produces nonlinearity of a very peculiar type. It is with this phenomenon that the meteorologists must contend.

There seem to be only two ways which are available to solve the problem of the motions of the weather systems and therefore the problem of weather forecasting: one is the dynamical approach and the other is the statistical approach. Oftentimes one thinks of these two methods as conflicting programs but actually they are attempting to get at one and the same thing. In the dynamical approach the laws connecting various meteorological phenomena are investigated. These laws are considered to be precise in action even though the data are subject to fluctuations which are random and are thus necessarily incomplete. On the other hand, in the statistical approach the quantities are taken as they are found and the distributions examined both singly and in such combinations as one chooses for the purposes of investigation. In an ideal survey all possible statistical parameters would be considered and not merely a partial selection, but such an undertaking is impractical because of the sheer magnitude of the task. If, however, there exist among the statistical parameters a few which are connected by sharp dynamic laws, then some of the parameters would be determined by a knowledge of the remainder, and the dynamics would be obvious as a statistical fact. The failure to date of statistical methods to contribute markedly to the progress of meteorology may have been due to one or more of three facts:

1. The parameters in the analyses to date are not the important ones.

2. The parameters considered are insufficient in number to give us a true picture of the operation.

3. These parameters have been observed so inaccurately that they are not in fact the significant parameters of the dynamics.

It might however be said that it is impossible for dynamics to exist and be really significant and not be brought out by a proper statistical examination of the relevant quantities, and in fact, techniques available in the statistical category have the added advantage that it is unnecessary to make many simplifying assumptions in order to yield relevant information concerning the meteorological phenomenon.

At this point it cannot be too strongly emphasized that the use of statistical techniques for the solution of the behavior of the weather systems is equivalent to the setting up of equations of motion and obtaining the solution. The use of generalized harmonic analysis (discussed in a later paragraph) as a method of attack on the problem has the advantage that it automatically takes care of data which have superimposed a random component upon the dynamic motion. In other words, it is a technique which is especially designed to handle situations where, because of ignorance, there has to be omitted a certain number of factors which can be considered in combination as a random phenomenon superimposed on the dynamic movement. There is no doubt that the ideal way to solve any dynamical problem is to set up a physical model in terms of mathematical symbols and, after having solved the resulting mathematical model, to use statistical methods to solve for the basic parameters. However, if the mathematical model does not contain all of the variables which are actually important, the attempt to solve for the parameters by statistical methods will give an unreliable result, and it is for this reason that a technique which takes account of this unknown group of variables is very appropriate for this problem. An example of such a situation would be one in which the phenomenon in which we were interested had a displacement y given by $y = A \sin kt$. Superimposed upon this oscillation might be a group of frequencies which had periods entirely different from those of the phenomenon. This group of frequencies would have been reflected in our observations since they each enter the picture for short periods of time and more or less at random. It would be extremely difficult by observing a small section of the data to fit the parameters A and k, the constants in our equation. However, a statistical analysis would be much more successful in separating the basic signal from the random noise.

It is perhaps during the last ten years that an added impetus has been given to this method of approach because of the growing conviction on the part of many investigators that the problems of the general circulation and of specific forecasting were not to be solved in the near future by the usual dynamic methods. This is reminiscent of other physical sciences wherein, at the beginning, a conceptual foundation was borrowed

from physics and mathematics, but it was only after extended programs of experimental work had been carried out that the subjects progressed independently and produced the astounding developments which have occurred in the last century. A continual succession of experimentation, followed by new theory to explain the results obtained, and then a new period of experimentation, has characterized the development of most of the physical sciences. Unfortunately, meteorology is not in the same position because it is impossible to conduct experiments with controlled variables since no formal method for the inclusion of all the pertinent variables into a single mathematical system has yet been found as a substitute for experimental control. Thus the most powerful techniques which have been used in the development of other physical sciences are not available to the meteorologist at the present time and he must search elsewhere for his method of attack upon this formidable problem.

According to a prevalent misconception, statistical methods mean the neglect of root causes and the substitution of shadow for substance. To be sure, statistical methods often lead to useful rules of thumb even when qualitative understanding is absent, but these rules should never be regarded as anything but makeshift. Doubtless the facility with which empirical recipes can be invented, together with a natural human tendency to let well enough alone, has engendered a willingness on the part of some statistical practitioners to content themselves with ersatz. But we do not hold medicine in contempt because of quackery, and it would be fallacious to condemn statistics on account of superficiality. It is perfectly true that at the present time too many meteorologists and statisticians attempt to indulge in an orgy of correlation analysis. Because the processes which they are examining lack the property of being stationary, results are obtained which are inconsistent from one period of time to the next. This difficulty becomes less and less important if a certain amount of physical reasoning is the basis for the correlation; and as time goes on and more is understood about the phenomenon, this operational approach of examining the physics of the situation will correct much of the condemnation which is now directed at statistical studies. Thus the future of meteorology depends decisively upon an enlightened and energetic use of this important tool.

The meteorologist is primarily interested in the behavior of his phenomenon as a function of time, and all his observations are either taken continuously in terms of this variable or are taken at discrete points along the time axis. Each one of the series, therefore, which are considered in the problem of prediction of single meteorological elements or combinations of them can be looked at from the time-series point of view. Since the beginning of World War II, considerable impetus has been given to the development of generalized harmonic analysis because of its importance in the analysis of time series which occur not only in the weather problem but also in all fields where prediction is important. Unfortunately, most of the work has been done in the field of what might be termed *stationary time series.* In this type of series the actual dynamics which motivate the series itself is assumed constant from one period of time to the next.

Considering the characteristics of these time series by themselves, we note that the sequence of observations has certain inherent dynamic properties as well as a superimposed random component. This random component may well be due to other variables not considered. The actual statistical problem is to separate the dynamics from the random element so that the dynamics can be studied and classified. This situation is entirely analogous to a similar one encountered when information is transmitted by mechanical or electrical methods. In this case, the signal frequently becomes distorted and when this distortion phenomenon is of a purely random statistical nature it is called "noise." Hence, as also in weather phenomena, the thing that we observe, or the message, contains the original signal plus a random noise, and the problem is to isolate the signal from the message.

In the case of pressure, if we consider the sequence of values as a continuous function, the behavior is analogous to the response of a sluggish oscillator to a series of impulses, where the dynamics are represented by the parameters of the oscillator. Because the oscillator is sluggish, the effect of the impulse at any one time is not immediately worn off but is carried over to affect the pressure at a future time. Even the random components, introduced probably by the variables not considered, affect the future value of the pressure variable since they are equivalent to an additional impulse on the oscillator.

The problem of weather forecasting can therefore be thought of in the following terms: In Fig. 1 the solid

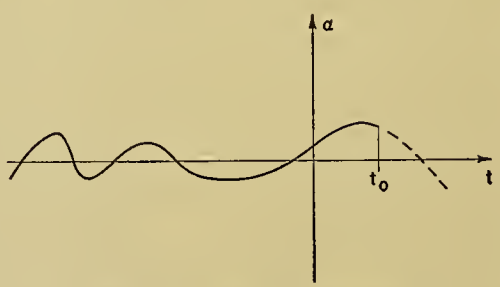

Fig. 1.—Schematic time series.

line represents the past performance of some meteorological phenomenon α. For example, it might be past values of the pressure at a single station or even a characteristic of an entire synoptic map. By analyzing this sequence from some period of time in the distant past up to the present time t_0, the predictable part of this sequence is to be determined. This predictable part represents the true dynamical component, and it is this component which permits one to extrapolate the solid line into the future to give a prediction (dotted line). Naturally, the further one extends this prediction

the worse the agreement is between the predicted and actual values if there exists a random component. In other words, even after the entire past of all the variables has been exploited, there may exist an upper limit to the attainable accuracy of prediction; this limit decreases as the forecast period increases. The complete problem, then, is the consideration of an ensemble of such sequences, all of which are known in the past up to a specific present time t_0, and, regarding them as a group, the evaluation of that component which represents the true mechanism through which the phenomenon is operating.

In the theory of generalized harmonic analysis as it affects the prediction of time series, we are approaching the problem from a more general point of view than either that of harmonic analysis, where only certain frequencies or periodicities were assumed to be present, or that of difference equations where a differential relationship is assumed connecting present and past values of the time series. In generalized harmonic analysis, advantage is taken of the entire spectrum of frequencies, and this spectrum in most geophysical phenomena does not consist of a series of discrete lines (exact frequencies) but rather of a continuous distribution of frequencies over the entire range of frequency, usually from zero to infinity. This technique permits us to develop the best linear operator in a very general sense in order to predict the future. Actually, it is this ability to predict which expresses how much dynamics there exists in the series. The linear operator is a weighting function which is applied to past values of a time series in order to obtain estimates of future values, and this weighting function is determined mathematically in such a way that the mean square error of prediction is minimized. Actually, of course, this technique can be extended to more than one variable, and thus many time series can be considered simultaneously.

Unfortunately, the basic arguments and ideas are true only if the process or processes are stationary. This, of course, cannot be true in meteorological phenomena since the basic movements of the weather systems certainly are different, at least from season to season. To a certain extent this lack of stationary property can be overcome by dividing the data into what might be termed more homogeneous periods, but, nevertheless, this difficulty is inherent in a simple analysis since the seasons themselves do not arrive and leave at any fixed time. Another factor which markedly affects the analysis of time series of this type is the fact that most of the elements have definite trends which are functions of the time of year. It is always possible to compute what might be termed a normal by averaging over a large number of years, but it is extremely doubtful whether this normal has any particular significance for a specific year. The dynamics are determined by the movement above and below a state of equilibrium which might be called the normal for a specific year, although it unquestionably is different from the over-all normal for all years. The shift of this trend line from one year to the next has a very marked effect upon the dynamics. Since it is necessary to deal with relatively short periods of time in order to obtain compatible data, it is very hard to separate that part of the spectrum which deals with long-period phenomena from the short-period oscillations which tend to dominate a rather minute portion of the entire record.

Actually, of course, the solution of a nonstationary time series has no meaning in the strict sense. The basic problem is to make the time series approximately stationary through appropriate changes in variables as a function of time. This approach will be increasingly successful as a clearer understanding of the mechanics of the phenomena is attained. In order to appreciate the immensity of the task of solving this problem, let us review briefly what is known about the behavior of some of the meteorological elements, utilizing the simple hypothesis of a stationary time series, and consider what can be gleaned from this information as to possible future courses of fruitful action.

One often hears the statement that abnormally warm winters and cold winters recur in a definite cycle. On this basis one might expect to find long-term effects in the analysis of the frequency-density function of average monthly temperatures taken, of course, as deviations from normal. If one considers either the monthly temperature or the daily temperature at any one particular locality, it may be regarded as an individual time series in itself. Actually there exists on the average a correlation of only about 0.35 between the predicted and observed values when one predicts one month in advance. This accounts for only around 10 per cent of the variability, implying merely that there is slightly more than a 50-50 chance that if the present month is above normal the next one will also be above normal. No matter how far one goes back in the past to obtain information (which means no matter how high an order of a linear differential equation one considers as representing this phenomenon) no additional information seems to be available, so that the past of the sequence has practically nothing to do with the future. Naturally other variables exist which might improve this situation, but we are dealing with a phenomenon which in itself shows no statistical regularity as far as long cycles are concerned. On the other hand one may be interested in a daily 24-hr forecast of temperature. If one restricts the mechanism to a given month during the year, a developmental sample based on four or five years will give a good estimate of the linear operator. In a 24-hr forecast, a correlation of about 0.75 between the predicted and actual values can easily be realized. Furthermore, interestingly enough, this same correlation will be obtained if one picks any other year at random for the same month and applies the operator to this other year. This shows that there exists a certain amount of high-frequency oscillations which are similar from year to year and actually represent dynamics in the time series. In other words there exists a true signal which can be separated from a disturbance which we know nothing about but designate as random noise. The properties of the air mass can be introduced by considering a network of

stations and using the entire group as predictors for an individual station. Correlations as high as 0.97 for 24 hr and remaining between 0.80 and 0.90 for 48- and 72-hr intervals show that a certain degree of statistical regularity is demonstrably present. Despite these high correlations, the forecasts leave much to be desired, for the linear operator seems incapable of detecting sudden changes in weather regime. Unfortunately, nonlinear techniques, in the elementary sense, have not yet succeeded so that it is impossible to improve the forecasts without some form of subjective analysis, such as a synoptic classification of the regime. Unquestionably there exist additional variables which, if clearly understood, would change the linear dynamics slightly from year to year and permit better predictions.

Equivalent studies have been made on pressure, including daily mean pressures, nonoverlapping five-day means, and running averages taken over five, fifteen, and thirty-one days. No long-term predictable components in any one of these time series taken at many localities over the Northern Hemisphere ever produced spectra which would indicate any long-term periods. Once again, networks involving a group of stations surrounding the one to be predicted give the best daily predictions. Correlations in the neighborhood of 0.70, which remain stable from year to year, indicate the order of the linear component, while four or five stations surrounding a given station at a distance of about 500 mi seem to produce all of the dynamics of a linear type which is in the network. Thus, increasing the network of stations either in number or in radius seems in no way to increase this predictability. Studies of this nature seem to afford ample proof that the synoptic situation expressed in terms of present temperature, pressure, humidity, etc., does not uniquely determine the future distribution and that the behavior of the pressure distribution outside this ring of 500 mi does not have much influence upon the future of the pressure at the center of the ring. Furthermore, if a forecast is made for 24 or 48 hr in advance by predicting a group of stations individually (considering each one as made up of an individual network), the correlation of the actual predicted map with the observed conditions is not much better than the correlation that one would obtain between predicted and observed pressures at an individual station. This indicates that the errors of forecast are correlated over the entire country and that we are not making a series of individual random predictions. The fact that the errors prove to be highly correlated means, of course, that an outside influence has moved into the picture and that all of the mechanisms fail to predict simultaneously. This brings out rather clearly the concept of changes in regimes in the entire weather pattern, followed again by a stabilization of whatever linear component exists. Once the regime has established itself, pressure changes of considerable magnitude can be forecast quite accurately, but the physical bases for the changes must already exist within the network. Six principal conclusions can be arrived at through a close analysis of pressure forecasting utilizing straightforward statistical techniques: (1) The performance of the linear forecast from year to year is stable in that the mean errors of prediction show no significant difference between years and the root-mean-square errors are homogeneous, (2) a small network is adequate, (3) errors cannot be ascribed to improper weighting of the predictors, (4) it is extremely doubtful that linear prediction can be improved upon by using fixed functions of higher degree, and therefore additional variables not considered at the present time are important, (5) the errors in the forecast are not caused primarily by a failure to indicate pressure changes as such, but rather by an inability to predict extreme values whether they represent changes from the initial situation or not, and (6) statistical forecasts fail under the same circumstances that synoptic forecasts fail and apparently for the same reasons.

In order to give a little more background to the direction that future research should follow, let us consider for a moment the combined motion of the four major centers of action for the North American continent, namely, the semipermanent highs and lows—the Atlantic high, the Pacific high, the Icelandic low, and the Aleutian low. It is in the motion of these centers of action that one can first observe the fact that considerable dynamics exists in the atmosphere and that it is not a random phenomenon nor anywhere near random. If we consider any one of these cells as the one to be predicted and utilize its past and the present and past of the other three cells as predictors, prediction for a considerable time in advance is possible for any particular year. One can think of this prediction process, of course, merely as a reproduction of the data after the fact, but nevertheless the reproduction of the data by means of the operator is so startling that it deserves notice. Both the spectra obtained from the autocorrelation functions and those obtained from the cross-correlation functions are extremely active, showing that the density of frequency is located in rather narrow bands. The graphs of these spectra are, however, quite different from year to year, indicating that we are dealing with a phenomenon which has certain specific characteristics at any one time but that these characteristics vary from year to year because of some outside influence. The sharp spectral characteristics which occur in these control cells unquestionably lead oftentimes to the wrong conclusions, namely, that periodicities exist in the atmosphere in the sense of being true line spectra. For periods of time, therefore, one can observe certain fluctuations of these meteorological elements and erroneously conclude that there is a law, perfectly determined, which is influencing their behavior. This is the clearest indication of why it is possible to tie up cycle theory with weather phenomena of various types, particularly for specific short periods of time.

Although a large amount of work has been done by many investigators in computing correlations of pressure at one point in the atmosphere with that at another point, correlations of precipitation and tem-

perature with the forward movement of ice in the North Pole region, etc., the illustrations set forth in the preceding paragraphs give a picture of about the order of magnitude of the results which one can expect to find in setting up linear hypotheses involving pressure, temperature, humidity, etc., either singly or in combination and at one station or in the network. With this background, I should like to discuss possible future courses which statistical analysis can follow toward the solution of this complicated situation involving dynamics and thermodynamics.

Perhaps one of the greatest contributions which statistical methods can, at the moment, make to the field of meteorology is in the classification of climatological information. It is well known, for example, that the forecasters in the short-range verification program during World War II greatly improved their accuracy by being given the probability of the occurrence of the events for which they were forecasting. This climatological information, however, is only part of that which is available to the forecasters to improve their forecasting techniques. There exist certain statistical laws which hold individually for all climatological elements and for all possible locations. These relationships have very profound effects upon the distribution of these elements for a given week or a given month and are entirely different from the over-all distributions that are at present given as the climatological expression of the variability. It is the peculiar behavior of these daily, weekly, monthly, and seasonal distributions at various localities which are the real characteristics of the climatology and could be extremely useful in understanding better the weather processes themselves and also in improving the forecasts at a particular location. Thus a re-evaluation of the whole method of presenting the climatology of various localities and the individual behavior of climate during reasonably short periods of time at a particular locality might do much to increase our knowledge concerning the general behavior of the circulation. In fact, it might be stated that if the basic characteristics of the climatology were plotted on a Northern Hemisphere map, obvious simultaneous relationships could be studied and the whole forecasting problem could be reduced to a group of much more specific questions.

A great deal of thought has been given by many meteorologists to the use of analogues as a method of forecasting. The basic argument against the use of analogues is, of course, that the weather never follows exactly the same pattern. However, in the light of past experience in forecasting by statistical methods, it is obvious that in order to progress much further it is going to be necessary to find a way of classifying the dynamics. Dynamic classification might be achieved through the use of analogues, and in that event it should be possible to utilize the correct statistical operator for the prediction mechanism. Many attempts have been made by various people to express the dynamics of a present system in terms of some linear combination of the dynamics of past experience or similar situations. This seems to be extremely logical.

One can set up a practical analogy. An engineer wishes to determine the dynamics of a particular machine which, for some reason, he is unable to analyze completely. It might, however, be possible for him to analyze three or four machines which are similar to the original machine but differ in some minor details. It is then quite possible that by observing the dynamics of the similar machines he may infer how the machine in question will behave and operate. Actually if the dynamics are changing, in the sense of the series' being nonstationary, about the only way that one can judge what these dynamics might be in the future is through the use of such a technique. Our failure up to this time to extrapolate the dynamics properly from the known situations is probably due to the fact that the parameters used to express the synoptic picture are not dynamic in themselves. It is therefore necessary for us to solve more completely the following problems:

1. Parameters must be found that will adequately classify the static picture of the weather situation over a large area. They should represent the general features, particularly the flow patterns, over a region even though they might not bring out every individual detail. The analogue technique calls for a classification in terms of a general flow pattern, and such a classification would tend to eliminate the influence of extremely random fluctuations which hinder progress in fathoming the dynamics. Whatever parameters are used should maximize the discrimination between different synoptic situations.

2. Parameters should be found which actually classify the dynamic features of large areas. Having real physical significance, they would have some chance of being associated with both the static picture and the dynamic processes of the weather elements over an area.

3. The relationship between the static and dynamic properties of the parameters should be distinguishable so that it would be possible to go from one to the other and realize what is important from both points of view.

Because the entire Northern Hemisphere affects the weather patterns at one single locality, it would seem advisable to attempt to make these parameters of a Northern Hemisphere character. If the characteristics of the general flow could be determined by examining the dynamics of past situations and extrapolating them in order to obtain the dynamics of the present one in the correct manner, then it is entirely possible that the network theory of simple linear hypothesis would be sufficient to predict the individual weather at various localities by the use of an operator fitted to a correct dynamic model.

Although none of the problems mentioned above have to my knowledge been solved as yet, there are certain specific conclusions about analogues in general which seem to indicate that the method holds some hope for future development: (1) When the correlations between the sequence of past and current maps main-

tain themselves with a reasonable value for at least three days, the analogues are, on the average, synoptically and kinematically sound, (2) for the purpose of making long-range forecasts up to ten days' duration there usually exists one analogue which gives a precipitation forecast as good as, if not better than, the present 24-hr forecast (this, of course, is after the fact, and at the present time no method is available for detecting such an analogue in advance), (3) there are indications that certain previous temperature distributions aid materially in picking that analogue, and (4) maps which show the same general movement of the essential features are usually good analogues.

In order to determine why it is that the major centers of action have such variable dynamics from year to year, it may be desirable to examine more carefully variations in sea-surface temperature. Preliminary studies have indicated that in certain regions the sea surface has undergone rather marked changes in temperatures and that the variation of the difference between the air temperature and the water temperature shows considerable change from year to year. Since the water temperature is a very persistent phenomenon, these long swings of above and below normal over a period of many months may have considerable influence on the behavior of the weather. Also, since about three-quarters of the world is ocean, perhaps too little thought has been given to these variations as potential sources of the fluctuations in the dynamics of the weather system.

There are, of course, many variables which should be considered in attempting to get a complete statistical model, particularly in light of the fact that we are dealing with a servomechanism. The low-pressure area produces the clouds, the clouds change the energy input, the change of the energy input causes a change in the energy of the system, and that in turn affects the movement of the low in its future course. Sunspot activity, variations in total pressure over the poles and over the equatorial regions—all these must contribute their part. It therefore seems advisable that investigations utilizing the statistical approach be greatly increased so that more and more information will be available, thus clarifying the nature of the phenomenon with which we are dealing. As this statistical information establishes the variables which have dynamic properties, it should be possible to set up mathematical models on the bases of reasonable hypotheses inferred from the observational facts, and in this way we may hope that the final solution of the weather forecasting problem will be reached. On the other hand, it might develop that meteorology is faced with a situation analogous to that treated in the kinetic theory of gases, wherein the behavior of an individual molecule is impossible to predict, and only certain average features of all the molecules can be computed. Nevertheless, if the problem has to be reduced to this type of conclusion, it would at least be possible to estimate the respective probabilities for the occurrence of each possible state.

Thus it appears that if the general forecasting problem of meteorology is to progress as rapidly as possible toward its solution, meteorologists and statisticians should combine their efforts in a more united fashion. It is clear from the type of problem with which we are dealing that it is only through the statistician's understanding the meteorological point of view and his being able to understand and utilize the experience of the men who have been watching the progress of weather situations for a long period of time that he can be effective. Reciprocally, the meteorologist cannot take advantage of statistical techniques which would be of great material aid until he himself understands the basic principles upon which the techniques are based and also understands what the statistician wishes to accomplish.

TROPICAL METEOROLOGY

By C. E. PALMER

Institute of Geophysics, University of California

INTRODUCTION: THREE METHODS OF ANALYSIS

In 1947, when the University of California established its Institute of Geophysics at Los Angeles, one of the research projects initiated with the Institute was an investigation of the synoptic meteorology of the tropical Pacific Ocean. Although the literature contained only scanty references to the topic, it was known that many meteorological data had been collected during World War II and that new ideas had been fermenting in the area throughout the period of conflict. In order to obtain some insight into the general condition of synoptic meteorology in the Pacific as a preliminary to the investigation the Director of the Institute at that time (Dr. J. Kaplan) issued a questionnaire to meteorologists who were known to have been associated with Pacific observation and research during the war, and answers from about half of those addressed were finally received in the Institute. It would serve no good purpose to enter here into a detailed analysis of the replies; however, one striking feature revealed by the survey is relevant, since it turns out to be characteristic of the present state of tropical meteorology in general. The replies fell into three well-marked classes, distinguished by the method of approach to tropical weather problems displayed, in some cases consciously, in others unconsciously, by the authors.

The meteorologists whose replies fell into the first class tended to put the greatest emphasis on climatological concepts: even in their approaches to synoptic problems they were dominated by the results of statistical analysis, by mean maps, by statistical notions like the *trades*, the *monsoons*, the *doldrums*, by the conviction that the day-to-day weather in the tropical Pacific differs very little from that revealed by monthly and annual means. They extended this approach to the forecasting problem. Some felt, for example, that the best guide to forecasting the tracks of individual typhoons and tropical storms might lie in the study of mean storm tracks. Their dynamic theories, when they had any, were expressed in terms of a hypothetical general circulation of the tropics, and this was the entity whose characteristics were to be explained by physical reasoning from first principles, not the vagaries of the daily weather map. For the purposes we have in mind here, we may term the method of approach which is based upon these conceptions, the *climatological method.*

In the second group we must place those meteorologists whose thinking was much under the influence of concepts derived originally from the study of high-latitude weather, the followers of the *air-mass method.* The more extreme replies of this class maintained more or less explicitly that the tropical atmosphere differed from that in higher latitudes only in having a higher temperature and an easterly instead of a westerly mean wind direction. The dynamics, and by this they usually meant the frontal dynamics, remained the same. In the tropics there were fronts, air masses with source regions and modifications as in higher latitudes, an equatorial front similar in principle to the polar front, and above all an occlusion process that resulted in the formation of typhoons and tropical storms. Small temperature differences became important, and the "slope" of systems a matter of earnest discussion.

Finally we have the third group of replies, sent in by workers originating in or influenced by the Institute of Tropical Meteorology at San Juan, Puerto Rico, a school set up by the University of Chicago during World War II but now, so far as I know, no longer active. This group takes its origin from Gordon E. Dunn's paper on easterly waves [25] and its members have at some time been closely associated with the University of Chicago, drawing their theoretical stimulus from C.-G. Rossby. It is natural to term the method followed by this group the *perturbation method.* The concepts of the climatological group, referring to a hypothetical general circulation of trades, monsoons, doldrums, etc., identifiable as such on the mean maps, were taken over by these meteorologists. However, the basic currents were now considered to be for the most part zonal but subject to perturbations, and the perturbations to be accompanied by characteristic weather and pressure patterns, identifiable on daily weather maps. This group was much preoccupied with *models* of various kinds of perturbations. In dynamics, one gets the impression that they considered all dynamical problems connected with the perturbations as already solved by Rossby's work and that their great task was to explain the dynamics of the general and zonal circulation.

The significance of the three broad classes of Pacific meteorologists revealed by this survey lies in the fact that, once one knows what to look for, the same divisions can be discerned in the work of all tropical meteorologists. It is not that they may be divided into those whose interests are primarily in climatology, or in synoptic meteorology, or in dynamic meteorology. On the contrary, the division rests upon distinct methods of approach to all branches of tropical meteorology, statistical, dynamic, and synoptic alike. It is therefore convenient to regard writings on tropical meteorological topics as emanating from three distinct schools of thought, the climatological, the air-mass, and the perturbation schools, even though it is only in the last class that the opinions have been common to a locally concentrated group of workers. And, of course, it must be remembered that there will be many borderline cases,

writings that are hard to place unequivocally in one of the three groups. These things understood, however, we will find it easy enough to survey the present state of tropical meteorology. It will consist of the conflicts of these schools as revealed in the literature. The scope and detail of the conflicts is likely to astonish the meteorologist working on high-latitude problems, accustomed as he is to a large measure of agreement on the fundamental descriptions of temperate and high-latitude weather. In the tropics there is not even agreement on the common forms of tropical clouds or on the meteorological conditions accompanying precipitation. It has become the custom to generalize in haste and to reject inconvenient observations at leisure. Large areas of the tropical atmosphere have not been explored by observation and even the better-known areas have not yet yielded statistics of sufficient scope or reliability to justify the tropical parts of the "models" which are incorporated into the textbook descriptions of the general circulation of the atmosphere. In synoptic meteorology, conditions are little better than in climatology. The role of water substance in the genesis of tropical depressions is a matter of dispute, the existence or nonexistence of fronts the subject of irreconcilable speculations. A dynamical meteorology of the tropics can hardly be said to exist. The assumptions of such work as has been done are usually overlooked, and the results applied in a manner quite beyond the expectation of the original authors. Worse than this, however, is the tendency to apply dynamic theories depending for their validity on assumptions that hold in high latitudes but not in low latitudes. For example, the extent to which reasoning resting implicitly on the geostrophic-wind equation has been applied in equatorial meteorology is disquieting. This state of affairs, however, should not give occasion for pessimism; it is a sign that tropical meteorology, the oldest branch of scientific weather study, is undergoing a new development and that that development is a vigorous one. Each school of thought has had its achievements, has clarified some previously obscure field of knowledge, and has had its defects subject to sharp criticism. It is our task now to estimate the extent of these achievements and to mitigate the evil of those defects.

THE CLIMATOLOGICAL METHOD

There is no doubt that, at least over the oceans, the observed values of the meteorological elements deviate from their monthly, seasonal, and annual means to a far lesser degree in the tropics than in higher latitudes. The mean values therefore can be said, in a special sense, to be more representative of the synoptic values. The steadiness of the wind, for example, has long been known, and the representativeness, in the above sense, of the mean trades and mean monsoons is perhaps the most ancient fact of modern meteorology, antedating in its origin the very notion of a synoptic map.

The word "trade" itself is a contraction of "to blow trade," that is, to blow constantly in the same direction, along the same track. The empirical discovery implicit in the expression has, of course, been well confirmed by scientific investigation. Gallé,[1] for example, has given an analysis of the *persistence* of the wind in various parts of the Indian Ocean. The *persistence* may be defined as the ratio of the mean vectorial wind speed to the mean speed without regard to direction. If, over the period covered by the means, the wind has the same direction, the persistence would be 100 per cent; on the other hand, if the directions were distributed at random, the persistence would be zero. According to Gallé, the persistence of the trade in the square 10°S–20°S, 80°E–90°E does not fall below 69 per cent and for most months lies between 80 per cent and 90 per cent. This can be contrasted with the corresponding figures for the square 35°S–45°S, 70°E–80°E, where the persistence over any month does not rise above 57 per cent and, in the mean, amounts to 45 per cent for the year. But Gallé's figures merely give quantitative expression to the conclusion which anyone can draw from the surface-wind maps that are published from time to time by national meteorological organizations [69]. Scrutiny of the wind data on these maps confirms not only the great persistence of the trades but also a similar large persistence, within the seasons of their greatest development, of the monsoons. To a lesser degree the maps also give one the impression of *uniformity*: over a very large proportion of the tropical oceans, the predominant component of the wind is the east component and this, combined with the known persistence of the trades, leads even careful workers to fall into the habit of regarding all tropical west winds occurring outside the monsoon regions as anomalous.

At first sight the representativeness of the means of meteorological elements other than the wind appears not to be so striking. Temperature and pressure, for example, show synoptic variations that may depart widely from the monthly, seasonal, or yearly means. However, the periodic nature of these variations is evident, the pressure showing semidiurnal oscillations whose amplitudes are largest at or near the equator, while the temperature has a clear diurnal periodicity whose amplitude becomes less the more closely the conditions of observation approach those typical of the open sea. When allowance is made for the periodicity and for calculable orographical effects by correction of the synoptic observations, the mean values for a month or a season turn out to be as highly representative of the corrected synoptic values for temperature and pressure as for wind. Further, in the case of temperature, remarkable uniformity is disclosed. Over vast stretches of the western Pacific, for instance, the temperature of the surface air during the whole "wet season" varies little from 85F [61]. Even in monsoon regions, where we might expect to find large seasonal variations of temperature, remarkable instances of uniformity are known.

> At Colombo the mean difference [sic] in surface temperature between the North-East and South-West monsoon seasons is less than 2°F. and just about as much rain falls

1. Quoted in [36, p. 45]. The original paper is not available to me.

during one monsoon as the other, notwithstanding that the North-East monsoon starts out as a cold, dry continental air mass and the South-West monsoon as a warm, maritime air mass [46, p. 27].

Connected with the uniformity of surface temperature over the oceans is the well-known uniformity in the height of the base of tropical cumulus. This rarely is less than 1500 ft or greater than 2000 ft, and departures from these values are so clearly connected with the occurrence of precipitation that the problem of forecasting cloud bases reduces to that of forecasting the presence or absence of precipitation.

The persistent and uniform values of the meteorological elements are correlated. Both the trades and the monsoons are more than winds blowing with great regularity. Other elements, such as the precipitation and the cloud amount, the temperature, pressure, and humidity regimes, and the vertical variation of the elements all have structures or values characteristic of the trades or of the monsoons. Bergeron [5] has emphasized these correlated characteristics and has held up the trade and monsoon of the tropical climatologist as paradigms of concepts that should be used in the air-mass climatology of higher latitudes. As an example he pointed out that "good monsoon" in India means a complex of heavy rains, strong steady southwest wind, and a characteristic vertical temperature and humidity distribution. The term monsoon, therefore, is to be applied to a persistent kinematic and thermodynamic complex. Similarly numerous observations, culminating in the *Meteor* results [18], have shown that the trade is a persistent complex. Here again we have not only a characteristic and persistent wind, but also a typical associated cloud form, precipitation regime, and lapse rate of temperature and humidity. The "trade-wind inversion" is indeed well known and the equally well-known trade cumulus owes its peculiarities to the association of the inversion with a typical vertical wind-shear.

So far we have mentioned the representativeness of the statistical parameters that are derived from observations over the great tropical oceans. At first sight, conditions are different over the land, particularly over the continents. The highly developed land and sea breezes of tropical islands, and the thunderstorms that break out with great regularity in the archipelagos of the East and West Indies are departures from mean conditions that are, through travelogue and fiction, known even to the layman of high latitudes. But these departures are clearly periodic, and synoptic observations may be corrected for them, either quantitatively or qualitatively. The *seasonal* means for the tropical islands are then representative of these corrected synoptic values. Moreover, the diurnal departures from the mean can be so clearly related to astronomical and orographical causes that the short-period forecast seems to depend only upon an adequate knowledge of the statistics and of geography. Upon close examination the same principle seems to apply to forecasting in continental regions. Here we have the added advantage that the seasonal variations themselves appear to be due to the same causes as the diurnal changes, though operating on a larger scale and over longer periods of time. On this view, we may take the slowly varying oceanic conditions as the ground state and regard both diurnal and seasonal variations over the land as perturbations whose causes, orographic and astronomical, are known. The perturbations are thus thermal in their immediate origin and there appears to be no problem of explanation so far as synoptic variations are concerned. Similarly there ought to be no forecasting problem for periods shorter than a season that cannot be solved with an adequate knowledge of statistics and of orography.

In the foregoing account I have outlined an extreme climatological view of tropical meteorology. On this view, there are no synoptic problems in the tropics. Synoptic problems become climatological problems; the future advance of tropical meteorology therefore depends on the collection and reduction of longer and longer series of observations from more stations in order to obtain maps of stable statistical parameters and their seasonal variations which are to be combined with a more detailed knowledge of orographical peculiarities. The remaining problems are then dynamical and relate almost entirely to the "ground state" that was mentioned above. If corrections for diurnal and seasonal variations may be made by assigning them to known astronomical and orographic causes, it is clear that we are left with the statistical picture of the "trades" considered as kinematic-thermodynamic complexes to be explained by the methods of mathematical physics. Since the complexes are regarded as the most persistent features of the atmosphere, they represent a steady state in the dynamic sense and the statistics give us a direct insight into what is known as the general circulation, at least for latitudes below 20°. What has to be explained, therefore, is the tropical part of the "planetary circulation" or "winds of the globe" and this explanation turns out to be one of the easiest ever attempted in meteorology. If it should appear that I have represented a very extreme view and one which would not be defended in this form by any modern meteorologist, I suggest that almost all textbooks that refer to the tropics at all (*e.g.* [49]), and certainly some recent authors of research papers dealing with the general circulation [45, 56], imply this view in their treatment of the dynamics of the tropical atmosphere. This is true not only of those we may rightly classify as belonging to the climatological school but also of those in the frontal and perturbation schools, insofar as they treat the general circulation. Those authors will be dealt with in their proper place.

What kind of picture, then, is obtained by pursuing these principles to their final conclusion? First, let us look at the now-modified empirical laws governing the general circulation in the tropics. Abstracting the data in such a way as to omit the diurnal and seasonal perturbations of thermal and mechanical origin, we are left with a system of trade winds, blowing steadily from the east and toward the equator in the lower layers of the atmosphere. The trades of the two hemi-

spheres approach one another at the equator, as is clear from the statistics. There, they become light and variable and this weakening is obviously part of the observed horizontal velocity convergence in the two currents, with a correlated increased vertical component in the motion. The lapse rates of temperature and humidity confirm this conception. At some distance from the equator, the lower atmosphere is characterized by the presence of an inversion of temperature, the trade-wind inversion, above which the humidity drops to very low values, both absolutely and relatively. But this inversion, under the influence of the predominantly vertical motions, becomes higher and weaker as the equator is approached, finally disappearing in the zone of intense upward convection at or near that boundary. At high levels, the motion of the air is predominantly and necessarily (on continuity considerations) away from the equator, and at relatively small latitudes it takes on a westerly component to form the *antitrades*. The antitrades are thus westerly winds with a poleward component and a downward vertical component that reaches its maximum values in the neighborhood of 30°. A circulation cell is thus completed and the composition of the air in it agrees well with the distribution of the vertical component of the steady-state motion. In particular the region of light variable winds near the equator, which we shall now call the *doldrums*, is, as the statistics show, also a region of large cumulonimbus clouds, with attendant heavy precipitation, the "squalls" of the early navigators. On the other hand the trade-wind zone is the region of trade cumulus, with only light showers or none. The *horse latitudes*, finally, are regions in which fair-weather cumulus or stratocumulus predominate; sometimes they are clear of cloud.

When we come to explain this abstracted picture of the tropical circulation we find the necessary concepts ready to our hands. The equatorward component of the trades was first explained by Halley in 1686; this constitutes, in fact, the first attempt to explain any feature of the general circulation. According to Halley, the equatorward component is to be attributed to the replacement of air that has risen by upward convection at the equator. Surface heating at the equator, supposedly the region receiving the greatest amount of heat from external sources, is sufficient on this view to drive the whole meridional circulation of trades and antitrades. Halley's explanation of the *zonal* components of the motion, however, was not accepted. In 1735 John Hadley gave the accepted theory, invoking the conservation of absolute angular momentum. Since that time the combined explanation has been handed on from text to text. It was, for example, embodied in the earlier dynamic theories of the Chicago group. Rossby [56] specifically has used it under the guise of the "direct cell" in the general circulation. Although little quantitative work has been done, the qualitative use of the explanation, it is assumed, solves the dynamic problem for the tropical atmosphere. On this assumption, any further work would be directed to improving the theory quantitatively, by referring to better and better climatological data.

Summing up the extreme climatological view, we have the following conceptual apparatus: the tropical atmosphere is composed of persistent wind systems, with their associated composition and thermodynamic properties, the *trades* and the *monsoons*. Diurnal variations of the meteorological elements are due to perturbations of these systems, attributable to thermal and orographic disturbances of known origin. The monsoons are seasonal perturbations of the trades due to the same causes. The trades themselves are thermally driven and all features of that circulation are explicable in terms of what happens in the *doldrums*, a region of intense convection and light variable winds coinciding with the equator in the ideal model. Astronomical variations, combined with the different absorptive properties of land and sea, therefore account for everything—trades, doldrums, monsoons, land and sea breezes, the regime of precipitation, temperature and humidity, cloudy and fine weather, and lastly (by dynamic functional relations embodied in the equations of motion) the pressure distribution. There are no problems left to solve. On this basis, a large part of the more successful short-range tropical forecasting in World War II was implicitly conducted; the little long-range forecasting that was done was based explicitly on this statistical method; on this basis, also, most present-day models of the general circulation incorporate the tropical atmosphere.

Two unfortunate circumstances mar the beauty of the picture. The first is a fact that has been known to western science for four hundred years or more. Oceanic tropical regions are not only the seat of steady trades and monsoons, they are also, in their season, notorious for the presence of the most violent storms dealt with by synoptic meteorologists—typhoons, hurricanes, and tropical cyclones. How are these storms to be accounted for in terms of the causal theories of the climatological school? The first impulse is to explain their origin in terms of the standard astronomical and orographical variables previously invoked. During the last century, the tendency was to regard tropical cyclones as being perturbations due to local intensifications of convection in the doldrums [43]. Those who wished to advance more explicit causes attributed the convection to local maxima of heating [27]. But this explanation was soon seen to be untenable, since the region of origin of at least some typhoons was discovered to be over the parts of the Pacific Ocean where the temperature gradients in the lower layers were very weak. It must be confessed that the climatological school never successfully dealt with the problem of the origin of tropical storms. The best that could be done was to chart the regions and seasons in which they occurred, to show that the mean tracks generally followed the march of the sun and that there was some justification in the statistics for regarding tropical storms as connected in some way with the only region, in the view of the school, that showed the necessary high variability of the meteorological elements:

the doldrums. But even the doldrum origin of tropical storms was not quite general.

At least some of the hurricanes that afflict the West Indies and the southern coast of the United States originate in the Caribbean or in the Gulf of Mexico, and when this happens they appear almost without warning in the trade current, not in the doldrums [25].

The second circumstance that is fatal to the extreme climatological view is that the really steady trades occupy only a small fraction of the total oceanic areas in the tropics. Further, the antitrades are similarly found only in comparatively restricted areas. The typical trades, as described in models of the general circulation, are found only in the eastern parts of the equatorial branches of the great subtropical anticyclones. The regions of high persistence are these same areas. In the western fractions of the tropical oceans the trade wind is variable, not as variable as the belt of the westerlies, it is true, but still subject to perturbations of the wind field, so clearly independent of thermal causes as to belie the classical description. In the western oceans also, the meridional component of the wind may not be directed toward the equator, even in the mean. At Pukapuka (11°S, 166°W), for example, the mean wind at the surface is directed during the summer away from the equator, though this station always lies south of the doldrums [24]. Similarly the antitrade at higher levels is best developed and most easily discovered above the eastern borders of the subtropical highs. To the west, the westerlies are found at higher and higher levels, and in the lower latitudes and near the western borders of the anticyclones they may not be present below the tropopause. The deathblow to the notion of universal antitrades in tropical latitudes was given by J. Bjerknes in his discussion of the subtropical anticyclones [6]. It is clear from that paper that the oceanic anticyclones are major perturbations of the atmosphere with features independent of any direct thermal cause, and that any explanation that leaves them out of account by dismissing the trades as part of a simple "direct cell" symmetrical on all longitudes is artificial. While such explanations may suffice in a discussion that is directed mainly toward clarifying the vagaries of the westerlies, they are too unrealistic to be useful in tropical meteorology.

A more serious difficulty arises when, having recognized this oversimplification of the general circulation, we attempt to discuss the details of the observed tropical circulations, daily, seasonal, or annual. While we have an excellent series of observations over the oceans (excellent, that is, from the climatologists' point of view), we have very few observations and those for comparatively short periods over most of the land masses. India, it is true, has long provided observations from a dense network, but we still lack long and reliable series from Southeast Asia. The data are even more unreliable and sparse from equatorial Africa and from Brazil. As we shall see later, the wartime synoptic data from the latter areas strongly suggest that the simple picture of the monsoons in those areas is probably a climatological abstraction as misleading as that of the trades. What good data we have, moreover, consists of surface observations. Upper-air observations are still so widely spaced, even at the present day, that most high-latitude analysts would refuse to commit themselves to a space analysis of either the synoptic data or the means. It must be remembered, also, that except for some Indian stations, and a few in the Caribbean and Panama, practically no radiosonde or meteorograph data antedates World War II. Further, the upper winds in India and the East Indies, upon which much emphasis has been placed in some papers [23], are derived from the observations of pilot balloons. Dr. Mintz of the Meteorology Department of the University of California at Los Angeles has pointed out to me how misleading mean winds derived from such observations in the tropics can be. In "The General Circulation of the Atmosphere over India and Its Neighbourhood" [51], for example, are published data giving the mean wind at 4 and 8 km according to the pilot balloons. In the same volume are also given the mean directions of the clouds at and about those levels. The mean circulations for January derived from these two independent sources are directly opposite to one another, that indicated by the balloons corresponding to the east end of an anticyclone situated at the appropriate level, that from the clouds corresponding to the west end. It is clear that the pilot balloons are selective and that mean winds derived from them are probably typical of clear weather; the balloons are very easily lost from view in tropical regions even with small amounts of convective cloud, since the cloud pillars are so much higher in low than in high latitudes. On the other hand, winds derived from middle and upper clouds are selective in the opposite direction, since such clouds are, in low latitudes, most commonly the result of convection, being formed from the middle and upper parts of cumulonimbus.

Such considerations as the foregoing ought to make us hesitate to generalize when discussing the upper parts of the tropical circulations, either in the trade or in the monsoon regions, especially when our point of view leads us to place the greatest emphasis on seasonal and annual means. There are literally not sufficient data to make a single reliable statistical generalization applicable to the upper levels. Our best hope is to allow the lapse of time and the gradual extension of the tropical observing networks to accumulate data that might later give us an insight into the upper circulation in low latitudes. In the meantime, the chief problems seem to be synoptic and dynamic, particularly the dynamic problems growing out of synoptic experience.

THE AIR-MASS METHOD

When, after World War I, meteorologists of the Bergen group began to extend their application of frontal and air-mass analysis to regions outside Scandinavia, they found the climatological concepts of tropical meteorology already adapted to their purpose. We have already referred to Bergeron's approval of the notions, *trade* and *monsoon*, as modified to include not

only the wind structure of those entities but also the associated temperature and humidity distributions and the typical cloud and precipitation regimes. For kinematic and thermodynamic complexes of this kind were precisely the new elements the Bergen group had introduced into the synoptic meteorology of high latitudes under the name, "air mass." Both the trade and monsoon of the climatological school of tropical meteorologists fitted the prescription of an air mass perfectly. The trade, for example, had a specific source region: the subtropical anticyclone. Its path from the source was well determined and the character of the surface over which it had to pass, the great tropical ocean, had already been investigated and its thermodynamic effect evaluated. These factors together gave to the trade its uniform, persistent features; the relatively steep lapse rate in the lower layers could clearly be attributed to the fact that it moved across the sea-surface isotherms toward the heat equator; it was clearly a cold mass of maritime subtropical origin ("tropical" in the new vocabulary) and the presence and variation of the convective cloud in it confirmed, through indirect aerology, the thermodynamic classification. The trade at its source was a stagnant slowly subsiding mass, almost in equilibrium at all times with the sea surface; here there were no clouds or perhaps small amounts of low stratiform cloud. As it moved toward the equator, however, the mass became heated by the warmer waters in lower latitudes so that a relatively steep lapse rate was characteristic of the lower layers, while the air above continued to be warmed by subsidence in the antitrades, thus stabilizing the trade-wind inversion. The closer the mass approached the equator, the more intense became the heating from below and the less the subsidence aloft; the result was that a deeper lower layer was overturned by convection, the trade-wind inversion was found at a higher level, and became weaker as it approached the doldrum region corresponding to the heat equator. The clouds used in indirect aerology confirmed this history, for as the mass moved toward the equator the cumulus reached to higher and higher levels and showers associated with cumulonimbus became more frequent. This picture not only fitted the older climatological view of the trade remarkably well, it also removed some of the difficulties of the older theory by emphasizing the role of the subtropical highs as source regions. The most typical trade would be found at the eastern ends of the anticyclones, because there the trade had the largest component toward the equator, and moreover the reconstruction of the vertical motions around a subtropical cell, suggested by J. Bjerknes, required that the predominantly downward motion be confined to the eastern ends. Toward the west the circulation in the cell required an increasingly great upward component in the middle atmosphere—it was in those regions, empirical investigations showed, that the trade wind was more variable, the trade-wind inversion frequently weak or absent, and the weather worse than the older theorists could allow.

The monsoon, wherever it occurred, in Africa, Southeastern Asia, or Australia, was also an air mass. It was, in fact, a trade that had passed from one hemisphere to the other, and thus, under the influence of a Coriolis force of opposite sign from that in its place of origin, acquired a westerly, instead of an easterly, component. This mass was accelerated under the influence of a solenoidal field that could be attributed ultimately to the different absorptive properties of land and sea, as required by the older theory. It was considered to be unstable to great heights and to have, in the upper layer, a higher specific humidity than the trade because it had been subjected to the destabilizing influences of the equatorial passage for a long time; further, it was moving on to a continent during the warmest season, and hence might be expected to show cold-mass characteristics to a high degree.

What, then, could be said about fronts in the tropics? On the new view, the air masses were tremendous volumes of air, moving away from their source regions and preserving the marks of their origin in their homogeneous properties and of their history in the modifications of their lower layers; ultimately they came into juxtaposition with other air masses along more or less sharp boundaries, the fronts, where the meteorological elements would necessarily show rapid space variations, particularly in the horizontal planes. Were there such boundaries to the trades? This question had already been answered for the Pacific. In 1921 Brooks and Braby [11] had described in the western South Pacific what they called a zone of convergence between the trades of the two hemispheres. The title of their paper, "The Clash of the Trades in the Pacific," is suggestive. In the central Pacific the mean trades from the two hemispheres meet at a small angle along a line that corresponds very well with the mean position of the equatorial low-pressure trough. Farther west, however, the mean trades meet at a larger angle and, in the extreme west, near the Solomons and New Hebrides during the wet season, the boundary is well marked, separating westerly "monsoons" to the north from easterly trades to the south. Rainfall follows the intensity of the convergence[2] as judged from the angle of impact of the currents. In the east, the rain zone is narrow and corresponds in position with the boundary; in the west, the rain zone, while roughly corresponding with the boundary, is broader and, in the mean, the rainfall is heavier. Finally, the tropical cyclones of the South Pacific seem to originate near or at the boundary, to move along it for a time, but in most cases to curve away from it into higher latitudes. Brooks and Braby had done their work and prepared the paper, it seems, before they had heard of the new polar-front theory; before publication, however, they added a footnote, drawing attention to the similarities of the boundary between the trades and the polar front of higher latitudes of which they had just heard a description by V. Bjerknes at a seminar in England. They then pro-

2. In the paper by Brooks and Braby [11], it is clear that "convergence" means convergence of the streamlines, not horizontal velocity convergence.

posed to call the new entity they had introduced into tropical meteorology, *the equatorial front.*

The work of Brooks and Braby seems to have been overlooked by the Norwegians, for they proceeded more or less along the same path without referring to it. However, their researches, in which they used the same method of analyzing surface mean winds and rainfall, were more extensive, ultimately covering all the tropics. They describe the "intertropical front" in the Pacific [10] and Atlantic and Indian Oceans, and in addition attempt to trace its course over the land in Africa and southeastern Asia. Seasonal movements of the front are attributed to different mean temperature conditions in the trades of the winter and of the summer hemispheres.

It is clear that, up to 1933, the new tropical meteorology still followed, at least implicitly, the assumptions of the climatological school. It was implied that the equatorial or intertropical front, being found on maps of mean winds, pressure, and rainfall, would therefore be found also on synoptic maps. As far as I can discover, this assumption was not questioned at any time; indeed, many authors did not recognize that it was an assumption. After 1933, therefore, there was a concerted attempt to apply frontal and air-mass analysis to synoptic maps in the tropics. The movement started slowly, being most active in the Pacific and the Caribbean. By 1939 the standard high-latitude methods of frontal analysis had been adopted by the Philippine Weather Service, by the meteorologists of Pan American Airways [17], in New Zealand [3], Australia [50], and in Martinique and other parts of the Caribbean [31]. World War II brought an immense increase in the amount of forecasting required in the tropics and, with it, a large influx of meteorologists whose training and experience had been largely in high latitudes. The latter applied standard air-mass analysis to their new problems, almost without question; the literature at that time gave them every reason for doing this. The only paper that might have thrown some doubt on the accepted view [25] had at that time attracted little attention. Today, as the survey mentioned in the introduction shows, almost half the meteorologists who have had experience in the tropics still adhere to the tenets of the air-mass and frontal school. We are, therefore, entering the most controversial part of this review and it is well to pause and examine our fundamental conceptions closely. For it is often found that an irreconcilable conflict of scientific views concerns not the facts but the explanations; most of the difficulties may be semantic in origin.

It must be realized that the complex of ideas advanced by Norwegian meteorologists may be divided into two sections. The first section is concerned with certain readily verified facts. The term front, in empirics, is applied to a set of atmospheric phenomena that are frequently discovered by our instruments and by visual observation to be closely associated. The most striking feature is the occurrence of an organized system of clouds, extending over immense horizontal distances; one type of cloud system is called a warm front, another a cold front, and combinations of the two are termed occlusions. However, these terms are only applied if, accompanying the cloud system, there is a narrow zone in which the meteorological elements humidity, temperature, and wind show rapid changes whose sense is defined for each of the three different types of cloud systems. Further, in high latitudes, the pressure gradient should have an oppositely directed component on either side of the system. In this sense an observer on the ground or a pilot in the air may identify a front without ever seeing a synoptic map. It is an observable entity. The Norwegians, however, did not stop at the descriptive stage of meteorology. They had also an explanation, a *theory about fronts.* This theory accounts for the observed fronts as being boundaries, approximating atmospheric discontinuities, between air masses which possess characteristic and more or less homogeneous values of the meteorological elements. Further, the theory requires that the fronts can be maintained for any length of time only if there is a density contrast accompanied by cyclonic shear at the discontinuity. Now this theory is not a priori true. There is no general theory of the atmospheric circulation by which we can derive from the principles of physics the result that fronts must form in this manner. The confidence we have in the theory as an explanation applicable to high latitudes comes not from dynamic meteorology but from experience with synoptic maps, by means of which we check the contention that the fronts observed at a single station or by the airman are in fact boundaries between air masses. This experience leads us to give the name front to regions where certain meteorological elements show steep gradients even in the absence of the typical cloud and weather pattern. This is done because such systems preserve the two most essential features of the theoretical front, viz., the density contrast and the cyclonic wind-shear.

The density contrast and the wind shear are essential to the further development of the theory. For, according to the Bergen school, the frontal surface is not always in stable equilibrium. Waves develop in it and some of these waves are dynamically unstable. Such unstable waves give rise to vortical circulations which roll up the surface and form the cyclones of middle and high latitudes. The kinetic energy of these cyclones is derived from the potential energy of the mass distribution at the undisturbed fronts. It is now obvious why *both* the density contrast and the cyclonic shear are needed at the theoretical front. The first provides the necessary source of energy for the storm, and the second is the destabilizing influence that leads to the occlusion process. They, of course, play other roles in the theory, but this is their part in the wave theory of cyclones. To emphasize the independence of the empirical and theoretical fronts, I should like to remind the reader that line squalls were known long before the frontal theory was promulgated and that very accurate descriptions of cold fronts exist, dating back to the last century [42]. If the theory of extratropical cyclone formation should ever be upset and discredited, cold fronts, warm fronts, and occlusions would continue to be observed and to be identified on synoptic maps,

though the explanation of their relations to one another and to the field of motion would be different.

I have labored the distinction between the empirical and the theoretical front because it was undoubtedly not made by the early workers of the frontal school in tropical meteorology. They succeeded in establishing the following facts by observation and synoptic analysis:

1. In all tropical latitudes, organized lines of cumulonimbus cloud, closely resembling the cold-frontal cloud systems of high latitudes, are encountered by airmen and are observed to pass over fixed observing stations.

2. In the great majority of cases, these lines of cloud are accompanied by zones of rapid wind change. The total shift is not as pronounced as in high latitudes and is generally more gradual. The shear at the shift is often cyclonic. These facts have been emphasized by Deppermann [20], by Harmantas [35], by Frolow [31], and by Alpert [1]. From personal experience I can assure the reader that they are facts.

3. Differences of temperature can sometimes be found between the air on either side of the cloud line. This is reported by Sawyer [60] and by Solot [67]. However, in certain oceanic regions, though there is often an abrupt drop in temperature at the surface with the passage of the cloud line, it may recover its former value when the weather clears.

4. There may be very marked differences in specific humidity across the cloud line—not, it is true, at the surface, but in the middle atmosphere.

5. The lines are frequently but not always associated with a low-pressure center or trough at the surface, but owing to the weak pressure gradients and the great amplitude of the semidiurnal pressure oscillation, it is difficult to correlate any sharp change in the barogram with the passage of the cloud line, unless a violent thunderstorm occurs at the station.

6. One can sometimes find these cloud and wind-shift lines day after day in the region of lighter winds around and outside typhoons, hurricanes, and tropical cyclones [21]. Moreover, the storms sometimes appear to originate in the regions where such lines have previously been discovered.

To most tropical meteorologists, after 1933, these discoveries were sufficient to identify the lines as fronts, and since they made no distinction between the empirical and the theoretical front, they adopted the entire high-latitude apparatus of frontal and air-mass analysis and forecasting. The way had been prepared, as we have seen, by Brooks and Braby, by Bergeron and, most authoritatively, by the authors of *Physikalische Hydrodynamik* [10]. The frontal wave theory of storm formation was adopted without question; indeed it seemed to be confirmed by (5) and (6) above. A few meteorologists were concerned by the frequent lack of temperature differences across the fronts and were careful to distinguish "tropical fronts" where the differences were very small (in many cases they were, in fact, absent) from extratropical fronts where there was usually no difficulty in detecting the difference, at least by radiosonde. Deppermann in particular was always careful to make the distinction. Having decided that fronts and air masses existed in the tropics, the frontal analysts of the decade 1933–1943 were concerned to describe and classify the major discontinuities of the tropics. First, and most important, came the equatorial or intertropical front, whose synoptic existence was never doubted during this period. But there were other major systems, particularly in the western Pacific. Thus Deppermann distinguished a "tropical" front between the winter monsoon of eastern Asia and the trade of the North Pacific [20]. Other "major fronts" were described in different parts of the tropics [17] but these are now of only historical interest. In addition, much attention was given to the passage of polar fronts from the belt of the westerlies on into tropical latitudes.

Some extraordinarily detailed frontal analyses of hurricanes and tropical storms were produced during the thirties. In the South Pacific the full occlusion process leading to the development of tropical cyclones was illustrated by Kidson and Holmboe [38]. Similar analyses were published for storms in the Caribbean [37, 64] and in the Bay of Bengal [59]. An elaborate triple-point theory due originally to Scherhag was applied to North Pacific storms [20]. If one were to judge by the literature up to 1940, one could not doubt that the application of the frontal and air-mass theory to the tropics was completely justified. The chief problem seemed to be, not to account for the origin and development of tropical storms, but to explain why many more than were actually observed did not develop. The tentative theory advanced in *Physikalische Hydrodynamik*, accounting for the maintenance of the equatorial front in terms of temperature differences between the trades of the winter and the summer hemispheres, was extended to account for this also. The equatorial front, on this view, tended to become a sharp discontinuity, "to become active" in the words of the air-mass school, after the air in a great polar outbreak in the winter hemisphere reached the equatorial regions. This would communicate an impulse of an unspecified kind to the equatorial front which would thereupon become unstable and form a tropical cyclone. As early as 1935 De Monts had published a paper with the significant title "Rôle catalyseur de l'air polaire dans la génèse d'un cyclone tropical" [19] describing this process in the South Indian Ocean. Japanese meteorologists seemed particularly attached to this explanation [2]. Later Grimes [33] endeavored to specify the nature of the impulse that would be given to the equatorial front by the arrival of winter-hemisphere air after a polar outbreak. He considered that a "cyclone only forms when there is a surge across the equator of air which in the hemisphere of origin had sufficient anticyclonic vorticity, which is conserved as cyclonic vorticity in the other hemisphere."

Since shearing motion at the frontal surface would be the only destabilizing agent leading to waves of increasing amplitude, Grimes was evidently looking for some process which would bring about a sudden increase in cyclonic shear at the supposed frontal surface. The process was made to depend upon the conservation of the vertical component of absolute vorticity, which it is

now fashionable to suppose actually occurs in the atmosphere. In "The Movement of Air Across the Equator" [33], he enunciates this principle and applies it, under very restrictive special assumptions as to the nature of the motion. In brief, the motion must be horizontal, nonviscous, and autobarotropic, with a constant meridional component. Although as far as I know no investigation has been undertaken to find out whether vertical motion, frictional forces, solenoids, and variations in the meridional component of the wind can be neglected in the tropics, the results of this paper are frequently quoted without mention of the assumptions and applied as if they were perfectly general. Moreover, the efficacy of the deduction from the principle of the conservation of vorticity, as assigning a cause for cyclone formation in this context, depends upon the validity of the frontal theory in the tropics. If that theory is found to be inapplicable, the principle of the conservation of vorticity would have to be invoked in some entirely different context, with results that cannot at present be anticipated.

Although there are still a large number of meteorologists who adhere to the principles outlined above, with greater or lesser modification, the synoptic experiences of World War II, especially in the Pacific and the Caribbean, gave a death blow to the air-mass theory in its extreme form. This theory failed to pass the test to which all theoretical work in meteorology must finally come (though the evil day may be put off for almost a decade); it was found almost useless as a guide to short-period forecasting in low latitudes. The writer can vouch for this through personal experience, through conversation with many tropical meteorologists in the Pacific, the Caribbean, and the United States (where people with experience in all tropical areas are now to be found), and through the answers to the questionnaire issued by the Institute of Geophysics. But the reader need not depend on these sources of information; the recent literature reflects the disillusionment of a whole generation of tropical meteorologists. This is shown in attempts to doctor and patch the frontal theory in such a way as to take into account the many anomalous movements and the sudden appearances and disappearances of the fronts, especially of the equatorial front, or in frank abandonment of the air-mass theory altogether. The following modifications of the frontal theory, as previously outlined, have been proposed:

1. The polar front enters the tropics, not as a typical surface front but as a front aloft, in the westerlies. It persists in that situation but may come down to the surface in lower tropical latitudes and at a later time.[3] Forsdyke [29, p. 82] says,

> Waves in the circumpolar westerlies occur at the surface on the poleward sides of the subtropical high-pressure belts, and at higher levels they extend to low latitudes where the westerlies overlie the trades. It is tempting to identify these with the upper parts of cold fronts associated with the depressions of middle latitudes. At Mauritius they are frequently associated with nimbostratus cloud and rain which spread from the southwest above the lower current from the east-south-east. They should be indicated on the charts as upper fronts. It is possible, therefore, to have in the same part of the chart a lower front moving from an easterly, and an upper front moving from a westerly point, and crossed lower and upper fronts may occur.

2. On entering the tropics, the polar front separates into two portions: (a) the density discontinuity or shear line, and (b) the polar trough (see [16, 53, 65]).

3. The polar front is destroyed soon after entering the tropics. The very rational Memo 131/44 of the British Naval Meteorological Branch [46, p. 28], says,

> So far we have considered only discontinuities which *originate* in the tropics, notably the I.T.F. What happens to fronts which move into the tropics from higher latitudes? Generally speaking, they lose their well-defined slope and become diffuse: their movement becomes slow and indefinite and by the time they get near the equator, if they get that far, they bear little resemblance to their text-book prototypes. Most of them ultimately lose their identity in the equatorial low pressure trough which is a great leveller of air mass disparities. A good many of them get no further than the subsidence zone of the sub-tropical highs where they "dry-out."

4. There is little or no temperature contrast at the equatorial front which is, indeed, simply a more or less narrow zone at which the trades of the two hemispheres converge and rise. This represents a return to the original position of Brooks and Braby, and the climatological school. Brooks and Braby were careful to point out that no temperature contrast could be found across the equatorial front in the regions where, judged by the mean winds and precipitation, it was strongest. Numerous quotations are available on this point [15, Chap. 10; 46, 65]. Garbell [32, p. 70] says,

> The discontinuity between the two tropical air masses coming from the two hemispheres usually consists not so much in a difference in surface temperature as in a difference mainly in the vertical distributions of temperature, moisture, stability and wind velocity between the two easterly air streams.

5. The equatorial front is single and continuous [14].

6. The equatorial front is double [28, 72].

7. The equatorial front is part single, part double [32].

8. The equatorial front is discontinuous. There are many equatorial fronts [54].

9. The equatorial front may slope toward the summer hemisphere [13].

10. The equatorial front may slope one way in the lower atmosphere and the opposite way in the upper atmosphere [34].

11. The equatorial front does not slope at all [46].

12. The equatorial front moves discontinuously. It may jump from one position to another without passing through intermediate points [29].

13. The equatorial front may move by disappearing in one position while another forms in a different position [17].

The list of suggested modifications to the frontal

3. See Rep. No. 600-50, Publications of the Weather Division, USAAF, p. 15.

theory in the tropics could be extended almost indefinitely. To anyone, like the writer, who has had to review the literature on tropical fronts published in the last ten years, the total effect is one of intolerable confusion. And this confusion exists at the present time, unresolved. Where possible, I have purposely chosen the latest quotations for inclusion in the above list, which is, of course, very incomplete. Thus Garbell's textbook was published in 1947; Forsdyke's summary of tropical meteorology in 1949. Both these works will give the reader some idea of the complexities introduced by members of the air-mass school in an endeavor to remove the difficulties associated with the attempt to forecast tropical weather by high-latitude techniques. Forsdyke, indeed, frankly admits in places the impossibility of using standard methods. On page 37 of his paper he says,

> The pressure distribution is of little or no assistance in forecasting the movement of the intertropical convergence zone. The streamline chart is the best aid, the frontal zone usually being located at the line of separation between winds having northerly and southerly components respectively. Over wide areas, however, the surface winds are often the only winds available; hence it is usually the surface front which is so placed, whereas observation shows that the worst weather often occurs up to 200 miles away from the surface front. It may be assumed that the front will move toward the side on which the winds are weaker, but it is difficult to estimate the speed of motion from the observed winds. Often the front appears to jump.

It is easy to be wise after the event, but one may legitimately speculate on what the history of tropical meteorology would have been, during the last fifteen years, if the distinction between the observed wind-shift line accompanied by cumulonimbus, the old "line squall," and the theoretical front of the Bergen group had been kept in mind. Would not the early workers, realizing that the empirical front of the tropics was not necessarily a discontinuity in the density field, have also realized that frontal dynamics would not be applicable to it, that new synoptic entities were being investigated and that therefore new explanations were required? That is the position in which we now find ourselves. At a time when the tropical observing networks are beginning to deteriorate, when we have fewer and less accurate observations than at any time since 1939, we are realizing that tropical meteorology, in investigating these entities, has a contribution to make to general meteorology. Nowhere in the atmosphere are we better able to study the direct effect of horizontal velocity divergence in the lower atmosphere, free from other effects, than in the tropics. The tropical "fronts," which have been dismissed as particular, well-understood examples of a common atmospheric discontinuity, are now seen to be completely without dynamical explanation. When the explanation is forthcoming, it cannot but react on the theory of high-latitude fronts.

THE PERTURBATION METHOD

One of the most serious objections to either the doldrum or the frontal explanation of the origin of tropical storms is that a proportion of the hurricanes that affect the West Indies and the southern United States originate within a comparatively strong east current of great depth prevailing during the wet season over the Caribbean. The storms deepen rapidly and are often of great violence. They are usually of smaller diameter than the hurricanes that move in from the east and which clearly originate in the doldrum region of the eastern Atlantic. In 1940, Gordon E. Dunn published a paper dealing with the origin of these storms [25] and the ideas expressed in it have led to the development of a new outlook on tropical problems.

Dunn, using 24-hr isallobars to eliminate the great semidiurnal oscillations of pressure, showed that:

1. The deep easterly belt of the Caribbean in the wet season is subject to pressure waves of small amplitude, which move from east to west.
2. Ahead of the wave the trade-wind inversion is relatively low, and the weather is fine, with small clouds and little precipitation.
3. Behind the trough the trade inversion is high or absent and the region is the seat of many shower-clouds. He speaks of this as the "rolling away" of the inversion.
4. Some of the waves, and a proportion that increases as the season advances, grow in amplitude and give rise to small but violent hurricanes.
5. The isallobaric highs and lows associated with the waves, whether hurricanes are formed or not, follow tracks that correspond with the mean hurricane tracks of the appropriate month in the season.

Subsequent writers elaborated this picture of the easterly wave. The most active worker was Riehl [53] who investigated the vertical structure of the wave more closely and showed that it was easier to detect in the wind field than in the pressure field and aloft than near the surface. Later the easterly wave analysis was applied to the North Pacific and the North Atlantic. More recently easterly waves have been identified in the Indian Ocean [29] and in West Africa [63].

In opposition to earlier writers on the Caribbean, such as Kidson [37] and Scofield [64], Dunn insisted that no temperature discontinuity could be found either in the easterly wave or in the developing hurricane. Later research has confirmed his contention and there seems now to be no dispute on this point as far as the West Indian hurricanes are concerned. Radar investigation of the storms as they pass over the southern seaboard of the United States, however, seems to show that there are well-marked cloud and precipitation discontinuities in the mature storm [73]. As this topic will be discussed in the next section, I wish only to point out here that Dunn was explicit only on the absence of *temperature* discontinuities. He admits, however, that the southwest wind at Panama in the wet season may be colder in the lower layers than the easterly on the other side of the equatorial convergence zone. One gets the impression that he is willing to admit a frontal origin

for those storms that clearly originate in the doldrums but that he denies such an origin in cases where the storm can be traced to an easterly wave. Temperature differences have been reported at the equatorial front in other parts of the world, for example in India [60] and in equatorial Africa [67]; this probably predisposed Dunn to concede that a frontal origin of doldrum hurricanes was possible.

This concession, either in the form of an outright admission of a frontal origin of *some* tropical storms, or the lesser concession that storms that originate in the neighborhood of the equatorial low-pressure trough differ fundamentally from those that can be traced back to easterly waves, has been a characteristic of workers of the perturbation school. It has, in fact, done much to prevent their presenting a unified theory of the origin of tropical storms. Apart from this admission, however, the workers as a group have been rather extreme in denying the existence of fronts in the tropics. They have, rightly I think, insisted on the absence or irrelevance of temperature contrasts in the Caribbean and the western Pacific; but their zeal has also led them to minimize the well-authenticated accounts of cloud systems and wind-shift lines near the equator, lines that look like the cold fronts of high latitudes. As I have said, they may admit that such lines can exist in the equatorial low-pressure trough but deny their presence in the easterly wave in the Caribbean. Yet nothing is easier, with good aircraft reports, than to demonstrate the presence of such lines in certain Caribbean easterly waves. To admit this, perhaps, would seem to them to destroy the value of the contributions they have made; we would be back in the confusion that prevailed during the ascendancy of the frontal theory. The resolution of their difficulty must be left to the next section.

The detailed structure of the easterly wave was worked out by Riehl [53]. He assumes that the basic undisturbed current in the Caribbean is a deep easterly. If this assumption is conceded, it is a simple matter to define and to detect the chief axes of the easterly wave, both at the surface and aloft, for the axes, horizontal and vertical, along which the wind is easterly will be the "trough" and "wedge" axes. In the Northern Hemisphere we shall find northeast winds ahead of the trough and southeast winds behind it. By the analysis of upper-level wind maps, supplemented by time cross-sections at individual stations, it is then possible to discuss the slope of the systems. Riehl showed that the perturbations of the wind field were of greater amplitude than those in the pressure field, and that the amplitude of the former also seemed greater in the middle troposphere than at low levels. Generally, the trough axis slopes toward the east with height. Further, the lower wind fields are positively divergent[4] ahead of the trough and negatively divergent behind it; with this distribution of the horizontal velocity divergence, and (to a high degree of approximation) of the mass divergence, the westward passage of the wave is explained, as is also the "rolling up" of the trade inversion behind the wave axis and the consequent distribution of cloud and precipitation in the perturbation. The virtue of Riehl's work is that he establishes the correlations of the fields of motion, pressure, composition, and temperature to form a simple integrated picture of the perturbation; this has hardly been achieved for any perturbation in high latitudes except, perhaps, the frontal wave.

Riehl also discusses another type of perturbation observed in the Caribbean area, one we have mentioned before. During the winter in that region, the east wind near and at the surface is frequently accompanied aloft by winds with a westerly component; in other words there may be a typical trade-antitrade regime. In the lower easterlies, perturbations that look superficially like easterly waves on the low-level synoptic map appear; however, these disturbances move, not toward the west, but toward the east, against the lower easterly current. It is always possible to show that the trough in the easterlies is continuous with a surface trough in the westerlies of the higher latitudes and with an upper-level trough in the westerlies of the tropics. This trough Riehl called the *polar trough*; he accounted for the eastward movement of the system in the lower tropical atmosphere as being a reflection of the movement of the trough aloft in the circumpolar westerlies. This explanation had been advanced before, of course, but in a different form. The older explanations were in terms of an upper front in the westerlies—Riehl simply omitted the front, thus effecting a great simplification in this part of the model. However, it is a fact that true surface fronts move southward over the United States in wintertime and that they may move off the continent into the Gulf of Mexico and the Caribbean. The surface front becomes weak, but can often be traced far to the south into Central America. It is then found that it is dissociated from the polar trough (especially in the pressure field) and that the chief cloudiness and precipitation accompany the eastern part of that trough rather than the surface front. This picture has been elaborated by Cressman [16], Simpson, and others. As time goes on more and more complexities are introduced into it; one suspects that all is not well with the polar-trough model and that several different synoptic phenomena are being confused under one heading. At present, however, little research is being done on winter disturbances in the tropics and the time seems to be ripe for new investigations. In the meantime, if current synoptic maps from weather stations in the Pacific are a guide, there seem to be two rival explanations of winter disturbances in the higher tropical latitudes: the polar trough explanation and the older one which accounts for all winter precipitation in the trades in terms of classical fronts traveling from higher latitudes toward the equator.

In 1948 Freeman [30], on the basis of wartime experiences in the New Guinea area, introduced a new

4. Riehl is careful to show that the total horizontal velocity divergence, not merely the streamline divergence, varies in this manner. The distinction was never clear to workers of the air-mass school.

type of perturbation into equatorial meteorology. The easterly current near the equator was described by him as being on occasion the seat of a disturbance in the *speed* field in the lower atmosphere. The streamlines are not disturbed from their easterly direction, but maxima and minima of speed travel downstream in the current. Freeman places great emphasis on a "jump" in speed corresponding to the passage of the trough in the normal type of wave. However, it is probable that this is merely an extreme form of a longitudinal wave common in the New Guinea area and known to forecasters there since the elaboration of the pilot-balloon network in 1942 and 1943. For convenience in this discussion, I shall call all easterly waves that are detectable in the speed field but not in the streamline field, *Freeman waves*, without necessarily agreeing with the dynamical explanations advanced by Freeman. As far as I know this type of wave is found only in the New Guinea area, and there is reason to suspect that the peculiar orography and geographical position of that island play an important part in its genesis. However that may be, we may fairly add a new type of disturbance, independent of fronts or convergence zones, to those already known to affect the homogeneous air streams of low latitudes.

It was one of the great advantages of the air-mass theory that it seemed to give a complete or almost complete explanation of a multitude of different weather phenomena in both high and low latitudes. For low latitudes, the climatological school also appeared to have a complete system of explanation. This is not the case, at least explicitly, with the newer concepts advanced by the perturbation school. The ideas are new, the whole movement being less than ten years old. As a consequence there has been a tendency to emphasize methods of analysis, especially synoptic analysis, rather than to attempt complete theories. Further, the workers on perturbations of homogeneous streams have rightly adopted explanations from earlier meteorologists, where these have seemed to them to fit the facts, even though at the time it seemed difficult to reconcile those explanations with the newer outlook. We have already mentioned the fact that the equatorial front was accepted by the perturbation school; it was, of course, regarded as a zone of intense horizontal velocity convergence in the lower atmosphere, and its role as an atmospheric discontinuity was minimized. Nevertheless the newer analyses in the vicinity of the equator were almost indistinguishable in practice from those of the more enlightened members of the air-mass school, such as Deppermann. Similarly, in their treatment of the monsoons of Asia, Africa, and Australia, the group adopted almost without question the explanations of the climatological school. Thus, although no unified theory has yet been presented, we may reconstruct such a theory from these adaptations, from hints in the literature, and from the evident dependence of the group upon the dynamical conceptions of Rossby and his coworkers in Chicago.

In this reconstruction, the trade winds, considered as broad streams of air largely homogeneous in the lower horizontal planes, play a major role. Less emphasis than formerly is placed on the meridional components of these winds. They are, indeed, regarded as part of the circumpolar vortex, which happens to be retarded with respect to the earth's surface in low latitudes but which moves faster than the earth in higher latitudes and in the upper air over the tropical zone. The base currents of the general circulation, on this view, are primarily zonal. Meridional circulations arise as perturbations on these currents; the only *synoptic* problem in tropical regions, with the sole exception of the study of the equatorial front, is to describe and explain the perturbation of the zonal currents in the tropics. After description, the perturbations are classified as we have seen; there are (1) the major "dynamic" perturbations of the zonal motion, the subtropical anticyclones and the semipermanent lows of high latitudes; (2) the great seasonal perturbations of the trades, the monsoons, due to thermal causes, as understood by the climatological school; (3) the perturbations of the trades themselves—in winter the polar troughs, in summer the easterly waves and Freeman waves; and (4) the minor diurnal and orographic perturbations, for which an explanation has already been advanced. Hurricanes and tropical storms arise in two ways: (1) as a result of dynamic instability in the trade current, leading to the growth in amplitude of the easterly wave and its transformation into a vortex, and (2) as a result of some unknown process affecting the equatorial front (or, if one wishes to be free of all frontal taint, the intertropical convergence zone). The causes of the instability are unknown, though Riehl has advanced two accounts of the sufficient conditions [54, 55]; of conditions both necessary and sufficient there has been so far no hint in the literature. Whatever may be the difficulties of explaining the origin of hurricanes, typhoons, and other tropical storms, explanation of the major features of the perturbations (again, with the exception of the equatorial front) is achieved by the methods of dynamic meteorology as set forth by Rossby. The central notion of these methods is that the vertical component of vorticity is conserved during the isentropic motion of the air particles in the trade-wind zones. However, in the case of the easterly wave, the horizontal velocity divergence of the lower parts of the trade must be taken into account, and this makes the so-called vorticity equation so intractable mathematically that no quantitative evaluation of the wave characteristics can be carried out—the explanation must therefore follow the original qualitative discussion of Bjerknes [7], *i.e.*, in terms of a latitude and a curvature effect. Greater precision was given to this latter explanation by Bjerknes and Holmboe [8], but unfortunately the theory as handled by them leads to the result that all easterly waves of the type described by Riehl must deepen and give rise to vortices.[5] Freeman, moreover, has advanced an entirely

5. Professor J. Bjerknes has directed my attention to the possibility of effecting a reconciliation between the theoretical results and the Riehl model by taking into account convergence due to friction in the lowest levels of the divergent part of the wave. He thinks that this might bring about a balance in the integrated mass divergence over the region and thus stabilize the wave.

different theory for the origin of the waves he describes; so far no one has attempted to reconcile the two dynamic explanations.

The confusion that results from attempts to explain the dynamics of the perturbations in the tropics is probably temporary; at all events it is negligible compared with the greater confusion of ideas concerning the general circulation in low latitudes. Here the workers have followed Rossby with implicit confidence, and it is in his writings that we find the most complete expression of their views. We shall therefore examine in some detail those parts of his papers that relate to the tropics.

In 1941 Rossby published "The Scientific Basis of Modern Meteorology" [56], summarizing his views on the dynamics of the general circulation; presumably he held the same views in 1945, since the same paper was republished in the *Handbook of Meteorology* [57]. In this paper Rossby gives a masterly exposition of the climatological explanation of the tropical circulation. It is in fact Hadley's explanation in modern dress. First, we have the direct circulation cell, on a nonrotating earth. As the result of the surplus of incoming over outgoing radiation in the lowest layers of the atmosphere near the equator, the temperature in very low latitudes tends to increase, with consequent expansion of equatorial air columns; the contrasting radiative regime in higher latitudes produces a tendency to contraction of the vertical air columns. "Thus," says Rossby, "at a fixed level of, say, 5 km (3 miles) above sea level, a greater portion of the total atmospheric air column would be found overhead near the equator than near the poles." A direct circulation converting potential into kinetic energy would result; the air motion would have a component toward the equator in the lower layers and away from the equator aloft. On a rotating earth, zonal components would be introduced. The motion, the same on every longitude, would be subject to the conservation of angular momentum. "A ring of air extending around the earth at the equator at rest relative to the earth, spins around the polar axis with a speed equal to that of the earth itself at the equator. If somehow this ring is pushed northward over the surface of the earth, its radius is correspondingly reduced; and it follows from the principle set forth that the absolute speed of the ring from west to east increases." Here we have the origin of the antitrades. The trades, in like manner, acquire their easterly component as a result of the conservation of angular momentum. The final result is that though east winds prevail between 30°N and 30°S in the lower atmosphere, "Above 4 to 5 km (2½ to 3 miles), westerly winds prevail in all latitudes." Thus the observed features of the mean circulation in the tropics, after the abstraction of diurnal, seasonal, and orographical perturbations, is completely explained.

In 1947 Rossby completely rejected this model of the tropical circulation, for the following reasons [58]:

1. He quotes Vuorela [71], Kuhlbrodt [39], and the wartime data from the Marianas and Marshalls as showing that the easterlies near the equator extend farther upward and poleward than would be compatible with the direct-cell theory. He says, ". . . it is fairly clear that the simple thermal circulation outlined by Hadley cannot be the sole, or even the dominating, feature in the mechanism of the trade winds."

2. He then goes on to point out the great uniformity of the meteorological elements, especially temperature, in the tropics, and the difficulty of reconciling these observations with the simple thermal explanation.

3. He next mentions the "discovery" of Fletcher [28] that in some longitudes there is a mean west, not east, wind near the equator, and this in oceanic regions. Defant also is mentioned in this connection. Further, the well-known zone of divergence in the equatorial central Pacific is cited in support of the thesis that the direct-cell theory is inadequate.

4. "The remarkably small annual march of the doldrum belt" seems to Rossby to contradict the direct-cell theory.

Each of these points has long been known to tropical meteorologists. For example, both van Bemmelen [70] and Kuhlbrodt [39] have emphasized point (1) and it was thoroughly established by 1939 in the Pacific as a result of pilot-balloon observations; point (2) is as old as the earliest climatological maps (see also [61]); point (3) has been discussed by Deppermann [23]; and, further, the explanation of persistent west winds at the equator was first advanced by Piddington and Reid [52] one hundred years ago. The dry zone in the central Pacific has been discussed by Schott [62] and the New Zealand meteorologists, particularly Seelye. All these points, and others I have already mentioned, long ago led many tropical meteorologists to reject the extreme climatological view and some to embrace the frontal and air-mass theory as applied to the tropics.

After summing up these objections, Rossby generalizes from them, implying that because the direct-cell theory fails to apply over certain longitudes it fails over all. But this is to commit the typical fallacy of the climatological school: what I may call fallacious generalization from a given longitude. It arises when we become acquainted with new observations restricted to a narrow longitudinal band. Thus, when the older climatologists first became acquainted with the very persistent trade winds typical of the eastern border of the subtropical anticyclones, they generalized to form a model in which, along every longitude, these winds and the associated antitrades prevailed. We have recently become more aware of the mean state at the western ends of the subtropical highs, where "double equatorial fronts" and west winds on the equator are common; there is therefore a tendency to generalize from these longitudes to the whole tropical belt. The same remarks apply to the temperature distribution: at the eastern ends of the anticyclones, horizontal temperature gradients may be found both on the synoptic and on the mean maps, aloft and at the surface [18, 61]. The older climatologists could therefore justify their model of the trades by appealing to observations from these longitudes. However, if we concentrate our attention on the western parts of the tropical oceans, particularly of the Pacific, and generalize to all longi-

tudes, we become convinced that there are no horizontal temperature gradients in latitudes below 20°.

The new model, then, is open to the same empirical objections as the old. But there are also serious objections to the theoretical explanations which have been advanced, inasmuch as the principle of the conservation of the vertical component of the absolute vorticity is appealed to. Without entering into the details of the new theory, which would take us beyond the limits of this article, we may sum up these objections by saying that it has yet to be shown that the mean motion of the tropical atmosphere is autobarotropic, horizontal, frictionless, and nondivergent to a high degree of approximation. Until this has been shown, we must suspend judgement as to the applicability of Rossby's concepts in low latitudes. Even if we admit them, it will be only in certain longitudes, and not as a general explanation of the tropical part of the planetary circulation.

It is clear now that the great success of the perturbation school has been in the realm of descriptive synoptic meteorology; the models of the perturbations which they have promulgated have been applied in the field with far greater success than was ever achieved by the air-mass school. In dynamical meteorology and in their treatment of the general circulation, members of this school have been less successful. There have been complaints, moreover, that the model of the easterly wave published by Riehl is far too rigid. In particular, the slope of the actual systems is frequently different from what might be expected from the published accounts and, what is more important, the weather distribution about the wave axes departs widely from the model [26].

But these, as we shall see, are not serious objections; they can be removed by a more careful study of the perturbations in low latitudes and by avoiding the tendency to apply models to synoptic maps as if they were rubber stamps. I ought perhaps to point out that my sympathies lie with the perturbation school and that if the criticisms here seem to be harsh, it is because I believe that future advances in tropical meteorology will come through the application of the concepts and methods of this school, provided they are freed from fallacious generalizations.

THE PRESENT AND THE FUTURE

General Observations. Each of the methods of approach to the tropical problems which were described in the preceding sections has something to recommend it; each has contributed something to our empirical knowledge and our understanding. As far as we can see at present, progress will come by pursuing to further lengths, with new and more detailed data, the lines of investigation that have already proved profitable. It is unlikely, that is, that we shall entertain any radically new theory of tropical meteorology in the near future. As a guide to the assessment of the present state and possible future development of the science we ought therefore to extract from the confusion of present conflicts those concepts upon which the majority of tropical meteorologists would agree. Before we do this we ought, however, to make a few general observations on method, deriving our principles from the study, not only of the achievements of the three schools, but of the errors they have committed.

1. Before attempting causal analyses of tropical phenomena, or dynamic explanations, we ought to be sure that our empirical descriptions are correct. This principle was violated by the climatological school in describing the doldrums, particularly the doldrums in the Pacific; by the air-mass school in describing fronts, since they neglected to describe accurately the temperature and wind changes observed at the supposed discontinuities; and by the perturbation school in omitting all mention of the convergence lines of the frontal school in their description of the model of the easterly wave.

2. The fallacy of generalization from a given longitude should be avoided as far as possible. We ought always to be on guard against it, particularly when dealing with the mean circulation in the tropics. But faulty generalization also enters in other contexts, especially when we have theoretical preconceptions. Thus the frontal school, as soon as it found evidence of empirical "fronts" in the neighborhood of the equatorial low-pressure trough, assumed that the occlusion process would also occur. No evidence was, so far as I know, ever produced to back this up. We ought then to remember at all times that, owing to the fact that we never have as much data as we really need, the habit of hasty generalization is an occupational disease of meteorologists. All the geophysical sciences suffer from this handicap; we ought to be at least as careful as the pure physicists, and probably more careful.

3. We ought to guard against the statistical fallacy in meteorology. This consists in assuming that a mean motion of the atmosphere, arrived at by the standard methods of climatology, represents a physically possible steady-state motion.

Achievements and Future of the Climatological School. There is no doubt that the departures from the mean values of the meteorological elements that are attributable to the diurnal cycle of radiation and to orographical effects can be of great magnitude in the tropics. It is the virtue of the climatological school that they have always emphasized these variations. However, in recent years little research work that might lead to a better understanding of the phenomena has been carried out. It is encouraging to notice that Leopold [41] has entered this field with papers on the so-called sea-breeze fronts in the Hawaiian Islands. Wartime synoptic experience everywhere in the tropics has confirmed the existence of organized lines of cumulus or cumulonimbus, accompanied by wind shifts, which simulate the cold fronts of high latitudes but which are demonstrably due to diurnal and orographical causes. The dynamical problems raised by these "fronts" are among the most interesting problems of tropical meteorology. Their properties, however, can be investigated only on location; it is to be hoped that young meteorologists resident in tropical areas of high relief will, in the future, undertake the investigation. Apart from the theoretical interest of such "fronts,"

the greater precision that would be given to local forecasting in the tropics by a complete understanding and description of the diurnal variation of orographical organized cumulonimbus well merits military and commercial support of such investigations.

It is difficult to deny that, as far as the most general features of the monsoons are concerned, the climatological school seemed to have analyzed the mean data and to have correctly assigned astronomical and orographical causes to the variations. But it is probable that the monsoons are far more complex in their details than that school supposed. There are several reasons for this conjecture. First, the so-called monsoon lows over the land, whatever may be their properties in the mean, on synoptic maps show day-to-day variations which could be attributed to the westward movement of individual cyclonic circulations through the area. Moreover, where the conformations of the continents are favorable, it can be observed that these minor cyclones come in from the sea, fully formed. They cannot under any circumstances be regarded as "heat lows." These local circulations are known in India, in Australia, in Indo-China and China, and in East Africa. Second, and this is probably correlated with the facts first mentioned, the wartime synoptic observations confirmed what was after all known locally for many years: that the weather in the Asiatic monsoons is far more variable than popular and textbook accounts would lead one to suppose. It does not rain continuously for three or four months in the wet season. There are frequent spells, lasting sometimes for days, during which there is little precipitation and sometimes little cloudiness. Third, there are, on certain longitudes, quasi-permanent low-pressure areas which migrate to and away from the equator, lagging behind the sun in the same manner as the monsoon lows, and having, on their equatorward borders, belts of winds with a westerly component; they are situated, however, not over the land but over the ocean. There is a very persistent mean low of this type which migrates from eastern New Guinea to the eastern borders of the Philippines and back. There is another west of Mexico and Central America. If these lows had been situated over a land mass, we would have no hesitation in calling them monsoon lows, and in accounting for their movements and the distribution of the meteorological elements about them in the usual manner of the climatological school. We ought, perhaps, to follow up these climatological hints and, combining them with an intense synoptic and dynamic research into subequatorial semipermanent lows in general, improve our understanding and prediction of monsoon weather. Largely because of historical accidents, research has been concentrated in the trade-wind zones of the Pacific and Atlantic. The time is now ripe for a more intensive investigation of those parts of the tropics that show large seasonal variations in the meteorological elements.

We should, however, not neglect the oceanic regions. Particularly we should not completely reject the classical climatological explanation of the trades, as Rossby has done. It is possible that that explanation is still valid for the longitudes where the trade is really a trade, *i.e.*, where it shows, in the lower level, great persistence, a large meridional wind component, a comparatively strong meridional temperature gradient and, aloft, the typical antitrade, evidence of persistent and marked subsidence, with a low and strong trade-wind inversion. These conditions obtain, as has been pointed out, in the eastern and southeastern branches of the great quasi-permanent anticyclones. Downstream, toward the west, however, factors other than those invoked by the climatological school may dominate the motion. Here, Rossby's new explanations may hold.

Above all, our survey shows, the greatest need is for more complete data, especially from the upper air. At present the distribution of observing stations in all latitudes is largely determined not on scientific, but on economic and military grounds. This, it is to be presumed, will not be changed in the foreseeable future. Nevertheless, it seems to be accepted that improvement in practical forecasting for periods longer than forty-eight hours depends on improvement in our empirical and theoretical knowledge of the mean circulation of the earth's atmosphere. How this knowledge can be built upon an observing network that is half-way adequate only in North America and in Europe is something that, to my knowledge, has never been explained. In particular, if scientific meteorologists are content to advance models of the general circulation based upon the North American atmospheric section and theoretical explanations of this model based upon an obsession with the circular vortex, ignoring the tremendous gaps in our knowledge of the meteorology of the tropics (over half the troposphere), of the high latitudes in the Southern Hemisphere, of Asia, even of Central America—then they cannot blame those that hold the purse strings for supposing that all is well with the present setup. The fact that acquaintance with new data is enough to cause a complete *volte-face* in the theoretical work of an outstanding leader in dynamic meteorology, at least so far as the tropics is concerned, should show that the filling of the gaps mentioned above is an absolutely necessary (although not sufficient) condition of the solution of the long-range forecasting problem.

Achievements and Future of the Air-Mass School. The achievements of the air-mass school were two in number. First, they drew attention to the great horizontal homogeneity of the easterly and the westerly air streams found in tropical latitudes, described the sources and modifications of these masses, and accounted for them with varying degrees of plausibility. The work on the trades still goes on, at all events. There has recently been a study of the east wind in the Caribbean by Haurwitz and his collaborators that is a model for all future work of this type [12]. Similar work in the far eastern equatorial Pacific, based on the Panama Canal Zone, would be very welcome, particularly in giving us precise knowledge of the structure of the west winds in that area during the summer. Later, the researches could profitably be extended to the Far East.

The second achievement of the air-mass school is that the earlier frontal workers discovered in the tropics, and

described, the organized lines of cumulonimbus cloud, accompanied by appropriate wind changes, which they identified as fronts. The existence of the lines has been confirmed, but it now appears that the frontal explanation must be rejected. The following empirical facts may be regarded as established:

1. If an adequate streamline analysis of the lower wind field in which the cumulonimbus line is embedded is carried out, using the isogon method of V. Bjerknes and his collaborators [9], the line of cumulonimbus coincides in position with an asymptote of convergence *in the streamline field*. But not all asymptotes in the field are accompanied by a "front"; there is an organized cloud system only if, at the same time, the total horizontal velocity divergence is negative in the neighborhood of the line. Aloft, say at 20,000 ft, the cloud line may correspond to an asymptote of positive divergence in the horizontal wind field. We shall henceforth call organized lines of cumulonimbus (or tall cumulus, on occasion) *convergence lines*, not fronts. We ought to point out that regions in which there is negative horizontal velocity divergence in the lowest layers are not always the seat of lines of convergence; these occur only if there is also convergence in the streamline along an asymptote. Figures 1 and 2 illustrate some of the properties of convergence lines in the Marshall Islands.

2. Lines of convergence form readily as a result of diurnal and orographic disturbances of the wind field in the neighborhood of large mountainous islands. We may then get temperature contrasts across the line, but these contrasts are confined to the lowest layers of the atmosphere. Aloft there is usually horizontal homogeneity. Orographic lines are rarely more than 200 miles long.

3. Except on such mountainous islands, the lines rarely show temperature contrast in the lowest layers but may do so in the upper air, as a reflection of different lapse rates in the air on either side of the line. The contrast may intensify, vanish, or reverse its sign both in space and in time but without, as far as can be discovered, affecting the location, movement, or intensity of the cloud line.

4. By far the greatest number of the lines in the equatorial Pacific, and in the Caribbean in summer, show no temperature contrast whatever below 20,000 ft. Above this level, temperature gradients across the line may have either sign or be absent.

5. In low latitudes, the vertical component of the vorticity along the line may be positive, negative, or zero. Cyclonic vorticity is not a necessary condition for the existence of the line.

6. The convergence line may or may not be accompanied by a trough in the pressure field.

7. Convergence lines may develop within an air mass which is, within the limits of observational error, completely homogeneous.

8. Convergence lines do not move with the wind, nor are pressure changes useful in forecasting the movement.

We conclude: Density contrasts and cyclonic shear are conditions which are neither necessary nor sufficient for the formation of convergence lines and hence these lines are not fronts in the sense that that concept is employed in the frontal and air-mass theory. The

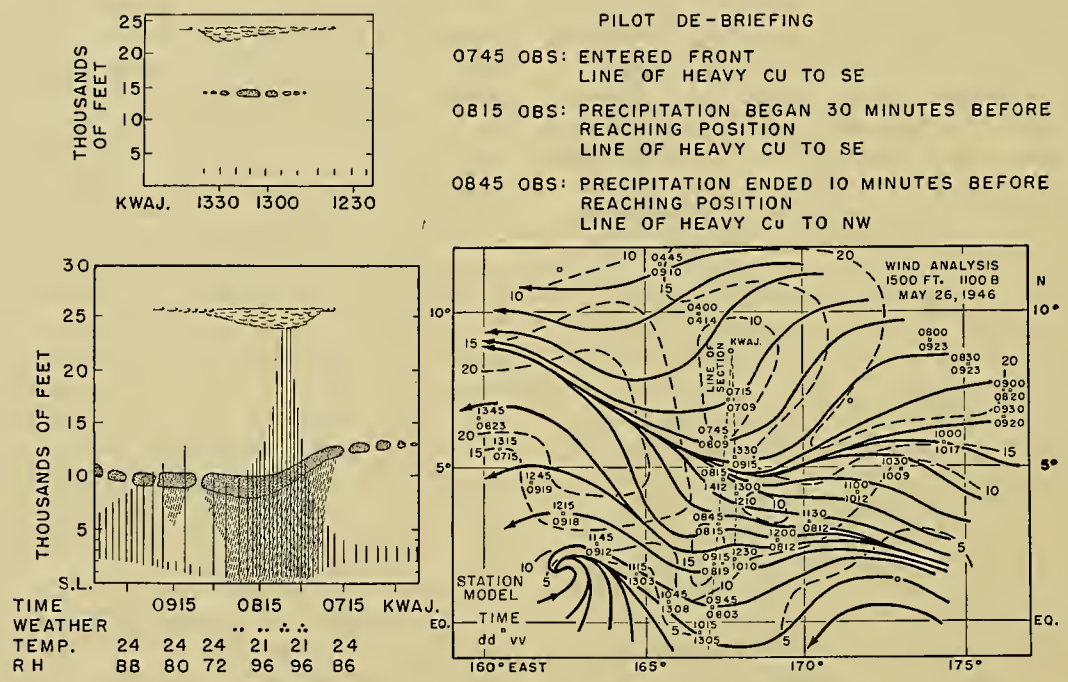

Fig. 1.—Streamline and isovel analysis at 1500 ft of an equatorial wave passing the Marshall Islands, 1100 Bikini Time, May 26, 1946, with two cloud sections observed by weather reconnaissance aircraft. Speed in knots. (Reprinted from the 7th quarterly report of the Tropical Pacific Project, U.C.L.A., a research supported by funds provided by the Geophysical Research Directorate, Air Materiel Command.)

only empirical conditions so far discovered which are necessary and sufficient are the existence of horizontal velocity convergence in the lowest layers of the atmosphere *plus* the existence of an asymptotic line in the streamline field. This statement, of course, in no sense gives a causal explanation of the lines; it merely gives descriptive correlations.

With these conclusions, we must dismiss the whole body of theoretical explanation developed by the air-mass school in the tropics, but at the same time we must incorporate their empirical findings with those of the perturbation school; this we shall attempt in the next section.

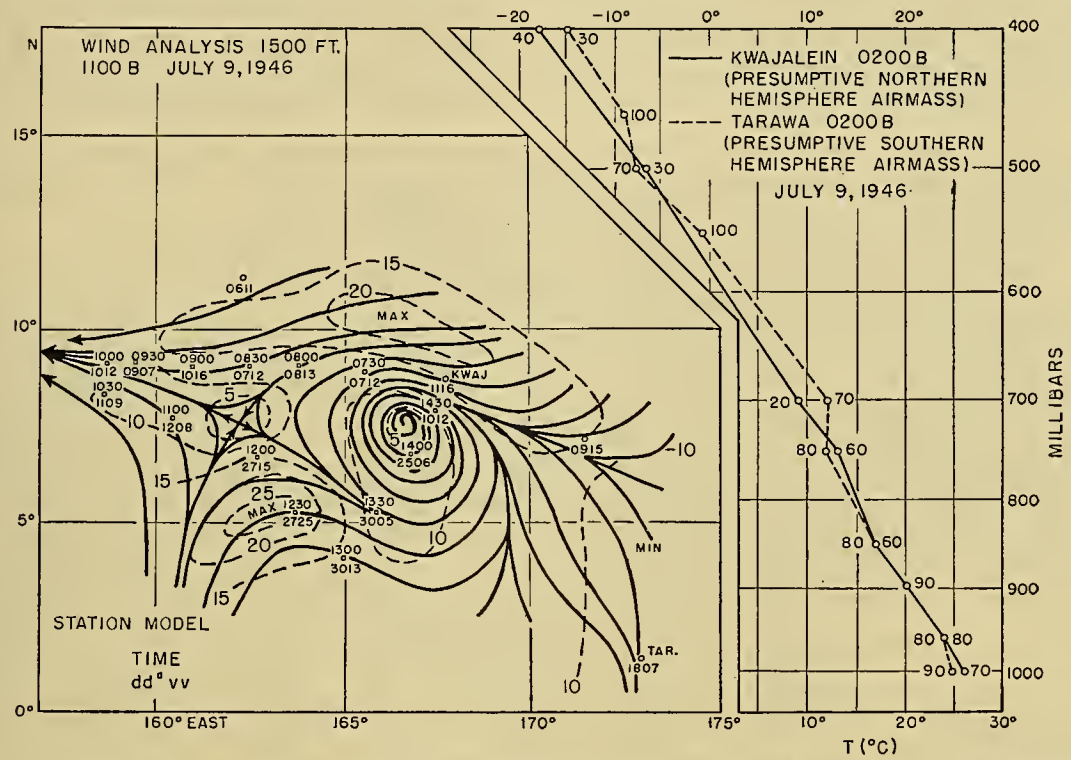

Fig. 2.—Streamline and isovel analysis at 1500 ft of an equatorial vortex passing the Marshall Islands, 1100 Bikini Time July 9, 1946, with soundings from Tarawa and Kwajalein. Speed in knots. (Reprinted from the 7th quarterly report of the Tropical Pacific Project, U.C.L.A., a research supported by funds provided by the Geophysical Research Directorate, Air Materiel Command.)

Achievements and Future of the Perturbation School. The outstanding achievement of this school is undoubtedly the discovery and description of the easterly wave and its relation to Caribbean hurricanes. Its fault lies in an almost complete neglect of the empirical findings of the air-mass school. This is to be attributed to the fact that members of the school have consistently used a streamline technique that is inadequate for the study of detailed features of the wind field. As a result, the school has placed great emphasis on the "trough" in the wind field and has marked it with a heavy line on the map, but at the same time has completely missed the asymptotes of the field which, indeed, are accurately located only by using the standard methods described by V. Bjerknes. This weakness in the synoptic methods of the school has recently been emphasized by Riehl's investigation [54] of the structure of the equatorial trough in the western Pacific. He comes to the conclusion, a correct one in my opinion, that the western part of the equatorial trough is the seat of a large number of eddies which for the most part move from east to west, either recurving ultimately as hurricanes and tropical storms or passing on to the continent of Asia. But his method of analysis is incapable of showing the relation of the "fronts" that develop *pari passu* with the vortices to the early stages of their development. From Figs. 16 and 17 in his paper, for example, and from the text, it is clear that Riehl envisages the lines of convergence as existing before the formation of the vortices. Further, the equatorial westerlies are conceived as being part of the general circulation, so that convergence lines between them and the trades, though not continuous throughout the equatorial low-pressure trough, may nevertheless exist independently of the vortex series. The result is a very complex picture of the normal state of equatorial circulation in the wet season.

When the standard methods of streamline analysis are applied to maps from this area, however, a much simpler picture is seen. Upstream, in the central Pacific, the trade winds of the two hemispheres lie side by side for the most part, forming an extensive easterly current that overlaps the equatorial low-pressure trough in both the Southern and the Northern Hemispheres. This easterly current is subject to perturbations of the same type as the easterly waves of the Caribbean save that they are at much lower latitudes and extend *across* the low-pressure trough. No lines of convergence are

found in or near the trough so long as the waves are of small amplitude. There is, of course, horizontal velocity convergence in the lower layers, associated with the wave motion, but it may be said to be "unorganized." As the waves move toward the west, some of them at least become unstable, growing in amplitude. The wave in the pressure field can now be detected with good observations, and an asymptote of convergence usually appears behind the "trough" of a wave and a corresponding asymptote of divergence ahead of it. The asymptote of convergence may be detected in flight as a line of cumulonimbus or tall cumulus. With further increase in amplitude of the wave a small vortex appears in the wave pattern, usually, but not always, in the equatorial trough itself. With the formation of this vortex, westerly winds near the equator *appear for the first time.* The vortex proceeds on its westward track; it may deepen very rapidly, forming a typhoon or storm, or it may remain weak, being accompanied in this case by one of the slight depressions that are characteristic of the doldrums in the western Pacific. When the vortex is well developed a complicated system of asymptotes accompanies it and the movement of these "equatorial fronts" is dependent not on the winds on either side of them but on the motion of the vortex itself. This brief summary of the equatorial waves and vortices is based upon recent study of the data collected during the Bikini and Eniwetok bomb tests and the whole subject has been more fully treated in recent publications [47, 48].

We are now in a position to reconcile the conflicting views that have been held concerning oceanic equatorial meteorology. We see first that the equatorial westerlies, as long ago realized by Piddington and Reid, are merely the mean expression of the fact that the vortices form in the central parts of the Pacific and move toward the west; there the passage of so many of them north and south of the equator and in both the wet and the dry season results in a mean west wind on the equator *in the western part of the ocean.* Since this west wind is the statistical result of the vortices it is clearly fallacious to import them into a hypothetical general circulation which is then perturbed to produce the vortices. Our task is to explain the mean maps as the integration of numerous synoptic maps, not to explain the synoptic map in terms of the mean and its perturbations. In other words synoptic models must always be checked by what is known of the mean circulation, but we cannot, except under very special circumstances, infer the synoptic models from the mean map. Figures 3 and 4 show schematically the correct explanation for the tropical Pacific. Neglect of this principle led to the conception of the continuous equatorial front; because it can easily be detected on the mean maps, it was assumed that it would be found on the synoptic maps. Recent research has shown that the synoptic convergence lines are quite different from the mean convergence line; the latter, however, can be derived as the statistical result of the properties and positions of the former.

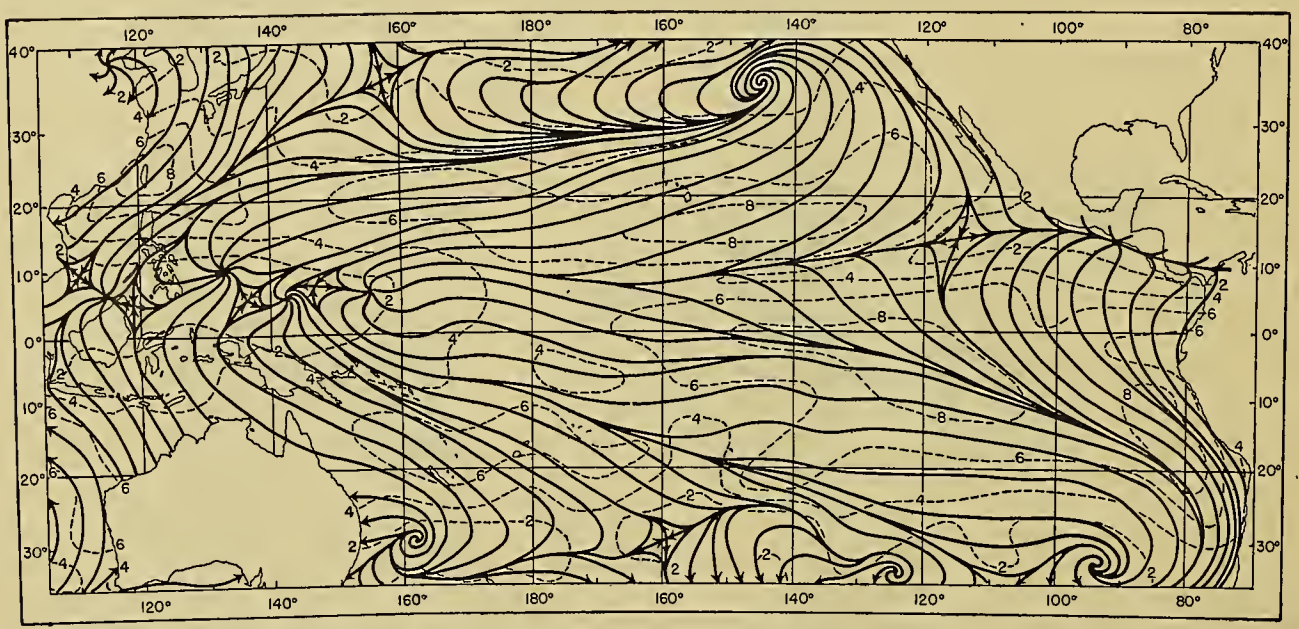

Fig. 3.—Streamline and isovel analysis of the mean resultant surface winds, tropical Pacific Ocean, Northern Hemisphere autumn. Speed in meters per second. Data derived from Deppermann and Werenskiold, and analyzed by G. A. Dean.

The special conditions under which we can pass from the mean map to the synoptic map obviously hold in the eastern parts of the oceans. Here we know that departures from the mean are very small compared with the mean. And it seems that in these regions the thermal effects long ago described by the climatological school must play at least the dominant part in driving the southeast and northeast trades. Here the direct-cell model is probably a good approximation to what actually occurs in the atmosphere. The result of the action of the direct cell, however, is not a mass ascent of the trades at the equator, and their return aloft as anti-

trades. A large part of the trade air, both at the ground and aloft, passes westward as a solid east current, quite analogous to a jet of fluid being directed into another fluid at rest. Like that jet, the east stream spreads downstream into its surroundings. It is also unstable, so that the slightest disturbance of the stream leads to waves which grow in amplitude and ultimately form a series of vortices which either move out of the stream into higher latitudes or end stagnating in the "monsoon low" over the land in the extreme west. Downstream the air is thoroughly mixed, there are only small temperature gradients, and it is here, if anywhere, that the dynamic mechanisms suggested by Rossby in his latest paper will be valid (see Fig. 4).

We have not, it will be noticed, done more than suggest a working hypothesis to apply to the large-scale features of the motion in a single ocean. It is premature to advance beyond this point while we have so little data over the land. But a great step forward would be taken if we could explain the main features of the circulation over one ocean. The gap in the data is clearly in the eastern oceanic sectors. The only extended series of observations in such a sector are those of the *Meteor* in the Atlantic [18]. We require similar data for the eastern sectors of the North and South Pacific and the South Indian Oceans, and clearly the first region to investigate should be the eastern sectors of the tropical Pacific, about which little is known. A full program of upper-air soundings in this region would enable us to decide whether the direct-cell model of the trades is to be taken seriously, for, with comparative isolation by the high mountain barriers to the east, it is here that we would expect the most favorable conditions for a direct thermal circulation to develop.

There remain other projects which we have suggested in the previous discussion of the perturbation school. The elucidation of the dynamics of easterly waves in very low latitudes is badly needed—an elucidation that, by including vertical motions as well as horizontal, would cover the main features of both the equatorial and the Freeman wave, since the latter is clearly only a limiting case of the former. It is probably too early to ask for a dynamic explanation of the kinematic features we now know attend the transformation of an equatorial wave into a vortex, since these will clearly involve perturbations of large and changing amplitude, with the consequent difficulty of solving nonlinear equations. But we may fairly ask the dynamic meteorologists for a treatment of the relation between the energy of the equatorial perturbations and that of the east current, particularly as the synoptic evidence suggests that kinetic energy is transferred from the east current to the perturbations as the latter move downstream. The approach of Kuo [40] here seems the most promising.

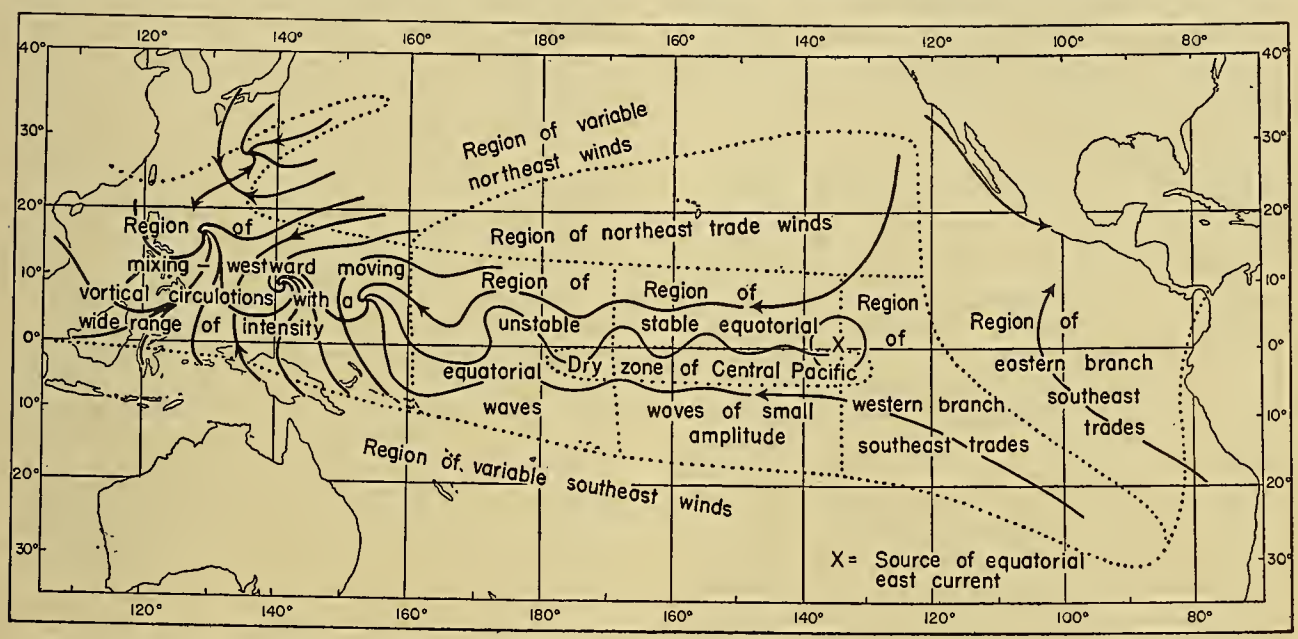

FIG. 4.—Schematic explanation of the mean circulation of Fig. 3 in terms of a "general circulation" (trades and equatorial easterliès) and its perturbations, stable and unstable.

The problem of tropical-cyclone formation is at present so different in aspect from what it was ten years ago that one is encouraged to think that the rate of progress will be maintained and will result in a complete solution in the near future. It now appears that the problem is that of deciding the sufficient and necessary conditions for the rapid deepening of a vortex already formed from an easterly wave, whether this be in high tropical latitudes, as in the Caribbean, or in low latitudes, as in the eastern Atlantic and the Pacific. We know that this deepening never occurs over the land, in spite of a plentiful supply of vortices; clearly a very moist atmosphere is necessary for the process to occur. But, though we have cause for optimism concerning the future of hurricane research, the problems connected with forecasting the movement, especially the recurvature, of tropical storms, remain as they were

twenty years ago, in spite of much work [44, 55, 66]. All forecasting methods so far suggested suffer from the defect that exceptions to the deduced rules occur too frequently in practice. Some methods suffer from the defect that they merely shift the forecasting problem from one field to another and often more difficult field. Thus all methods based upon isotherm steering suffer from the fact that it is frequently more difficult to forecast the isothermal field at upper levels than to forecast the track of the storm itself.

Above all we need an extensive investigation of the necessary and sufficient conditions for the formation of rain in the tropics. In spite of published accounts of the precipitation of cumulus clouds whose tops are well below the zero isotherm, and in spite of the use of this fact by all forecasters operating in oceanic tropical regions, one is constantly surprised by the scepticism concerning it among high-latitude meteorologists. The first worker to publish a complete atlas of precipitating tropical clouds will be performing a great service to meteorology, for though he may solve no problems he will at least draw the attention of the scientific world to the fact that the Bergeron-Findeisen theory of precipitation gives a very incomplete account of the causes of colloidal instability in clouds. In that atlas, I hope, will appear good pictures of the *complete* precipitation of a cumulus, *i.e.*, precipitation not only from the bottom but also from the sides and overhanging top of the cumulus—the almost explosive upsetting of the colloidal stability throughout the cloud mass. Deppermann has already published photographs of such clouds, which he calls "melting" cumulus—a very descriptive term [22]—but apparently he did not realize the great theoretical importance of the phenomenon he was depicting. The problem of precipitation has its synoptic aspects also. The present observations, as transmitted in the international code, give us very little clue to the type of rain that is falling, whether it be from an upper sheet of altostratus, unconnected with cumulonimbus, from altostratus connected with very distant cumulonimbus pillars, from cumulonimbus, from cumulus of great vertical extent, or from comparatively shallow cumulus. The result often enough is that the forecaster cannot tell whether the rain is connected with an extensive region of convergence in the lower atmosphere or whether it is to be attributed to the colloidal instability of cumulus clouds in a region which is in total divergent and subsiding.

Connected with this problem is that of the lapse rates of temperature and humidity within tropical clouds. It has been claimed that, level for level, tropical clouds are colder than their environment. A recent paper by Barrett and Riehl [4] has, however, pointed out the possible origin of such claims and has rightly emphasized the observational difficulties. More work, however, needs to be done. On the theoretical side, the recent work on entrainment [68] of air in tropical clouds seems to be capable of leading to the solution of an old problem of tropical forecasters—the problem of what to do with the radiosonde observations. Many soundings in the tropics seem to be completely uninformative. The lapse rate approaches very closely to the moist-adiabatic over a deep layer, and this can be clearly correlated with existing weather. However, without noticeable change in the weather one may next receive a sounding that differs from the first in the lapse rate both of temperature and of humidity, without apparent reason. It might be suggested that these vagaries are connected with the passage of the apparatus through different parts of cumulus and cumulonimbus clouds and that the soundings reflect the microstructure of the tropical air, not the broad-scale features we wish to study synoptically. Theoretical knowledge of the factors affecting the lapse rates in clouds derived from entrainment studies, together with information on the path of the sonde with respect to existing cloud masses, might do much to remove the perplexity that the present soundings sometimes cause.

Conclusion. One would like to conclude as a result of this survey that tropical meteorology, the most ancient branch of scientific meteorology, has shown more progress in the last ten years than in the previous fifty. However that may be, it is certain that it now offers a rich field for research to the climatologist, synoptician, and dynamic meteorologist alike. To the climatologist it offers the challenging task of collecting, reducing, and studying the unique wartime tropical data before they become lost forever; to the synoptician it offers the prospect of new empirical discoveries in a field from which the major errors have just been cleared away—discoveries, moreover, that cannot fail to react on the theory of fronts and air masses in high latitudes; to the dynamic meteorologists it presents a series of problems in perturbation theory, applicable to an atmospheric region which, more closely than any other on this earth, resembles his ideal: the homogeneous, horizontally moving, frictionless, and incompressible fluid.

EQUATORIAL METEOROLOGY

By A. GRIMES[1]

Farnborough, Hants, England

INTRODUCTION

Equatorial meteorology may be regarded as the meteorology of the region about the equator where the Coriolis term in the equations of motion is no longer the only one which is of the same order of magnitude as the pressure term. Indeed, on the equator itself the Coriolis force is zero and the other terms must balance the pressure gradients which undoubtedly exist. One cannot quote any investigation which will indicate the limits of the region thus defined, but the general impression given by most writers is that the Coriolis force ceases to predominate between the latitudes of 15°N and 15°S, and it is to this region, roughly one-quarter of the surface of the earth, that the following discussion will be confined. The region, extending over the central portion of the Atlantic, Pacific, and Indian Oceans, is largely water broken by the land masses of central Africa, Central America and the northern part of South America, the East Indies, southern India, and Ceylon. Generally speaking, the land areas are sparsely populated and meteorological history is comparatively short, extending back only so far as the beginning of international civil aviation for most places in the region. This is not to say that no extended series of meteorological records exists in the region, but the number of stations with reliable records over a period greater than ten to twenty years is pitifully small for the large area that has to be considered. The situation is steadily improving, because of the pressing needs of international aviation, and the meteorological services in the more backward—meteorologically speaking—of the countries in the region are being more and more extended as time goes on. Nevertheless, the advancement lags considerably behind the development in the temperate zone. This is principally due to the high cost of meteorological equipment, such as the radiosonde, which puts modern methods of observation beyond the resources of the local governments. The number of scientific workers in the region is very small, and since even this small number exist almost entirely for the purpose of issuing forecasts to aircraft, it is not surprising that little meteorological information of any importance has emerged, and it is fairly certain that little will emerge until more equipment and more scientists become available to the region. The standard of observing, except at a few stations, is low in many cases because of the poorness of the equipment, and in many more cases because of the shortage of competent observers. Steps are being taken to improve the observations, but it must be many years before adequate and accurate climatological statistics will be available for most of the region.

1. Formerly Director, British West African Meteorological Services.

The greatest impetus to the study of meteorology was given during World War II when the need for developing lines of communication through the region brought an influx of men and equipment far greater than in prewar days. During this period it was realised that our knowledge of the area was meagre, and a large number of reports, both statistical and otherwise, were published to remedy this defect. Not all the reports were of great value but at least attempts were made to explain the phenomena of the equatorial zone on a scientific basis: if little in the way of coherent meteorological theory emerged, there were at least some ideas suggested that might serve as a starting point for further investigation.

THE AIR MASSES

Except for the occasional intrusion of polar air into the South China Sea area, it seems certain that the only air masses affecting the region are tropical and equatorial. The tropical air masses are those of the trade winds giving on an average a belt of northeast winds in the Northern Hemisphere and of southeast winds in the Southern Hemisphere, both derived from the subtropical anticyclones. During the summer of the Northern Hemisphere the trade wind of the Southern Hemisphere crosses the equator everywhere, so far as can be determined, and becomes what is usually known as the monsoon. In the Northern Hemisphere winter the reverse process takes place everywhere except in the Atlantic and West African areas, and it is these annual movements of air which provide the variations in the weather of the equatorial zone. When the tropical air from either hemisphere has passed into the equatorial zone and becomes relatively stagnant it is known as equatorial air and is therefore not an "air mass" as one usually thinks of the term. Such stagnant air, which frequently develops a light anticyclonic circulation over land masses, is invariably moist (or becomes moist) in the lower layers. This air is a common feature of the synoptic situation and is therefore of great importance.

The properties of tropical air are quite well known up to 4 or 5 km, but observations are too few above 5 km for reliable conclusions to be drawn. It seems that above this level the winds are mainly easterly. Some investigators consider that these winds play a large part in the variation of weather along the equator, but what part they play has not yet been demonstrated with any assurance. It is not in fact clear from the study of daily charts where the trade winds end and the overriding easterlies begin, because in most cases the maximum speed of the trade is reached between 500 and 1500 m above the surface, and there is only a gradual variation of speed in the higher levels. When the tropical air has a continental source it is usual to

regard the top of the haze layer (2–3 km) as the upper surface. This condition is confirmed by the sudden rise in humidity above this level, but when the tropical air has an oceanic source the surface of separation is ill-defined. Upper-air observations with instruments more accurate than ordinary aircraft thermometers might make it possible to define the separation of upper and lower layers with more precision.

When the surface air is equatorial, there is frequently a layer of trade or monsoon air before the overrunning easterlies are reached. The lower boundary of the trade or monsoon air is well marked by a rapid increase in wind speed with height, but the separation of trade or monsoon air and the easterlies is still ill-defined. It is quite clear that the day-to-day determination of the vertical structure of the air masses will not be possible until observations are available in greater quantity and with more precision.

FRONTAL PHENOMENA

The question of the existence or nonexistence of true frontal discontinuities in the equatorial region is one of the most controversial issues of tropical meteorology. The majority of opinion, however, favours the existence of fronts, but the very fact that many writers disagree makes it important that factual evidence should be produced. The acquisition of convincing evidence is hampered by the lack of close networks of upper-air stations, and the main arguments put forward for the existence of fronts depend on the recognition of wind discontinuities and the acceptance of such discontinuities in wind as evidence of discontinuities in the air masses. Three distinct types of discontinuity are normally recognised: the intertropical front, the meridional front, and subsidiary fronts.

The intertropical front is regarded as being formed in the intertropical convergence zone, the zone completely surrounding the earth in which the trade winds from the two hemispheres meet. In earlier days the zone was simply known as the doldrums and all the bad weather associated with the zone was regarded as due to the instability of the moist stagnant air which gave rise to convectional rain and thunderstorms. It is now more common to regard the zone as being one in which true frontal discontinuities between the northern and southern trades exist, interspersed with semi-stagnant equatorial air masses or doldrum areas. The boundary between the equatorial air masses and the trades will usually orient itself parallel to the direction of the active trade wind but with an increase or "surge" of the trade wind the relatively cold air will tend to undercut the equatorial air and give rise to frontal phenomena which are well marked and easy to identify. The front between the trades, which is known as the intertropical front, forms most frequently at the times when the trade from the winter hemisphere is beginning its penetration into the summer hemisphere and when it is receding (*i.e.*, just after the equinoxes). The advance of the trade across the equator is not a steady continuous process but is made up of surges and temporary retreats, each surge being accompanied by typical cold-frontal type phenomena; when the advancing trade dies down temporarily, the frontal effect disappears to give place to a region of equatorial air, or the trade of the summer hemisphere temporarily reasserts itself. The retreat is a little more regular, until the intertropical convergence zone has recrossed the equator, and is often accompanied by warm-front phenomena due to the flow of the freshening trade of the autumn hemisphere over the retreating trade, but more usually the activity of both trades at this period is small, and large areas of stagnant equatorial air appear on the synoptic chart.

The meridional front is the front that forms between tropical air masses from two distinct anticyclonic cells in the same hemisphere. In the Southern Hemisphere, this takes place usually between a weak ESE/E stream from the more easterly of the two anticyclonic cells and a stronger SE/SSE stream from the more westerly cell. Because of the persistence of such cells during the winters of the respective hemispheres, these fronts are of a semipermanent character and are readily identifiable. In the summer of the hemisphere being considered, the portions of the cells are more variable with a consequent greater variation in the position of the meridional front. Where the air from the other hemisphere crosses the equator the meridional front crosses from the winter to the summer hemisphere, giving rise at its junction with the intertropical convergence zone to a "triple point." There is some evidence for the belief that this "triple point" is associated with the formation of tropical cyclones.

Subsidiary fronts are of a more local character than the ones already described and are caused by local variations within an otherwise homogeneous air mass. The cause of the local variations may be orographic diversion of one portion of the air stream or the diversion of a portion of the air stream because of the breakdown of geostrophic control as it enters the equatorial region. The diverted portion subsequently meets the undiverted portion again and gives rise to a local zone of convergence, which may be very limited in extent and may fluctuate rapidly in position. The movements of these zones are very difficult to follow since the cause of the movements is not necessarily related to the winds in the neighbourhood of the zone but is related to the previous history of the air mass in which the zone has formed. The slopes of the fronts have been determined in many cases, the criterion almost invariably being the height at which the wind change occurs at various points. Most of the values lie between 1 in 300 and 1 in 500. There is no theoretical value for the slope with which comparison can be made because of the breakdown of the geostrophic equations in the area and the absence of suitable equations to replace them. It has also not been determined satisfactorily to what height the discontinuities extend, the main difficulty here being the similarity between the upper layers of the trade winds and the lower layers of the overrunning easterlies. Where a front is formed from undercutting

by a surge of the trade wind, however, the tongue of fresh air very often does not exceed 1500 m in thickness so that the frontal surface has a well-marked slope at the leading edge up to 1500 m but trails off horizontally behind. It is beyond the scope of this article to go into fuller detail in this matter of fronts; a complete account has been given by Forder [3].

THE EQUATIONS OF MOTION

The equatorial region was defined earlier as the region in which the Coriolis term in the equations of motion was no longer predominant in balancing the pressure term, so that although many of the problems of the equatorial zone are the same as those of the tropics generally, the particular problem of finding dynamical equations applicable to the movements of air within the region is peculiar to the region.

When one examines synoptic charts of the region, particularly during the northern summer, one is struck immediately by the remarkable uniformity in the speed and direction of the winds a little south of the equator and the great diversity of the winds, arising from the same air stream, after crossing the equator. Between 5°S and 10°S in the Indian Ocean–Pacific area, for example, the winds are consistently from southeast to east, whereas north of the equator the winds may be from any direction from west through south to east. At the same time, the winds to the south are not very far from being geostrophic, whereas north of the equator the winds are far from being geostrophic in most cases.

Grimes [6] showed that it was possible to obtain integrable equations of motion allowing for the variation of the Coriolis force with latitude, provided the conditions were very much simplified. The simplifications involved the assumption of steady horizontal motion with no friction and no variation in the motion with changing longitude. The further assumption that $\sin\phi = \phi$ (ϕ = latitude) was also made. Starting with an assumed value for the wind speed and direction at latitude 5°S and using Bjerknes' circulation theorem, Grimes was able to compute the paths of the air across the equator and, from the same initial wind, to arrive at a variety of paths by simply changing the value of the assumed circulation of the air at latitude 5°S. It was also possible to compute the isobaric configuration that was necessary to maintain the motion, but the computed gradients of pressure were much smaller than the ones found in practice. The equations showed, too, that if an isobar crossed the equator, it must do so at right angles, but this was a consequence of the assumption of no variation with longitude and Crossley [1] pointed out that when this restriction was removed the necessity of an isobar's crossing the equator at right angles disappeared. Crossley [2] has recently modified Grimes's treatment to obtain an exact solution using spherical polar coordinates instead of Cartesian coordinates. On the assumption that the motion is steady and frictionless and that there is no change of velocity with longitude, the solution of the equations of motion becomes

$$u = -2\Omega a\cos\phi + B\phi + C, \tag{1}$$

$$v = A\sec\phi, \tag{2}$$

where ϕ is the latitude, λ is the longitude, a is the radius of earth, and A, B, and C are arbitrary constants. The streamlines are given by

$$A\lambda + 2\Omega a\sin\phi - \tfrac{1}{2}B\phi^2 - C\phi = \text{const}, \tag{3}$$

and the pressure distribution by

$$-\frac{p}{\rho} = AB\lambda + \tfrac{1}{2}A\tan^2\phi + \Omega a[\Omega a\cos 2\phi + 2B(\sin\phi - \phi\cos\phi) - 2C\cos\phi] + \text{const}. \tag{4}$$

The arbitrary constant A can be interpreted as the northward component of velocity at the equator.

If we set $B = 0$ so that the pressure distribution is independent of longitude, we arrive at Grimes's solution in spherical polar form:

$$u = C - 2\Omega a\cos\phi, \tag{5}$$

$$v = A\sec\phi. \tag{6}$$

The constant C is related to the assumed initial velocity and vorticity.

Crossley goes on to say that if solutions of the Grimes type are found to exist, it follows that the gradient of pressure by itself is not sufficient to determine the horizontal motion of air in the tropics. In middle latitudes the assumption that the wind vanishes with the pressure gradient is in accord with experience, but this is not necessarily the case in the tropics. The theory indicates that once a motion across the isobars has come into existence on a large scale, this type of flow can continue in a similar fashion without any marked tendency to approximate the direction of the isobars unless higher latitudes are reached. It is clearly important, as Crossley says, to determine how much cross-isobar motion exists in the free air and whether there is, in fact, any wind in the absence of a pressure gradient.

Treloar [9] and Gibbs [5] have separately discussed the same problem, introducing the frictional effect but ignoring the space accelerations. Their treatment, however, cannot be regarded as altogether satisfactory.

Another method of approach to the problem may be suggested. The equations for frictionless horizontal motion may be written

$$\frac{du}{dt} - 2\Omega v\sin\phi = -\frac{1}{\rho}\frac{\partial p}{\partial x}, \qquad \frac{dv}{dt} + 2\Omega u\sin\phi = -\frac{1}{\rho}\frac{\partial p}{\partial y}, \tag{7}$$

where all the symbols have their usual significance.

These equations may be expanded and rewritten

$$\begin{aligned}\frac{\partial u}{\partial t}+\frac{\partial}{\partial x}\left(\frac{u^2+v^2}{2}\right)-v\left(\frac{\partial v}{\partial x}-\frac{\partial u}{\partial y}\right)-2\Omega v\sin\phi \\ =-\frac{1}{\rho}\frac{\partial p}{\partial x},\\ \frac{\partial v}{\partial t}+\frac{\partial}{\partial y}\left(\frac{u^2+v^2}{2}\right)+u\left(\frac{\partial v}{\partial x}-\frac{\partial u}{\partial y}\right)+2\Omega u\sin\phi \\ =-\frac{1}{\rho}\frac{\partial p}{\partial y}.\end{aligned} \tag{8}$$

Equating the vorticity $(\partial v/\partial x - \partial u/\partial y)$ to 2ω and writing $u^2 + v^2 = V^2$, we obtain

$$\begin{aligned}\frac{\partial u}{\partial t}-(2\omega+2\Omega\sin\phi)v&=-\frac{1}{\rho}\frac{\partial}{\partial x}(p+\tfrac{1}{2}\rho V^2),\\ \frac{\partial v}{\partial t}+(2\omega+2\Omega\sin\phi)u&=-\frac{1}{\rho}\frac{\partial}{\partial y}(p+\tfrac{1}{2}\rho V^2),\end{aligned} \tag{9}$$

if we may assume that the density ρ is sensibly constant —an assumption which appears legitimate in the equatorial region.

Following Rossby [7], we shall call 2ω the relative vorticity and $(2\omega + 2\Omega \sin \phi)$ the absolute vorticity of the motion. Rossby [7, p. 71] has shown that after pressure has been eliminated the equations of motion reduce to

$$\begin{aligned}\frac{d}{dt}(2\omega+2\Omega\sin\phi)\\ =-(2\omega+2\Omega\sin\phi)\left(\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}\right),\end{aligned} \tag{10}$$

so that with the equation of continuity $(\partial u/\partial x + \partial v/\partial y = 0)$ we obtain

$$\frac{d}{dt}(2\omega+2\Omega\sin\phi)=0. \tag{11}$$

Therefore, $2\omega + 2\Omega \sin \phi = k$, where k is a constant along a trajectory but may differ from one trajectory to another. Writing k for $(2\omega + 2\Omega \sin \phi)$ and P for $(p + \frac{1}{2}\rho V^2)$ in equations (9) (P is the dynamic pressure), we obtain

$$\begin{aligned}\frac{\partial u}{\partial t}-kv&=-\frac{1}{\rho}\frac{\partial P}{\partial x},\\ \frac{\partial v}{\partial t}+ku&=-\frac{1}{\rho}\frac{\partial P}{\partial y}.\end{aligned} \tag{12}$$

The equations for steady streaming $(\partial u/\partial t = \partial v/\partial t = 0)$ reduce to

$$\begin{aligned}-kv&=-\frac{1}{\rho}\frac{\partial P}{\partial x},\\ ku&=-\frac{1}{\rho}\frac{\partial P}{\partial y}.\end{aligned} \tag{13}$$

Equations (13) represent a pseudogeostrophic motion in which the streamlines are strictly parallel to the isobars of P and in which the space accelerations are allowed for, so that no further allowance need be made for the accelerations along the path or for the centripetal acceleration perpendicular to the path. Furthermore, the equations are independent of variations in latitude, and the variations imposed upon the motion by the change of latitude are controlled by the constancy of the absolute vorticity along the streamlines.

The constant k may vary from streamline to streamline but will be constant along any particular streamline; for practical purposes it may be regarded as constant between any pair of consecutive isobars (of P) regarded as streamlines.

If we draw isobars of P at intervals of whole millibars, we can determine the value of k with an ordinary geostrophic wind scale at any point where a value of V is known. If we write

$$k = 2\omega + 2\Omega \sin \phi = 2\Omega \sin \phi', \tag{14}$$

the value of ϕ' can be read from the scale as the value appropriate to the known value of V and the separation of the isobars at the points. Since k is constant along the whole length of the stream "tube" enclosed by the particular pair of isobars, the value of relative vorticity 2ω can be determined immediately from the equation,

$$2\omega = 2\Omega (\sin \phi' - \sin \phi). \tag{15}$$

It is thus possible to identify the areas of cyclonic and anticyclonic vorticity when the motion is one of steady streaming and where values of P can be determined.

Near the equator, where the geostrophic component of acceleration becomes small and the space accelerations become relatively more important, the advantage of explicitly eliminating changes in ϕ and in the space accelerations from the equations of motion is obvious. Practically, if time changes can be ignored, the advantage in using dynamic pressure is that the streamlines should be parallel to the isobars of P so that wind direction will indicate the direction of the isobars and vice versa, a facility so far denied to equatorial analysts.

The practical usefulness of this method depends on the feasibility (or possibility) of drawing the isobars of dynamic pressure P. Wind speeds are small in the equatorial region and so are pressure gradients, so that an accuracy in pressure reductions of at least a fifth of a millibar will be necessary if the method is to be tested. In British West Africa the altitudes of the stations above sea level are not known with an accuracy sufficient to guarantee this, and attempts to verify the deductions in this area have had to be abandoned until the altitudes of the stations have been redetermined.

It was stated earlier that the measured pressure gradients were much greater than previous theory demanded. This difficulty may now be overcome by assuming values of the relative vorticity near the equator greater than the ones Grimes assumed in his first calculations.

So far we have discussed only cases of steady streaming, but one of the most important features of equa-

torial weather is the undercutting of stagnant equatorial air by a surge of fresh tropical air, producing effects similar to those of a cold front in temperate latitudes. This situation has been treated in a most ingenious manner by Freeman [4], who draws an analogy between the undercutting of the equatorial air by a sudden surge of cold air and the supersonic gas flows resulting from the action of a piston. In his discussion Freeman assumes that the air is at rest under an inversion of constant height near the equator and that a cold-air mass, acting as a piston, moves into the area, undercutting the stagnant air. He then computes the characteristic or Mach lines for the resulting flow and shows that the theory admits of three types of disturbance oriented normal to the current, that is, a rarefaction wave, a compression wave, and a "jump." The compression wave, of course, arises from a surge of cold air, while the rarefaction wave may be caused by the falling off in the trade, although this latter case is relatively unimportant. Freeman considers that the "jump" may be the explanation of the "easterly wave" because, as he points out, when a "jump" moves into an atmosphere at rest, the energy required to maintain the "jump" is derived from the atmosphere at rest and no other source of energy is required to maintain the flow. The moving fluid will show rapid vertical motions at the "jump" which would lead to the typical weather phenomena associated with the easterly wave. The theory also provides a model for a sloping surface of discontinuity in these low latitudes which, so far, has been produced by no other theory. In the example which Freeman gives for a case in the New Guinea area, the agreement between the calculated and the observed values is most remarkable in view of the difficulties inherent in the problem.

One of the major problems that remain to be tackled is how to allow for the effect of the diurnal and semidiurnal variations of pressure which dominate the barograms of the equatorial region. The daily change in pressure is very much greater than the secular change and if one treats it loosely as the result of pressure waves that travel from east to west around the equator, the effect is to produce variable gradients of pressure which attain values of the same order of magnitude as the geostrophic and space-acceleration terms in the equations. The problem is a difficult one and not much progress appears to have been made up to now in solving it.

On the whole it is fair to say that although some progress has been made, we are still very far from a satisfactory solution to the dynamical problems of the equatorial region, but the problems are well worth attention and success in solving them might have a profound effect on meteorological theory as a whole.

FORECASTING

Since most of the meteorologists in the equatorial region owe their presence there to the necessity of providing weather forecasts, forecasts have to be made even when the methods of preparing the forecasts are only incompletely understood. Generally speaking, the forecaster labours under great difficulties, not only the economic ones of poor equipment and inadequate communications but also those which result from the fact that he is usually a stranger to the area and lacks the long familiarity with the weather changes which help to guide forecasters in temperate climates. He has no textbook methods which he can study and he has to obtain his knowledge of local conditions from woefully incomplete climatological statistics which hide rather than emphasize the variations in weather which he must account for.

For a forecaster trained in the temperate zone the greatest difficulty is caused by the breakdown of the geostrophic relationship between wind and pressure which makes the drawing of isobars within the region, especially in view of the small number of stations, appear to be a matter for imagination rather than reason. The result is that the isobaric pattern has to be drawn independently of the wind distribution and it has become usual to construct additional charts of lines of flow for the various levels independently of the pressure. By superimposing the streamline and isobaric charts it is sometimes possible to determine areas of acceleration or retardation of the streams and eventually to formulate some empirical rules for development.

One of the difficulties which have exercised the minds of many people is how to handle the diurnal variation of pressure and weather on the synoptic chart. Now that universal time has been adopted for synoptic observations the effect of the diurnal variation must be very carefully watched on any chart which has a large east–west extent so that afternoon convective effects will not be confused with frontal effects. There is a body of opinion that the pressure readings should be "corrected" for the relatively large diurnal variations of pressure in order to obtain "representative" pressures for each station, but the day-to-day irregularities, especially in the diurnal wave, make the correction of the pressures a rather doubtful project. It is indeed questionable whether such a "representative" pressure chart would have any dynamical significance and whether more might not be lost than gained in the process. It is, however, beyond question that the comparison between successive three-hourly synoptic charts is exceedingly difficult because of the diurnal variation of pressure. The tendency has been to compare each chart with the one prepared 24 hr earlier and thus obtain an overlapping series of 24-hr changes. There appears to have been no prolonged investigation into the application of corrections for diurnal variations, owing no doubt to the pressure of routine work. However, such an investigation would be of great value whatever the result.

Some workers prefer to ignore the isobaric chart almost completely and rely on the streamline charts for their analyses. It is usual to draw the streamlines for different levels in order to get a three-dimensional picture of the atmospheric structure. Usually the charts are not drawn conventionally, with the distance between the lines being inversely proportioned to the

speeds, but consist of lines of flow (direction only) with the speeds indicated by isopleths or by feathers on the arrows. It is possible, with these charts, to identify areas of convergence and divergence with reasonable reliability and also to pick out sloping surfaces of well-marked wind discontinuity. Short-period forecasts of good reliability can be made by an experienced forecaster using this method, but much more satisfactory results appear to be possible if the streamline charts are related to the isobaric charts. Sen [8] in India has advanced the method a stage further by assuming the equatorial circulation to consist of a Kármán vortex street, the location of each vortex being determined with the assistance of streamline charts and the surface isobaric chart. This conception involves the existence in the Northern Hemisphere of a line of anticyclonic vortices near the equator and a line of cyclonic vortices to the north, with the corresponding zones of weak anticyclonic and cyclonic pressure centres, respectively, to mark their positions. From the spacing ratio of the "street," the stability or instability of the system is determined, and developments are forecast accordingly. The distribution of humidity is brought into the discussion of the degree of development that is expected to take place. It is necessary, however, to assume that the geostrophic balance of wind and pressure holds to within a few degrees of the equator, which is not in accordance with the experience of most workers in the region.

The recognition of convection and orographic effects is, of course, of great importance, but since these are not features peculiar to the equatorial zone they will not be discussed here. It must be remarked, however, that by far the greater amount of rain and thunderstorms arises from these effects so that their recognition is of primary importance to the forecaster.

U. S. Weather Bureau, Chicago, Illinois

INTRODUCTION

Tropical cyclones of certain degrees of intensity are known as *hurricanes* in the Atlantic Ocean, the Caribbean Sea, the Gulf of Mexico, and the eastern North Pacific Ocean (off the coast of Mexico); as *typhoons* in the western North Pacific and over most of the South Pacific Ocean; and as *cyclones* in the Indian Ocean. Locally in the Philippines these storms are called *baguios* and in Australia *willy-willies*. All have essentially the same origin, structure, and behavior.

Interest in tropical meteorology and tropical storms received considerable impetus in the 1930's with the extension of airline routes through the tropics and the consequent need of more accurate weather observations and forecasts in these areas. However, the meteorological requirements of the various military forces engaged in the tropics during World War II resulted in the collection of more observational data and in more rapid progress toward the solution of several of the more urgent and vexing problems of tropical meteorology than ever before.

A tropical cyclone is essentially a maritime phenomenon and, therefore, as a rule, aerological data are relatively sparse over large areas traversed by tropical storms. Even in the Antilles and along the South Atlantic and Gulf coasts of the United States, where raob and pilot-balloon stations are located, it has been extremely difficult to obtain upper-air observations within the storm area itself. Therefore, many of the characteristics and mechanics of the tropical storm model are still not definitely known.

SURFACE CHARACTERISTICS OF TROPICAL CYCLONES

Sources of Information. Knowledge of the surface characteristics of tropical cyclones has gradually accumulated from a half century of observations. Mitchell's work [11] on areas of origin and normal rate and direction of movement of hurricanes in the North Atlantic Ocean, together with forecasting precepts, was one of the earliest and most important studies. Several years later Cline [1] published the results of many years' study of hurricanes in the Gulf of Mexico region with considerable emphasis on their characteristics. Probably the most systematic analysis and compilation of the characteristics of tropical cyclones were those of Deppermann [2, 3, 4] for the Philippine area. Tannehill [18] has compiled a large amount of statistical information on North Atlantic hurricanes for as far back as 1494. Information on the surface characteristics of tropical cyclones from these and many other sources such as G. Norton, E. Gherzi, and others, has been summarized by Dunn [5]. These and similar sources are incomplete and in many respects not entirely satisfactory otherwise. All weather services in the tropical cyclone areas should set up procedures for a systematic tabulation of all surface and upper-air observational data to establish more definitely many of the characteristics of tropical cyclones.

Apparently very small changes in lapse rates, specific humidities, and the field of motion will result in marked deviation from the so-called "normal" features of tropical cyclones, in addition to the normal changes as they move from low to higher latitudes. In general, only those characteristics observed before recurvature are considered here.

Classification of Tropical Cyclones According to Intensity. Tropical storms are variously described as cyclones, hurricanes, storms, depressions, lows, etc. It is desirable that these terms be defined; the following classification of tropical storms has received general acceptance in the United States:

1. *Tropical Disturbance.* Circulation slight on the surface, possibly more marked aloft, one or no closed isobars. Common throughout the tropics and subtropics.
2. *Tropical Depression.* One or more closed isobars, wind force equal to or less than Beaufort 6. Frequently observed in the intertropical trough, much less frequently in the trades.
3. *Tropical Storm.* Closed isobars, wind force more than Beaufort 6 and less than Beaufort 12.
4. *Hurricane or Typhoon.* Wind force Beaufort 12 (75 mph or more).

All, of course, must originate in the tropics, but many tropical disturbances and depressions never reach hurricane intensity. An International Meteorological Conference in Manila in June 1949 adopted slightly different definitions as follows: tropical depression—winds up to 34 knots; tropical storm—winds 35–64 knots; typhoon —winds 65+ knots.

Classification of Tropical Cyclones According to Stage of Development. Like extratropical disturbances, tropical cyclones undergo constant metamorphosis from birth through maturity to decay. The general characteristics of a tropical cyclone vary considerably both as regards surface and upper-air structure as the storm progresses from one phase of development to another. Thus tropical cyclones will rather consistently exhibit different characteristics at latitude 30° than at latitude 20°. The life history of tropical cyclones may be divided into four stages:

1. The formative or incipient stage, which begins when a tropical disturbance first develops surface circulation and ends when it reaches hurricane intensity.
2. The stage of immaturity or deepening, during which the cyclone continues to deepen until the lowest central pressure and the maximum intensity are

reached. The storm is most symmetrical during this period and only a relatively small area is as yet involved.

3. The stage of maturity, when there is no further deepening, the isobars are gradually spreading out, and the area covered by gales and hurricane winds is larger than at any other period, but the intensity is gradually decreasing.

4. The stage of decay, when the storm is dissipating over land or is recurving northward and assuming extratropical characteristics.

Air-Mass Arrangements around Tropical Cyclones. Tropical cyclones develop in homogeneous air and during the early and middle stages of their existence encounter only *Tm*, tropical maritime air (the trades), and *Em*, equatorial maritime air (the equatorial westerlies and the intertropical convergence zone). During or immediately following recurvature *Np*, transitional polar air, may be encountered. There is little difference between all three air masses below 10,000 ft. Above that level *Em* is the most moist and *Np* usually the driest. The air masses around tropical cyclones are essentially homogeneous, at least until the close of the stage of maturity. There are no fronts until the stage of decay, although distortions in the wind field analogous to fronts may be found in cyclones having a strong northerly component[1] in the direction of movement.

Barometry of Tropical Cyclones. A tropical disturbance may persist for a number of days without deepening and, particularly in the intertropical convergence zone, may never develop into a depression. When the depression has intensified to Beaufort 6–7, deepening takes place rather rapidly and maximum deepening is usually reached within 72–84 hr in the Atlantic and from four to five days in the Pacific. Little change then occurs if the storm remains over water until it recurves and begins to assume extratropical characteristics and the central pressure begins to rise. There is apparently some limiting intensity, or state of equilibrium, dependent upon the moisture content and possibly the lapse rate of the lower atmosphere.

Deppermann [2] has investigated the pressure gradients of typhoons with minima less than 28.75 inches (973.6 mb) with results as follows:

Minimum pressure	Number of storms	Mean fall $in.\ hr^{-1}$	Mean fall $in.\ mile^{-1}$
Below 27.56 in. (933.3 mb)	4	0.79	0.06
27.57–27.95 in. (946.5 mb)	4	0.43	0.03
27.96–28.35 in. (960.0 mb)	7	0.45	0.03
28.36–28.75 in. (973.2 mb)	8	0.40	0.025

He concludes that, as a rule, steepness of gradient increases with depth of the barometric minimum. However, as Deppermann himself points out, the mean pressure fall per hour is determined to a considerable extent by the rate of movement of the storm and does not truly represent the pressure gradient of the storm but rather the steepness of the barograph trace. The last column does represent the actual pressure gradient, which may or may not approximate the normal pressure gradient in severe typhoons since it is based on a relatively small number of storms. Cline [1] found an average pressure gradient of 0.02 inches per mile, indicating the further spread of the isobars in the later hurricane stages which are normally found as these storms reach the coast line of the Gulf of Mexico.

There are many authentic instances of gradients much steeper than those in the table above, usually in storms in the immature stage. Several examples of steep gradients are given by Deppermann: The *Pathfinder*, anchored at Aras, Samar, P. I., recorded a pressure fall of 1.07 inches in twenty-seven minutes. In a Tacloban, P. I., typhoon there was a drop of 1.14 inches in thirty minutes, with a measured fall by mercurial barometer of 0.49 inches in five minutes. The S.S. *Virginia* in the Central Caribbean, on September 20, 1943, experienced a barometer reading of 28.74 inches at 8:00 P.M. and 27.40 inches twenty minutes later, a fall of 1.34 inches, and rose to 28.60 inches by 9:00 P.M. The pressure fell more than 2 inches in ninety minutes. The diameter of the circle enclosed by the 29.5-inch isobar was estimated at fifty miles; the calm center, from eight to twelve miles. If a flat minimum in the calm center is assumed, the pressure gradient was 2.10 inches (71.1 mb) in nineteen miles or 0.11 inches per mile. This was a young, immature hurricane which had undergone its principal development during the previous two days. In the Labor Day hurricane over the Florida Keys in 1935 there was evidence of a pressure gradient in excess of one inch in six miles.

There has been general agreement that in the immature and mature stages of the tropical cyclone isobars are nearly circular from the center outward to around the 29.4-inch (995.6-mb) isobar. However, there has never been a sufficiently dense network of accurate barometer readings to verify this completely. Indeed, evidence in recent years tends to indicate that isobars are not absolutely circular except possibly quite close to the center. Soon after the beginning of recurvature, more apparent distortion of most of the isobars is usually evident. Isobars are more truly circular in the rapidly deepening stage than at any other time.

The accepted lowest barometer reading of record in the world is 26.185 inches in a typhoon encountered by the Dutch steamship *Sapoeroea* about 460 miles east of Luzon, P.I., on August 18, 1927. The official record for the barometric minimum in the Atlantic is 26.35 inches on September 2, 1935, on Lower Matecumbe Key, Florida. Readings between 27.00 and 27.50 inches (914.3–931.3 mb) are fairly common.

Pumping—the rapid and possibly rhythmic oscillation of atmospheric pressure—has frequently been observed in tropical cyclones. Gherzi [7] claims to find a mean period of about six seconds corresponding with the period of typhoon swells, which would indicate that the oscillations in this case are produced by microseismic waves set up by the typhoon swells. Deppermann believes that oscillations of such periodicity do not occur in the Philippines, nor have they been noted in the Atlantic, although they may be masked by other

1. This expression should be interpreted to mean "a component toward the north."

oscillations. Deppermann, upon examining all Philippine barograms of tropical cyclones found [2]:

	No. of cases
1. Traces with no oscillations observable	143
2. Traces with only long-period oscillations or with long-period superimposed on short-period	79
3. Traces with only long-period oscillations (10–30 min)	21
4. Traces with doubtful oscillations, *i.e.*, doubtful due to blots and blurs	25
5. Traces which possess, almost surely, only oscillations of very small period	2

He concludes that, for the Philippines, short-period oscillations are the exception rather than the rule. This has also been considered true of the Atlantic. However, most barographs are designed to damp out minor short-term oscillations.

Deppermann found evidence of long-period oscillations in 100 out of 270 barograms with minima under 29.14 inches. He states that the simplest and most clear-cut cases resemble very much in form and period the oscillations on the microbarograph when there are thunderstorms quite near but not actually over the station.

No generally accepted explanation for these oscillations has been advanced. Short-period oscillations may be due to the pounding of the long hurricane swells on the beaches, strong rhythmic gusts of the wind, and the effect of gusts on buildings including the swaying of tall buildings. Long-period oscillations may be due to the regular march of intense squalls around the storm. In the most intense storms, violent pumping of the barometer may occur near and in the storm center. Violent kinks in the barogram are occasionally observed. In the July 1943 hurricane at Galveston, Texas, the Weather Bureau City Office barogram contained a kink just before and another just after the barometric minimum, but neither appeared on the barogram at the airport five miles away.

Temperature. At the surface no change in temperature is noted with the approach and passage of the tropical cyclone other than the lowering of the free air temperature to or near the dew-point or wet-bulb temperature incident to the heavy rain.

Wind Circulation. Winds in tropical cyclones of the Northern Hemisphere blow counterclockwise around, and incline inward toward, the center of the storm. However, the degree of incurvature toward the center is not uniform in the various quadrants. Cline noted that there is a systematic difference in the inclination of the winds in the four quadrants, and others have attempted to calculate the exact degree of incurvature. However, it appears that the incurvature varies considerably with individual storms and with their stage of development, size, latitude, and other factors. The winds in the right rear quadrant usually blow more directly toward the center (greatest incurvature) than is the case elsewhere. The intense storms of the immature stage have the most symmetrical circulation. While there is some lack of uniformity from one storm to another with regard to winds in the right front quadrant, they usually appear to move directly across the line along which the storm is moving and are tangential to the isobars. However, more definite information is needed on the surface circulation, the cross-isobar components, and the field of convergence.

If a hurricane is moving between west and northwest, the most commonly experienced wind along the line over which the central calm will move, preceding the calm, is north or north-northeast, usually the latter, and the wind may blow from this direction for hours, without veering or backing, prior to the arrival of the storm center. If the wind tends to veer or back, the center is unlikely to pass over the station. If the storm is moving in a northeasterly direction, the most usual wind preceding the arrival of the storm center is north-northeast to east-southeast.

The wind velocities encountered around the storm are affected by the stronger pressure gradient usually present to the right, since in westward-moving storms the semipermanent subtropical high is to the right and the intertropical trough to the left. Thus gales and hurricane winds extend farther to the right than to the left. In intense immature storms velocities increase until a few minutes before the calm, but in the mature and decaying stages the highest winds may occur as much as two hours before and one hour after the central calm. The dimensions of the hurricane winds will vary with a number of factors: maturity of the storm, pressure gradient, central pressure, etc. In the large Cape Verde storms, the diameter of hurricane winds may exceed 100 miles by the time the storm has reached the western Atlantic.

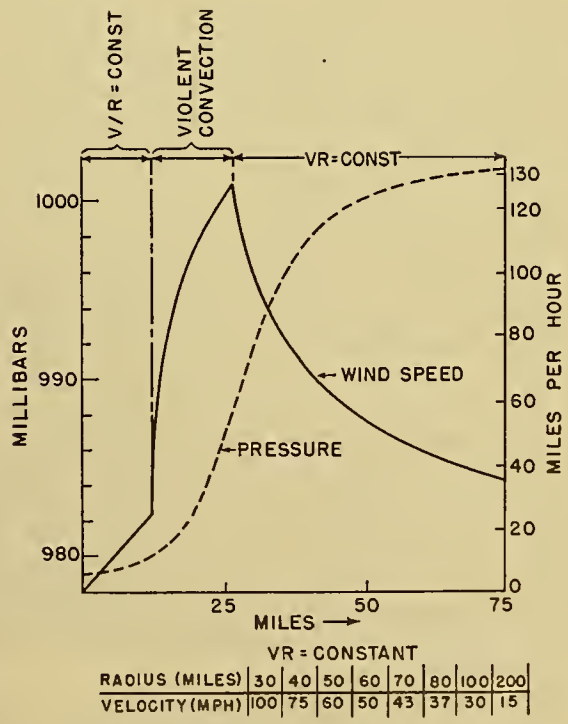

FIG. 1.—Deppermann's typhoon model.

In the Labor Day storm in 1935 over the Florida Keys, the most intense hurricane in the history of the United States, the diameter of hurricane winds was

only about thirty-five miles, therefore neither minimum barometer nor intensity of the storm is necessarily an indication of the area of hurricane winds.

Some writers have suggested various means of computing the distribution of surface wind velocities in a cyclone vortex by developing reasonable theoretical velocity profiles. Deppermann [4] has developed an idealized profile of the type shown in Fig. 1 as most typical of tropical cyclones. Here we have a Rankine vortex in which V/R = constant for the innermost cone including the eye and its adjacent areas, and VR = constant in the outer vortex. Deppermann describes the area between these two as a ring of violent convection characterized by a still different velocity variation. While this may serve as an average distribution for a large number of storms of various intensities, the range of deviations from this average will probably be quite considerable, both from quadrant to quadrant and from one stage of storm development to another. In the small immature storms maximum wind velocities will be reached closer to the eye. Since the required dense network of observing stations has never been available, no rigorous study of surface wind velocities and directions and associated pressure gradients has ever been made.

Clouds. Cloud arrangements, in common with other tropical-cyclone characteristics, will vary considerably with individual storms. As a rule the cloud sequence is much the same as in advance of a warm front in middle latitudes. First to appear are the cirrus clouds which frequently seem to radiate from a point on the horizon in the general direction of the storm. The cirrus will thicken to cirrostratus and then to altostratus and altocumulus. Soon occasional cumulonimbus, extending through the upper deck with passing squalls, will appear. Finally a dark wall of cloud, sometimes called the "bar" of the storm, appears, and squalls become almost continuous with stratus based at from 500 to 2500 ft or with a precipitation ceiling.

There is occasional reference in the literature to lurid sunsets preceding the advent of a hurricane. This condition may precede a hurricane but handsome sunsets are frequent in the tropics and subtropics where cirrus (nothus) formed from dissipated cumulonimbus are present.

In the hurricane vortex high clouds are rarely visible. Low clouds will have about the same direction as the surface wind although usually more tangential to the isobars. At sea, clouds are occasionally reported down to the water, but these reports are considered unreliable since rain and flying spray will frequently lower visibility to zero. On land, even at the height of the storm, the ceiling is usually reported as above 1000 ft, although in later stages of recurvature 500-ft ceilings are not infrequent.

Vines [19] believed that cirrus radiate from and move outward from the center of the tropical cyclone. Most of the observations during the past twenty years indicate that, in general, cirrus move forward in the general air stream in which the cyclone is imbedded. It does not necessarily follow that the hurricane circulation does not at times reach the cirrus level since cirrus cannot ordinarily be observed over the vortex. However, outside the periphery of low and middle cloud decks associated with the vortex, cirrus appear to be unaffected by the storm's circulation.

Precipitation. The distribution of rainfall around a tropical cyclone varies markedly from one storm to another. In general the more immature the storm and the lower the latitude, the more symmetrical the rain pattern from the standpoint of intensity and area. As the storm begins to recurve and reaches more northern latitudes, rainfall, from the standpoint of both intensity and area, becomes concentrated in the front quadrants. Notable exceptions, however, have occurred. In the "Yankee" hurricane of 1935, 0.04 inches of rain fell before the arrival of the center and 3.40 inches afterward. In October 1941 a hurricane passed over Miami, Dinner Key reporting a maximum wind of 123 mph, with only a trace of precipitation.

A check on three fairly recent Puerto Rican hurricanes reveals that at San Juan, 3.03 inches fell in the front half and 7.85 inches in the rear half of the storm of September 1926. This was a mature Cape Verde storm and the center passed to the south of the station. On September 27, 1932, a relatively immature hurricane passed over Rio Piedras seven miles southeast of San Juan, and 1.17 inches fell before and 1.59 inches after the center passed. On September 19, 1931, 0.71 inches fell before the calm center and 1.15 inches after it passed. This was a very young storm which had reached hurricane intensity less than twelve hours before it arrived over Rio Piedras. It is believed the distribution of rainfall around these three storms is normal for moderately low latitudes, although the total amount in the two later storms was subnormal.

Vines indicated that in Cuba rainfall extends farther in advance of the storm than to the rear, but there are also cases when the reverse is true. Most storms affecting Cuba have a strong northerly component and occur late in the season.

Deppermann has not reached very definite conclusions on the distribution of precipitation around tropical cyclones but states that most of the rain in the so-called "triple-point" typhoons in the Philippine area occurs in the rear and most of the rain in the "trade-norther" type in the right front quadrant.

Tropical cyclones in the Gulf of Mexico, according to Cline [1], have the greatest precipitation intensity 60–80 miles in front of the cyclone center and mostly to the right of the line along which the cyclone is advancing, and with relatively little precipitation in the rear half. Cline suggests that this is due to the winds of high velocities moving through the right rear quadrant and converging with winds in the right front quadrant of lesser velocity and greater cross-isobar components. He cites a rather extreme example, in the cyclone of October 10–12, 1909, when Key West received 12.04 inches before passage of the center and only 0.24 inches afterward. This storm had already recurved and was moving northeastward and, indeed, most of the storms cited by Cline were recurving and in stages 3 and 4.

The total rainfall in a tropical cyclone is dependent upon many factors, including rate of ascent of air in the storm area, location of the rain gage relative to the storm center, rate of movement of the storm, and especially topography. The rainfall averages 5–10 inches but varies greatly. Thirty to forty inches have occurred where topographical influences were favorable, but in other storms precipitation amounts have been less than an inch and in one instance only a trace was observed. Loss of rain from gages is considerable in high winds; in hurricane winds it may reach 50 per cent.

Some records of heavy rains in connection with tropical cyclones follow:

Baguio, Philippine Islands—46 inches in twenty-four hours, 88 inches in four days.

Silver Hill, Jamaica—96.5 inches in four days.

Mount Molloy, Queensland, Australia—63 inches in three days.

Réunion, Indian Ocean—47 inches in four days.

Adjuntas, Puerto Rico—29.60 inches in little over twenty-four hours.

Texas, several instances—22 and 23 inches in twenty-four hours.

In most of the foregoing cases orographic influences were pronounced. As a rule a station will not remain under the direct influence of a tropical cyclone more than two days; therefore, it is doubtful if the tropical storm was entirely responsible for the total rainfall in all of these cases. In some storms much more rain fell during the stage of advanced decay than during the period of greatest intensity.

Radar Bands. In recent years radar has been used during aerial reconnaissance to track tropical cyclones and to locate their centers. Many of the radar photographs have revealed the presence of large-scale squall or convection zones spiraling inward toward the center. A rather typical example is shown in Fig. 2. This photograph was taken at Orlando, Florida, at 0220 EST on September 16, 1945, when the storm center was some 136 miles south of the station. The quasi-circular heavy precipitation bands are clearly outlined. The lack of such bands in the southwest quadrant is real and probably due to the decreased convergence normally found in that section of the storm in this particular stage of development. Wexler [22] concluded from a study of this hurricane and of two typhoons in the Pacific that, in these three storms at least, the precipitation bands were symmetrical while the storm was over the ocean but rapidly developed asymmetry over land. Friction over land develops a deformation in the pressure and wind fields which also changes the distribution of convergence. Between these bands or zones there is a thick altostratus or nimbostratus sheet from which light rain falls continuously.

The exact mechanism of these bands has not yet been fully explained. Haurwitz [9] suggests that internal wave motion occurring when vertical wind-shear is present may lead to patterns very similar to the convection patterns observed in the laboratory. If these convection patterns are introduced into a circular vortex attended by general convergence, then the bands will spiral inward toward the center. Their width and spacing, according to Wexler, will change depending on the vertical wind and density gradients and the

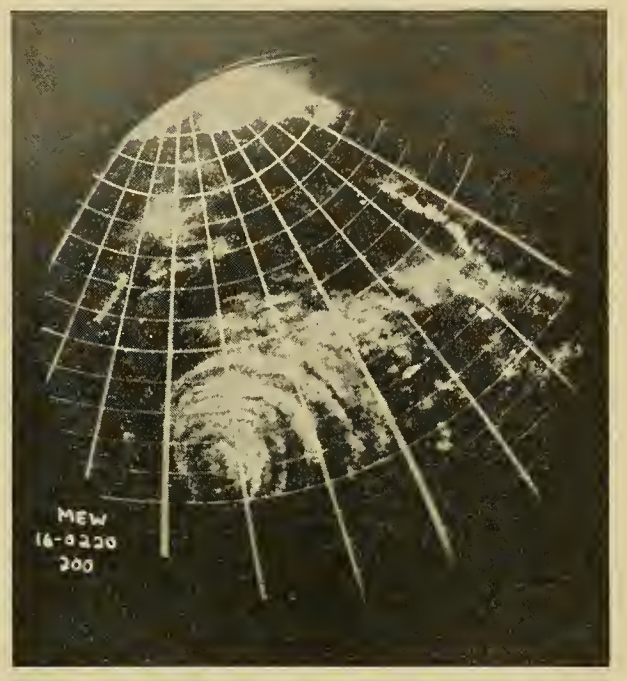

Fig. 2.—Radarscope photograph, Orlando, Florida, 0220 EST, September 16, 1945. Hurricane center 136 miles from station. (*Courtesy H. Wexler and U. S. Army Air Forces.*)

distribution and magnitude of the horizontal convergence associated with the vortex.

The "Eye" of the Storm. One of the most spectacular aspects of the tropical cyclone is the central calm or "eye" of the storm. At the center of the storm the wind rather suddenly diminishes from extreme violence to 15 mph or less. At the same time the rain ceases, the low clouds may be visible only on the horizon, and the middle deck becomes broken and often scattered. Cirrus and cirrostratus clouds are almost always present. In the middle of the "eye," winds may lessen to 5 mph and dead calms have been reported for short periods, and the sun or stars may be visible. Observers have described conditions in the relatively calm center as "oppressive," "sultry," and "suffocating," but this reaction is apparently psychological and due to the rapid transition from hurricane winds and torrential rain to relatively calm and humid conditions. The few cases of noticeable rise in the temperature at the surface and consequent changes in humidity have been explained by insolation or foehn effect.

Deppermann [2] has tabulated the duration of calms for some 59 typhoons as follows:

Central pressure	No. of cases	Mean duration of calm
Below 27.56 in. (933.3 mb)	4	18 min
27.56–27.95 in. (946.5 mb)	7	16 min
27.95–28.35 in. (960.0 mb)	5	37 min
28.35–28.74 in. (973.2 mb)	11	32 min
28.74–29.14 in. (986.8 mb)	15	39 min
29.14–29.53 in. (1000.0 mb)	17	64 min

These figures would indicate that weak storms have longer calms than more intense storms. However, it does not appear that Deppermann considered rate of movement, or whether merely a chord near the edge of the calm center instead of the diameter passed over the station. Since the rate of movement varies from one storm to another, the duration of the calm is not necessarily a measure of the diameter of the calm center. In the United States the diameter appears to be less in immature storms than in the larger mature storms. In the latter the calm center seems to increase in about the same proportion as the storm area. The smallest eye reported has been about 4 miles in diameter in a storm in the formative stage; diameters of 20–25 miles in large mature storms are not unusual. An average value appears to be 12–15 miles. Upon recurvature the eye may assume a very elongated shape in the direction in which the storm is moving. On occasion a double eye has been observed, usually when the cyclone is decaying.

Frequency of Thunderstorms and Tornadoes. Thunderstorms are frequently observed in the early and decaying stages of tropical cyclones and also around the periphery of the storm. They are not usually observed in the area of winds over 60 mph in immature and mature storms. Tornadoes have been reported in a few instances in connection with tropical storms in the Bahamas and in Cuba and fairly frequently in Florida. The tornado paths are very short (only a mile or two in length) and several appear to have formed over the ocean as waterspouts. Indeed, from the standpoint of intensity, they seem to resemble waterspouts more closely than inland tornadoes. Information is not available as to whether any particular quadrant is preferred.

Inundations. The *hurricane wave*, sometimes erroneously called a tidal wave, is the lifting up of the level of the sea at and near the center of intense hurricanes. It is usually not a series of individual waves but a rapid uplift of water and is most noticeable in the calm center. It has been noted in all areas where tropical storms occur.

Hurricane waves occur on the shores of small islands as readily as on continental coast lines. They have been responsible for heavy losses of life and precautions should always be taken against their possible occurrence, especially at and for a short distance to the right of the point where the center will cross the coast line. The hurricane wave is superimposed on the gravitational and hurricane tides prevailing at the time but will usually subside quickly within an hour or two after the center passes.

The wave has been ascribed to the decrease in atmospheric pressure, but even in the most severe hurricanes the maximum possible rise from decreased pressure has been calculated to be less than 4 ft and any such rise should be gradual. It is thought that the wave is caused by the damming effect of the wind on the forward side of the calm center against the current set up by the violent winds from the opposite direction to the rear of the calm center. The average height of the hurricane wave is 10–20 ft but higher waves have been reported, especially where the shore line permits a funneling effect.

The Hurricane Tide. There is little or no actual transfer of water in waves and swells, but sustained winds of only moderate force will set up a current flowing with the wind. The rise in the water level on the shore line may begin when the tropical cyclone is 500 miles or more distant and will continue until the storm passes inland or beyond the area. This tidal rise is called the hurricane tide and is superimposed on the normal gravitational tide. It is most pronounced in a partially enclosed body of water such as the Gulf of Mexico, where the concave coast line does not readily permit the escape of water which is thus piled up on the shore line. The strongest winds and the greatest fetch is in the right rear quadrant; therefore, the strongest current is directed with and to the right of the line along which the storm is moving.

Heights of storm tides on concave coast lines vary from 3 to 10 ft above normal. On straight shore lines the average is less and in very small island groups, around which the current may easily flow, there is little or no tidal effect of this type.

VERTICAL STRUCTURE OF TROPICAL CYCLONES[2]

Theory. Observations necessary for proof of the various theories in regard to the vertical structure of tropical cyclones are extremely sparse. Nevertheless, through contributions from Shaw, Durst and Sutcliffe, Willett, Haurwitz, Simpson, Riehl, and many others, a fairly coherent and logical theory has been developed which has found general acceptance in a broad sense but in many details is subject to further verification and, no doubt, to revision on the basis of future observational data.

The tropical cyclone is definitely a warm-core phenomenon, in contrast to all other tropical disturbances which are cold-core phenomena. The circulation is strongest near the surface, but as the storm intensifies it extends rapidly to great heights. With the approach of the vortex, temperatures and specific humidities increase at almost all levels at least up to 15–20 km. It further appears that convergence near tropical-cyclone centers is limited to a fairly shallow layer near the surface.

The problem of how evacuation of air from tropical cyclones takes place is the most controversial portion of the theory of tropical-cyclone structure. The theory of many earlier meteorologists, and even of some who are currently engaged in tropical research (see [15]), that the pressure gradient reverses its sign at some level above 10–20 km, is still inconclusive. Vines' observations in the 1890's of cirrus radiating outward in all directions from a point over the storm center have not been reaffirmed for many years. Riehl [12], while believing that a reversal of pressure gradient is

2. This phase of tropical cyclones is discussed in greater detail in "Aerology of Tropical Storms" by H. Riehl, pp. 902–913 in this volume.

likely at some altitude high above the storm center, has summarized how considerable outflow may take place otherwise. Following Durst and Sutcliffe [6] he has considered the effect of angular momentum of rising surface air. Because of the decrease of pressure-gradient force with height, the rising air seeks to draw away from the center as soon as the centrifugal force exceeds the pressure-gradient force. Values indicating the variations of the pressure-gradient force with height are tabulated below. The values in the right-hand column are the ratios (expressed in per cent) of the pressure-gradient force at different elevations to that at the surface.

H(km)	Per cent	H(km)	Per cent
Sfc	100	10	3
1	98	11	−17
2	92	12	−31
3	90	13	−35
4	80	14	−60
5	70	15	−84
6	63	16	−59
7	54	17	−131
8	28	18	−142
9	25		

(*After Riehl*)

If it is assumed that the ascending current retains its angular momentum, withdrawal from the central area would start approximately at the 3-km level, according to Riehl. At this elevation the magnitude of the pressure-gradient force directed toward the hurricane center begins to drop significantly with height. In reality, outflow will begin at even lower heights, owing to the decrease of the frictional force above the surface.

Durst and Sutcliffe also postulate an increase of the vertical velocity with height and show that such an increase may contribute to the radial outflow of the air aloft. In view of the probability that convergence is restricted to the vicinity of the surface, Riehl concludes it is unlikely that the upward vertical motion increases with height except near the surface.

Height of Tropical Cyclones. Tropical cyclones are associated with stronger pressure gradients than are observed in any other weather phenomenon where we must deal with hydrostatic equilibrium. The equalization of this pressure difference between the center and the periphery of the storm at some point in the upper air is dependent primarily upon a thermal gradient directed so that the warmest air is in the core of the storm. Haurwitz [10] has shown impressively how high this temperature must be if the circulations of very small storms are to disappear at levels at or below twenty thousand feet. For example, in a relatively moderate tropical cyclone with a pressure difference of only 40 mb from the center to the outer edge of the surface vortex, and assuming a reasonable lapse rate in the outer vortex, he found that the temperature in the eye must increase with elevation at the rate of 18C km^{-1} if the circulation of the storm is to disappear at ten thousand feet. The lapse rate must be zero, or isothermal, if the circulation is to disappear at twenty thousand feet. For the circulation to disappear at thirty thousand feet the lapse rate must be only slightly more than 4.5C km^{-1}. The two storms for which soundings in the eye are available had average lapse rates of not less than 4C km^{-1}. Since the more severe hurricanes are not infrequently associated with pressure differences of 70–90 mb between the center and the periphery, it can readily be seen that such storms must extend high into the upper troposphere.

Figure 3 shows a sounding in the eye made at Tampa, Florida, on October 18–19, 1944, and two

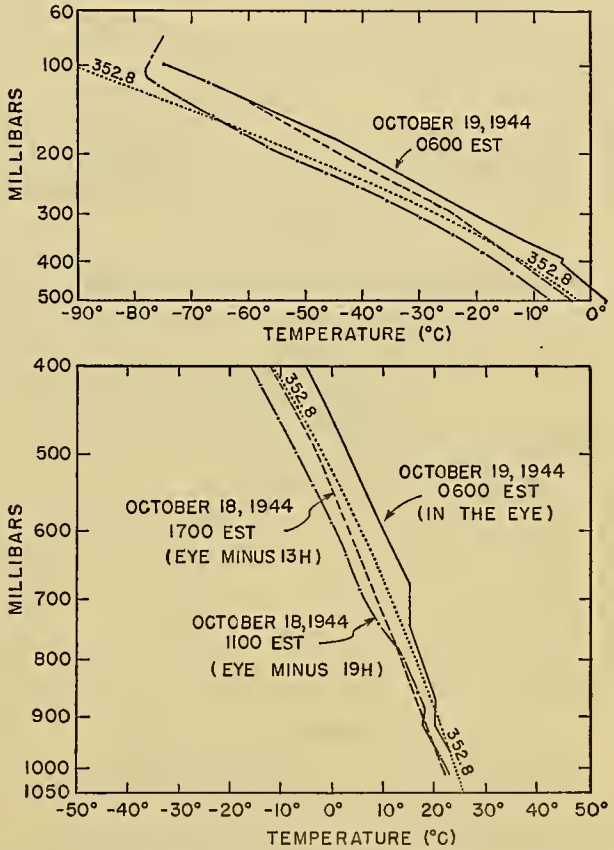

FIG. 3.—Soundings at Tampa, Florida, during the approach and arrival of a hurricane center, October 18–19, 1944.

soundings made earlier. Figure 4 presents a similar series for October 7–8, 1946. Both series represent conditions during the approach of a hurricane, and the warmth of the eye is clearly indicated. It should be noted, however, that both storms were in a state of recurvature and it is not certain that the radiosonde did not pass out of the eye.

Thermal Structure. There is as yet little actual data to verify theoretical models of temperature distribution in tropical cyclones above the surface. A number of pressure-anomaly cross-section charts by Simpson have indicated that these storms extend to very high levels and have a double cellular structure with the lower warm-core cell capped by an upper cold-core cell.

Tropopause Heights in Tropical Cyclones. Until recently it was generally thought that low tropopauses accompanied tropical cyclones. The reasons most commonly advanced for the low tropopause were the supposed absence of convection in the eye and the stronger

temperature gradients in the upper troposphere required to reverse the circulation. Of the two soundings available from centers of tropical cyclones, one reached 17½ km and the other 17 km; neither showed much evidence of having reached the tropopause, although the sounding in the October 1944 storm showed extraordinary stability in the middle troposphere. Figure 5 shows probable tropopause variation in three tropical cyclones, and in Fig. 6 Simpson indicates the probable relation between temperature in the outer and inner vortex of a mature hurricane.

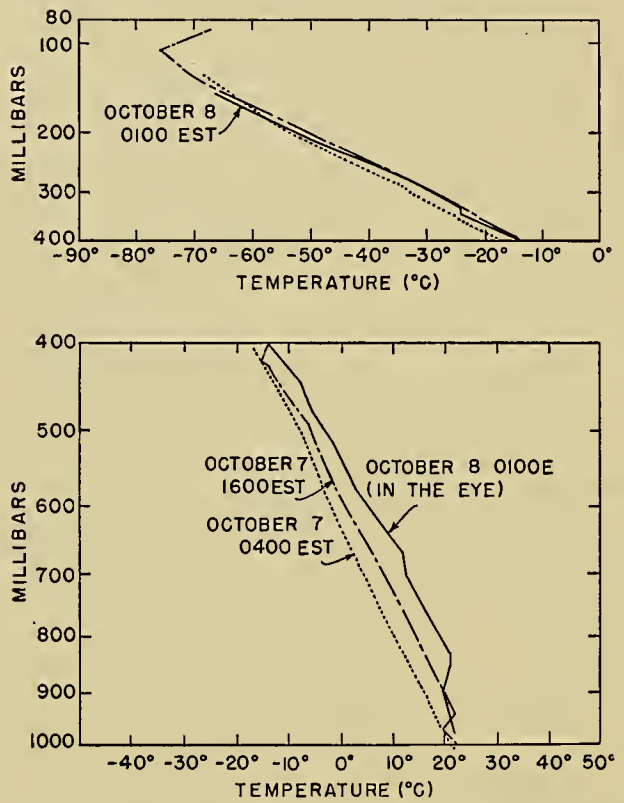

Fig. 4.—Soundings at Tampa, Florida, during the approach and arrival of a hurricane center, October 7–8, 1946.

ORIGIN OF TROPICAL CYCLONES

Theories of Tropical Cyclone Development. The convective theory of the formation of tropical cyclones was developed many years ago and was generally accepted until the early 1930's. It was believed that the following series of events occurred in the equatorial trough: The warm moist surface air rose because of both insolation and widespread convergence, resulting in numerous cumulonimbus clouds and widespread heavy showers. Then the pressure began falling slowly (for reasons never very well explained), the cumulonimbus clouds gradually coalesced, and if the equatorial trough was sufficiently far from the equator for the Coriolis force to be effective, a cyclonic circulation was initiated. The development of the circulation continued until full intensity was obtained by release of latent heat through condensation. In some areas, notably the North Atlantic, it is now apparent that many, if not the majority, of the tropical cyclones do not develop in the equatorial trough.

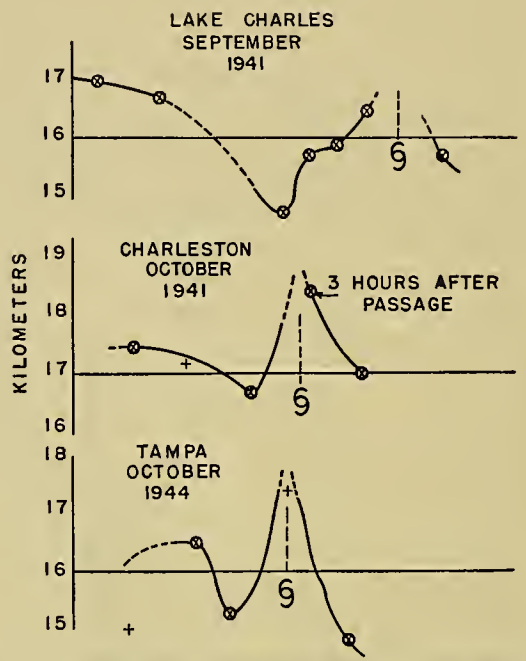

Fig. 5.—Soundings at selected stations during the near-approach or arrival of a hurricane center. (⊗—height of tropopause; +—top of sounding, tropopause not reached.) (*Hurricane Notes—Weather Bureau Training Paper No. 1, Washington, D. C., July 1948.*)

Some attempt was made in the middle 1930's to apply Norwegian methods to tropical analysis. Hurricanes were supposed to develop on the equatorial front which at that time had several different definitions but which now is considered as a narrow zone, usually associated with the equatorial trough, in which air is undergoing horizontal convergence. However, there are no significant temperature differences along the equatorial front, there is no density discontinuity, and the air is essentially homogeneous.

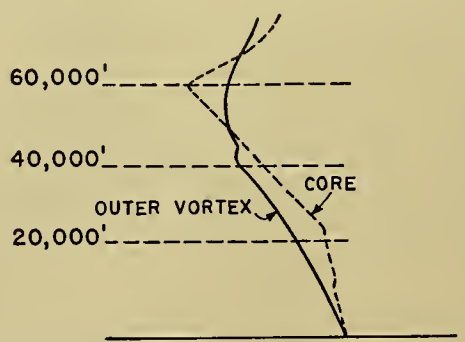

Fig. 6.—Probable relation between temperature in the outer and inner vortex of a mature hurricane. (*After R. H. Simpson.*)

Tropical cyclones originate in easterly waves, in the intertropical convergence zone, and occasionally in the trailing southerly portions of old polar troughs. Cer-

tainly it appears that tropical cyclones will develop only over comparatively warm water, probably 82F or higher. In 1890 only one tropical storm was noted in the North Atlantic and in several other years the total was only two. Therefore, it is apparent that a very special set of circumstances is necessary for their development. There is as yet no generally accepted definition of exactly what synoptic situation is responsible for the formation of a tropical cyclone.

In the North Atlantic, Riehl [12] found that intensification of low-level tropical perturbations or a change from a stable to an unstable condition resulted from the superposition of high-level extratropical disturbances. In all cases of hurricane formation noted in the course of this study, deepening began, without exception, in pre-existing tropical disturbances.

Cape Verde Island region—August and September. (It may be that most of these storms do not reach hurricane intensity until they reach longitude 50–60°W.)

Northern Caribbean Sea—late May through November.

Just to the east and north of the West Indies—June through October.

Southwestern Caribbean Sea—principally June and October.

Gulf of Mexico—June through October.

2. *North Pacific Ocean off the west coast of Mexico*—June through November.

3. *North Pacific Ocean, longitude 170°E westward including the Philippines and the China Sea*—May through December and (rarely) other months.

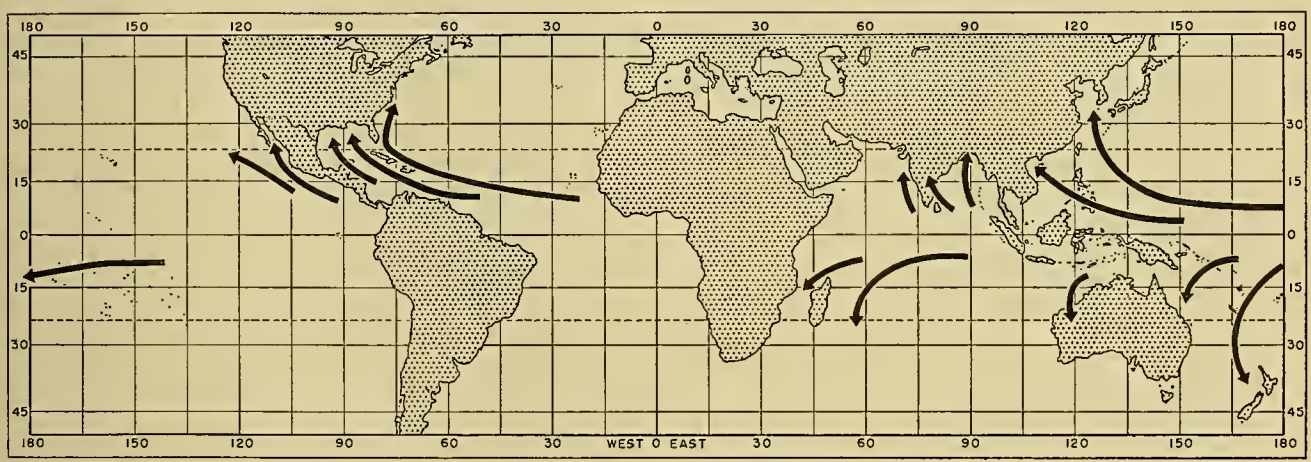

Fig. 7.—Areas of tropical cyclone development.

Tropical cyclones in the southwestern North Pacific Ocean for the year 1945, and to some extent for 1946 and 1947, have been analyzed by Riehl [13] and several other members of the Institute of Meteorology, University of Chicago. Riehl found that typhoon development can begin in consequence of instability of the Northern Hemisphere trades, not necessarily as a result of interaction between currents of the two hemispheres. Instability of the trades appeared to set in just as a low-level wave was bypassed by a broad-scale ridge in the high troposphere. Riehl suggests that a tropical disturbance will intensify when moving from an upper trough to a high-level ridge, since this pressure distribution facilitates upper outflow from the storm. So far observational data have been insufficient to test these relationships in the tropical North Atlantic.

An intensification of the observational network which will permit accurate trough and ridge analyses between the equator and latitude 30° during the tropical cyclone season is badly needed for further research on the interrelationship between upper troposphere troughs and ridges and the development of tropical cyclones.

Region of Origin and Season. Tropical cyclones develop in the following areas and seasons:

1. *South portion of the North Atlantic Ocean.*

4. *North Indian Ocean.*

Bay of Bengal—April through December.

Arabian Sea—April through June, September through December.

5. *South Indian Ocean.*

Madagascar eastward to 90°E—November through May.

Off northwest coast of Australia—November through April.

6. *South Pacific Ocean from east of Australia eastward to 140°W*—December through April.

Probably no portion of the tropical oceanic area in either hemisphere is entirely free from tropical storms, but there is no record of a true tropical cyclone of hurricane intensity in the South Atlantic Ocean or in the South Pacific east of about longitude 140°W. During the Southern Hemisphere summer, the intertropical front in these areas moves only a degree or so south of the equator, not far enough for the Coriolis force to become effective. Few, if any, tropical cyclones have been observed within 5 degrees of the equator. In Fig. 7 are shown the principal areas of the world where tropical cyclones develop and are observed.

Frequencies of Tropical Cyclones. Data on the frequencies of tropical cyclones by months are summarized in Table I.

Detection of Tropical Cyclones. Since tropical cyclones develop over water surfaces, where observational data are often sparse and occasionally nonexistent, detection is a primary problem. Ship and island observations provide information on surface conditions, and a few pilot-balloon and radiosonde reports are available. In some areas pilot reports from aircraft provide limited and often none too accurate upper-air information. To detect tropical disturbances in the early stages, a careful analysis of all observational information is necessary, but it is still possible in some areas for tropical storms to travel a number of days and hundreds of miles over water without detection.

Surface Indications of a Tropical Storm. Within the trade-wind area winds blow with great steadiness with respect to both direction and velocity. Over the ocean area the trade winds will blow from northeast to southeast at 15–22 mph. If a ship within the trades reports a wind with a westerly component, a tropical disturbance has formed; the stronger the westerly wind the more intense is the storm. If the easterly trade-wind velocities are 25 per cent or more above normal, a disturbed situation has developed.

South Pacific Ocean	According to Visher [20], the average number of tropical cyclones is in excess of 27 per year. However, this includes several more or less separate areas of development. A number of island groups such as Fiji, Samoa, Hebrides, Tongo, and New Caledonia average 2 to 3 per year. Data are insufficient for monthly percentages, but the tropical cyclones are apparently well concentrated in the period December through March.												

* Less than 0.1.

† Very few of the storms listed in the winter months reach hurricane intensity. The proportion of storms in other months reaching full hurricane intensity is unknown.

‡ Few of the midwinter and midsummer storms reach full hurricane intensity, and the midwinter storms may not be true tropical cyclones.

§ The intensities of these storms are not indicated.

Pressure fluctuates within narrow limits in the tropics, with the 24-hr net pressure change usually less than the diurnal variati n. The existence of a tropical storm may be recognized by a 24-hr fall of from 3 to 3.5 mb or more, or by a fall in pressure to 5 mb or more below normal.

Precipitation normally occurs in the form of scattered showers and occasional thunderstorms, with variable middle cloudiness from none to broken. If unusually

heavy or steady rain is reported from several nearby points, a developing or approaching tropical storm may be suspected. Solid cirrostratus or altostratus also indicates a disturbed condition.

In the North Atlantic Ocean, tropical storms do not as a rule develop in the equatorial convergence zone. The only exceptions may be those developing off the coast of Africa (the Cape Verde hurricanes) and in the southwestern Caribbean, north of Panama. In the Pacific Ocean it appears that some do develop along the equatorial front. Along this front a low-pressure envelope with a longitudinal extent of 5–25 degrees may appear. It will contain several depressions which drift irregularly westward until a polar trough aloft or major ridge aloft (high troposphere) is encountered, when deepening of one of the depressions may result.

Trade winds of relatively constant direction and speed set up swells which may travel for several thousand miles. The normal frequency of swells in the trade region is 8 per minute over the Atlantic and 14 per minute in the Gulf of Mexico. Hurricane winds set up swells with a greater wave length and periodicity, and in severe storms the frequency decreases to 4 per minute. Swells move outward in all directions from the storm center and will approach the observer, in areas where the swells remain unmodified by large islands and irregular coast lines, from the approximate location of the storm center. Therefore, abnormally high swells or an abnormal direction of movement will indicate the existence of a tropical storm. The height and periodicity of the swells indicate the intensity of the storm. The usefulness of swells in forecasting the movement of tropical cyclones is discussed in the next section.

Modern technique in the detection of tropical storms involves the dispatch of reconnaissance planes into the area where any observations may have indicated the possibility of the existence of a tropical storm.

Upper-Air Indications of a Tropical Storm. In the very early stages of development, tropical storms are occasionally better developed between 10,000 ft and 20,000 ft than at the surface. Therefore, streamline analysis is recommended for pibal charts at these levels, or a very careful analysis of the 700-mb and 500-mb constant-pressure charts if sufficient data are available for their preparation. Perturbations in the normal easterly flow should be carefully watched.

FORECASTING MOVEMENT OF TROPICAL CYCLONES

Monthly Variation in Normal Storm Track. Tropical storm development is a seasonal phenomenon wherever it occurs, embracing principally the summer and fall months in each hemisphere. In most, if not all, of the tropical-cyclone-susceptible areas the mean storm track, and to a lesser extent the place of most frequent origin, changes from month to month during the storm season. In Fig. 8 the change from month to month in the mean storm track is evident. However, from year to year the individual storm tracks scatter considerably.

May is an unimportant hurricane month in the tropical North Atlantic, with a tropical storm occurring once in only about every ten years. It is not included in Fig. 8. The official record includes no tropical storm of full hurricane intensity in May although at least

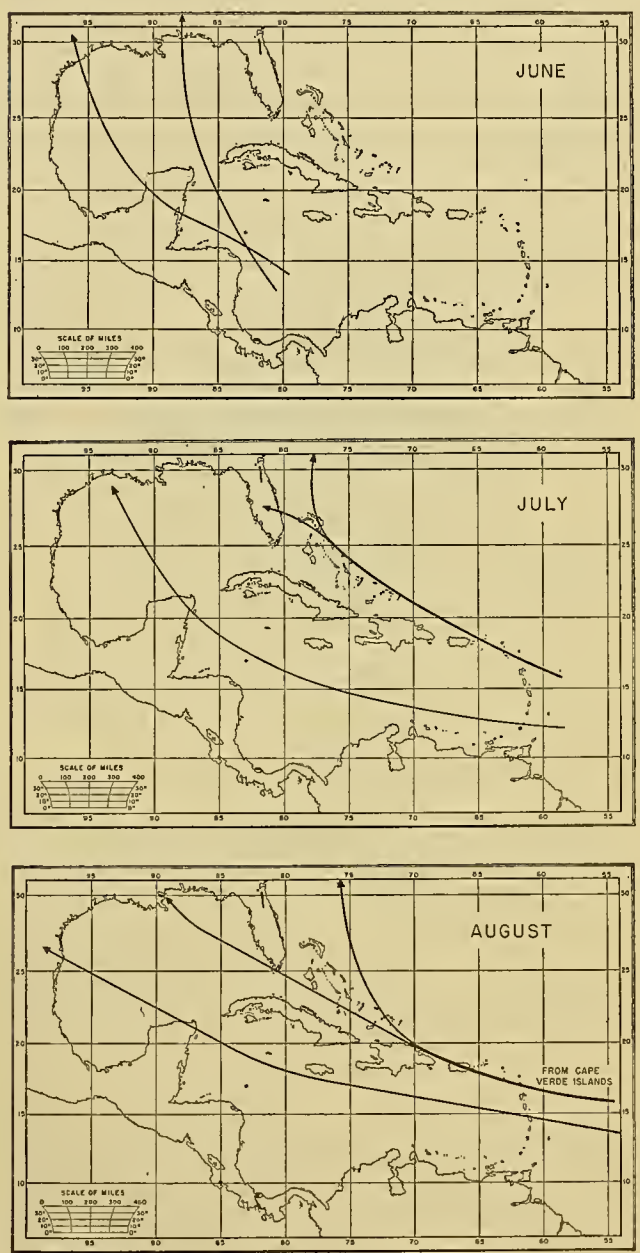

FIG. 8.—Mean track of tropical cyclones, southwestern North Atlantic Ocean, June–October. (Continued on p. 898.)

one was attended by winds of more than 60 mph for a day or more. All storms developed in the Caribbean or near Florida with one exception, the most severe, which developed to the east of Trinidad.

June storms are rather small in area but may be quite intense. A tropical storm will develop on the average every other year but one will reach hurricane intensity only once every five years. Such storms usually develop in the extreme western Caribbean or

in the Gulf of Mexico and have a strong northerly component.

Tropical storms in July are only slightly more frequent than in June and are slightly larger, but none of the outstanding hurricanes have occurred in this month. Most develop just to the north or to the south of the Antilles and have a more westerly component.

A marked increase in the frequency and intensity of tropical cyclones takes place in August and some of the most severe of record have occurred in this month. Many form in the Cape Verde region and travel across the entire Atlantic. August storms have strong westerly components and the most regular paths of any month.

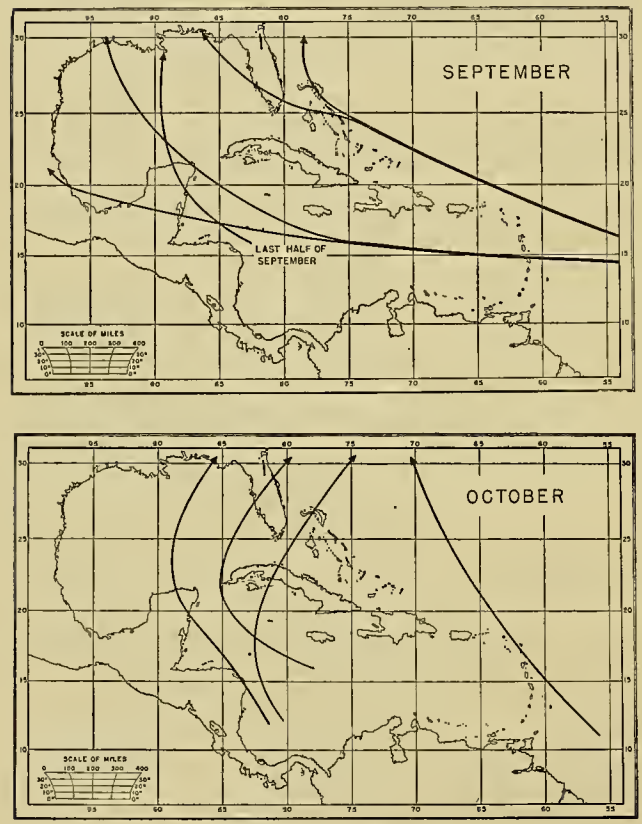

FIG. 8.—Continued

The height of the hurricane season is reached in the first half of September. During this period many still develop in the Cape Verde region. During the last half of the month the area of most frequent origin shifts back to the southwestern Atlantic and storms again develop strong northerly components as the polar westerlies move southward.

October continues to have a large number of tropical storms but the frequency and average intensity decline rapidly after mid-October. All have strong northerly components and recurve quickly. Many develop in the western Caribbean north of Panama and move northward across Cuba. Rarely do they reach as far west as Texas.

November is an unimportant hurricane month. The few storms mostly develop in the Carribbean and move northward immediately.

The stronger northerly components in the early and late portions of the tropical cyclone season and the more westerly component during the middle of the season are characteristic of all areas with the possible exception of the Bay of Bengal and the Arabian Sea. Of course, many exceptions to the mean tracks occur, depending upon the mean position of polar troughs which influence recurvature.

Steering Currents. The direction and rate of movement of a tropical cyclone are dependent upon the direction and speed of the air in which the storm is imbedded. There is no physical basis for believing the current at any single level is responsible for steering a storm, but Norton, Riehl, and others have found that the winds at or just above the top of the warm lower cell of the storm, where the vortical circulation virtually disappears, best approximate the direction of movement of the storm. This level will vary in individual storms from 20,000 ft to 30,000 ft or higher. It has been noted that most storms appear to have some deflection to the right of the steering current. The angle varies with the speed of movement of the storm, being as much as 20 degrees with speeds under 20 mph.

At times the pressure situation may be changing rapidly at the steering level and the steering current may change materially with time. Wide-scale changes of quarter-hemisphere dimensions may be taking place with resulting strong anticyclogenesis upstream, as in the Atlantic hurricane of September 17, 1947. Such a development may, in turn, alter the steering current over a large area within a 24-hr period.

Hurricane forecasters in the United States believe tropical cyclones usually move at a rate of 60–80 per cent of the velocity of the winds at the steering level, and that winds ahead of the storm are more representative than those to the rear in computing its movement. Some forecasters have indicated that the relationship between rate of movement and the 20,000-ft winds ahead of the storm is always better than the 70 per cent value.

Simpson [16] has developed a technique which he called "warm-tongue steering" for forecasting the direction of movement of tropical cyclones. This method gave good results when tested on 25 storms during the period 1941–45. An analysis of the mean virtual-temperature field between the 500- and 700-mb pressure surfaces indicated that a tongue of warmer lighter air is associated with and extends some 800 to 1200 miles in advance of the tropical cyclone. The tests seemed to indicate that a good lag-correlation exists (for 24 hr and often 48 hr) between the orientation of the warm tongue and the future movement of the storm. This correlation was least effective in small immature storms. A theoretical explanation of this relationship is not apparent. It is understood that unpublished tests by other groups fail to show substantial agreement with Simpson's results.

The problem of recurvature is the most difficult one facing the forecaster, since it takes place frequently within 24-hr striking distance of the coast line and over

oceanic areas where upper-air data are lacking. Satisfactory forecasting of recurvature is impossible without accurate constant-pressure charts. Riehl and Shafer [14] studied some 57 tropical cyclones occurring between 1935 and 1943 and classified them in groups as follows: (1) seventeen which curved north or northeastward, (2) twenty-three which continued between west and north without recurvature, and (3) seventeen which had irregular tracks, particularly motion with a southward component for a portion of the track. It should be noted that the "abnormal" storm tracks of the last group were as frequent as the "normal" tracks of the first group.

Riehl and Shafer found that a tropical cyclone will begin to react when the forward edge of the westerlies—at least as low as 8000–14,000 ft—is found 500–700 miles to the west. As the polar trough advances eastward, the storm turns from a westward to a northward path. The most difficult, though frequent, cases occurred when storms encountered strong troughs and an intrusion of the polar westerlies into the tropics similar to group (1). In that group, however, the base of the westerlies not only lowered but remained low in the subtropics and part of the tropics. In group (2), however, the westerlies died away quickly to the rear of the polar troughs and the easterlies were re-established quickly and storms continued in a westerly direction. This condition developed when a warm high follows or develops to the rear of a polar trough and also if the polar trough advances from the west against a blocking high resulting in fracture. The tropical cyclone usually responds within 24 hr after the easterlies build back to 14,000 ft and above. Group (3), the "abnormal" tracks, result from a number of causes. A storm which has already completely or partially recurved may turn back northwestward or westward when blocked by a warm high (October 13–16, 1938). A storm recurving up a polar trough may be overtaken by the trough, become imbedded in a northwesterly current, and turn southeastward (October 8–9, 1941). Storms may move southwestward when they are overtaken by a narrow trough and encounter a deep northeasterly current (November 2–5, 1935). Even at the present time sufficient upper-air information is not available to forecast or explain 5–10 per cent of the "abnormal" movement.

Forecasting direction of movement, particularly recurvature, is the most acute problem facing the forecaster. Previous checks on the correlation between the steering current and actual rate and direction of movements of tropical storms have not been completely satisfactory and, among hurricane forecasters, any further research on this problem should have the highest priority.

Forecasting Significance of Storm Swells. The appearance of a swell of a particular type may give quite reliable indications of a tropical storm as much as 500 to 1000 miles or more distant.[3] The height of the waves from which swells develop is determined by the force of the wind and the "fetch" or water distance over which the wind has blown without significant deviation in direction. According to Thomas Stevenson [17], the maximum height of a wave as a function of "fetch" is $H = 1.5\sqrt{F}$, where H is in feet, and F, the fetch, is in nautical miles.

The magnitude of waves is dependent not only upon the fetch, but also upon the wind velocity. Over oceanic areas with 600–1000 miles or more of sea room, waves 35–40 ft high are developed in ordinary storms and in more intense storms may exceed 45 ft. According to Cline [1], the quotient obtained by dividing the wind velocity (probably average for one hour) in miles per hour by 2.05 represents the average height in feet of waves developed by the wind. This should be used with caution and only as an approximation, since there are always other factors to be taken into consideration, and a wind, constant in speed and direction (in a hurricane at least), does not act on a wave for any great length of time. The breaking wave or swell is one of the most destructive elements of a tropical cyclone, since a cubic yard of water weighs about 1500 pounds and waves moving forward many feet per second may be very destructive to beaches and harbor facilities, especially when they contain debris such as tree trunks and heavy beams.

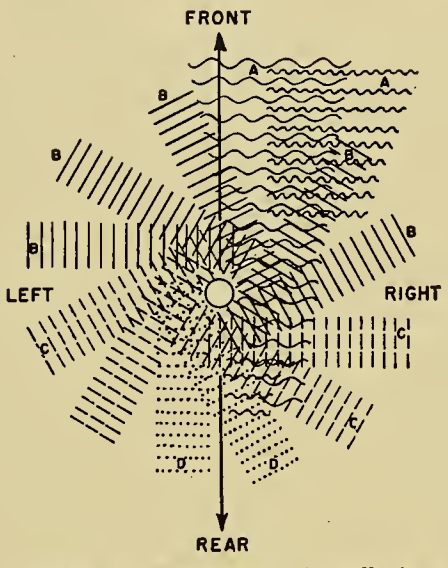

Fig. 9.—Schematic development of swells in a tropical cyclone:
A—swells of greatest length and magnitude, traveling in the line of advance of the tropical cyclone.
B—swells and waves of moderate length and magnitude in the front segment moving outward to the right and left of the line of advance.
C—swells and waves of smaller length and lesser magnitude in the rear segment moving outward to the right and left of the line of advance.
D—swells and waves of least magnitude moving outward from the rear of the hurricane. (*After Tannehill.*)

The generation of swells in a tropical cyclone is a rather complex phenomenon because of the curving wind flow. Therefore, since the wind-generated waves move in the same direction as the wind, swells tend to emanate in all directions from the center of the hur-

3. Consult "Ocean Waves as a Meteorological Tool" by W. H. Munk, pp. 1090–1100 in this volume.

ricane. Waves generated in the right half of the storm travel *with* the storm, so they are under the influence of winds with relatively little deviation in direction for a longer time, *i.e.*, they have a comparatively long fetch. Thus the strongest swells, which move through the storm and eventually a long distance ahead of the storm, are produced in this half. Conversely, swells traveling opposite to the direction of movement of the storm will be weaker. (See Fig. 9.)

It has been stated earlier that swells emanating from the region of a tropical cyclone are useful in its early detection and location and in the determination of its intensity. Swells also have further forecast value. If the direction of movement of the swells remains the same, the storm is either approaching directly or going away from the observer. If the direction changes counterclockwise, the storm is passing from the observer's right to his left; if it changes clockwise, it has passed or is passing from his left to his right, as he faces the swell. The direction from which the swell approaches indicates the direction of the storm from the observer at the time the swell was generated.

Forecasting Significance of Storm Tides. Particularly along the shore lines of partially enclosed bodies of water, such as the Gulf of Mexico, tides have some forecast value. Abnormally high tides are indicative of the presence of a storm. An area along the coast line where the tide exceeds the predicted gravitational tide and continues rising is in line with the advance of the tropical storm at the time the water started on its journey. If the point of greatest plus departure from the predicted tide shifts right or left, this indicates that the storm is changing direction toward the point where the increased rise is taking place.

Microseisms. Microseisms are more or less regular elastic surface waves which may result from a number of causes, including ocean waves and surf. Microseisms of these two types may be propagated over considerable distances, if no deep geological discontinuities exist, and may be measured at seismographic stations. Gutenberg [8] has pointed out that the location of tropical cyclones, and their intensities, direction, and rate of movement, can be determined from the differences in arrival time at three stations on a triangle, by plotting relative amplitudes and considering the changes with time. It appears that this technique might have its greatest application where airplane reconnaissance and ship reports are not available.

NEEDED RESEARCH ON TROPICAL CYCLONES

Additional Data Required. Since tropical cyclones usually develop in and often traverse remote oceanic areas, the acquisition of data required for a rigorous evaluation of many of the current theories of structure and development of these storms and for a solution of urgent forecast problems has been difficult or impossible. This is especially true with respect to upper-air information. Since tropical cyclones are relatively small, a denser network of observing stations is a prerequisite to further progress. Over large oceanic areas upper-air data have been negligible. Southern and western Florida, the most hurricane-susceptible area in the United States, would provide an excellent laboratory for hurricane study if a satisfactory network of observing stations could be set up. This network should be supplemented by a fleet of "weather-trucks" and mobile weather stations which could be dispatched and located to form any desired observing grid. Over adjacent water areas squadrons of planes, equipped with the latest meteorological devices for measuring winds, convergence, divergence, updrafts and downdrafts, should be dispatched into and over the storm area for inflight and parachute-radiosonde observations. Photographs over the top of the storm and in the eye should be taken for study purposes. For a period of at least two years, during the hurricane season, stationary ships should be placed at 300–500 mile intervals in the Gulf of Mexico, in the Caribbean Sea, and between latitudes 8°N and 30°N in the Atlantic for the purpose of securing regular surface and upper-air observations.

Urgent Research Needs for Forecasting. *Antecedent Prerequisites for Tropical Cyclone Development.* The exact combination of conditions which produces tropical cyclones must occur rarely, since the phenomenon itself is infrequent. The original causative factors which change the normally very weak and transitory pressure and wind deformations in the trades and the intertropical convergence zone to unstable waves and from the latter to intense tropical storms are not fully known. The testing of Riehl's recently published ideas on tropical cyclogenesis based on the interaction of surface perturbations and upper troughs and ridges should have very high priority as a research project. Radiosonde data, preferably from stationary ships, would be required. In the event the currently most persuasive theories are not substantiated, the new data would prove invaluable in deriving new ideas and further clues on the origin of tropical cyclones.

Differences in the intensities of tropical cyclones, which may be of the order of 80 to 90 mb, appear to depend upon apparently slight differences in the moisture and stability of inflowing air during the stage of marked development, with little change thereafter. Practicable techniques of adequately measuring and determining these differences and the establishment of criteria for limiting pressure gradients and wind shears in the developing storm would provide valuable tools for the forecaster.

Effective Steering Level. Although forecasters are using certain techniques based on steering at some arbitrary level or immediately above the storm circulation, further objective tests of these empirical rules are desirable. Recurvature is the most difficult problem facing the forecaster and, while lack of adequate observational data may always be a problem in certain areas, more definitive techniques seem possible.

Research Needed for More Complete Knowledge of Tropical-Cyclone Structure. 1. Tropical meteorology is deeply in debt to Father Deppermann for his painstaking assembly and analysis of typhoon characteristics in the Philippine area, but a further systematic collec-

tion of all observational data from tropical cyclones for statistical and physical analysis is badly needed. Evidence is far from conclusive about the actual facts with respect to the shape of inner isobars, the symmetry or asymmetry of distribution of certain elements around the storm, pressure-gradient and wind relationships, and many other characteristics which are taken more or less for granted at the present time.

2. Further studies are required to determine the exact relationship between the computed cyclostrophic term of the gradient wind and the observed wind, as a function of wind direction, velocity, storm movement, and other characteristics. More data on the actual pressure-gradient and wind-velocity relationships are needed.

3. Theories on the exact mechanics of evacuating air from the storm area are mainly deductive in nature, and data are insufficient to substantiate or disprove them. It should not be too difficult to obtain the necessary data from properly equipped airplanes.

4. A flight by Wexler [21] into a tropical cyclone in a plane equipped with a radio altimeter indicated areas of convergence considerably at variance with the normal concept of convergence and divergence in the storm area. It should be noted, however, that the storm was in an advanced stage of recurvature. Again the accumulation of data required for an answer to this question should not be difficult. Traverses should be made into storms at lower latitudes.

5. By means of planes or parachute radiosondes, more observational data, including rate of descending air, should be secured from the eye of the storm.

AEROLOGY OF TROPICAL STORMS

By HERBERT RIEHL

University of Chicago

INTRODUCTION

One of the earliest controversies that arose in regard to tropical storms concerned their vertical extent. Some writers claimed that disturbances disappeared at heights as low as 3 km—that people standing on high mountain tops could look down on the violent cyclonic whirls beneath them. They believed that the cirrus motion at upper levels remained undisturbed and indicated the direction in which the cyclone was moving. Others insisted that hurricanes must reach to great heights, 10 km or more. They thought that cirrus radiated in all directions from the storms and used the change of direction of cirrus movement with time to locate position and track of centers.

The answer to this argument is now well known. As shown theoretically by Haurwitz [17] and empirically by high-level observations, mature storms extend through the troposphere. This affects such practical problems as routing of aircraft and forecasting storm movement. Since storms extend to the high troposphere, the upper layers should in part control the movement. We cannot hope to find the solution solely on sea-level or low-tropospheric charts, which very often do not reveal the state of the upper levels.

As we ascend from the surface to the higher atmosphere, the simple trade-wind current and the clear demarkation line separating tropics and middle latitudes disappear. Above 500–400 mb we encounter a chain of complex vortices of large dimension that are interlocked with the troughs and ridges of the long waves in the westerlies [27, 29]. Interaction between low- and high-latitude disturbances largely controls short-term developments in the tropical vortex train aloft and affects the motion of typhoons and hurricanes. It also plays a decisive role in the events that lead up to storm generation.

Formerly, formation and movement of hurricanes was forecast with detailed local analysis in a small area of the tropics. Since we know today that external forces are a major variable, we must expand the map analysis to include wide regions of the globe at all latitudes. Nevertheless the possibilities of detailed analysis are by no means exhausted. A complete three-dimensional description of hurricanes, such as has been rendered for middle-latitude cyclones, is as yet in the distant future.

In the following pages we shall consider the state of knowledge regarding the structure, formation, and movement of tropical cyclones. Since all knowledge depends on the observations and their evaluation, we shall begin with tropical data and methods of analysis.

TROPICAL DATA AND METHODS OF ANALYSIS

Observations. Tropical storms form and move over water. Therefore the number of observations available for analysis and forecasting have always been notoriously scarce. Even if perfect forecast methods were developed, the actual prediction would largely remain a guessing game for this reason. Apart from persistence and statistics on mean paths, even the best forecast method cannot help if there are no observations.

The data useful for three-dimensional analysis are cloud observations, and commercial-aircraft, pibal, rawin, and raob reports. Cloud observations and reports from commercial aircraft are most frequent, least costly, and also least useful. Wind observations from aircraft help only if pilots take double or triple drift measurements. This seldom happens. A good description of the state of the sky in surface observations still is hampered by the archaic code. Writers have pointed out the variety of cumuliform clouds that exist and have shown that broad inferences can be drawn from knowledge of the field distribution of cumulus types; but the code admits only the conventional L_1, L_2, and L_3 clouds.

Many forecasters have also complained that the quality of cloud reports has gone down with the advent of sounding balloons. This holds particularly for direction of middle- and high-cloud drift. At the beginning of this century the quality of these observations was high and the nephoscope was in frequent use. In those early days some of the articles which appeared were based on information about wind currents at high levels which we cannot match today. No wonder that some of the deductions rose far above the general level of the day and that they still form our major source of knowledge on upper-air currents over many areas, notably the tropical Atlantic Ocean.

It is unreasonable that the tropical forecaster should be deprived of the potentially largest source of information and have to rely on the few stations with expensive sounding-equipment. The writer proposes the following action:

1. Revision of the surface code to permit inclusion of at least three types of cumulus in one message. (There are about eight basic types that should be entered in the manuals on surface observations.)
2. Insistence on careful estimates of altitude and motion of middle and high clouds. (The code should allow for transmission of cloud direction in two layers.)
3. Installation of nephoscopes at all stations that make six-hourly reports, on naval vessels, and on reliable commercial ships on the principal shipping lanes.

Instrumental Measurements. Up to the present, the pilot-balloon observation has enjoyed the widest use among the instrumental measurements, but its drawbacks are numerous and well known. Balloons seldom reach the high troposphere. They are lost in clouds. In bad-weather areas where information is most needed,

wind data are often missing completely. Gradually, rawins should replace pibals everywhere.

The value of the raob in tropical analysis has been much discussed. This writer, along with others, used to think that they were useless. Horizontal gradients of pressure and temperature in the tropics are very small. At 300 mb, the height gradient may be as low as 200 ft per 10 degrees of latitude. A small error in sounding evaluation will produce an error of this magnitude at 300 mb. Moreover, local horizontal temperature gradients can be as large as the synoptic gradients. A single observation with such errors can grossly distort a whole map pattern.

In spite of these difficulties, raob analysis has turned out to be valuable when we are concerned with reports from stations where the quality of observations is high, such as San Juan in Puerto Rico, Swan Island, and Honolulu. Time sequences, especially when considered together with wind data, are reasonable. Obviously incorrect soundings are rare at such stations and stand out very clearly, especially in the case of nighttime observations. The soundings taken during the day give more erratic results and are not so useful. It is suggested that nighttime soundings be continued and expanded.

Methods of Analysis. *Area to be Analyzed.* As already noted, recent years have brought to light the strong influence that the upper layers exert on surface conditions. They have also revealed the large extent of interaction across the subtropical ridge. Thus tropical analysis should be extended to high levels and high latitudes. Writers, however, disagree on the usefulness of cross-equator analysis for short-term hurricane forecasting. Some, for example, state that West Pacific and Indian Ocean typhoons form *following* an intensification of flow across the equator. Others maintain that such an increase occurs *after* and *in consequence of* typhoon development. This writer has seen instances of the second type of situation but would not maintain that this is always the case. Experimental analysis across the equator is obviously useful. But as yet we cannot say that its value for short-term forecasting has been proven.

Contour Analysis. As in higher latitudes, the interest of the analyst centers on the fields of mass and motion. Since tropical storms decrease in intensity upward, surface analysis is a logical tool in hurricane situations. Outside of storm areas, Riehl and Schacht [32] have proposed adoption of the 850-mb (5000-ft) level as the basic level in order to eliminate many of the local features contained in surface reports.

Upper levels in regular or experimental use are 700, 500, 300, and 200 mb. The 700-mb level is situated in the center of the lower trade stream and reflects the disturbances in this current very well. At 500 mb we are in the zone of transition from trade-wind to upper-vortex regime. Winds are light and variable and height gradients are erratic. This surface often is not suitable for hurricane work, especially in the Pacific. Even the 300-mb level is not very satisfactory, although it serves well for many purposes of general tropical forecasting. Over the western portions of the oceans in summer, the high tropospheric vortices reach their greatest intensity near 200–150 mb. Analysis of the 200-mb level is essential for hurricane forecasting.

Because of the uncertainties involved in drawing contours in the tropics, described earlier, differential analysis and time sections must supplement the contour fields at all times. There is also the question of the pressure-wind relation. Opinions differ widely as to the latitude at which the gradient-wind relation becomes useless. It has been noted that aircraft dispatched with the "pressure-pattern" method [1] have arrived at their destination with considerable exactness in low latitudes. Some authors wish to apply the thermal-wind equation even at latitude 5°. Of course, there must be variations with synoptic conditions. In a strongly disturbed region, cross-isobar flow will be pronounced. It is of obvious importance to determine the true nongeostrophic flow. This could be done by using the pressure-pattern method to dispatch aircraft at different levels in selected situations and calculating the drift of the aircraft and the error between the computed and actual flight time. Until this is carried out, it is hazardous to make assumptions about the size of the angle between streamlines and contours when drawing upper-level charts.

Streamline Analysis. Because of the weak contour gradients that prevail especially at low levels outside of storm areas, streamline analysis can bring out many details of the field of motion. Some analysts, including the writer, at times have replaced contour and isobaric analysis entirely with qualitative streamline methods. The lines are drawn parallel to the wind direction and qualitative allowance for convergence and divergence is made by starting and ending some streamlines. Although this technique leads to clear and illustrative-looking charts, it has a distinct drawback: the charts are not suited for computations. An alternative is the construction of exact streamline and convergence charts. There is no doubt that exact streamline fields are one of the best potential tools for future research, especially for research concerning the structure of hurricanes.

Stability Charts. Since the thermodynamic hypothesis of tropical storms is the oldest, the literature carries many descriptions of vertical stability conditions in and near hurricanes. The trade-wind inversion disappears in storms. It has been a favorite argument to say that moisture accumulates under an inversion over the oceans. Then, as the inversion breaks down through heat accumulation below, or for some other reason, large quantities of water vapor suddenly become available for upward transport and condensation. The release of this latent heat provides an unbalanced energy source and can initiate storms.

This writer has applied this argument to the problem of driving mechanisms for the general circulation in low latitudes [29]. Local application to incipient hurricanes, however, has not proved fruitful. Storms often form in an atmosphere that has been nearly moist-adiabatic for a long time. We know that the steepest lapse rates occur in subsiding dry air above the trade inversion. Except for analysis of the inversion itself, the writer believes that stability charts are not likely

to yield results beyond the obvious. But the subject is popular, and there will be no shortage of studies of the stability consideration in the future.

Base of the Westerlies. Preparation of charts showing contours of the base of the westerlies (axis of the subtropical ridge) have been proposed by Riehl and Shafer [33]. Such charts can be a potent analysis tool. They furnish indications of temperature distribution and baroclinity of the atmosphere that greatly help to determine the upper-contour analysis where there are no raobs. The base of the westerlies is tied to many empirical forecast rules on hurricanes. For example, many storms develop from just south of the latitude where the base reaches the high troposphere (200 mb). If there is no base at all and the easterlies increase upward in intensity through the troposphere, hurricane development is not common. In the same situation, existing hurricanes will be steered strictly by the deep easterly current. The writer suggests that this simple tool be tried out in practice.

STRUCTURE OF TROPICAL STORMS

The early literature carries long and sometimes acrimonious debates on the structure of tropical storms. In recent years the arguments have abated. It has become clear that the structure varies with the age of a storm. Hurricanes that are just forming differ from those that have attained full intensity and those that are leaving the tropics. The stage of the fully grown storm has attracted the greatest amount of attention. Mature storms may travel wide distances over the tropical oceans with relatively little change of structure, and it is possible to make attempts at application of steady-state dynamics. In this section we shall also concern ourselves with mature storms.

Thermal Structure of the Rain Area. Observations taken during the last ten years have confirmed the classical idea that the air in the interior of tropical storms is less dense than its surroundings. A detailed discussion of radiosonde observations in hurricanes has been given by Schacht [37], Riehl [26], and Palmén [23]. The principal result is the following: Inside the rain area the vertical temperature distribution is the same as that obtained by raising an air particle dry-adiabatically from the sea surface to the condensation level, and then moist-adiabatically to 200 mb or even higher (Fig. 1*a*). Byers [6] adequately likens the hurricane to a huge parcel of air. Temperatures observed aloft in the rain area are the highest possible that can be obtained through ascent.

The situation is quite different from the ordinary zones of organized convection in low latitudes (wave troughs, shear lines). In these disturbances some ascent of surface air takes place. But convergence extends to relatively high levels (700–500 mb). Air initially situated anywhere between sea level and 500 mb is entrained and moves upward. Usually, this air is unsaturated at first and its moisture content is lower than that of the surface air that has risen. As shown by Stommel [41] and others, entrainment lowers the virtual temperature aloft in cumulus clouds compared to that which would prevail without entrainment. Very often air at upper levels in the convective zones is actually denser than the surrounding air. As shown by rawins, the cyclonic circulation increases upward in intensity.

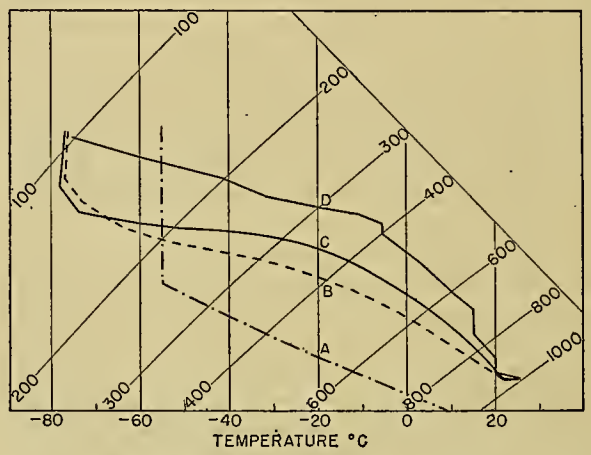

FIG. 1*a*.—Tephigram showing (*A*) U. S. Standard Atmosphere, (*B*) mean tropical atmosphere of the Caribbean in summer [37], (*C*) sounding in rain area of hurricanes, and (*D*) eye sounding [28]. In the diagram vertical lines are isotherms (°C) and slanting lines isobars (mb). Curve *C* follows a moist-adiabatic path from 900 to 200 mb.

Comparison of the vertical structure of these disturbances with tropical storms forces us to the conclusion that entrainment does not take place in the core of hurricanes and that convergence is restricted to the mixed "subcloud" layer [5].

The question arises, Does the foregoing hold true over the entire rain area? If it does, horizontal temperature gradients should not exist in the rain area,

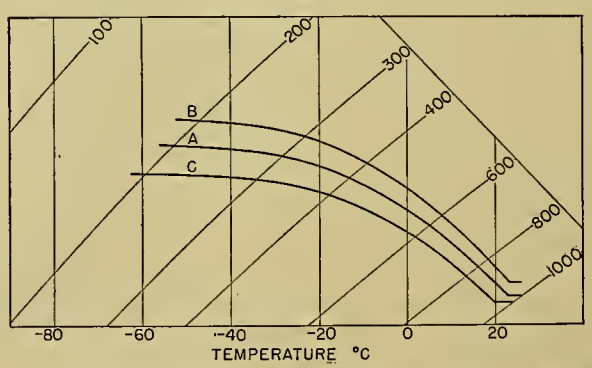

FIG. 1*b*.—Tephigram showing (*A*) ascent curve of surface air with T = 26C, spec. hum. = 18 g kg^{-1} (repetition of curve *C* of Fig. 1*a*), (*B*) ascent of the same air after isothermal expansion to 960 mb and moisture increase of 1.5 g kg^{-1}, and (*C*) ascent of surface air with T = 24C, spec. hum. = 16 g kg^{-1}.

and there should be a frontlike boundary at its outer edge. Deppermann [11] postulated such a boundary when, on the basis of empirical evidence from the Philippine area, he spoke of an outer and an inner ring of convection. The notion of a "wall" of hurricanes, often mentioned, supports Deppermann.

Palmén [23] was the first to venture a detailed vertical cross section through a hurricane. He showed, con-

trary to Deppermann, a gradual horizontal increase of temperature across the rain area, based largely on three-hourly special radiosonde observations at Miami, Florida, during the approach of a severe hurricane in September, 1947. Other series of special observations also fail to disclose a sharp boundary.

Several explanations of the difference between these authors are possible. Of these the most plausible one is that conditions are not symmetrical around hurricanes. A "wall" may be present in one or two quadrants but not the others. There is another interesting possibility. As pointed out by Byers [6], the temperature of the surface air spiralling toward a center must fall 3C or more during horizontal motion because of the large pressure reduction. Such a temperature decrease is seldom, if ever, observed. The temperature difference between ocean and surface air suddenly increases with lowering air pressure. As the ocean is greatly agitated and as large amounts of water are thrown into the atmosphere in the form of spray, very favorable conditions exist for rapid transfer of sensible and latent heat from ocean to air. Such transfer could account for a gradual increase of upper-level temperatures across the rain area. Figures 1*a* and 1*b* show that the effect referred to is very large. It roughly doubles the size of the positive area enclosed by inside and outside soundings on the thermodynamic diagram.

Microstructure of the Rain Area. There is conclusive evidence that conditions are not uniform as we circle a hurricane. Deppermann [10] showed that barometric fluctuations of shorter period are superimposed on the general barometric trace. These fluctuations have different periods, varying from minutes to hours. Deppermann [10] associated them in part with variations in cloud thickness and rain intensity.

The existence of a nonuniform cloud structure was proved by radar photographs of cloud systems in hurricanes [43]. On these photographs we can see that the rain area is composed of a number of bands of heavy precipitation that alternate with more settled conditions. The bands spiral cyclonically toward the center. Photographs of this kind have since been taken in large numbers. Further descriptive and analytical discussion of this aspect of the microstructure is one of the more interesting topics that await the investigator. A possible explanation is the development of internal waves. Another is the effect of falling rain and vertical downdrafts as discussed by Byers and Braham [7]. An analogy between the radar bands of Wexler and the thunderstorm-cell propagation proposed by Byers and Braham is by no means illogical.

Thermal Structure of the Eye. The eye of the hurricane has held the attention of all who have written on hurricanes from the earliest days. It is one of the oddest curiosities in meteorology. The precipitation ceases abruptly at the boundary of well-developed eyes, the skies clear, and the wind subsides suddenly. Observers inferred early that the vertical motion in the eye should be downward, the air therefore very warm and dry. Some thought that the tropopause was "sucked down."

Aerological observations have confirmed a part of these inferences. Pilots flying into eyes at various altitudes have reported large and sudden temperature increases. The best evidence comes from two radiosonde flights taken at Tampa, Florida, in two hurricanes [28, 39]. It is, of course, very difficult to send up balloons in an eye. In particular, there is no certainty that the balloons were still in the eye when they reached the high troposphere. In both cases, however, the eye was large. Chances are good that the balloons did not drift outside and that the temperatures reported at all levels are really indicative of the structure of vertical columns.

The sounding of October, 1945 [28] (Fig. 1*a*) showed great stability in the lower troposphere and a very steep lapse rate higher up. From the 100-mb level downward, temperatures were higher than otherwise observed in the tropics. Departures from the normal tropical atmosphere were extreme from 800 to 400 mb. They indicated subsidence amounting to several kilometers. The two Tampa soundings disagreed as to temperature in the high troposphere. In the case described by Simpson [39] the air above 300 mb was colder than that outside the eye. This observation is very difficult to interpret. The October 1945 ascent showed equalization of temperature with the surroundings only near 100 mb. Above this level, the air probably was colder inside the eye, so that the entire thermal structure relative to the outside resembled that of dynamic highs. Neither sounding reached the tropopause, and there was no evidence of "sucking down." On the contrary, it is probable that the tropopause is highest above the eye, again in analogy to warm anticyclones.

The extremely warm air of the eye is necessary to explain the very low surface pressures observed, at least statically. Haurwitz [17] has shown that application of the hydrostatic equation is entirely valid for computations of the vertical pressure distribution even in hurricanes. We can calculate, for example, what reduction of sea-level pressure is possible if the normal tropical atmosphere is replaced by the atmosphere of the rain area and if the pressure remains constant at the level where the two soundings intersect. This reduction is of the order of 30 mb and may reach 40 mb on the outside. It does not suffice to explain the very low sea-level pressures observed in many cases (900–950 mb). If we introduce an eye with a sloping boundary, however, following Haurwitz [17] and others (Fig. 2), the problem is resolved. Introduction of air still warmer than that of the rain area makes possible additional large pressure reductions.

Broadly speaking, the thermal structure of the eye, at least below 300 mb, is relatively well established. Many observations, of course, are needed to give all details, especially the slope of the boundary at different heights. Such observations would be of great scientific interest, but probably of little practical value.

Dynamical Aspects of the Rain Area. The thermal structure of the rain area permits some direct inferences regarding the dynamical structure of hurricanes. We have seen that soundings in the rain area coincide with

the computed ascent curve of air from the mixed layer. It followed that the entire rain area of a mature storm consists of air that has risen from the vicinity of the surface. The low-level convergence is restricted to the mixed layer, and a level of nondivergence is situated at its top.

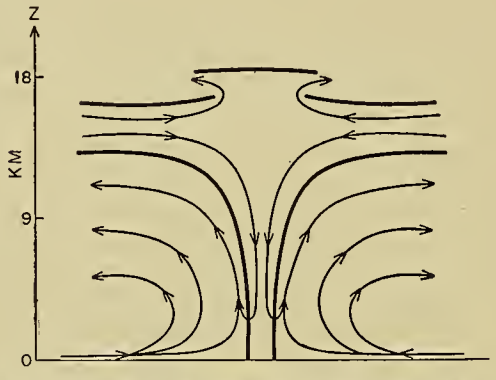

FIG. 2.—Vertical cross section through mature tropical storm showing hypothetical model of the vertical circulation. Heavy solid lines are eye boundaries and tropopauses. The model is based in part on Durst and Sutcliffe [13], Wexler [42], and Palmén [23].

Heat Transfer. We can estimate the size of the area from which a hurricane must draw surface air in order to build up the thermal structure actually encountered in the interior. Let r_0 denote the radius of this area and r the radius of the rain area as encountered. The eye may be neglected for this computation since its area is very small (10 per cent or less of the rain area). The depth of the mixed layer is about 50 mb and the clouds extend at least to 200 mb. It follows that $A_0 = 16A$, where A_0 is the initial area and A the rain area. Also, $A_0 = \pi r_0^2$ and $A = \pi r^2$. Therefore, $r_0 = 4r$. If $r = 100$ km, a moderate value, $r_0 = 400$ km, and the diameter of the initial area is about 8 degrees of latitude. This is a large value and shows how far the influence of even a small storm extends during the time of formation. In the course of its further life history, a very sizable fraction of the surface air initially situated over a tropical ocean is drawn into the circulation.

Up to now, no one has calculated the total effect that storms can exert on the general circulation as a result of the upward transfer of heat. Evidently an enormous gain of heat—both sensible and latent—accrues to the upper troposphere from the large-scale funnelling. It has been suggested that the frequency of tropical storms should be great when the normal processes of heat exchange between low and high levels are weaker than usual for some reason. But so far it has not been possible to establish a clear relation between hurricane frequency or duration and other factors of the general circulation.

Wind Distribution near the Surface. Estimates of lateral convergence of air into tropical storms and the amount of vertical motion present usually treat instantaneous values only, rather than totals integrated over some unit of time. Many observations have been published on the rate of inflow near the ground, as determined from surface-wind measurements. General laws, however, have not been formulated. The rate of inflow is quite variable. Usually it is not symmetrical, but confined to one or two quadrants. During the life of one storm, the quadrant of greatest inflow will often change.

Various forecast rules have been offered concerning the relation between storm movement and quadrant of greatest inflow. One such rule states that a storm will move toward the region of heaviest rainfall (greatest convergence); another states that the heaviest precipitation occurs to the rear of a center. Observations can be found to demonstrate practically any relation between direction of motion and rainfall concentration. This merely shows that a variety of synoptic influences are operative. A considerable advance could be gained through a serious attack on the connection between synoptic situation, distribution of convergence, and storm motion.

Our knowledge regarding the wind distribution within tropical storms and the dynamical laws that guide the air from the outskirts to the center of the cyclones is so deficient as to be deplorable. Deppermann is one of the few writers who has made a detailed effort to calculate radial and tangential velocity components. He also has presented a theoretical model [11] which discusses the tropical storm as a Rankine vortex with two "rings" of convection. Apart from Deppermann, writers have contented themselves with application of simple hydrodynamics, generally only a treatment of the vr vortex. The best discussion is found in Brunt's textbook [4, pp. 298–306]. Even Brunt, however, treats only a few elementary concepts—circulation, vorticity, and the wind distribution in a stationary vortex with point convergence at the center.

It is easy to understand why the synoptic meteorologist is discouraged from attacking the problem of the dynamics of the tropical storm. He rarely has data at his disposal for which he can claim general validity. But the apathy on the part of theorists is hard to comprehend. To the best of the writer's understanding, no laboratory experiment has been carried out to determine whether "simple" vortices can be generated in air as in liquids. It would be quite feasible to construct theoretical hurricane models, dropping some of the assumptions contained in the simple theory. If the air did move under conservation of momentum, the absolute rather than the relative motion of air about a hurricane center should be considered. The absolute rather than the relative vorticity should become zero throughout the body of a hurricane. This, however, never happens. There are a few famous cases—often quoted—in which the relative vorticity was found to be nearly zero. Since we know of no physical law that demands conservation of relative angular momentum in a hurricane, the rare cases quoted must be regarded as accidental.

It is certain that the absolute angular momentum is not conserved in the air flowing toward a center. Ground and eddy friction can be responsible for this, as well as the asymmetrical shape of many storms. None of these factors has been properly investigated, especially the

important frictional term in the equation of motion. As a prelude for further objective work, an extensive theoretical study should be executed.

Upper Outflow. The laws governing the outflow aloft (Fig. 2) have been described more satisfactorily than those governing the lower inflow. The pressure-gradient force decreases upward on account of the temperature distribution and the gradient actually reverses above 10–13 km [37]. Outflow will take place throughout the layer of decreasing pressure gradient if the air conserves its absolute angular momentum [13]. This conservation principle is more likely to hold true for the upper outflow, since ground friction is absent. Above the friction layer, the principal problem is the almost complete absence of data. There are many reasons that suggest an upward decrease of the circulation. Such wind measurements as have been made have shown the decrease and eventual disappearance of the vortices between 300 mb and 100 mb. In some cases, the circulation has actually become anticyclonic at 200 mb.

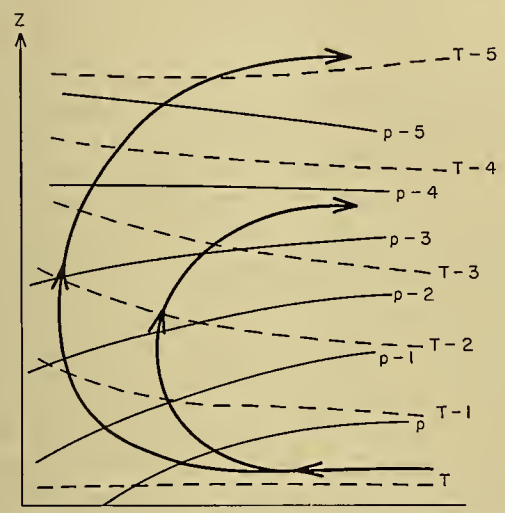

FIG. 3.—Same as Fig. 2, outside the eye. Solid lines are isobars and dashed lines are isotherms.

Dynamical Aspects of the Eye. The only explanation given for the eye so far is that the law, vr = const, cannot hold near a vortex center, as wind speeds and kinetic energy there would have to become infinite. Friction alone would act to prevent this. This negative statement is reasonable, but it hardly explains the absolute calms frequently observed or the variable diameter of eyes. We also have no knowledge concerning the rate of vertical motion in the eye. The direction evidently is downward, at least below 300 mb. Convergence must exist in the upper troposphere and divergence in the lower layers [28]. This is indicated by the stability distribution in the few available eye soundings (Fig. 1*a*). It follows from continuity reasons that air must constantly seep through the boundary of the eye in the low troposphere and enter the rain area. Beyond this statement, little progress is likely to take place in the future until actual observations of winds aloft in and near eyes become available.

Maintenance of Tropical Storms. Qualitatively, it is easier to understand the maintenance of tropical cyclones than of extratropical storms. The pressure decreases toward the center and the temperature rises (Fig. 3). Air moves inward near the ground and upward in the central region of convergence, while the outflow is aloft. Thus the circulation about the vertical solenoids is in the kinetic-energy-producing sense (excepting the eye). This solenoid field will be maintained as long as colder air with lower moisture content does not enter the center; and as long as the air evicted aloft does not descend in the immediate outskirts but is removed considerable distances. A hurricane and its surroundings cannot be a closed thermodynamic system.

As the maintenance of tropical storms does not appear to offer very difficult problems in principle, future research can turn to quantitative considerations: the measurement of heat generation, conversion into kinetic energy, frictional dissipation, etc. Again the need for accurate data stands out as the foremost requirement to advance such research.

FORMATION OF HURRICANES

Scanty as is the literature on storm structure, the number of papers written on formation is very large. Up to very recent days, investigators generally have sought some grounds leading to extensive surface convergence and attendant development of cyclonic circulation. As Brunt [4] points out, the question of the upper outflow necessary to account for the observed surface pressure falls has not been answered. Convergence near the ground should lead to pressure rise and not fall at the center. This is a basic paradox of meteorology, an obstacle to the explanation of extratropical as well as tropical cyclones. It is true that upper warming caused by convection currents will produce radial outward acceleration aloft. Yet it is not clear—and has not been shown—why this outflow should become greater than the inflow. If the low levels lead in producing storms, the surface convergence must precede the high-level divergence. It is only in the last few years that attempts have been made to reverse the problem and consider the high-level events as leading [30, 35]. If these attempts should sustain the test of time, it would follow that the low-level convergence develops as a reaction to the pressure changes imposed from aloft.

Convection Theory. The classical thermodynamic (convective) theory of hurricane formation has few defenders today. Many of the heaviest tropical rainfalls occur without the existence of a cyclonic circulation, and even closed depressions with torrential precipitation often fail to deepen. Such centers have been observed to travel in relatively steady state over distances in excess of 1000–1500 miles. It follows that convection is not a sufficient criterion for storm development.

No one, however, denies that convection is necessary for generation of tropical storms. As stated before, the air that fills the body of a hurricane is all drawn from the mixed layer near the surface. Therefore the properties of the surface air and their variation with time in part determine whether or not storms will form. Pal-

mén [23], for example, notes that the temperature difference between air ascending from the surface and the surroundings aloft is much less in winter than in summer at Swan Island (17°N, 84°W). There are no hurricanes over the Caribbean Sea in winter. Storm occurrence is also rare over the cool waters of the eastern parts of the tropical oceans. It is most plentiful in the west where the sea surface is warmest. By analogy, it is possible to argue that storm frequency should be less than average in a year when the sea-surface temperature is below normal.

It is evident that research following up this suggestion can prove most fruitful. Caution, however, is necessary in interpretation. Temperatures aloft are as much of a variable as surface temperatures. Anomalies of temperature at different altitudes may not be independent of each other but produced by some common dynamical factor. The same may be true even for sea-surface temperatures.

Frontal Theory. Ever since the formulation of the polar-front theory there have been persistent attempts, beginning with that of Brooks and Braby [3], to transplant the Bergen reasoning to the equatorial zone. Advocates of this theory visualize the equatorial convergence zone (ECZ) as a front with inverted temperature gradient. The peaks of warm sectors and developing cyclone centers should therefore be found where the ECZ bulges equatorward. Actually, there is practically universal agreement today that forming centers are initially situated near poleward bulges. This observation has led some analysts to become skeptical regarding the wholesale importation of the Norwegian ideas into the tropics. A large group of meteorologists, however, today adhere to the view that hurricanes are generated at boundaries between warm and relatively cold air. Even textbooks of high renown (Brunt [4] p. 304) carry statements to that effect. Brunt, however, is quite conscious that the frontal approach solves the basic cyclone problem no more in low than in high latitudes.

It is not possible here to examine in detail the reasoning of the adherents of the frontal theory. Only one additional point will be presented that throws doubt on the validity of the frontal concept. This is again the matter of the properties of the surface air. If a rapid occlusion of a portion of ECZ takes place, when there is a real density difference across this boundary, the whole surface layer of the nascent cyclone will soon consist of the denser air only. This must prevent deepening. It is a principal difference between high- and low-latitude cyclones that all air entering the orbit of the latter ascends in the core, while outside the tropics the polar air sinks in disturbances and only the tropical air rises. Occlusion must be an acute hindrance to hurricane development. Actually, we can observe that even mature hurricanes weaken and sometimes disappear when a current with relatively polar characteristics enters the core while it is still situated in the tropics. A forecast of filling will generally succeed in such cases.

For comparison, the data of Figs. 1*a* and 1*b* are presented in tabular form in Table I. Temperatures at certain isobaric surfaces are given for (1) the average tropical atmosphere in the Caribbean [37]; (2) the ascent of the surface air of average properties (26C, 18 g kg^{-1}), (3) the ascent of the same air after isothermal motion to 960 mb and addition of 1.5 g kg^{-1} of moisture, and (4) the ascent of air with very slight polar characteristics (24C, 15.5 g kg^{-1}).

TABLE I.—TEMPERATURES ALOFT FOR THE CONDITIONS (1)-(4) DESCRIBED IN THE TEXT

Pressure *mb*	(1)	(2)	(3)	(4)
surface	26.0C	26.0C	26.0C	24.0C
900	20.0	20.5	22.5	18.0
700	8.0	11.0	13.5	8.0
500	− 6.0	− 3.0	0.5	− 6.5
300	−33.0	−28.5	−23.5	−34.0
200	−55.0	−53.0	−47.0	−59.0

The temperature differences between the four soundings are quite large at 700 mb and very large at 300 and 200 mb. If virtual instead of dry temperature had been used, they would be still somewhat larger (up to 1C near the ground). It is seen, as stated earlier, that the temperature difference between the rain area and the surroundings doubles if we consider sounding (3) instead of sounding (2). The slightly polar air is nowhere warmer than the average tropical atmosphere, and it is cooler at most levels. This shows clearly in what measure a slight temperature and humidity drop acts as a deterrent for an incipient hurricane circulation.

These observations throw doubt on the frontal hypothesis. Some writers, however, have maintained that the frontal temperature contrast is very small and merely serves as "trigger action" to start heavy convection. But we have seen that heavy convection is not a sufficient condition for typhoon development. Moreover, if the air-mass contrast at the ECZ is as minute as suggested by these writers, it would seem that they are trying to employ a very dubious mechanism.

Synoptic Conditions During Storm Formation. Although the physical reasoning of the frontal advocates is open to doubt, their geometrical picture is to some extent correct. Storms never develop spontaneously in the undisturbed tropical currents but always in a preexisting disturbance. Such a disturbance may be of the shear-line type described (ECZ) or it may have the character of a transverse wave (Riehl [25]). Intensification of the bad weather zone attending such a disturbance and formation of a closed depression generally takes place when two or more disturbances meet [8, 26]. Considerable synoptic evidence supports this statement. The combination or superposition of disturbances usually results from motion in different directions or at different rates. Among many possibilities, a common type is westward travel of a wave trough in the easterlies that intersects an ECZ extending east-west. At other times such wave troughs become coupled with the southern extensions of eastward-moving troughs in the upper westerlies of the polar zone. The superpositions, therefore, can be horizontal and/or vertical.

To date, only the synoptic circumstances of super-

position have been explored, while the dynamics have been neglected. It is certain that most tropical depressions form in consequence of superposition. Yet the great majority of these circulations do not develop beyond a weak wind field with maximum speeds of about Beaufort 6. Sometimes such weak centers will persist in steady state up to a week and then suddenly deepen.

The Hypothesis of J. S. Sawyer. A major synoptic problem, therefore, remains: Under what circumstances will storms attain great intensity? The solution of this question must be connected with the mechanism of the upper outflow. Durst and Sutcliffe [13] have given a plausible explanation for the outflow in case of the mature hurricane. Their reasoning, however, is not applicable to the period of establishment of a storm. Sawyer [35] adopts a line of thought that has also been put forward to explain cyclone formation in higher latitudes.[1] The basic principle is given by Solberg [40], who showed that a ring of air particles may become "dynamically unstable" provided that

$$f + \zeta < 0,$$

where f is the Coriolis parameter and ζ the relative vorticity about the axis normal to the earth's surface. For an explanation of the criterion the reader is referred to the articles quoted.

Although Sawyer's approach is novel and attractive, there are serious objections. In particular, it is dubious whether zones of "dynamic instability" exist in the tropics prior to storm development. It is true that the criterion is much more easily realized in low than in high latitudes, since the value of the Coriolis parameter is much smaller. But a plausible mechanism for production and maintenance of negative absolute vorticity has not been given, nor has its actual existence in tropical currents prior to cyclogenesis been demonstrated. Within the writer's experience, a zone of strong anticyclonic shear, comparable to that on the south side of the circumpolar westerlies, does not exist in the tropics, at least within the latitude belt where tropical storms form. Sawyer himself [36] appears to be a little worried about his 1947 statements.

The Hypothesis of H. Riehl. The attempt by Riehl [30] to explain the increase in intensity, does not postulate any special internal characteristics within the zone of cyclone formation. It is based on the introduction of external forces aloft to produce the initial upper divergence. A number of observational facts are utilized for depicting the setting in which certain types of storms—but not all—develop:

1. Deepening takes place when the curvature of the high-level flow is anticyclonic, or changes from cyclonic to anticyclonic. A high-level anticyclone or wedge is situated near (commonly west of) the surface disturbance, and an upper-level cyclone or trough lies to its east (Fig. 4).

2. Superposition of these high-level centers and the wave troughs and ridges in the polar westerlies occurs so that high- and low-latitude systems are in phase. This strengthens the meridional flow components aloft and weakens the zonal component (Fig. 5). The intensification of the current above the surface depression must be brought about by acceleration toward lower pressure, therefore toward the east in the model chosen (Fig. 4). This eastward acceleration will give an initial pressure fall at the surface in the tropical disturbance.

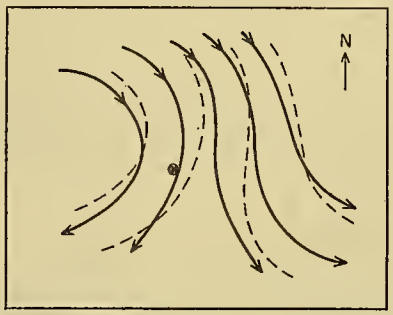

FIG. 4.—Model of streamlines and contours (dashed lines) at 200 mb during deepening of a tropical disturbance (heavy dot) in the Northern Hemisphere.

3. There is a general equatorward advance of polar air over the ocean east of the depression. This polar air does not enter the circulation. It subsides and diverges,[2] as usual, on its way toward lower latitudes. Continuity demands upper inflow above the region of subsidence. This further contributes to eastward deflection of the high tropospheric air toward the east. Convergence and descent take place at the left edge of the upper current, looking downstream (Fig. 6). Divergence aloft develops at the right edge. It produces a surface pressure fall,

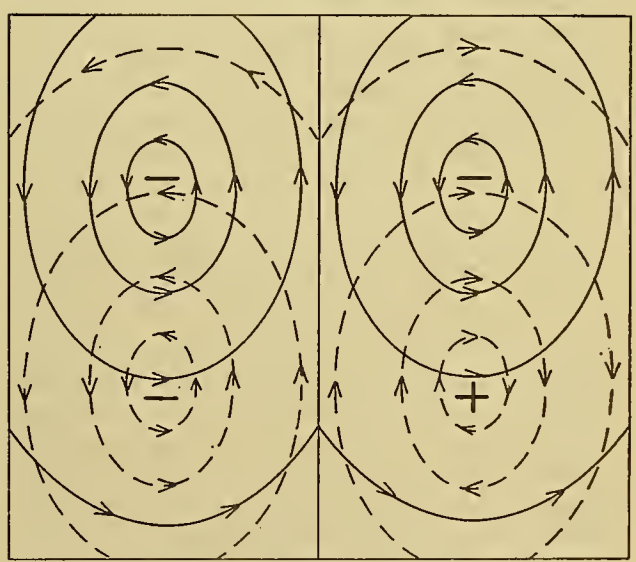

FIG. 5.—Streamlines of perturbation centers at 200 mb during in-phase (left) and out-of-phase (right) superposition of a trough in the westerlies on disturbances in the tropical vortex train aloft.

1. Consult "Extratropical Cyclones" by J. Bjerknes, pp. 577–598 in this Compendium.

2. Such divergence can also be obtained by "instability of the trades" [27].

followed by convergence at the ground and ascent of the low-level air in the initial tropical depression.

4. The vertical cross-stream circulation described is "direct," therefore kinetic-energy producing, as the air is less dense in the tropical disturbance where ascent takes place than in the surroundings. Maintenance of the vertical circulation is accomplished by continuous advection of more polar air at the left of the upper current and moist-adiabatic ascent at the right, looking downstream.

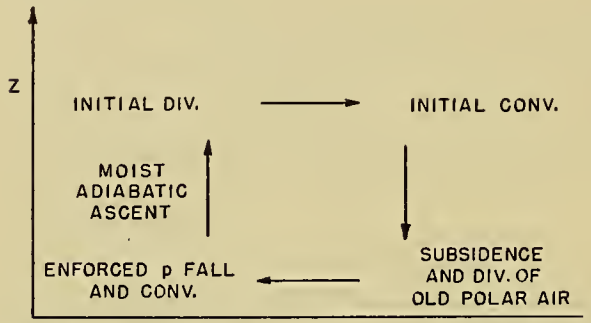

Fig. 6.—Vertical cross section taken eastward from position of tropical depression shown in Fig. 4. Model illustrates hypothetical development of vertical cross-stream circulation leading to deepening of the surface depression.

5. Several energy sources have been used in creating and maintaining the direct vertical circulation cell. The in-phase superposition of high- and low-latitude wave trains in the upper troposphere directly intensifies the speed of the high-level current above the surface depression. Use has also been made of old polar air, but in a manner quite different from that implied in the frontal theory of hurricane formation. The polar air does not enter the forming storm but moves equatorward at some distance and subsides. This subsidence is partly responsible for creating an organized circulation cell.

6. The existence of the direct circulation, initiated by the large-scale synoptic picture, increases the efficiency of the convective motion in the surface disturbance in generating kinetic energy. A priori there is no preferred direction for motion produced from condensation. The small-scale circulation cells initiated in different parts of a disturbed area tend to cancel each other. Introduction of the large-scale circulation cell, however, aligns the smaller convection cells in a definite direction. The air that rises in the zone of convection is removed a considerable distance before it sinks again.

At this time it is not possible to tell whether this latest model will withstand the test of experience. The sequence described is not the only one that can lead to cyclogenesis. Both in high and low latitudes, more than one synoptic pattern can lead to deepening. It is fair to say, however, that it is reasonable to attack the problem by placing emphasis on the upper divergence as an initiating mechanism. All efforts to explain deepening from low-level considerations have failed to date, since none of them can explain the surface pressure falls. The future evidently must concern itself with further development of models that lead to cyclogenesis. It is probable that the interrelation between different latitude belts will ultimately be recognized as an important factor. If that holds true, there is also some hope for preparation of extended forecasts of hurricane formation. The interrelation between high and low latitudes is a function of the state of the general circulation. If it should become possible to predict longer term trends of the general circulation, success in forecasting hurricanes on an extended basis could also follow.

MOVEMENT OF HURRICANES

This is the most widely discussed aspect of tropical forecasting, certainly one of the most vital. Contrary to the topic of formation, recognition of the importance of external forces for predicting the motion of storms dates from the last century. The close relation between storm tracks and the position and intensity of the subtropical highs (steering) was recognized very early [16]. Mitchell [21] was the first to provide an extensive set of rules for forecasting recurvature, based largely on the effect of travelling surface lows and highs in the westerlies on the tropical storms. Dunn [12] used similar reasoning, but applied it to 10,000-ft streamline charts. His attack was extended by Riehl and Shafer [33], who sought to determine under what circumstances hurricanes that meet a polar trough will recurve and when they will bypass this trough and continue westward. The height of the base of the polar westerlies played the principal role in their argument.

Recently, Simpson [38] introduced the "warm tongue" steering method, which from the dynamical point of view is similar to that of Dunn [12] and Riehl and Shafer [33]. Mintz [20], and Moore [22] applied the ideas of Bjerknes and Holmboe [2] to make quantitative forecasts of displacement. This is an interesting proposal and has led to some good forecasts. A purely dynamical approach is that of Yeh [44], who at first computes the path of a hurricane situated in an easterly current and then superimposes a general meridional component. He finds that storms execute oscillations of minor but definite amplitude while in the easterlies. There is, however, no total deviation of the storm track to the right of the steering current as maintained in some previous studies. When a storm comes under the influence of a polar trough, a northward displacement occurs. But this displacement will vary widely, depending on certain initial conditions, when the polar trough appears.

Riehl and Burgner [31] made a quantitative test of the steering principle. The method used was applicable to the zonal component only. An area 90 degrees of longitude long and 5 degrees of latitude wide, centered on the storm, was defined as the region of influence. Within this area, the mean zonal component of motion at 700 mb was computed and correlated against the 24-hr zonal component of storm displacement. The resulting scatter diagram showed that in the mean the zonal components of storm movement and steering current are equal. Numerous deviations, however, occurred and these were relatively large in that portion

of the graph where the zonal motion approached zero. The mean deviation was about 1 degree of latitude per day.

Steering Principle. It is no accident that the study of motion of disturbances has stood in the foreground of literature on the tropics. Contrary to other aspects of meteorology, this aspect of forecasting is more developed for the tropics than for middle latitudes. The reason for this can be seen readily when we examine what Petterssen [24] has termed the "area of uncertainty." Most tropical storms are small and have a tight circulation compared to extratropical cyclones. An error of 1–2 degrees of latitude in forecasting the position of a middle-latitude storm affects the forecast verification but little. In the tropics, however, an entire storm is often contained within this distance. An error of 1–2 degrees will make all the difference at any given station between wind of hurricane force and no wind at all.

The steering concept at first was used in a directional sense only. Hurricane tracks appeared to parallel the sea-level isobars over the Atlantic to a large extent. It is only since the late 1930's that some forecasters attempted to obtain the speed of displacement from the upper wind field. Difficulties arose at once in choice of steering level since speeds varied with height. This difficulty also applied to direction whenever the wind direction changed with height, especially near the subtropical ridgeline. Simpson [38] pointed out that there has been a tendency to shift the level thought representative of steering higher and higher as the upper-wind observations were extended upward with the advent of rawins. The difficulties of making a proper choice of steering level have led to doubts on the part of many forecasters as to the usefulness of the method in principle.

In the writer's opinion, the difficulties result mainly from application of steering techniques to situations in which they should not be used. In a strict sense, steering refers to the forces that guide a very small disturbance in a broad zonal current that is steady and usually considered uniform along all space axes. The disturbance also does not change shape or intensity with time. These restrictions never are fulfilled in reality. Two questions come up: Under what actual conditions can the simple theory be applied without much loss of forecast accuracy? and To what extent can theory itself modify the restrictions listed above? Not much has been tried along the latter line. But the problem is quite urgent. It is easy to see that formal solutions of the equations of motion will not be possible if many restrictions are dropped. But a numerical integration procedure may carry quite far, provided some good information exists as to what quantities to put into a computing machine. In this respect, studies of the kind attempted by Riehl and Burgner [31] may provide the necessary background. They can determine which theoretical restrictions are immaterial for the forecast and which impose limitations. It is almost certain, for example, that variations along the vertical axis will turn out to be important. This is amply indicated by the literature of the last ten years cited above. Probably the concept of "steering level" must be replaced by that of "steering layer." Tropical storms extend through almost the entire troposphere. It is quite reasonable to expect that some integral function of conditions at all heights will serve much better than conditions at one level alone.

Recurvature. The motion of tropical storms from the tropics into the middle latitudes can take place in several ways. Sometimes the forecast is very easy, as when upper winds are nearly uniform through a deep layer and gradually turn from east through south to southwest as we follow them around the western edge of a subtropical high pressure cell. For such cases, methods like those developed by Yeh [44] should be fully applicable. Important difficulties arise whenever winds are weak and/or when the vertical wind-shear is large. In such situations we can no longer speak of steering.

The literature on the subject, referred to above, gives empirical forecast rules for several types of tropical storms. No one, however, has claimed to have developed a perfect qualitative forecast method. The occasional failures of all systems stand out. Quantitative calculations of recurvature from empirical data have not been attempted or have been unsuccessful. Theory has bypassed the problem. Thus the state of knowledge with respect to the many situations when recurvature hangs in the balance is unsatisfactory.

It is not easy to make suggestions for future work that can readily be carried out. The trouble stems from two sources. One of the missing elements in the recurvature forecasts is a knowledge of the internal forces within a storm. These cannot be measured at all at present. The other difficulty lies in the fact that the net external force operating on storms in recurvature positions is a small resultant of large opposing forces; this is also indicated by the slow motion of storms at recurvature points. It is practically impossible to evaluate the net force from north or south acting on a storm even at one level, to say nothing of an integral from sea level to the tropopause. The station network necessary to calculate such resultant forces simply does not exist anywhere.

Thus we must again demand more data if physical analysis of recurvature is to make much headway. Unfortunately, it is probable that the great density of stations really necessary for this problem will never be realized on a routine basis because of cost. For practical purposes, future recurvature work should follow statistical rather than physical approaches. Mitchell [21], for example, has already shown the importance of the rate of motion of extratropical troughs. Riehl and Shafer [33] have emphasized the vertical structure of the subtropical high-pressure belt. Together with the paper by Klein and Winston [19] this literature yields a great number of starting points for statistical correlation. If future efforts are applied in this direction, it may be possible to bypass the obstacle furnished by the balance of forces at the recurvature point.

Large Storms. The problem of forecasting the motion of large storms occurs mainly in the Pacific Ocean in

the Northern Hemisphere. Typhoons at times can become as big as any Aleutian or Icelandic lows. Such centers move quite slowly at times. Frequently they are entirely stationary for days, usually near latitudes 25–30°. Evidently it is of greatest importance to forecast when such storms will stagnate and when and how they will resume motion.

In the whole field of hurricane work, this topic has been left untouched more than any other. From both theoretical and practical viewpoints the difficulties have appeared to be almost insurmountable. Among the older literature only the work of Fujiwhara [14, 15] is applicable. He has taken up the problem of rotation of vortices about each other. If a storm is situated as described above, it will be flanked by other vortices east, west, south, and frequently even north, especially in the upper troposphere. A mean zonal motion does not exist at high levels. Attempts at forecasting must turn to the relation between the upper vortices.

Theoretically, the problem of internal forces also moves into the foreground. This subject remained dormant until 1948. Since then two theoretical papers have appeared that treat the analysis of internal forces in vortices on the rotating earth [9, 34]. At this time, it is impossible to say how useful these particular papers will prove in practice, since again there are no direct data and application depends entirely on inference. But it is gratifying to note that the theoretical deadlock has been broken. Now that a way has been shown, dynamic meteorologists have a good opportunity to advance the understanding of the movement of large typhoons.

On the practical side, recent studies of the high-tropospheric wind structure over the tropical oceans [27] and the interrelation between high- and low-latitude circulations [8] have produced an opening. The problem of large storms evidently can be solved only by considering the atmosphere over very wide areas. Events in the entire belt of polar westerlies, the motion of long waves in the westerlies, and the structure and movement of the high-tropospheric vortex train in low latitudes must determine the fate of typhoons of huge size. A southward shift of a westerly jet stream or its formation in low latitudes, plus development of an extended trough near or west of a typhoon, might be favorable for acceleration of the typhoon into middle latitudes. Settling of a major ridge to its north could produce stagnation. These are merely suggestions which outline the direction which new efforts could take.

CONCLUSION

This report has tried to demonstrate briefly the current knowledge on structure, formation, and movement of tropical storms, shortcomings of this knowledge, and suggested paths for future research. The outstanding deficiency is the lack of observations which is so keenly felt in all low-latitude work. A network of upper-air data such as exists in the United States has never been at the disposal of the tropical analyst. Moreover, the quality of the high-level data is sometimes poor since errors in radiosonde flight evaluation can be as large as synoptic changes. If many upper-wind observations are taken, however, the quality of the reported heights and temperatures aloft can be judged easily. For this reason it is proposed to have as many rawins as possible and to revive the old and relatively inexpensive reports of middle- and high-cloud direction.

For scientific purposes, detailed observational programs should be initiated for short periods in low latitudes during the hurricane season. If this is done, it may be possible to derive analysis and forecast principles that are also applicable when less detailed data are at hand. The suggestions for the future take on several forms. Regarding structure, new observations and theoretical studies alone can bring advances. Formation is a subject that for the present should be continued with standard qualitative synoptic methods plus theoretical calculations based on the empirical inferences. As the release of several forms of energy is involved, quantitative computations appear premature at this time. Methods of numerical integration are recommended for forecasting the movement of hurricanes by steering currents. Statistical correlations are most likely to yield an advance on the problem of recurvature.

ANTARCTIC ATMOSPHERIC CIRCULATION

By ARNOLD COURT[1]

Meteorologist, U. S. Antarctic Service, 1939–1941

INTRODUCTION

Antarctica's atmospheric circulation and its causes and effects are major gaps in current meteorological knowledge. Until they are filled, there can be no complete understanding of the weather processes of the earth as a whole, and especially of the radiative balance of the earth's surface and upper atmosphere and of the mechanics of variations in the general circulation. Yet there is almost no direct information on the antarctic circulation, because Antarctica is a continent, covering one-ninth of the land area of the world, for which the only meteorological data apply to a dozen isolated spots on the periphery.

This paper discusses previous concepts of the circulation over the interior and over the surrounding oceans, and of "pressure waves," then cites the additional observational material gained since these concepts were enunciated, and finally suggests a general circulation scheme which agrees with these newer data, especially concerning the upper air and the topography.

"Antarctica" is the south polar continent, and "antarctic" applies only to it and its immediate offshore islands and seas. The open ocean surrounding the continent, with a dozen or so islands, is "subantarctic." The outstanding features of the generally circular coastline are the narrow, mountainous Palmer Peninsula ("Graham Land" to the British) which extends northward to within 600 miles of Cape Horn, and two deep embayments almost opposite each other: the Weddell Sea east of the Palmer Peninsula, and the Ross Sea south of New Zealand.

At the head of the Weddell Sea is the Filchner Shelf Ice (renamed "Lassiter" by Ronne [127]), descending from the high interior; on the east side, and around the continent through almost 180°, the ice descends rather sharply to the ocean, with mountains in several areas and a few ice-free spots among them, and several ice sheets projecting into the open ocean or the various bays. More than two million square miles in the interior are wholly unknown; they may be a rocky desert, they may contain the world's highest mountain, or they may in fact be a featureless snow plain averaging 10,000 ft above sea level, as is supposed because of conditions at the geographic and magnetic poles. There is also some evidence that this area may contain a large basin.

This largest unknown area in the world ends at the massive mountain chain which borders the Ross Sea on the west and south, and up whose intervening glaciers Amundsen and Scott toiled to reach the Pole. The southern half of the Ross Sea is covered by the vast Ross Shelf Ice (or Ross Barrier), whose face rises 100 to 200 ft above open water; it is generally grounded, although extensive portions near the edge are afloat. East of the Ross Sea are complex mountain areas, and farther east the coast, as outlined by United States aircraft in 1940 [121] and 1947 [116], is quite rugged, with many mountains, one reaching 20,000 ft, and numerous bays and glaciers. The adjacent waters are so ice-filled that no ship has even penetrated within sight of the coast. The interior is an "unbroken desert of snow" about 6000 ft high [120] with a few mountains near the base of the Palmer Peninsula.

Until 1950, only three expeditions had ever wintered on the rocks of the continent proper; all others were based on small islands just offshore, on board ships frozen in near such islands, or on solid ice sheets extending out from the continent. All bases have been practically at sea level—at the edge of a continent assumed to average several thousand feet in height. No one has ever been more than a few miles inland from March through September, and even in summer no spot in the interior has ever been occupied for more than a week. All expedition bases have been on the shores of the Palmer Peninsula or of the Ross Sea, except for two on the coast facing Australia.

Exploration of Antarctica's interior began with the "Homeric period" [125] from the first wintering on the *Belgica* in 1898–99 to Shackleton's unsuccessful transcontinental attempt in 1914–16. The continent was first sighted in 1820 (but whether by an American or a Briton—or even a Russian—is argued actively) and circumnavigated around 1840 by American, British, and French expeditions, all sighting land at various places and the British one, under Sir James Clark Ross, penetrating the encircling pack ice to reach the Ross Sea in two successive years.

The "mechanical period," beginning with Admiral Byrd's first expedition in 1928, has seen several American expeditions, one British venture, and in recent years the large-scale occupation of the Palmer Peninsula by rival British, Argentine, and Chilean weather stations. During 1950, these stations were augmented by two expeditions, French and Norwegian-British-Swedish, based respectively south of Australia and south of Africa, and by weather stations on several subantarctic islands (Table I).

Most of the extant theories of Antarctica's weather processes are based on the observations of the "Homeric expeditions," generally published in detail and often discussed extensively. The "mechanical expeditions" have provided the best upper-air information, but their

1. Climatologist, Research and Development Branch, Office of The Quartermaster General. This article represents the personal views of the author and not necessarily those of the Department of Defense.

surface observations have generally been far less complete than those of their predecessors.

When Meinardus [14] compiled his comprehensive "Klimakunde der Antarktis" in 1937 for the monumental Köppen-Geiger *Handbuch der Klimatologie*, he had available observations for one or more years at only twelve places on the continental margin (only six of them for as much as two years), for three ice-bound ships drifting slowly during the winter, and for four subantarctic islands. Since then, summaries of observations made earlier at three other places have been published [25, 88] and later expeditions have made year-long observations at two new places [30, 37, 40] and one previously studied [47], besides the Palmer Peninsula stations whose data have not appeared.

Climatic summaries for all available stations are given in detail by Meinardus, whose extensive discussion of the general climate and individual peculiarities can hardly be surpassed. But recent information about upper-air conditions, antarctic geography, atmospheric dynamics, and oceanic synoptic meteorology makes it advisable to re-examine the older theories and to study critically the newer information on Antarctica's meteorology.

Table I. Antarctic and Subantarctic Weather Stations South of 50°S*

Lat. S.	Long.	Station name	General location	Index	Nationality
Antarctica Proper:					
71°03′	10°54′W	Maudheim‡	Kap Norvegia, Queen Maud Land	61903	Nor.-Brit.-Swed.
66°50′	141°25′E	Port Martin‡	Cap de Margerie, Adélie Land	95501	French
Palmer Peninsula:					
68°12′	67°03′W	Neny Fjord†	Stonington Island, Marguerite Bay	07023	British
65°15′	64°16′W	Argentine Island	Off West Coast Palmer Peninsula	88952	British
64°50′	63°31′W	Port Lockroy‡	Wiencke Island, off West Coast	88949	British
64°19′	62°58′W	1° de Mayo	Gamma Island, Melchior Archipelago	87970	Argentine
63°24′	56°59′W	Hope Bay†	Antarctic Sound, Northern tip Palmer Peninsula	10533	British
63°19′	56°54′W	Base O'Higgins	Cape Legoupil Northern tip Palmer Peninsula	85988	Chilean
West Subantarctic Islands:					
63°00′	60°30′W	Isla Decepcion	Deception Island, South Shetlands	87978	Argentine
62°56′	60°33′W	Deception Island	(Whalers Bay), South Shetlands	88098	British
62°30′	59°41′W	Bahia Soberania	Greenwich Island, South Shetlands	85986	Chilean
62°03′	58°23′W	Admiralty Bay	King George Island, South Shetlands	88934	British
60°44′	44°44′W	Orcadas del Sud	Scotia Bay, Laurie Island, South Orkneys	87981	Argentine
60°43′	45°36′W	Signy Island	South Orkneys	88925	British
South Atlantic Islands:					
54°16′	36°30′W	Grytviken	South Georgia	88903	British
54°16′	36°30′W	Georgia del Sud†	South Georgia	87992	Argentine
51°42′	57°51′W	Port Stanley	Falkland Islands	88890	British
East Subantarctic Islands:					
54°30′	158°57′E	Macquarie Island	Southwest of New Zealand	94998	Australian
53°06′	72°31′E	Heard Island	South Indian Ocean	94997	Australian
52°32′	168°59′E	Campbell Island	South of New Zealand	93944	New Zealand

* Except for seven stations in South America between 50°S and 55°S.

† Active in 1949, but not in 1950.

‡ Active in 1950, but not in 1949.

Most positions were taken from IMO Publication No. 9, and may differ somewhat from those given in other sources. Index numbers were taken from the same publication, except that the numbers for the active British stations are revisions to be effective in 1951.

THE ANTICYCLONE

Antarctica's basic atmospheric circulation pattern is generally assumed to be anticyclonic at the surface and cyclonic above, but there has been marked diversity as to the areal and vertical extent of the anticyclone, and even as to its permanence. Until the end of the 19th century, meteorologists could not agree whether pressure at the Pole was high due to cold or low due to "the excessive equatorward centrifugal force of the great circumpolar whirl." Expeditions early in the 20th century found a barometric trough around 60°S with pressure increasing southward, but Shaw [110] remarked in 1909 that "The Antarctic anticyclone, if it exists,

is a comparatively superficial effect attributable to the surface cold."

Others, however, postulated a vast continental anticyclone around which rotate a succession of huge oceanic cyclones [103, 105]. To this anticyclone Hobbs gave a unique character and a distinctive name [104]: a "fixed glacial anticyclone, modelled on the form of an hour-glass, . . .roughly centered near the South Pole," in which a continuous downdraft supplies air which flows out radially in bursts of strong winds. The vast snowfall presumably required to maintain the icecap against its own slow outflow and the outward sweeping of the winds comes from "the ice spicules of the cirrus and other closely related cloud forms . . . adiabatically vaporized in the downdraft and reprecipitated as they approach the glacier surface," which is radiatively cooled. This precipitation mechanism did not appear quantitatively sufficient to most other meteorologists studying Antarctica, and the analogous permanent anticyclone of Greenland is not accepted *in toto* by many meteorologists today.[2]

Meinardus [107] interpreted the strong easterly winds common at the *Gauss*, frozen in for a year some 40 miles off the coast at 90°E, on the 1902–4 German expedition, as due to passages of cyclones to the north, and felt that "If there is an Antarctic anticyclone it can exist only in the inner portion."

> The Antarctic anticyclone, so much discussed in the past, is a pressure distribution peculiar to the lower atmospheric strata only, appearing with distinctness only in the sea-level pressure distribution. On the other hand the low Antarctic temperature must produce such a rapid vertical decrease in pressure that above a certain level the Antarctic pressure must be lower and not higher than that of surrounding regions. Thus the sea-level anticyclone must be overlain by a cyclone, the so-called "polar whirl" in the general circulation of the globe.

From available information, Meinardus estimated that this transition occurs at about 2 km above sea level, and that most of the continental interior is higher, at the level at which cyclonic conditions prevail, with moisture-laden air flowing in east of the Ross and Weddell Seas, and a cold dry outflow on their western sides. This concept was attacked by Simpson, meteorologist of the last Scott expedition of 1911–13, who insisted [112] that a continental mass like Antarctica would establish its own regime above its surface, and not penetrate into the circulation like an isolated mountain peak:

> A statement of the general air circulation over the Antarctic is now quite simple. Over the snow-covered surface of the Antarctic whether at sea-level or at the height of the plateau radiation is so strong that the air is abnormally cooled especially in the layers of air immediately above the surface. This cooled air is heavier than the surrounding air and therefore the pressure increases from the exterior to the interior of the Polar area; in other words the pressure distribution is anticyclonic and the air motion is in general outwards. Above each anticyclone a cyclone forms on account of the relatively rapid vertical pressure change caused by the cold dense air. These cyclones convey air from higher latitudes over the Polar region and supply the air which passes outwards near the surface. In the normal steady state the air circulation takes place slowly and th descending air is warmed up dynamically so dissolving cloud and giving clear cloudless skies, thus accounting for the decreasing cloud amounts observed as one penetrates the Antarctic.
>
> The clear skies in their turn facilitate radiation as also does the small absolute humidity of the air. In consequence the air and the snow surface become abnormally cold and there is a great tendency to the formation of temperature inversions especially in the lower atmosphere . . . . The abnormally cold surface air is forced upwards in these [forced ascending] currents, rapidly cooled in the ascent, and the water obtained is precipitated as snow, which when combined with the high surface winds produces the typical Antarctic blizzard.

Simpson also disputed Meinardus' interpretation of the *Gauss* winds, considering them too constant in force and direction to be due entirely to cyclonic passages. His general model was followed, in preference to that of Meinardus, by Barkow, meteorologist on the *Deutschland* during its year-long drift in the Weddell Sea, and Knoch, editor of the report [101] after Barkow's death:

> The circulation over the Antarctic continent is dominated by an anticyclonic cap of air which probably flows outward in a series of waves moving in a south to north direction. Above this cap of cold air there is a cyclonic stratum connected with the circulation of temperate latitudes and in this wandering depressions travel in a west to east direction. The two air-systems mutually influence each other; on the whole the lower system dominates the upper at least so far as atmospheric pressure is concerned. The surface winds are dominated on the whole by the lower system for the most part on the continent and in less degree as the distance from land increases. In the Cirrus region, and especially in the stratosphere, cloud movements appear to show that there is a current of air moving right across the continent from the Indian Ocean to the region of the West Antarctic. . . .

However, Shaw [111] evened the score by abandoning his thin anticyclone of twenty-five years earlier in favor of Meinardus' model rather than that of his own colleague, Simpson, or that of Hobbs:

> The circulation would correspond with a permanent anticyclone covering the continent if the space which the anticyclone should occupy were not already filled by a huge mass of land. . . . We should not expect to find evidence of the so-called [glacial] anticyclone on the top of the land-mass; the conditions there may be the reverse of those which are indicated by the margins at sea-level.

In turn, Kidson, although opposing Simpson's theories on some points (see p. 927), accepted his surface anticyclone rather than Meinardus' peripheral sea-level anticyclone or Hobbs's glacial anticyclone. In his discussion [75] of the results of Mawson's 1911–13 expedition (he had previously edited and analyzed the data of Shackleton's 1907–9 expedition), he said:

2. Consult "Some Climatological Problems of the Arctic and Sub-Arctic" by F. K. Hare, pp. 952–964 in this Compendium.

The cold surface of the Antarctic continent is continually removing air from the general circulation. This lies over it as a cold layer of varying thickness which flows outward to the periphery under the influence of gravity, giving the well-known katabatic winds. . . . The cold air accumulates especially along the coast of the continent where it appears to raise the air pressure by about 0.2 inch above what is observed over the open sea, far from the shore, in corresponding latitudes (for example, over the Ross Sea). It is responsible for a prevalence of easterly winds along the antarctic coastline and its effect extends, on the average, for about 200 miles from the coast. Pressure systems, fronts, waves, cyclones, etc., move to a large extent, over and independently of the cold layer. Fluctuations in the katabatic flow are, of course, produced.

Seasons. These various models of Antarctica's circulation make no great distinction between summer and winter, yet all seem in general to be based on winter conditions. Meinardus [14] did suggest that the north-south pressure gradient above 2 km is especially strong in winter. As will be explained later, it is likely that both the temperature and pressure gradients aloft reverse from summer to winter, and it is gross oversimplification to say, as did Haurwitz and Austin [133], "Even though the south polar sea-level anticyclone is very pronounced, the strong north-south temperature gradient probably results in a polar cyclone at low altitudes."

By contrast, most of the comments of recent years imply some seasonal variation in Antarctica's circulation. Thus Serra and Ratisbonna [42] considered that "The cold antarctic anticyclone [is] greatly weakened in summer and forced back toward the pole," and that the upper cyclone is found above 2 km in summer, and above 3 km in winter. Coyle [27], like them primarily interested in antarctic influences on South American weather, reasoned similarly. Gentilli [9] recently assumed that "the area of prevailing polar easterlies contracts in summer and expands in winter."

Meteorologists of the U. S. Navy's Operation Highjump[3] during the summer of 1946–47 suggested [2] that "The south polar anticyclone is broken up into a number of cells with their centers displaced to the northward." Two such cells, representing persistent outflows of cold air, were found around 120°W and 145°E, plus a narrow wedge along the Palmer Peninsula (65°W), a semipermanent wedge along 80°E, and a migratory or transitory wedge between the MacKenzie and Weddell Seas (20°W to 70°E). The 145°E position was given by the Ross Sea group; the western group placed this "Balleny Island wedge" along 155°E.

No such cells had been shown by Meinardus [14] on his map of mean annual pressures, but Lamb's revision [83] suggested three areas with pressures greater than 995 mb centered on 80°S, at 20°E, 130°E, and 90°W. Earlier Lamb concluded [81] that "we should think of the south polar anticyclone not as a permanency but as a recurrent feature subject to most of the same laws of life and decay that apply to high pressure systems everywhere."

Upper winds at Little America during two full years [50] show the circulation to be far more complex than would result from a permanent surface anticyclone with upper cyclone, or any other simple model. Grimminger, who tabulated and summarized the data, said [49]:

> The annual means show very clearly winds with south and east components at the low levels and with north and west components at the higher levels and agree qualitatively with the concept of the outward drainage of cold air below and a compensating inflow aloft. . . . The south components are distinctly larger in winter than in summer up to 1,000 m; this is even more pronounced during the coldest period and extends to 2,000 m. In the upper layers. . . there are larger north components in winter than in summer at 7 and 8 km and in the coldest period from 5 to 9 km.
>
> In general, the seasonal variation of the north-south components agrees with what would be expected if the circulation over the continent were controlled mainly by the drainage of the cold lower layers. The seasonal variation of the east-west components in the upper layers also agrees with this; but that of the lower layers does not, since as pointed out above the east components are smaller in winter and are lacking entirely during the 3 coldest months. . . . Just why these east components do not appear in the coldest months when the drainage should be a maximum is not clear.

From the same data, Palmer [62] found deep easterly winds, *i.e.*, continuously between north-northeast and south-southeast up to 5 km, on 38 per cent of all days with flights to 5 km or higher, and on 44 per cent of days with flights to 3 km or higher. These easterlies aloft "are far more frequent than would be expected from the theory of the polar vortex."

It is obvious from its derivation that the idea of a "polar vortex" is an abstraction, adequate, perhaps, as a summary of average conditions, but misleading if applied to the analysis of individual synoptic situations in the far south. To find, by the manipulation of mean values, that the antarctic anticyclone is on the average a shallow pressure feature may be justified, but to deduce from this that all easterly, southeasterly and southerly winds, and in particular the blizzards, are "katabatic" or are shallow surface flows is to obtain a result that is really beyond the capacity of climatological methods.

Similarly, Meinardus pointed out repeatedly that mean annual pressure maps are merely averages of daily weather patterns, and [14] that "the direction and force of the air motion on the inland ice are governed not only by the direction of the slope but also by the general pressure distribution," which changes from day to day.

The 426 pilot balloon and rawin ascents made on Highjump [2], operating at sea all around the continental margin, were summarized for three levels: "2,000

3. While the full aerological reports of Operation Highjump [2] and Task Force 39 [4] are classified as "Restricted" by the Navy Department, the actual observations [3] are unclassified, and the discussions and conclusions in the Restricted reports are considered unclassified, so that one unclassified summary [1] of conclusions has appeared. The generous co-operation of Capt. H. T. Orville, Chief of Aerology, permitted access to the full reports and obtained official clearance for their use and quotation here.

m, predominantly under the influence of the polar anticyclone; 3,000 m, the zone of transition between the low-level polar anticyclone and upper-level cyclone; and 5,000 m, definitely under the influence of the polar cyclone. The winds show a steady increase in velocity with heights to a marked maximum at the tropopause, 25,000 to 30,000 ft, [and also] a slow increase in average velocity as fall approached, coinciding with an increase in the intensity and rate of movement of low-pressure areas."

The Interior. Only four areas of Antarctica more than 100 miles from the coast have been explored on the surface: two converging routes to the South Pole, two routes from opposite directions to the south magnetic pole, the plateau due west of McMurdo Sound, and the center of Ellsworth Highland midway from the Palmer Peninsula to the Ross Sea. In all four areas, midsummer weather is variable, with clear days and cloudy, strong winds and light, snowfall and ablation.

Prevailing winds observed by parties in these four areas are shown in Table II, adapted from Taylor [114], who considered both winds and *sastrugi*, the ridges or dunes of snow which indicate wind direction. Since convergence of the meridians makes it difficult to compare directions in different longitudes, directions are indicated by the parallel direction at the South Pole, measured in degrees eastward from Greenwich.

Table II. Prevailing Winds of Interior Antarctica in Summer.
(Referred to directions at the South Pole: 90°E = 90°, 90°W = 270°)

Party	Year	Area	Wind
Mawson and Bage	1912–13	Adélie Land to the magnetic pole	300°
David	1908–09	Victoria Land to the magnetic pole	300°
Scott	1903–04	West of McMurdo Sound	360°
Shackleton	1908–09	South of Beardmore Glacier	320°
Amundsen and Scott	1911–12	South Polar Plateau	326°
Ellsworth	1935	Hollick-Kenyon Plateau	20°

These half-dozen average wind directions might indicate a general surface air motion in summer from the Weddell Sea toward the Ross Sea or Australia, opposite to the upper-air flow deduced by Barkow. They are compatible with a single surface anticyclone centered around 80°S, 70°E. By themselves, the prevailing winds around the magnetic pole and west of the Ross Sea are compatible with an anticyclonic cell centered around 70°S, 155°E, roughly the position given by the High-jump aerologists and by Lamb for one cell of the polar anticyclone. The south polar plateau winds similarly would agree with another lobe, or perhaps the central cell, centered around 85°S, 70°E.

Neither of these postulated cells, however, can be even semipermanent. "The wind," David [118] reported, "had helped us by blowing from the southeast, just before we reached the Magnetic Pole, and now it was blowing in the opposite direction, helping us home." On 22 January 1909, "a clear day with bright sunshine, the wind started soon after 5 A.M., constantly freshening, as it usually did in this part of the plateau, till about 3 P.M., then it gradually died down by about 10 P.M."

On the south polar plateau, wind and weather in December 1911 and January 1912 were similarly variable. There, Simpson's painstaking analysis [112] showed, 63 per cent of all the winds recorded by Amundsen and Scott, representing 75 per cent of the total movement, were from 320°, 340°, or 360°, with resultant 326° at 8.5 mph. But there were calms, winds from other directions, wide variation in the strength of the prevailing winds, and fresh snow as well as blowing snow.

Most surprising, and least compatible with a theory of anticyclone cells, are the winds observed by Ellsworth [120] at three camps (at 80°S between 104° and 115°W) made to wait out blizzards whose "hard, fine-grained" snow "is dry, fine as flour, sifts into everything, and packs hard as rock." The first landing was made when clouds appeared and visibility grew poor; after nineteen hours there, "the weather was fine, though the horizon ahead looked thick" and after 30 minutes' flying, weather forced a second landing.

"Three days of varying thick and clear weather" ensued; after a 50-minute flight "the weather became so thick we could scarcely see to land" and a three-day blizzard followed, with east to southeast winds estimated at 45 mph. On the fourth day, "December 1, the storm moderated . . . with intervals of sunshine . . . . Buffeting wind, snow, and thick weather . . . bitterly cold" came on the fifth day, and heavy snow that night. On the sixth day, another "heavy storm broke from the southeast—thick snow and a high wind.".

Finally on the seventh day, although "the weather was anything but promising, with thick horizons all around and a sullen sky overhead," the flight was resumed, and an hour later they encountered "blue sky with a clean horizon all around" at the western edge of the plateau. "Evidently the storm area had been hanging stationary near the western edge" of the plateau. Both in the air (usually at 10,000 ft, some 4000 ft above the surface) and on the ground, during these eleven days of the only visit to date to this area, all winds were from east or southeast, except for two brief periods of north wind; "it never did blow from the west"; south winds were first encountered as the Ross Shelf Ice was reached.

These weather conditions are similar to those along the coasts and seem out of keeping for the center of an "unbroken desert of snow" 6000 ft above sea level. Ellsworth thought the then unknown coastline was "450 miles to the north," but explorations in 1940 [121] and 1947 [116] revealed a large bay or a large island-choked, ice-filled gulf at the head of Amundsen (formerly Roosevelt) Sea. This indentation, as yet unnamed and unmapped in detail from the available aerial photographs, appears to reach to about 77°S at 105°W, or only some 200 miles from Ellsworth's first camp, explaining "the water sky observed by Hollick-Kenyon on Nov. 23 in the conjectured position of 76°S and 100°W."

If this bay or gulf is as large as preliminary reports indicated, the weather sequence could readily be explained in terms of a family of occluded cyclones entering from the north and stagnating there. In fact, the weather reported by Ellsworth is evidence that this coastal feature is extensive. There is a strong possibility that the general pressure field during this period was considerably lower than at Dundee Island, where the flight started in good weather (high pressure), so that the altimeter readings of the heights of the camps (and the various mountains) may be too high by as much as 1000 ft or even more.

At any rate, the variable winds, chiefly southeast, recorded by Ellsworth from 23 November to 4 December at 80°S, 104° to 115°W, do not fit Lamb's anticyclonic cell at 80°S, 90°W [83], and are hardly compatible with "the anticyclone located near 120°W" inferred by the Highjump aerologists [2] twelve years and two months later. Perhaps those two months are significant, and the anticyclone, varying from 90°W to 120°W, develops only in late summer; perhaps the 1946–47 summer saw a northward displacement of an anticyclone which in late 1935 was centered much farther south.

These are some of the problems of Antarctica's anticyclone, which exists only around the edges according to Meinardus and Shaw, is a thin layer according to Simpson, Barkow, Kidson, and Grimminger, is broken up into several cells according to Lamb and the Navy aerologists, shrinks markedly from winter to summer according to Serra and Ratisbonna, Coyle, and Gentilli, and is a major feature fed by an upper cyclone according to Hobbs, with Palmer considering the upper cyclone to be an abstraction derived from averages of widely varying conditions.

CYCLONES

Mariners encountered and named the "roaring forties" several centuries ago, and later reached and named, with more alliteration, the "furious fifties" and "shrieking sixties." But only slowly has the meteorological nature of these subantarctic "brave west winds" become known, and there is still much to be learned about them. The type and extent of the frontal zones surrounding Antarctica are far from established, the number and character of air masses are uncertain, and the formation, travel, and dissipation of subantarctic cyclones are still subjects of speculation. Yet understanding of these processes is fundamental to any theory of the meteorology of Antarctica, because almost all the weather phenomena thus far encountered (around the coasts, the only part so far studied) appear related to systems impinging on the continent from the surrounding seas.

Knowledge of weather processes over the southern oceans has kept pace with Northern Hemisphere findings as well as the scanty observations have permitted. As late as 1929 Barlow [102] said that the subantarctic "depressions travel from west to east around the globe in nearly unbroken succession," as had been similarly assumed for the Northern Hemisphere. Emergence of the concept of cyclone life cycles and cyclone families was traced in detail by Palmer [89], as background for his preliminary (1942) theory of subantarctic meteorology.

This theory appears in more mature and concise form in the *Handbook of Meteorology*, in an article [18] credited to "Civilian Staff, Institute of Tropical Meteorology, Rio Piedras, Puerto Rico," but actually written in 1944 by Palmer. It describes quasi-permanent anticyclones lying along 30°S in the central South Atlantic and Indian Oceans and the eastern Pacific Ocean, with "a train of warm migratory anticyclones" between each pair; between these migratory anticyclones are found "inverted **V**-shaped" troughs extending northward from great closed cyclonic systems "somewhat similar to the stationary Icelandic and Aleutian lows of the Northern Hemisphere but, unlike those depressions, moving from west to east with the anticyclones to the north."

Even more extensive than Palmer's first treatise was Kidson's series [75] of daily weather maps for 1912 for all Australia and New Zealand and the region southward almost to the Pole, using data of the Australasian Antarctic Expedition and others. A pioneer in the application of frontal analysis to the Southern Hemisphere, he drew very involved systems to account for all the meagre observations, but did not "make analysis conform very strictly with kinematic laws" and tended to ignore the contrast of sea and land.

Kidson died on 12 June 1939 without writing the final summary discussion of his work. His charts and analyses, made during the 1930's but not published until 1946, seem out of date, but as Gibbs [73] pointed out, "he was a pioneer of frontal analysis in the southern hemisphere and was using a new and somewhat unfamiliar tool of analysis, with a particularly scanty observational network. . . .His work should be accorded recognition for its pioneering aspect but his conclusions may be discarded where later, more soundly based evidence disproves them." Gibbs also emphasized that he studied conditions throughout the year while most other reports deal with summer conditions only.

Three extensive reviews [67, 72, 80] of Kidson's work agreed as to its historical value, but took issue with various aspects. Lamb cited summertime "evidence of a distinct change of regime in the atmospheric circulation in the higher southern latitudes east and west of about the hundredth meridian. Points west of 100°E come under the influence of systems circulating southwards from the Indian Ocean and often recurving towards the west in their later stages," involving a westward movement which Kidson did not conceive.

Fronts. Kidson felt that his charts proved that there is no "continuous polar front encircling the southern hemisphere in high latitudes"; G.C.S. (Simpson?) [72] doubted this conclusion. Meinardus [14] was not sure that the boundary between continental and marine air "should be considered as the polar front," but conceded that such boundaries were quite marked on the east

side of the Palmer Peninsula, along the Adélie Land Coast, and near McMurdo Sound, and must influence weather processes there.

Actually, there are two frontal zones in the subantarctic oceans: the antarctic front, encircling the continent at least in segments, and the southern polar front, trending diagonally southeastward across each ocean and interrupted over the continents [41, 70, 133]. Palmer [18] identified

> . . .three major frontal systems in the Southern Hemisphere (1) that which runs from a point a little south of Tahiti southeastward along the southern boundary of the quasi-stationary subtropical anticyclone of the South Pacific, (2) that which crosses South Africa somewhere between 30 and 40°S latitude and extends southeastward on the poleward side of the South Indian anticyclone, and (3) that which lies in the vicinity of the mouth of the Plata River and stretches across the South Atlantic Ocean and far to the south of South Africa.

While the southeastern ends of these polar-front segments enter subantarctic waters and may even reach the continent, they are less directly connected with Antarctica's circulation than the antarctic front, about which far less is known, especially in winter. For the area south of Cape Horn, Serra and Ratisbonna [42] postulated that

> The Antarctic front follows a SW-NE direction. It passes from the Pacific to the Atlantic, extending from the pressure trough of the Belgica [Bellingshausen] Sea around through the low of the Weddell Sea. It is most intense in winter when the gradient is particularly steep and the circulation most active because of the deepening of the depressions over the Antarctic seas.

This last assumption was not accepted by Coyle [27]. Allowing for wintertime semipermanent lows in the Weddell and Ross Seas, he said:

> We get a very sinuous picture of the Antarctic front during the winter months and here we meet one of the strange Southern Hemisphere facts, namely, that contrary to expectation there seems to be a lesser easterly stream behind the front in the wintertime than there is in the summertime. It is during the summertime that the Weddell and Ross Sea lows disappear, thus theoretically allowing the Antarctic front to straighten out and recede poleward as the summertime weakening of the Antarctic anticyclone becomes effective. . . .
>
> We therefore come to a picture of the Southern Hemisphere wintertime westerly band (30° to 60° south) being composed of two parts, an equatorward warm westerly stream between 30° and 45° south and a cool band of transitional Antarctic air, seen as a west to southwest stream between 45° and 60° south. The Southern Hemisphere "Polar" front then would seem to be this boundary between the . . . currents. . . .
>
> It seems that the cold southwest streams which invade the [South American] continent are breaks through the Antarctic front of cold air drawn up about the westward side of the cyclones, and these streams, with continental transport equatorward, become deflected to south and southeast streams to form the migratory anticyclones which then move up over Argentina and Brazil. It is only when this cool transitional Antarctic air moves north of latitude 45° that it becomes well defined and the "Polar" front becomes well developed as it moves against the tropical continental masses. . . . It is difficult to say just when the leading edge of a cold mass ceases to be the Antarctic front and becomes the Polar front.

On their January and July maps, which extend only to 70°S, Haurwitz and Austin [133] showed an antarctic front northwest of the Palmer Peninsula in July, northeast of the Weddell Sea in January.

No continuous antarctic front, but only segments of it, were found by those in the best position to observe it, the aerologists [2] of Operation Highjump; on their mean surface pressure chart, "The mean position of the zone of convergence between the polar easterlies and maritime westerlies, [which] represents the antarctic front, is not accurate because the methods of summarizing and presentation of data obscure the minute details of the pressure trough." In summer, semipermanent segments of the antarctic front were found along the pack-ice edge in the Bellingshausen Sea and south of Australia, extending west from 170°E along 65°S.

Each section was either warm or cold, depending on the relative strengths of the warm moist air to the north and the cold dry air to the south. The segment south of Australia was normally 50 to 150 miles north of the ice pack, sometimes 500 miles north, and occasionally pushed onto the continental plateau itself by extremely strong northerly circulation. Strong outbursts from the anticyclone along 145°E, which was bounded by this front, at times drove it eastward to trend southeastward across the Ross Sea. As a cold front, it had a line of snow showers, a wind shift of as much as 90°, and a temperature drop of 2 to 3F, occasionally 5 to 7F. As a warm front, it had a well-defined cloud shield, but without cirriform clouds, and snow showers ahead of the snow shield.

As long as the anticyclone located along 120°W during the 1947 summer was strong, its cold air mass did not "meet a barrier or front that would separate it from the warmer air mass to the north," but when it was reestablished after an intense low had penetrated the southeastern Ross Sea, a weak cold front formed near 65°S.

The following summer another group of aerologists found [4] "the antarctic front . . . observed on numerous occasions . . . to be very similar to the Equatorial front . . . a zone of convergence of two air masses with similar properties. The slope of the front varies according to which air mass is the colder."

Air Masses. The Highjump aerologists operating south of Australia assumed that the cold dry polar continental (*cP*) air of the high antarctic plateau was transformed by slight humidifying of the lower layers and subsidence aloft into continental antarctic (*cA*) air of the coastal area and solid pack ice, then into maritime antarctic (*mA*) air by rapid humidification as it passed over open pack ice or open water for 50 to 100 miles, after which it became fresh polar maritime (*mP*) air, with "the antarctic front the northern boundary of this *cA* or *mA* air mass."

Of the eleven air masses affecting South America, distinguished by Serra and Ratisbonna [42] in their pioneer study, "the originally continental mass, *A*, changes into *At* (transitional Antarctic) and finally into *Pm* (polar maritime)" as the air is humidified and warmed in leaving the continent, generally west of the Weddell and Ross Seas. In winter, *Pm* stagnating over Patagonia becomes continental polar air (*Pc*); active polar masses (*Pk*) moving northward were distinguished from returning polar masses (*Pw*) returning poleward over South America.

Although basing his discussion to some extent on this study, Coyle [27] did not use these names or indicators, preferring to consider currents rather than air masses. Apparently without reference to this or other previous Southern Hemisphere classifications, Robin [38] identified three air masses in the area south of Cape Horn: "Antarctic air (*A*) . . . over the continental and barrier ice of Antarctica, Polar maritime air (*Pm*) . . . in the southern half of the westerly wind belt of the southern hemisphere, [and] a more temperate type of maritime air (*Tm*) was also occasionally experienced, this air coming from a more northerly portion of the westerly wind belt." The antarctic front separated *A* and *Pm* air, and was strongest when it lay along the edge of the pack ice.

Generalizing at second hand, Haurwitz and Austin [133] concluded:

> The air masses of the continental antarctic resemble the *cP* air of northeastern Asia. The principal differences are the high frequency of steep lapse rates near the stirred surface layer and the very cold temperatures at all levels over the southern continent. During summer, antarctic *cP* air is still very cold and, except for a gradual rise in temperature, appears to resemble the winter air mass. Throughout the year, low specific humidities are characteristic of the southern *cP* air masses. . . .
>
> Because of the high topography, *mP* air masses affect only the periphery of Antarctica, where the cyclonic circulation is reasonably intense in summer and winter. Consequently, the summer air mass probably lacks the stability of the Northern Hemisphere air mass. Therefore, the lapse rate is likely to be approximately moist adiabatic throughout the year. Besides increasing the temperature and cloudiness of the coastal area, *mP* air must also supply the moisture for the light precipitation of the interior plateau.

Six air masses were deduced for the Southern Hemisphere by Gentilli [9] by applying to Shaw's classic maps of mean temperature and pressure [111] the air-mass criteria in use in the Northern Hemisphere:

Air Mass		*A*	*Pm*	*Tm*	*Eq*	*Tc*	*Pc*
Area of source in millions of square miles	summer	8	20	34	34	?	
	winter	11	30	31	16		?

The greatest contrasts, and hence most active fronts, occur between the polar maritime air (found between 40° and 68°S in summer and between 34° and 65°S in winter) and tropical continental air (found typically in Australia in summer). Polar continental air occurs only in South America in winter, equatorial air is formed as far as 24°S in summer, and superior (*S*) air is presumed to descend under certain conditions.

While conflicting in notation and definition, these various air-mass classifications can be harmonized. Despite Kidson's warning [75] that there is no "air mass to which the application of the term 'antarctic' could be justified," there seem to be three such masses: continental antarctic (*cA*) in the interior, transitional antarctic (*nA*) along the coasts, and maritime antarctic (*mA*) over the pack ice and the ocean south of the pressure trough, convergence zone, or antarctic front. To the north is a vast mass of maritime polar (*mP*) air. The symbols of various authors apparently fit this classification as follows:

	cA	*nA*	*mA*	*mP*
Highjump	*cP*	*cA*	*mA*	*mP*
Serra and Ratisbonna	*A*	*A*	*At*	*Pm*
Robin	*A*	*A*	*Pm*	*Tm*
Gentilli	*A*	*A*	*A*	*Pm*
Haurwitz and Austin	*cP*	*cP*	*mP*	*mP*

Proof of the existence of these masses (perhaps *nA* is really *cAk*), and better definitions and criteria, must come from meteorologists drawing regular synoptic maps of extensive antarctic and subantarctic areas.

Storms. Waves formed on the antarctic front west of the Ross and Bellingshausen Seas, the Highjump aerologists found, moved eastward and occluded, often merging with deeper systems which had approached from the northwest. Some antarctic frontal waves dissipated near the Balleny Islands, others curved southeastward into the Ross Sea and dissipated before reaching its southeastern corner; in the Bellingshausen Sea they merged into old Pacific Ocean occlusions. These storms were minor compared with those from the north:

> Wave formations developing on the polar fronts of the Atlantic, Indian, and Australia-New Zealand areas occlude and approach the continent usually on an east-southeast track [at 20 to 25 knots in January, 35 to 45 in March]. During periods of low circulation index these lows, upon approaching the continent, tend to stagnate in. . .semi-permanent low pressure areas. . .in the Ross Sea, near 120°E along the edge of the ice pack, in the western part of the MacKenzie Sea [60°E], and in the eastern part of the Weddell Sea. During high index conditions these lows stagnate only intermittently in these areas. . . .
>
> When a migratory low pressure center stagnated in the Bellingshausen Sea, a new center developed off the northern tip of the Palmer Peninsula,. . .deepened slowly but moved rapidly off to the eastward. . . . A northward outbreak of cold continental air [occurred] along the east coast of the Palmer Peninsula and behind the low as it moved into the Weddell Sea.

These summertime conclusions are reinforced by those reached during the ensuing months by Robin [38], meteorologist in charge of the British station at Signy Island, South Orkneys, during 1947–48 (and currently with the Norwegian-British-Swedish expedition): "Cyclones observed in the Antarctic front were either well-developed cyclones which approached Graham Land and from the west, or were young cyclones which formed near the north tip of Graham Land, the latter being more in evidence in late autumn and spring." Both types moved rather rapidly (about 600 miles per day) east-

ward and not, as previously presumed, southeast into the Weddell Sea. Both young and old cyclones occur in groups of twos and threes followed by an "injection of a cold air mass over the South American continent" which may reach Brazil, as others [27, 32, 33, 41] have found.

Mean monthly pressure charts for the same area, based on unpublished observations of Rymill's 1935–37 expedition [40] and available reports from South America and the South Orkneys, indicated to Mirrlees [36] either that the main track of depressions is farther south than previously described or that there may be actually two such tracks.

Two such separate tracks were found in the southeast Indian Ocean by Gibbs [73] who studied the reports of Palmer, Kidson, and Operation Highjump, and 6-hourly maps of the southern Indian Ocean during the first year (1948) of complete weather observations at Marion, Heard, and Macquarie Islands. Gibbs concluded that depressions in this area originate north of 45°S, as wave cyclones in winter and spring but frequently as frontless cyclones in summer and autumn. They travel southeast, intensifying between Marion and Heard, occlude and retard after passing Heard, become old cyclones by the time they pass Macquarie, and "probably move to the Ross Sea area, where they weaken and finally disappear"; a second track runs from western Australia to Macquarie.

The Antarctic front is generally impelled northward into the latitudes of the westerlies by the approach of one of the great depressions to the vicinity of the Antarctic coastline. Subsequently on reaching lower latitudes wave development may occur on it and the waves so developing may become one of the great southern depressions.

Substantially similar concepts of fronts, air masses, and weather processes over the oceans south of Australia and New Zealand were reached independently by Japanese meteorologists[4] on board whalers in recent years.

Circulation. In Palmer's concept of Southern Hemisphere circulation [18], cyclones are formed in groups off the east coasts of continents by the interaction of polar maritime air of the westerlies and tropical air flowing southward around the three subtropical anticyclones. These cyclones travel southeastward, first in the general circulation around the highs and then with the westerlies, developing, occluding, and finally filling as they approach Antarctica. New depressions form as waves on their fronts and continue somewhat farther. This model implies that cyclones which actually reach Antarctica are the second or third generation of systems which formed originally in low latitudes several thousand miles to the northwest

Frontal zones were of less interest to Lamb [81, 82, 83] than the general circulation of the Southern Hemisphere. By the end of his three summer months in subantarctic waters he was drawing usable maps for the entire hemisphere, although he was unable to obtain reports from whalers other than those in his own group or from the contemporaneous Operation Highjump. Analyses were based on North Atlantic experience and the postulate that "stable, warm anticyclones exercise a controlling influence on the circulation patterns far beyond their own limits."

These 1947 summer maps showed groups of occlusions symmetrically located, with a pattern of six such groups spaced 60° of longitude apart (and six intervening subtropical anticyclones) characteristic of low-index conditions, four groups 90° apart with higher zonal index, and a hint that as winter approached the pattern would reduce to three groups 120° apart.

Earlier, Kidson [75] had found "a strong suggestion that the moving anticyclones originate as some periodic function of the upper atmosphere, or of the atmosphere as a whole, which is continually tending to produce them at intervals of about 45° of longitude." This was based on his daily charts of 1912–13, when the mean speed of anticyclones, 8.8° per day, "was certainly above normal"; "more anticyclones passed during the year than usual," and their "mean latitudes were ... unusually high." Such 45° spacing implies a hemispheric pattern of eight anticyclones and intervening occlusion groups and, by extension of Lamb's conclusions, an unusually low zonal index with greatly increased meridional exchange of air.

The period from 2 February 1912 to 31 January 1913, studied by Kidson, may well have been different in general characteristics from the late summer of 1946–47, on which Lamb based his analysis. In the Northern Hemisphere, the latter period was quite abnormal; Namias [137] found pressures in the Arctic basin somewhat below normal during December and January and greatly above normal in February and March. Throughout this winter, the zonal index was below average and the total mass of air over the Northern Hemisphere above normal. On the other hand, during the 12 months studied by Kidson, the Northern Hemisphere zonal index varied from slightly below average to exceptionally above average; on the whole it was nearly 0.6 m sec^{-1} stronger than average, or about one-third stronger.

These departures from average of the Northern Hemisphere zonal index are directly opposite to those suggested by Lamb's and Kidson's analyses, and it is tempting to think that the indexes vary in opposite senses in the two hemispheres. If the negative correlation between zonal index and total atmospheric mass north of 20°N, found by Brier [128], represents interhemisphere transfer, a complementary relation of the hemispheric indexes is to be expected; but it may merely represent mass transfer from low to high latitudes. Opposing any inverse relation between the zonal indexes of the two hemispheres is the belief that all climatic changes, from ice ages to unusual years, are due basically to similar changes in the atmospheric circulation; since the larger climatic variations were simultaneous

4. Two Japanese reports were received after completion of the bibliography: Oceanographical Section, Central Meteorological Observatory, "Report on Sea and Weather Observations on Antarctic Whaling Ground (1947–48)." *Oceanogr. Mag.* (Tokyo) 1: 49–88 (1949); "Report ... (1948–49)." *Ibid.*, 1: 142–173 (1949).

in both hemispheres, parallel variations in circulation would be expected.

As yet, no series of Southern Hemisphere maps is adequate to give zonal index data for comparison with the Northern Hemisphere, but current research should provide preliminary answers. With any correlation thus established between indexes of the two hemispheres, the Southern Hemisphere index can be estimated, from Northern Hemisphere values available back to 1899, for those periods of detailed antarctic observations. Pending such further study, the possibility remains that the two periods whose weather has been studied intensively, 1912 and the 1946–47 summer, were both rather abnormal, 1912 having a very low zonal index with more storms and more meridional air exchange than usual, and the 1946–47 summer having a very high zonal index with fewer storms and much less meridional exchange than usual. Furthermore, variations in the circulation must be considered in evaluating any meteorological data from Antarctica.

WAVES

Characteristics. Nonperiodic *waves* of atmospheric pressure, found on the barograms (actual or reconstructed from barometer readings) of all antarctic stations with an amplitude of about 0.6 in., are a very controversial phenomenon of antarctic meteorology. Only the nature of the polar anticyclone has aroused more discussion than these waves, which are defined by agreement as having a change from minimum to maximum of at least 0.2 in. or 5 mm (6.7 mb).

That such waves can be found is not denied; the argument is whether they are "true pressure waves traversing the upper atmosphere,... travelling outwards from the center of the antarctic continent," as postulated by Simpson [112] and supported by Loewe [87] and Lamb [81, 82, 83], or merely reflect the passage of ordinary fronts and depressions, as vehemently maintained by Meinardus [14], Reuter [98], Kidson [74, 75], Palmer [89], and Ramage [64].

Unfortunately, these waves, about whose cause and exact place of origin Simpson did not speculate, have been often confused with the long-period *surges*, for which he gave both cause and place of origin. These surges, found from 10-day running means of pressure, have a constant period of about one month, but decrease in amplitude about 0.162 in. per thousand miles as they travel outward in all directions from 80°S, 120°W, where the extrapolated amplitude is 0.677 in. They are "due to increases and decreases in the intensity" of the upper-level cyclone "with the centre of lowest pressure over the low-lying region which we have reason to believe exists in the Pacific quadrant of the antarctic"; the epicenter was determined so that the observed amplitudes would fit the assumed law of linear decrease with distance. The surges explain why monthly pressure departures throughout Antarctica tend to vary similarly, and inversely from pressure departures in South America and the southern portions of Africa and Australia; surges are not reflected in local weather phenomena.

The only visit thus far to the presumed epicenter of these surges, by Ellsworth [120] in the spring of 1935, encountered twelve days of variable bad weather, apparently from occlusions penetrating a deep bay to the north (see p. 921). Since it is likely that low pressure prevailed during this period, the daily pressure readings from Rymill's Argentine Island base (65°15′S, 64°16′W) and Laurie Island, the only antarctic and subantarctic stations operating during 1935, could be tabulated in 10-day running means to determine whether Ellsworth's visit corresponded with a surge minimum.

Waves and surges were discussed by Simpson separately, the only connection between the two being that the apparent line of wave propagation, extended backward, "passes very near to the position 80°S, 120°W about which the pressure surges were found to have their maximum intensity." Yet Kidson, Ramage, and Lamb have given the surge epicenter as that of the *waves*, whose origin Simpson did not particularize any more closely than "the center of the antarctic continent"; even Meinardus confused waves and surges.

Table III. Antarctic Pressure Waves

Location (westward)	No. of years*	Period (hours)	Amplitude (inches)
Framheim	1	163	.624
McMurdo Sound	4 S	152	.572
" "	5 L	152	.560
Cape Adare	1	119	.549
Macquarie Island	2	98	.66
Cape Denison	2 L	102	.57
" "	– M	108	.61
Queen Mary Land	1	131	.59
Gauss	1	122	.642
Kerguelen Island	1	69	.634
Deutschland	1	124	.61
Laurie Island, South Orkneys	–	91	.642
Snow Hill Island	2	107	.567
Belgica	1 S	124	.630
"	1 M	134	.63

* Values cited by Simpson (S), Meinardus (M), Loewe (L).

Average amplitudes and periods of waves found for all the earlier antarctic stations, and the number of years on which they are based, are given in Table III. Data of expeditions of the last two decades have not been analyzed for such pressure waves, largely because their hourly values have not been published, or even computed in many cases. Although from 1935 to 1949 there were nearly 40 station-years of observations in the Palmer Peninsula area by the British, Americans, Argentines, and Chileans, the only data published so far are brief monthly summaries for Rymill's 2-year expedition [40] and Ronne's recent wintering [37], and a note on the British observations [38]. Three years of hourly pressures for Little America have been published [47, 50], but they have not been analyzed for waves.

Movement. The crux of the pressure-wave dispute is the asserted northwestward travel of the waves. This direction of propagation is taken to prove that the pressure changes which they cause (and from which they are found) cannot be due to the eastward motion of subantarctic pressure systems. Constancy of wind speed

and direction, despite marked pressure fluctuations at several antarctic stations, notably the *Gauss*, has been cited to prove that these waves, and not cyclones, control the weather processes.

Northwestward travel of the waves was assumed by Simpson because of their progressively later occurrence at stations at greater and greater distances northwest of Framheim, the easternmost of the three 1911 Ross Sea stations. Superposition of barograms for the three stations shows good correspondence, with such time lags in occurrence of crests and troughs that Simpson concluded the waves "travel with a linear wave front . . . along a direction parallel to a line joining Cape Adare and Framheim" at about 35 mph. In all, Simpson found waves in the barograms of eight antarctic and subantarctic stations, but only the three Ross Sea locations were simultaneous and close enough to indicate the direction of travel.

From detailed analyses, Simpson concluded that west-moving pressure waves alter the existing local pressure distributions so as to cause blizzards and other phenomena, not readily explained otherwise, at various antarctic stations. This he considered stronger proof of the waves' existence than the apparent motion; for his own station, "it is difficult to see any close relationship between the winds at Cape Evans and the actual pressure waves, as would be the case if the pressure waves were due to the passage of high- and low-pressure systems."

Using data subsequently published for three stations to the northwest of the Ross Sea, Loewe extended the general westward movement by comparison of barograms for Macquarie Island, Cape Denison, and Queen Mary Land with each other and with barograms for Cape Evans. He also found a higher statistical correlation between pressures at pairs of these stations, assuming westward motion at the rate indicated by this comparison, than for eastward motion corresponding to the average travel times of subantarctic pressure systems.

However, since "the southwest-to-northeast direction of wave fronts in the Ross Sea, as found by Simpson, cannot be extended as far west as Cape Denison," Loewe postulated that "the crest and trough lines of the waves west of the Ross Sea run rather from west to east, the waves radiating outwards from the continent," so that the 35-mph speed would be maintained. But his waves reach Macquarie Island, twice as far from Cape Evans as is Cape Denison, too quickly for such a pattern, and his later finding that waves reach Queen Mary Land 19 hours later than Cape Denison, 1300 miles due east, requires either northwestward motion or rapidly accelerating westward progress.

Objections. Travelling pressure waves were deemed unnecessary by Meinardus, Reuter, Kidson, Palmer, and Ramage to account for observed conditions in Antarctica. Meinardus considered the waves found for the different stations as indicating the "unrest of the atmosphere," and insisted that the *Gauss's* weather phenomena were adequately explained by the eastward passage to the north of pressure systems which are not circular; Simpson had assumed circular systems in proving that the *Gauss* winds were too steady to be cyclonic. However, Meinardus admitted [14] that in a few cases pressure waves from the interior could account for the *Gauss* weather.

Palmer was not so generous: after reviewing Meinardus' discussion, he redrew some of the 1902 maps on the same patterns he used for a 1932 series based on whaler [96] reports and concluded that Simpson's "interpretation of the *Gauss* observations was, to say the least, far-fetched," and that "there is no evidence for the existence of Simpson's 'pressure waves' in the far southern Indian Ocean."

In his discussions of Shackleton's 1907–9 expedition and Mawson's 1911–14 data, as well as elsewhere, Kidson maintained that passage of complex frontal systems could account for all the observed pressure and weather phenomena, including the apparent westward motion of pressure maxima. This motion he verified for Simpson's original three stations by superimposing curves of the average pressure difference for each two hours before and after pressure maxima and minima at Cape Evans and the corresponding values at Framheim 9.1 hours earlier and at Cape Adare 10.7 hours later, finding "remarkably close relationship between the pressure changes at the three stations."

For the 1912–13 data, in which Loewe "found pressure waves radiating outward from the antarctic continent," Kidson agreed that:

> On the average, the changes at Adélie Land lag considerably behind those at Cape Evans. . . . The amount of this lag is, however, very variable. Sometimes it amounts to practically nothing and there are even occasions when changes occur earlier at Adélie Land than at Cape Evans. It would be extremely difficult to account for all phases of the relationship between the two stations on the basis of Simpson's waves. . . . It is not possible to account for the Queen Mary Land pressure variations as being due to waves which have passed Framheim, Cape Evans, Cape Adare, and Adélie Land. . . . [It is] still more difficult to imagine. . .that the waves which have reached Adélie Land 13½ hours after Cape Evans pass Macquarie Island only 7 hours later.

He explained the whole mystery by assuming that "the fronts are, on the average, inclined at a large angle to the meridian. In the Ross Sea region, indeed, they must lie almost east and west." Kidson's table of the mean travel times of fronts indicates "the average interval in hours after the passage of Queen Mary Land at which each station would be passed": Framheim 39, Cape Evans 48, Cape Adare 55, Adélie Land 57, Perth 68, Macquarie Island 114, etc.

All the phenomena which Simpson explained as due to pressure waves, Ramage attributed to the passage of Types *A* or *D* of the six types of cyclones which he found in a detailed single-station analysis of two years of Little America data; these two types, both moving eastward over the Ross Sea north of Little America and one (*D*) later curving southward, "make up 35 percent of the cases considered," and two pressure-wave examples cited by Simpson were, to Ramage, *D* types:

Fluctuations of the meteorological variables in the Ross Sea area can be attributed to a succession of depressions not differing materially from those of lower latitudes. . . .Apart from some brief periods, the pressure systems of the Ross Sea are connected with, and have a definite effect on, the systems further north. . . .Blizzards set in when the isobars (usually in the rear of a depression) coincide with the direction of the down slope winds.

Except for some rather forced analyses, Ramage's interpretations are rather convincing: there is an obvious relation between the Ross Sea cyclones and westward-moving pressure waves, but whether the relation is one of simple cause-and-effect or one of steering-and-intensification cannot be determined.

Suggestions. Little attention has been given to one aspect of the pressure waves: while their amplitude is constant (about 0.6 in.) throughout Antarctica and even at subantarctic islands, their period decreases steadily from Framheim to Cape Denison. (Simpson and Loewe confusingly called the duration in hours the wave length.) If these are classical waves, in which the product of wave speed and period gives wave length (distance, not duration), then waves travelling from Framheim to Cape Denison with period decreasing from 163 to 102 hours must either increase in speed or shorten in length, or both.

As Lamb has suggested, it is likely that Antarctica's coast is affected both by westward-moving pressure waves and "the familiar effects of fronts and depressions;. . .these apparently conflicting influences can be seen as interlocking parts of the same atmospheric circulation." Much of the wide variation in pressure waves, and the several anomalous weather sequences which have forced wave opponents into rather tortuous synoptic analyses, can be explained by assuming that both processes are at work.

Arctowski, the first meteorologist to winter in antarctic regions (on the *Belgica*, 1898–99), has suggested [5] that

> Even the formation of lows and highs of pressure, their tracks and their changes in form and extent, may be directly produced by atmospheric waves. . . .' Most probably the pressure changes observed on Kerguelen Island are the product of two intercrossing systems of waves, one of them originating on the Antarctic continent.

Synoptic evidence of a westward-moving antarctic pressure wave (misnamed a surge), and a possible explanation for it, were found by Lamb [81] on the maps covering all Antarctica which he drew at the end of a summer on Antarctica's Indian Ocean coast:

> Between 19 and 23 March 1947 a pressure surge [wave] moved from east to west across Antarctica, starting from James W. Ellsworth Land, but. . .seems to have come in from outside, originating in the breakdown of the subtropical high-pressure system of the south-west Pacific east of New Zealand. This view carries with it the further suggestion that warm air of subtropical origin was transferred, particularly in the levels of the atmosphere above about 4,000 feet, far to the south and possibly right over Antarctica. No information exists to show what temperatures might be observed in this air upon its arrival over Antarctica or how rapidly it would be chilled thereafter by the radiation conditions of high latitudes; such invading warm air would in any case normally be separated by a shallow surface layer of extremely cold air from the actual ice of the antarctic plateau, but it is likely that the more abrupt mountain peaks and ranges would penetrate it. (See also [76])

Another example of a warm polar anticyclone, "its warmth due to subsidence in the whole air mass of which it was constituted" and maintained by inflow of air at high levels from the northeast above a vigorous and extensive disturbance over New Zealand, was studied in detail by Palmer [62]. However, he did not recognize that this anticyclone, or a part of it, caused a typical pressure wave at Little America on 29 November 1929 as it moved northwest.

The anticyclone, deduced from hodograph analysis of two long balloon runs on the 29th to be "south of Little America," was actually over the polar plateau. Byrd's South Pole flight [115] through it on the 29th (GMT) encountered southerly winds throughout, and reported clouds forming to the east over the mountains. Gould [124], heading the geological party 350 miles south of Little America at the southern head of the Ross Shelf Ice, noted on the 27th that "our bad weather was moving northward for, as conditions improved with us, they had grown less favorable at Little America." Gould's camp had "perfect weather" all of the 28th (GMT); it remained warm and clear until late on the 30th, when a slight south breeze freshened into "a veritable antarctic blizzard" which was "the warmest southern wind we had ever faced and grew warmer as we neared the mountains"; southerly winds usually were biting cold, but this one was uncomfortable because of its strength, not because of its temperature.

Hypothesis. To incorporate this information, Palmer's three synoptic maps for 28, 29, and 30 November may be revised and extended south and west of Little America to show a lobe of a polar anticyclone moving out along about 140°E (one of the anticyclone cells postulated by the Highjump aerologists, representing frequent outflow, is along 145°E or 155°E; one of Lamb's high pressure centers is at 130°E). Palmer's hodograph for 1600 on the 29th indicates "that the anticyclone was becoming less intense and was probably re-oriented to extend off the continent somewhere in the northwest."

Pressure at Little America reached a maximum of 29.55 in. from 1000 to 1200 on the 29th (GMT), a rise of 0.22 in. in 26 hours, then fell 0.21 in. in 21 hours as an occlusion approached from the northwest. Both these changes exceed 0.20 in., the criterion for a "pressure wave." Winds remained easterly during the entire two days between pressure minima, but were 12 to 18 mph during the day and a half preceding the maximum and decreased to 3 mph or less for ten hours during the subsequent pressure fall, then turned NE and increased as the occlusion passed.

In this case, passage of a relatively weak warm anticyclone several hundred miles to the westward did little

more than affect the pressure and modify the strength of the prevailing easterly winds. A much stronger anticyclone, or one passing closer, would give Little America the "deep southerly current aloft (which) attended or preceded settled clear conditions and good visibility," as Harrison [55] found on the first Byrd expedition, and as successive meteorologists at Little America have verified.

To attribute all weather phenomena of the Ross Sea to dying cyclones from the northwest, as Palmer and Ramage have done, is to consider only half the picture. Perhaps the antarctic anticyclone develops lobes which become separate centers, one or more of which flow out into the westerly circulation. This process may be caused by the invasion of air from lower latitudes in another quadrant, as Lamb suggested, or by the impinging of cyclones on the anticyclone in such places as the Ross and Bellingshausen Seas; possibly such impinging occurs only because the anticyclone already has broken into separate cells. In the present state of meteorological ignorance, these points cannot be determined definitely.

Regardless of the first cause, such interplay of subantarctic cyclones and polar anticyclones is a plausible explanation of observed conditions. The anticyclones, travelling north or northwest, will give pressure maxima as they progress, so that pressure waves may be found moving in the same direction. The cyclones, moving east or southeast, will give pressure minima moving in that general direction.

Probably most of the minima of the controversial antarctic pressure waves are due to subantarctic cyclones, and many of the maxima may represent only the wedges between these cyclones, but the more pronounced maxima are apparently caused by outbreaks of the polar anticyclone. Application of this hypothesis to the available data, and examination of the newer data, particularly those for the summer of 1946–47, from this viewpoint, should provide much information on antarctic meteorology and help settle the acrimonious dispute over antarctic pressure waves.

TEMPERATURES

Upper-air temperatures and pressures were first measured over Antarctica in 1911 (Table IV), but only the nine-month series at Little America III during 1940–41 [47] and the 1947 summertime observations are sufficiently extensive, in number and height, to shed much light on the atmospheric circulation. Simpson's 12 balloon meteorograph flights at Cape Evans in 1911 [112], Barkow's 128 kite meteorograph flights from the *Deutschland* in 1912 [101], and the 57 kite and airplane meteorograph ascents at Little America in 1928 and 1934 [50] all ended well below the tropopause, and have been used chiefly to study the height and variations of the surface inversion [63, 99]. Antarctica's first radiosonde ascents, made in 1934 by Dr. Jörgen Holmboe, meteorologist on Lincoln Ellsworth's attempted transantarctic flight, were so erratic that they have never been worked up. Records of the first successful radiosonde ascents close to Antarctica, the 36 made from the *Schwabenland* in 1939 [94], were destroyed during the war, and only partial extracts are available [97] for the analyses which have recently appeared [8, 91].

Table IV. Antarctic and Subantarctic Upper-Air Temperature Soundings
(Information to 1 January 1950 for all places south of 50°S, except South America.)

From	To	Location	Method*	No.	Highest level (m)
13 Aug. 1911	25 Dec. 1911	Cape Evans, McMurdo Sound, Ross Sea	B	12	6743

— Feb. 1949	— Feb. 1949	*Commandant Charcot*, 136° to 164°E	R	25	—

* Balloon meteorograph (B), kite meteorograph (K), airplane meteorograph (A), radiosonde (R).

Meteorological observations in phenomenal quantity were made in antarctic and subantarctic waters during January and February of 1947, including 348 radiosonde ascents by the three groups of the U. S. Navy's Operation Highjump and about 90 by the Dutch whaler *Willem Barendsz* in the north Weddell Sea. All the Highjump ascents have been published [3], albeit only by standard pressure levels and arranged chronologically regardless of location; the Dutch soundings mentioned by Lamb [83] have not yet appeared.

The following summer, two U. S. Navy icebreakers obtained 104 more radiosonde observations around the continental edge; these are available on microfilm but have not been published because of the lack of prompt

response to the thorough publication of the more extensive Highjump data, whose use has just begun [60, 91]. At Macquarie and Heard Islands, the Australians [69] began daily radiosonde observations early in 1948, and at Marion Island, the South Africans [92] began regular radiosonde ascents in May 1949. During February 1949, twenty-five flights were made from the *Commandant Charcot* [71] off the Adélie Land coast, south of Australia between 136°E and 164°E, as it unsuccessfully tried to land a French expedition which did establish a base a year later.

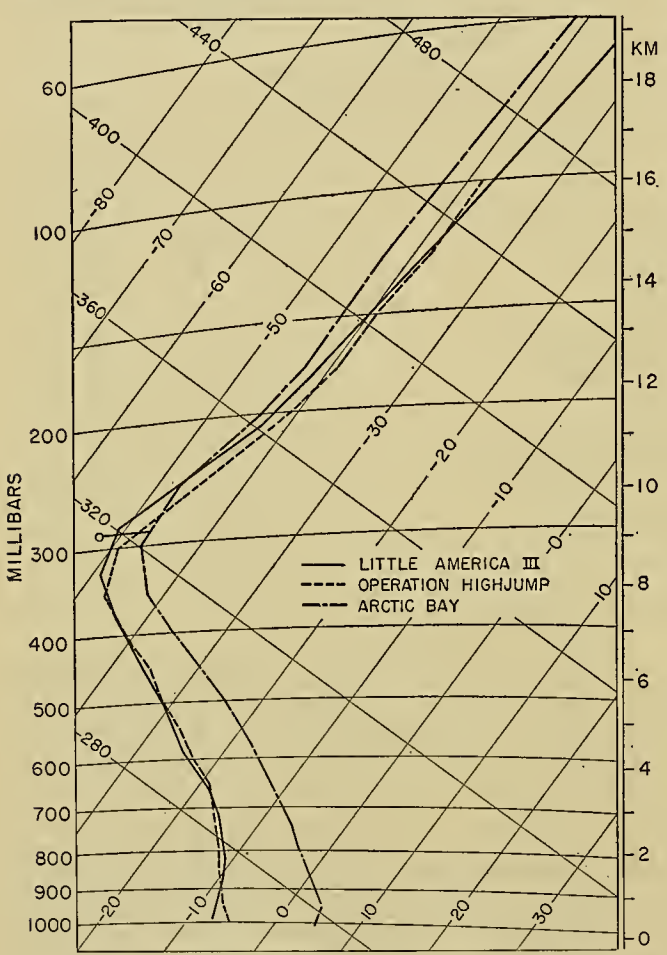

FIG. 1.—Antarctic and arctic summertime soundings. The curve for Little America III (78°30′S, 163°50′W) is based on thirteen soundings during the period 1–15 January 1941 [47]. The curve for Operation Highjump (70°–75°S, 160°W–165°E) is based on thirty-four soundings from 14 January to 8 February 1947 [3]. The data for Arctic Bay, Canada (73°16′N, 84°17′W) are from 152 soundings during July, 1943–47 [134]. The tropopause at Arctic Bay was computed separately.

Despite these extensive summertime soundings, the 1940–41 series provides the only information to date on the entire troposphere and lower stratosphere throughout the year. The 265 days covered by the 1940–41 data can be extended another twenty-two days by the 13 Highjump flights made from ships in the Bay of Whales and 21 others made in the Ross Sea south of 75°S. Close agreement between the averages of these 34 shipboard ascents and the 13 at Little America six years earlier is shown in Fig. 1; also plotted for comparison are the average temperatures of the warmest month, July, at North America's coldest aerological station: Arctic Bay, Canada (73°16′N, 84°17′W, 11 m m.s.l.), the only station on the continent at which the mean monthly temperature at 850 mb is never above freezing [134].

Wintertime. The Little America soundings show the tropopause in summer at roughly 9 km, −50C, and slightly higher and much colder in winter, at 10 km, −70C. The annual variation in stratosphere temperatures and lapse rates is so great that in summer it is warmer than −40C above 14 km, while in winter the stratosphere lapse rate approaches that of the troposphere and the tropopause tends to disappear [45].

Interpretation of the wintertime soundings is difficult because the extreme cold imposed an effective ceiling on the balloons, so that the higher soundings were all in warmer-than-average air. This tendency is shown by a diagram (Fig. 2) of the extreme temperatures at each

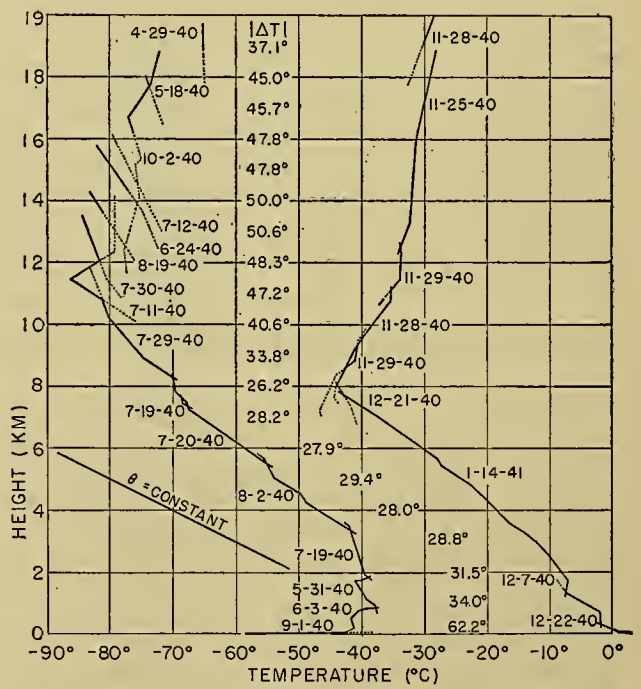

FIG. 2.—Observed temperature extremes and absolute range $|\Delta T|$ at standard levels over Little America III [47]. Dates are those of individual soundings. A dry-adiabatic (θ = const) is drawn for comparison.

kilometer level, with portions of the soundings in which they occurred. The envelope thus formed is smooth for both extremes in the troposphere and for the warmest values in the stratosphere, but shows that the coldest stratosphere temperatures always occurred in soundings which terminated soon thereafter.

From June through September, none of eighty-eight soundings (one with a 700-gram balloon) rose to 18 km, only two to 17 km, three to 16 km, and five to 15 km. At 17 km, temperatures were −70.8C on 5 June and −75.8C on 14 September. At 16 km, these same soundings gave −69.2C and −75.0C, but the third

sounding, on 12 July, gave −79.3C. At 15 km, the coldest value, −79.5C, was reached on 24 June in a sounding ending at 15,770 m, −82.1C, and was almost 3C lower than the next coldest reading (on 12 July). At 14 km, the coldest reading, −82.1C, was reached on 19 August; only one other August sounding reached 14 km, finding −80.7C, a temperature colder than found at this level in any other month.

Thus it seems that at 14 km and for an unknown distance above, winter temperatures must often be below −80C. Consequently, the absolute ranges of temperatures given in the diagram for each kilometer level are valid only up to about 13 km, where they attain the phenomenal value of 50.6C. They are misleading at higher levels: at 20 km, where the warmest temperature was −28.4C on 28 November, the lowest in late winter was probably colder than −100C, for an absolute range of more than 70C in three months. In the mid-troposphere, however, the absolute range was only about 29C and the range between extreme monthly means is only some 15C, about 40 per cent of the greatest such range in North America, over Hudson Bay [131].

This wide variation of temperatures in the lower stratosphere, unparalleled in the Northern Hemisphere, is for a station not in the interior of Antarctica, but for one several hundred miles from the continent proper, at the very edge of the thick Ross Shelf Ice with open water four miles away in summer and not more than twenty or thirty miles distant in winter. Conditions over the continent can only be inferred from the Little America data, until soundings from the interior are actually available. And inference, with so many factors unknown, can be very misleading.

For instance, Grimminger [49] deduced from the 969 pilot balloon ascents of the first two Byrd expeditions that the tropopause was about 1 km higher in summer than in winter and averaged 7.7 km; his computation assumed that, with increasing latitude, troposphere temperatures decrease and stratosphere temperatures increase, as they do in middle latitudes. Later measurements, however, showed the tropopause lower in summer than in winter, and about 2 km higher than the level of strongest winds, which was around 8 km in 1940 as in 1928 and 1933.

Summertime. Temperatures do decrease with latitude all the way to the Pole in *winter*, in both troposphere and stratosphere, as Grimminger assumed. This is shown in the first meridional atmospheric cross section [60] to use winter data from high southern latitudes, those for Little America already discussed as well as one year's values for Macquarie Island. But the *summer* diagram, for which in addition the Highjump data were used, is open to question: not only do stratosphere temperatures *increase* continuously from Equator to Pole, as it shows, but in the troposphere it is more probable that the lowest temperatures in midsummer occur at about the margin of Antarctica, and that toward the interior temperatures actually increase again.

Poleward increase of temperature in summer in the upper troposphere and in the stratosphere is indicated by the *downward* progress of the springtime warming over Little America, from October at the upper limit of observation, in the mid-stratosphere, to December in the lower troposphere. The pattern is revealed clearly in the individual observations: at 4 km warming does not start until December, at 8 km (just below the tropopause) it occurs chiefly in November, at 12 km in late October and November, and at 16 km in October and early November. At 20 km the warming had already occurred by the time the lower layers became warm enough for a balloon to reach that height on 1 November. The trend is shown even in monthly means (C):

Height (km)	Aug.	Sept.	Oct.	Nov.	Dec.	Jan.
20	...	...	...	−31	−33	−34
16	...	−79	−65	−37	−38	−37
12	−74	−75	−69	−46	−43	−42
8	−64	−63	−62	−53	−49	−49
4	−38	−38	−33	−32	−25	−25

Obviously, advection cannot be the major cause of the stratospheric warming, since the temperatures become warmer than those at the same elevations farther north. The warming at 16 km of about 1C per day could be caused by subsidence of some 100 m per day, about one-third the rate of the downward progress of the start of the warming, which is around 2 km per week. However, the most plausible explanation of the rapid warming is that it is due chiefly to absorption of solar radiation: in the summer half-year, the duration of sunlight increases not only with latitude, but with elevation [130]. At 16 km over Little America, continuous sunshine is received from 10 October onward, but at the surface it does not start until 20 October; at the South Pole, it starts about 10 September at 16 km, and about 20 September at the surface.

This downward progress of available solar energy can explain the apparent heating from above of the atmosphere over Little America, provided the energy is absorbed. Presumably, it is absorbed by ozone, which is known to exist in greater concentrations and at lower levels in the arctic atmosphere than in lower latitudes, and to have its maximum concentration in spring. No measurements of ozone concentration have been reported from Antarctica, but the atmospheric temperature regime seems to indicate that it may be higher than in arctic regions.

This explanation of the springtime warming over Little America implies that farther south, where continuous sunshine begins earlier, the temperature rises sooner, and thus that in spring and up to the solstice the temperature increases poleward at all levels above the surface layer. Consequently, any diagram of summer temperatures over Antarctica, such as those of Loewe and Radok [60] and Flohn [91], should show the −50C isotherm as sloping downward from lower latitudes to about 60° or 70°S, then bending upward vertically; likewise the −40C isotherm probably does not reach the pole, but bends upward similarly around 85°S. At lower levels, the warmer isotherms extrapolated poleward from Little America (78°30′S) should

bend upward, rather than continue downward as in the published figures.

These temperatures, warmer in interior Antarctica than at the periphery, coupled with slightly higher surface pressure, would cause pressures near the Pole to be higher at all levels than around the coasts. Consequently, the isobaric surfaces should be lowest at 60° to 80°S and then rise slightly toward the interior, rather than continue to slant downward (as in Fig. 4 of Loewe and Radok, and up to 300 mb in Flohn's Fig. 8). More precisely, the trough in the isobaric surfaces in early summer probably inclines poleward with height up to the tropopause, so that the 300 mb surface is lowest (5 km) at about the coastline and the 200 mb surface lowest (11 km) some distance inland; Flohn's diagram suggests such a pattern, with a trough around 65°S at 150 mb and higher. Thus upper-level west winds at coastal stations may not indicate an upper-level polar cyclone, but the southern edge of the westerly flow. Implications of these suggestions are discussed in the final section.

The Loewe-Radok cross section for 150°E shows the tropical tropopause extending to 40°S and the polar tropopause beginning under it at 30°S, where it is at 12.6 km in summer, 8.5 km in winter. At 55°S the height is the same, 10 km, throughout the year, and farther south the height decreases in both seasons, but is slightly greater in winter. The twenty-five soundings from the *Commandant Charcot* [71] around 65°S in the coastal icepack, some 400 miles south of Macquarie Island, during February 1949 found the tropopause at 6 to 9 km, −50 to −57C, slightly lower but in general agreement with this diagram. Flohn's summer cross section for the South Atlantic, with Little America data added, shows only one continuous tropopause.

The Loewe-Radok cross section shows tropopause height as nearly constant between southern Australia and Macquarie Island (36° to 55°S), but 1000 miles to the east, in New Zealand, a winter "reversal of the slope of the tropopause" has been noted [57], the average height during July 1945 increasing[5] from 9.7 km at Auckland (37°S) to 10.1 at Hokitika (43°S) and 10.3 at Taeri (46°S). Earlier, Kidson [11] assumed that the "annual variation of temperature in the stratosphere can be little less than that at the surface in subantarctic latitudes and...the base of the stratosphere must vary little," because ocean temperatures between 45°S and 60°S change little through the year.

Other Aspects. Water temperatures at Campbell Island (52°32′S, 169°08′E), about 400 miles south of New Zealand, vary [56] only 6F through the year, from 42.8F in July to 49.1F in February (1942–47). Air temperatures there are 2F warmer in winter, 7F warmer in summer than at Macquarie Island (54°30′S, 158°57′E), 500 miles to the west, which in turn is noticeably warmer [73] than Heard Island (52°01′S, 73°08′E), 3400 miles farther west. Marion Island (46°51′S, 37°52′E), 1600 miles farther west-northwest of Heard, appears from preliminary reports [92] to be substantially warmer than Heard, but colder than Macquarie.

Month by month during 1948, Macquarie was 10F or more warmer than Heard [73], with the difference gradually diminishing with height so that at the tropopause, around 300 mb at both stations, the modal temperature at Macquarie was −50C, Heard −53C. Despite local topographic effects (both stations are a few feet above sea level on the low, narrow necks of peninsulas extending northward from their main rocky islands), winds at Macquarie were northerly, at Heard southerly, showing that the wind regime is far from zonal.

Why should the maximum temperature on clear days during the antarctic night occur, almost without exception, in the hours after midnight? Simpson pondered this problem longer than any other of the many he investigated in compiling the meteorological reports [112] of the last Scott expedition, without developing a satisfactory hypothesis. "In McMurdo Sound there is an excess of temperature at 4 A.M. compared with 2 A.M. and 6 A.M. [only bihourly readings were made] in every month from April to September, and the same effect is possibly present in October, November, and March,...is clearly seen in the temperature observations at the *Gauss*...[and] the Snow Hill observations also show the same effect in July and August." In all cases it was characteristic of cloudless or partly cloudy weather; on cloudy days "during the three winter months when there is no direct solar radiation the day is warmer than the night."

Similar relations were found by Rouch on the Charcot expedition and later in the data of the two Byrd expeditions [65], where the average daily variation of 2C on 33 clear days "is a simple curve with maximum around 1 or 2 A.M. and minimum after noon...I cannot give a satisfactory explanation." Nor is van Everdingen's advective explanation [24] very plausible.

Less mysterious, but still not satisfactorily explained, is the annual march of temperature at Little America [47], which shows a single maximum in early January, but three distinct and progressively colder minima: in early May, in July, and in early September. Evidenced in monthly means, this is shown most clearly by 10-day means (Fig. 3). Temperature averages at other antarctic stations do not show such triple minima, although individual years at many stations do show double minima as found, although not adequately explained, at arctic coastal stations.

Other aspects of Antarctica's temperature regime offer no peculiarities. The interdiurnal variation and the mean daily range [16] change little through the year between 50° and 60°S. They are greatest in winter south of 60°, greatest in summer north of 50°. The

5. This anomaly is shown also on an excellent winter cross section along 170°E from Little America to the equator, published since preparation of this article. Otherwise it and the companion summer diagram are quite similar to those of Loewe and Radok for 20° farther west, but do not attempt extrapolation poleward from Little America. (See Hutchings, J. W., "A Meridional Cross-Section for an Oceanic Region." *J. Meteor.*, 7: 94–100 (1950).)

meridional temperature gradient is strongest in winter south of 55° or 60°S, and also north of 30°S, and weakest in winter between 30° and 55°S.

Atmospheric pressure around Antarctica is exceptionally low; readings as high as 1000 mb are unusual and at Little America on 24 September 1940 sea-level pressure was only 932.5 mb. Meinardus [14] distinguished two types of annual pressure variation: a deep minimum in the Ross Sea area in late winter or early spring (July to October) with a very steep rise to a sharp maximum in midsummer (December or January), and a double period with minima around the equinoxes and maxima near the solstices in the Palmer Peninsula area. Whether this difference is regional, latitudinal, or

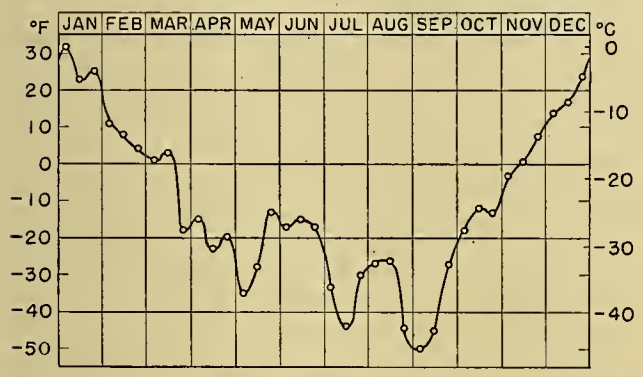

FIG. 3.—Mean surface air temperature for 10-day periods at Little America, based on three years of data.

due to the differing years of observation is not certain; the more recent data from the Palmer Peninsula [36, 37, 40] show no pronounced pattern. In the Ross Sea, the lowest monthly values at Little America have always come in September, while in McMurdo Sound each year has had its minimum in a different month.

Antarctica is the only part of the world where the atmosphere appears to have less oxygen than "normal." Everywhere else oxygen represents 20.95 per cent of the dry constituents of surface air, but the only analyses made of antarctic air [58] gave an average of only 20.56 per cent in summer, and 20.64 in winter except for one day (22 July 1940) which averaged 20.50. Although two leading authorities on atmospheric composition [132] do not regard this deficiency "as well established, since no check analyses with normal air were carried out," these are the only analyses to date and their implications must be considered until they are proven definitely erroneous.

'Atmospheric oxygen is being removed constantly by rock weathering, while burial of organic material results in a net gain. Rock weathering in Antarctica, however, seems insufficient to maintain the observed deficiency, even if all the presently unknown continental areas contained bare rocks undergoing weathering. A possible link between antarctic air and that of the middle-latitude stratosphere, which was considered in 1936 to have an oxygen content of about 20.50 per cent, has been destroyed by recent indications [129] "that the chemical composition of stratospheric air at 70 km is practically the same as that of the troposphere."

PRECIPITATION

Precipitation in Antarctica cannot be measured as it falls, but its total accumulation over a year can be determined by measuring the daily changes in height of the snow surface, using a graduated stick imbedded in the snow. At Little America during 1940 [47], such a program, involving four pairs of sticks several hundred feet distant in four directions from the camp, showed a total accretion during 348 days of 170 cm due to new snow, hoarfrost, or drift snow, and total decrease of 85 cm due to ablation, deflation, or settling. The net increase of 85 cm had an average density of 0.35 and therefore represented a net accumulation of 30 cm or 12 inches of water during 11½ months, most of it in March, June, and July.

In the western Ross Sea the 1902–1909 average (computed from the accumulation over a depot on the Ross Shelf Ice) was 19 cm (water equivalent); other estimates for various years were: Cape Evans 41 cm, Cape Royds 23 cm, Cape Adare 36 cm. Annual precipitation at the *Gauss* was estimated at 80 cm, at Charcot's two Palmer Peninsula bases 34 and 38 cm, and at the *Deutschland* only 11 cm.

At the South Pole, Meinardus [14] estimated annual precipitation to be 2 cm, ablation 1 cm, for a net accumulation of 1 cm; independently, Kidson [74] found it "difficult to imagine that the precipitation at the Pole is greater than 2 inches per year," or 5 cm. For all Antarctica, Meinardus estimated precipitation 7 cm, ablation 3 cm, net accumulation 4 cm; Kidson deduced total continental precipitation at less than 9 cm.

Kidson's estimate assumed that precipitation of all the moisture in the lowermost 2 km of an air mass initially saturated at 32F would give 0.5 cm, and that this process would require twenty days. An entirely different approach was used by Meinardus [107]: "If the interior of Antarctica is covered with snow and ice and there is a discharge of the same to the marginal oceans, it follows that over Antarctica as a whole the precipitation exceeds the evaporation." Outflow of the inland ice, 250 m high and 17,000 km in perimeter, at 150 m per year, totals 640 km³ of ice or 550 km³ of water, requiring an annual net precipitation of about 4 cm over Antarctica to maintain balance [108].

Although Meinardus considered his figures conservative, each of the three factors in this computation seems excessive in the light of recent exploration. Furthermore, there is considerable doubt that the ice which does flow out around Antarctica originates very far inland.

Height. Eighty years ago, an ice thickness of 24 miles at the South Pole was estimated by Croll [117], assuming that the ice cap extended to 70°S and had a one-degree slope, as required "to produce the necessary outflow of ice." However, "to avoid all objections on the score of over-estimating the thickness of the cap," he used a thickness of only 6 miles in his computations, explaining that "the greater thickness of an ice-cap at its centre is a physical necessity not depending on the rate of snowfall," which anyhow would not be negligible

because "the currents carrying moisture move in from all directions towards the pole."

Forty years ago a mean height of 2000 m for Antarctica was deduced by Meinardus [106], since the annual variation in the amount of air over the rest of the world, as computed from mean station pressure values, would be just compensated if the entire surface inside the Antarctic Circle were 1350 m above sea level; if one-third the area inside the circle is at sea level, the rest must be at 2000 m—a value which has been used extensively and uncritically by geographers, geologists, and others. Using the same pressures but different antarctic mean surface and free-air temperatures, Simpson [112] obtained an average height of only 852 m, which he considered just as plausible as 1350; Meinardus' recomputation [109] for the area inside the circle, based on later data, was 1500 m, and for the continent, 2200 m.

Meanwhile, the altitude of the snow surface at the Pole itself was found by Simpson [112], from exhaustive study of Amundsen's and Scott's barometric readings, to be 9172 ft or 2.8 km, 700 ft *lower* than the ice divide crossed by both explorers at 88°30′S, some 200 miles back of the crests of the Queen Maud Mountains which form the south side of the Ross Sea. A similar ridge was found behind the Admiralty Range on the west side of the Ross Sea.

The German *Schwabenland* expedition in 1939 found a new chain of east-west mountains athwart the Greenwich meridian about 250 miles inland. Behind this range, which stretches at least 500 miles and has peaks up to 4 km, the ice surface rises even higher. Herrmann [126] offered an antarctic cross section along the 0°–180° meridian, showing a trough between these mountains and the Queen Mauds, with 1 to 2 km of ice in the trough so that the highest point, at 80°S, is more than 5 km above sea level, and the lowest point of the snow surface is 3 km m.s.l., at the Pole. This range, extending along 80°S eastward to at least 20°E, the limit of German exploration, may be a continuation of one postulated[6] by Lamb [81] to explain the apparent behavior of weather along Antarctica's Indian Ocean coast, and which he found "for my meteorological purposes. . .was a satisfactory working assumption":

> The whole trend of recurving depression tracks, both from the Ross Sea-Wilkes Land sector and in the Indian Ocean sector,. . .lend support to the belief in a topographical barrier in the interior of the continent of similar order of magnitude to the Alps or Rocky Mountains, say 12,000 to 15,000 feet in height. There is no evidence to suggest how far the barrier may extend west and south-west beyond 80°S, 80°E, nor whether it may be a great range of mountains or the main crest of the antarctic ice-cap. Nor can one say whether its crest presents an unbroken contour or is interrupted; but I think its north-eastern end is likely to be nearer 70°S and 97° to 100°E than at the coast itself. . . . The principal south polar anticyclones tend to take up positions centered. . .near the line of this supposed summit and show signs of dividing across it when they decay. . . . Very occasionally a depression moved right across the ice-cap on one side or other of the line of this supposed barrier, but probably never crossed it.

The *Schwabenland* findings, Manley pointed out [12], "go far to alter the simple concept of an antarctic dome more or less symmetrical about the pole." Similarly, the chain of east-west mountains found by Operation Highjump along 76°S from 110° to 140°W have one peak some 6 km high, although the Hollick-Kenyon Plateau behind them, on which Ellsworth landed, is less than 2 km high. Thus recent exploration has generally invalidated the simple model of a high East Antarctica plateau and a low West Antarctica plain, the model on which Simpson based his theory of antarctic weather processes.

Even more important, if there is no central dome to the ice cap, but instead a central trough or basin, then "the greatest problem of the antarctic anticyclone, namely, the origin of the precipitation within the anticyclone," as Simpson put it, disappears. Instead, the continental interior is an area of little or no precipitation, which can well have a perpetual anticyclonic regime, as long as the circulation provides snowfall up to the observed ice crest.

Recession. Even this peripheral snowfall need not equal the annual ice outflow, because Antarctica's present ice is merely "the remains of the Pleistocene glacial ice-sheet and. . .at present a complete recession is taking place." (The rapidity and course of this recession are major problems of the present Norwegian-British-Swedish expedition.) Although in his *Handbuch* monograph [14] Meinardus assumed climatic equilibrium in estimating Antarctica's precipitation, his earlier study [108] pointed out that equilibrium probably does not obtain. There he concluded "that Antarctica during the ice age had, in association with an increased air circulation, higher temperatures, augmented water vapor turnover, greater precipitation, and greater evaporation." Higher antarctic temperatures arose chiefly from increased circulation, so that elsewhere temperatures were lowered, but whether "increased precipitation or lowered temperatures [were] the primary cause of glaciation" in lower latitudes was uncertain.

Manley's mechanism for the original glaciation of Antarctica [12] starts with a relatively ice-free continent surrounded by seas without permanent ice, so that the resulting heavy precipitation along the coasts, and particularly in the mountains adjacent to the Ross and Weddell Seas, would cause glaciation. Outflow glaciers would so chill these seas that their present ice sheets

6. An earlier geographic postulation from meteorological evidence proved unfortunate: "Before the *Scotia* had left the Antarctic Seas, Mr. Mossman was able to demonstrate meteorologically the existence of the land reported by Johnson and Morrell, extending northward to about 65°S at 44°W," largely by the coldness of SW winds at Laurie Island. "Since that time, with the additional data furnished by the Scotia Bay Station during eight years, it has become more than ever certain that New South Greenland, as Johnson called it, really exists." Within a year after Dr. W. S. Bruce wrote thus in *Polar Exploration* (New York & London, 1911), Dr. Wilhelm Filchner sledged 40 miles from the beset *Deutschland* and found no bottom at 600 fathoms where New South Greenland was postulated; three years later Shackleton's *Endurance* drifted across the supposed land area and finally sank in the middle of it.

would be the result (although glaciologists [119] estimate that less than a third of the present Ross Shelf Ice is derived from glacier outflow).

Snow and ice flow away more rapidly from the seaward faces of the coastal mountains than from their backs, "so that after a time the ice-shed lies inland from the mountains," a phenomenon observed in Antarctica and deduced for the Pleistocene ice sheets of Scandinavia and Canada. Behind this divide, any inflowing air is descending, so in the interior "precipitation is small and...the ice in that region must have largely accumulated at a time when the Ross Barrier did not exist."

Finally, Manley reasoned, glaciers from the coastal mountains so cool the surrounding ocean that the open water, moisture source for the precipitation, is found farther and farther away, and precipitation decreases. This involves a cycle perhaps several centuries long: heavy coastal precipitation, glacial outflow, sea cooling and freezing, reduced precipitation, starved glaciers, less sea ice and warmer seas, increased precipitation.

Manley's glaciation cycle is self-generating, as opposed to others which require some external change, be it variation in solar energy, in mountain heights, or in submarine topography affecting ocean currents. Simpson has maintained consistently [138] that "the glacial epochs were the consequence of an increase and not a decrease in the solar radiation," and that "higher temperatures and greater general circulation of the atmosphere are absolutely essential to produce increased outflow of ice in the Antarctic."

Kidson [74] questioned this precept, because "in temperate, and probably also antarctic, regions of the southern hemisphere, precipitation is heaviest in winter," so that "a marked fall of temperature would be necessary to produce the conditions at the maxima of glaciation." Flint [7], who has reviewed Pleistocene glaciation in all parts of the world, pointed out this conflict. His excellent treatise [123] expresses the prevailing view of geologists that Pleistocene glaciation was due to a general lowering of the earth's mean temperature, presumably by reduction in solar radiation, so that a greater proportion of the earth's precipitation fell as snow.

Modern meteorological principles led Willett [139] to support Simpson: "The general circulation and worldwide precipitation are greatly intensified during an ice age, results which cannot be brought about by a general lowering of the earth's mean temperature." From a detailed study of the present temperature and precipitation regime along 49°N, Leighly [136] concluded that the North American glaciation was due to increased wintertime transport of warm moist air from the Gulf of Mexico to the St. Lawrence region, such as obtains with low-index conditions.

The various hypotheses about Pleistocene atmospheric processes, summarized extensively by Willett [139] and more briefly by Landsberg [135], do not help materially to define Antarctica's circulation; instead, they require its independent elucidation for their full development. In one way, however, they have removed one of the unknown variables from the circulation equation: production of precipitation in the continental interior is not a requirement for an acceptable description of Antarctica's present circulation.

CONCLUSION

Antarctica's atmospheric circulation has been described in terms of various versions of a polar anticyclone—glacial, laminar, cellular, peripheral, and abstract. Their review in the light of present knowledge of topography and precipitation distribution, of pressure waves and oceanic storms, of upper-air temperatures and surface temperature and pressure regimes, shows first that Antarctica's circulation cannot be described adequately by its annual pattern alone.

Variations in the extent of ice around the continental edge, effectively expanding the land area in winter and spring and decreasing it in summer and fall, have profound influence. More important are the changes from continuous summer sunshine to continuous winter darkness with outgoing radiation. Because the snow surface absorbs little solar energy but readily radiates away its own heat, winter cooling is primarily at the surface while summer heating occurs in all layers, beginning in the stratosphere.

Throughout the year, the planetary pattern causes pressures to be lower around 60°S than at the Pole; the lower temperature of the continental snow surface as compared to the subantarctic waters intensifies the surface pressure gradient. But in the upper air, as already mentioned, the gradients apparently reverse with the seasons: temperature and pressure in winter decrease from middle latitudes to the Pole, while in summer their decrease stops at about Antarctica's margin and over the continent they increase poleward. The insolation which warms the lower stratosphere over Little America to almost −30C in November and December should cause even higher temperatures farther poleward, so that on the average Antarctica is overlain by a deep warm semipermanent anticyclone in early summer.

By late summer, insolation is no longer able to maintain midsummer temperatures in the upper air; possibly the ozone concentration decreases markedly by midsummer, stopping the warming. The upper layers then cool slowly but steadily so that by midwinter the lapse rate in the stratosphere approaches that of the troposphere and the tropopause disappears. Cooling lowers all the isobaric surfaces, creating over the surface anticyclone an upper-level cyclone which deepens as the cooling progresses; at the surface, pressure falls during fall and winter to a September minimum. Spring sunshine affects the stratosphere first, warming it rapidly; the cyclonic layers expand and rise, and by summer the cyclone disappears, with surface pressure rising rapidly.

In summer and winter, the surface distribution may have the form of a large central anticyclone, or one with several pronounced lobes, or several cells around a weak center. During periods of high zonal index the polar anticyclone is apparently central, during low-

index periods several cells may exist. Each of these patterns may thus be found in different years, or they may appear in succession as the hemispheric flow pattern changes. Consequently, isolated observations in different years may indicate conflicting results.

Cyclones travel in families south-southeastward across the three great oceans to stagnate in the seas which indent the coast to greater or lesser degree: Ross, Amundsen, Bellingshausen, Weddell, and "Mackenzie" (70° to 80°E). These cyclones may go inland when the zonal index is low and there are several anticyclonic cells, especially in summer, but they are confined to the coast when the index is high and there is an extensive central anticyclone. Those which do go inland provide some precipitation in the interior, but fill rapidly as they leave open water and lose energy.

Exchange. Expansion of the atmosphere in summer by the warming of both troposphere and stratosphere causes a net outflow of air from Antarctica. This outflow occurs chiefly in those areas where anticyclonic lobes or cells form during moderate- or low-index conditions: in the southeastern corners of the three oceans washing Antarctica, or roughly 10°W to 20°E, 130° to 160°E, and 120° to 100°W. A fourth area is along the Palmer Peninsula (60° to 70°W), for topographic reasons.

Outflow in these areas is reinforced by meridional exchange, which occurs throughout the year at a rate inversely proportional to the zonal index. It is not a continuous flow, but occurs as outbreaks of anticyclones from the interior; as they progress outward, these anticyclones cause "pressure waves." Their formation, in turn, may be associated with the poleward motion in other longitudes of warm anticyclones of subtropical origin, so that the waves at times appear to have travelled across the entire continent. The warm anticyclones from the subtropics provide some of the compensating air influx.

Even under very-low-index conditions, when the meridional exchange between antarctic and subantarctic regions is greatest, it is very slight compared to the amount of air exchanged between continents and oceans in the rest of the world. The first report [45] on the extreme cold of the winter stratosphere over Little America suggested that "lack of circulation between Antarctica and lower latitudes would permit air there to cool unmolested in the winter until it attained lower temperatures than anywhere else on earth," and that the subantarctic westerlies "may largely confine the antarctic air."

This hypothesis and those of Hobbs, Meinardus, Simpson, and others were doubted by Ramage [64] insofar as they involved a "disconnection between antarctic and temperate circulations," because "before such a circulation theory, unparalleled anywhere else in the world, can be put forward successfully, detailed and accurate observations must be made in the region where the discontinuity is thought to exist." However, he conceded that "a temporary interruption of atmospheric interchange with lower latitudes would be sufficient to cause the tropopause inversion to disappear in winter."

Strong support for the hypothesis of a general lack of air exchange between Antarctica and the rest of the world is provided in an "exclusion principle" postulated by Starr and reported by Willett [140]: "A strong circumpolar cyclonic vortex or zonal westerlies should necessarily repress" transport of heat and kinetic energy. Even at their weakest, the subantarctic westerlies are far stronger than the Northern Hemisphere westerlies [8], so that by this principle the meridional flow in high southern latitudes should be far less than in the north polar region—as Bjerknes and others had suggested much earlier. After several months of drawing and analyzing complete Southern Hemisphere maps, Willett and his staff felt tentatively that "real polar outbreaks of the large-scale type involving the equatorward movement of large polar anticyclones, such as we observe in the Northern Hemisphere, do not occur on the same scale in the Southern."[7]

Slight as this exchange is when compared to that of the Northern Hemisphere, variations in it affect the general hemispheric circulation. Seasonal changes in the pressure field induce less meridional exchange in some seasons than in others. The flow apparently is least in late spring and early summer (October and November) because of the rapid heating at all levels, and isobars then should be most nearly zonal without pronounced lobes on the vertically expanding continental cyclone. Consequently, the zonal westerlies are strongest in spring, as Gabites [48] has found. This seasonal variation may account for the early summer cyclonic weather encountered by Ellsworth in an area later postulated as having an anticyclonic wedge or cell in late summer.

Implications. The general hypothesis outlined above differs from earlier versions of the polar anticyclone postulated by others in allowing two types of modification: seasonal and circulational. In winter it is similar to Simpson's laminar model, and during low-index periods not markedly different from Hobbs's glacial anticyclone—except that no artifices are needed to provide central precipitation since recent evidence indicates that little occurs. In summer it follows the cellular or lobar pattern suggested by Lamb and the Highjump aerologists, recognizing that their limited period of analysis was one of moderate westerly flow. And in recognizing the penetration of warm air masses, it agrees with Palmer's contention that the anticyclone is not a permanent feature but a model picture, though somewhat more than a statistical abstraction. The only model with which it is completely at variance is the peripheral anticyclone of Meinardus, which has been vitiated by more recent findings that Antarctica is not a simple elevated plateau.

Although the processes suggested above explain the upper-air temperatures and the surface pressure regime at Little America, they seem to offer no ready explanation for the three progressively colder temperature

7. Private communication, 4 November 1949.

minima there, and certainly none for the anomalous post-midnight diurnal temperature maximum of clear days during winter at various coastal stations.

As to specific situations, it is suggested that 1912 was a year of low zonal index with stronger-than-usual meridional exchange, so that there were abnormally strong south gales at Mawson's "Home of the Blizzard" in Adélie Land, in the path of one of the preferred outflow paths. Simpson [113] long ago suggested that February and March, 1912, were unusually cold on the Ross Shelf Ice, imposing unexpected hardships which proved fatal to Scott and his party returning from the pole, and Kidson [75] pointed out that "1912 was the windiest year experienced in McMurdo Sound." Conversely, the summer of 1908–9, when David found rather variable winds near the magnetic pole, may have been a period of reduced outflow.

Obviously, the variations in hemispheric circulation patterns which are considered to be reflected in the pressure and circulation distributions of Antarctica are intimately related to the variations in the amount of ice in the subantarctic seas. Coasts accessible by ship in some years are completely ice-jammed in others; some ships entering the Ross Sea have fought hundreds of miles of ice, others at the same time of year have found no pack ice at all, as shown in English's [122] exhaustive tabulation. The relation between the hemispheric circulation and sea-ice conditions is a complex problem, but one of the most important in Antarctica's meteorology.

Prospects. For the first time in history, prospects are bright that a good understanding of Antarctica's atmospheric circulation, and thus its climate, can be achieved in the near future. Two well-equipped expeditions have established bases on the coast south of the string of full-scale weather stations on subantarctic islands (Marion, Kerguelen, Heard, Macquarie, Campbell), and the British, Chilean, and Argentine stations in and around Palmer Peninsula are continuing (although the southernmost, in Marguerite Bay, was abandoned by air in February 1950 because ice conditions made it inaccessible by sea for two consecutive summers).

These, however, are still coastal stations. Sorely needed are a few year-round stations well in the interior of the continent, located for example along 80°S at 0°, 90°E, and 90°W; occupation of the South Pole itself, while spectacular, would be of less meteorological benefit than a single station at the world's "pole of inaccessibility," around 80°S, 80°E. Such stations, operating simultaneously with those active during 1950, and making radiosonde flights (and rawin flights if possible) at least twice weekly, would finally provide enough information on the seasonal changes in Antarctica's atmosphere to permit the circulation to be established definitely—and to permit a full solution of the puzzle of the pressure waves.

Meanwhile, there are several problems which require study. Ozone concentrations must be measured throughout the year at several places, and air samples should be procured weekly at antarctic bases, for later laboratory analysis, until the apparent oxygen deficiency is established or disproved. Pressure surges (not waves) can be sought in the more recent data (the 1935 problem has already been cited) to determine whether any benefits to forecasting can be obtained, such as the correlation cited by Diaz [28] that "polar air invasions over Argentina are preceded by . . . a barometric maximum over Antarctica (South Orkneys and Little America) from 6 to 5 days before." The anomalous post-midnight maximum of temperature on clear winter days requires explanation; unfortunately, clockwork deficiencies precluded a thermograph record during the 1940 winter at Little America, so that as yet there are no examples of this anomaly with simultaneous radiosonde observations.

Of course, further exploration of the continent is needed, since the meteorologist must know the nature of the land (or ice) surface in order to understand the weather processes above it. However, merely flying over the interior in a camera-equipped airplane will not give adequate information: the elevation is important, and to obtain it with sufficient accuracy requires ground surveys. As long as the basic circulation is uncertain, elevations cannot be determined by pressure altimeters hundreds of miles from the nearest barometer of known height or from the nearest ocean.

Expeditions which do go to Antarctica should have meteorologists not only competent to obtain the needed observations under adverse conditions, but meteorologists who understand the problems which they are to help solve. "It is not enough to give a man an instrument and then send him to some outlandish place to expose that instrument and take readings," said Sir George Simpson. He must know what he is doing, how others did it before, and above all why he is doing it and the significance of the results. Yet too many expedition meteorologists have been chosen more for availability than for ability, more for backpacking than for background, more for eagerness than for erudition.

Finally, the problems of Antarctica's meteorology cannot be solved in Antarctica. Observations must be made there, both by accurate instrument and by understanding eye, but they must be published quickly and in full detail and then synthesized and interpreted in the calm of office and library. An expedition cannot be termed scientific if it does not provide its meteorologists (and other scientists as well) as much time for study of the results, after the expedition, as was spent on the entire trip itself, and under the most favorable conditions for study; arrangements for prompt publication must also be made. Only through such prior commitments can any expedition hope to help materially in dispelling the present uncertainty concerning the climate and atmospheric circulation of Antarctica.

REFERENCES

In the past twenty years, more than one hundred books, articles, and notes concerning antarctic meteorology have been published. The most important of these are listed in

Section I of the extensive classified bibliography below, which overlaps Meinardus' list [14] by five years to include all results of the "mechanical period" expeditions beginning in 1928.

These hundred entries are arranged alphabetically within each of five regional groupings: General, Palmer Peninsula Sector, Ross Sea Sector, Australian and South Indian Ocean Sectors, and African Sector. Some entries with nonspecific titles, not discussed in the text, have short explanatory notes. Asterisks indicate 33 entries considered most significant because of either discussion or data.

The bibliography's second portion contains 40 other references cited, arranged alphabetically in each of three groups: Antarctic Meteorology before 1930, Antarctic Geography and Glaciology, and General Meteorology.

ARCTIC METEOROLOGY*

By HERBERT G. DORSEY, Jr.

Arctic Weather Central, Air Weather Service

ARCTIC ATMOSPHERIC CIRCULATION STUDIES

About a century ago theoretical considerations of the probable pressure distribution over the Arctic led to the postulation of a zonal system of westerly winds converging toward a center of low pressure at the North Pole. Shortly afterward an increasing amount of expedition data revealed a trend toward higher pressures and relatively frequent easterlies north of the great oceanic storm belts. These new data enabled Teisserenc de Bort to identify the large-scale features of the pressure distribution as early as 1881. Concurrent studies of the probable radiative cooling over the ice-covered polar basin were summarized by Helmholtz in 1888 in his first paper on atmospheric motion, in which he indicated that the relatively high pressure at sea level should be replaced by a low-pressure system aloft. During this period the role of polar air in the origin of storms was being investigated. A successful culmination to many important contributions was achieved in 1922 by J. Bjerknes and H. Solberg with their paper, "The Life Cycle of Cyclones and the Polar Front Theory of Atmospheric Circulation."

Perhaps worthy of brief comment at this point is the thought that possibly Bjerknes and Solberg's fundamental statement of modern meteorological principles in that paper was assumed by some glaciologists to be an attack on the "Glacial Anticyclones" of Professor William H. Hobbs. His theories, giving Greenland's "Glacial Anticyclones" a dominant role in the general circulation, were first published in 1910 [8] and have been rigidly reiterated up to now [10] despite a steady increase in adverse meteorological evidence[1] [5, 11].

Following the discussions appearing in *Problems of Polar Research*, compiled and published by the American Geographical Society in 1928, one of the earliest and most detailed studies to appear on weather conditions in the Arctic was that by Baur [1], presenting results in the form of monthly average charts for various elements, including temperature, cloudiness, and pressure. Baur showed in 1929 that the polar maximum of pressure was closely related to minimum temperature regions, and traced its movement from eastern Siberia in winter to a position north of the Arctic Archipelago in spring when the subarctic continental regions became relatively warm, with a continued eastward movement toward northeast Greenland and Spitsbergen in early summer. The decreasing central pressure was down to about 1014 mb at the summer minimum. In early autumn the Canadian Arctic Archipelago and the adjoining polar pack ice cool rapidly to attain a secondary maximum in the annual pressure trend, but this is soon exceeded by the Siberian anticyclone and its weaker counterpart over the Yukon Territory. Baur's charts, obtained from station pressures and corrected for large-scale anomalies presumably present in some of the shorter records, lose little in comparison with the indications of modern data.

The theoretical basis for much subsequent research on the heat balance of the earth and the general circulation of its atmosphere was published by V. Bjerknes in 1933 [2]. In the same year, Shaw [18] included in his comprehensive *Manual of Meteorology* charts of sea-level normal pressure and upper-air normal pressure charts (partially from earlier work of Teisserenc de Bort) for heights up to 8 km. However, Shaw's charts were not intended to be relied upon over the north polar region. The next sea-level pressure charts to be prepared for the Arctic were those resulting from the joint studies of Sverdrup, Petersen, and Loewe, published in the Köppen-Geiger *Handbuch der Klimatologie* in 1935 [19]. Their pressure patterns were quite similar to those of Baur.

Upper-air research conducted by the U. S. Weather Bureau was temporarily concentrated on a revision of Shaw's 2- and 4-km charts, after Wexler [23] investigated the formation of polar anticyclones. Many new data were available, and the final charts by Byers and Starr for January [4] gave the first definite indication that the elongated circumpolar vortex had separate closed centers, one over northeastern Siberia and the other over northern Hudson Bay. Subsequently, Namias and Smith [13] prepared monthly normal charts for the 10,000-ft level, then converted these to 700-mb contours. Revisions are made by Namias whenever new data suggest possible improvements in the work of the Extended Forecast Section, U. S. Weather Bureau.

In the great amount of theoretical research on the general circulation drawn upon by Rossby to obtain his schematic model of 1941 [15], and in later work, the north polar region has not been neglected. The principal results contributing to arctic meteorology are those pertaining to displacements of the principal centers of action. Appropriate reference will be made to some extended-range forecasting principles derived by Willett [24] which have significant value for arctic operational planning purposes. A recent contribution by Rossby [16] discusses the release of potential energy involved in the southward displacement of anticyclonic cold domes from high latitudes.

A 1946 publication of the U. S. Weather Bureau [20] contains monthly normal sea-level pressure maps for the Northern Hemisphere. These normals, computed from the noteworthy 40-yr series of daily synoptic charts, are no better over the polar basin than are the

---

* Submitted with the permission of the Air Weather Service. Conclusions and opinions are those of the author.

1. For an appraisal of the controversy over this point see "Some Climatological Problems of the Arctic and Sub-Arctic" by F. K. Hare, pp. 952–964 in this Compendium.

original daily charts. There were little data in high latitudes to restrict most of the original analysts, who seem to have had a fairly uniform tendency toward overemphasis of arctic anticyclones.

Petterssen [14] has good sea-level and upper-air pressure charts for January and July, but meteorologists must refer back to Sverdrup [19] for realistic seasonal pressure patterns, unless the new charts by Dzerdzeevskii [6] become more readily accessible. Dzerdzeevskii analyzed the data obtained by the Russian Polar Expedition, 1937–38, and included the results of previous studies in a new investigation of circulation patterns in the central Arctic. He shows that intense cyclonic and frontal activity was encountered near the Pole, and that the coldest air came from the American Arctic. His monthly average sea-level pressure charts are generally similar to those of Baur and Sverdrup, but fail to account completely for the midwinter secondary minimum in pressure over northern arctic America.

In 1949 an important study of the upper air over northern Canada was published by Henry and Armstrong of the Canadian Meteorological Service [7]. Using the data collected from the new aerological stations set up in the Canadian Arctic under the joint United States–Canadian program, the authors have carried out an exhaustive climatological analysis. Isotherms and contours are shown in map form for the 850-, 700-, 500-, and 300-mb surfaces for January, April, July, and October. The maps cover the greater part of Canada, including the Archipelago. Tabulated upper-air data are given for all stations, not only for the average year, but for each individual year of the record. Finally, there is an excellent discussion of the mean circulation over the Canadian Arctic. The work represents the most ambitious attempt yet published to clarify our picture of the circulation on the American side of the Arctic.

OPPOSED CONCEPTS OF ARCTIC CIRCULATION PATTERNS

It is difficult to believe that cooperating groups of modern scientists, such as meteorologists and explorer-geographers, could have sharply contrasting concepts of the Arctic, yet that rather surprising contention has been repeatedly expressed by Professor Hobbs. His restatement in 1948 of this viewpoint [10] was based on concepts of the atmospheric circulation patterns over two different arctic regions. Meteorologists have rarely published refutations of his contentions, but since his unacceptable theories have received wide publicity it now seems highly desirable to compare the meteorologists' concept of the Arctic with that ascribed to them by his analysis of supposedly contrasting concepts. The arctic data used by meteorologists and climatologists have been gleaned from expedition reports wherever required to supplement those from fixed stations. No conflict exists and no contrast can be found between explorers and meteorologists in this matter, despite Hobbs's statements to the contrary. While it has often been impossible to incorporate the roving explorer's data into current weather maps, these hard-won data have always been considered in thorough investigations of regional characteristics. Indeed, during the last two decades and even today, a major proportion of all field journeys into the Arctic and the Antarctic have had meteorological objectives.

Characteristics of the Central Arctic Basin. Since meteorologists and other scientists familiar with the atmospheric circulation of the Northern Hemisphere know that the continental interior regions of Canada and Siberia supply the polar air for the intense frontogenetic zones off the east coasts of North America and Asia, with Greenland and the arctic ice fields acting as secondary source regions because of the lesser contrasts at high latitudes, there is no clear reason for Hobbs's reference to Bjerknes [10], "... the hypothesis of the North Polar Front, or polar anticyclone, above the Arctic Basin was, at the time of its promulgation, contrary to all that had then been learned concerning its climate...." Over western Europe, Bjerknes' polar "high" is rarely an anticyclonic cell from the North Pole, but is more likely to be developed from an anticyclonic circulation in maritime polar air over the North Atlantic Ocean or in an extreme westward flow of continental polar air from Eurasia.

A remark that Nansen was able to *confirm* the Helmholtz theory would appear to be counter to all of Hobbs's elaboration on mean annual air pressure as observed by explorers in and about the Central Arctic Basin [10], but that is not intended nor is any such implication required to aid in the elimination of imaginary controversies between explorers and meteorologists. While meteorologists prefer to deal with average pressures on a monthly, semimonthly, ten-day, or five-day basis when analyzing atmospheric circulation patterns, they are quite ready to accept Hobbs's emphasis on the fact that the "normal" pressure isobar of "1013 millibars surrounds the Central Polar basin" [10]. Thereby he has shown it to be the area of *relatively* high pressure that Helmholtz anticipated, and with which meteorologists are familiar. This is true because what is "normal" pressure for the temperate zone is relatively "high" pressure north of the almost globe-circling belts of lower pressure associated with the Aleutian and Icelandic centers of cyclonic activity in winter, and with their related but westward displaced centers over northern Siberia and Canada in summer.

On profiles of Northern Hemisphere pressure the latitude of minimum pressure averages about 62°N when taken on an annual basis. Much of the winter contribution to the higher pressure north of 60°N comes from the North American anticyclone in the Yukon territory, and from part of the Siberian anticyclone. Only in early autumn, in late spring, and in summer, when the Arctic Basin is colder than continental areas, is there a relatively strong arctic anticyclone with pressures consistently higher than over polar continental areas. In summer the North Pole itself is more often in a weak trough or ridge situation between "lows" over northern Baffin Bay and the Laptev-Kara Sea areas, or between "highs" cresting over the Spitsbergen-

Fridtjof Nansen Land area and the Canadian Arctic Archipelago.

In the array of evidence supporting his "normal" pressure regime for the North Pole area, it appears that Hobbs would have done better to stress, rather than suppress, the fact that cyclonic storms have been encountered in the Central Arctic Basin. He cited Dzerdzeevskii as to the mean annual pressure of 1013 mb [10], but did not mention the frequent large fluctuations in pressure and temperature observed by the Soviet North Pole station before it drifted between northeast Greenland and Spitsbergen. Dzerdzeevskii noted correctly that these changes, reaching as much as 40 mb in pressure and 29C in temperature, were associated with the passage of intense cyclonic disturbances, frontal systems, and different air masses. Furthermore, popular accounts of the Soviet expedition also mention the stormy conditions experienced while they were still close to the North Pole: "North Pole, June 10th. There was a violent snow storm on the 8th and 9th ... the gusts of wind attained a speed of 60 feet per second (41 m.p.h.)" [3], and on June 29th, "A savage north wind has been raging for more than twenty-four hours. . . . Rain has been pouring down . . . " [3].

During the last few years, cooperative action between the United States, Canada, and Denmark has resulted in the establishment of new meteorological stations in the Canadian Arctic Archipelago and northern Greenland. They are all in locations formerly visited only by explorers, and the annual resupply of each constitutes an undertaking comparable to that expended on an entire expedition of former years. As for the North Pole area, of which Hobbs has said, "For all time it is likely that meteorologists . . . will be unable to gain any knowledge of the weather of the Polar Basin" [9], meteorological reconnaissance flights have been made more often than twice weekly over the American sector of the arctic ice-fields by the U. S. Air Weather Service through the last three years. Meteorologists have used the explorer's hard-won observations and are adding daily increments to their knowledge of the arctic region. Where is the sharp contrast between concepts and methods of explorer-geographers and professional meteorologists investigating the Central Arctic Basin?

RECENT IMPROVEMENTS IN ARCTIC OBSERVATIONAL DATA

New Stations in Northern Arctic America. This region had long been a "blind spot" on North American synoptic weather charts and was a logical focal point of meteorological planning when the end of World War II allowed consideration of necessary improvements in the existing observational network. Canada, the United States, and Denmark agreed upon the desirability of cooperative effort, and plans for several new stations were implemented in 1946. A joint Danish–U. S. Weather Bureau station was established and in full operation at Thule, Greenland, by October 1946. Air transportation was used in the spring of 1947 to install the second of the new stations, operated jointly by Canada and the United States, at the northern end of Eureka Sound, Ellesmere Island, Canada. Four additional stations in the Arctic Archipelago are now maintained by Canadian–United States cooperation, as follows: Resolute Bay, southern Cornwallis Island, since October 1947; Mould Bay, Prince Patrick Island, and Isachsen Peninsula, Ellef Ringnes Island, by air lift since the spring of 1948; and Alert, Ellesmere Island, by air lift since the spring of 1950. Locations in Peary Land, Greenland, have been considered for a possible future station in this new net.

The short period of record for these stations does not permit comprehensive statistical treatment of the new meteorological data, but the analysis of sea-level and upper-air charts over this region has become more accurate with each increment of observations. Furthermore, the predominance of the arctic air mass is such that its local and seasonal characteristics have been approximately determined from a relatively short series of upper-air soundings.

Weather Reconnaissance Flights. When the elimination of the North American meteorological "blind spot" was being planned, the problem of obtaining weather information from the American sector of the arctic pack ice received considerable attention. The consolidated ice fields in the central portion of this area do not drift as rapidly as does the North Pole ice toward the Greenland Sea, so a drifting station might stay there for several years. It was finally agreed that weather reconnaissance flights would furnish a maximum of meteorological data at a relative minimum of hazard for the personnel involved. In March 1947 the Air Weather Service was able to begin occasional reconnaissance flights near the 700-mb level over the region between Alaska and the North Pole. Two flights a week were planned for a trial period, but three or more flights a week near the 500-mb level were made at times during 1948–49.

Expedition Stations. A Danish expedition to northeast Greenland was in that area during 1948–49. Its main base, with radiosonde equipment, was located near the former Danmarkshavn. An outpost station, established and supplied by air lift, wintered at Brönlunds Fjord in Peary Land to obtain the first cold-season scientific data from this part of Greenland. Observations from both these stations appeared intermittently with the Greenland collective reports in 1948–50.

The arctic division of the French National Polar Expeditions, directed by Paul E. Victor, established an observatory on the Greenland Ice Cap in July 1949. A location (70°54′N, 40°42′W) approximating that of Wegener's "Eismitte" at an elevation of about 3000 m was selected in order to obtain data comparable with those [22] of the 1930–31 expedition. Ice-cap meteorology should be further clarified when these new data become available.

ARCTIC CIRCULATION PATTERNS

Average Monthly Sea-Level Pressure Charts. Consideration of the typical properties of arctic air should be facilitated by a prior knowledge of the large-scale air

currents normally flowing toward and across northern arctic America. Seasonal variations in arctic circulation patterns at the gradient wind level will be described in terms of average sea-level pressure charts for the midseason months: July, October, January, and April. These charts represent a personal synthesis of what are conceived to be the most realistic features appearing in the previously discussed charts of Baur, Sverdrup, and Dzerdzeevskii. In describing the seasonal trends in arctic circulation patterns, it was thought more logical to start with the minimum stage of air flow, represented by July conditions, than to break in near the annual maximum of atmospheric motion.

July. The chart of average sea-level pressure for the month of July (Fig. 1) shows the relative weakness of

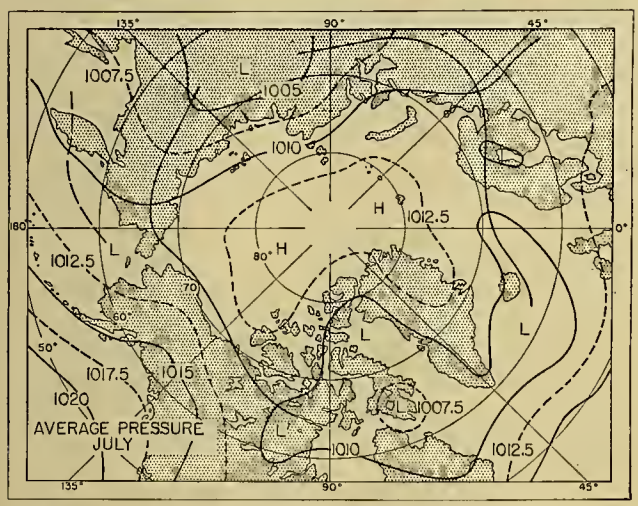

Fig. 1.—Average sea-level pressure (mb) during July.

the circulation patterns in this midsummer period of minimum thermal contrast between the polar and temperate zones. The circumpolar belt of low pressure is at its highest latitude in this month, with a definite extension of cyclonic activity toward the North Pole itself, although a feeble anticyclonic circulation persists over the congested pack-ice area northwest of the Canadian Archipelago and over the northeast Greenland–Fridtjof Nansen Land area. Along the Laptev Sea coast line, the contrast between warm air from the interior of Siberia and cool air from the pack ice is sufficient to maintain persistent cyclonic activity. Weak disturbances, originally associated with poleward thrusts of North Atlantic maritime air masses, may here be reintensified to resume their eastward progression toward the similar but milder thermal gradients along the arctic coast of Canada.

It has been mentioned that the July chart retains the best features derived by prior research of other arctic specialists [1, 6, 19]. The more widely circulated publication, "Normal Weather Maps, Northern Hemisphere, Sea-Level Pressure," [20] has presented a different pattern for July, especially over northern arctic America. With a 1017-mb isobar encircling the well-substantiated col area (average pressure less than 1013 mb) of the North Pole, and with little hint of a semi-permanent cyclonic system over northern Baffin Bay, the "40-yr normal July" could be very misleading. However "abnormal" the recent Julys may have appeared to be in this area, expedition reports indicate that midsummers over a hundred years ago were more dominated by cyclonic than by anticyclonic conditions.

Because of the simple thermal aspects of the July circulation scheme and the annual return to relatively the same percentages of ice-covered or ice-free surfaces and total solar heating, radical departures from the flow patterns described by this critique are not expected. Cyclonic activity develops and travels along the major frontal zones indicated by continuous thin lines on Fig. 1, except in some Julys when the Okhotsk-Bering Sea frontal zone becomes more active. The secondary cyclonic centers may be occupied by individual low-pressure cells, depending on the relative strength of the zonal circulation in the observed July. Frontogenesis in the North Greenland–Ellesmere Island topographic trough is associated with the reintensification of northern Baffin Bay disturbances and their subsequent rapid movement toward the North Pole. The arctic anticyclone usually centers on one or the other of the lobes shown, but not on both.

October. Comparison of the average October pressure patterns (Fig. 2) with those of the Weather Bureau

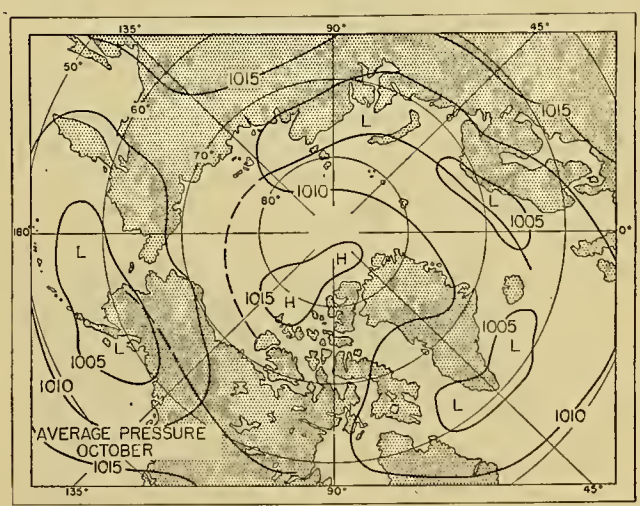

Fig. 2.—Average sea-level pressure (mb) during October.

"normal" map reveals errors of greater importance than for July, considering the increased zonal circulation and the onset of autumn storms. The many years of few data and extrapolated analyses apparently resulted in too great an over-all smoothing and in a loss of knowledge regarding the *terrain-imposed location of cyclonic centers associated with variations in the general circulation.* Again the arctic high is overemphasized, although shown at a *lower* central pressure than July. The important eastward extension of North Atlantic cyclonic activity to the Kara Sea is not definitely shown, nor is there sufficient indication that two cyclonic cells are to be expected in the Icelandic system. The arctic high tends to be centered over North Greenland or west

of the Canadian Archipelago. It rarely spreads over both.

January. Among the many sources of "normal" pressure patterns it is believed that none except the 40-yr series have a January chart showing higher pressure over the Arctic Ocean than in the Canadian Yukon Territory. An occasional January mean map will have an Arctic Ocean high, January 1948 for example, but such a January is known to be relatively rare. By comparison with Fig. 3, the Weather Bureau January map

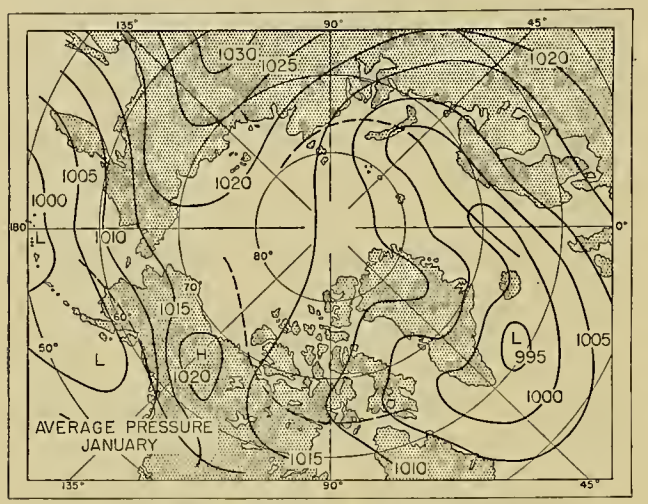

Fig. 3.—Average sea-level pressure (mb) during January.

fails to indicate the true intensity and relative frequency of cyclonic activity in the Kara Sea, nor does it place sufficient emphasis on Greenland's effect as a topographic barrier.

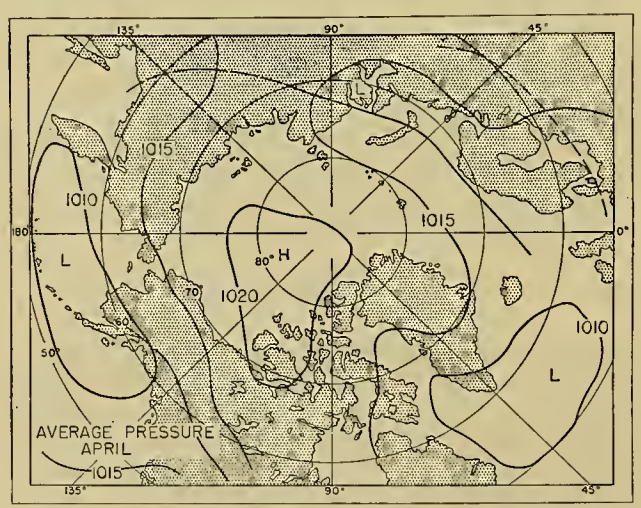

Fig. 4.—Average sea-level pressure (mb) during April.

April. By this time the mid-latitude continental warming has become well established although the Arctic remains cold with predominantly anticyclonic conditions. Pressures over the Canadian Archipelago and northern Greenland reach their annual maximum in April (Fig. 4). Arctic air flow southward over eastern North America is favored by the reduced zonal circulation.

The principal weakness in the Weather Bureau "normal" pressure map for April is found in its failure to indicate the southwestward displacement of the North Atlantic cyclonic activity to an annual minimum latitude. The arctic anticyclonic circulation rarely departs from the single-cell pattern indicated for April, but its center may be located over northeast Greenland or the Canadian Archipelago when large-scale circulation anomalies disrupt the average pressure distribution.

Average 700-mb Contour Patterns. A survey of previous research on the upper-level circulation over the Arctic was presented earlier in this article. The use of mean circulation methods developed by Rossby, Willett, and Namias has emphasized the importance of major anomalies in flow patterns aloft. Extended forecasting for the Arctic and elsewhere requires almost continuous reference to the upper-level "normal" maps published by the U. S. Weather Bureau [12, 13]. As a result of this writer's research, it appears that many of the errors found in the 40-yr sea-level normals have been extrapolated up to the 700-mb charts. Namias [13] used many short-term radiosonde records, especially for high-latitude stations, by applying a correction based on the concurrent departure from normal of the local sea-level pressure and surface temperature. In preparing July and January average 700-mb contour charts for this article, the elimination of errors attributable to incorrect "normal" sea-level pressures has received primary emphasis.

July. The suggested revision of the Namias 700-mb contours for July is shown in Fig. 5. A comparison with

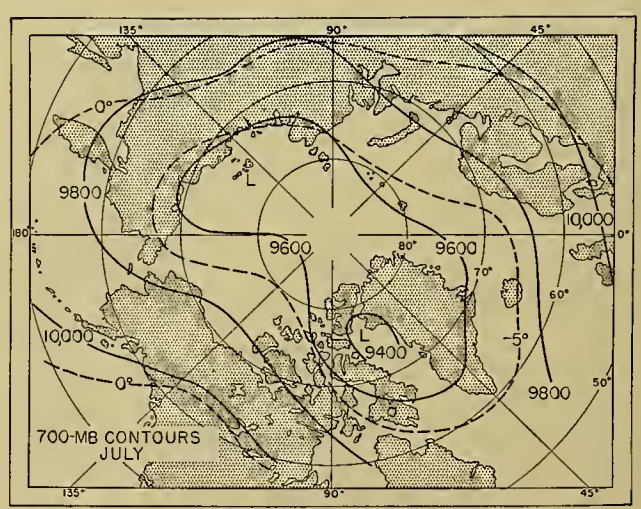

Fig. 5.—Average 700-mb contours (ft) and isotherms (°C) during July.

the corresponding Namias [12] chart shows the reduced heights over northern Baffin Bay and the Laptev Sea that are associated with the average greater than "normal" cyclonic activity mentioned in the earlier criticism of the July "normal" map. Reference has been made to Petterssen's summer charts of 2-km and

4-km isobars [14] and to the new series of Historical Weather Maps, for additional support of the height increases required over the Okhotsk and Bering Seas.

The air flow over northern arctic America, and over the Siberian Arctic, is seen to be predominantly cyclonic at the 700-mb level in July, closely corresponding to the gradient circulation derived from average sea-level pressure. Weak anticyclonic flow is frequently observed over the northeast Greenland–Fridtjof Nansen Land area and western sections of the American Arctic, but is rare and of brief duration over northern Baffin Bay.

January. The major revisions appearing in the new 700-mb chart for January (Fig. 6) are directly related

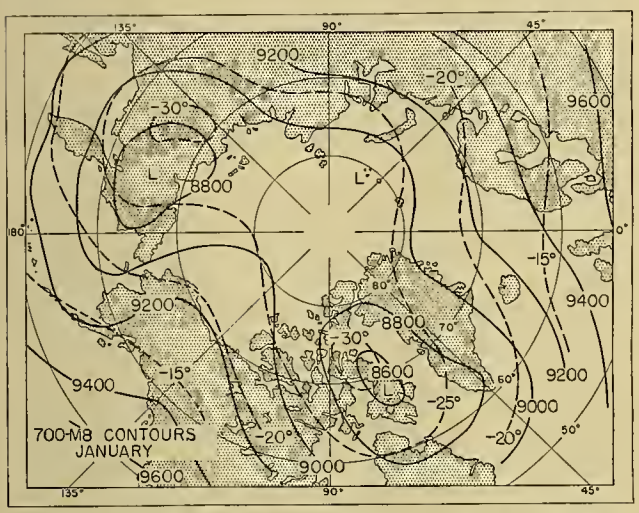

Fig. 6.—Average 700-mb contours (ft) and isotherms (°C) during January.

to the areas of excessive sea-level pressure, as previously noted over northern Baffin Bay and over the Kara Sea, on the Weather Bureau "normal" map. With the introduction of more realistic perturbations in the circumpolar westerlies over these areas came an equally logical intensification and southward displacement of the east Asiatic cyclonic cell. It is suggested that the intensity of the American cell will be exceeded by that of the Asiatic cell only during the anomalous absence, or complete enclosure, of the Barents-Kara perturbation.

The cold-season cyclonic circulation over northern arctic America, being mainly a dynamic system of cold dry air, is relatively cloud free except during periods of reintensification.

SEASONAL VARIATIONS IN ARCTIC AIR

Variations over Northern Arctic America. The foregoing summary of average circulation patterns, and the geographical location of the American Arctic, indicate that all the large-scale air currents will have been subjected to arctic influences before their arrival over this region. The region itself provides the cold source area of arctic air masses affecting central and eastern North America. Variations in the observed properties of arctic air are directly related to the seasonal variations of the underlying surfaces and the air flow over them. The vertical structure of arctic air over the Canadian Archipelago during the different seasons of the year is shown by the average soundings for July, October, January, and April, which are plotted in Fig. 7.

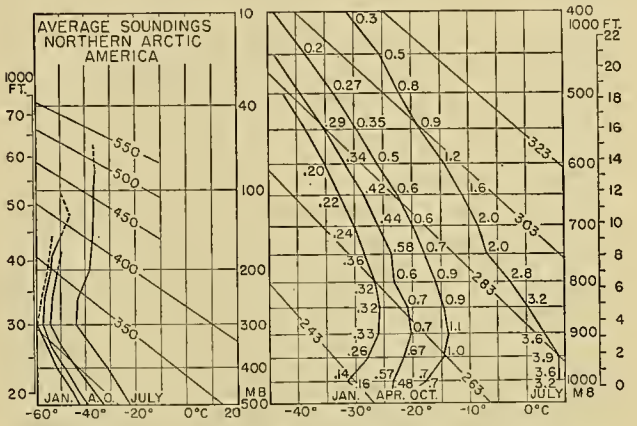

Fig. 7.—Average soundings over northern arctic America.

July. The average sounding for July, based on 28 ascents to the 250-mb level obtained at the Eureka station during July 1947, shows the midsummer structure of arctic air over ice-free interior areas. Because of the predominantly cool and moist underlying surface conditions, the regional air mass is maritime arctic in summer. There is a characteristic surface inversion over the pack ice and cold water, but convective instability in the lower levels is readily produced by land heating after a short period of onshore flow. A moisture content of about 4 g kg^{-1} near the surface is fairly representative of the regional air masses. The cyclonic circulation around northern Baffin Bay and the associated middle-cloud system create a characteristic moisture inversion near the 700-mb level of the average July sounding. During this individual month, the average height of the tropopause was about 9000 m (29,500 ft).

October. In sharp contrast to the relative warmth caused by 24-hr insolation in summer, the autumn conditions of almost no solar heating and predominantly frozen surfaces are relatively ideal for the rapid modification of maritime polar air. The average sounding for October, derived from 27 Eureka ascents to the 250-mb level in October 1947, shows well-developed continental characteristics at this early stage in the transition to the deep, cold, continental arctic air of winter. The average October circulation pattern was closely approximated in 1947. Moderate anticyclonic conditions dominated northern arctic America, and the sounding has no obvious traces of Baffin Bay cyclonic activity. The tropopause was about 8600 m (28,000 ft) high, 400 m lower than in July. Continental arctic air of this type begins to form over the pack ice during early autumn, but it becomes unstable and produces heavy snow showers as it flows southward over unfrozen waterways and warmer land masses in the rear quadrants of autumn storms.

January. The average sounding for January, based on 21 ascents to the 350-mb level above the Resolute

Bay station in 1948, shows the vertical structure of continental arctic air as it flows southward from the Canadian Archipelago in the Baffin Bay cyclonic circulation. The arctic air arrives at Resolute Bay after passing over frozen waterways en route from a colder source region, exhibiting characteristic surface turbulence and instability. Specific humidity values are near the annual minimums of 0.2 to 0.3 g kg^{-1} with little variability throughout the deep and surface-controlled thermal equilibrium below the 700-mb level. The average height of the tropopause is about 8300 m (27,500 ft) in winter.

January 1948 had a number of striking departures from the normal circulation patterns. The existence of an arctic "high" has been mentioned, and that—in conjunction with an active arctic frontal zone across northern Canada—created an unusually strong flow across southern sections of the Archipelago. Thus, the January average sounding probably shows more warmth and moisture than would be observed in a long-term average.

April. Despite the 24-hr insolation in spring over the region investigated, there is little immediate change in the surfaces underlying arctic air masses, and April retains much of winter's coldness. The average sounding, from 26 ascents to the 250-mb level above Resolute Bay in April 1948, is still typical for continental arctic air but shows a distinct moderation from the severe winter characteristics of the regional air mass. The winter temperature contrast between ice fields and land has been eliminated, allowing an increase in surface stability, but the Baffin Bay cyclonic circulation extends back over Resolute Bay above the 800-mb level. Apparently the tropopause height varies between the 7500- and 8500-m levels in April.

The American Arctic Versus the Eurasian Arctic. A brief survey of the Eurasian arctic data has provided a few "typical" soundings which are included in Fig. 8 to illustrate characteristic regional variations in arctic air. Because of its high latitude and great distance from the major frontal zones, northern arctic America produces a distinctive continental type of arctic air.

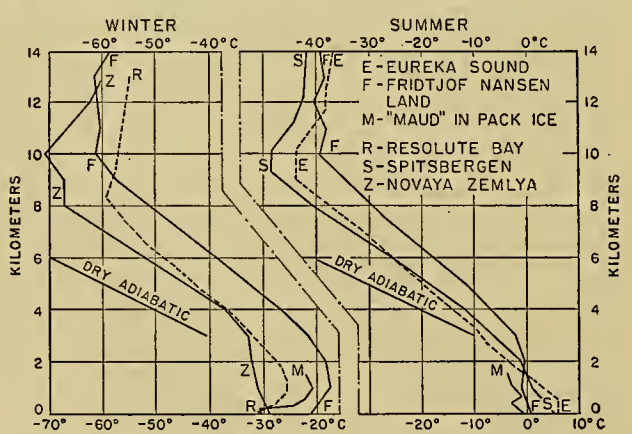

Fig. 8.—Comparative soundings.

With reference again to Fig. 8 for summertime comparisons, it will be seen that the surface temperatures are lowest over the pack ice and highest over the relatively large ice-free land areas of northern arctic America. The coldness and low-level instability of the *Maud* sounding result from the incorporation of June and August data in the summer "average," and from the fact that steady winds and stirred air were necessarily present during successful kite flights. The Fridtjof Nansen Land sounding shows relatively warm maritime polar air, cooled in its lower levels over the arctic ice fields, and brought onshore in a strong return flow over cold water. Maritime arctic air reaches Spitsbergen in a steady flow across relatively warm water. Land heating of the coldest type of maritime arctic air produces convective instability over arctic America, but near icy waterways the lowest levels are stabilized by the sea-breeze circulation. The tropopause heights show maritime influences over Fridtjof Nansen Land, but Eureka and Spitsbergen have the typical, uncomplicated arctic tropopause, with Eureka's lower because of greater insolation aloft and proximity to a "normal" upper-level vortex.

In winter the Arctic Archipelago is colder than the pack ice, but the Baffin Bay circulation prevents the formation of extreme temperature inversions of the pack ice or continental interior type. The Fridtjof Nansen Land sounding shows maritime polar air after a relatively short period of cooling from below, with a maritime polar tropopause being frequently observed. Many of the "winter" soundings at Novaya Zemlya were made in the rear quadrants of intense storms. They show evidence of strong stirring in continental arctic air and a complex tropopause mixture of low arctic and extremely cold maritime types. The Resolute Bay sounding shows the comparatively stable continental arctic air extending all the way to a warm arctic tropopause.

In addition to the temperature-versus-height curves compared in Fig. 8, the annual range of average moisture and stability conditions in Eurasian and American arctic air masses is shown by means of a brief tabular comparison (Tables I and II). The Eurasian data for arctic air in winter and summer were obtained from Petterssen [14]. The physical properties chosen for comparative purposes, specific humidity (q) and potential psuedo-wet-bulb temperature (θ_{sw}), are conservative

Table I. Arctic Air in Winter

Station	p (mb)	H (m)	T (°C)	q (g kg^{-1})	θ_{sw} (°C)
Resolute Bay (all soundings)	1000	75	−31	0.16	−32
	900	800	−26	0.32	−19
	800	1650	−26	0.30	−13
	700	2600	−30	0.25	− 9
	600	3700	−35	0.22	− 4
	500	4950	−43	0.06	− 2
Fridtjof Nansen Land (stirred air)	1000	—	—	—	—
	900	750	−30	0.29	−24
	800	1550	−34	0.21	−20
	700	2450	−38	0.16	−15
	600	3500	−42	0.12	−10
	500	4650	−49	0.07	− 6

indicators of moisture content and stability, and are easily computed from radiosonde data. The tabulated data are not strictly comparable, since the Eurasian soundings were selected to include only fresh outbreaks of arctic air, while only the average January and July soundings were available for the American Arctic. Even so, there was a strong tendency for decreasing θ_{sw}-values between 950 and 850 mb above Eureka Sound in July. Individual ascents would certainly show convective instability similar to that observed along the Barents Sea Coast.

TABLE II. ARCTIC AIR IN SUMMER

Station	p (mb)	H (m)	T (°C)	q (g kg^{-1})	θ_{sw} (°C)
Eureka Sound (all soundings)	1000	30	+ 6	3.6	+ 3
	900	900	+ 1	3.6	+ 5
	800	1800	− 3	2.8	+ 7
	700	2800	− 8	2.0	+ 8
	600	4000	−14	1.2	+10
	500	5400	−22	0.8	+12
Barents Sea Coast (stirred air)	1000	—	+ 9	5.1	+ 6
	900	850	+ 2	3.7	+ 5
	800	1750	− 2	3.5	+ 8
	700	2800	−11	1.8	+ 6
	600	3850	−16	0.8	+ 8
	500	5150	−27	0.3	+ 8

TYPICAL ARCTIC CIRCULATION PATTERNS

Variations in the Average Circulation Patterns. The discussion of the midseason average arctic circulation patterns, based on maps of average pressure for July, October, January, and April, has already indicated the major centers of cyclonic and anticyclonic activity and traced the frontal zones associated with the development and movement of cyclonic storms. A knowledge of the major variations to be expected in the average flow patterns is always a valuable aid in the analysis and prognosis of daily weather situations, especially in the Arctic where observing stations are widely separated and where there is not much past experience to draw upon. Much useful information on anomalous circulation patterns has been gained from research on forecasting by mean circulation methods, but no specific studies on the truly arctic regions have been made.

Since this article is concerned with a region which has not entirely ceased to be a "blind spot" on Northern Hemisphere charts, a general application of mean circulation principles will be described for the principal seasons. A more detailed application would require extensive research along synoptic lines as suggested by Willett [24].

Summer Variations. The strong thermal control of the average summer circulation has been mentioned. Thus, as shown by Schell [17], large-scale anomalies in the semipermanent ice and snow cover would undoubtedly be locally important, but could hardly counteract an opposing anomaly in the general circulation. A strong summer circulation (high index) might at first be considered unfavorable for polar anticyclonic developments, but it is thought that summer conditions are quite probably the reverse of winter. It is the subtropical anticyclones, at unusually high latitudes over the oceans, that are associated with the periods of weak zonal index in summer. At such times, the circumpolar cyclones are forced into the Arctic much more persistently than is normal.

The fact that summer circulation patterns tend to persist and change but slowly should in itself be of considerable guidance to forecasters in the high latitude arctic regions—provided they have at least one daily set of surface and upper charts with a reasonable synoptic coverage.

Late spring and early fall disturbances may be strong, but the cyclonic systems of the true summer period are relatively weak unless abnormally cool conditions prevail over the Arctic Ocean area. As suggested by the average July chart, disturbances coming from Siberia are often reintensified along the Canadian Arctic coast line. Their subsequent movement depends mainly on the position and intensity of the Baffin Bay upper-level cyclonic circulation. Normally no summertime disturbances approach arctic America from the direction of the North Pole, though northern Baffin Bay cyclonic systems frequently move poleward up the North Greenland-Ellesmere trough. Some part of almost every disturbance reaching the vicinity of Hudson Bay from the west or south will eventually affect the northern Baffin Bay section. Summer occurrences of other seasonal patterns will be noted.

Autumn Variations. Early autumn is a season of strong thermal contrast between the Arctic, which is already producing a winter type of air mass, and the more slowly cooling subarctic continental mainland areas with their summer-type maritime polar air. The average circulation pattern is one of strong zonal westerlies, representing a great increase over average summer conditions, but usually there is an anomalous return to a summer type after the first onset of autumn. Continental mainland areas warm up again and, with the high latitude Arctic cooling rapidly, the stage is set for a strong intensification of weak disturbances crossing coastal sections of Siberia and/or Canada. With specific reference to arctic America, deepening over the Mackenzie or Coppermine valleys completes the genesis of extreme types of autumn storms, which will curve into the Archipelago or northern Baffin Bay and dominate the circulation for possibly a week as they slowly fill. Weaker variations of the above anomalous type account for a high percentage of summer disturbances affecting this region. As this is also true for autumn and early winter, the so-called "autumn type" is very important to northern arctic America.

Winter Variations. Since the cold season includes November and March, minor variations of the average January circulation pattern are common throughout the winter. Strong zonal westerlies are characteristic of the average pattern. Circulation anomalies of the high-index type frequently result in a pattern similar to that of October, with the required strengthening of pressure gradients. Except for occasional high-latitude cyclonic eddy systems, northern arctic America is usually cut

off from the subpolar cyclonic disturbances at such times and has a preponderance of fine weather. On the other hand, the meridional flow patterns of low index may be similar to an accentuated pattern of the April type, with intense low-latitude storms recurving into arctic areas. Much of the cold season storminess affecting northern arctic America is associated with this type of development which will occasionally equal or exceed the intensity of the autumn-type circulation anomaly.

Spring Variations. The continuation of winter cold in the Arctic, while the continents are warming, results in exceptionally favorable conditions for anticyclonic developments over high-latitude arctic regions. April's average circulation pattern is typical of the best spring weather, but anomalies in the general circulation may cause the April pattern to appear in March and again in May, with an April pattern resembling January's strong circulation. An April anomaly of the above type does not seriously affect arctic America, except rarely when an Atlantic storm makes the polar circuit and approaches the Canadian Archipelago from the northwest. Variations of the winter low-index type are the more frequent and more serious circulation anomalies affecting arctic areas especially in early spring.

ARCTIC METEOROLOGICAL PROBLEMS

Observational Data. Because our knowledge is severely limited as to the relationship between the arctic tropospheric and stratospheric circulations themselves, and because our understanding of the more general relationship between the arctic and the hemispheric circulation is by no means complete, it is difficult to visualize or suggest what might eventually constitute a representative coverage of arctic meteorological data. The problem of observational coverage was easier to resolve in 1945 when the synoptic reporting network for the North American Arctic was entirely inadequate. Since then the situation in that area has been greatly improved by the establishment of the new stations and by the weather reconnaissance described in the third section of this article.

At this time the existing arctic weather station network (and the availability of data from these stations) is probably adequate for the preparation of routine synoptic analyses. However, the existing situation is not entirely satisfactory with respect to the availability of upper-air research data from the Eurasian Arctic. To solve this problem it will be necessary to achieve a higher degree of cooperation than apparently exists in the international exchange of current arctic meteorological data. Granting the relative adequacy of arctic tropospheric data, trends in current and planned meteorological research indicate that arctic soundings to altitudes well above 120,000 ft will be desirable when similar data from mid-latitude soundings to the ozonosphere are available. These high-level observational data will be required in connection with the continuation and expansion of studies on the general atmospheric circulation, on its large-scale short- and long-period fluctuations, and on the possible linkage between solar activity and tropospheric meteorological phenomena.

Synoptic Studies. Because of the short period for which relatively adequate data have been available, there are several aspects of arctic synoptic meteorology which have not received thorough consideration. Valuable contributions to existing information should result from studies on the connections and interactions between the state of the general circulation and semipermanent systems, such as, the Aleutian low, Icelandic low, Siberian high, polar high, and North American high.

There can be little doubt as to the desirability of undertaking further studies on the general circulation as regards that of the Arctic in relation to the tropospheric jet stream of middle latitudes.

It also is suggested that another worth-while objective for future investigations would be the comparatively unknown nature and extent of control imposed on the arctic circulation by contrasts between continental and oceanic regions in the Arctic and in adjacent temperate areas.

Basic Research. Investigations of a more fundamental nature than the suggested and expected investigations of synoptic relationships between arctic flow patterns and the hemispheric circulation will be undertaken because of the simple fact that the Arctic must necessarily be involved in much basic research on the dynamics of the earth's atmosphere. An associated product of such studies will be the accomplishment of essential research on the interactions between arctic and middle-latitude regions with respect to transfer of mass, momentum, angular momentum or vorticity, entropy, heat content and moisture content, and the propagation of horizontal oscillations or perturbations between different latitudinal zones. Attainment of these research objectives would concurrently require solutions to the problem of heat balance and exchange by various causes, such as radiation, conduction, convection, advection, and latent heat changes.

SOME CLIMATOLOGICAL PROBLEMS OF THE ARCTIC AND SUB-ARCTIC

By F. KENNETH HARE

McGill University

INTRODUCTION

The Arctic is pioneer territory for the climatologist. For generations, students of the atmosphere have depended for their views of the arctic circulation upon hypotheses rather than facts. Because it has lain beyond the reach of large-scale observation, the Arctic has been the happy hunting ground of partisan theorists. One sometimes suspects that the compilers of world maps of pressure, temperature, and precipitation distribution have breathed a sigh of relief when they reached the Arctic, for here at last was a region where statistics were rarely troublesome. For every painstaking study of the calibre of Sverdrup's work on the *Maud*, or Georgi's at Eismitte, there have been tens of superficial interpretations.

Until World War II the initiative in the climatological study of the Arctic rested with the Scandinavians, and to some extent (chiefly since 1930) with the Soviet Union. The growth of air transport and the unstable international situation have altered the North American viewpoint, and both Canada and the United States are now belatedly committed to a large-scale meteorological invasion of high latitudes. That it has taken so long to awaken our interest in this vital field, and then only under the grimmest necessity, is no tribute to our scientific initiative.

Throughout the Arctic, lack of observational data is an acute problem. Except along the subarctic margin, long observational series are extremely rare. Enormous areas, like the permanent pack ice of the Arctic Ocean, are entirely unknown. Though the situation is improving rapidly, it will be some time before thoroughly standardised climatological normals will be available for enough stations to allow the preparation of reasonably accurate distribution maps across the Arctic. Even then the pack-ice belt will remain the largest observational gap in the Northern Hemisphere.

It is not proposed in this article to attempt a general account of the physical climatology of the Arctic. A brief review of the more important literature will be presented, but thereafter attention will be directed towards certain specialised fields in which scholarly research is possible with existing materials. For the moment these seem to have more to offer than broad syntheses.

The terms "Arctic" and "sub-Arctic" require definition. The Arctic is usually regarded as consisting of the tundra lands beyond the poleward limit of tree growth. The isotherm of 50F (10C) for the warmest month happens to coincide very roughly with the limit, and is often taken as the arctic boundary. At sea, those areas heavily affected by coastal and pack-ice are properly regarded as arctic. The sub-Arctic has no accepted connotation. The author usually applies it to the Boreal forest region of the Northern Hemisphere, that is, the great ring of coniferous forest stretching from Alaska to Labrador and from Norway to eastern Siberia. Neither definition, however, is rigorously adhered to in the following account.

Previous General Literature. Apart from certain brief reviews like that of Nordenskjöld [45], no general climatology of the arctic regions has been attempted. The available literature is thus regional in scope and must be discussed on this basis.

Over the Arctic Ocean, existing knowledge still depends very largely on the published results of the *Fram* [44] and *Maud* [54] expeditions, and to some extent from less accessible Russian sources. The best general summary remains that of Sverdrup [55]. Though published fifteen years ago, Sverdrup's distribution maps, and the data published in the *Maud* results, are the usual sources today of climatic maps of the inner Arctic.

In North America, the most comprehensive accounts are those of Ward, Brooks, Connor, and Fitton for Alaska [63], Sverdrup for the Canadian Archipelago [55], and Connor for the Canadian mainland [8]. All these are parts of the Köppen-Geiger *Handbuch der Klimatologie*, published in the middle 1930's, and are now considerably out of date. Since then various summary accounts have appeared in official papers, but few have been given wide circulation. The Canadian Department of Transport published a pamphlet on the meteorology of the Canadian Arctic in 1944 [6], the scope being actually climatological. The only other general work of consequence was a report by Döll [10] on the climate of the Labrador coast, as exemplified by the records of the Moravian Missions, which have maintained climatological diaries for many years.

Since 1945 the newly accumulated records from this region have allowed more intensive studies. Though as yet unpublished, detailed works are available on various parts of the Canadian North, many of them in thesis form. Among these we may list studies by Montgomery [42] on coastal Labrador, Hare [19] on the eastern Canadian Arctic and sub-Arctic, Wonders [68] on the Canadian Archipelago, and Currie [9] on the Keewatin-Mackenzie district.

The Greenland region was discussed by Petersen (coastal region) [55] and Loewe[1] (inland ice) [55] in the Köppen-Geiger series. A recent publication of the Greenland administration [46] brings the picture up to 1939, after which little is available.

Northern Russia and Siberia are adequately covered by certain Russian publications. A simple treatment is given by Borisov [2], who has been considerably

1. F. Loewe was an observer with the Wegener Eismitte party.

influenced by the idea of "dynamic climatology" put forward by Bergeron. Borisov's study is illustrated by numerous distribution maps, some of them drawn from the U. S. S. R. *Great Soviet World Atlas* [61], and all of them emerging from official sources. An invaluable supplement is the exhaustive study of Tikhomirov [58] on the Arctic and sub-Arctic of Soviet Asia. Tikhomirov presents tabulated summaries of the chief observational data from most of the new Siberian stations set up since 1930 by the resurgent Soviet states. A general review of Russian climates from the point of view of the normal circulation has been given by Alisov [1].

To these general studies must be added a large volume of local or specialised work scattered through the literature, almost entirely from Scandinavian sources. When reading either the general studies or the more specialised papers, one should bear in mind the scattered nature of the observations upon which they are based. The peninsula of Labrador-Ungava may be taken as an instance. This great land mass has an area of over 500,000 square miles; from north to south the peninsula extends over 14° of latitude, the same span as that separating New York and Palm Beach, Florida, and in longitude it extends over 22°, a distance equivalent to that separating New York from Minneapolis. In area, the peninsula is thus equivalent to the whole of United States territory lying east of the Mississippi and south of latitude 40°. Yet in the whole of this area there were no inland climatological stations before 1915, and only one from 1915–37 (Mistassini Post). Today there are ten, corresponding to less than one per state in the southeastern United States as defined above.

It is plain, then, that the time for comprehensive climatological synthesis is far distant. Yet there are many specialised fields in which the climatologist can work, and in which much valuable material has already been published. The author has selected for discussion below those special fields of research that seem to him most profitable with our present limited resources. They are:

1. The ecological climatology of the Arctic and sub-Arctic, a field that tends to be neglected by the climatologist; and
2. The climatological relation of sea ice, a vast and disorderly field in which much research is now progressing.

In addition, some attention is given below to the highly significant question of Greenland's icecap climate, a topic much bedevilled by controversy.

Inevitably this selection omits many subjects considered important by others. Prominent among these will be the physical characteristics of arctic snow cover. Restrictions in space and the author's experience must excuse these omissions.

ECOLOGICAL CLIMATOLOGY

The relation of climate to natural vegetation is one of the most significant branches of modern climatology. Vegetation and soils are mirrors of the normal climate of a region; the concepts of climax vegetation and of the great world soil groups both depend on the idea that climate is the ultimate ecological control. There is fairly general agreement that the type of fully developed natural vegetation and the mature soil profile are faithful climatic indicators. Soil and vegetation maps divided into regions ought therefore to give us a useful method of defining rational climatic regions. Most systems of climatic classification, like those of Köppen [36] and Thornthwaite [56, 57], have been based upon this assumption.

The ecological approach to climatology is especially valuable in the Arctic and sub-Arctic, for these are by definition major world regions in which climate restricts growth and economic potential through the agency of excessive cold. The natural vegetation of the cold northern lands falls into two major formations:

1. The *tundra*, the truly arctic landscape with no tree growth, where the dominant plants are the sedges, rushes, mosses and lichens, with some small shrubs and bushes. Very little work has been done on the climatic relations of the tundra in North America, and the Russian tundra is still being mapped.
2. The *Boreal forest*, which is the term applied to the great forest formation that everywhere borders the tundra along the latter's southern flank. The tundra and Boreal forest formations are separated by a transition zone in which both occur, the so-called *forest-tundra*, or *forest-tundra ecotone*.[2] The arctic tree line is the extreme northern limit of tree growth and may in general be regarded as the northern edge of the forest-tundra. As so defined, the line is the absolute northern limit, not of the forest, but of patchy and often stunted tree growth, extensive islands or "peninsulas" of tundra associations lying to the south of it.

Tundra associations occur in places far south of the true arctic limit. These anomalous areas occur in two types of environment: (1) on high ground, where the effect of altitude lowers the summer temperatures to the point at which only tundra vegetation can be supported (this is the so-called *alpine tundra*, and one also speaks of the *alpine tree line*); and (2) on certain exposed coasts in high latitudes, as for example in Labrador, Iceland, and parts of Arctic Scandinavia (to these anomalies the term "maritime tundra" may be applied).

The Nature of Climatic Control. It has long been assumed that temperature and the length of the growing season are the climatic elements controlling the distribution of climax vegetation in the north. It is a demonstrable fact that interformational boundaries tend to follow the general trend of the mean isotherms across continental masses. This correlation of the great vegetation regions with thermal climate has been used by such climatologists as Köppen and Thornthwaite to define climatic boundaries, which will be discussed later. Thornthwaite explicitly states [56, p. 648] that in the cold climates restriction of growth by cold far

2. The term *ecotone* is used ecologically to indicate a zone of transition from one major plant community to another. See Weaver and Clements [64, p. 104].

outweighs the effect of scanty precipitation. In his view, precipitation is everywhere sufficient to meet the very limited demands of plant growth throughout the Boreal and Arctic regions.

This common assumption rests upon very little serious research or experiment. The Scandinavian school of ecologists appear to have been pioneers in this field. Several workers have studied the effects of climate upon radial and vertical growth of common coniferous species, such as the Scotch pine (*Pinus sylvestris* L.) (Hustich [29, 30]) and European spruce (*Picea abies* (L.) Karst.) (Eidem, quoted by Hustich [30]). Though the climatic relations of individual species are not strictly comparable with the relations of a vegetation formation, they offer a valuable indication of the mechanism of climatic control near the poleward limits of tree growth, and are hence of outstanding interest.

The most recent review of this work comes from Hustich [30], who has carried out important field surveys in Labrador and Arctic Scandinavia, and who has thus had an opportunity to study the problem in differing environments. He found that both vertical and radial growth in northern conifers near their northward limit were closely dependent on midsummer temperature. His results are of such interest that they deserve a comprehensive summary. In a stand of Scotch pine at Utsjoki (Lapland, lat. 69°30′N) he found the following correlations:

1. Radial growth (*i.e.*, increase in diameter due to addition of annual ring of woody tissue) was highly correlated with July mean temperature for the same year at nearby Inari (68°57′N, 26°49′E, 153 m (502 ft) above sea level).

2. Vertical growth (*i.e.*, increase in height) was correlated with July mean temperature *for the previous year*, though less clearly than in the case of radial growth.

He also showed that variations in radial growth had followed quite closely secular variation of July temperature since 1890. In another series near Sodankylä [29] he obtained a correlation coefficient of $+0.54 \pm 0.12$ between July temperature and radial growth. In this series the corresponding coefficient between July rainfall and radial growth was -0.24 ± 0.16. All other attempts to show correlation between rainfall and growth proved equally abortive. Accordingly, he concluded that ". . . in the northern part of the temperate zone the correlation between temperature and growth is stronger than the correlation between precipitation and growth." He ascribes this independence of growth on summer rainfall to the maintenance of soil moisture content by melting snow.

Erlandsson [12] obtained even more convincing evidence from Karesuanda in northern Sweden. He was able to correlate radial growth in Scotch pine with mean temperatures over the period 1879–1931. His results are presented in Table I.

This table emphasises the importance of July temperature, rather than that of the summer as a whole. Apparently the critical season is extremely short in these high latitudes. Like Hustich, Erlandsson concluded that precipitation was a negligible factor in determining growth.

Table I. Correlation Coefficients Between Climatic Factors and Radial Growth of Scotch Pine at Karesuanda, Sweden, 1879–1931
(*After Erlandsson* [12])

Climatic factor	Correlation coefficient
June, mean temperature	$+0.29 \pm 0.13$
July, mean temperature	$+0.70 \pm 0.07$
August, mean temperature	$+0.24 \pm 0.13$
Rainfall, June–September	-0.19 ± 0.13

These important results depend upon the well-established technique of tree-ring analysis; the width of the annual ring of xylem is carefully measured, variations from year to year in thickness being assumed to indicate variations in climatic stimulus to growth.

Hustich [30] points out that the northern conifers, though they grow in a region of great climatic hazard, have a remarkable freedom from "suppressed" or "missing" annual rings, such as are constantly referred to by the Arizona school of tree-ring workers. In lower latitudes, where temperatures are high enough to support growth for a large part of the year, summer drought becomes an all-important factor. Along the forest-steppe margin, occasional drought years may virtually suppress radial growth, and the tree trunk therefore contains only a stunted, incomplete, or vestigial "ring" as a record. This is true of all parts of the world in which occasional droughts occur, even, for example, in equable southern England [33]. Precipitation is a notoriously variable element; hence in any region in which the maintenance of soil moisture through a long growing season depends on summer rainfall, the annual-ring spectra of trees will contain marked variations and "suppressed" rings.

If precipitation is unimportant as a factor influencing growth in northern regions, the annual-ring spectra should show only small variations in annual growth, for July temperature, the apparent prime control, is nowhere very variable. Hustich's observation that suppressed rings are absent from northern Scandinavian conifers confirms this deduction. Hustich's finding is in turn confirmed by several investigations in North America. Thus Giddings, accustomed to work in the dry western part of the United States, apparently did not notice suppressed rings in the Alaskan [14] and Mackenzie regions [15]. Marr, in an important monograph on the forest-tundra ecotone of western Labrador-Ungava [38, pp. 142, 143], was even more specific. Referring to white spruce (*Picea glauca* (Moench) Voss), he writes ". . . annual growth has been so uniform at Gulf Hazard during the last 230 years, that only 41 growth-rings are sufficiently below average width to permit visual detection of the deviation."

There is thus ample support for the view that summer temperatures, and especially July temperatures, are the major factor determining radial growth (and probably vertical growth and volume increment too)

in the coniferous trees that dominate the Boreal forest, at least in its northern parts. This does not mean that precipitation is unnecessary to the growth, but that the combined snow melt of May and July and the precipitation of June, July, August, and September are everywhere enough to support the restricted growth these subarctic temperatures can sustain.

This view has been challenged by Sanderson [50], who found that drought is a marked restricting factor in the Boreal forest of western Canada. By using Thornthwaite's new system of climatic classification, she was able to show that widespread moisture deficiencies occur throughout the part of the Canadian Boreal forest lying west of Ontario; the entire region is dry sub-humid or semi-arid, according to her results. She maintained that the forest is stunted by this summer drought, or may even be replaced by scrub or prairie [48]. Soil acidity is much lower than one might expect for the typical Boreal forest podsols, *p*H determinations varying from 7.0 to 7.6 in northern Saskatchewan, and from 6.3 to 7.8 at Fort Simpson on the Mackenzie. These are values ranging from mildly acid to mildly alkaline, far different from the strongly acid reactions of soils from Quebec, Labrador, and the Finnish plateau.

It is probable that the truth lies somewhere between these two opposed views. Hustich, Erlandsson, and the other workers of the European school have been accustomed to the Boreal forest in its wetter phase—the Finnish and Lapp plateaus resembling Labrador and Northern Ontario in climate—and may have been misled by sheer lack of exposure to the drier types of microthermal climate. On the other hand Giddings' tree-ring work on the Mackenzie [15] confirms Hustich's view rather than Sanderson's: he makes no mention of stunted rings due to drought years. Sanderson is also open to attack on the grounds that Thornthwaite's scheme contains sweeping assumptions about available soil moisture that may not apply in permafrost areas, or in areas of glacially disturbed drainage. As Clark [7] says, her view that drought restricts growth in the Canadian northwest is ". . . a somewhat startling conclusion for the many who have spent summers there with almost perpetually wet feet! This apparent anomaly is explained as the result of poor drainage rather than of humid climate . . . ."

It appears quite probable that there are certain areas of the Boreal forest where summer drought is effective in the manner Sanderson suggests, not only in Canada but in Siberia: salty or alkaline marshes and prairies occur in the Yakutsk basin of the Lena Valley, just as they do in the Peace River Valley [53]. But it also seems likely that *once enough moisture is provided during the growing season*, as it is in most areas, further moisture has little or no influence on the forest: it cannot induce greater luxuriance, nor can variations in available moisture above this quantity have any effect on the annual-ring record. In all but a few areas the effective climatic control within the Boreal forest appears to be thermal; the regional subdivisions of the forest are hence correlated with isopleths of temperature or functions of temperature, and ignore the precipitation distribution.

Zonal Divisions of Arctic and Sub-Arctic Vegetation. With this background, we can now examine the climatic correlations of the major divisions of natural vegetation.

The Arctic Tree Line, the Northern Limit of Tree Growth. This line is often extremely sinuous, and is hard to map, but its course is now tolerably well known round the world. As it divides the truly Arctic tundras on the north from the Boreal forest formation, it is an extremely important boundary.

Early attempts to find the poleward limits of tree growth stressed July temperature. Supan [52] observed that the isotherm of 10C (50F) for the warmest month followed the arctic tree line closely. Later Köppen [36] adopted this isotherm as the division between tundra (Ekistothermal) and microthermal climates. The general correspondence of the two lines can be seen on world maps, though in detail they may diverge considerably. The 10C isotherm has enjoyed a prestige among biologists and geographers far exceeding its merit.

Vahl [62] differed from Köppen in assigning some significance to winter temperatures. Forests are observed to flourish in certain maritime regions right up to or even beyond the 10C isotherm. Thus Tierra del Fuego, at the southern tip of South America, is forested, though the warmest month is only 8–9.8C (46–50F). Here the mean daily temperatures remain above 0C throughout the winter, and it is evident that the mildness of the cooler season is the permissive factor. In continental interiors, on the other hand, the tree line fails to reach the 10C isotherm for the warmest month. This isotherm passes just north of Baker Lake in Keewatin, for example, some 200 mi north of the tree line. Presumably the much greater winter cold of the continents is the operative factor. In short, the colder the winter, the warmer the summer has to be to support tree growth.

Nordenskjöld [45] tried to express this idea in a rough-and-ready substitute for the Köppen-Supan line. He suggested that the tree line was most closely followed by the isotherm

$$W = 9 - 0.1k, \tag{1}$$

where W is the mean temperature of the warmest month and k is the mean temperature of the coldest month, both in centigrade degrees. In Fahrenheit, this identity becomes

$$W = 51.4 - 0.1k. \tag{2}$$

The "Nordenskjöld line," as it is often called, fits the arctic tree line better than any other purely climatic isopleth. Figure 1 shows its course.

The attempts so far discussed are hit-and-miss affairs with no rational basis. No adequate discussion of tree-line climates is known to the present author. Thornthwaite has proposed a climatic classification supposedly "rational" in that it depends upon a reasoned consideration of the soil moisture cycle and the water needs of

plants in growth [57]. He divides the world into thermal regions defined by reference to what he calls "potential evapotranspiration."[3] The latter is a function of the temperature, whose value for a month is given by

$$E = 1.6\ (10T/I)^a \text{ cm}, \qquad (3)$$

where T is the centigrade mean air temperature, I is a heat index dependent on the annual course of mean temperature and is equal to the sum of the twelve monthly values of $(T/5)^{1.514}$, and a is a constant dependent on I. The twelve monthly values of E are added (after they have been adjusted for variations in length of day and month) to give an annual value of potential evapotranspiration.

FIG. 1.—The extent of the Arctic. Solid line—isotherm of 10C (50F) for warmest month. Dashed line (with capital *N*'s)—the Nordenskjöld arctic boundary (see text). Alternating dots and dashes—southern limit of general permafrost. Dotted line—southern limit of permafrost in patches. The shaded area is tundra or icecap. Alpine tundra is not shown, except along the Urals (for reference) and again in northeastern Siberia, where it is included to indicate the isolated area of wooded country in the Anadyr Valley.

This value forms the basis of Thornthwaite's thermal zones. Along the tundra/microthermal boundary, E should be 28.5 cm (11.2 in.), according to Thornthwaite's divisions. In practice, this theoretical line

3. This function is defined as the amount of water that would evaporate from a plant-covered soil if there were no restriction in water supply in the root zone. It is considered independent of the floral composition of the vegetation.

lies well north of the tree line in North America, as well as in most parts of Siberia. The northernmost trees in Keewatin do not get far beyond the line $E = 33.0$ cm. In Labrador-Ungava they locally attain $E = 29.5$ cm, but again tend to halt at the 33-cm value.

Attempts to find climatic equivalents for the tree line assume that the latter is in fact "climax," that is, has reached the northernmost limit of feasible tree growth. In many areas this is not the case. The trees have not yet reoccupied all the climatically suitable lands from which they were driven by the Wisconsin glaciation and its attendant cold. Thus Marr has shown that active northward migration of the tree line is in progress on the east coast of Hudson Bay [38]. Griggs has similarly described the spread of the Pacific and Boreal forests into the Alaskan maritime tundra [17], notably on Kodiak Island and the Alaskan peninsula. It seems quite evident that the tree line has not yet attained its equilibrium position in many areas; furthermore the rapid fluctuation characteristic of recent subarctic climates makes it doubtful whether any such equilibrium can be struck at all. In the circumstances, it is unlikely that any rational climatic equivalent can be found for the tree line. Nordenskjöld's line, arbitrary though it is, comes closer to the present position than any "rational" attempt. A glance at Fig. 1 will convince the reader of this close fit.

The "maritime tundra" already briefly discussed presents many interesting problems. Along many coastal belts of the sub-Arctic, treeless tundras, usually with a high proportion of typically arctic species, descend far south of the normal poleward limit of trees. Excellent examples are the Aleutian-Alaskan peninsula region, the Labrador coast, parts of Iceland, coastal Fennoscandia, and certain localities on the coast of the Maritime Provinces of Siberia, facing the Okhotsk and Bering Seas. Similar coastal treeless formations occur still farther south, as in the moss-barrens of south-coastal Newfoundland, the coasts of Ireland and Scotland, and the Kuril Islands. These regions are different, however, in that floristically the vegetation has many nonarctic affinities; furthermore, human agencies may have destroyed pre-existing forests, except in Newfoundland.

The best-studied case is that of coastal Labrador [28, 66], where maritime tundra forms a narrow belt extending as far south as the Strait of Belle Isle. Though rarely more than a few miles wide, the strip grades inland into the Boreal forest through a well-marked tree line and a zone of stunted brushwood like the *krummholz* of the Vorarlberg and the thickets of Mount Washington. It was long assumed that this tundra was the result of the chilling of summer temperatures by drifting ice in the Labrador current. It has been shown, however, that the "thermal efficiency" of the coastal climate is adequate to support a poor forest or woodland cover [19, pp. 237, 238; 19*a*, p. 631]. The absence of trees is ascribed by Wenner to excessive transpiration (and hence physiological drought) induced by the strong coastal winds. Whether the explanation holds or not, it is certainly true that the forest finds it more difficult to invade the coastal sub-Arctic than the interior.

There are very few studies of the montane tree line in subarctic regions comparable with those on high, isolated summits in temperate and tropical latitudes.

The Forest-Tundra Ecotone. This zone is a belt of variable width in which treeless and woodland associations intermingle. In North America it has been delimited in Labrador by Hustich [31], its southern boundary being thermally adjusted to the isopleths of

$$E = 35\text{–}37 \text{ cm}$$

potential evapotranspiration [19*a*, p. 630]. Elsewhere its boundary has yet to be adequately mapped. In Siberia its extent is well known west of the Yenisei, where again its southern edge is at about $E = 35$ cm. It is clear that in these regions the ecotone is a belt whose position and width are thermally determined, thus conforming to the expectations raised by the work of Hustich, Erlandsson, and others discussed above.

The Boreal Forest Itself. This zone can be divided into two broad subdivisions that have been recognized both in North America and in the Soviet Union. On the northern flank there is a belt of open woodland, characterised by widely spaced spruce (*Picea* spp.), pine (*Pinus* spp.), or larch (*Larix* spp.) set in a rich lichen floor, the dominant genus of lichen being *Cladonia* ("reindeer" or "caribou moss"). On the southern flank lies a broad belt of true forest, with close stands of spruce, fir, pine, larch, and some hardwoods. The ground is in deep shadow and is usually carpeted with mosses and shade-loving herbs. The two belts are fairly distinct, meeting along a mappable boundary; they go by various names, but the term "Boreal woodland" and "main Boreal forest" will be used for them here.

The boundary between them is indicated for Canada in the official publication "Native Trees of Canada" [5], the Boreal woodland being indicated as "transitional" to the Arctic to the north. Hustich, however, distinguishes (1) a forest-tundra ecotone, already discussed, (2) a "taiga" belt, or Boreal woodland of the lichen-floored type, and (3) a southern Boreal forest, equivalent to the main Boreal forest defined above [31]. Hustich's divisions correspond structurally with those widely recognised for the Boreal forest of Finland and Soviet Russia, and are hence of great interest [53].

In Labrador-Ungava, it is at once clear that the woodland/forest boundary coincides very closely with the isopleth of potential evapotranspiration $E = 43$ cm [19*a*, p. 630], which is that selected by Thornthwaite to divide the microthermal climates into warmer and cooler halves. Though a similar investigation of the Russian climate has not been carried out, Arkhangelsk, about 100 mi south of the boundary, has $E = 44.5$ cm, and Ust-Sylma, on the Pechora River some 50 mi within the Boreal woodland has $E = 40.3$ cm. Furthermore, it is clear that all the belts of the Boreal forest west of the Yenisei extend zonally along the isopleths of potential evapotranspiration, as they do in Labrador-Ungava [31]. Obviously the woodland/close-forest boundary is

a thermally controlled divide in the same position climatically in both Labrador and Russia.

The Southern Limit of the Boreal Forest. This zone is less clearly defined climatically and is variable in ecological character. In Alberta, Saskatchewan, and Manitoba, the forest passes south into prairie (or steppe) lands through the so-called parklands, or *forest-steppe ecotone.* A similar forest-steppe boundary is observed in Siberia from the Urals to the Yenisei. In eastern North America the Boreal forest passes southwards into a mixed hardwood-softwood formation, the *Great Lakes–St. Lawrence forest* of Halliday [18], or the *Lake forest* of Weaver and Clements [64, pp. 496–500]. A similar passage is observed in European Russia along a line extending from Estonia through Yaroslavl to the Urals near Sverdlovsk. Both in America and Russia, the mixed forest is distinct floristically from the Boreal forest to the north and the deciduous forest to the south, though it has some elements in common with both.

In eastern North America, certain species typical of the Great Lakes-St. Lawrence forest penetrate the true Boreal forest, reaching an east-west line with potential evapotranspiration about 48 cm. South of the isopleth $E = 51$ cm, the dominants are everywhere the white and red pine (*Pinus Strobus* L., *Pinus resinosa* Ait.), yellow birch (*Betula lutea* Michx. f.), and various maples; the spruces (*Picea* spp.), balsam fir (*Abies balsamea* (L.) Mill.), and Jack pine (*Pinus Banksiana* Lamb.), typical of the Boreal forest, are subsidiary elements. Here again we are faced with a thermally-correlated boundary; the southern limit of the Boreal forest follows an isopleth of Thornthwaite's thermal efficiency function.

Once more the same value appears, on a casual inspection, to hold for the Russian forests. Moscow, 150 mi south of the Boreal-mixed forest line at Yaroslavl, has a value of $E = 54.2$ cm, which in North America would put it well into the mixed belt. On the other hand, Perm (Molotov), 75 mi north of the line, has $E = 50.8$ cm. These values are obviously very close to those applicable in eastern North America. What is even more surprising is that the inner (forest) edge of the forest steppe *both in the Canadian Prairies and in western Siberia* closely corresponds to the same value of potential evapotranspiration.

Gathering all these threads of evidence, we can draw these conclusions, all of which remain tentative because of the fragmentary evidence employed:

1. Through most parts of the Boreal region of the earth, the temperature of midsummer is the main factor determining variations in growth of the common tree species.

2. Variations in summer precipitation have little or no effect on growth, except near the forest-steppe margin.

3. The Boreal-forest formation shows a broad division into latitudinal zones: a forest-tundra ecotone, next a woodland belt, then a close-forest region. The arctic tree line and all the interzonal boundaries are highly correlated with Thornthwaite's thermal efficiency function, the potential evapotranspiration (E). The values of E applying along these lines are much the same in the Soviet Union west of the Yenisei River.

Obviously these conclusions need to be checked and rechecked. There are probable sources of error at every stage of the analysis. For the ecologist, there is the task of more adequately mapping the zonal boundaries of the Boreal forest. For the climatologist, there is the responsibility of collecting and analysing more and more climatic data. Thornthwaite's stimulating climatic classification, used above to illustrate the dependence of the Boreal forest on thermal efficiency, needs to be scrupulously examined as to its applicability to the cold climates. Sanderson's work in the Mackenzie Valley [51] is an important contribution in this particular. Above all, the type of analysis here attempted needs to be applied to the mountainous lands of Alaska and the Yukon, and of Siberia east of the Yenisei. Here the montane effect must vastly complicate the correlations quite easily established in Labrador and the western Soviet Union.

Permafrost Distribution. A widespread condition in the cold lands is that of permanently frozen soil, christened "permafrost" by Muller [43]. This condition is achieved when the annual wave of summer heating fails to descend to the base of the layer of frozen soil. The mechanical properties of permafrost are the business of the engineer, but its distribution is of interest to climatologists. Figure 1 shows its approximate extent in the Northern Hemisphere. The data used in its preparation come from studies by Muller [43] and Jenness [32].

Few attempts have been made to correlate permafrost with climate. Sumgin (quoted by Muller [43, p. 4]) states that Russian estimates give 0C (32F) annual mean temperature as the outer limit of patchy permafrost, and that geographically continuous permafrost occurs north of the annual mean isotherms of −3C to −6C (26–21F). Thomson (quoted by Jenness [32]) suggests that the −5C (23F) isotherm comes closest in Canada. All these are approximate estimates, and it is quite obvious that such quantities as depth and duration of snow cover must also affect the distribution. In detail, the occurrence of permafrost is affected by soil drainage, slope, exposure, the presence of large bodies of water, and the geological history of the region. The climatological correlations of permafrost urgently await study.

THE DISTRIBUTION OF SEA ICE

It was earlier suggested (p. 952) that the term "Arctic" might well refer at sea to those areas perennially or annually affected by sea ice, either landfast or pack. The presence or absence of sea ice is of prime importance to both the meteorologist and the climatologist, who are confronted with questions of two sorts: (1) the effect of ice formation on air-mass structure, and hence upon climate; and (2) the climatological requirements for the formation of ice, and for its drift into other waters. The literature on these questions is abundant but scattered; moreover much of it comes from

Russian sources and is hence inaccessible. The review that follows is as inadequate as the subject is important. All that can be attempted is a review of the fields in which research is at present active.

The physics of sea-ice formation, of its drift, and of the deformation induced in it by atmospheric disturbance lies beyond the scope of this article. A general summary of present knowledge was recently prepared by Gordon and Woodsworth [16], and a review of Russian work in the field has been published by Zubov [69]. In North America most research in this field is contained in various publications of the U. S. Hydrographic Office [60].

Much time has been spent by research climatologists on the influence of arctic sea ice on the climate of the middle latitudes. Particular attention has been paid to the Labrador and East Greenland Currents, which are the chief routes by which heavy arctic pack enters lower latitudes [21]. This is a question of vital importance in the study of climatic change, but has less direct reference to the arctic climates themselves. In Greenland and along the Labrador Sea, however, the relationship is direct, and will be discussed later.

Hudson Bay: A Concrete Example. Until 1945, it was generally assumed that Hudson Bay remained unfrozen throughout the winter, despite the grim cold of nearby land areas. This assumption had the support of Canadian, British, and American official papers. Many authorities entered into considerable detail in describing the narrow belt of fast ice along the shores, but insisted that the central area rarely or never froze from shore to shore. The coastal fast ice was variously stated as being 5 to 60 mi wide [59].

This early view was first challenged when military aircraft began flying across the northwestern flanks of the Bay during World War II [49]. In March 1948, Lamont [37] flew directly across the central area of the Bay, photographing an unbroken pack covering the whole area. Since then regular reconnaissance flights have been made across all parts of the Bay by the Royal Canadian Air Force, with scientific observers on all flights and with complete photographic records. These flights have established that the Bay freezes annually in the late fall and is completely frozen from January until June, except for (1) a coastal lead, separating fast ice from the central pack, and (2) small, temporary leads or fissures set up in the central parts by storms, tides, and other sources of stress. These new facts have been summarised by Montgomery [20, Part II]. Associated with the reconnaissance program, there has been some active research, to be described below.

Burbidge [3] set out to examine the changes wrought in continental polar air masses in their travel across the Bay. By plotting trajectories at the main aerological levels, he was able to trace changes in the air before it arrived at the east coast aerological station of Port Harrison (58°27′N, 78°08′W). His results can be summarised as follows:

1. In the fall, before the freeze-up, great heating and dampening occur in the airstreams as they cross the warm open water. This effect rises to a maximum in late November and early December, when the surface temperature rises an average of over 20F (11C) in the crossing from west to east. Thereafter, the consolidation of sea ice cuts off the source of heat, and heating is negligible from mid-January on; apparently the snow-covered ice surface entirely insulates the water below. Curve (*f*) in Fig. 2 shows the amount of this

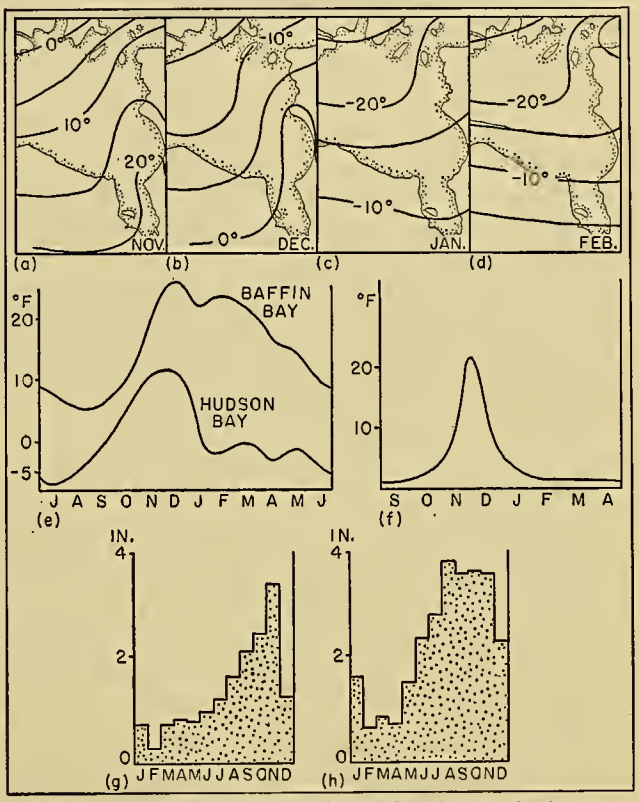

Fig. 2.—A summary of the evidence bearing on the freeze-up of Hudson Bay. Maps (*a–d*)—mean air temperature, 1930–48, November–February. Curve (*e*)—temperature differences (upper curve) between west and east coast of Baffin Bay at latitude 70°N, showing year-round mildness of Greenland coast; (lower curve) between west and east coast of Hudson Bay, showing greater warmth of east coast *during fall months only*. Curve (*f*)—Burbidge's modification curve for *cP* airstreams (see text). Curves (*g*) and (*h*)—mean monthly precipitation for Port Harrison (*g*) and Great Whale River (*h*) on east coast of Hudson Bay.

warming effect month by month. The rapid decline after December is very striking.

2. This heating leads to the development of an unstable layer at low levels, with lapse rates close to the dry adiabatic. By late November, the peak time, the average depth of the unstable layer is 7000 ft, and may attain 10,000 ft. Dense cumuliform cloud and frequent snow flurries occur within the layer, and total snowfalls along the Quebec coast are heavy (over 30 in. in November). With the freeze-up, the unstable layer disappears or becomes very shallow (less than 1000 ft) as do the cloud and snow. In Fig. 2, diagrams (*g*) and (*h*) represent mean monthly precipitation at Port Harrison and Great Whale River, respectively, on the east coast of the Bay. In both cases heavy autumnal snow gives way to light falls in the new year.

It is noteworthy that Burbidge obtained these results before reconnaissance had proved them beyond all doubt, thus demonstrating the value of careful meteorological analysis. His findings are quite what one would expect, but it was not until 1949 that they were proved or even suspected by many.

A similar result was obtained by Hare and Montgomery in a climatological analysis [20]. They showed that conspicuous gulfs of warmth characterise the winter mean air temperature maps in areas where open water persists. Three such gulfs were noted in the North American Arctic:

1. Along the east shore of Baffin Bay, where considerable open water persists in the warm West Greenland Current as far north as latitude 70°N.

2. Along Hudson Strait, where high tidal range and exposure to storms keep the pack ice well broken throughout winter.

3. Over eastern Hudson Bay. This gulf was visible, however, only until December, after which it vanished. The authors therefore assumed with Burbidge that the Bay was entirely frozen over by the new year. Diagrams (*a*)–(*d*) in Fig. 2 show mean temperature over the Bay from November to February. The conspicuous gulf of warmth on the November (*a*) and December (*b*) maps vanishes in January.

The reconnaissance flights in the winter of 1949–50 showed that in that year the freeze-up began along the northern and western flanks of the Bay; by November 22, 1949, continuous though thin ice extended as far south as Portland Promontory on the east coast and beyond Churchill on the west. The last area to freeze (in late December) was south and east of the Belcher Islands.

Other Seas in the American Arctic. In several other areas problems comparable with those of Hudson Bay are awaiting solution by similar methods. By direct reconnaissance, by meteorological inference, or by the observation of climatological anomalies, it will shortly be possible to achieve greater precision in our ideas about their winter ice cover.

Outstanding among these problem areas is Baffin Bay, and its narrow link with the Labrador Sea, Davis Strait. Its winter ice cover comprises three components: (1) fast ice forming along the shores and in the fjords of Baffin Land and of Greenland north of Holsteinsborg; (2) the central pack ice, composed of heavy arctic ice from Lancaster, Jones, and Smith Sounds, together with locally formed floes; the whole mass drifts southwards on the Canadian Current, ultimately discharging into the Labrador Current, which in turn may carry it to the Grand Banks late in the season; and (3) the Storis, a drift of heavy arctic ice from the East Greenland Current; rounding Cape Farewell in January, it advances northwards in the West Greenland Current, reaching farthest north (about 63°–64°N) between April and June.

It has already been mentioned that open water tends to persist through most of the winter between the central pack and the fast ice of Greenland (see p. 959). This break extends at least as far north as 70°N at most times. Furthermore, the central pack rarely approaches the Greenland coast south of Holsteinsborg, and probably never makes lasting contact with the Storis. The lane of open water up West Greenland, then, must extend without a break from the Labrador Sea. Small wonder that the climate of the West Greenland coast is so remarkably mild in winter. Disko Island, for example, is some 25F (14C) warmer than the Baffin Land coast. See curve (*e*) in Fig. 2

However confidently these claims are made, one should remember the extent to which they depend on inference. The open water off the Greenland coast has never been precisely mapped. The warming effect of subsidence from the icecap to the east, seemingly required by the mean winter pressure distribution, may also contribute to the warmth of the West Greenland coast. The tendency for warm maritime polar air to travel northwards along the Bay may be yet another factor. A general study of the circulation over Baffin Bay, with an associated survey of ice conditions by aerial reconnaissance, has much to offer the arctic climatologist.

An area of special interest lies at the northwest corner of the Bay near the entrance to Smith, Jones, and Lancaster Sounds. This area is the celebrated "North Water," a region free of ice and with quite warm surface waters during the navigation season. It is believed to remain partially unfrozen during the winter [34], and it is well known that Lancaster Sound never freezes solidly from shore to shore. Stations on Devon Island (Dundas Harbour), Baffin (Arctic Bay), and Bellot Strait (Fort Ross) plainly show the warming influence of open water throughout the winter [20, Part I]. The North Water must be mapped by aerial reconnaissance to determine both its position and its extent far more adequately.

The Scope for Research. Research into the climatological significance of sea ice has much to offer, being still in its infancy as far as North America is concerned. The obvious fields for investigation can be summarised as follows:

1. The modification of air masses over ice-covered seas is a fertile field for the dynamic meteorologist. Since Sverdrup's careful work on the *Maud* [54], very little has been done on this important subject. Burbidge's analysis over Hudson Bay suggests that a thorough understanding of the mechanics of modification may ultimately make it possible to predict both the extent and surface characteristics of offshore ice by shore-based aerological stations. Quantitative studies like those for *cP* air overland by Wexler [67] and for the transformation of *cP* to *mP* by Burke [4] and Klein [35] are urgently needed for the flow of intensely cold arctic air masses over unfrozen sea surfaces.

2. The climatological background of the freeze-up of the open sea areas also requires investigation, obviously in conjunction with the foregoing problem. This is a task requiring the co-operation of oceanographers. Hudson Bay, as a virtually enclosed body of water,

ringed by aerological stations and passing annually through the cycle from completely frozen to completely ice-free, seems an obvious laboratory for such a study.

3. The characteristics of coastal ice, especially in harbours, is another topic worthy of study by the climatologist. At present the relation between climate and freeze-up, breakup, and thickness of coastal ice is only qualitatively understood. In 1943 the United States Air Weather Service began serious observation of both fresh water and sea ice, as well as of snow cover, at all its Canadian, Alaskan, and Greenland stations. It is to be hoped that these records will ultimately become available to research workers.

THE PROBLEM OF GREENLAND

Most problems of arctic climatology are hemispheric: they are widespread in character, and are as much problems in Siberia, for example, as they are in Alaska. Greenland presents us with an entirely distinct set of questions, to which highly controversial answers are sometimes given. Since many of these problems are critically important to students of Pleistocene glaciation and to glaciologists as well as to climatologists, they demand a brief review here.

The central icecap of Greenland, occupying as it does the great bulk of the land mass, has remained throughout the past hundred years a virtual blank on the weather map. Our knowledge of its climate rests upon the reports of the handful of explorers who have crossed it, and on the two or three brief periods of observation by icecap meteorological stations. In place of real knowledge, we have had a generation or more of heated controversy concerning the theory of the so-called "glacial anticyclone." This controversy has recently [26] been likened to a debate between explorers (who have seen for themselves) and absentee meteorologists (who persist in ignoring the evidence provided by the explorers). This is a grave oversimplification, but it does contain the seeds of the truth; the controversy wages over different interpretations of the evidence, that of the explorers—which is essentially inexpert—and that of the meteorologists, many of whom have had practical experience in Greenland.

Nearly all the explorers who have crossed or penetrated the icecap refer [47] to a remarkable wind and weather régime. They speak of strong and monotonously regular downslope winds blowing out from the central core, and pouring out through the coastal fjords to the surrounding seas. Peary [47] described the flow as being analogous to the flow of water down a slope. In a sense these stories represent very large scale parallels of the *Gletscherwinde* of the Alps.

In 1910 the well-known geologist, W. H. Hobbs, presented in its earliest form the theory of the glacial anticyclone [22], by which he explained not only the Greenland climate but also the general characteristics of Pleistocene icecap climates. With added experience he published a greatly expanded version of this theory in his book *The Glacial Anticyclones* [23] and his views have remained substantially unchanged ever since [25]. Though he has been hotly attacked, Hobbs has maintained his position with great tenacity; the "glacial anticyclone" has become an established part of the legend of Pleistocene geology, and has coloured the thinking of arctic specialists for a generation.

We may summarise the main features of Hobbs's theory as follows:

1. An ice surface is a good reflector and a good radiator; hence the air resting on the icecap should be subject to intense radiative cooling which cannot be counteracted by absorption of insolation.

2. The cooling must lead first to an accumulation of very cold air in the central regions of the cap, and hence to rising pressure. Finally, the accumulated mass of cold air must break out to the coast in a spectacular downslope surge or "stroph" of the glacial anticyclone. To replace the outflowing air, general subsidence begins, and at very high levels there are radially inflowing winds. The subsiding air, however, is warmed thermodynamically, and eventually destroys the cold of the central regions. In a few days the "stroph" is finished, and the icecap settles down to a fresh period of refrigeration, after which the cycle is repeated.

3. In effect, this view postulates that a fixed, permanent anticyclone lies over the icecap; in it the normal clockwise circulation of the anticyclone is replaced by a gigantic downhill, gravity-impelled divergence of the chilled surface air. The presence of such an anticyclone over the cap must plainly inhibit the passage of cyclones, and it is a fundamental tenet of Hobbs's theory that cyclones do not penetrate more than a few miles inland. He has published several papers [27] designed to prove this.

4. The alimentation of the icecap, however, presents a problem, for if cyclones do not cross it, from where does the snow come to make good the large annual loss by ablation? In Hobbs's view, hoarfrost, not snow, feeds the Greenland ice, as it did the Pleistocene sheets. The radiative cooling of the subsiding air at the ice surface causes the condensation of huge quantities of hoarfrost, enough to make good all losses by ablation.

5. Hobbs's final point—and in some ways the most pregnant—is that the "strophs" of the glacial anticyclone set off the main frontal cyclones of the Atlantic; the icecap acts, in fact, as the "North Pole of the winds," to use his own picturesque phrase. At all seasons the air over the icecap is the coldest in the Arctic, and hence must replace the polar cap itself as the source of true arctic outbreaks.

All aspects of this remarkable theory have been hotly debated for more than a generation. It is not too much to claim that Hobbs's work was directly responsible for the bulk of the exploration of the Greenland interior carried out after World War I. The University of Michigan sent several expeditions to the west coast between 1926 and 1933 under the leadership of Hobbs himself and L. Gould [40]. These expeditions set up stations both on the coast and on the icecap, carrying out an elaborate series of surface and upper-air observations. In 1930–31 Alfred Wegener organised a re-

markable excursion which maintained stations on both flanks as well as in mid-ice (Eismitte) for a calendar year. The Wegener results provide by far the most important evidences yet at hand concerning the icecap climate. In the same year an official British party established an icecap station on the east slope, rather to the south of the Wegener station. Thereafter there was a period of inactivity until the United States established stations during 1944. In 1949 a well-equipped French party led by P. E. Victor reoccupied the Eismitte site, resuming the Wegener observations on an enlarged scale. The station is still in operation (June, 1950) and efforts are being made to keep it open for another year.

As a result of these studies the consensus of meteorologists is that the glacial anticyclone is in large measure based on a confusion of fact with deduction. To summarise the present position:

1. The radial wind system, the basis for Hobbs's views, is more complex than early accounts allowed. Stations established on the slopes [40, 41] reveal that the surface wind most commonly flows downslope, but by no means invariably so. At the Eismitte station, where, according to Hobbs, the wind should have been light, variable, or easterly, the winds were actually strong [65]. All stations showed periods of upslope flow, and considerable variability was general. The University of Michigan station on the west slope indicated that the outblowing winds might extend to 4 km (13,000 ft) or above [40, Part I].

The general view today is that the radial wind system is a katabatic circulation; the cooled air flows down the slope under gravity, eventually reaching sea level along the numerous fjords with which the coast abounds. General subsidence in the central regions of Greenland must occur to feed the katabatic flow. In this sense the term "anticyclone" is faintly justified, since anticyclones are regions of subsiding air. In every other sense, however, the term is a complete misnomer.

Several writers have expressed the opinion that the katabatic winds blow only during periods of feeble general circulation over the icecap. Dorsey [11], who operated the U. S. Icecap station during 1944, states that the katabatic winds are absent if there is an appreciable upslope component in the regional circulation. Much the same conclusion is drawn by Mirrlees [41]. Both these writers produce evidence that exceptionally strong flow down the east slope occurs in the rear quadrants of cyclones in the vicinity of Denmark Strait or Iceland; in other words, excessively strong "strophs" of icecap air require the joint action of the katabatic flow and a parallel regional flow.

2. The alimentation of the cap by hoarfrost has been similarly disputed. Matthes [39], in a closely argued critique of Hobbs's views, points out that the air subsiding into the central regions of the Greenland "anticyclone" can contain only negligible amounts of moisture; furthermore, it must have been rendered relatively drier by the adiabatic warming postulated by Hobbs.

The condensation of rime (liquid cloud or cloud droplets frozen onto solid surfaces) is a well-known phenomenon in moist air masses. Mount Washington Observatory affords numerous striking and photogenic examples every winter. It is very possible that rime accretion is appreciable on the lower slopes of the Greenland cap. Hobbs, however, has specifically ruled that moist maritime air does not penetrate more than a few miles inland, and rime cannot possibly form from the subsiding air of the icecap.

On the other hand, there is abundant evidence that there is frequent heavy snow on the icecap. Georgi [13, pp. 52–87], observer at Eismitte, was almost overwhelmed by the heavy snow of August 1930, when he established the station; Courtauld, hero of the celebrated six-month vigil on the icecap of the British Arctic Air Route Expedition, was actually buried, and had to be rescued through the ventilating shaft of his quarters [41]. Moreover the periods of snow fell during spells of upslope winds, and were preceded by cloud sequences similar to those observed at lower levels during frontal passages. It is impossible to believe that experienced observers like Georgi and Courtauld could have confused snow and hoarfrost.

Most of these observers concluded that cyclones could and did cross the icecap, and that the snow was normal cyclonic snow. Dorsey [11], however, felt that it was unrealistic to talk of sea-level pressure systems crossing a 10,000-ft barrier; he suggested, with convincing evidence, that it is the higher-level perturbation that overlies a surface cyclone that crosses the icecap. This is the mechanism, for example, by which Pacific cyclones appear to enter central North America across the Western Cordillera. Dorsey argued that it was the height of the barrier that blocked the free movement of cyclones, and not the presence of a fixed anticyclone. A similar blocking action is exerted by many mountain systems such as the Alps, the Pyrenees, and the Caucasus.

An inspection of the remarkable observational diagram drawn up by Georgi [24] makes it impossible to doubt the force of these objections. The record shows the rapid fluctuations of pressure, temperature, and wind velocity typical of a disturbed cyclonic climate. To quote Georgi [13, p. 19]: "... the wind régime over the icecap is much more complicated than the simple model of the glacial anticyclone allows." To a reader of Georgi's diary this seems a conservative comment.

3. Dorsey [11] has also pointed out the basic fallacy in Hobbs's argument that the Greenland cap is the source of the cold waves which touch off the Northern Hemisphere's chief cyclonic storms. It is true, he admits, that the icecap air is the coldest in the hemisphere on a year-round basis. Potentially, however, it is much warmer than the air over, for example, Arctic Canada, and it loses its coldness when it descends to sea level. Actually, icecap air enters the circulation of the Atlantic very much warmer than the typical continental polar air masses of Canadian provenance.

In sum, then, the idealised model of a glacial anticyclone appears quite inadequate to account for the observed facts; the theory has elements of the truth,

but in general goes too far in deducing mechanisms that do not exist. Only a refusal to examine evidence has made it possible for Hobbs to maintain his position unchanged for so many years.

A mere rejection of Hobbs's views does not remove the need for further investigation of the icecap climate. The cap is the only existing continental glacier where complete scientific exploration seems within the bounds of possibility with available means of transportation. As such, it offers us enormous rewards. Nowhere else on earth can the climatology of glaciation be so effectively studied.

So far, the attention of climatologists has chiefly been upon establishing the character of the circulation over the cap. The work of assessing the distribution of fresh snowfall and its redistribution to the margins by the strongly divergent winds has hardly begun. It is imperative that the ablation cycle of the cap be studied, not merely along the route to Eismitte, but also round the little known northern and northeastern flanks. Though such work is normally reckoned the proper field of the glaciologist, the climatological significance of this problem is obvious.

CONCLUSION

The review of arctic climatological problems presented here is by itself an inadequate document. Within this Compendium there are several other papers that also discuss problems of climate that affect high latitudes, and these should be read alongside the present account. The vast, intricate, and controversial subject of climatic change, for example, has been left in other hands. Nowhere on earth have secular changes in climate been more conspicuous than in the Arctic, especially along its Atlantic flank, and the reader should seek out the facts of these changes in this volume and elsewhere.

It seems likely that the next ten years will see a great lifting of the obscurity now extending across the Arctic. The author earnestly hopes that this chapter will become out-of-date more rapidly than any other in the Compendium.

CLIMATE—THE SYNTHESIS OF WEATHER

By C. S. DURST

Meteorological Office, Air Ministry, London

Introduction

Looking back over the last half century, one sees how greatly the approach of scientists to the meteorological problem has changed. The nineteenth-century meteorologist was in most cases an amateur; even the professional forecasters were not educated in a scientific approach and learnt their trade by experience and observation.

It was Shaw who first saw the possibilities of a professional meteorological service and it was Shaw's researches reported in the *Life History of Surface Air Currents* which started the great wave of scientific meteorological thought on synoptic matters which has transformed meteorology into a science. If, however, one looks at our progress dispassionately, it is apparent that the greatest advance in this scientific attitude has been in those branches which deal with the forecasting of weather and the physical problems which are associated with it; one can trace the stimulus in that direction back to the illumination of the problem by V. and J. Bjerknes in the second decade of this century.

The emphasis which has been placed, in the scientific mind, on forecasting has been reinforced by the insistent demands which have arisen from aviators for help in their day-to-day flights, in much the same way that the necessity of knowledge of the climate of the oceans stimulated Maury and FitzRoy in the nineteenth century to the organisation of the charting of the winds of the sea areas in the very earliest days of organised meteorology. One must admit that the scientific approach has not permeated so deeply into some other branches of meteorology as into forecasting. In spite of the great work of systematisation done by Köppen and Hann and their persistent groping for the physical causes, there has not generally been an insistence on knowledge of the physical reasoning which must underlie climatology. In its application to hydrology, in its use in agriculture, particularly in climatological application of rainfall data to the needs of man, there has been a woeful tendency to the use of the bones of bare statistics and mean values without the flesh of physical understanding. But it is not hydrology and rainfall that are to be discussed in this article. A more general proposition is put forward: that climatology, as at present practised, is primarily a statistical study without the basis of physical understanding which is essential to progress. As I see them, the essential needs of climatology are in the first place a reorientation of the expression of climate and of the teaching of climate, and secondly, the explanation of climate as a physical and dynamical phenomenon. The latter needs to show the process by which one season succeeds another.

The Expression of the Climate of the World

Twenty years ago, climatology was assumed to consist of the meticulous amassing of the monthly means and extremes of elements, the mapping of normals, and the description of climate in terms of those normals and extremes. Yearbooks were published and the mass of data increased, but the meanings of those data were not examined. Of the attempts made to summarise and systematise them the best, at any rate in English, was that due to Kendrew [17] whose *Climate of the Continents*, after more than a quarter of a century, is still the most lucid description of the normal distribution of the elements over the land masses of the world. In reading it, however, one has a certain feeling of suspended animation, of unreality because everything is static; monsoonal wind arrows, indicating speeds of 10 or 20 mph on the average, change the pattern of flow not a whit from month to month. Of this Kendrew was himself well aware and in the preface to a later work entitled *Climate* [18] he says:

> . . . between the Tropics and the Poles the weather is so variable . . . that it is difficult to form a conception of the climate unless it be the idea of something very changeable. Certainly no picture of climate is at all true unless it is painted in all the colours of the constant variation of weather and the changes of season which are the really prominent features, and it is inadequate to express merely the mean condition of any element of climate.

The treatment that Kendrew then gave is by elements in contrast to the *Climate of the Continents*, which as its name implies discusses climatology on a regional basis. Very recently Kendrew has revised his *Climate* and renamed it *Climatology* [19]. In this revision he has taken the various elements and discussed the physical causes which lead to their changes and then has endeavoured to synthesise the picture into the description of the climate of mountain and plateau and the climate of typical regions—the Sudan, the Mediterranean, and the Westerlies. Here, one is aware that the elements obey physical laws and some of the tools are provided with which to work out for oneself the picture of the climate of any locality in which one may be interested; however the completeness which the perfect climatology should express is still lacking.

Mention must also be made of Miller's *Climatology* [25], which originally treated the subject in the conventional manner, but into which, in the most recent edition, is inserted a chapter on the more modern ideas of air masses, though the more statistical approach is retained in the rest of the volume. More recently Haurwitz and Austin [14] have combined in one volume what Kendrew did in two. They logically treat first

the elements severally, and then in a second part discuss the various regions of the earth.

Undoubtedly as a general introduction to climatic studies some such textbooks as those mentioned above are an essential on which to build, but there remains still an indefinite desire for a new approach; perhaps this desire cannot be satisfied in any work which embraces the whole world in its purview and we must be content to treat the regions in turn.

The Demands of Aviation Climatology

Fifteen or twenty years ago a new demand arose. Aviation was spreading. The new machine could be persuaded to cover longer and longer distances. Weather was all-important, but the machine flew out of the weather map—and indeed we were ignorant of how we could use a weather map in the tropics even if we had observations with which to make one. The aviator clamoured for guidance for his flight and none could be given but the data of the climatologist. He was shown temperature and rainfall maps and the data accumulated in Knox's *Climate of the Continent of Africa* [20]. The rude aviator said that was not what he wanted. He did not greatly care if it were hot or cold. He wanted to know about the winds, and even so he was not flying on the ground. He was more interested in cloud than rain. He did not mind getting wet; what he wanted was to see where he was going. The International Commission on Air Navigation had indeed, in its wisdom, recommended that frequency summaries should be made of upper winds, of visibility, and of cloud heights. But as yet there were no frequencies for Africa and there would not be any for many years. But the rude aviator said he was flying to the Cape forthwith and he could not fly on Knox.

Clearly a new type of climatology was needed—descriptive rather than statistical—a translation by the meteorologist of means and summaries into something that the aviator could comprehend. In this, synoptic training came to the help of the climatologist. He was forced back on the physical processes underlying Knox's data and on their basis described what he expected the clouds and the winds would be. In this, the idea of air-mass characteristics was ever-present on the lines developed by J. Bjerknes and applied to the world at large by Bergeron [7], but in those days (the twenties) the method had been little applied in detail and the tropical air masses were even less comprehended than they are today. For the African Continent, with which our rude aviator was concerned, much help was obtained from the analysis by Brooks and Mirrlees [11]. In those days, when the writing of descriptive climatology was so little developed, some passages in Braak's "Climate of the Netherlands Indies" [9] were an inspiration, particularly the one in which he described the scene from Mount Pangerango and the changes of the clouds in their regular daily variation. This recalled the same sequence visible from the Malayan Mountains; but, and here is the necessary caution, it was remembered that the sequence may break and for some days give place to another and different order of events. Why? The facile answer is "a change in air mass," but the physical basis has not yet been explained.

The Description of Climate by Air Masses

During the latter part of the second decade of this century, air-mass analysis came to the fore under the lead of Bergeron [7] and Schinze [26]. The conception was that there are definite regions in which the air tends to become horizontally homogeneous. These regions are those where the surface of the earth is uniform, whether land or sea, and where winds are light for a sufficiently long time for the properties of the atmosphere to reach equilibrium. These regions were defined as *source regions*. As air drifted from a source region over some other surface, modification took place and the structure and characteristics of the air mass changed with time.

In 1930 Bergeron [7] propounded the use of air masses as a method of describing climate that would give a picture less static than that given by monthly normals.

In the same year Linke and Dinies [23] formulated a system of designation of air masses for central Europe, which Dinies [12] used in 1932 to assess the frequency with which Germany lay under the influence of different air masses, denominated in eight classes, depending on their origin and their track. This paper was, it would seem, the first serious attempt to present the climate of a region as an entity built up from the characteristics of the air masses. Average values were obtained for temperature and humidity at the surface in each type of air. Frequencies of those air masses, given in numerous tables, are summarized in Table I.

Dinies' investigation was focussed on Frankfurt am Main. The results were of considerable interest, showing up, as would be expected, the strong contrast between air of tropical and polar origins, not only in temperature but also in humidity and cloudiness. The bitter polar continental air of winter stands out in strong contrast to the moist and mild tropical maritime air, a contrast stronger indeed than between any of the summer air masses. For comparison with Table I it may be mentioned that Belasco [6] has given a mean winter temperature of −1C for arctic air which had arrived at Kew Observatory via Russia and Germany. On the other hand he gives the mean value of temperature in tropical air in winter as 10C.

Dinies also surveyed the frequency with which the air masses penetrated to the several parts of Germany. He showed this by means of maps of the average number of days on which the different air masses were over various places in Germany. These maps are on an annual basis and they show the not unexpected effect of penetration of maritime air from the west and southwest and the countersurging of continental air from the east, as well as the sweep of the polar and polar continental air from the northeast.

The object of Dinies' treatment was to present climatology in a much more dynamic picture than had been possible in the past when the climatologist dealt

primarily in the "sterile mean." In this he achieved a considerable measure of success as may be judged even from the brief summary in Table I. His treatment certainly did present the month or season as one of change and conflict. More recently the description of the climate of Germany has been carried a stage further by Flohn [13] who has discussed the regional climatology and has pointed out the effects of the major topographic features on local weather in the different air masses.

Dinies' example has been followed by others, notably by Landsberg [21] who examined the air masses of central Pennsylvania, by Batschurina and his collaborators [5] who reviewed the air masses of Western Russia, by Schamp [31] who applied a classification to the mass properties of America, adopting a somewhat different classification from that of Bergeron in order to suit the local circumstances.

In 1940 Petterssen [29] summarized and reviewed the various assessments of the thermal structure of different air masses and presented original maps of the Northern Hemisphere, setting out the positions of the different sources in winter and summer.

Still more recently Belasco [6] has made elaborate assessments of the temperature and humidity structure of the air of various types reaching the British Isles along a large number of tracks. Perhaps the most interesting feature of this paper is the comparison which he makes of the structure of the air over the Azores

Table I. Frequencies and Characteristics of Air Masses at Frankfurt am Main 1924 to 1929

	Polar	Tropical	Maritime	Continental	Polar Maritime	Polar Continental	Tropical Maritime	Tropical Continental	Ill-defined	Mixed
Frequency of air masses										
Winter (1924–30)%	4.6	2.2	30.2	20.6	11.4	2.6	8.2	1.3	7.0	11.9

Greek Islands, and by Roy [30] who has more recently attempted to apply air-mass analysis to the Indian Peninsula. In this careful study Roy has not only classified the air masses, using the data of modern synoptic charts and aerological ascents, but in addition he has described concisely the climatological features of the air masses of the various seasons in regard not only to their temperatures, humidities, and thermal structure, but also in regard to the incidence of fog, and the characteristics of cloud. Roy suggests that there should be compiled in India detailed air-mass climatological tables for a number of representative stations as a routine to form the basis of the discussion of the air-mass climatology of the subcontinent.

An extension of the examination of air masses was made by Palmén [27] by forming mean values of temperature and humidity in the upper air in the several air masses, using data for the British Isles. In this he used essentially Bergeron's classification of air masses [7]. Willett [33] at about the same time listed the air- and Iceland with that which reaches the British Isles after travelling from those directions. In Tables II and III are set out the comparisons of mean temperatures in winter and summer.

A caution must be given that in Belasco's work the air trajectories were not taken back to the source but only for a distance of about 1500 miles from the British Isles. Hence there is, for example, no certainty concerning the actual source region of the trajectories which passed over the Denmark Strait on their course to the British Isles. Table II however does give some idea of the manner in which modification takes place in the temperature of the air when it passes over long stretches of water and at the same time travels into a latitude where the radiation balance is reached at a different temperature level.

All these studies of the upper air in relation to air-mass classification were intended primarily to further the task of the synoptic forecaster. To a great extent, however, they can be made to serve the climatologist in

the manner which Bergeron, Linke, and Dinies envisaged, though it must be remembered that they are typical values and not means or normals.

Table II. Comparison of Temperatures over the Azores with Those of Air Reaching Britain from the Azores

	Summer					Winter				
Height (mb)	900	800	700	600	500	900	800	700	600	500
Tropical air arriving over Azores (°C)	16	13	8	1	−7	10	7	1	−6	−15
Tropical air arriving over Britain from the Azores (°C)	14	11	5	−2	−11	8	4	−2	−9	−18
Maritime polar air arriving over Britain from the Azores (°C)	11	4	−2	−9	−19	4	−3	−9	−17	−27

Table III. Comparison of Temperatures over Iceland with Those of Air Reaching Britain from Iceland

	Summer					Winter				
Height (mb)	900	800	700	600	500	900	800	700	600	500
Polar air arriving over Iceland (°C)	1	−6	−12	−18	−28	−13	−19	−26	−33	−43
Polar air reaching Britain from Denmark Strait (°C)	8	1	−4	−11	−20	−2	−8	−15	−23	−32
Polar air reaching Britain from Jan Mayen (°C)	5	−1	−7	−16	−26	−6	−12	−20	−29	−39

Difficulties of Air-Mass Climatic Description

The primary difficulties in using air masses in climatological work are (1) the difficulty of a definition of air masses which can have world-wide application, (2) the difficulty of dealing with frontal weather, and (3) the complications introduced by vertical motion in anticyclones and wedges.

To some extent the first difficulty is also encountered by the synoptic meteorologist, but in practice the forecaster for a particular region concentrates on the air-mass types which are most likely to occur in that region. It is of far less importance to him that the definitions in the more remote parts of his chart are not precisely in accordance with the physical conditions there, since before the air from those remote regions has entered into his working area, it will have become modified to a great extent. In his original formulation Bergeron [7] set out a comparatively simple classification, but as is pointed out by Willett [33] this classification was made primarily from the study of the air masses which affected northwestern Europe and though it was possible to apply it on world-wide scale, it did not suit the local conditions of the North American Continent. To a very considerable extent the difficulties in adopting a world-wide classification are difficulties of scale. The broad view which encompasses the world will fail if attention is fixed on one continent alone, because of necessity the detail considered will be greater. In the same way the classification suitable to the continent will be less applicable to a smaller unit, state or country. It would be logical to apply the same reasoning right down to microclimatic studies, since the essence of air-mass analysis is the vertical structure, and it is possible to conceive a discussion of microclimate by means of micro-air-mass analysis. Indeed that is in fact the method which leads to the insistence on the influence of atmospheric stability in the more recent studies of microclimate (*e.g.*, Pasquill's discussion of the diffusion of water vapor and heat near the ground [28]).

In the second place a difficulty, which has no counterpart for the synoptic meteorologist, arises in the use of air masses in climatology, namely the difficulty of the expression of the effects of frontal passages. It may be comparatively simple to give a generalised picture of the weather which is likely to occur in the cores of the air masses, even when they are suffering marked modifications, but the generalisation of the weather at frontal zones in all their manifold diversities is most complex. A smoothing of the elements, which is the result of the climatology of the mean, masks much that is essential, but how should frontal zones be shown and classified in air-mass climatology? The plotting of the normal position of deformation fields and fronts such as is shown by Bergeron [7] over the Pacific reveals much more, particularly in the tropics, but it is not an ideal generalisation of the arctic front nor of the polar fronts in higher latitudes, because of the wide range through which those fronts are likely to oscillate.

The third difficulty is the greatest of all. Air masses are not only transformed by the surfaces over which they move and the radiation which they receive; they are also profoundly influenced by subsidence and at present we are not in a position to estimate the magnitudes of those effects. All that seems possible, therefore, is to show how air masses have in the past been affected by moving over different surfaces with a proviso that no account is taken of the presence or absence of subsidence.

The Use of Synoptic Maps in Climatology

From what has been said above it is clear that for certain purposes the climatologist's task and that of the synoptic forecaster were becoming increasingly dependent on the same technique. Indeed the synoptic forecaster from his memory of his maps could write

down the climate of a particular locality with a facility which might not be available to a statistical climatologist. It is true the forecaster had to contend with difficulties not least of which was that he knew too much. To him, intent on his daily synoptic charts with their infinite diversity, it was not easy to generalise without so much detail as to mar the climatological picture. But it could be done, and it was possible thereby to convey a far more graphic picture than would be possible from the consideration of any number of statistics and normal charts.

With the coming of World War II the need for descriptive climatic information became more pressing, and this technique for the use of synoptic charts and daily observations was developed in Britain in a series of manifolded reports on the climate of various regions. In these the attempt was made to describe the effects which were likely to be produced in the neighbourhood of different topographic features when certain air streams impinged on them, the object being to convey to the reader the idea of climate as a synthesis of the daily weather as opposed to the rather static presentation given by a conventional write-up of the normal maps.

One great advantage of this method was that the climatic description was readily assimilable for forecasters, so that a forecaster arriving in a new region could have a broad outline of his forecasting problem before him from the outset.

An example of this presentation is the description of the climate of Southeast Asia by Hare [1]. From the examination of whatever weather maps could be obtained or constructed—and in this the *Daily Synoptic Series, Historical Weather Maps* [32] was of the greatest value—Hare isolated certain air flow patterns to which the weather map tended to return if it were disturbed, and he identified certain positions of the quasi-permanent fronts to which they too returned. Thus he was able to describe the climate associated with the flow pattern, particularly in the case of the winter monsoon, in some detail, and moreover to emphasise what departures could be expected with changing synoptic situations and how those situations once more reverted to the standard pattern. At the same time he drew attention to the characteristics of the air masses, using a local modification due to Huang [15]. The known high frequency with which the fully developed winter monsoon held sway served to guide the reader as to what climate to expect, and the simplification led him to a concept of change within a repeating pattern. It is true that the simplification, like all simplifications, masked some degree of detail, but in climatology some detail must inevitably be lost and the generalisation of weather into this climatic representation gave something that was easily assimilated.

The season of the summer monsoon was less easily generalised, but here too on the basis of the synoptic charts it was possible to establish a broad outline of the repeating patterns of the air streams. The transition periods of spring and autumn were treated in a similar way.

After Hare's work had been produced, Lu's "Winter Frontology of China" [24] was published in the *Bulletin of the American Meteorological Society*. Lu's account was on a more elaborate scale, but was essentially a statement of climate in terms of air masses and fronts. It bore out Hare's analysis to a high degree and the comparison is interesting in that it shows how much can be achieved in this type of representation by one who has no greater acquaintance with the country of which he is writing than is afforded by a series of weather maps.

At different dates from 1939 onwards British reports on similar lines were prepared for most of the theatres of war. They were manifolded, but the number of copies was limited.

To impress on the reader the variability of the climate, some of these reports included diagrams which

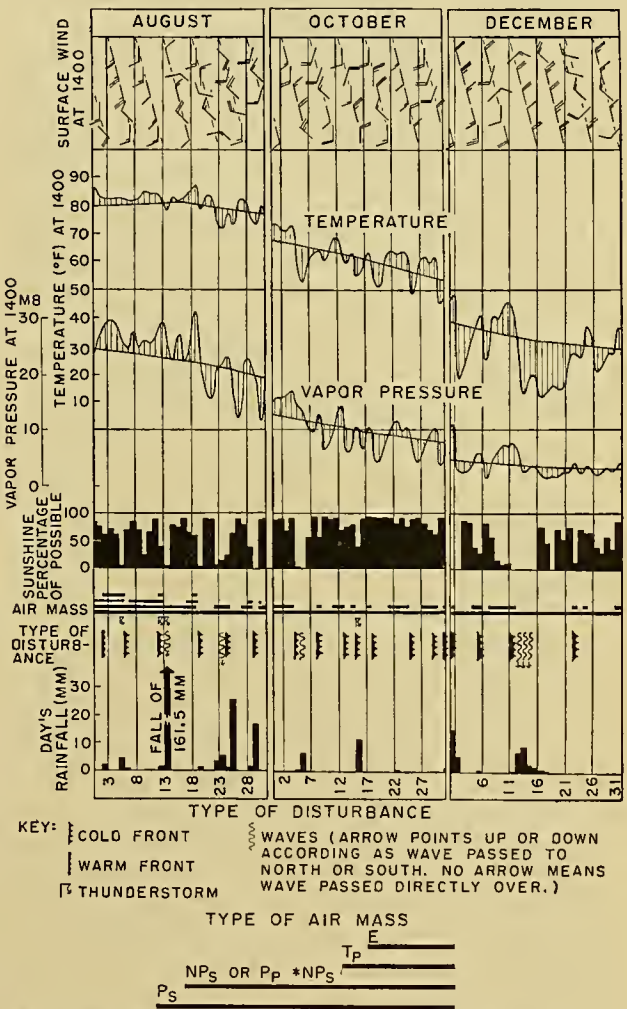

Fig. 1—Daily weather at Dairen, Manchuria, for August, October, and December, 1929.

gave the daily observations of a year ranged out on a single sheet of paper. An extract from one such diagram is shown in Fig. 1 in which the months August, October, and December, 1929 are illustrated for Dairen in Man-

churia. It is not possible to reproduce conveniently more than this extract and, as would be expected, the complete specimen year conveys a far better idea of the normal change, but even from these three months one receives the impression of how the elements vary from one day to another. In this diagram, wind, temperature, and humidity are illustrated as well as sunshine, pressure, and rain. In addition, the air-mass classification and the fronts which lie in the neighbourhood of the station are shown.

These studies were essentially climatic and contained, in addition to the descriptive matter, tables of normals to serve as the inevitable background. Here it may be emphasised that, however the climatological data are discussed, accurate and well-arranged general tables of normals must be published if only to serve as a yardstick against which to measure the variability.

By way of contrast between the description according to conventional climatology and that which can be built up from the study of synoptic situations, it is of interest to compare the description of the winter climate of China as given in Kendrew's *Climate of the Continents* [17] with that given by Hare [1] and Lu [24]. Admittedly it may be objected that readers for whom Kendrew wrote were less erudite than Lu's audience or even than Hare's, but if one type of description is read and then the other, it will at once be apparent which is the truer account.

In making this contrast between the conventional approach and that of the synoptic meteorologist, I do not wish to veil the value of the mass of information which conventional climatology has provided. It has indeed formed the basic background from which it seems there is now scope for advance in a more detailed description of climate, a description based on the physical causes which in the aggregate produce that which is called climate.

Since World War II, the procedure which has been described above in regard to the use of synoptic charts has provided the basis for several reports such as *Aviation Meteorology of South America* [4] for which J. S. Sawyer was responsible, and *Aviation Meteorology of the Azores* [3] by L. Jacobs and R. M. Murray.

This method of approach was the natural outcome of the need for a similar type of information in other countries. In Germany it would seem that methods of air-mass climatology were more or less dropped during the war, at any rate in their more detailed application. In a number of climatic reports the Germans made use of representative types of weather, illustrating them with typical weather maps for individual days, but there does not seem to have been the systematisation which might have been expected. The Germans in their reports seem to have relied largely on a great mass of statistics suitably arranged for aviation and related needs.

In America the stress on securing information as a basis for planning during World War II led to a rather similar approach under the lead of W. C. Jacobs [16], who assembled large masses of data on punch cards for the region in which he was interested. By sorting for one element (*e.g.*, air flow) he was able to draw up a picture of the probable weather with which each type of flow was associated. However, with the advantages of the punch-card system it was possible to break down the problem still further in whatever direction was most advantageous, to calculate, for example, the chance that low cloud would occur with a particular general wind flow and the chance that the low cloud would affect one region when another was clear.

From the practical point of view these summaries could be linked effectively with the weather map, for the forecaster could tell at a glance which particular type of the numerous arrangements of the data was most like the chart with which he was dealing. However, the presentation of the data was essentially statistical; it masked rather than emphasised the physical processes underlying the significant weather. Nevertheless, as a practical tool in climatology, the punch card, wisely used, will undoubtedly play its part in the final solution of the climatic problem.

The Russian approach to the problem of climatic representation is shown in a recent publication by Alisov [2]. In his foreword, Alisov is emphatic that the study of climatology must not end with the collection of data, but that it must be discussed on the basis of the physical process by which the climatological phenomena have been developed. He then proceeds to discuss the general climatology of Soviet Russia as a whole on the basis of the origin of the air masses and their modifications in transport. The remainder of his extensive book is devoted to a more detailed description of the climates of the different regions, but in each case the description is based on an integrated knowledge of the synoptic charts rather than on normal values.

Climate as a Physical and Dynamical Problem

The climatologist will not be content with the mere recording of observations nor with their description, even if that description is based on the physical processes in the atmosphere. It will be his natural desire to seek a physical explanation of climatic change, the change from one month to the next, as well as the changes which occur from one period of years to another. The climatologist has for long been intensely interested in long-range forecasting—seasonal foreshadowing as Sir Gilbert Walker termed it. But the methods by which the mechanism of climate is investigated have been sadly lacking in a reasoned approach.

The methods most frequently adopted are (1) the determination of correlation coefficients between a meteorological element in one place and the same element (or another) in some other place, perhaps with a time lag, (2) the association of the pattern of a mean distribution of a particular element in a particular month with the pattern of the mean distribution of some other element in the same or a different month, and (3) the association of maps of monthly pressure or temperature anomalies with the anomalies of the same element in the succeeding month. One should add to these (4) the

relation of the circumpolar pressure (or wind) distribution averaged over a short period (five days) with subsequent developments of the pressure pattern.

In the first three of these methods the choice of element and the position on the globe are purely at the caprice of the investigator. They are in fact almost entirely blind speculation—hit or miss, if miss, try again. It may be said that, in the past, many of the discoveries in physics were based on such procedure, but in a subject such as climatology covering so wide a geographical field and with so many physical variables the chances for success by such methods are very small. The fourth method based on the movement of long-wave patterns has a dynamical basis and as such is in a different category. The movement of these waves and the meridional flux of air profoundly influence spells of weather, therefore in some manner these long waves and in particular the blocking anticyclones must be taken into account in any concept of physical and dynamic climatology. Nevertheless the path which should be pursued in the construction of such a climatology is not clear.

Following the line of thought in the previous part of this article, we are led to consider the climatological map of any element as the representation of an integration of the values of that element derived from trajectories which have their origins in certain source regions. Now the appropriate value of the element on any occasion is influenced firstly by the state in the source regions and secondly by any modification of that state introduced during its travel, whether by diffusion or radiation or change in pressure or by any other cause.

Clearly we may consider the map for a single month in the same way, and we may review the change in that map by consideration of the change in the source regions or the change in the modifications introduced in the travel of the air masses, as well as by the frequency with which the air travels from the different sources. Such an approach to the problem of climatology has the merit that it endeavours to link the mechanism of climatic change with physical properties, and it is clear that if any advance were possible from this approach, the horizon of usefulness would extend greatly.

The source regions of the Northern Hemisphere are enumerated in considerable detail by Petterssen [29]. They are generally recognised as being regions in which the surface of the earth has a homogeneous covering; there is the additional proviso that the air motion must be sluggish in order that the air mass may acquire uniformity of character. It is known from the synoptic charts that these source regions are liable to considerable movement from one period to another, some indeed may be swept entirely away at times. Their boundaries in any case are rather indeterminate, yet the very fact of the use that is made of the air-mass characteristics in synoptic meteorology emphasises that there is a recognisable continuity in them and gives hope that the examination of the variation with time of the character of source regions is a practicable step. That such an examination has not been made before now, so far as the present writer knows, is probably because a number of the source regions, and those the most important ones, are in locations that are by no means readily accessible, particularly to upper-air observation. However, this difficulty is becoming less with the extension of information.

Now that the drawing of synoptic charts of the whole hemisphere is a practicable process, not only daily but two or even more times each day, there would seem to be an urgent need for an analysis of the variations from day to day in the position, the intensity, and the growth (or decay) of the major sources. Admittedly any such examination is liable to a measure of subjectivity, since the definitions of the source regions are elastic, but even with that limitation such an analysis would teach the meteorologist much.

The next problem is that of the modification of air masses in translation over various surfaces.

Belasco's calculations of the modification of polar air travelling from Iceland to Britain and of tropical air travelling from the Azores are given in Tables II and III. From these figures it would seem that in summer the air in travelling from Iceland to Britain (say 1000 miles) is warmed by about 5C or 6C all the way up from 900 mb to 500 mb, whereas in winter it is warmed by about 9C at 900 mb, but by only about 7C at 500 mb. On the other hand tropical air, in travelling from the Azores (say 1200 miles), is cooled by about 3C all the way up in winter, but by only 1C in summer at 900 mb and by about 3C at the higher levels. In these calculations no allowance is made for change in direction of the wind streams at the greater heights, but the figures would seem to show the magnitudes of the changes.

We still do not know to what extent these changes in temperature arise from convection of heat from the surface, from radiation, or from vertical movements; fields of deformation will have to be considered and the consequential effects on frontogenesis as suggested by Bergeron [7]. However, with the more complete modern maps of the upper air a survey of the changes of temperature (and possibly of humidity) along the tracks of the air masses becomes possible. By these means we may be able to set out more exactly the manner in which the air masses tend to be changed in relation to the surfaces over which they move, and the atmospheric processes affecting them.

After these basic data have been determined, an examination could be made of the life history of the air masses which combined to form the monthly mean values for individual years. A summary of such life histories in a suitable form would undoubtedly enlarge our knowledge.

Severe winters, for example, are in many places chiefly due to the advection of air from intensely cold sources, but we do not know whether they are greatly affected by the intensity of the source, or whether the severity is the result merely of the persistence of the flow; on the other hand, the source may have moved

nearer to the climatic station in those winters, or possibly the track of air has been consistently more direct.

In this way, with much initial labour no doubt, there is hope of getting an insight into the mechanism of climate. It seems very probable that we should learn what factors exert the greatest control, as, for example, in the case cited above, whether proximity of the cold source or persistence of flow carries the major weight in severe winters. If we were able to do this, it might then be possible to resort to statistical methods as a means of foreshadowing the change of the climatic mean from one month to the next, for if we had a better conception of the mechanism of climate, we should be in a far more favourable position for selecting the right form that should be taken by the regression equation.

Some Basic Requirements for the Discussion of Climate

From this review of the methods adopted in the last twenty-five years to express climate certain principles seem to have emerged.

It is clear that scale is the ruling factor in the treatment of climate; nevertheless, the treatment at each level of the scale has to be based on stability or instability characteristics, not necessarily in the rigorous classification of the air-mass climatology school. In some way, descriptions ranging from a world-wide review to a local microclimatic study have to be permeated with the sense of the facilities for vertical transport in the air. It may be that the shorthand expressions used in air-mass analysis are the best; it may be that some better method of describing stability could be devised. The reason for these necessities is patent in the fact that the phenomena of rain and cloud are so closely associated with the stability of the atmosphere; clouds control the amount of heat reaching the earth or escaping from it. Temperature lapse rate too is intimately connected with turbulence and consequently with heat transport from the surface.

The treatment of a world-wide climatology would admit a scale such as that designed by Bergeron in his original exposition, but no greater elaboration. The scale for treatment of an area such as a state or country would need, as Willett and Linke have agreed, an elaboration of detail that would be overwhelmingly cumbrous for the world as a whole. And so on down to the microclimatic studies which, in the case of agriculture, might well need to consider the modifications in the vertical structure of the micro-air-mass due to variations in the surfaces of neighbouring fields.

Perhaps the next lesson to be learnt is the necessity for the synoptic worker and the climatologist to become accustomed to thinking in each other's terms; indeed, to thinking that there should be no demarkation between them, that they should use each other's tools. There would seem to be good ground for maintaining that climatological literature should be written, in part at least, by synoptic meteorologists, though of course this in no way means the exclusion of tables of climatic normals; they are essential as a basis to be used for reference.

There is a great need for detailed climatological literature, based on synoptic information, to be prepared for all parts of the world. One of the advances in climatology which is most likely to take place in the near future is the publication of papers dealing with this type of synoptic climatology.

For the understanding of climate it seems that we need to know much more about the quasi-permanent sources of air masses. In comparison with our knowledge of the structure of depressions, the comprehension of the processes in anticyclones is very small; but anticyclones may be the key of the climatic mechanism because they are the source regions of the air. Perhaps then one of the most interesting problems is that of the process by which air flows into the anticyclone and the reason why it does so. A solution of this problem would throw light on the mechanism of climate.

In regard to sources we need to know more about the time taken for stagnant air to become homogeneous, and what influence radiation has on the establishment of homogeneity. Also we should have information on the movements and the variation in intensity of sources from year to year and whether that intensity is associated with extraterrestrial phenomena.

It may be objected that all the problems just mentioned are those of the synoptic forecaster. Perhaps this is the crux of the whole matter. The physical problem of synoptic forecasting and climatology is the same, for climate is but the synthesis of weather.

APPLIED CLIMATOLOGY

By HELMUT E. LANDSBERG

Research and Development Board, Washington, D. C.

and WOODROW C. JACOBS

Headquarters, Air Weather Service, Washington, D. C.

Introduction

Definition. If we consider climate as the statistical collective of individual conditions of weather, we can define *applied climatology* as the scientific analysis of this collective in the light of a useful application for an operational purpose. The term *weather* includes all atmospheric events and the observation of individual weather elements as single series synoptically or otherwise combined. The term *operational* is also broadly interpreted as any useful endeavor, such as industrial, manufacturing, agricultural, or technological pursuits.

Historical Note. This type of climatological work reflects an old and historical approach to the subject. The earliest scientific climatic observations, such as the ones sponsored by the Societas Meteorologica Palatina, were made for the sake of knowledge. However, the networks of climatological stations inaugurated upon the urging of Thomas Jefferson, Surgeon General Joseph Lovell, Alexander von Humboldt, and others were directed toward the practical ends of land utilization, agriculture, and health. This pioneering work took place considerably before meteorological networks were established to provide data for weather forecasting. Meteorological observations later became subservient to the aims of synoptic meteorology and remained so for many decades. Climatology became an adjunct devoted to a mere statistical summarization of the data. Only lately has there been a resurgence of the idea that the accumulated climatic data have a high practical value, far beyond their use for the descriptive *average* picture of the atmosphere used in comparative geography, a use which has dominated the field of climatology.

Prefatory Note. The following discussion does not attempt to treat the subject of applied climatology exhaustively. Within the allotted space the current state of the art can, in many instances, be given only by references to pertinent papers. Most stress will be laid on the inadequacies and on the lines that might be explored profitably by future research work.

Analysis of Requirements for Climatic Data in Various Activities

The objective is to make climatic information useful for other pursuits. Therefore, the particular climatic data desired in each instance must be established. It is a fallacy to assume that the usual climatological observations, summarized in the classical format now standard at most weather offices, can immediately be applied to the practical problems at hand. Misuse of the readily available climatic data has led to many misconceptions and faulty interpretations, and in some cases has even discredited the science of climatology.

First of all, climatic data should be interpreted by the expert climatologist. His position in relation to the user of this material is analogous to that of a physician or a lawyer or an architect in relation to his client. This makes it imperative that the climatologist should not only know the weather data but should also *diagnose the case* to which the data are to be applied. Usually, a thorough analysis of the operations for which the climatic data are needed has to be made. Two questions have to be answered:

1. Which climatic elements affect the operation?
2. How can the available climatic material be interpreted for the particular purpose at hand?

In practice it is essential to go through a thought process which is roughly sketched in the two questionnaires given below. These lists of questions are not prepared for any specific case and must be altered to fit each individual problem.

Questionnaire I: Analysis of Operation

(*Climatic Anamnesis*)

1. Class of enterprise (business, industry, agriculture, etc.)?
2. What operational subdivisions exist?
3. Class of problem?
   - *a.* To lead to a design.
   - *b.* To affect a procedure.
   - *c.* To make an operational decision as to "where" or "when."
4. How does the prospective user of the weather information define his *weather* problem?
5. How does he define his *operational* problem?
6. Will the climatic or weather information the user believes he needs furnish a solution to the operational problem?
7. Have solutions previously been obtained for analogous operational problems?
8. Can the operational problem be redefined in more realistic climatological terms?
   - *a.* What periodic fluctuations (diurnal, seasonal, etc.) exist?
   - *b.* What are the critical climatic and weather limitations on the operation?

c. Is it of importance to stay below critical limits or are there known or desirable optimum conditions?

9. Are operational figures (production, yield, etc.) available for correlation purposes? For how many years (cases)?

QUESTIONNAIRE II: ANALYSIS OF CLIMATIC DATA

(*Climatic Diagnosis*)

1. Class of climatological technique required (see Table III)?
2. What types of data are desirable?
   a. Elements (pressure, temperature, winds, etc.)?
   b. Are combinations of elements required? If so, what combinations? Are their relationships known?
   c. What length of record is needed for an adequate solution?
3. What climatic data are available?
   a. At the spot; in the area; over the region?
   b. In what form are the data? Are existing summarizations suitable?
   c. What length of record is available?
   d. Are climatic data available for the same periods covered by the operational information? (See Questionnaire I, Item 9).
4. What are the local peculiarities in climate that may affect the usefulness of existing climatic data?
5. What are the physical or statistical limitations imposed on the data and their interpretation?
6. Does theoretical information (or a suitable technique) exist that can serve to supplement, evaluate, or be substituted for, the inadequate observational materials?
7. Are solutions available for analogous climatological problems?
8. Is there a need to elaborate a new theory of interrelations?
9. What form of presentation of the conclusions is desirable?
   a. Graphs.
   b. Tables.
   c. Formulas.
   d. Alignment diagrams.

It is very essential that both parties involved in the climatological analysis of an operation, the climatologist and the *operator*, collaborate. They should understand each other's problems. As far as possible, this understanding should be reached before the job is begun. Frequent consultations during the progress of the actual work are indispensable.

Data for Applied Climatology

The amount of climatic material in the files of the various weather services is staggering. The number of surface observations is running into at least nine digits. Much of this material has undergone some elementary summarization. We estimate that mean monthly temperature and precipitation data are available for not less than 25,000 localities in the world. Some one hundred million synoptic observations (including data on pressure, temperature, cloudiness, current weather, etc., as expressed in the international code) are now available on punched cards. Upper-air data are also accumulating on punched cards at a rapid rate, although techniques allowing their use in the three-dimensional sense remain to be developed. The major depository of these punched cards is the joint U. S. Weather Bureau—Air Force—Navy punched-card library at New Orleans, Louisiana. This material has a great deal of flexibility. Summarizations and frequency distributions can readily be obtained from the raw material at high speeds [2, 37, 68]. There are, however, important limitations inherent in the sorting and tabulating machines [31]. The climatologist has to realize this. The essence of these limitations is that one cannot get more out of a machine than is put into it. Also, the machine will do no thinking.

Spot observations of meteorological data are useful for a variety of problems in applied climatology, but a great many cases require simultaneous observations at several points or over areas. In many cases it is necessary to associate the observations in time and space with the help of synoptic weather maps. For Northern Hemisphere areas the best source material is the series of daily surface weather maps, extending back to 1899 [84]. Since the end of 1945, the available issues include also five hundred millibar charts and the synoptic telegrams on which the charts are based. Some of this synoptic material has been summarized into mean charts (for a detailed bibliography see [87]). Pressure values and storm tracks for ocean areas have also been placed on punched cards.

It cannot be our task to list here all the multifold sources of climatological material. Only a very few standard works of an international character and some of the most important sources in the United States have been singled out [90].

Much of this material, excellent as it may be, restricts itself to only a few climatic elements. Pressuret temperature, and precipitation amounts are most com, mon. Some sources include elements such as frosoccurrence, which were thought to be of agricultural importance. On the whole, however, the standard climatic summarizations leave much to be desired as yet. Most of them are *mean value* climatologies. Frequently, the series from which they are obtained are inhomogeneous. Another shortcoming is the lack of observations other than the type desired for the purposes of synoptic meteorology.

The climatologist can present a long list of observational desiderata for applied purposes. For many of these the proper observational techniques are inadequate or even nonexistent. Table I lists some such additional observations which would be most welcome in applied climatology. They are listed in two categories. One comprises those where current techniques will yield useful data, and the present difficulty is that data are obtained at too few places; the other lists the elements for which new techniques of observation are needed.

Irrespective of how many stations there are or will be and how many elements are observed at each, we will never have complete and homogeneous coverage of the whole surface of the earth. Even in the densest networks there remain blind spots. One of the important questions is therefore, How can we interpolate between stations? The synoptic reconstruction of an observation which is lacking, or the bridging of an observational gap, is an important technique. Given a series of good synoptic charts, the meteorological analyst can make a guess about the probable values for a given locality. This is not much different from making a forecast, except that the whole sequence of events is synoptically known. However, the reliability of such guesses has seldom been put to a controlled test. Hence the limitations and errors of the method are usually not available to the climatologist. Such information can be obtained by applying objective tests to representative analyses.

The question of how to interpolate between stations also enters into the problem of the representativeness of individual climatic stations for various elements. It can, for example, be assumed that a mean pressure value and a frequency distribution of pressures for a station are valid for distances of many miles. The synoptic method can also be trusted to yield readily corrections to these values over distances of more than a hundred miles. It is doubtful if such extrapolations can be made for other elements. Temperature adjustments have occasionally been attempted by making corrections for topography, but it is doubtful if any reliable extrapolations can be made for temperature, precipitation, and surface winds except, perhaps, over the simplest terrain forms such as the ocean. The reasons for this are (1) that present methods of measuring these elements constitute very poor sampling, and (2) that our present knowledge of terrain influence on temperature, wind, and precipitation is inadequate.

Table I. Some Climatic Elements Requiring (*A*) Additional Observations or (*B*) Better Observations

(*A*) *Insufficient coverage with existing equipment (extent).*	
Solar radiation:	Total intensity, spectral distribution, various exposure angles, illumination, vertical variation in intensity, cloud and surface albedos.
Precipitation:	Weight of ice deposits, weight of snow accumulations, dew, horizontal patterns of intensity (simultaneous), extent of snow cover, depth of snow, character of snow cover, vertical variations in precipitation intensity.
Other:	Soil temperatures, depth of penetration of frost.
	Water temperatures.
	Frequency of lightning discharges to ground.
	Cooling power.
	Suspended particles (dust, condensation nuclei).
	Soil moisture.
	Soil temperatures (vertical distribution).
	Soil and surface temperatures (horizontal distribution).
	Extent and character of sea, lake, and river ice.
(*B*) *Inadequate techniques or instruments.*	
Evaporation.	
Corrosive substances in air.	
Composition of rain water.	
Drop sizes.	
Radiation losses.	
Soil conditions (state of ground).	
Slant visibility.	
Vertical component of wind.	
Cloud thickness and layering.	
Rainfall over oceanic areas.	
Evaporation from water and soil surfaces; rates of transpiration.	
Foliage temperatures.	
Cloud density; areal extent of cloud cover as a function of altitude of observer above or below cloud deck; cloud temperatures.	
Vertical temperature, moisture, and wind structure near ground.	
Rate of heat transfer between soil or water surface and atmosphere (instantaneous rates).	

A daily task in applied climatology is the substitution of an observed element for one that is desired but has remained unobserved. Such substitution can often legitimately be made because of known theoretical relations or correlations which have been established from statistics. For example, it is certainly possible and permissible to obtain wind vectors in the free atmosphere from a set of upper-level pressure charts. To use shelter temperatures for an estimate of frost at the soil surface is less reliable, but still within the capabilities of the experienced meteorologist. In many areas it is possible to translate mean cloudiness data into frequencies of clear and cloudy days [53]. On the other hand, very little faith can be placed in an interpretation of precipitation data in terms of limitations to flying conditions (ceiling and visibilities), although that has been tried on occasion. In this field there is a great need for establishing correlations among various meteorological elements at one point and of spatial correlations between one and the same element.

In many practical cases the climatologist is confronted with the question: How long a period of records is needed to give an answer to a problem within an appropriate safety factor? There is no universal rule. In the past there has been a tendency to require decades of records. Many times this proves to be unnecessary in practice. Often suitable statistical techniques, evolved from the theory of sampling, can give quite satisfactory results on the basis of a small universe. The question reduces to this: When does a frequency distribution become essentially stable, so that adding another year of observations would not add significantly to the result?

Experience has shown that this time limit varies from element to element, season to season, and region to region. Preliminary investigations have shown that the orders of magnitude given in Table II may serve as a guide.

The data given in Table II are very tentative. They are based on a few pilot tests [5]. The studies leading to this type of information should be expanded to verify the statements and to cover additional elements.

We frequently encounter the following situation: A short record is available from a locality which is of interest. A long-record station is also located in the same region. The problem is to reduce the short to the long record. This question is dealt with in many stand-

ard climatological texts [19]. The procedure is reasonably straightforward for stations in proximity. But how does the reliability decrease with distance? Further, how reliable are the techniques of constant differences

Table II. Approximate Number of Years Needed to Obtain a Stable Frequency Distribution

Climatic element	Islands	Shore	Plains	Mountains
	Extratropical regions			
Temperature	10	15	15	25
Humidity	3	6	5	10
Cloudiness	4	4	8	12
Visibility	5	5	5	8
Precipitation amounts	25	30	40	50
	Tropical regions			
Temperature	5	8	10	15
Humidity	1	2	3	6
Cloudiness	2	3	4	6
Visibility	3	3	4	6
Precipitation amounts	30	40	40	50

or constant ratios if the two stations have completely different topography or exposure? Finally, suppose the short-record station has temperature and precipitation records but the practical problem requires knowledge of humidity, and such observations are available from the long-record station. How far can comparative techniques be applied? In the past, investigators have usually relied on the synoptic technique but have bypassed statistical procedures. This leaves open a fruitful field for future research.

A strikingly parallel question arises when there are no records of any kind available for the point at which information is desired. Major undertakings warrant the establishment of a temporary climatic station. The data thus collected can serve for comparison. How long should such an auxiliary record be maintained? In case of microclimatic investigations a few clear nights may suffice in order to establish, for example, the spots in an orchard which are most likely to be affected by frost. But the problem has never been studied on a broad scale.

Closely related is the general climatic question of the density of station networks. Should the weather services maintain for climatological purposes only a few *climatic bench marks* and shift other stations at frequent intervals in order to get a quicker coverage of a large territory? And what is the optimal distance for records of the different elements? [15, 74].

There is a need for the development of better statistical techniques specifically adapted to climatological problems. The classical methods developed for genetics or quality control may cover some problems, but satisfactory as they may be for the original purpose for which they were designed, they are not necessarily universally useful. For one thing, the basic assumption of *independence of observations* underlying most of them is almost never fulfilled for meteorological events. Interdependence in time and space, such as persistence, is almost always present in our data. Some work along this line has been done, especially as applied to singularities [6, 7, 12]. Many statistical tests are valid only for the so-called *normal* frequency distributions. Quite a few climatic values are not normally distributed and even mathematical transformations cannot always produce statistical normality. More adequate techniques are gradually being developed. Attention has been given to theories of extreme values [39] and to the multimodal distributions often found in climatological work [21]. There is a great need for the formulation of new criteria of the *significance* applicable to climatic data. A great deal of the modern statistical theory of time series has not yet found entrance into climatological work [65].

Classes of Problems in Applied Climatology

There are four major categories of problems in applied climatology. The major objectives of these are in the fields of (1) designs and specifications, (2) location and operation of a facility or equipment, (3) planning of an operation, and (4) relations between climatic and biological processes.

In the first class of problems we are usually confronted with a question about most frequent or extreme conditions. Sometimes the whole frequency spectrum is involved. Almost always long series of observations are required. In practice, wherever a good series of data is available, this group comprises the simplest type of problem. Even so, the climatic factor is usually very important because it often determines a major capital investment and the end product has to endure for a considerable length of time.

The second class of problems, dealing with location and operation of a facility or equipment, requires generally a greater degree of sophistication in the climatological analysis. The practical question is usually the choice of optimal conditions among several possibilities. The climatic factors are normally only one group out of many others which have equal or greater importance. The analysis will therefore have to illuminate the various advantages and disadvantages which arise from the climatic environment. Frequency distributions, extremes, interrelations of various climatic factors, and their relative importance must be presented to the client.

At the present time perhaps the greatest demand upon the climatologist is for an interpretation of climatic factors that enter into the third class of problems, the planning of an operation. This demand grew out of wartime experiences when weather conditions affected every military operation. In the absence of reliable long-range forecasts the chances had to be assessed on the basis of climatic risks. The peacetime applications are as numerous as the military ones. The basic climatic problems of strategic bombing, for example, are not much different from those of long-distance commercial airline operations; the climatic conditions affecting the logistics for maintaining an army in the field are essentially the same as the industrial distribution problems of peacetime; the weather influences on soil trafficability for military

vehicles are those also encountered in large-scale farming or construction jobs which require tractors, graders, bulldozers, and plows.

In all cases the climatic information is needed for decisions on *where*, *when*, and *how* to perform the job best. In simple terms, the climatological problem is one of giving odds based on past performance of the climatic factors. These odds cannot be given as a single value. One reason is that, in spite of many attempts, the climate cannot be reduced to a single figure. It is always a mixture of elements, some favorable, some unfavorable for the operation. Another reason is the natural variability of climate. The various elements always cover a range. A pessimistic planner will prefer to figure on the worst, an optimistic planner will gamble on the best, the conservative will play the middle ground of the *most likely* event. The prudent planner will want to know *all* the various contingencies.

The climatological analysis for operational planning purposes will almost invariably turn out to be a composite frequency analysis based on the synoptic material. Mean-value climatology is most out of place in this field, even though still used by some analysts. The procedures of synoptic climatology are by far superior [45].

The knottiest problems are encountered in the last major class listed above, in which the aim is to relate climatic factors to biological questions. The requirement is to establish the degree of influence between two very involved complexes of variables. We know, for example, that plant growth and crop yields are dependent upon complex accumulations of temperature, intensity of radiation in certain spectral regions, and soil moisture derived from precipitation. The degree to which each of these climatic elements influences growth and yield is variable within the life cycle of the particular plant. There are various critical times when minimum and optimum requirements exist for heat, light, and water. The climatic data as recorded are not immediately useful. They have to be transposed into intensity-duration frequencies with variable weights. Often only statistical stratification of past records will make it possible to determine the degree of dependency, and multiple correlations will be called for. Moreover, each species of plant has its own peculiar optimal and marginal climatic environment. The studies of this phase of the ecology, while of tremendous practical importance, are at present still in a primitive stage. Most of the time, only the standard meteorological mean values of temperature and total precipitation have been used for analysis. Recently there have been some refinements with the use of cumulative degree days [85], but not nearly enough has been accomplished. The fallacy of using ordinary weather-station data, sometimes from miles distant, has been pointed out [88], but much remains to be done.

The problem of agricultural climatology becomes even more complicated because of the secondary influences of weather conditions upon plant pests and diseases. Their growth and spread are dependent upon environmental factors favorable to them.[1] These nearly always include temperature, humidity, and wind. This second ecological complex is superimposed upon the one directly influencing the plant. It becomes most important for the planning of spraying and dusting operations. In turn, the chemicals and aerosols involved in these protective operations are subjected to the weather elements. The economy and effectiveness of the procedures for fighting fungi, insects, and bacteria are often directly dependent upon such factors as temperature, atmospheric turbulence, and precipitation intensity.

The study of climatic factors in relation to animal life has been a rather neglected field. Some work has been done on livestock [30] and a few investigations have been directed toward weather problems in relation to insects [86].

A whole science of its own is concerned with the influence of climate on human comfort and health. A great deal of information has been accumulated on the reaction of the healthy human body to heat stress. Most of the pertinent physiological studies have been carried on in the laboratory and specially designed climatic chambers. Investigations have been made concerning the influence of several variables, separately and jointly: pressure, temperature, humidity, air movement, radiation [1, 22, 49, 50]. Some instrumentation, supposedly simulating the reaction of man to the total environmental stress, has been designed. This started with the simple katathermometer of Hill [42], became more refined in the Davos frigorimeter [78], and developed into the present frigorimeter of Büttner and Pfleiderer [17, pp. 100–103] and the construction of a *copper man* [32]. These devices record heat requirements and overheating. Some notable field work has also been done, especially in the tropics [23]. A great many devices have been introduced to express the climatic stress in terms of readily measured and available parameters. The most widespread use has been made of the so-called *cooling power*, essentially based on dry-bulb or wet-bulb temperatures and wind speed. Skin temperature, effective temperature, and dew point have been used to assess the climatic heat and cold stress [17, pp. 90–95, 122–126].

It was realized that the reaction of a test individual could not reflect the wide variety of human responses, therefore group tests have also been made. They have covered comfort conditions [4], efficiency of workers [44], mental activity and output, and problems of human reproduction [64]. Admittedly, some of these studies could stand scrutinizing repetition to ascertain the validity of the results claimed. Even so, the conclusions have been used for practical purposes, such as assessing the suitability of various regions of the world for settlement [70]. For this purpose, the existing climatological data had to be translated into the physiologically effective factors established by experimental work. As the need becomes greater for space to ac-

1. Consult "Aerobiology" by W. C. Jacobs, pp. 1103–1111 in this Compendium.

commodate the ever-increasing population of the world, this type of investigation remains one of the most pressing tasks of applied climatology.

Perhaps the greatest challenge to the ingenuity of climatologists, however, is the problem of using climatic data in the field of human pathology—the question of the influence of climate on disease. There is little doubt that the climatic environment contributes to the spread of certain diseases and can also help in the treatment of diseases. The simplest of the many problems in this field is the selection of health resorts for the fatigued yet not completely diseased body. The results of much of the work discussed in the preceding paragraph have led to the establishment of climatic requirements for resort places. No final agreement has been reached on what constitutes a climatic resort, although good proposals have been advanced [61]. Climatic prerequisites for resorts for persons afflicted by various diseases which respond to climatotherapy raise even more complicated questions. Beneficial and adverse environments have been cited for a large group of pathological conditions. Among them are the respiratory ailments such as bronchitis, asthma, tuberculosis, and diseases of the circulatory system. As long as indications and contra-indications are not agreed upon by the physicians, the climatologist can only occasionally lend a helping hand, although some exceedingly fine climatological studies have been prepared for climatotherapeutic purposes [25–27, 52].

Even though the health of the population in general is improving and better drugs and other therapeutical devices, including climatic chambers in hospitals, are rapidly being developed, the problem will remain alive. Progress in health conditions has led to a spectacular increase of old people. The aged body cannot compensate for the climatic stresses as well as the young one can. Gerontologists have repeatedly pointed out that life expectancy increases in areas with favorable climates. What constitutes a *favorable* climate in this sense is at present ill-defined, although certain regions of the world have literally developed into *retirement eldorados.*

Climatic influences on the incidence of certain diseases have been claimed ever since Hippocrates. Modern medical science has accepted some of these claims and has rejected others. But in many cases it has not applied the refined tools of modern physical science to establish undisputed facts. The basic idea of climatic influence on many diseases is generally taken for granted; the details of the mechanism of this influence are ill-understood, matters of opinion, or simply ignored. It is uncertain which diseases are influenced by climatic conditions and which are the specific climatic elements involved in each case. It is further uncertain whether these influences are mainly on the causative agents, bacteria and virus, or on the disease vectors, insects and other carriers, or on the human body. It is quite likely that a concerted effort by teams of physicians, statisticians, and climatologists could solve many of the riddles in this field. (Pertinent literature is extensive. See [3, 13, 67, 73].)

Techniques of Applied Climatology

In the solution of applied climatological problems the technique will vary with the degree of complexity. Three major parameters enter into every problem:

1. Climate, composed of the various weather elements.
2. Space, consisting of the surface and upper layers of the atmosphere.
3. Time, comprising the series and sequence of weather observations.

Each of these parameters can appear in the problem either as a simple or as a complex element. In other words, the climatic factor can involve one weather element or many. Space can mean a single point, several points, or an area. Time may enter only in the restricted sense that the observations cover an interval of time or the problem may pose specific time limitations in terms of cumulative effects or conditioning of subsequent events by preceding situations. These considerations lead to various combinations of the three parameters (Table III).

Table III. Combination of Parameters in Climatic Problems

Space	Time	Climate
Single point	Simple series	Single element Multiple element
	Complex relation	Single element Multiple element
Multiple point or area	Simple series	Single element Multiple element
	Complex relation	Single element Multiple element

Each of the combinations listed in Table III can be illustrated by examples. These can serve to elucidate the problem and show what techniques have been employed to furnish the answers to practical questions. For some of the combinations many examples are available, for others only a few have so far been investigated. Some of the solutions are adequate, others are only makeshift.

Single Point—Simple Time Series—Single Climatic Element

The classical problem in this category is that of insurance against an adverse weather factor. The most common weather risks for which insurance protection is offered are hail, rain, and violent windstorms.

According to Roth [72], hail insurance on crops has been written in Europe for over a century and in the United States since 1880. Insurance rates must be based on the frequency and severity of hailstorms. Data on these storms during the growing season determine the risk. At present, risks are calculated for

counties or townships. Records are based on Weather Bureau observations and claims against the various insurance companies. There is a considerable variation in occurrence of damaging hailstorms from locality to locality. These variations are quite startling. Roth reports that the probability of hail damage varies so much that in extreme eastern Nebraska the insurance rate is 3 per cent of the amount insured, while in western Nebraska 18 per cent is charged.

Rain insurance is generally written for the protection of outdoor events against losses. These include carnivals, fairs, and sport contests. The insurance is paid when rainfall at the particular locality exceeds a minimum amount on the specified days or within the specified hours. This amount is often fixed at 0.1 in. It is easy to calculate the risk for such an occurrence from the extensive available rainfall statistics. At present, the insurance companies use weekly rainfall statistics. The frequency of occurrence of amounts above the minimum during the period of record is established and the risk is computed. Many decades of records are needed for this purpose.

Windstorms are similarly treated. In that case the damaging limit has to be established. Normally, wind speeds of less than 30 mph do not cause appreciable damage. However, it is not quite as easy to establish the frequency of windstorms above this or a similar limit as it is to establish the frequency with which rainfall exceeds a certain amount. At many stations winds are merely estimated according to the Beaufort scale. Not until recent years has there been a widespread network of stations equipped with recording anemometers. Even so, older instruments (such as the U. S. Weather Bureau triple register) are not very useful for determining peak gusts, because the instruments integrate the wind velocity over a period of time, but the peak gusts are the ones that cause the damage.

In this last case, the climatologist has to use his meteorological judgment to supplement the records. Where upper-air data are available, atmospheric-stability criteria can serve as useful guides to estimate gustiness. The frequency of incidence of hurricanes and tornadoes is also helpful. Yet the statistics are quite incomplete and we may find that one station which was affected by a severe storm has recorded winds in excess of gale force, while another close by has not, during the period of record, experienced such an unusual event. Adjustments of the records by analogies have then to be made in order to arrive at an appropriate risk factor.

In areas with sparse records this procedure may also have to be applied to other elements for calculation of insurance risks. Long-record stations will give the climatologist the probable shape of the frequency distribution. This shape, but not the absolute values, can then be used for the adjustment of shorter records at nearby stations.

In all these cases it is tacitly assumed that the past performance of climate is likely to continue essentially in the same fashion in the future. By and large this condition is fulfilled, but risks. once established, should be recalculated whenever a sufficient number of new observations become available.

Single Point—Simple Time Series—Multiple Climatic Element

Examples *par excellence* for this category of problems can be found in the field of design and specifications for protection of man against his environment. Clothing and housing fall into this group. When we build a house we want it to compensate for the exigencies of climate so that conditions indoors approach the zone of comfort as much of the time as possible. This aim governs all design factors. Nearly all climatic elements have to be considered for the purpose. In a preliminary fashion, analyses of the effects of various weather factors upon architecture and construction have been made [38, 77].

Table IV. Climatic Factors in Housing Design*

Climatic factors		Site, orientation, planting	Interior layout	Roof and walls	Openings	Foundation and basement	Mechanical equipment (for house)
Thermal heat	Temperature frequencies	X	X	X	X	X	X
	Frequency of hot and cold days	X					X
	Degree days		X				X
Radiation	Sunshine hours	X			X		X
	Clear and cloudy days		X	X		X	X
	Solar intensity	X	X	X	X		
	Solar height		X	X	X		
Winds	Wind direction	X	X	X	X		X
	Wind speed	X	X		X		X
	Strong winds			X			
Atmospheric moisture	Precipitation	X	X	X	X		X
	Snowfall	X		X	X		
	Excess precipitation	X		X	X	X	X
	Rainy days	X	X		X		
	Fogs				X		
	Thunderstorms						X
	Humidity		X	X	X	X	X

* Crosses (X) are entered for those elements which are of some importance for design of the particular feature.

Without going into the details of the reasoning involved, we can give a schematic picture of the relation of various weather factors to diverse phases of housing construction (Table IV).

The design of the individual features of the house will have to be geared to the climatic conditions. Houses are

built to withstand the elements for half-a-century or more. Hence the most probable values and the extremes of climatic elements must be known. As almost all climatic elements are involved, there will have to be compromises. For example, a roof design best for good drainage of rainfall and for avoiding excessive accumulations of snow may result in undesirably high absorption of solar radiation in summer. But at least the designer should have the basic information on climate available, so that he can plan for optimal results.

Even though the side-by-side data on all the climatic elements are valuable, they are by no means the final solution for problems of housing climatology. This is best illustrated by the specific case of heating requirements. Insulation and heating plants are commonly planned on the basis of *heating degree days*.[2] This factor is a derivative of temperature alone but is supposed to be an index for the heat loss of a house. Obviously, there is correlation between the temperature gradient "indoors-outdoors" and the heating required. Yet the degree-day index completely neglects the radiation and wind factors. The latter is quite important. Hence the design engineer would prefer to get from the climatologist a suitably combined factor of temperature and wind speed, reflecting the total cooling power of the atmosphere. Such joint relationships have been elaborated by the use of test houses [43]. However, this factor is neither directly measured nor generally used in design, because it is not usually known to both architects and meteorologists. This factor can be calculated approximately from simultaneous observations of temperature and wind speeds. But wind observations obtained on airport towers or other high structures are not directly applicable. They have to be reduced to the height of the building for which the design values are desired. For this purpose one can safely assume a logarithmic distribution of wind speed with height. Somewhat more refined aerodynamic procedures are also available in case very high accuracy is needed [69]. These calculations should not be applied to *mean* values of temperature and wind because in all practical cases the frequency distribution of cooling power is actually needed and, furthermore, at many stations there exist peculiar interrelations of temperature and wind speeds. At present these calculations are somewhat tedious, but they could easily be reduced to a minimum because the pertinent equations are readily adaptable to nomographic solutions.

We run into an analogous problem when evaluating climatic data for clothing design or issue. Several aspects of this last problem have recently been discussed in the literature [9, 18, 22, 60, 82]. The dry atmospheric cooling power in the shade as a function of wind speed and temperature has been measured as well as calculated. Among the measuring devices, the frigorigraph of Büttner and Pfleiderer has undergone rigid tests [48] and proved to be a rather satisfactory instrument for climatological purposes. Very few stations have this, or even more primitive types of equipment such as the katathermometer, and series of records are scarce. Therefore, for some time to come, climatic problems in clothing design have to be solved by means of the empirical formulas developed by Hill, Büttner, Plummer, Siple, and others. These are fairly satisfactory for the dry cooling power and they are reduced to nomographic form [60, p. 202]. These formulas, however, cover only part of the heat or cold stress problem. Radiation influence is neglected and evaporative cooling from sweating is not included. Formulas considering these additional terms are much less reliable for conversion of climatological data into values applicable to clothing problems. The experimental bodies used in establishing the relations give only a very poor first-order approximation of human physiological reactions. The real physiological process includes such complicated functions as the effect of body position on radiative heat exchange and the effect of rate of activity on sweating and hence evaporative cooling. These factors cannot be reduced readily to universally applicable quantitative terms that can be translated into the simple climatic elements which are observed at many stations. A further complication is that no *standard* human being exists. Individual reactions to environment cover a broad band. Studies on various types of individuals, registering their subjective feeling of comfort, will have to be made in order to provide the link for the proper interpretation of climatic data. A start in this direction is contained in the formulas proposed by Burton [16]. These are designed to give the effect of clothing on heat loss from the surface of the human body. It has been pointed out that these formulas apply only to equilibrium conditions. They make no allowance for convection inside the clothing, nor are the empirical constants of the equations well determined. From theoretical considerations Lee has arrived at some qualitative criteria for the design of tropical clothing. The complexity of clothing design can be grasped from a list of the climatic conditions and the clothing factors (Table V).

Table V. Climatic and Clothing Factors in Tropical Clothing Design

Climatic factors.....	Solar radiation, radiation from hot objects, hot dry air, hot humid air, tropical rain
Clothing factors.....	Color, texture, thickness, permeability for water vapor, weight, extent of body covering, openings, fit, water repellency, underwear

Quantitative solutions for five to ten variables, as listed in Table V, are not yet within reach. As in the case of housing design, microclimatic problems are encountered; for example, the reduction of shelter-measured temperatures to various body heights and the application of wind data from the usual meteorological exposures to "surface-near" data. The difficulty of ob-

2. Heating degree-days per day = 65F minus actually observed mean temperature for the day when below 65F.

Heating degree-days per month or year = cumulative values of degree-days per day.

taining satisfactory climatic information for the design of shoes from these conventional observations needs no further elaboration [10].

Single Point—Complex Time Relation—Single Climatic Element

In most existing works on problems of climatology the whole series of climatological observations has been used. All observations are accorded equal weight. The time factor enters only as length of the series or as a periodic variation, such as diurnal or annual changes. Many problems, however, include the duration of a climatic condition, or duration above or below limiting values, or intensities per unit time. These complex time relations present difficulties. Usually one difficulty is the lack of continuous records of the climatic element.

A very simple example in this group is the design of a heating system for the melting of snow falling on a pavement. For this purpose, the rates of fall of snow (or sleet) must be known. We must construct amount-frequency-duration curves for the particular locality (generally only for temperatures below the freezing point). Complications are encountered in establishing rates and durations of snowfalls in the absence of heated recording precipitation gages. A first approximation can be arrived at from cumulative 12-hr or 24-hr precipitation measurements, temperature data, and hourly or three-hourly reports of the synoptic network.

A rather simple example of the type of problem associated with this class is afforded by the evaluation *in situ* of the "frost hazard" to tender fruits and vegetables. For each fruit or plant (at a given stage of development) there exists a minimum temperature which constitutes an upper limit for damage through freezing. Freezing damage to the fruit, blossom, or plant will not occur at temperatures above this level. Nevertheless, experience and experiment have shown that freezing damage is a function of both the actual minimum temperature and the duration of temperatures below the critical limit for freezing. For example, a fifty per cent commercial damage to a particular crop can result from a minimum temperature of 28F with a duration of four hours, whereas no more than fifteen per cent damage might result from the situation in which the minimum temperature is 26F for a duration of thirty minutes, below 27F for forty-five minutes, and below 28F for one hour. For this reason, attempts to correlate frost damage and the frequencies of minimum temperatures have seldom been successful, although excellent results have been obtained when the temperature-duration data have been substituted [89].

In evaluating the probability of frost damage, *time* becomes a further complex to the extent that the dates of susceptibility of the plant or crop to freezing may vary widely from year to year. For example, in the case of deciduous fruit crops, the most susceptible period for freezing damage is during the blossom (or small green fruit) stage of development. However, the phenological data from a single orchard between earliest and latest dates of blossoming may show an extreme range of five weeks. Obviously, the probability of a complete or partial loss of crop through frost damage is much greater in an early-bloom year than when the blossoming period occurs so late in the season that there exists a small probability that freezing temperatures will occur. A somewhat similar problem exists in the evaluation of the frost hazard during autumn to the seed corn crop at points in the Middle West [79-81]. In the latter case the probability of frost damage to the crop is increased during a season of late seed maturity. In neither case will a simple frequency distribution of the occurrences of critical temperature durations according to calendar dates give a true measure of the probability of frost damage to the crop. In all such agricultural problems, the reference base is the "crop calendar," not the Gregorian calendar.

Another intensity-duration problem of a single element at a single locality concerns solar radiation as related to the design of window surfaces, blinds, and awnings. Their practical purpose may be either the use of solar energy for supplemental heating, or the elimination of excessive radiation. Theoretically, the problem is readily solved. Practical difficulties arise from the lack of radiation measurements, especially on exposures other than the horizontal surface [35, 40].

Another example which illustrates this category of problems deals with the exploitation of wind for power production. In contrast to other possible examples we are favored in this instance by the existence of an excellently documented case history [71]. A brief summary of the meteorological phases of the New England experiment for engineering exploitation of the wind is given below. In it we follow Putnam's conclusions closely.

There are many basic questions concerning wind behavior that have to be answered in the selection of a site for a wind power plant. In the specific case analyzed here, the choice of a suitable locality for a test site was an important problem. We can pass over the restricting operational requirements, such as accessibility and proximity to the center of maximum electric load, although in any practical case these limit the choice between all meteorologically favorable sites.

The basic ingredients for a preliminary climatic evaluation are:

1. Free-air wind speed at mountain-top height.
2. Effect of the geometry of a mountain on retardation or speed-up of wind flow over the summit.
3. Prevailing wind direction.
4. Influence of the turbulence structure of the wind on design.
5. Influence of the wind structure on estimates of output.
6. Influence of atmospheric density on estimates of output.
7. Influence of estimates of icing at higher elevation on design.

Factor 6 can be derived from theoretical considerations with sufficient accuracy; factor 7 is of importance

in some regions only. We will therefore omit further discussion of these factors and concentrate on the other five factors, all of which relate directly to the wind.

The energy of the wind varies with the third power of the speed. Hence, speed is the most important single consideration. The preliminary climatological investigation must proceed from the available anemometer data, the pilot-balloon information, the known relations of gradient winds to pressure distribution, and the general change of the wind vector with height. In most areas this will yield a first approximation on strength and constancy of winds at possible power sites. The lack of direct meteorological observations can often be supplemented by ecological studies in the area. Strong, steady winds will produce deformations in trees, which act as suitable integrators of the wind vector.

Factor 2 mentioned above will, after preliminary selection of possible sites, have to be supplied by wind-tunnel tests on models of the particular terrain. The local structure of the wind, such as gustiness, cannot be predicted with a great deal of confidence. It depends on local topography and roughness. A series of observations at various heights in the low layers above the ground will be necessary. Such special observations do not have to extend over a long period of time. Sets of measurements under a variety of conditions of stability can give enough information. The data thus collected are not only of value for the mechanical design of the wind turbine and its support, but are also essential for the choice of the best height of the windmill above the ground at the site.

The frequency distribution of hourly wind speeds must be known. The New England study has revealed several points that are universally useful. The speed-frequency curves are Pearson Type III curves with sharp modes, skewed toward lower speeds. Such a curve can be approximated quickly from a number of fixes. The following relations hold (at least for the New England area):

1. A small percentage of hours are calm.
2. The sides of the frequency curve are concave upward.
3. The skewness increases with the mean speed.
4. The most-frequent speed is lower than the mean speed, but increases with higher mean speeds.
5. The number of hours during which the wind blows at the most-frequent speed decreases as the mean speed increases.

Similar general relationships can undoubtedly be developed for other environments.

The mean velocity at a possible site can be established from a short record by reduction to a nearby long-record station, since the ratios of simultaneous values stay essentially constant. The study also established the requirements for the length of simultaneous records needed in order to establish this ratio of mean speeds within specified limits of error. For a 10 per cent error limitation, the lengths of record listed in Table VI were found.

Of further importance are the periodic variations (seasonal and diurnal changes) and the reliability of wind power (maximum positive and negative departures from the mean). These will require long records, but a nearby station (within about a fifty-mile radius and with not too different an exposure) can be used for this purpose. This means in essence that short-record sta-

Table VI. Length of Record Needed to Reduce Short-Record Station to Long-Record Station

Horizontal distance (mi)	Difference in elevation (ft)	Length of time (days)
38	+2000	90
12	+2000	30
10	+400	10
Same locality	+65	0.6

tions, operating for about three months, will yield the most essential basic data for a climatological analysis of this type of case. The low-layer vertical distribution at the auxiliary stations should also be established by anemometers at three or four levels between the surface and two hundred feet elevation. If possible, the three months of records should not be continuous but should be composed of several periods of two or three weeks each, spread over the seasons.

Single Point—Complex Time Relation—Multiple Climatic Element

Instead of establishing classes, the climatic influences can often be expressed by a formula. This scheme has been employed for determining deterioration of materials under weather influences. According to C. E. P. Brooks [14], the following elements enter into the problem:

1. Effects due to high temperatures alone.
   - *a.* Mechanical effects.
   - *b.* Speed-up of chemical reactions by heat.
   - *c.* Flowing due to decreased viscosity.
   - *d.* Increased activity of bacteria.
2. Effects due to high temperature in conjunction with moisture.
   - *a.* Corrosion of exposed surfaces.
   - *b.* Effect of diurnal cycle—*breathing* of partly sealed packages.
   - *c.* Organic changes—molds and rotting.
3. Effects due to impurities in the air.

The combined effects of temperature, humidity, atmospheric impurities, and wind can be stated in a general equation of the form

$$A = ax^t + b\frac{(H - K)}{100}(1.054)^t(1 + cI)(1 + 0.067W),$$

where A is the rate of deterioration of a fresh sample, t the temperature in degrees centigrade at the surface of deterioration, H the relative humidity at the temperature t, I the concentration of effective impurities, bacteria, fungi, or spores, and W the effective wind speed in mph. The quantities a, x, b, c, K are constants which have to be determined in each case. The complex

time relation enters into the rates of deterioration because of variable diurnal and seasonal durations of the effective factors, which often have upper and lower limits.

The analysis by Brooks covers only a limited group of cases. For example, deterioration of rubber, modifications of glass by certain ultraviolet wave lengths, and the weathering of paint by light and rainfall coupled with high temperatures have not been considered. In this field much work remains to be done before climatic data can be applied intelligently to the many practical problems of *weathering*.

An example of the lack of weather planning of this type is the recent case in which importers of a particular type of French silk print accused the European exporters of dumping an inferior product on the American market because the silks did not hold up as they had done in Paris. The silk prints, long-lived in a damp, cloudy atmosphere, literally went to pieces in a few weeks under the influence of the more frequent and intense direct sunlight found in New York, Chicago, and other American cities. The prior determination of the comparative sunshine (solar radiation) conditions would not have been a difficult task for the climatologist [46].

Multiple Point or Areal Problem—Simple Time Series —Single Climatic Element

The prime examples in this category are to be found among the large number of problems which are concerned with the marketing, on a state-wide or national scale, of the so-called "weather goods." Weather goods are referred to by those in the trade as goods whose use and sale are primarily determined by nonperiodic changes in such weather elements as temperature or precipitation. The national distributing system, as it serves the retailer, is more closely adjusted to the distribution of population than to the synoptic weather probabilities. As a result, it happens only too often that the bulk of the saleable goods are found where there are the most people but not where the actual demand is greatest.

There are of the order of one hundred cities in the United States with populations of 100,000 and over and these cities account for well over a third of the country's total population. Yet, how many climatologists (or distributors) have a knowledge of the number and location of cities that are likely to be affected *simultaneously* by the same abnormal weather conditions? A knowledge of the geographical extent and relative locations of areas which may be affected *simultaneously* by abnormally high temperatures is extremely important in planning the marketing and distribution facilities for such "hot-weather items" as lemons or soft drinks. If a study of synoptic weather data reveals that the odds are 5 to 1 that a summer "heat wave" which affects cities in the East with fifteen million people will also affect areas in the Middle West or South with a population of ten million people, then it is obviously poor planning to have 75 per cent of the product warehoused in New York and only 10 per cent in Chicago [28].

Another example chosen to illustrate this category of problem involves the evaluation of the possible increased demand for electric power that may result when heavily populated but dispersed urban areas, which are serviced largely by a common interlocking power facility, are affected simultaneously by abnormal and sudden decreases in the natural illumination. Such a condition can be caused by a sudden development of widespread thunderstorm activity, by a fortuitous grouping of individual thunderstorms or by the unusually rapid development of a heavy cloud or fog layer over the area. It is doubtful if such information can be obtained by inspection of data available from the usual station network. A synoptic-analytic approach appears to be the most promising method for the solution of such a problem at the moment, although there is the possibility that a statistical analysis of the data acquired by special thunderstorm-research projects might give quantitative information on the probable spacing of thunderstorms or on the areal extent of thunderstorm activity as related to the spacing (or areal extent) of the service areas. However, actual observational material may subsequently become available through radar storm-detection programs or, perhaps, through special thunderstorm-observing programs similar to those sponsored by the Amateur Weathermen of America.

Multiple Point or Areal Problem—Simple Time Series —Multiple Climatic Element

This group of problems is peculiarly the province of the synoptic-climatic technique of approach. An example is the planning for the aerial mapping of large geographic areas or boundaries. The technique of aerial photographic mapping requires that given strips of the earth's surface of the order of 100 or more miles in length be free of clouds at all levels below the flight altitude; that illumination conditions (as determined by solar altitude, haze, and upper-cloud conditions) be favorable; that there be no turbulence at flight altitudes; and that the surface to be photographed be free of snow cover and not otherwise obscured. The element of time is not a complex, because the photographic flight strips are run in a matter of minutes or hours. The possibility or probability of occurrence of the proper combination of meteorological circumstances over the area cannot be obtained from frequency data at a single station alone. However, the analysis of the several meteorological factors as they occur simultaneously over large areas will reveal whether or not the aerial photographic technique is feasible, determine the favorable period for mapping, and may also serve to indicate the most economical photographic flight plan (flight altitude, order, and orientation of photo strips).

Another application could perhaps be cited with equal validity under the types discussed in the next section. It is the use of the synoptic-climatic method for weather forecasting. This procedure is now frequently referred to as *objective forecasting*.

The use of climatological information for forecasting is really nothing new. The recognition of certain persistencies in series of observations led to some early forecasting rules. Other autocorrelations in time-series of meteorological observations at one point have been discussed repeatedly as aids to forecasting [36, 54].

The modern approach substitutes an areal net of observations for local time series. From series of synoptic charts, stratified or multiple correlations of meteorological parameters at distant stations are used as *predictors* for the locality for which a forecast is desired. Frequency distributions of antecedent and subsequent events are obtained and stochastical relations are worked out so that the probability of a given event (in dependence upon previous events) can be obtained. Machine tabulations have facilitated this approach. Subjective forecasting experience, which in many cases is nothing but a subconscious system of statistics, is replaced by an objective summarization of the past performance of weather. While this is a potent tool, it should not be overlooked that it is essentially a static extrapolation technique and disregards dynamic and energetic factors which can influence the weather in the interval for which the time-lag relations are worked out. The procedures have been adequately presented in several recent papers to which reference only is made here [91]. Much useful work in this direction remains to be done.

Multiple Point or Areal Problem—Complex Time Relation—Single Climatic Element

Problems of this class are most frequently encountered among the large number of questions concerned with the probable maximum runoff of flood waters as determined by the areal patterns of intensity-durations of rainfall. Such information is essential in the evaluation of possible peak floods or in the design of storage or flood-control dams, levees, culverts, storm sewers, and the like. The hydrometeorological literature abounds with examples of the employment of the technique which, in its best form, makes use of the detailed precipitation intensity-duration data accumulated from the records of a large number of precipitation gages (preferably recording gages) distributed over a given drainage area. Where such detailed data are not available, the use of theory is required to supplement the inadequacy of the observational record. The technique, itself, is so commonplace that there appears to be little requirement that it be further elaborated upon in this section. For further details the reader is referred to the extensive and readily available hydrologic literature on the subject [34, 76].

Another example of this class is afforded by the necessity for evaluating the frost hazard or assessing frost damage to crops as the problem applies to large agricultural areas of diverse topography. In an earlier section the evaluation of the frost hazard as it applies to a single point in an orchard or to a small agricultural plot was discussed. In the present case the identical temperature-duration data are required, but now we are concerned with the pattern of such conditions as they occur over a large area during a given time interval. For the rapid evaluation of the probable freezing damage from a single frost, the temperature-duration data from a large number of representative points within the agricultural area for the single frost night may be considered sufficient. For crop estimation purposes, however, the cumulative data for the several series of frost occurrences during the entire growing period are required.

The variations in minimum temperatures and durations that occur over a region are due largely to differences in (1) exposure to winds, (2) relative elevation (in the local sense), and (3) nature of the soil cover (whether wet or dry, cultivated or fallow). Of the three factors, only (2) remains constant throughout the growing season. The most exposed areas will present fewer frost nights and the duration of critical temperatures will be shorter than in more sheltered locations, due to the "mixing" effects of the frequent nocturnal winds. The temperature effect of the wind, however, will depend upon the degree of stability that has been attained in the lower layers of the atmosphere at the time the wind is initiated; the degree of exposure to winds will vary from night to night depending upon the direction of the pressure gradient during the frost period. It is doubtful if the pattern of damaging temperatures recorded for an area during a given frost period is ever other than *unique*.

For the purpose of rapidly evaluating the frost damage to the crop, the citrus industry in the Far West makes extensive use of temperature-duration data obtained from thermographs exposed in a large number (approximately 400) of representative citrus plantings. Through the mechanical or manual integration of the individual thermograms, the analysts can estimate the probable frost damage with surprising accuracy within a day or two after the frost occurrence. Similar estimates based on field sampling of the fruit would require weeks to accomplish.

Multiple Point or Areal Problem—Complex Time Relation—Multiple Climatic Element

As we expand the variables into all dimensions the applied climatological problems become very involved. At the same time well-analyzed examples become rare. The problem of agricultural land usage in relation to climate has probably had more attention than any other. In agriculture we are dealing with complicated questions that can be disentangled only by the cooperation of four sciences: soil science, plant biology, land management, and climatology.

But even with proper soil, proper tillage methods, proper fertilization, and proper seed material, the climatic conditions determine to a large extent what plants will or will not grow, mature, and ripen at a given locality. A most intricate system of time sequences of various climatic elements enters into the problem. We find that photosynthesis is dependent on radiation intensities in specific wave lengths. In some

cases the amount of sunshine received at special times in the growth cycle of the plant will determine the commercial value of the fruits (an example is the August-September influence of sunshine on the sugar content of grapes). The rapidity of development depends on cumulative temperatures above a limiting value, that is, a certain *degree-day* value. The occurrence during the growing period of a temperature below a critical value, such as the freezing point, can determine the partial or complete loss of a crop. Further, the proper water balance is of particular importance in plant development. There are times when too much water is as detrimental as is insufficient moisture at other times. The requirements within the life cycle of maximal and minimal amounts of water are very different from one plant species to the other. The water balance is not determined by a simple climatic element, such as rainfall, but is governed by precipitation, transpiration of the plant, and evaporation. This last element itself is a function of humidity, temperature, and wind speed. Thornthwaite has tried to establish some of these relations of *evapotranspiration* [83].

The literature abounds with studies of crop yields in relation to weather conditions [90*e*, pp. 293–476]. These relations can be used to establish facts about optimal growing conditions. In turn, these can serve to establish from long climatic records the risks to a given crop at various localities. A great deal depends here again on microclimatic conditions. This is particularly true of frost risks [47]. An area may, for example, be in general quite favorable for apple or peach orchards and yet some topographically poor exposures may be veritable *frost holes* and entirely unsuited for this type of cultivation.

Climatological principles have been applied to the introduction of plant seeds from one territory to another [66]. These studies of comparative climato-ecology are still in their infancy and amenable to much improvement. The difficulties involved have already been pointed out (see page 980) and allusion was made to the problem of climatic influences upon pests.

Experience has shown that a definitive *fire weather* exists, especially in forests. For effective fire-fighting procedures it is useful to estimate the *danger class* of each day and season. This will result in better dispositions for lookout posts, fire-fighting equipment, and personnel. The climatic information serves both for planning purposes and for the anticipation of fire-weather stations. These are later supplemented by special weather forecasts.

For many forest areas of the United States special *fire-danger meters* have been worked out. These are composite slide rules which have been described in the literature [41]. A case history for an urban area may, however, be of interest. It shows the technique of arriving at a fire-danger scale. This scale was derived for grass and rubbish fires in the city of Raleigh, N. C. It was assumed that the immediate causes for such fires, namely flying embers, carelessly dropped burning matches and cigarettes, etc., remain essentially constant so that weather conditions contribute most to the variability of incidence.

The climatic elements mainly entering into a classification of fire hazards are precipitation, relative humidity, and wind speed. Precipitation and relative humidity are important for the period preceding the fire, while the wind speed enters at the time of ignition. For establishing the scale, the conditioning and coexisting weather conditions were noted for 90 days on which three or more grass or rubbish fires were observed. It is not surprising that precipitation and humidity values immediately preceding the fires were more important than those further back in time. This required weighting factors for the sequences of these elements. These were simply obtained by multiplying the values on the *fire day* (three or more rubbish or grass fires) by 4, on the preceeding day by 3, on the second preceding day by 2, and by using the actually-observed values for the third day prior.

The statistics showed immediately that 70 per cent of the fire days had a relative-humidity factor of less than 40 per cent, while only 18 per cent of *all* days had a humidity factor of less than 40 per cent. Over 80 per cent of the fire days also had a weighted precipitation factor of 0.01 in. rainfall or less (of *all* days only 37 per cent have a precipitation factor of less than 0.01 in.). The simultaneous wind speed did not show quite as good a discrimination, although 88 per cent of the days with five or more fires had wind speeds of 13 mph or more. However, 75 per cent of *all* days have winds exceeding 12 mph at one hour or another.

These statistics resulted in the following scale:

	Weighted relative humidity %		Weighted precipitation *in.*		Wind speed *mph*
Good fire days	$\leqq 40$	and	$\leqq 0.01$	and	$\leqq 13$
Poor fire days	$\leqq 60$	and	$\leqq 0.05$		
	or $\leqq 70$				
	or		$\leqq 0.25$		

Days that did not fall into the classes *good* or *poor* were classified *indifferent*, that is, the weather would not contribute to the fire hazard nor would it definitely retard fires. The discrimination of the scale is shown for four test months (January–April = 120 days) for four years (total 480 days) (Table VII).

Table VII. Fire Occurrences and Fire Danger Class

Fire Class	Total days	Total fires	Fires per day
Good fire day	110	226	2.05
Indifferent fire day	224	193	0.86
Poor fire day	146	32	0.22

The table shows that the scale is quite satisfactory. The *good fire days* had over nine times as many fires as the *poor fire days*.

This group of problems is also peculiarly the province of the synoptic-climatic technique of approach. An example is the establishment of a time schedule for

flights optimally adapted to weather conditions. A flight operation will be the more economical the better the weather conditions are at the terminals and over the route. Poor terminal conditions, as expressed by weather minimums of combined ceilings and visibilities, prohibit or delay take-offs and landings. Hazardous conditions en route, such as severe icing and severe turbulence due to fronts and thunderstorms, may require detours or delays and hence are not conducive to the maintenance of a smooth flying schedule. A good flying day can be defined in terms of absence of such *limiting weather conditions* in sequence at the take-off point, en route, and at the landing terminal. This sequence of events cannot be established readily by spot observations. But it can be obtained on sequences of synoptic weather maps. Statistics of the annual variation of good and poor flying days, the change from year to year, at least in terms of largest and smallest number, will give a planner the weather factor for a decision on whether or not a specific air route can be operated profitably.

The identical technique was applied to logistic and other planning problems during World War II. Strategic bombardment operations were a case in question. The limiting weather conditions for take-off and landing in friendly territory, the route conditions, and the availability of targets for visual or blind bombing entered the picture. This application of synoptic-climatic techniques has been discussed in more detail by Jacobs [45, pp. 20–22].

This type of study for airline operations can be considerably refined by considering, for example, diurnal variations of limiting conditions for each hour at the terminals and en route. There is no reason to elaborate on this because every meteorologist knows that during certain times of the day in various seasons limiting conditions are particularly prevalent at certain airports. It is elementary to expect higher frequency of dense fogs in the hours before sunrise. Also the high summer frequency of fogs in areas like Newfoundland is notorious. The climatic analysis can place such knowledge on a systematic basis. The same applies to the seasonal variations of air trajectories. These can be obtained from the upper-level synoptic maps and used for laying out the most advantageous routes over great distances in accordance with the principles of *pressure pattern flying*.

Additional Unsolved Problems

The foregoing review of the state of the art of applied climatology had to point to a great variety of only partially solved problems. In fact, each new application will require its own specific solution. In many respects this part of the *Compendium of Meteorology* is a series of *confessions of ignorance*.

We have already pointed out in sufficient detail the need for new types of observations, many of which require new instrumental approaches. The requirement for statistical solutions better adapted to the specific problems has also been discussed. These are not the only deficiencies. The classical methods of summarization and graphical presentation need radical overhauling in many respects [55]. Some very remarkable advances of graphical and pictorial presentation of climatic data, growing out of wartime experiences, have been placed in the scientific record [45, pp. 44–51].

Yet we still lack adequate methods for multidimensional representation of data. We need more nomographic charts to simplify the presentation of complex relations and to allow for a quick solution of empirical equations.

We have indicated that, in contrast to classical climatology and climatography, applied climatology is a broad, two-way meeting ground between the synoptic meteorologist and the climatologist. A fruitful field for joint efforts lies in the methods of *air-mass* climatology. There has been insufficient space to discuss these in detail here. This approach, however, has shown increasing promise for problems of bioclimatology [24, 33, 56, 62]. It is likely that further work along this line can find useful applications.

Other advances in applied climatology are intimately tied to progress in *microclimatology*. The research needs in this field have recently been presented by Baum and Court [11]. Their very pertinent remarks can be summarized as follows: There is need for standardization of microclimatic procedures and equipment. More measurements are needed on the vertical distribution of the usual climatic elements in the boundary layer over various forms of terrain and vegetation. Coincidentally, measurements of the following factors should be made:[3]

1. Temperature gradient in the soil.
2. Soil conductivity as a variable quantity.
3. Insolation, direct and diffuse.
4. Atmospheric radiation.
5. Terrestrial radiation.
6. Eddy conductivity in the air.
7. Evaporation.

As basic problems Baum and Court propose studies and causal understanding of the heat balance at the surface of the earth, the existence and extent of laminar layers near the surface, and the interrelation of microclimatic factors and evaporation.

Lastly, it should again be stressed that applied climatology should be in each instance a cooperative venture. It deals with borderline fields. Climatology is on one side; on the other side are a great many other disciplines (medicine, ecology, agronomy, hydrology, pedology, architecture, strategy, business management, and various phases of engineering). The solutions to the many joint problems can best be found by teamwork.

Appendix

Table VIII lists areas of practical problems in applied climatology, by classes. Some of these areas have

3. Some of these have been mentioned in Table I, above, but are repeated to present Baum and Court's ideas completely.

been studied and reference is made to pertinent papers that have not already been quoted. The list is by no means complete, but it indicates what a broad and

MICROCLIMATOLOGY*

By RUDOLF GEIGER

University of Munich

INTRODUCTION

Origin and History of Microclimatological Research. Microclimatology is the science of climate on the smallest scale. It developed as a separate branch of our meteorological science in two entirely different ways. First, the progressive development of a network of meteorological observation stations attracted attention to local peculiarities of climate. Data gathered in mountainous regions, at stations on slopes, in valleys, and on mountain peaks revealed characteristic peculiarities. Soon differences were detected also in level regions, between stations in larger cities and those in the open country, near forests, or in agricultural territories. The attempt to distribute observation instruments expediently led, as early as the end of the nineteenth century, to the recognition that the type and condition of the soil, as well as the vegetation, had a considerable effect on the climatic data obtained. At the time, emphasis was placed on large-scale climate rather than on local peculiarities, and consequently measuring instruments were placed at a height where they would lie above the region of surface effects (about two meters above the ground). Only later did investigation of the climate near the ground become of interest. This interest was prompted by the fact that the thermodynamics and hydrodynamics of the earth's surface determine changes in the state of the atmosphere above.

The development of microclimatology would never have taken place so rapidly had it not been for the fact that new demands were placed on meteorologists by entirely different fields such as agriculture, forestry, and horticulture, as well as by industry, transportation, and the building industry.

As the population in each country grew and the degree of cultivation was extended, it became necessary to exploit the natural resources of the land to an ever-increasing extent. Simultaneously, the demands placed on climatological data rose. Information recorded in almanacs became quite insufficient for the requirements of practice. The situation is best illustrated by an example (Table I).

Table I refers to a German forest range selected at random, located in flat country (Eberswalde, near Berlin); it shows differences in the danger of late frost in the spring of 1939. The forester is concerned with the climate prevailing at the height of sprouting pine trees, 10 cm above ground. Table I provides the pertinent information, namely the frequency with which late frosts occurred as well as the date of last occurrence. Furthermore, the temperature minima of a damaging frost-night in May and of one in midsummer are given. It is seen that frost incidence and intensity are entirely different at the nearest climatological observation station only a few kilometers away. The measurements were confirmed by the existence of large areas of frozen vegetation.

TABLE I. DIFFERENCES IN THE INCIDENCE OF LATE FROST IN A GIVEN FOREST RANGE (*After Geiger and Fritzsche* [13])

Location	No. night frosts May 14–July 19 1939	Last frost	Temperature minimum May 29–30 1939 (°C)	Temperature minimum July 11–12 1939 (°C)
Meteorological station at Eberswalde, given for comparison.	0	April 10	+3.0 (−1.2)*	+11.2 (+7.5)*
Forest range outside Eberswalde at the same altitude, 10 cm above ground level.				
1. Farm area plowed two months previously to a depth of 24 cm.	7	June 12	−3.4	+5.9
2. Uncultivated ground overgrown with grass.	11	June 21	−6.5	+1.5
3. Abandoned farm area covered by weeds.	17	July 7	−9.0	−2.5

* Minimum at 5 cm.

Every forester, farmer, and horticulturist must select his plant varieties and his cultivating methods on the basis of the climate actually prevailing in small regions—we call this the *microclimate*. Location considerations in plant growth are always microclimatological in nature; whether a plant is located in an open field, or at the north side of a large boulder, or at the foot of a high oak tree is a decisive factor with respect to the conditions affecting its growth. The vineyard owner is interested in knowing the temperature conditions to which a ripening grape is subjected when it is located at a height above the ground which can be determined by the method of cultivation. Similarly, every engineer must know what climatic conditions his work will be subjected to, for instance the frequency with which his concrete road will be subjected to freezing and thawing in spring and fall. The scientist also requires such data for research purposes. The biology of bees can be understood only if one knows the microclimate of the beehive. The list of examples could be continued indefinitely. It is the problem of the microclimatologist to investigate these small-scale climates.

* Translated from the original German.

In some of these cases one deals with a single weather process, that is, a meteorological event. Thus there exists also a science of *micrometeorology*. Thornthwaite [31] ascribed the difference between these disciplines to the research methodology used, stating that

> Micrometeorology deals with the physics of a layer and aims at discovering physical principles, whereas microclimatology is concerned with the geographical distribution, both areally and vertically, of the various properties of the air, and seeks patterns of geographical distribution.

It has so far been customary (and will probably also prove expedient in the future) not to distinguish between two separate disciplines, but to assemble all small-scale investigations under the collective term *microclimatology*. For just as modern climatology with its method of frequency statistics accepts the synoptic weather processes in the domain of its studies, so microclimatology will also include small-scale single weather processes, that is, micrometeorological events.

THE PRESENT STATE OF RESEARCH

Microclimate as the Climate near the Ground. We shall first consider microclimate as the special climate prevailing in a layer of air about two meters in height adjacent to the surface of the ground. In this layer, friction between the air and the earth's surface plays a decisive role. In the lowest few decimeters, wind velocity is very low; mixing of the air due to turbulence is therefore also slight. However, the greatest portion of radiation from the sun and ground is absorbed at the surface of the ground. Heat radiation during the night also takes place at the surface. Precipitation is absorbed by the ground. The ground furnishes water vapor as well as carbon dioxide and other substances to the atmosphere. Exchange of heat and water thus takes place in the boundary layer between ground and atmosphere. The layer near the ground is the first intermediary between ground and atmosphere, and it is precisely here that the vertical transport of all properties is greatly impeded by wind resistance along the ground. It is therefore in this layer that we encounter the greatest differences in the smallest space.

Temperature Conditions. The slight air movement, the strong radiation reflected by the ground surface, and the large vertical temperature gradients make it difficult to obtain exact measurements of the temperature of the air layer near the ground. The problem of the measuring technique is not as yet satisfactorily solved.

The use of thermometers which are artificially ventilated and protected from radiation is possible only at heights above roughly one meter. The first exemplary experimental arrangement of this kind was applied to microclimatology by Flower [7] in England. Closer to the surface, ventilation destroys the natural temperature stratification that is to be measured. Moreover, no suitable protection from radiation by the sun, the sky, and the earth's surface has yet been found. In most cases, the unavoidable radiational error increases systematically with the approach of the thermometers to the ground surface. Thereby, excessively large gradients are simulated when the insolation is strong. In addition, the protective device also shades the ground and thus affects the measuring field.

At present, Albrecht's method of temperature measurement [1], involving a single platinum wire as an electrical resistance, is probably the best. It is well known that the radiational error of a wire exposed to sunshine decreases with decreasing diameter. If wires of only 0.015-mm diameter are used, the error becomes negligibly small even in calm air, a fact that now can also be proven theoretically. Such a wire is stretched horizontally at the desired height of measurement. Its length serves to average the temperature of many eddies at the selected height of measurement. This is an advantage considering the extraordinary temperature fluctuations near the ground. This arrangement has proved satisfactory even for temperature measurements in the Gobi Desert.

The most important characteristic of the air temperature near the ground is the unusually large vertical temperature gradient, especially by day. Table II refers to measurements by Mal, Desai, and Sircar [21]; it lists the frequency distribution of temperature gradients observed at the Karachi airport by means of ventilated electric-resistance thermometers; values are converted to degrees Fahrenheit per 100 m for the purpose of comparison. The measurements were not actually made in the layer near the ground. They serve to illustrate, however, how variation in the prevailing gradient increases as the ground is approached. According to measurements made by Best in England, by means of ventilated thermoelements, the gradient in the layer between 1.2-m and 0.3-m altitude at 12 noon, even in the middle of June, amounts to 139F per 100 m, and as much as 1230F per 100 m in a layer between 0.300 and 0.025 m, if conversion to a 100-m altitude is made.

Table II. Yearly Percentage Frequencies of Lapse Rates of Various Magnitudes in Karachi

Lapse rate (°F/100 m)	+57	+43	+31	+21	+13	+7	+3	+1
Layer 4–56 ft (%)	0.1	0.4	2.0	8.5	13.0	13.0	12.0	7.1
Layer 56–156 ft (%)	—	—	—	—	0.6	2.5	24.1	23.7

Lapse rate (°F/100 m)	−1	−3	−7	−13	−21	−31	−43	−57
Layer 4–56 ft (%)	6.6	5.3	7.6	6.7	6.2	6.4	3.6	1.1	0.3
Layer 56–156 ft (%)	16.7	7.9	7.3	7.2	6.3	2.7	0.7	—	—

These high gradients are accompanied by a number of other phenomena which are equally characteristic. Rapidly recording electric thermometers reveal extraordinarily great temperature fluctuations which never subside and are particularly strong during periods when the incident radiation is large. They are caused by the rising of hot air parcels in proximity to descending

cold air parcels. These fluctuations are visible in the form of scintillations which can be observed at noon above heated roads or railroad embankments. If, in making this observation, one moves his eye downward until a layer directly above the ground is observed, one will be surprised to note a considerable increase in scintillation. The high lapse rate, moreover, gives rise to reflections by air strata, also known as *road mirages* which also occur only in the microclimate near the ground.

From the great decrease in temperature with altitude at noon (incoming-radiation type) and the great increase during the night (outgoing-radiation type) it follows that daytime temperature fluctuations near the ground are considerable. If a meteorological station located 2 m above ground observes a daytime fluctuation of 10C, the value at 1 m increases to about 15C, at 10 cm to about 20C, and at the ground to a value of 30C or even 40C. This variation can occasionally be observed in the erosion of vertical rocks or buildings.

Effect of the Type of Ground. Since microclimate is controlled by the ground, it follows that the type and condition of the soil must have a considerable effect on the microclimate near the ground. Surface properties determine, first of all, how much radiation is absorbed or reflected. Dark areas (peat bogs) absorb more, light areas less; moist ground absorbs more than dry ground. Surface properties are usually different for the absorption of short-wave radiation from sun and sky during the day than they are for the emission of longer wave lengths during the night. The thermal conductivity of the surface controls the distribution of absorbed heat between the ground and the air. If the thermal conductivity is large, the ground absorbs much heat during the day and then conducts much heat to the radiating ground surface during the night. Temperature conditions in the air layer near the ground are consequently moderate. Ground of poor conductivity transmits much heat to the air during the day and removes heat from the air during the night. In such cases harmful air temperatures are attained at noon, and at night the danger of frost is correspondingly great. Thermal conductivity depends on the condition and composition of the soil, and on its structure. The latter is determined by the treatment which the soil has been given. A table of various soil constants (which can serve merely as a qualitative indication in view of the great variety of soil conditions) will be found in the textbook on microclimatology by Geiger [11].

The microclimatologist can understand the climate near the ground only if he is familiar with the climate prevailing in the ground itself. The farmer, however, by his practice of cultivating and fertilizing the soil, changes its condition and thus affects the climate near the ground—the climatic environment of the plants he cultivates. Even changes in the ground's surface and its properties often have a great effect, for instance covering the ground with evergreen twigs, straw, etc. (mulching) and covering peat bogs with sand. The greatest obstacle to the investigation of this ground climate is the difficulty of measuring in a simple manner the water content and the water balance of the ground. Nevertheless, at the present time, investigations that raise hope for progress in the near future are being conducted in various countries. If soil volumes of more than one cubic meter are sunk into the ground flush with the surface, and if the weight of this soil can be measured with sufficient accuracy, the water loss (evaporation) or the water gain (dew and frost formation) of the soil can be determined from the precipitation and the seepage. In 1930–1937, J. Bartels and J. Schubert [3, 10] obtained a good series of measurements of this kind in Eberswalde. However, the instrumental equipment is very expensive because of the extensive installation work and the balances that must have a high accuracy (about 0.1 kg) under great loads (about 1500 kg). For this reason, employment of this method at many locations can hardly be expected. At present, C. W. Thornthwaite is undertaking promising experiments at Seabrook, N. J., on the evapotranspiration of natural and cultivated soil surfaces. In India, Ramdas [25] found a method for measuring the water content of the soil without changing (digging) the soil itself; this method consists in electrically heating a soil thermometer (mercury) and measuring the subsequent rate of temperature change. As soon as progress has been made in these instrumental problems, it will be possible to study the influence of the type and state of the soil more adequately than has been the case thus far.

The air layers near water and snow are of special interest for the further systematic development of microclimatology. The uniformity of the water surface and of the freshly fallen snow cover facilitates the elimination of all advective influences. Because of its small heat conductivity, the snow cover also eliminates the influence of the soil. Investigations by Bruch [4] and Roll [26] of the temperature and wind field over water surfaces have greatly promoted knowledge of the air layer near a water surface. Moreover, these researches have furnished new information regarding the process of wave formation, the change of an air mass in moving from land to sea, and the usefulness of the temperature of the water surface reported by ships in the synoptic weather service.

Moisture Conditions. The measurement of the atmospheric humidity near the ground is nowadays attempted in three different ways: (1) by hair hygrometers in which the orientation of the hair and the construction of the instrument are adapted to the horizontal stratification of the humidity (Diem [6]), (2) by psychrometers with very fine thermoelements whose radiational error can be neglected (Franssila [9]), (3) by aspirating air from the desired height into a modern dew-point hygrometer (Thornthwaite [31, 33]). The first two methods are distinguished by their simplicity, the third method by its high accuracy.

Unfortunately, extensive series of measurements of the water-vapor distribution near the ground are as yet unavailable. As with temperature, this distribution is quite different from the conditions prevailing at a height of 2 m. The temperature at ground level may

be lower at times and higher at other times than the air above; deviations in humidity, however, are almost always in the same direction. Just as wind velocity is lower near the earth's surface, so the absolute and relative humidities are always higher. Only in the morning hours is the ground surface sufficiently colder than the air for water vapor, in the form of heavy dew, to condense there in a quantity sufficient to dry out temporarily the lowest meter of the atmosphere. (Often this applies only to a layer several centimeters deep.) A relative humidity at 10 cm which is 30 to 50 per cent higher than that at 2 cm is not rare. Thus the climate near the ground is also entirely different in this respect.

Rapid fluctuations of humidity with time are as characteristic of the microclimate near ground as are temperature fluctuations. Air parcels enriched in moisture content rise upward from the ground, dry parcels sink downward. Because of poor mixing they cause the indicators of special hygrometers to move back and forth in jumps. When the ground is covered with drought cracks, saturated air rises from the depths of these crevices and causes deep layers to dry out more quickly.

Moisture layers near the ground are sometimes visible in the form of flat fog banks in enclosed spaces or as the steam above highways which is so annoying to the motorist (for instance after a shower strikes a hot road surface). However, the formation and dissolution of fog above the ground, as well as the formation of dew, have not yet been investigated sufficiently. Exact investigation is rendered difficult by the discontinuous structure of the layer near the ground, varying conditions of exchange, and the effects of colloido-chemical and aero-electrical processes superimposed on the thermodynamic changes. Moreover, humidity changes in the ground air as well as condensation within the ground must also be taken into consideration. Investigations along these lines seem promising and may provide new information basic to the entire field of microclimatology.

Wind Conditions. Today we are well informed on the variations of the wind speed in the air layer near the ground. All measurements in the air layer near ground and water surfaces are, according to investigations by Thornthwaite and Halstead [32], represented with sufficient accuracy by the equation

$$u^p = (\log z - \log z_0)/\log a,$$

where u is the wind speed (m $\sec^{-1}$) at the height z (m); p is a parameter whose value depends on the magnitude of the vertical temperature gradient. If $p = 1$, the equation above is transformed into the logarithmic law that was formerly in general use. In this case, the observed values, when graphically shown in a coordinate system with u as abscissa and $\log z$ as ordinate, lie on a straight line whose slope is determined by the value of $\log a$ and whose point of intersection with the ordinate is determined by the magnitude of $\log z_0$.

However, in the same coordinate system, the measured values do not lie on a straight line but on a curve that is concave upward, if the temperature stratification is unstable. In reverse, during a stable nocturnal inversion a curve is found that is convex upward. The parameter p in the equation above takes care of this influence of the vertical temperature gradient. When a strong temperature decrease exists with increasing height, then $p > 1$; with great instability, p may reach the value of 2. For stable stratification $p < 1$. For the smallest amount of turbulent mixing of the air that may occur in practice, p has the value of approximately 0.5.

According to the equation given above, a value $u = 0$ is reached at a height z_0. The value of z_0 (roughness height) depends on the nature of the surface and on the existing meteorological conditions. Over water, snow, and level bare soil, a value of $z_0 = 0.02$ m can be used as an approximation.

Eddy Diffusion. Whereas the variation of wind with height above the ground is very well known, the determination of the austausch coefficient A represents one of the most difficult and immediate problems of microclimatology.

At the surface, a boundary layer of about 1-mm thickness is assumed, in which molecular processes (molecular heat conduction, and diffusion) are almost exclusively effective. Above this layer, eddy diffusion determines the vertical exchange of all properties in the air layer near the ground. Although the value of A is of greatest importance for the understanding of the total heat and water balance at the ground, only a few measurements of A in the air space near the ground are available.

The measurement of A is accomplished by the simultaneous observation of the short-period fluctuations of a meteorological element (temperature, momentum, water-vapor content) and its vertical gradient. This method assumes that, for example, with a very unstable temperature stratification a relatively warm air particle comes from below, a relatively cold one from above. Since the same mixing process exchanges all properties simultaneously, it might be expected that, at a given place and time, the same value of A would be found independently of the meteorological element that is employed for the determination of the magnitude of A. This universal character of the austausch forms the basis of many computations of the heat balance of our earth. However, more recent measurements show that quite different values of A are obtained when different elements are used. Thus, the austausch proceeds in a different manner for the different elements (unless the differences are attributed to the properties of the instrumental arrangement). None of the several explanations found in the literature is completely satisfactory.

Frankenberger [8] made simultaneous measurements of the microstructure of the horizontal and vertical wind speed by means of a very sensitive instrument and showed that there exist two entirely different types of austausch motion. As regards the magnitude of this motion, he proved not only that faster air particles come from above, slower ones from below (which represents vertical motion promoting aus-

tausch), but that in more than one-third of the cases faster air particles come from below, slower ones from above. The latter motions impede austausch and increase, rather than diminish, the existing gradient. Future measurements of A must, therefore, be made separately for the two types of vertical austausch motion. This makes the measuring technique even more difficult. Nevertheless, all heat and water vapor problems of the air layer near the ground will not be solved unless an exact and, from the practical point of view, not excessively difficult determination of the quantity A is made possible.

Contour Microclimates. Another group of microclimates is caused by topographic formations. The differences between sunny and shady locations or between valleys and mountain peaks which are known in large-scale climatology occur even in minute dimensions. An anthill of some 10-cm height, for instance, with its conical shape, possesses all the climate typical of slope locations, even though only within the air layer immediately adjacent to the surface: there is a warm, dry, south side (which the ants systematically use for breeding) and a shady, cool, moist, north side. Typical differences between east and west are also observed; in the case of uniformly incident radiation on cloudless days these differences are caused by the fact that the morning sun serves primarily to dry out the ground, while the afternoon sun mainly serves to heat it up.

Plowed furrows represent mountain chains on a small scale; the corresponding microclimate is determined by the orientation of these furrows. Kaempfert [17, 18] has investigated the radiation conditions for this case in detail. Variations are occasionally visible in the form of differences in the variety of weeds growing on the two sides of the furrow. Every large rock represents a climatic divide on a small scale. Ullrich and Mäde [34] even found that the air, which is stratified in curved layers during the night, reveals a temperature stratification, in millimeter dimensions, entirely analogous to the temperature distribution in flat valleys.

A continuous range of intermediate conditions exists between these small-scale phenomena and the large-scale climatic differences observed by the mountain, valley, and slope stations of meteorological observation networks. Frequently, however, the laws of microclimatology are different from those applicable to large-scale climatology. For instance, in the case of high mountains located in a region of predominant west winds the west slopes are rich in rain because here the water vapor in the rising air is forced to condense. In the case of low hills, on the other hand, such thermodynamic processes have no effect. On the contrary, in this latter case the east side is the more humid because the field of motion of the wind determines the distribution of precipitation. Precipitation is lacking on the windward side of obstacles. During snow this can sometimes be observed directly, but it should not be confused with the redistribution of already fallen snow by the wind. We do not know as yet just where the line between "large-scale" and "small-scale" is to be drawn in this sense.

The effect of exposure on the microclimate is also determined decisively by the large-scale climate. In tropical regions where the sun is almost vertical at noon there is little variation between differently oriented slopes. The variation increases with decreasing height of the noon sun, that is, with increasing latitude. On the other hand, it is only the direct radiation from the sun which produces differences due to the direction of exposure, while diffuse radiation from the sky affects all slope orientations almost equally. The portion of total radiation which is diffused increases with latitude; differences in exposure are consequently decreased again in polar climates. In the far north, where there is a deficiency of heat, plants flourish only on southern slopes. In subtropical steppes, on the other hand, where there is a deficiency of water, it is often found that microclimatological conditions are adequate for plant growth only on the north side of rocks or hills.

Mountain and valley winds are known to arise locally in mountainous regions. They frequently make the microclimate *dependent*. A microclimate is referred to as *independent* if it can be explained solely on the basis of local meteorological conditions; it is *dependent* if it is determined also by extraneous effects in surrounding regions. This distinction is essential to a rapid and complete understanding of the various microclimates. A field immediately adjacent to a concrete road, or a meadow next to a pond, has a different microclimate than it would have if situated in surroundings of the same type. In any territory it is the wind peculiar to the time of day which makes extraneous effects felt over wide regions. This is particularly true of night winds, which move cold air toward depressions in a slow but steady flow persisting during the entire night. Local pools of cold air result, an example of which has already been offered in Table I. They are decisively affected by the "source regions," that is, the space from which cold air can be supplied. Railroad embankments, hedges, and forests are sufficient to stop or deflect these shallow cold air masses; underpasses, excavations, or gulleys may cause them to drain off. This explains the fact that forests are located everywhere above the vineyards along the Rhine; these forests prevent cold air from flowing down into the vineyards during the frost period in spring.

A normal decrease of temperature with altitude and the accumulation of cold air in valleys are responsible for the fact that a "thermal belt" is found to extend along a line halfway up most slopes; it is here that plants sprout earliest in the spring, that damage due to late frost is slightest, and consequently that the plant and fruit varieties most sensitive to climate thrive. Table III lists measurements made at twenty-four observation stations on the east slope of the Arber (Bavaria) during spring nights in 1931 and 1932. Here the thermal belt is located at about 820 m above sea level during radiation nights (continental winds); during west-weather nights (maritime winds) it is situated several decameters lower. The last column shows the

frequency with which the thermal belt can be found at certain altitudes. The maximum (16 per cent) in the valley (660 m) includes the cases of stormy weather

TABLE III. THERMAL BELT ON THE EAST SLOPE OF THE ARBER, BAVARIA
(Summary of Measurements Made at 24 Observation Stations)

Altitude above sea level (m)	Temperature minimum		Frequency of inversion (%)
	36 spring nights with continental breeze (°C)	24 spring nights with maritime breeze (°C)	
860	8.2	6.5	10
820	9.0	7.0	45
780	8.2	7.4	17
740	6.8	7.0	6
700	5.3	6.5	6
660	4.1	6.1	16

when no thermal belts were formed and consequently, in view of the normal temperature gradient, the foot of the valley was warmest. Otherwise, however, the highest night temperatures were found regularly at altitudes of about 820 m. Such facts are of the greatest importance in farming and fruit growing.

Microclimates in the Vegetation Layer. An intimate mutual dependence exists between a plant and the microclimate within the stand of vegetation. As soon as a young sprout has pierced the ground and developed its first leaves, it is no longer passively subjected to climatic conditions, but helps to form them. The surface is uniformly roughened. The air layer near the ground becomes more quiet, plant organs absorb radiation from the sun, casting a proportionate amount of shadow on the ground. Incident heat radiation is distributed vertically, extremes of surface temperature are decreased. In order to live, the plant must evaporate water which it obtains, if necessary, from layers deep below the ground. Humidity is thereby increased and then maintained nearly constant in the layer of stagnant air near the ground.

Microclimate is affected to an even greater extent by an entire society of plants. It is well known that plant societies grow more vigorously as soon as single plants have become large enough to touch the leaves of their neighbors. This is primarily due to the effect of the change in microclimate which also exerts a favorable influence on the nature of the soil. Research has been initiated during the past few years to investigate the dependence of these conditions on the type of plant, the density of planting, and the cultivation of the soil. This will offer the farmer, gardener, and horticulturist numerous artificial methods by which the growth of plant societies and their yield can be improved.

In high, close-knit plant societies, most clearly in the case of forests, new conditions arise because of the fact that an independent microclimate develops in an enclosed air space, separated from the free atmosphere. The ground surface has become a secondary boundary. Transfer of heat and water vapor takes place almost exclusively at the surface of the plant society. The interior climate is characterized by the fact that all meteorological quantities change very slowly, air humidity is high, the air is extremely quiet, and temperature conditions are moderate. This microclimate can often be understood most readily if one conceives of the space occupied by the plant society as being part of the ground, and then works with a heat conductivity and air exchange which are larger than within the ground, but very small compared to the conditions in the free atmosphere.

Now every plant society produces microclimates at its periphery which are widely different in nature, depending on the direction of exposure. To a first approximation, these can be compared with the corresponding microclimates near vertical walls. However, the analogy is not entirely accurate, in view of the fact that air exchange takes place between the interior climate of the plant society and the peripheral climates. In forestry these peripheral climates have been exploited for about a century to favor young forest growth. Young forests are raised in the climatic protection of old forests. The effect of peripheral climate, however, is not always favorable. At a southern periphery it may become too dry and hot, whereas a northern edge may be too shady; at an eastern periphery plants may be deprived of dew too soon. Frequently the danger of late frost is increased because of the forced quiescence of air near forests, particularly where plants have been stimulated to early sprouting, as at southern peripheries. These microclimatological conditions, which are known and exploited in practice, have hardly been investigated scientifically so far. Work in this field seems very promising. In particular, questions concerning the extent to which experience gained in one forest range can be applied to another region cannot be decided without a scientific basis.

APPLICATIONS AND FUTURE PROBLEMS OF MICROCLIMATOLOGY

Agriculture and Microclimatology. No branch of economics is associated with microclimatology as intimately and in as many ways as agriculture and the related fields of horticulture, viticulture, and fruitgrowing. Preceding sections have shown that the location environment of all cultivated plants depends upon the microclimate and the way in which it is affected by topography, surroundings, soil treatment, and the type of plant. An agriculture designed for maximum yield must therefore be based on a knowledge of and an expedient control of microclimatological effects. Without microclimatology it is not possible to deal effectively with the three major problems which face farmers all over the world. These are (1) wind protection, (2) frost protection, and (3) artificial watering.

The problem of *wind protection* has been comprehensively treated in the international literature. However, the present state of our research is very unsatisfactory because many occasional observations, but few systematic experiments, have been made. Distinction must be made between the changes of the wind field, which are caused by the measures taken for wind protection, and the effect of these changes on the microclimate and the harvest yield.

The changes of the wind field depend on the height, width, substance, and arrangement of the shelter belts. Most recently, the best pertinent investigations were carried out by Naegeli [22–24] in Switzerland from 1943 to 1947. Thus far, the following results are certain: An obstacle of height h reduces the wind speed at 1 ½ m height above the ground (or plant surface) by at least 10 per cent; the distance to which this effect is felt amounts to about $5h$ to the windward, about $25h$ to the leeward. The effect is almost independent of the wind speed; also the protective effect decreases only slightly up to the height h. Within the sheltered area, the distribution of wind speed is always nonuniform. Directly behind the shelter belt, the reduction of wind speed is greatest and amounts to 60 to 80 per cent. Easily penetrable obstacles always produce a better effect than do impenetrable obstacles (walls, very dense pine hedges). The minimum width of the shelter belts is determined by the requirement that the wind-breaking effect must be fully realized. (Otherwise, the width of the belts is determined by silvicultural and botanical considerations.)

The effect of artificial wind protection on the harvest yield does not depend directly on the changed wind field but on the changed microclimate. The macroclimate, the local features, and the existing weather conditions determine the reaction of the microclimate to the changed wind field. However, the same change of the microclimate may have an entirely different influence on the harvest yield. For example, in a semiarid area (such as the Ukraine) the reduction of evaporation by wind protection will improve the water balance and increase the harvest yield. In a humid marshland near a stormy coast (such as parts of Holstein), on the other hand, the reduced evaporation can be detrimental to the harvest. For this reason, harvest statistics are hardly a suitable approach to the microclimatic problem of artificial wind protection. In order to study the microclimate in a wind shelter, not only wind measurements, but, especially, simultaneous measurements of the heat and water balance are needed (radiation, temperature, humidity, evaporation, dew formation, austausch coefficient). This could best be achieved by strictly comparable observations made over a period of several years under different conditions of wind protection in an experimental field whose construction and equipment is reserved for this purpose. With increasing population of the earth and increasing utilization of the soil, the problem of artificial wind protection will become more urgent in the future. Microclimatological research should, in anticipation, prepare the necessary material.

The problem of *frost protection* is a different matter. Today, we are well informed regarding the possibilities of artificial frost protection. Kessler and Kaempfert [20] have summarized in their work all the necessary fundamentals. Only the measurements of the radiation balance within and without the artificial smoke clouds should be extended. Otherwise, the problem of frost protection is only a question of economic feasibility. This depends entirely on the location, the climate, and the market for the fruits which are grown. In the individual case, the microclimatologist must, above all, furnish statistics on the frost probability. Such statistics are the most important basis for the computation of the economic feasibility and must take into consideration the microclimate of the object to be protected.

As with the problem of wind protection, *artificial irrigation* assumes increasing importance. Irrigation was originally employed to help avoid crop failures. Today, however, it generally serves to increase the crop yields by offering the most favorable growing conditions to the plants. In some instances, irrigation makes possible multiple crops in a single growing season, where otherwise the natural aridity would prevent this (for example, the secondary crop yield in western Europe).

In localities where water for irrigation is not available in unlimited quantities, the timing and the amount of irrigation must be adjusted to the weather and climatic conditions. The effect of irrigation by day is different from that by night, because of varying temperature and humidity conditions in soil and air, and because of the varying temperature differences between the irrigation water and the plants. Likewise, frequent small amounts of water have an effect different from infrequent large amounts. Moreover, the plant in its various stages of development has a different sensitivity to water deficiencies. Also it is not yet certain what portion of the irrigation water returns through the soil to the ground-water table so that it is really not lost to the water balance of the land. This consideration is of great importance in countries in which conflicting interests in water (for household, industrial, shipping, and hydroelectric use) have arisen. All these questions can be answered only by carefully designed experiments. Work on these problems already has been initiated, and it is to be hoped that the status of microclimatology will soon be rapidly advanced.

Of importance, moreover, to future work is a microclimatological mapping project. There are agricultural maps which serve to give a general picture of the quality and yield of the soil (also used for the just assessment of taxes) and the possibility of planting various products; similarly, there is an increasing desire to map microclimate in an analogous manner. In 1948 Weger [35] mapped a vineyard region near Geisenheim on the Rhine from this point of view for the first time. In the same year Schüepp [30] in Switzerland mapped the possibility of raising potatoes in the Davos valley by distinguishing eight zones with different degrees of microclimatological frost incidence. Schnelle [28] is currently mapping large valleys in the Odenwald (Germany) in order to determine microclimatological conditions affecting fruitgrowing. These maps are to serve as the basis for a systematic expansion of fruit production and are held in high esteem by men engaged in practical work. All of these first attempts at mapping are thus connected with particular economic tasks, and they are therefore concerned with only a selected few of the microclimatological factors considered. The success achieved justifies a continuation of these

investigations. They provide the most effective methods of combating climatic damage; as W. J. Humphreys once said with regard to fruitgrowing, "The best time to protect fruit from frost injury is before the orchard is set out; obviously by carefully considering what kind, or even variety, to grow and where to grow it."

Often the farmer makes use of the artificial microclimate inside a greenhouse. In general, greenhouses are still being constructed extensively according to traditional practical experience. Investigations by Mäde and Kreutz concerning greenhouse climates reveal the extent to which microclimate depends on the materials and the methods of constructing and erecting various types of greenhouses. Air humidification by spraying has opened new possibilities of climatic control. Great progress is yet to be expected from systematic investigation along these lines.

After a farmer has brought in his harvest, the durability and quality of his product are determined by the microclimate of barns, shocks in the open air, silos, and storehouses. In the American occupation zone of Germany farmers are currently being advised by radio, on the basis of microclimatic measurements in experimental shocks, when they should ventilate their shocks or cover them more thoroughly. This practice has contributed greatly to the preservation of agricultural products. The health of dairy cows, hogs, etc., and the work capacity of animals depend on the microclimate of stables. Here also, research is in its infancy and these factors are only beginning to be considered in the design of stables.

The additive effect of changes in microclimate can influence the fertility of an entire country. The elimination of innumerable small and minute windbreaks is known to have laid waste entire regions. The cultural planning of cities and industrial areas has caused disorder in the hydrology of many a region. Fortunately, however, opposite instances are not lacking. Thousands of small hedges have afforded wind protection which increased agricultural yield and even improved large-scale climate. An interesting new example is offered by work done in Yakut in Siberia (Keil [19]). In 1939, under the pressure of war, workers began to clear large areas of a cushion of moss which had formerly served as a heat insulator and had consumed much heat by evaporation. The exposed soil now absorbed heat from the sun. The frozen soil thawed to a greater depth from year to year; soon the first agricultural plants began to thrive. The virgin soil bore a good harvest. Today the region in question supports a large population, and this success was actually achieved by the application of microclimatological experience.

Phenology as an Auxiliary Science. Phenology is currently developing into an important auxiliary science of microclimatology (Schnelle [28]). Phenology of plants concerns itself with the chronology of plant growth and its dependence on weather and climate. Suitable plants are used to observe the visible stages in growth, such as the development of the first leaves in spring, the first blossoms, the ripening of fruit, and the discoloration of foliage. Numerous observers, in Germany sometimes as many as ten thousand farmers, gardeners, etc., make systematic entries in this "phenological network."

The plant is thus used as an instrument for meteorological observations. This procedure has the advantage that, with a judicious choice of plants, a large number of widely scattered observation points are obtained. In addition each plant reacts to the sum of all meteorological factors at its location near the ground (heat, rain, radiation, wind), thus representing a microclimatological instrument. The disadvantage of the method is the fact that every plant, as a living organism, is an individual. Not only are different plant varieties affected differently by given weather conditions, but a different behavior is shown by every specimen of a single species. This disadvantage can be compensated by the choice of particularly suitable varieties and by the observation of a large number of single plants. Wild plants are more suitable than cultivated plants because the development of the latter may still be affected by cultivating methods such as choice of the time at which seeds are planted, treatment of the soil, or fertilization.

As early as fifty years ago Ihne [15] prepared maps showing the arrival of spring in a region on the basis of such systematic phenological observations. These maps represent a survey of orographic microclimates on a correspondingly large scale. In judging the microclimate of a region it is therefore advisable to observe the development of the plants very closely. Such observations supplement a small number of accurate measurements made with the psychrometer and anemometer and aid in interpolating microclimatic data between points at which climatic conditions have been accurately determined by ordinary observing stations.

Forestry and the Microclimate. A threefold connection exists between microclimatology and forestry. Young forest growth develops either on large cultivated areas, in which case it is subject to local microclimatic conditions as are agricultural plants, or else it grows by natural seeding or is planted by a forester at the edge or in the midst of the mother forest. The section on "Microclimates in the Vegetation Layer" already described the effect of all silvicultural measures on the microclimate of locations. Microclimatology is thus an auxiliary science of forestry.

Secondly, the effect of weather damage in forests depends to a great extent on local conditions. Wind damage always begins at the weakest point. The practice of eliminating such danger points by silvicultural measures requires a knowledge of the meteorological wind conditions. Topographic and vegetative obstacles must be considered in this connection. Snow damage and frost damage are also greater for certain tree formations than for others. The effect of a drought depends upon the method of planting, the mixture of tree varieties, and the treatment of the soil. Even forest fires require certain conditions of the ground and the undergrowth which can be affected by cultivating techniques. The macroclimate and the location of the forest in question determine which kind of weather damage

is most to be feared. The practical forester must consult with the microclimatologist in an effort to prevent such weather damage or at least to reduce it to a minimum.

Thirdly, the microclimatologist aids in combating insect damage in forests. Insects breed partly in the ground, partly in forest litter, and partly in the trunks or crowns of trees. The rate of reproduction of insect pests is determined only by the meteorological conditions prevailing at these locations. In this connection we might quote the English biologist Buxton [5]:

> ...the meteorologist has studied the temperature in a ventilated white screen, [but] the biologist wants to know what differences exist between the forest and the shore, or the rat's hole and the bird's nest: in the white screen he finds no living thing, unless it be an earwig.

Today these microclimates are being investigated to an ever-increasing extent. In connection with pest control by airplane dusting, the distribution of the insecticide and its effectiveness in the infected growth are determined not only by the weather conditions prevailing above the forest, but also by the temperature stratification, air humidity, and field of air motion within the individual forest.

Microclimatology in City Planning and Industry. Every newly built house produces a quantity of opposing special climates. Radiation from the sun which formerly impinged on a horizontal surface is now absorbed by vertical walls and a sloping roof. A radiant, hot, and usually also dry microclimate is produced at the south wall; frequently varieties of fruit thrive in this climate which could normally grow only in a macroclimate many hundreds of miles nearer the equator. The north wall of the house, on the other hand, suffers from a rough, moist microclimate, deficient in radiant heat, of the type usually found in regions nearer the poles. In temperate latitudes of the Northern Hemisphere, the south wall receives a larger total of incident radiation on a clear day in January than it does in July, and consequently the wall climate possesses characteristic traits not found elsewhere. Within the house every room from the basement to the attic has a different climate depending on the exposure of windows, the height of the ceiling, and the size of the room; these climates have been investigated in great detail for bioclimatological purposes. In designing houses and apartments, clinics and schools, factories and warehouses, it is possible to allow for and to influence the microclimate on the basis of previous experience by the choice of location, orientation, and distribution of rooms. Frequently even artificial climatization of rooms (operating and treatment rooms in hospitals, warehouses for perishable goods, shipholds) is possible and necessary.

The over-all effect of buildings which are grouped into settlements, towns, and finally modern cities influences the microclimate to an ever-increasing extent. The climate of large cities is distinguished primarily by a concentration of waste gases from industrial and domestic furnaces as well as of dust; in winter and on quiet days the first predominates, in summer and in windy weather the latter predominates. Parks are most effective in filtering out impurities. The first turbid layer is found above roads, near the ground; a second is found at the altitude of smoking chimneys. Seen from a distance, a large city appears to be surrounded by a hemisphere of haze.

These impurities in the air attenuate incident radiation from the sun and radiation emitted from the ground during the night. A city is therefore warmer at night than the surrounding countryside; this is disagreeably noticeable, particularly on hot summer nights. The decreased amount of solar radiation incident during the day is compensated by intensive absorption by walls and roads and by the absence of heat loss due to evaporation. Consequently the climate of a city is also hotter than its surroundings during the daytime, more so if a city contains few parks. In the absence of a gradient wind this becomes noticeable on clear summer mornings because of the flow of air into the city from all sides (as shown by chimney smoke). Trees in a city consequently begin to sprout earlier and terminate their vegetation period sooner than those in the country.

Impurities present in city air favor the formation of fog and precipitation. London fogs are world-famed. Wherever a sufficiently long series of investigations is on record, an increase in the frequency and density of fog is seen to accompany the growth of a city. Only recently has the increased pollution of city atmospheres been halted by the increased application of electric power and a more efficient use of coal by industry and heating furnaces. Precipitation in the form of drizzle is favored in cities and industrial areas. Occasionally precipitation of larger droplets may be triggered by large cities.

Elsewhere, also, the engineer is constantly creating new microclimates; for example, the pile of tailings from a mine represents an artificial mountain surrounded by a variety of new slope-climates. A railroad embankment or a railroad cut not only creates two new embankment climates, but it frequently also affects the surroundings over a wider range, for instance, by controlling the flow of cold air. A concrete road possesses a microclimate of its own, and the road may also affect the local field of wind flow (*e.g.*, storm damage in forests along roads) as well as the runoff and evaporation characteristics of the soil. It is maintained by some that the destruction of flourishing cultures which occurs again and again in world history may be ascribed primarily to a disruption of the dynamics of nature by the hand of man.

THE METHODOLOGY OF MICROCLIMATOLOGICAL RESEARCH

There are many problems of microclimatological research which still await solution, and the practical applications of this research are almost unlimited.

Techniques learned from general climatology are applicable only to a limited extent. There are two reasons for this. In the first place, it is impossible to measure

the great variety of microclimates by building an ever more dense network of observing stations. Moreover, since the essential characteristics of microclimates are repeated everywhere, it suffices to study them in special experimental areas. This was done, for instance, by Schmidt [27] in Austria with a special climatic network near Lunz, which achieved world-wide fame. Similar networks were previously and subsequently constructed in Germany. The knowledge of microclimatic types obtained in such experimental fields may be applied to unknown regions located in the same macroclimate.

Furthermore, the necessity for working in small spaces requires the creation of a special field of instrumentation to provide instruments which will not affect natural conditions and which are capable of making accurate measurements even near the ground, with inadequate natural ventilation, and often in the presence of intense radiation (both direct and reflected). We might agree with Thornthwaite [31] that "instrumentation remains the basic problem of the investigation." In microclimatology as well as in other sciences, the development of new measuring instruments has stimulated research to advance by leaps and bounds. Thus, in addition to the experimental fields mentioned above, in which geographic considerations are the most essential, microclimatology also requires experimental areas well equipped with instruments, perhaps attached to observatories or universities. An excellent example of such a setup is the laboratory of climatology of the Johns Hopkins University in New Jersey, under Thornthwaite.

Finally, we might point out that it is of the greatest importance to the development of microclimatology that future research be conducted in the largest possible variety of the macroclimates of the earth. Our knowledge has already been extended greatly by the numerous measurements made in India by Ramdas, Ramanathan, and others, as well as by the observations which Haude [2, 14] made during the last Sven Hedin expedition in the Gobi Desert; scattered measurements made in tropical, arid, and arctic regions have raised many new questions. Here lies a great future for basic research in microclimatology.

GEOLOGICAL AND HISTORICAL ASPECTS OF CLIMATIC CHANGE

By C. E. P. BROOKS[1]

Ferring, Sussex, England

THE FACTS AS KNOWN AT PRESENT

The Mild Climates of the Greater Part of Geological Time. The oldest known rocks have been dated by the uranium-lead ratio as having been formed about 1600 million years ago, but the evidences of climate given by these very early deposits are scanty, and it is not until nearly the beginning of the Cambrian period, about 500 million years ago, that a picture of world climate begins to emerge. (The succession of geological periods is shown at the bottom of Fig. 4.) All we can say of the pre-Cambrian period is that at intervals of a few hundred million years glaciers or ice sheets covered various parts of the world; of the intervening periods we can say nothing. From the beginning of the Cambrian onwards our knowledge of the general level and zonal distribution of temperature becomes increasingly detailed, and it is quite clear that climate has alternated between mild and glacial, but that mildness has prevailed for nearly nine-tenths of the time. It seems appropriate, therefore, to begin this review of geological climates with a study of the warm periods. Two epochs may be selected as typical, the Jurassic and the Eocene.

The Jurassic was the age of corals which extended into fairly high latitudes, indicating that in 50°–60°N the temperature of the water in shallow seas was about 60F, or nearly 10F higher than the highest present-day ocean temperatures in those latitudes. Nearer the poles, however, corals were dwarfed or absent, and the general assemblage of animals differed from that in the tropics. This shows that climatic zones existed at that time, though they were less marked than at present. We know less about the climate of the land areas, but numerous salt beds in lake deposits point to a rather scanty rainfall which most probably fell in heavy showers of short duration instead of in prolonged cyclonic storms. There must have been sufficient vegetation to support the dinosaurs and other great land reptiles, but this was probably limited mainly to the river valleys. There is no sign of ice anywhere in the world; even the polar regions were too mild for ice sheets to form, and the absence of mountain ranges prevented the formation of glaciers.

In the Middle and Upper Eocene the climate was generally similar to that of the Jurassic, except that the rainfall of temperate regions was heavier. Land vegetation was abundant as far north as northern Greenland, and Chaney [8] has given us a clear picture of the climatic zones. The most northerly flora known was near Cape Murchison in Grinnell Land (72°N) and included horsetail, yew, pine, spruce, poplar, birch, hazel, and grass—a cool-temperate flora but one which was sufficiently remarkable when we think of the barrenness of the region at present. Everywhere the northern boundary of the temperate flora appears to have been 15° to 20° nearer the pole than at present. At the same time the subtropical flora also advanced northward by about 10° of latitude, extending well into the United States and in places almost reaching the Arctic Circle. The subtropical as well as the polar regions appear to have been warmer than they are today, but the difference decreased from high to low latitudes. The subtropical flora differed completely from that of the Arctic, indicating well-marked climatic zones.

The rainfall of temperate regions in the Eocene probably exceeded the present rainfall. In Europe it occurred mainly in winter and early spring, giving place to a long, hot, and dry summer—the Mediterranean type of climate. The vegetation often shows damage by hail, even quite early in spring, pointing to instability showers. In western United States, however, where the relief was more pronounced, rainfall was more evenly distributed through the year and may have averaged seventy inches.

The picture we form of the climate of middle latitudes during the warm periods is one of mild winters and hot summers, and the absence of cyclonic depressions and gales. The "polar front" as we know it either did not exist or lay far to the north. The subtropical anticyclones lay farther north than now. The arctic basin had prevailing west or southwest winds and mild humid weather with probably a good deal of rain, favouring a rich vegetation. Warm ocean currents extended into high latitudes, and zonal differences of temperature were reduced to a minimum.

Ice Ages. The great "Ice Ages" stand out in sharp contrast to the long mild periods. The climate of large areas of the earth was very severe, but it was also very changeable from one millennium to another. The latest and best-known, the Quaternary Ice Age, began roughly a million years ago, and in this (geologically speaking) short period there have been four major advances and retreats of the ice, as well as a number of minor oscillations. It is convenient to distinguish between the *Ice Age* as a whole, and the *Glacial* and *Interglacial Periods* into which it is divided. The details of the latter of these periods are described by R. F. Flint in this volume,[2] but as they are important for the study of the causes of glaciation, they are briefly recapitulated below. In North America, northern Europe, and probably also parts of northern Asia, great sheets of inland ice, thousands of feet thick, spread from high ground over the plains and even crossed the shallow epicontinental seas;

1. Retired from the Meteorological Office, London.

2. Consult "Climatic Implications of Glacier Research" by R. F. Flint, pp. 1019–1023.

ice from Scandinavia, for example, spread over eastern Britain and ice from Scotland occupied northern Ireland. In North America the southern margin of the ice at its greatest extension was everywhere south of the Canadian border and in the Mississippi Valley it reached almost to 37°N. In Europe the Scandinavian ice extended as far south as 50°N, and large piedmont glaciers spread out from the Alps. Mountain glaciers also reached far below their present limits in the Himalayas and the mountain ranges of the U.S.S.R., in the Rockies and coastal ranges of North America, the Andes, and New Zealand, and even on the equator in East Africa. Glaciers formed on many mountains now ice-free, including those in New Guinea and southeastern Australia. The latest estimates of the maximum area occupied by land ice during glacial periods are about 13 million square miles, including 5 million in the Antarctic, 4½ million in North America, 1¼ million in Europe and at least as much in Asia, and over 800,000 square miles in Greenland. The remainder is made up of a number of relatively small areas. The present ice-covered area is about 6 million square miles, almost entirely in the Antarctic and Greenland. In addition there was a great extension of floating ice in the oceans, especially the North Atlantic and probably also in the Antarctic. Altogether, nearly one-tenth of the earth's surface must have been ice-covered.

It is not likely that the ice everywhere reached its maximum extension and thickness simultaneously, since there was undoubtedly some migration of the centres of maximum accumulation. Flint [11] estimates that if the maxima were everywhere contemporaneous, sea level would have fallen by about 390 ft below the present level. This is a maximum figure, and is higher than previous estimates; it would have been considerably reduced by isostatic adjustment due to the weight of the ice. Shore deposits, coral reefs, etc., point to a lowering of sea level by more than 260 ft. The two figures are sufficiently close to provide good evidence that all the major ice sheets were in existence at the same time.

During glaciation, the snow line over the whole world was lowered by an average of about 2500 ft, more in the snowier and less in the drier regions. If this were due entirely to a fall of temperature, it would indicate a world temperature more than 7F below the present level. Probably the lowering of the snow line was due in part to heavier snowfall, but we can safely put the mean temperature at the peak of the Quaternary glaciation as at least 5F below the present.

It is difficult to estimate the mean global temperature at the peak of a warm period. In the Arctic it was enormously higher than it is now, and was probably of the order of 50F, but in lower latitudes the rise was much smaller. A rough estimate of the increase for the world as a whole would be 10F, which is not excessive considering that we are still in an Ice Age, though in an interglacial period. Thus we arrive at a difference of at least 15F as a measure of the contrast between a mild period and an Ice Age; less near the equator and much more near the poles.

Table I. Glacial Sequence, Quaternary Ice Age

	Alps [27] (thousands of years ago)	North German Plain	North America	Dating by Zeuner [36] (thousands of years ago)		
Glacial	Wurm (40-18)	Weichsel Warthe	Wisconsin { Mankato, Cary, Tazewell, Iowan }	Late glaciation	III II I	25 72 115
Interglacial	Riss-Wurm		Sangamon			
Glacial	Riss (130-100)	Saale	Illinoian	Penultimate glaciation	II I	187 230
Interglacial	Mindel-Riss		Yarmouth			
Glacial	Mindel (430-370)	Elster	Kansan	Antepenultimate glaciation	II I	435 476
Interglacial	Gunz-Mindel		Aftonian			
Glacial	Gunz (520-490)	?	Nebraskan	Early glaciation	II I	550 590

The Quaternary Ice Age was not a single uninterrupted episode, but consisted of a number of advances and retreats of the glaciers and ice sheets. Penck and Brückner [27], in their classic researches into the glaciation of the Alps, recognised four main advances separated by recessions to a climate not more unfavourable than the present. A similar arrangement has been found in North America, but in northern Europe the earliest glaciation has not been recognised, probably because its remains were swept away by subsequent more extensive ice sheets. The sequence is shown in Table I. In some areas the Mindel and in others the Riss glaciation was the most extensive; the Wurm was nearly everywhere much smaller. The extent of the Gunz is not well known. The Wurm glaciation included three or four main readvances and the Riss at least

two. There seems little doubt that the main glaciations were contemporaneous on both sides of the North Atlantic. In most other parts of the world only two or three glaciations have hitherto been recognised, but even on the equator in East Africa three separate extensions of the mountain glaciers can plausibly be equated to the Mindel, Riss, and Wurm glaciations. In Kashmir four distinct glaciations have been recognised; the fourth includes four glacial substages. Here the second interglacial period was the longest and the third the shortest.

Penck and Brückner [27] made the first approach to a time scale for the Quaternary glaciation. Their methods were crude but effective, and their results have never been seriously challenged on geological grounds. Their dates, in thousands of years before the present, are shown in the left-hand column of Table I. It may be remarked that de Geer[3] estimated that the Wurm ice sheet left the coast of Germany about 18,000 B.C. The durations of the various glacial periods naturally varied from place to place, being longest near the centres of the ice sheets and shortest near the peripheries. Thus in Iowa and Ohio the latest glaciation ended roughly 25,000 years ago, whereas in Sweden the duration of postglacial time is taken as only 8500 years. Recent estimates quoted by Flint [11] suggest that the durations of the interglacial periods may have been somewhat longer than the figures given by Penck and Brückner.

In the last few years striking evidence of the succession of glacial and interglacial periods has been recovered from the floor of the Atlantic Ocean by the Swedish Deep-sea Expedition under the leadership of Professor Hans Pettersson, using a special "corer" capable of extracting cores up to 50 ft long from great depths. These cores are estimated to include the deposits formed during a period of at least a million years. An account of the results of this investigation is given by Ovey [26]. Glacial periods are represented by beds rich in erratic debris, showing that icebergs drifted at least as far south as 30°N. Interglacial periods are represented by foraminiferal oozes between the beds of debris. The species of foraminifera indicate the temperature of the surface water very clearly; in the tropics the alternation of glacial and interglacial periods is shown by the alternation of layers with cool and warm species.

A core obtained in the Caribbean Sea shows a succession of four "glacial" periods which have been provisionally correlated with the Nebraskan, Kansan, Illinoian, and Wisconsin. The Nebraskan had three substages, the Kansan and Illinoian two each, and the Wisconsin four or five, but the most interesting point is that the second interglacial (Yarmouth stage) was about twice as long as the first (Aftonian) and three times as long as the third (Sangamon).

Pluvial Periods. Outside the borders of the glaciated regions, the rainfall during glacial periods was in most places appreciably greater than at present. In the middle latitudes of the Northern Hemisphere this was no doubt due to the fact that ice sheets deflected the storm tracks southwards, so that the Mediterranean regions, for example, had a rainfall two or three times that at present, distributed fairly evenly through the year. The Mediterranean storms continued into southwest Asia; v. Ficker [10] calculated that at the maximum glaciation the rainfall in northwest Pamir was four or five times greater than that at the present time. The change was most notable on the northern margins of the subtropical deserts: wandering storms penetrated into the Sahara and this area, now desert, was one of the main centres of population. Similar conditions prevailed south of the main ice masses of North America, the lakes of the Great Basin spreading to form large inland seas, the best known of which are Lakes Lahontan and Bonneville [32].

The most remarkable development of the pluvial periods took place in East Africa, near the equator, where a succession of great lakes grew from the union of a number of existing small lakes, left their deposits, and disappeared. The pluvial periods in nonglaciated regions coincided with the advances of the mountain glaciers, and almost certainly represent the glacial periods of Europe and North America. A very early lake left deposits, now fragmentary, termed Kafuan; Wayland [33] thinks that this lake had two maxima separated by a period of earth movements, and he provisionally equates the lake to the Gunz and Mindel glaciations. This was followed, after a long dry interval, by the "Great Pluvial" in which the very large Lake Kamasia was formed; Nilsson [25] equates this pluvial to the Riss glaciation. Lake Kamasia then dried up completely, and at the same time the mountain glaciers disappeared. Then followed a period of renewed lake formation, the Gamblian pluvial, less intense than the Kamasian, since the lakes did not overflow their separate basins. Nilsson distinguishes four successive Gamblian lake systems, probably corresponding to the three maxima of the Wurm glaciation and a late-glacial readvance. Following the close of the Quaternary Ice Age there have been a number of minor fluctuations of lake levels, which appear to correspond with minor advances and retreats of the mountain glaciers, and these fluctuations present a succession very similar to the postglacial history of northern Europe, though the exact correlation is not yet defined.

Closed lake basins are very sensitive to variations of rainfall. From botanical evidence Moreau [23] estimates the average rainfall in the last of the Gamblian (Wurm) stages as 44–50 inches, while during the postglacial dry period, when the lakes dried up completely, it cannot have been as low as 27 inches. The present rainfall in this region averages 37½ inches. On this scale even the Great Pluvial period may have had a rainfall less than twice the present average. Nevertheless these changes indicate climatic disturbances of large magnitude, which are important for the theory of climatic oscillations.

Earlier Ice Ages. Great ice ages have recurred at intervals of roughly 250 million years—the Late Pal-

3. For a general summary of de Geer's numerous papers see *Geogr. Ann. Stockh.*, 16: 1–52 (1934).

aeozoic (Permo-Carboniferous or Permian) about 250 million years ago; the Upper Proterozoic and earliest Cambrian about 500 million; and two or three in the early Proterozoic probably from 700 to 1000 million years ago. The Proterozoic Ice Ages are now represented only by scattered deposits, mostly in temperate regions. Early Cambrian or uppermost pre-Cambrian glacial deposits are found in small areas in the Lake Superior region and possibly in Utah, in the Yantze valley of China, near Simla (India), extensively in South Africa where they extend to within 29° of the equator, and in eastern and southern Australia. This glaciation was apparently similar to but more severe than that of the Quaternary. These early glaciations are chiefly of interest because they effectively dispose of the theories of a cooling earth.

The Late Palaeozoic Ice Age, on the other hand, reached its greatest development in low latitudes on both sides of the equator, but mainly in the Southern Hemisphere. A great continent extending from South America across Africa and India to Australia carried true ice sheets which reached the sea in many places. There were large mountain glaciers in the eastern United States, but at the same time there was a rich valley vegetation in Europe, Asia, and North America resulting in the formation of thick beds of coal, even as far north as Spitsbergen. This peculiar distribution of climatic zones has been a great puzzle to geologists and climatologists, and was one of the chief bases of the theory of continental drift. A plausible explanation can be given in terms of the peculiar geography of the period, but this is deferred until the geographic factors of climate have been considered (see p. 1014).

Between the major ice ages there is occasional evidence of local glaciation, but not all of it is accepted by geologists. The most important of these are (1) late Silurian and early Devonian in Alaska, eastern Canada, South Africa and, possibly southeast of Kashmir, and (2) late Cretaceous and early Eocene in the Cordilleras of North America and in the Antarctic. These periods of glaciation occur about midway between the major ice ages.

Postglacial Climatic Changes. The changes of climate since the last maximum of the Wurm or Wisconsin glaciation are important for the theory of climatic change, because during that period the changes in land and sea distribution and in the elements of the earth's orbit were small. Postglacial climatic changes in northern Europe are summarized in Table II and are based mainly on the study by Movius [24]. The dating is based on the work of de Geer on the glacial "varves" or annual layers of fluvio-glacial sediment.

The retreat of the glaciers took place from the periphery inwards, mostly by melting and ablation. They did not decay at the centre, leaving large masses of "dead ice" at the margins to melt gradually, but continued active until they had nearly vanished. Their retreat was interrupted by three halts or slight readvances, which differed from the main substages of the Wurm only in being superposed on a steady withdrawal. In the Alps, Britain, and Ireland there were similar stages which took the form of definite readvances or even new formation of mountain glaciers. In North America there were similar halts in the recession, but these have not yet been definitely correlated with the European sequence.

Table II. Postglacial Succession in Europe

Date (B.C.)	Climatic stage	Climate	Vegetation
18,000–14,800	Pomeranian end moraine	Arctic	Tundra
10,000–8300	Allerød Oscillation	Sub-Arctic–temperate	Pine, sedge, peat
8300–7800	Fenno-Scandian end moraine	Arctic	*Dryas*
7800–6800	Pre-boreal	Dry, cool	Pine, hazel
6800–5600	Boreal Ragunda stadium 6800–6500	Dry, cold winters, warm summers	Alder, oak, elm
5600–2500	Atlantic "Climatic Optimum"	Warm, humid	Peat, oak, alder, lime, elm
2500–500	Sub-boreal	Drier, becoming cooler, variable	Oak, giving place to pine
500–0	Sub-Atlantic	Cool, wet	Peat, beech

The Scandinavian geologists consider that the Ice Age ended about 6500 B.C., when the last remnants of the ice sheet split into two parts, but by this date the climate of most of Europe had become temperate. Near the periphery of the glaciated areas the Ice Age ended much earlier (about 20,000 B.C.), while Greenland and the Antarctic are still in the Ice Age, so that the choice of the date 6500 B.C. is arbitrary.

The climate of the early postglacial period in Europe was continental, with hot summers and cold winters. In the sixth millennium B.C. there was a change to a warm humid climate, with a mean temperature up to 5F higher than the present mean and a heavy rainfall which caused a considerable growth of peat. This is known as the *Climatic Optimum*. In Scandinavia it was accentuated by subsidence of the land, which permitted a greater influx of warm Atlantic water into the enlarged Baltic known as the *Litorina Sea*, but the Climatic Optimum was so widespread—probably worldwide—that this cannot have been the only cause. Judging by the flora of Spitsbergen, the Arctic Ocean was free of ice.

The sub-boreal climate was peculiar. On the whole there was a gradual decrease of temperature and rainfall from the Climatic Optimum, but this was interrupted by long droughts in which the surface of the peat dried up, followed by returns to more rainy conditions. This alternation occurred several times, the main dry periods falling about 2200–1900, 1200–1000, and 700–500 B.C. The latter, which is termed the "Grenzhorizont," was the best-developed and caused

a widespread interruption in the growth of peat in Europe. It has been described as a "dry heat wave" lasting for perhaps 200 years. Lakes decreased in area and in a few places trees grew on their floors below the level of the outlet. From four such lakes in Ireland, Germany, and Austria it is estimated that the annual rainfall was only about half the present amount. The drought was not sufficiently intense to interrupt the steady development of forests, but it caused extensive migrations of peoples from drier to wetter sites. About 1300 B.C. there was a period of heavy rainfall and floods which destroyed some of the Alpine lake villages.

About 500 B.C. there was a great and rapid change to a colder and wetter climate. Over large areas the forests were killed by a rapid growth of peat. The levels of the Alpine lakes rose suddenly, flooding many of the lake dwellings, and most of the mountain area became uninhabitable, the few settlements being limited to the warmest and driest valleys. Traffic across the Alpine passes, which had continued steadily since 1800 B.C., came to an end. As many of the peat bogs formed during this period are now drying up, it seems that the rainfall of this sub-Atlantic period must have been greater than at present. This change of climate was by far the greatest and most abrupt since the end of the Ice Age, and its effect on the civilisation of Europe was catastrophic. It did not last long, however, for by the beginning of the Christian era conditions did not differ much from the present.

Our knowledge of postglacial conditions in other parts of the world is less detailed, but the climatic changes appear to have run closely parallel. In Asia and northeast Africa the evidence consists mainly of the migration of whole peoples, and of the occupation and abandonment of marginal sites, where under average conditions there is only just enough water to support life. In North Africa, West and Central Asia, and China there was a wet period between 5000 and 4000 B.C. In China the cultivation of rice extended about five degrees north of its present boundary, pointing to a higher temperature. This warm wet period was followed by a period of gradually increasing drought which culminated about 2200 B.C. Conditions remained dry until 1900 B.C., when there was a "complaint" that the marshes of the Nile delta had dried up and the river could be crossed on foot, presumably during the low-water stage. Then followed a period of fluctuating rainfall, with another drought which the Chinese records place between 842 and 771 B.C. Migration and war almost ceased after 500 B.C., when caravans crossed deserts which are now almost impassable. A passage in Herodotus suggests that the level of the Caspian Sea stood much higher than now, and there is evidence of abundant water supply in Egypt and in the Saharan oases. On the whole, however, the case for a great increase of rainfall about 500 B.C. is not so strong in Asia and North Africa as it is in Europe.

There is abundant evidence of postglacial climatic change in North America, but until the tree rings take up the story about 1000 B.C., the dating is uncertain. In eastern North America the rate of recession of the ice sheets at the close of the glaciation ran parallel with the recession rate in northwest Europe, and the peat bogs show similar alternations of wet and dry periods; there seems no reason to doubt that the changes were approximately synchronous. Hansen [12] gives the following succession:

Eastern North America	*Northwest Europe*
Ice retreat (Hudsonian)	Late-glacial
Spruce, fir (cool, moist)	Pre-boreal
Pine (warmer but still cool)	Boreal
Oak and hemlock (warm, moist)	Atlantic
Oak and hickory (warm, dry)	Sub-boreal
Oak, chestnut, spruce (cooler, moister)	Sub-Atlantic

The history of the lakes of the Great Basin, described by Jones [32] and van Winkle [35], points to a long dry period which, according to the salt content of the lakes, ended some time between 2000 B.C. and A.D. 0. This period was brought to an end by a rainfall greater than that of the present and was followed by a gradual decrease.

The evidence of the tree rings is unfortunately doubtful, as comparatively few trees date from before 500 B.C. The curves drawn by Huntington and Antevs [32] both indicate a wet period which had definitely begun by 660 B.C. and reached an absolute maximum between 480 and 250 B.C. All these facts are in sufficiently good agreement with the dating of the sub-Atlantic in Europe at 500 B.C.

The fluctuations of the lakes in equatorial Africa appear to run parallel with the alternations of wet and dry periods in Europe, though they cannot be dated precisely. On the other hand, in the dry subtropical regions south of the main storm tracks the evidence for climatic change is much less definite. In the temperate parts of the Southern Hemisphere the postglacial variations of climate appear to have been generally similar to those of the Northern Hemisphere, but they have not yet been dated. In southern New Zealand the Climatic Optimum is represented by lowland rain forest, indicating increased rainfall and higher temperature, but in the southern Argentine in the rain shadow of the Andes the increased warmth was accompanied by greater aridity.

Climatic Changes during the Christian Era. After the beginning of the Christian era we have an increasingly detailed and accurately dated knowledge of climatic changes. The evidence includes fluctuations of lakes and rivers, growth of peat bogs, succession of floras, rate of growth of trees as shown by annual rings, advances and retreats of glaciers, locations of settlements and migrations of people (for which climatic reasons may be assigned with some show of probability), literary records and old weather journals, and finally instrumental records. The results of this great mass of detail, summarised in Table III, show that climatic oscillations are not entirely local events but tend to fit together into a world pattern. Asia and western North America tend to vary together; Europe partly varies with them but has changes of its own in addition. North Africa, represented principally by the Nile valley, varies partly with and partly against Asia. An opposition between the temperate and subtropical regions is shown more clearly in Yucatan, as was first pointed

out by Huntington [15]. At present that country is covered by dense forests and the hot moist climate is enervating and inimical to a high culture. Buried in the forests are the ruins of magnificent Mayan cities, and it is inconceivable that these could have been built under present conditions. The first period of culture lasted from about 400 B.C. to A.D. 300. From A.D. 300 to 450 the forest encroached from the south, and from 450 to 900 it extended over the whole country; culture declined to a low level. There was a climatic recrudescence from 900 to 1100, deterioration from 1100 to 1300, and a slight improvement from 1300 to 1450, after which conditions were continuously unfavourable. The dry periods in Yucatan coincide almost exactly with the rainy periods farther north.

Table III. Climatic Variations during the Christian Era

A.D.	Europe	Asia	Western North America	Africa
0	As present	Slightly rainier than now	As present	Good Nile floods
100	Somewhat drier	Rainy		Drier
200	Rainy			
300		Dry	Dry	Rainier
400		Less dry Caspian −15 ft	Dry	Rainy
500	Drier	Dry		Rainy
600	Rather dry		Slightly rainier	
		Rainfall increasing		Rainy
700	Dry, warm	Rainy	Drier	Drier
800			Dry period ended	Dry
	Rainier	Rainy in China		
900		Caspian + 29 ft	Rainier	Rainier
	Drier		Slightly drier	
1000	Colder	Dry in China	Very rainy	Drier
1100	Heavy rain	Dry Caspian −14 ft	Dry	Very dry
1200	Rainy Very stormy	Dry Rainfall increasing	Dry	Rainy
1300	Glacial advance, drier	Rainy, Caspian, etc. high	Rainy	Rainy
1400	Glacial min.	Dry in China	Dry	Rainy
1500	Oceanic Continental	Rainy, Caspian +16ft		Rainfall maximum
1600	Rapid advance of glaciers	Rainy Caspian +15 ft	Rainier	Drier
1700	Dry in west Glacial max.	Near present Caspian rather high		
1800	Cold, rainier		Rainy	
1900	Rapid retreat of glaciers	Caspian falling	Drier	

The dry periods in Yucatan coincide almost exactly with the rainy periods farther north.

Special mention must be made of the advance of the glaciers in the Alps, Scandinavia, and Iceland, which began near the middle of the 16th century and was so striking that it has come to be known as the "Little Ice Age." It may be divided into six periods:

1. First advance, A.D. 1550–1650 (first maximum). About 1605, glaciers overran settlements which had been occupied since early days.
2. Recession, 1650–1680, followed by fluctuations about a generally small extent until 1715.
3. Rapid advance to a maximum about 1750–1760, which in many districts marks the greatest extension of glaciers since the Ice Age.
4. Retreat until about 1790, but with fluctuations.
5. Advance to a third maximum about 1850, with a minor maximum about 1815.
6. General retreat, interrupted about 1890, then becoming increasingly rapid. In Norway and Iceland the glaciers have not yet retreated to the positions they occupied in the 14th century.

Generally speaking, the glacial advances were associated with cold winters and cool springs, and the retreats with strong westerly winds and a mild maritime climate. The variations do not appear to be related to variations of total precipitation, but most probably indicate variations in the length of the period of ablation.

Similar but less accurately dated fluctuations have occurred in glaciers in other parts of the world. In Spitsbergen they reached a maximum about the middle of the 19th century and have since retreated or become stagnant. The marginal glaciers of northeast Greenland have been receding since the late 18th or early 19th century. Alaskan glaciers for the most part reached maxima in the 18th or 19th century and have since receded, but some are still advancing, probably because their sources are at considerable heights.

The broad pattern of climatic change since the end of the Ice Age is consistent with the hypothesis of an alternate weakening and strengthening of the planetary atmospheric circulation, associated with a poleward and equatorward shift of the wind zones. At times of minimum circulation the circumpolar vortex is contracted and anticyclones are frequent in middle latitudes. Winds are variable, rainfall is small, and climate continental, with cold winters and hot summers. This was the general situation during the long dry period from about A.D. 400 to 1000. When the circulation is stronger, westerly winds predominate, rainfall is

heavier, and climate more oceanic. The shifts of the wind zones may have been associated to some extent with fluctuations in the ice-covering of the arctic seas. References in the works of classical geographers suggest that near the beginning of the Christian era Iceland was icebound. During the period of the Norse colonisation of Greenland there was little ice, but glacial conditions returned about 1200 and remained predominant throughout the "Little Ice Age"; they are now improving. The parallelism is not exact, however, and in the past 2000 years it is more likely that the variations of atmospheric circulation have governed the variations of arctic ice than that the reverse is the case.

THEORIES OF CLIMATIC CHANGE DEPENDENT ON EXTERNAL INFLUENCES

Variations of Solar Radiation. The most obvious reason for climatic changes is that the radiation which the earth receives from the sun varies with time. It has frequently been suggested that ice ages were due to decreased solar radiation, either because the sun emitted less radiation, or because some obstacle such as a cloud of cosmic matter was interposed between the sun and the earth. Conversely, the warm periods were attributed to increased solar radiation. In 1929, however, Simpson [30] argued that glaciation should result from an *increase* of solar radiation.

Simpson's theory is, briefly, that glaciation depends not so much on temperature as on an excess of snowfall over melting. The total precipitation over the earth as a whole must equal the total evaporation, which in turn depends very largely on the solar radiation. In high latitudes and at high elevations most of the precipitation falls as snow. Now consider the effect of two cycles of solar radiation (Fig. 1). Starting with a minimum of radiation most of the precipitation falls as snow, but the total amount is small. As the radiation increases, the proportion of snow to rain decreases, but at first this is more than counterbalanced by the increase of total precipitation, while summer melting is still unimportant. At this stage there is an accumulation of snow, resulting in glaciation. Eventually, however, the rise of temperature due to increased radiation reaches a stage at which the actual amount of snowfall begins to decrease and is exceeded by the summer melting. The glaciers and ice sheets break up and a mild rainy interglacial sets in. As the radiation passes its peak and decreases, the process is repeated in the reverse direction, bringing another glaciation, but eventually the decrease of precipitation starves the glaciers and ice sheets, causing a second interglacial, but this time with a cold dry climate, which persists until another increase of solar radiation begins a new cycle.

Simpson considered that the stage of glaciation is rather near the peaks of the solar cycle, so that the warm moist interglacials were short and the cold dry interglacial was long, giving the well-known Alpine succession (p. 1005). In low latitudes each solar cycle is represented by a single cycle of rainfall, giving two pluvial periods covering respectively Gunz plus Mindel and Riss plus Wurm.

The facts do not entirely support this theory. The Mindel-Riss interglacial was not cold; at its height Europe and North America were warmer than at present. In East Africa the Riss and Wurm were not combined and Wayland [33] thinks that the first pluvial also was double. A third objection, that there is no physical reason for the existence of a cycle of solar radiation of the order of 500,000 years, has been partly met by Hoyle and Lyttleton [13], who showed that the passage of the sun through a cloud of interstellar matter would cause an increase of solar radiation.

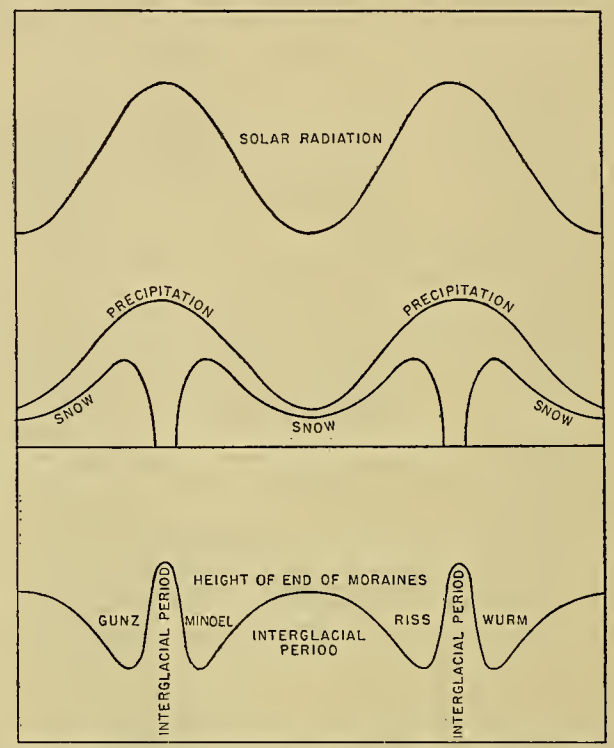

FIG. 1.—Effect of two cycles of solar radiation on glaciation. (*Reproduced by courtesy of Sir George Simpson and the Manchester Literary and Philosophical Society.*)

Willett [34] has pointed out that some of the objections to Simpson's theory are removed if we suppose that the Quaternary represents four solar maxima instead of two, the radiation never reaching the level necessary for a warm interglacial, and also that the cycle of radiation takes place mainly in the ultraviolet.

Another theory of solar control was put forward by Huntington and Visher [15]. There is some evidence that when sunspots are numerous and large, the storm tracks are displaced towards the equator and the climate of the earth as a whole is stormier, rainier, and cooler than at times of sunspot minimum. Since observations began, sunspots have varied, not only in the well-known 11-year cycle, but also over much longer periods, reaching a high maximum about 1372 and being almost absent from 1676 to 1725. Huntington and Visher suggested that there have been sunspot cycles of geological length, associated with changes in the distances of the nearest fixed stars, and that these have caused the geological changes of climate. This

theory raises many difficulties, and it breaks down completely over the Late Palaeozoic glaciation. It is true that the variations in the rainfall of the north temperate zone since A.D. 1000 have run fairly parallel with the variations of sunspots, but the geological variations of climate were on a scale many times greater and would require enormous and prolonged sunspot outbursts which seem quite improbable.

Changes of solar radiation could account for some, but not all, of the postglacial changes of climate. It is difficult to find any other explanation for the warmth and heavy rainfall of the Climatic Optimum, but the rainfall maximum about 500 B.C. was accompanied by a *fall* of temperature. The alternating halts and retreats of the late glacial period could have been due to solar changes, but other explanations have been put forward. Lewis [21] considered that a glacial period could be initiated by a comparatively small increase of precipitation, which might be due to the temporary diversion of an ocean current, and that once the ice sheets reached a size sufficient for the development of a glacial anticyclone, they grew by a "runaway" process until the increasing loss of solar energy by reflection from the ice and snow lowered world temperature, and consequently the precipitation level, below the subsistence level of the ice sheets. In this connection the recent recession of the glaciers of the "Little Ice Age" is especially interesting. By comparing the decrease in the volume of ice since 1850 with the rise of sea level, Ahlmann [1] found that the recession had been confined to the marginal glaciers, the central ice sheets of Greenland and the Antarctic being almost untouched. There has been no appreciable decrease of snowfall, so that the recession must be due to increased ablation. In the marginal areas ablation is due mainly to heat conduction from warm air, that is, to a stronger atmospheric circulation. On the main surfaces of the ice sheets ablation is due to solar radiation, and Ahlmann infers that the warming of the Arctic is associated with an increased atmospheric circulation without any appreciable change of solar radiation.

Changes in the Elements of the Earth's Orbit. With constant solar radiation, the heat reaching the outer limit of the earth's atmosphere in a year remains practically constant in any latitude, but the seasonal distribution changes. There are three variables:

1. The obliquity of the ecliptic, or the angle which the plane through the equator makes with the plane of the earth's orbit round the sun. The greater the obliquity, the greater the contrast between the heat received in summer and winter. Milankovitch [22] calculated the variation as $2\frac{1}{2}°$ in a period of 40,400 years; the last maximum was about 8000 B.C.

2. The eccentricity of the earth's orbit, which varies from 0.0 to about 0.07 in a period of 100,000 years. The hemisphere with winter in aphelion has a short hot summer and a long cold winter, that with winter in perihelion has a short mild winter and a long cool summer. At present the Northern Hemisphere is in perihelion in winter, but the excess of land quite outweighs the solar effect.

3. The precession of the equinoxes, by which the season in which perihelion falls advances through the year in a period of 21,000 years. About 8500 B.C. the Northern Hemisphere had winter in aphelion and a more extreme solar climate than now.

Many attempts have been made to account for the succession of glaciations by these astronomical changes. The early theories, such as that of Croll, require alternate glaciation in the two hemispheres; they were unsound meteorologically and the astronomical dating did not agree with the geological time scale. These defects in the theory have been overcome to a large extent, and the latest exposition, by Zeuner [36], is *qualitatively* in good agreement with the facts. Zeuner shows that the variation of the present snow line with latitude follows closely the variation of radiation in the summer half-year. A rise of winter temperature increases the snowfall and the corresponding decrease of summer temperature enables the snow cover to persist through the year. Hence small obliquity with high eccentricity and summer in aphelion lead to glaciation. Zeuner's dating of the various glacial stages is shown on the right of Table I, and is seen to agree reasonably well with the estimates by Penck and Brückner.

Undoubtedly these changes in the seasonal distribution of radiation must have some effect on climate, but they were almost certainly *quantitatively* insufficient to account for the enormous range between glaciation and deglaciation, even when secondary effects are exploited to the full. The variations of radiation are small and complex near the equator, and cannot possibly account *directly* for the alternation of pluvial and interpluvial periods. Moreover, as Zeuner recognises, such factors cannot account for the Ice Age as a whole. They have presumably been continuously in operation throughout geological time, but traces of them are rare. According to Bradley [3] the Eocene of Colorado, Utah, and Wyoming, covering several million years, shows a periodicity of 21,000 years. The Cretaceous in the United States also shows a cycle estimated as of this length. It is possible that the coal seams in the Upper Carboniferous (Pennsylvanian) represent periods of great eccentricity with northern winter in perihelion and a small obliquity of the ecliptic, giving little annual range of temperature; this would account for the absence of annual growth rings. The intercalated sandstones would represent the opposite condition of summer in perihelion.

The continental climate of the pre-boreal, about 8000 to 7000 B.C., fits in with the large obliquity and winter in aphelion, but could equally well have been due to the remains of the ice sheets and, in Europe, to the elevation of Scandinavia which converted the Baltic into the fresh-water *Ancylus* Lake. Astronomical changes cannot possibly account for the Climatic Optimum, the subsequent deterioration in the sub-Atlantic, and the "Little Ice Age" of the 17th to 19th centuries A.D. The trend of modern thought is against the astronomical theory.

Tidal Variations. We must mention here a suggestion by Pettersson [28] that changes of climate during

the past few thousand years were due to variations in the tides, especially in the submarine tides at the boundary of the Atlantic and Arctic Oceans, where a thin layer of cold arctic water overlies the warmer, more saline, Atlantic water. According to Pettersson, this "tide-generating" force reached maxima about 3500 B.C., 1900 B.C., 250 B.C., and A.D. 1433. At tidal maxima the arctic icecap is more readily broken up than at tidal minima, and more ice drifts out into the Atlantic. This floating ice, by lowering the surface temperature of the oceans and increasing the local contrasts, shifts the storm tracks southwards and causes an increase in the number and intensity of depressions, consequently tidal maxima should also be maxima of storminess and rainfall. There were in fact rainfall maxima about 2000 B.C. and 500 B.C. and a period of great storminess in the 12th to 14th centuries, but the agreement breaks down before 3000 B.C., during the Climatic Optimum. I think Pettersson's "tide-generating force" may have contributed to the climatic variations since 3000 B.C., but to be effective it requires a nice adjustment of ice conditions in the Arctic such as can have occurred very rarely and, geologically speaking, only for short periods.

THEORIES OF CLIMATIC CHANGE DUE TO TERRESTRIAL CAUSES

The Hypothesis of Continental Drift. Most theories of climatic change rest on the implicit assumption that geological deposits were laid down in the latitudes and longitudes in which they are now found. That assumption was seriously challenged by Wegener [19], who put forward the theory that in geological time the continents have drifted over the earth, moving relatively to each other and also, very widely, relative to the poles. He side-stepped the problem of climatic change completely; to him a decrease of temperature in any district simply meant that that district was moving into higher latitudes. Glacial deposits, wherever they are now, were all formed in high latitudes, the coal measures mark the Carboniferous equator, and so on.

For some time this theory attracted wide support, but difficulties, both geological and meteorological, have multiplied. The statement that the great glacial deposits of late Palaeozoic age in South America, Africa, India, and Australia were formed in a single primeval continent (Pangaea) through which the South Pole followed a wandering course, breaks down under detailed examination. The distribution of temperate floras of early Tertiary age in zones surrounding the present North Pole amounts to a proof that at those times the pole occupied its present position and not a point in the North Pacific as depicted by Wegener. His correlation of Quaternary glaciations is regarded by geologists as impossible. Finally, Wegener himself realised that continental drift cannot explain the succession of glacial and interglacial stages. The theory has no single definite fact to support it, for even the supposed westward drift of Greenland has not been proved; as a theory of geological climates it is now almost obsolete.

The Geographic Control of Climate. The zonal distribution of climates at present is by no means perfect; owing to warm and cold ocean currents and to the positions of the continents, any isotherm may cross many degrees of latitude at sea level. The isotherm of 32F in January, for example, ranges from 35°N in eastern China to 70°N north of Norway. There is also a strong vertical zoning of climate, temperature decreasing upwards at about 3F per 1000 ft. From this it appears that, other things being equal, a geological period with large high continents should be cold and one with wide oceans and low continents broken up into islands should be warm. It will be shown that this geographic factor is quantitatively sufficient.

The Geographic Cycle. The geological record shows that the world has passed through a number of cycles of elevation and erosion. At the close of a long period of quiet, folding of the earth's crust begins. The continents rise and extend to the full limit of the continental shelves, and the ocean floor sinks. Erosion forms great thicknesses of sedimentary deposits which cause further subsidence and folding into great mountain chains, accompanied by volcanic activity. Glaciers form on the mountains and in favourable conditions grow into ice sheets. This locking-up of water reduces the level of the sea still further. Eventually the period of disturbance ends, the mountain ranges reach their greatest elevation and are rapidly worn down by erosion, accentuated in many cases by the glaciers. The general level of the land falls and that of the oceans rises, and the continental borders are again flooded. This brings in a long period of low relief and small land masses which continues until another period of disturbance begins.

Geographic cycles are not all of the same intensity. The major cycles, culminating in widespread glaciation, appear to run their course in about 250 million years, but these tend to be broken by minor cycles which lead to nothing more than local glaciation. The succession of events is shown diagrammatically in Fig. 2.

An important point is that in the Quaternary, and probably in the earlier periods of disturbance also, glaciation was not coincident with mountain building, but lagged some five to ten million years behind it. Various reasons have been assigned for this lag:

1. At the end of a long period of warm climate the oceans are warm, and a long time is required to cool them. As soon as the polar seas froze, or extensive glaciers reached the sea, cooling of the great mass of the oceans would be fairly rapid, but until some ice existed, they would cool very slowly.

2. A smooth dome is not a favourable basis on which glaciers can grow into ice sheets. The mountains must first be eroded into peaks and valleys, with further isostatic elevation.

3. Mountain building alone is not enough for glaciation, which must wait until some other factor, such as a decrease of solar radiation, acts as a trigger.

4. Recently Wagner [31] suggested that mountain building is accompanied by a great release of earth heat, and this raises the temperature of the ground

sufficiently to prevent glaciers from forming; Wagner mentions a figure of 10F. Jeffreys [16], however, states that any appreciable rise of surface temperature from such a cause is not possible.

Mountain Building and Climate. It is now generally agreed that the presence of mountains is a *necessary* condition for glaciation, the mountains forming a gathering ground and nucleus. It remains to be considered whether mountain building alone can cause world-wide cooling which is quantitatively *sufficient* to explain glaciation. Four factors are involved:

1. The decrease of mean temperature with height.
2. Reflection of solar radiation from the surface of clouds.
3. Cooling power of surfaces of ice and snow.
4. Loss of heat owing to increased evaporation.

The average height of the land surface at present is about 2500 ft above sea level. At the maximum glaciation the average elevation may be taken as 3500 ft.

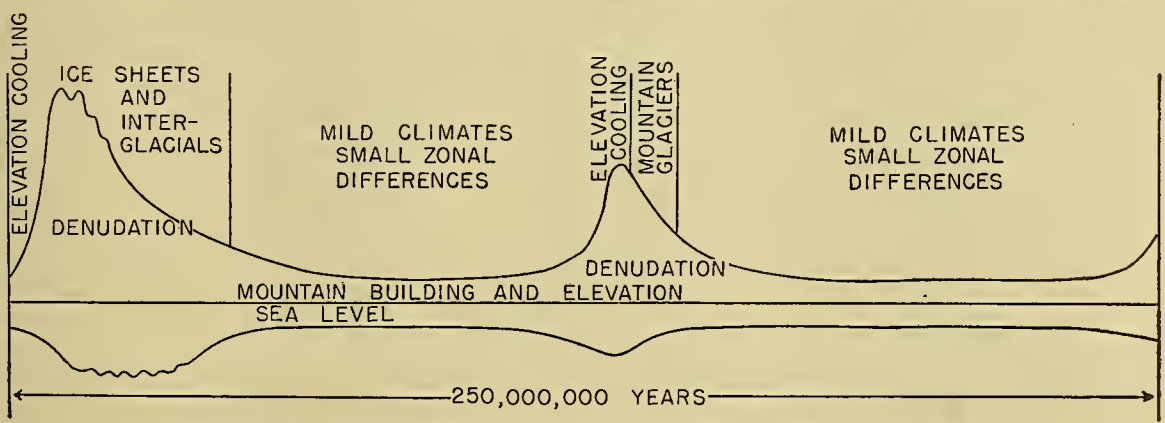

FIG. 2.—Geographic cycle of mountain building, sea level, and climate.

1. Owing to the cooling of ascending air by expansion the decrease of temperature with height is about 3F per 1000 ft. When the air descends again, it is warmed by compression, so that this effect is limited to the actual mountains. An elevation of 1000 ft is equivalent to an *average* cooling of 3F over the land areas, or 0.8F over the world as a whole.

2. Except in winter in high latitudes, clouds lower the mean temperature by reflecting from 60 to 75 per cent of the solar radiation back to space. On the average, an increase of one-tenth in the mean cloudiness lowers the mean temperature by about 6F. The level of condensation varies according to the humidity of the air, but probably averages around 5000 ft over land areas. A mountain range increases the cloud amount to windward and over the crest and decreases it to leeward, but to a less amount. As a rough estimate we may assume an average increase of the cloud amount by three-tenths of the sky. At present 12½ per cent of the land is above 5000 ft, and an increase in the average elevation by 1000 ft is estimated to increase this area to 21 per cent. At the time of maximum elevation, therefore, increased cloudiness would have lowered the mean temperature over the land areas by about 1.5F, or 0.4F over the world as a whole.

3. In calculating the cooling effect of increased areas of snow and ice, we must ignore for the moment the great Quaternary ice sheets, which were a consequence and not a cause of the initial cooling. Hence we must limit the calculation to the area above the snow line and the surface of mountain glaciers. At present this is about 3 per cent of the land surface, more than half of which is between latitude 70° and the poles. When the continents were at their greatest height, this figure was probably rather over 6 per cent. Brooks [5] has calculated that if a land surface in high latitudes, formerly bare, has one per cent of its area covered by ice or snow, the mean annual temperature would be lowered by 0.3F. Hence the increased snow cover would have resulted in an average cooling of about 1F over the continents. Since the Quaternary elevation was greatest in high latitudes, the figure was most probably greater than this, perhaps double. Something must be added for the formation of sea ice in polar waters, and the average figure for the world as a whole may be taken as 1–2F.

4. In the nonglaciated parts of the world the total precipitation, and therefore the total evaporation, during the great ice ages were considerably greater than they are now. The increase was due partly to the greater elevation of the land, and partly to stronger winds. It is difficult to form an estimate of the increase of rainfall, but considering all the evidence, a figure of 20 per cent is probably a minimum. If we put the net fall of surface temperature (after allowing for increased back radiation from the atmosphere) as 6F at present, we find that increased evaporation at glacial maxima would have lowered the temperature by another 1.2F.

Summing up, we find that the lowering of temperature at the maximum elevation in the Quaternary can be estimated as follows:

Decrease of temperature with height	0.8F
Increased cloud amount	0.4
Increased area of snow and ice	1.5
Increased evaporation	1.2

The total is about 4F, averaged over the whole world.

At the end of a long quiescent period the average

elevation may not have exceeded 500 ft. At such times the mean temperature of the world would be expected to be about 9F higher than now, merely because of the lower mean height. It will be seen later that the changes of land and sea distribution associated with mountain building and erosion bring other factors into operation which magnify the effect of elevation.

The Role of Polar Icecaps in Accentuating Climatic Changes. The geographic cycle affects the distribution of heat over the globe by means of ocean currents. Before discussing this factor we must consider the effect of floating ice. If the surface of the ocean were above the freezing point of sea water, there would be no ice. But if a general fall of temperature brought a small area near the North Pole below freezing point, a nucleus of ice would be formed, and this would act as an additional source of cooling, reducing the temperature still further. Brooks [6] showed that once the nascent ice sheet exceeded a diameter of about 250 miles, this additional cooling would exceed the rise of temperature due to decreasing latitude, and the floating icecap would grow until it nearly filled the arctic basin. The freezing point of sea water is 28F. Three independent calculations have shown [4] that if the arctic ice could all be cleared away, the mean winter temperature of the sea surface near the pole would be not far from 24F. This is the "nonglacial" temperature. A permanent rise of the nonglacial temperature by 5F would eventually sweep away the floating icecap and convert the Arctic Ocean into an open sea, with only some thin and scattered floating ice forming in winter and melting in summer.

The present low winter temperature of the Arctic, estimated as −40F near the pole in January, is due almost entirely to the existence of the icecap itself. A small access of heat only sufficient in itself to raise the temperature by 5F would result in an actual rise of nearly 70F, that is, in a complete change of climate which would permit cool temperate vegetation to extend to high latitudes.

There would also be a great change in the atmospheric circulation. The area of relatively high pressure in high latitudes is a surface effect, due to the weight of cold air in the lowest few thousand feet; at a height of 10,000 ft pressure falls continuously from low latitudes to the neighbourhood of the pole. The polar front is the boundary between the surface easterly winds associated with this area of high pressure and the westerly winds of middle latitudes. It is a reasonable inference that the removal of the surface cooling due to the floating ice would remove this layer of cold air, so that westerly or southwesterly winds would extend to much higher latitudes than at present. This in turn would accentuate the warming of the Arctic. Depressions would still occur, but in the absence of marked differences of temperature they would probably be weak; the necessary balance between easterly and westerly winds would be maintained chiefly by an extension of the subtropical anticyclones into higher latitudes.

The differences between completely ice-free and completely glaciated polar regions add up to the difference between the warm periods constituting most of geological time, which we may term "nonglacial," and the "glacial" periods such as the present, which culminated in ice ages. From this discussion it follows that the basic difference between a nonglacial and a glacial period is comparatively small—of the order of 10F in the temperature of high latitudes. Such a change could be brought about by a general rise of temperature over the whole earth, but it could also result from a greater transfer of heat from low to high latitudes by ocean currents.

Ocean Currents. At a time of maximum mountain building, the continents are most extensive and irregular in shape. The free circulation of the oceans between low and high latitudes is restricted and relatively little heat is carried to polar regions. At the end of quiescent periods the continents are small and ocean currents have free access to polar regions along several broad channels. The present situation in the Northern Hemisphere is rather unfavourable in this respect, access to the Arctic being possible only by the gap between Greenland and Europe, and part of this gap is occupied by the cold East Greenland Current, which owes its existence to arctic ice. There is no doubt that the Gulf Stream raises the temperature of the Arctic Ocean by several degrees, but this is not sufficient to keep the Arctic free of ice. In warm periods such as the Jurassic or early Tertiary, the Bering Strait was more open and there was a third channel, the Volga Sea, from the Indian Ocean across western Siberia. Brooks [4], on the basis of calculations by Kerner [18], estimated that the additional supply of heat was sufficient to raise the "nonglacial" temperature by 10–13F, more than enough to keep the Arctic free of ice. That, given the geography of these periods, such currents would exist has been shown experimentally by Lasareff [20] by means of models.

The Late Palaeozoic Ice Age. The greatest problem of geological climates is presented by the Late Palaeozoic—Upper Carboniferous (Pennsylvanian) and Lower Permian—in which an apparently highly favourable climate in the Northern Hemisphere, permitting the rich vegetation of the coal measures, coincided with or only preceded by a short time very extensive ice sheets in low latitudes of both hemispheres. The continental drift theory gives a plausible explanation of this distribution but as we have seen, it suffers from other objections. There remains the possibility that it was due to a peculiar distribution of sea, land, and mountains.

In the Late Palaeozoic a large continent, termed *Gondwanaland*, extended across South America, Africa, India, and Australia. As a result of a period of mountain building, this continent was most extensive and lofty in the Pennsylvanian and Lower Permian. To the north (Fig. 3) the Tethys Sea, a precursor of the Mediterranean, extended east-southeast to open into the equatorial Pacific, and was connected by the Volga Sea and the Atlantic with the Arctic. To the south the Southern Ocean had no direct connection with the

equatorial oceans. The result was a permanently large temperature difference between the seas north and south of Gondwanaland, giving rise to a permanent wind from south to north across the continent. The latter consisted of a lofty plateau or series of high mountain ranges extending well above the snow line. For most of its track the temperature of the air must have been below its dew point, causing an almost permanent cloud cover. In such circumstances glaciers could descend the mountain slopes and coalesce to form continental ice sheets, protected by the cloud cover from the tropical sun. On the other hand, the warm seas to the north encouraged the growth of rich vegetation. It is probable that the coal forests preceded the maximum glaciation, because when the ice sheets reached the sea the melting ice lowered the temperature of the ocean waters by almost 10F and spread the local cooling over the whole world. This fits in with the impoverishment of the fauna and flora and the period of drought which set in during the Permian.

The warmest conditions apparently occurred in Europe and western Asia, where the influence of the Tethys Sea was greatest, and here there is no good evidence of even small glaciers. In North America, where there was some local cooling due to a return circulation from north to south, there were large mountain glaciers, represented especially by the famous Squantum Tillite, but as the Arctic Ocean was apparently ice-free, the climate of the lowlands was favourable enough for coal forests.

The Late Palaeozoic Ice Age, like the Quaternary, was not continuous, but was broken up into glacial and interglacial periods. This suggests that either geographic conditions were not continuously favourable for glaciation or more probably that some other factor was superposed. This point is discussed on p. 1016.

Humphreys' Theory of Volcanic Dust. In 1913 Humphreys [14] showed that the presence of volcanic dust in the atmosphere lowered the mean temperature of the surface. The dust particles are large enough to scatter solar radiation, returning part of it to space unaltered, but too small to have any appreciable effect on long-wave terrestrial radiation. He calculated that during the period of instrumental observations explosive volcanic eruptions have lowered the mean temperature of the earth by about 1F. At present the amount of vulcanicity is small compared with some of the geological periods, and it is possible that volcanic dust has contributed towards the decrease of temperature in glacial periods. On the other hand, the complete absence of volcanoes could not alone have raised the temperature by more than 1F—a negligible amount. Vulcanicity can never have been more than a contributory cause; an attempt to estimate its effect quantitatively is described on p. 1016.

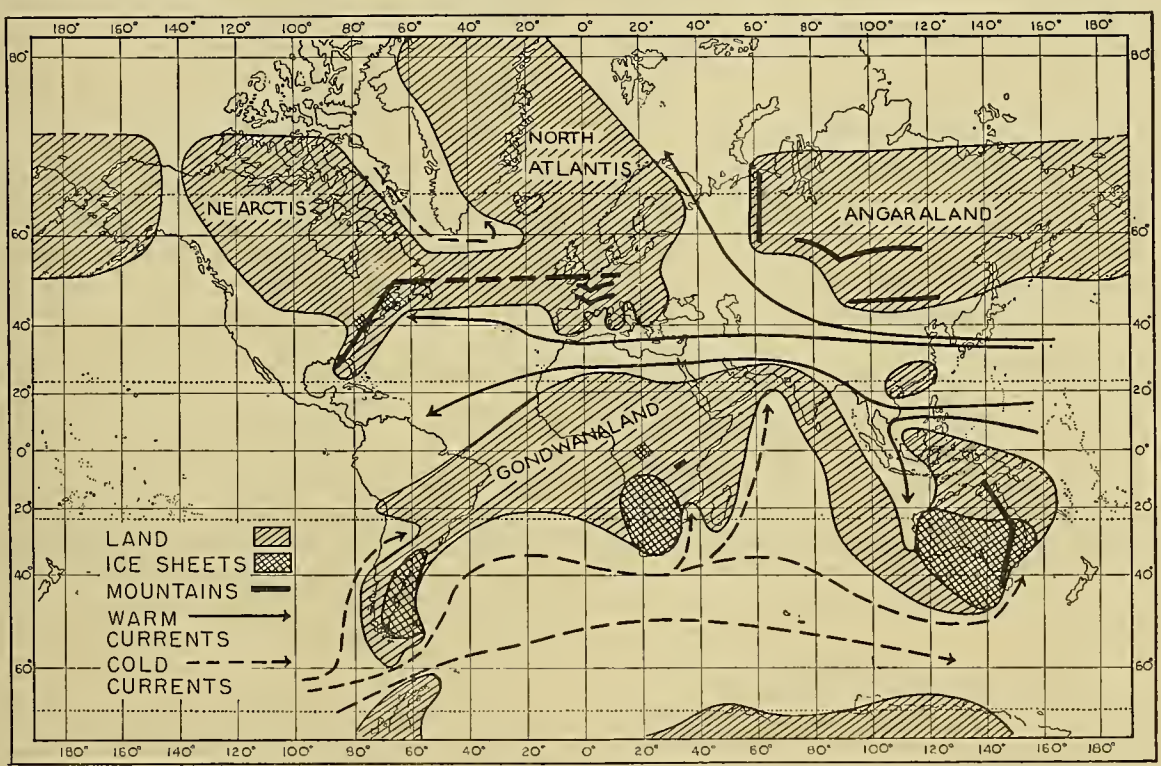

Fig. 3.—Geography, ocean currents, and ice sheets of the Late Palaeozoic.

Variations of Carbon Dioxide. Carbon dioxide absorbs long-wave radiation and so helps to maintain the temperature of the earth's surface above that at which it would otherwise be in equilibrium with solar radiation. The amount of CO_2 in the atmosphere must have varied greatly during geological time, being de-

pleted by the formation of limestones (carbonates) and coal measures, and replenished by volcanic action. Ordinarily the variation was slow, because a great reserve of CO_2 is dissolved in the oceans. Arrhenius and Chamberlin saw in this a cause of climatic changes, but the theory was never widely accepted and was abandoned when it was found that all the long-wave radiation absorbed by CO_2 is also absorbed by water vapour.

In the past hundred years the burning of coal has increased the amount of CO_2 by a measurable amount (from 0.028 to 0.030 per cent), and Callendar [7] sees in this an explanation of the recent rise of world temperature. But during the past 7000 years there have been greater fluctuations of temperature without the intervention of man, and there seems no reason to regard the recent rise as more than a coincidence. This theory is not considered further.

The Topographic Theory of Climatic Change. The theory that climatic changes are due to a combination of terrestrial factors—elevation, continentality, ocean currents, and vulcanicity—may be termed the "topographic theory." Palaeogeographers have given us a fairly complete history of the topographic changes since the Cambrian; palaeontologists and palaeobotanists have reconstructed the variations of temperature. From these data Brooks [4] made a statistical comparison of the topographic and climatic variations. The data used were:

1. Estimates of the mean temperature of middle and high latitudes (from 40° to 90°N) in each of thirty geological periods from Upper Proterozoic to Recent. For this purpose a curve given by Dacqué [9] for the zonal differentiation of climate was converted to mean temperatures using the present mean temperature of 33F and the assumed means of 53F in the Middle Jurassic and 28F in the Pleistocene. The assumption was made that the temperature of equatorial regions has varied little.

2. Estimates of the mean height of the continents based on a curve of mountain-building activity given by Dacqué, assuming a mean height of 3500 ft in the early Quaternary, 2500 ft at present, and 500 ft in the warm periods.

3. Estimates of "continentality," based on the areas of the continents in different latitudes from 80° to 40°N.

4. Estimates of the volume of the warm currents reaching the Arctic, as a percentage of that given by the most favourable conditions. Both these were based on the geographic reconstructions by Arldt [2].

5. Estimates of the vulcanicity on a scale of 0–10, from the amount of volcanic material in the different formations.

The mean temperature was compared with the four geographic variables by correlation, and the effect of one "unit" of each factor evaluated, separately for the Palaeozoic and for the Mesozoic and Tertiary together. The effect of one "unit" of each factor was also found from present-day conditions by independent, more or less theoretical calculations. The results are given in Table IV.

In spite of the roughness of the data and the approximations which had to be made in calculating the "theoretical" values, the three sets of figures agree well, except for Palaeozoic vulcanicity which was very difficult to estimate. The agreement strongly supports the theory that changes of orography and land distribution are a nearly complete explanation of the long-period changes of climate.

Table IV. The Temperature Effect of Terrestrial Factors in Climatic Change

Factor	"Unit"	Effect (°F) of one "unit"		
		Palaeozoic	Mesozoic	"Theoretical"
Height of continents	100 ft	−0.38	−0.47	−0.4
Continentality	%	−0.31	−0.32	−0.35
Ocean currents	%	+0.28	+0.28	+0.3
Vulcanicity	½ present	−1.68	−0.42	−0.5

Adopting the figures for Mesozoic and Tertiary as a basis, a partial regression equation was formed for temperature on the various geographic factors, and the "theoretical" temperature of each geological period was calculated. The result, compared with the "estimated" temperature from Dacqué's curve, is shown in Fig. 4. Here again the agreement is reasonably good, except for the earlier Palaeozoic, but there are some discrepancies. The three great glacial periods of the Upper Proterozoic, Late Palaeozoic, and Quaternary stand out clearly, but the "estimated" curve lags behind the "calculated" by five to ten million years, as if the earth took a long time both to cool and to warm up again in mountain-building periods. There is a steep drop in the "calculated" curve for the Lower Jurassic (Lias) which is barely represented in the "estimated" curve, either because the distribution of mountain ranges in relation to moisture-bearing winds was unfavourable for glaciation or because the cooling was not sufficient to freeze the polar seas. Finally, during the Palaeozoic the "calculated" curve is mostly above the "estimated," probably because the reconstructions showed too little land in high latitudes. Our knowledge of Palaeozoic geography is still rather fragmentary.

This statistical method of treatment automatically includes the secondary effects of freezing and thawing of the polar seas and changes in the atmospheric circulation, which would be difficult to handle quantitatively in any other way.

Shorter Climatic Oscillations—the "Solar-Topographic Hypothesis." The curves of temperature in Fig. 4 are generalised and do not show the fluctuations of relatively short period. For example, crowded into the narrow dip of the Quaternary were at least four oscillations with a range of more than 5F, and similar fluctuations undoubtedly occurred in the other Ice Ages. Even in the warm periods there must have been short-period oscillations, though the range was probably much less. The geographic factors (except vulcanicity) change slowly, and cannot account for these short-period changes.

We have seen that there are two causes which could have produced these shorter oscillations. Changes in

the elements of the earth's orbit (p. 1011) are known to have occurred, but are probably quantitatively insufficient. Variations of solar radiation could have produced most of the observed effects, and it is not inherently improbable that the sun is a variable star. The present trend of thought is therefore towards what Flint [11] terms the "solar-topographic hypothesis." A fluctuation of solar radiation by 10–20 per cent on either side of the mean value combined with the geographic cycle to produce the variations of geological climate. This hypothesis seems to offer the best basis for future research, but it is still doubtful whether the solar or topographic partner predominates. One view is that topography governs the major swings of climate but the solar factor determines the incidence of glaciation; the other view is that solar variations decide the main climatic variation but that mountains are essential for glaciation.

1006). The radioactive technique devised by Urry gives a prospect of dating the climatic changes revealed by these cores. Further, Ovey [26] foresees the possibility of tracing the sources of the marine glacial deposits and so tracking the paths of the icebergs, which will give us the ocean currents and winds of the glacial periods.

At present, especially as regards the pre-Tertiary periods, geologists are too apt to characterise the whole of a geological period, lasting millions of years, as having a certain unchanging type of climate. This is improbable, and careful detailed studies of the fauna, flora, and lithology will result in a picture of the minor fluctuations superposed on the broad swings shown in Fig. 4. If a rough time-scale (not necessarily absolute dating) can be added, this will go far towards solving the problem of causes.

The Factors of Climate. Parallel with the study of

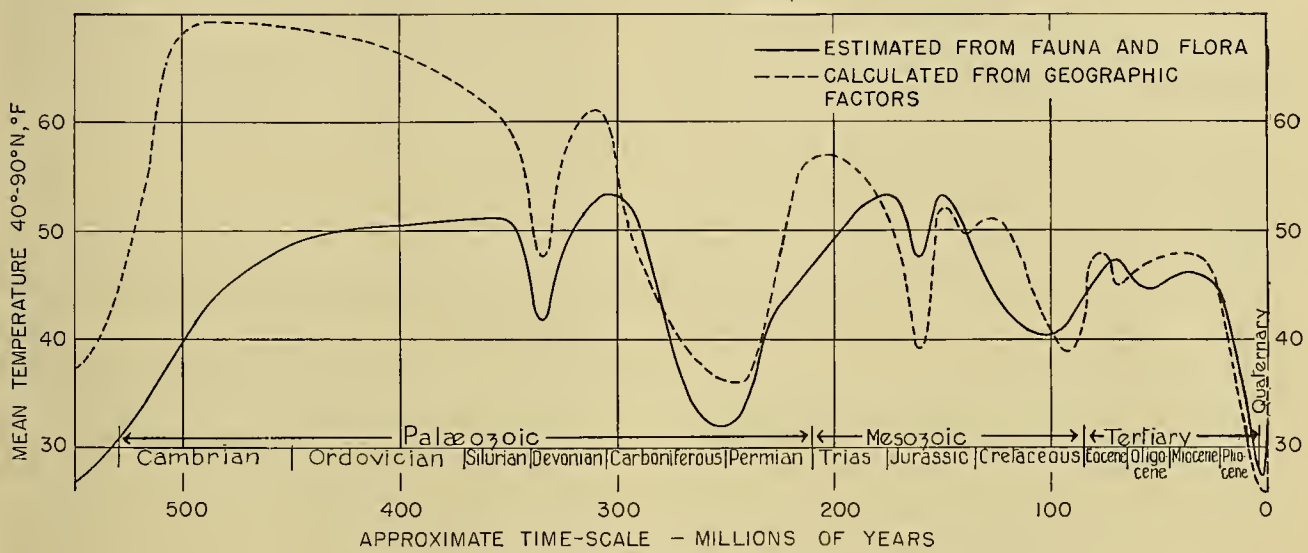

Fig. 4.—Variations of temperature in geological time.

The evidence from variations of rainfall is not clear. Increased solar radiation should increase total precipitation, and so far as we can determine, precipitation in the early Tertiary was greater than at present, On the other hand the long warm periods of the Mesozoic were characterised by desert deposits, pointing to a rainfall smaller than the present. This point needs further investigation.

THE FUTURE STUDY OF CLIMATIC CHANGES

The Palaeoclimatic Sequence. The greatest need at present is for a closer quantitative evaluation of climatic variations in geological time. We need better estimates of the distribution of mean annual temperature and annual range, and the amount and seasonal distribution of rainfall. These data, plotted in conjunction with the orography, may in time lead to an understanding of the wind systems. In particular, we need to know more about conditions over the oceans. This gap is being filled for the Quaternary and later Tertiary by the cores raised from the ocean floor (p. the palaeoclimatic sequence must go a more exhaustive quantitative study of the effect of the various solar and topographic factors on climate, and particularly on temperature and on the circulation of the earth's atmosphere. From a study of existing conditions we should be able to construct a more exact series of equations of climate which can be applied to any other topography. The temperature relations are already known to some extent, and the urgent problem now is to study the effect of topography on the atmospheric circulation.

When these parallel studies have reached a sufficiently advanced stage, we may be able to realise the dream of Kerner [18] that, from a large number of comparisons of quantitative estimates of local temperature from geological data with calculations of the same values from topography (both local and general), we can reconstruct the variations of extraterrestrial factors and especially of solar radiation. A few such comparisons already exist, made mostly by Kerner himself. An interesting case is the middle Eocene of southeast England.

Very detailed studies of the flora were made by Mrs. E. M. Reid and Miss Chandler [29], from which they inferred that the mean temperature was almost certainly not below 70F. On the other hand, from a careful study of the topography I estimated the probable upper limit of the mean temperature as 65F. In all other respects the climatic reconstruction agreed closely with the inferences from the vegetation, and it seems likely that the discrepancy of at least 5F was due to increased solar radiation.

It is only by the multiplication of such studies, both in space and time, that the fundamental problem of climatic variations can eventually be solved. The problem is not entirely academic, for signs are not wanting that we are even now in a period of climatic change which may have vital, but so far unpredictable, consequences for civilisation.

CLIMATIC IMPLICATIONS OF GLACIER RESEARCH[1]

By RICHARD FOSTER FLINT

Yale University

Glaciers as Climatic Indicators

Nature and Causes of Changes in Glaciers. Recognition of the relationship between changes in glaciers and changes in climate is older than the glacial theory as set forth by Agassiz. In 1821 Ignance Venetz [22], a Swiss civil engineer, announced an apparent correlation of fluctuations in Alpine glaciers with fluctuations of the regional snowline and of temperature. In land registers and other public records he found proof that these glaciers had been less extensive formerly than at the time of his investigation. Using glacier changes as a basis of inferences as to climatic changes, Venetz concluded that the average temperature fluctuates in an irregular manner, and that the abandoned end moraines of Alpine glaciers are very ancient and record earlier changes in climate. He even stated the opinion that the latest refrigeration had reached its climax, a statement that has proved to be remarkably true in the light of events since 1821.

Some years later Agassiz [1, pp. 237–239] placed the evidence of glacier behavior against that of thermometry which, it had been asserted in 1834, indicated no change in the average temperature at the earth's surface during historic time. In fact, Agassiz [1, p. 305] believed that the evidence of widespread former glaciation implied temperature changes of world-wide extent.

Thus glaciers were acknowledged as climatic indicators as soon as they were first studied scientifically. Refined observations, however, did not begin until long afterward. In the later part of the nineteenth century contemporary changes in glaciers so placed as to be capable of systematic observation were compared with changes in temperature and snowfall, both annually and over periods of years. Only recently, however, has an apparent correlation been established between glacier behavior and climatic changes[2] affecting wide regions.

Observed fluctuations of glaciers consist of changes in areal extent and thickness. Annual observations, begun in 1894, have been made on the positions of the termini of valley glaciers, notably in the Alps, western United States, western Canada, and Alaska (*e.g.*, Field [7]). Some of the data obtained are detailed, and will increase in significance as the record lengthens. More recently changes in thickness—more difficult to determine, but far greater in terms of volume—have been systematically recorded.

Since 1894 the assembling and recording of observations has been in the hands of capable committees. From 1894 to 1916 reports [19] were published by the International Committee on Glaciers of the International Geological Congress. From 1927 to date, reports have been published by the Commission Glaciologique of the Union Internationale de Géodesie et Géophysique, with the American Geophysical Union's Committee on Glaciers cooperating since 1931.

The value of the records obtained, as far as climatic implications are concerned, does not lie in fluctuations from year to year, which reflect only short-term changes in precipitation and temperature, as well as the avalanching of snow and other local factors. It lies rather in the cumulative changes, both during periods of several decades and during much greater spans of time. During the last few decades such cumulative changes have been so great that they have been described as "catastrophic."

It has become clear that change of temperature affects a glacier in at least two ways. First and most obviously, it determines the amount of ablation that occurs. Also, however, it determines the proportion of the precipitation that occurs in solid form, thus directly affecting the nourishment of the glacier. Hence it is apparent that a rise in temperature operates to diminish a glacier both through increased ablation and through decreased nourishment.

It has been observed, further, that decreased thickness is ordinarily accompanied by shrinkage in area, and vice versa. However, this is not true universally. Examples of valley glaciers that lengthened while becoming thinner were first noted very early [22, p. 15] and recently the Antarctic Ice Sheet, the world's largest existing glacier, has been thought [6, p. 392] to be increasing in extent while thinning. Accordingly the most refined observations take account of both thickness and area.

It is known further that although nearly all the glaciers within a region may be shrinking, one or two may be expanding at the same time, and vice versa. The exceptions are commonly explained as delayed responses to the latest climatic change, influenced by variations in local factors such as the volumes, slopes, and altitudes of the glaciers and in the relief of the surfaces on which they lie. An example is the Taku Glacier in coastal Alaska. Despite a general shrinkage in that region during recent years, this glacier has been expanding.

The most important qualitative-quantitative field study of glacier regimens ever undertaken is the work of Ahlmann [2] sustained throughout many years

1. Constructive reading of the manuscript by H. E. Landsberg and W. O. Field, Jr., is acknowledged.

2. The Climatological Commission of the International Meteorological Organization, meeting in Warsaw in 1935, distinguished between climatic *fluctuations* (differences between two 30-year means) and climatic *variations* (differences of a larger order, not specifically defined by the Commission). As far as practicable, this usage is followed in the present paper.

around the coasts bordering the North Atlantic Ocean. This work established that ablation of a glacier is controlled by two factors: direct radiation, which predominates in dry continental climates; and a combination of convection and condensation, which predominates in moist maritime climates. It established further that temperature is the dominant factor in the glacier regimen; glaciers are more responsive to changes in temperature than to changes in precipitation.

Correlation with Climatic Changes Determined Independently. Not until recently was the probability of a contemporary widespread temperature increase during the last 100 years established by actual compilation of weather records [10, 11], with the change affecting both polar hemispheres. Knowledge of this temperature increase was refined and enlarged through the subsequent appearance of several more compilations and interpretations of weather records (summarized and cited by Ahlmann [4, pp. 169–181]).

The modern temperature increase has been concomitant with a general shrinkage in the volumes of glaciers in both hemispheres [3, pp. 67–68; 15, p. 231]. It has been concomitant also with a reduction in the extent and thickness of floating ice in the Arctic Sea [4, p. 187] and with an apparent rise of sea level [9, 13], best explained as the result of an increment of water derived from the melting of glacier ice.

There appears, then, to be an obvious correlation among these observations: (1) secular increase of mean temperature, (2) shrinkage of glaciers, (3) shrinkage of sea ice, and (4) apparent rise of sea level generally within the span of the last 100 years.

This correlation seems to establish the relation between the fluctuations of climate, although data both more extensive and more precise would be desirable.

Ever since the pioneer announcement by Venetz, research workers have assumed that pronounced former variations in glaciers reflected changes in climate, and on this basis have inferred major climatic variations from the abundant geologic evidence of variations in glaciers. When the recent apparent correspondence between glaciers and climate has become more firmly established, the resulting quantitative data should prove useful in interpreting the climatic variations of earlier times.

Changes in Glaciers within Historic Time

As is true of most geologic phenomena, both the abundance and the quality of the evidence with which we have to work diminish conspicuously as we go backward in time. Therefore, in a review of the climatic evidence furnished by glaciers it is best to begin with the present and work back into the past.

Changes within the Last 100 Years. Abundant evidence supports the statement, made above, that glaciers have been generally shrinking during the last century. The evidence is derived from observations made in western North America (including Alaska), Greenland, Iceland, Spitsbergen, Scandinavia, the Alps, East Africa, South America, New Zealand, and the Antarctic Continent [3, 4, 15, 20]. Correlated with this are a contemporaneous shrinkage of lakes and a group of ecologic and oceanographic changes (summarized in [4]).

As Matthes [15] pointed out, the fact that glacier shrinkage has been occurring simultaneously in both polar hemispheres bears on existing hypotheses of the cause of climatic changes. This fact disfavors those "astronomic hypotheses" which demand, at least to some degree, temporal offsets of climatic effects between the polar hemispheres.

Changes since the Beginning of the Christian Era. Research in the historic period before the beginning of systematic glacier observations has consisted of extending the data on glacier changes backward in time through the study of official records made for other purposes. This was attempted first, and with considerable success, by Venetz [22]. Another example is a study of the archives of the town of Chamonix in the French Alps. In this study Rabot [18] succeeded in extending the record back to the year 1850 and demonstrated further that the present-day shrinkage commenced, in that district, about the middle of the nineteenth century, following a period of some 250 years during which the glaciers were relatively expanded. A more comprehensive reconstruction, covering a much wider area although it extended back only to the year 1700, was attempted by Brückner [5].

Similar research into the Iceland record by Thorarinsson [21] confirmed and extended these conclusions. Thorarinsson showed that glaciers on that island were far less extensive from the tenth century to the thirteenth than during the period since the beginning of the fourteenth century, and established changes of lesser degree within the latter period. This reconstruction is supported by various historical data not directly connected with glaciers (*e.g.*, [12, 23]).

Most of the first millenium of the Christian era is believed to have been relatively warm, but the evidence is derived from the fluctuations of lakes, from tree rings, and from other nonglacial data. Apparently nothing is on record as to the condition of glaciers during this time. A record may be present in the stratigraphy of glacial deposits, but if so, it does not seem to have been recognized.

Variations between the Wisconsin Maximum and the Beginning of the Christian Era

Still farther back in time the glacial evidence consists, not of observations on the glaciers themselves, but of stratigraphic and morphologic features. Many of these features are moraines built along the glacier margins and abandoned during shrinkage; from these, former glacier dimensions—extent or thickness or both—can be approximated. Research on this ancient period lies in the field of glacial geology rather than in that of glaciology.

The Wisconsin maximum is believed to represent the latest of a series of four major glacial expansions on a world-wide scale. It is generally assumed to date from about 60,000 years ago. The rough measurements available indicate that at that time glacier ice, mostly in the form of great ice sheets, covered about 27 per cent

of the world's present land area, as compared with a coverage of slightly more than 10 per cent by the glaciers of today [8, p. 451].

In North America, for example, the Wisconsin maximum is evidenced by the outer limit of a sheet of relatively fresh young drift stretching across the continent from the Atlantic near New York to the Pacific near Seattle. This drift is composite, consisting of thin, extensive layers of glacial deposits alternating in some regions with layers of loess and with beds of peat and other deposits of organic origin. Over wide sectors the individual layers of drift thicken to form series of subparallel, ridgelike moraines.

Each drift layer is interpreted as the product of a considerable glacial expansion, while the moraines are believed to have been built by lesser pulses of increase in the ice. As both drift layers and moraines generally occur in off-lapping relationship, like the clapboards on a frame house, the implied history since the great thrust at the Wisconsin maximum is one of gradual shrinkage interrupted by renewed but ever-lessening re-expansions.

The climatic implication of this sequence of events is, by analogy, a general increase of temperature punctuated by temporary, diminishing reversals of this trend. The implied climatic history is confirmed at various points by the ecologic relations of fossil organisms. No periodicity is apparent in the sequence.

The areal extent of the ice at various times is clearly recorded by the successive moraines and layers of drift. Owing to the low relief of most of the glaciated country, former ice thicknesses are rarely indicated directly. However, evidence of progressive thinning, particularly in the later part of the time span represented, exists in this fact: Inward from the periphery of the Wisconsin drift, moraines become fewer, smaller, and less continuous, and other features that indicate thin, slowly flowing or even stagnant ice become more abundant.

A generally comparable sequence exists in northern Europe; however, definite time correlations between events in Europe and those in North America have not yet been made.

The so-called *Climatic Optimum*, a warm period believed to have reached its climax some thousands of years before the beginning of the Christian era, is now widely recognized through the interpretation of organic evidence and through the history of fluctuations of lakes and sea level. The glacial record thus far includes very few indications of this warm time, doubtless because glaciers then were reduced in area. Thus the critical evidence is apparently covered up by present-day glaciers which, despite their recent shrinkage, are still large when compared with their condition during the Climatic Optimum. Fossil wood incorporated in young moraines at two localities in western United States is believed to record forests that flourished during the Optimum and were later overwhelmed by glacier ice. Matthes [14, p. 520] believed that most of the glaciers in western United States ceased to exist during the Optimum and have since been reconstituted in what he called the "Little Ice Age."

Major Variations within the Pleistocene Epoch

Glacial geology affords evidence of major climatic changes as far back as the beginning of the Pleistocene epoch, a million or more years ago. Because time and events have destroyed much of the record, it is far from complete, but the main outlines stand out with some distinctness [8].

In North America, and independently in Europe, four major glacial ages, of which the latest is the Wisconsin, are inferable. Geologists regard each of these ages as having been of the order of 100,000 years in duration, although it must be conceded that this figure is hardly more than a controlled guess.

As far as their positions are now known, the outer limits of the four major drift sheets are subparallel. This fact implies that over wide regions, at least, the major relief features of the lands, the mountains and lowlands, remained much the same throughout this whole time, for if there had been any widespread change the patterns of the successive drifts would have differed more than they seem to do. Mountain uplifts known to have occurred during the Pleistocene epoch, such as coastal mountains in California and the Himalayas in southern Asia, would have exerted only a limited influence on the world pattern of glaciers.

The area covered by ice when at its maximum extent was of the order of 32 per cent of the land area of the world, compared with about 10 per cent covered today.

That the climate was characterized by reduced temperatures and perhaps also greater precipitation in districts not covered by glaciers is established by two groups of phenomena. The first consists of large lakes and vigorous stream activity in western North America, central Asia, northern and eastern Africa, central Australia, and other regions now comparatively dry. The second consists of abundant evidence of former vigorous freezing and thawing of soil in districts where such activity is feeble or nonexistent today.

Additional glacial evidence of major climatic variation lies, in mountain districts, in the discrepancy between the altitudes of cirques occupied by valley glaciers today and the much lower altitudes of abandoned cirques. In some districts this discrepancy amounts to as much as 1200 meters. As there is an evident relationship between the general altitude of cirque floors in any district and the position of the regional snowline, the discrepancy between the two sets of cirques is a rough measure of the depression of the regional snowline during the glacial ages, as compared with its present position.

The extent of glaciers during the times between the glacial ages is virtually unknown. That climates in the temperate zones were mild by comparison with the glacial climates in those zones is indicated by the character of soils developed on glacial drift sheets and buried by the next succeeding drift sheets. The great thicknesses and deep alteration of such soils constitute the basis for a general belief that the interglacial ages were much longer than the glacial ages, that they may have lasted 200,000 to 300,000 years each. Direct evidence of the character of interglacial climates comes from

fossil plants and animals that occur between the layers of drift. In certain cases it has been possible to show that comparative ecologic assemblages are now living in climates milder than those prevailing at the fossil localities. From such relations it is inferred that interglacial climates, in some regions at least, were milder than those of today.

Accurate quantitative data on the fluctuation of mean annual temperature between glacial and interglacial times do not exist. Using altitudes of cirques, Penck [17] calculated the differences between glacial-age temperature and present temperature as being of the order of 7C to 8C on the Atlantic coast of Europe. From scanty organic evidence a difference of 2C between an interglacial maximum and the present time has been calculated. On this basis we have a total range of the order of 9C or 10C.

Owing to the presence of variables, however, these figures are more suggestive than accurate. Both apply to glaciated regions, and it may well be, as Willett [23, p. 43] suggested, that the differences would diminish in lower latitudes.

It seems probable that minor climatic variations, similar to those which have taken place during recent millenia, occurred also during earlier times, as irregularities superposed on the major glacial and interglacial fluctuations. For the most part, however, the geologic record is too meager to enable us to state definitely that such is the case.

Nonperiodic Character of Climatic Changes

Neither the facts of glaciology, evidencing recent climatic changes, nor the facts of glacial geology, evidencing more ancient ones, afford a basis for inferring a periodic recurrence of any particular climatic condition. Brückner [5] assembled a mass of data covering a modern 200-year period, from which he derived the concept of a climatic cycle with a period of about 35 years. Although widely quoted, this concept was later refuted by Willett [23, p. 36] and today has dubious standing. Paschinger [16] assembled data on regional snowlines, from which he concluded that climatic cycles occur in opposite phase in the north and south polar hemispheres. This conclusion was refuted by Matthes [15, p. 232].

Present Research Needs

The usefulness of glaciers as climatic indicators has been established. In view of this fact it is apparent that research on changes in glaciers should be pursued both more intensively and more extensively than hitherto. The research needed falls into two distinct fields, glaciology and glacial geology.

In the glaciologic field there is required a more nearly complete record of contemporary fluctuations of glaciers, so that after several decades curves prepared from annual observations will become available for comparison. The glaciers used for such observations should be carefully selected so as to include both polar hemispheres, both high and low latitudes, both maritime and continental glaciers, and both valley glaciers and ice sheets. If possible, one of the observed glaciers should be situated very close to the equator—in East Africa, the Andes, or New Guinea. Such a system of observations would require the existence of a vigorous international organization with centralized maintenance of records.

In the geologic field the greatest need is for a better knowledge of the areas of glaciers at various times during the last 10,000 years. In general, less is known about these comparatively recent variations than about variations of more ancient date. Specifically, what is required is the mapping and study of the abandoned younger end moraines of valley glaciers in selected mountain districts, and moraines and other deposits of the former ice sheet in northeastern North America, a region still little known.

Fulfillment of these two general needs would place our knowledge of climatic changes, as determined from past and present glaciers, on a firm basis.

Summary

In summary, an examination of the bearing of glacier research on the reconstruction of former climates leads to these conclusions:

1. A close relationship between changes in glaciers and changes in climate, particularly temperature, seems established.

2. Observations on glaciers themselves afford some climatic data for the last 1000 years.

3. Geologic features related to former glaciers afford much cruder climatic data for the last 1,000,000 years or more.

4. The climatic changes inferred from (2) and (3) are supported also by a variety of nonglacial evidence, much of it organic.

5. The climatic variations included four major cold ages, with extensive glaciers, three major warm ages, with greatly reduced glaciers, and lesser variations within the last few tens of thousands of years. The latest fluctuation consists of a general rise of temperature within the last 100 years.

6. As far as the existing evidence goes, the changes in climate seem to have been similar in character (though not of course in amount) throughout the world. There is no evidence that the changes recur in a periodic manner.

7. Rough calculation has suggested that in districts near the large ice sheets the amplitude of mean temperature fluctuation between cold ages and warm ages may have been of the order of 10C.

8. Present research needs include (*a*) a greatly expanded, coordinated system of observations on contemporary glacier fluctuations, and (*b*) a study of very late Wisconsin end moraines in order to throw more light on climatic changes during the last 10,000 years.

TREE-RING INDICES OF RAINFALL, TEMPERATURE, AND RIVER FLOW

By EDMUND SCHULMAN

University of Arizona

INTRODUCTION

History. Dendrochronology—the construction, based on tree-ring widths, of significant indices showing changes in climate from year to year and the use of these indices in dating and forecasting—had early beginnings. That the succession of wide and narrow growth rings of trees might provide a chronology of the wet and dry seasons of the past was noted at least as early as the fifteenth century by Leonardo da Vinci. As in other fields, research expanded tremendously during the 1800's, when botanists and foresters, particularly in central Europe and in Scandinavia, examined numerous details of growth-climate relationships [2]. About 1880, the Dutch astronomer, Kapteyn [19], succeeded in deriving a ring chronology several centuries long, which gave a first approximation to the annual rainfall of west Germany, but no clear index, which he sought, of solar activity. His concepts of tree selection and analysis, foreshadowing much later work, remained generally unknown, however, for some thirty-five years.

Dendrochronologic work was begun in the southwestern United States in 1904 by Douglass [5], who formulated the basic principles and who established the superiority of drought areas and coniferous species as sources of ring chronologies of rainfall. Since that time this research has been continuously developed by him and his co-workers at the University of Arizona. Although the main objectives of this research were climatic, there have been some fruitful offshoots, such as the setting up of a precise archaeological time-scale to A.D. 11 for the central part of the Pueblo area, which has been accomplished by the backward extension of the ring record in living trees, based on the ring dating of ancient timbers [6].

Dendrochronologic series have thus far been extensively developed in only three regions. The results of work in the semiarid western United States, as they bear on the climatology and hydrology of the dry lands, will form the bulk of the following survey. In arctic areas, Scandinavia has produced in recent years a number of long and significant chronologies of temperature changes, primarily for the June–July interval; specially long arctic chronologies, composites of records in living trees and ancient timbers after the fashion of those in the Southwest, have been derived for northern Alaska. Scant justice can be done here to a third region of active chronology work, the noncritical areas of the eastern and central United States; several thorough investigations have shown that chronologies of limited climatological significance can be obtained on some sites in this region, though many localities apparently cannot provide dendroclimatic indices.

Principles. It is now known that a great range of variability exists in all aspects of ring growth. In order to obtain climatic indices of maximum simplicity, fidelity, and length—the specific objective of dendrochronologic work in the Southwest—three basic principles have been developed: selection, crossdating, and sensitivity.

Proper field *selection* [25] of trees for sampling is of first importance, for many species, sites, and areas are found to yield ring chronologies of no apparent significance as climatic indices. By successive refinement of selection criteria, trees may be found in which the influence of one dominant factor, such as rainfall in the dry lands, is increasingly represented in the ring-width fluctuations.

The principle of *crossdating* [9] states that the approach to parallelism in ring chronology among the individual trees of a homogeneous set is a direct measure of the influence of some general factor or set of factors on the variations in ring-width from year to year. Such parallelism provides the scientific control for the discovery and evaluation of hidden irregularities in any ring series. This rather simple concept has proved very far-reaching in its thorough application to drought chronologies.

The approach to parallelism between highly sensitive ring series in a small area of the semiarid Southwest, where this phenomenon has been found to be near a maximum, is illustrated in Fig. 1. Although only a half-dozen or so specially long-lived Douglas firs have formed the basis of the record in the outer five centuries of the Mesa Verde and Tsegi indices, the similarity of these two series in light of their 115-mile separation indicates that the random term in individual tree growth has been largely cancelled in this interval; some earlier portions of both series are less well based. The Flagstaff index, more distant from Mesa Verde and based mainly on a different species (ponderosa pine), shows occasional substantial differences from the preceding two chronologies, yet is on the whole in good agreement. Fifty-year correlation coefficients for the twenty intervals from A.D. 900 to A.D. 1899 average +0.71 for Mesa Verde versus Tsegi (115 mi W by S) and +0.46 for Mesa Verde versus Flagstaff (220 mi SW). The high significance of the Mesa Verde index as a rainfall history is illustrated in a later section.

In ring series which crossdate with one another the average proportionate change in width from year to year is a quantitative index of *sensitivity*. Highly sensitive series have been found to show a close relation to rainfall in the dry lands of the Southwest; at the same time, even in this region, trees on sites which permit significant water carry-over from year to year show low sensitivity

Methods [8]. Some special techniques of dendrochronology which have been found of value but which can only be mentioned here, are (1) use of the Swedish increment borer, which permits wide and rapid core sampling, (2) mounting and surfacing of cores in such a fashion as to permit ease and rapidity of cross-comparison of gross features as well as good definition of cell structure under the microscope, (3) elimination of individual age trends (varying mean growth rates) in order to average the ring records in uneven-aged trees of a set and thus remove a part of the ever-present random term in the growth of each tree and make the data for different time intervals comparable, (4) use of extensive areal averages to remove still more of the random term in the mean growth at each site, and (5) use of skeleton plots as a reconnaissance tool in archaeological dating.

Errors in the Unit. Possible errors in dendrochronologic series are of two types: (1) identification of growth irregularities, such as locally absent or false rings, and (2) interpretation of the ring fluctuations in terms of climatic variation.

In particularly severe years much of the cambial area may be entirely inactive in terms of new cell growth. Locally absent rings may occur with a frequency of as much as 5 per cent or more in the most sensitive and slow-growing ring series in semiarid regions [27]; they are of rare occurrence in more humid regions [17], at upper timberline, and in the Arctic. Such rings are identifiable by comparison of approximately parallel patterns in climatically related trees of a site or area.

False annual rings are comparatively rare in conifers in high latitudes and near upper timberline, but are very common in the latitudes of southern Arizona. Nontraumatic false rings are found in general to occur as a function of species, climate, environment, and age. In such dendrochronologic species as Douglas fir and ponderosa pine they may be uniquely identified by crossdating as well as (in almost all instances) by absolute criteria [25]. Some species, such as Arizona cypress, are so subject to false-ring layering as to be unusable in chronology building.

Errors of Interpretation. It has long been accepted as a botanical axiom that the absolute growth of plants is subject to a matrix of environmental and transmitted factors, whose interactions are extremely complex [15]. Even when the problem is simplified by the use of growth departures, it appears that only on sites critically limited with respect to an important growth element, such as rainfall, can such departures be highly representative of that element. There may be hidden effects in the growth record of past fires, pest outbreaks, mechanical injury, changes in associated flora or microorganisms, and other factors. Some species are characterized by an inherent tendency to nonuniform cambial activity, so that the ring series along any radius seems to have no rational explanation [24].

Some meteorological and hydrological factors, too, tend to destroy any simple relation between seasonal rainfall and tree growth: variation in distribution of rainfall within the season significant for ring growth, varying influence of temperature and other meteorological elements, real differences in total rainfall between the tree sites and the correlated meteorological station, and the numerous influences affecting the rainfall-runoff relationships from basin to basin.

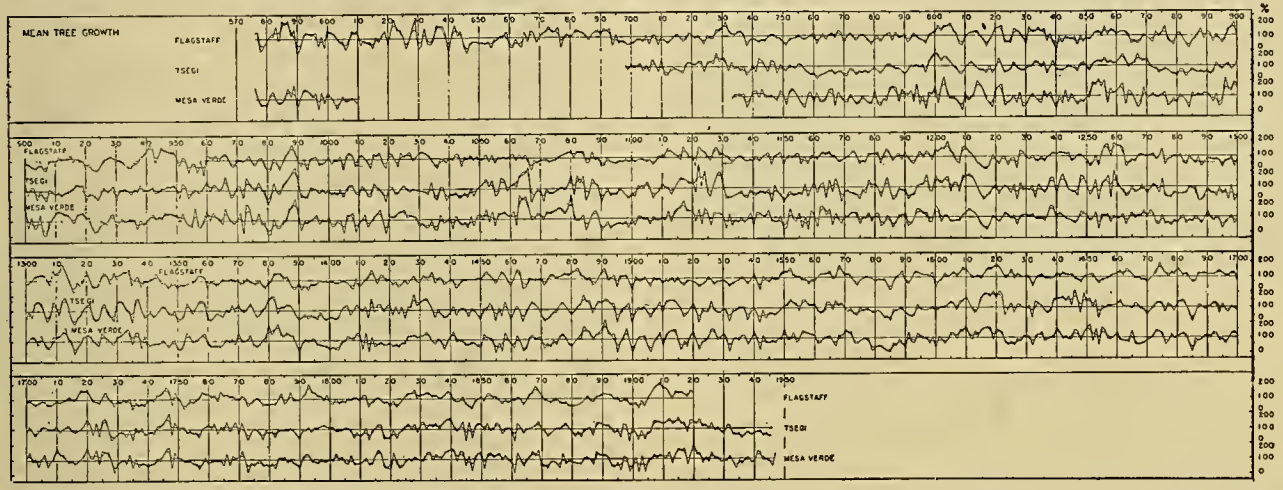

FIG. 1.—Comparison of the mean departures in tree-ring width for two localities in northern Arizona and Mesa Verde in southwestern Colorado. The records in living trees were extended backwards by use of overlapping series in archaeological beams. Smoothed curves were superposed to permit greater ease in visual comparison of the longer fluctuations. (*From Tree-Ring Bulletin.*)

It is thus a fundamental requirement for the production of significant dendroclimatic series that the ring record of any tree be checked against sufficient associated trees, and that the group mean, in which random errors have been permitted to cancel as far as possible, in turn be checked against and averaged with a sufficient number of associated groups.

Relation to Neighboring Sciences. Like most work outside the classical disciplines, dendrochronologic research is closely related to a number of fields: botany, ecology, forestry, meteorology, hydrology, archaeology, geology, and astronomy. The analyzed variable, tree-ring width, is in the domain of the first three of these fields. Its application to archaeology has

perhaps been the most spectacularly successful one to date, and has called forth very great cooperation from archaeologists in supplying specimens for analysis. Though tree-ring dating of ancient ruins in the Southwest is continuing and may well be extended to entirely new regions, it seems probable that the greatest potential contributions of dendrochronology will be in the fields of meteorology and hydrology.

TREE HISTORIES

Rainfall and River Flow in Western North America. Series which contain significant indications as to past rainfall and runoff have now been derived for a number of localities; for three of these, the Colorado River Basin as a whole [25], southern California [27], and eastern Oregon [20], the ring data are sufficiently sensitive and numerous to permit quantitative analysis in terms of climate. It must be recognized that no ring indices are yet available, nor is it likely that any will be derived, which are perfectly representative of the rainfall of any particular locality. Even the best of the present indices contain enough "random" variation to require caution in such quantitative conclusions. Yet these indices do show a fidelity to the march of rainfall which, in view of the potential refinements, leads to the expectation that a vast body of significant climatic data will eventually be obtained from selected trees. The more comprehensive drought chronologies now published are noted in Table I, which also lists the longer arctic chronologies of temperature.

TABLE I. TREE-RING INDICES*

Location and reference number	Number of trees	Rings measured (000)	Maximum length (yr)
Rainfall Chronologies			
Central California [5–I]	15	22	3219
Central Pueblo area (estimated) [7]			(to A.D. 150)
Colorado River Basin [25]	240	60	696
Eastern Oregon [20]	340	±35	668
Northern Arizona [5–I]	86	14	519
Oregon-California [3]	25	6	476
Pacific Slope, U. S. [27]	121	22	593
Southwestern Canada [26]	66	15	525
Southwestern U. S. ruins [28]	168	32	1551
Western Nevada [16]	±200	±13	685
Western United States [5-II]	305	52	371
Temperature Chronologies			
American Arctic [13, 14]	±250	±30	970
Finland [18]	214	11	55
Finland [11]	2641		50
Norway [1, 23]	+300	±50	537
Norway [10]	91	21	477
Sweden [12]	+300	±50	468

* Tabulations, in some cases of a number of series, are to be found in almost all cited references, supplemented by plotted curves. In some reports the total uumber of rings studied was several times the number used in the indices.

Throughout the West, sensitive timber conifers are found to provide histories primarily of winter precipitation, usually of the October–June interval. For several decades it has been generally accepted that the spotty convection storms of summer in the Rocky Mountains had no apparent systematic influence on ring-width fluctuations in these trees, though they were recognized as of occasional importance in producing false rings.[1]

Most fortunately for chronology building, it was found that the drought conifers show a tendency to extraordinary longevity, high sensitivity, and slow growth on particularly adverse sites. The extremely long unbroken records derivable from these trees provide the means for estimating the noncyclical trend in rainfall, if any, from one century to the next.

In developing a 658-year index for the Colorado River Basin the chronologies in a number of smaller drainage basins throughout the West were analyzed, the growth relationships in some of them being displayed in Fig. 2. Panel 1 of this figure is of special interest here, as it

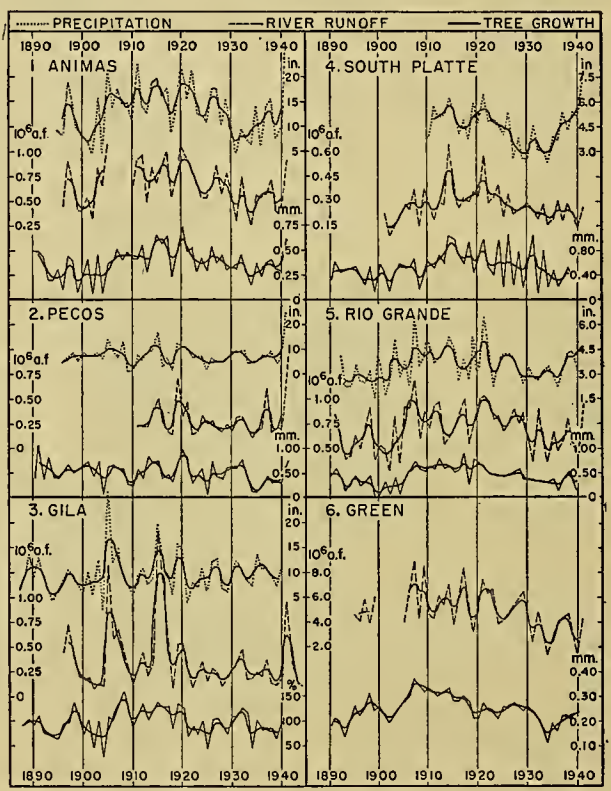

FIG. 2.—October–June rainfall and water-year runoff (in acre-feet) are compared with preliminary growth indices in six drainage basins of the Rocky Mountains. Superposed smooth curves emphasize the longer fluctuations.

compares the Mesa Verde growth index, plotted in Fig. 1 over its entire length of more than 1200 years, with the October–June rainfall at nearby Durango and the water-year runoff of the Animas River. The degree of fidelity and the limitations in the rainfall and runoff record in the best tree indices thus far derived are perhaps best

1. An extensive quantitative analysis now (June, 1951) in progress indicates that a small but significant additive influence of July–September rainfall on the growth of the *following* year is present in many ring series in this region. The reinterpretation of the numerous centuries-long indices of rainfall, now developed for the West, in terms of the total annual rainfall of July–June, rather than the more limited winter interval, may prove far more important climatically than the fact of a few per cent improvement in the tree-growth–rainfall correlations.

appreciated by a careful study of such comparisons as those in Fig. 2. Differences in growth response in the Gila area of southern Arizona and New Mexico, subject to flash floods, as compared with the conservative Green River area of Wyoming, may be specially noted.

The Douglas fir index for the Colorado River Basin above Hoover (Boulder) Dam is seen (Fig. 3) to provide a fair first approximation to the winter rainfall chronology of that region and to the river runoff. Independent 342-year indices for two types of pines support in general the main index, but show detailed differences in mean growth, which are probably only partly traceable to the relatively small number of component specimens in the pines. Correlation coefficients are shown in Table II.

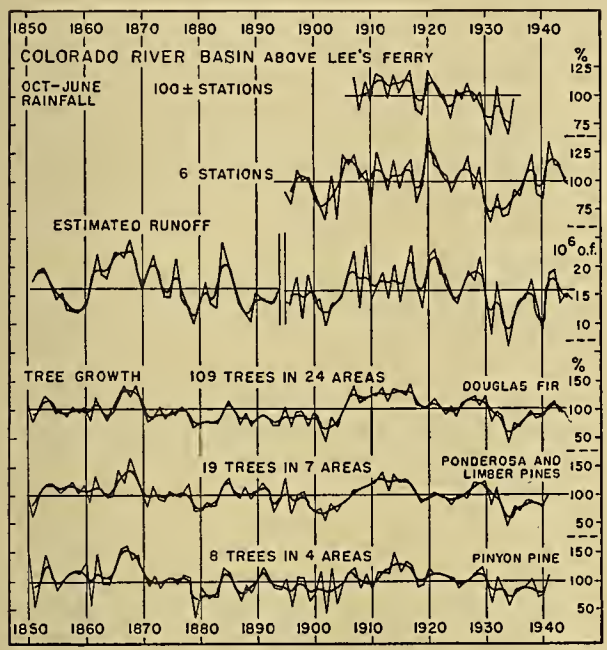

Fig. 3.—Regional tree-ring indices in the Colorado River Basin compared with gage data. Rainfall is expressed in per cent of the mean; tree growth in per cent of the mean trend; runoff in acre-feet × 10^6. The runoff of the Colorado River preceding 1895 is an approximation by E. C. LaRue (U.S.G.S. Water-Supply Paper 395, 1916) on the basis of Salt Lake levels. (*From University of Arizona Bulletin.*)

The giant sequoia of California has yielded by far the longest ring sequences, four of the trees analyzed by Douglass being over 3000 years of age [5]. Unfortunately, the relatively moist habitat of this species permits a sensitivity to rainfall fluctuations which is at best on a much lower level than that of drought-site trees.

The big-cone spruce of southern California has, however, been found to show a sensitivity rivalling that of the best trees of the Colorado Plateau; a 560-year record has been constructed. Its value as an index of rainfall and runoff is indicated in Fig. 4.

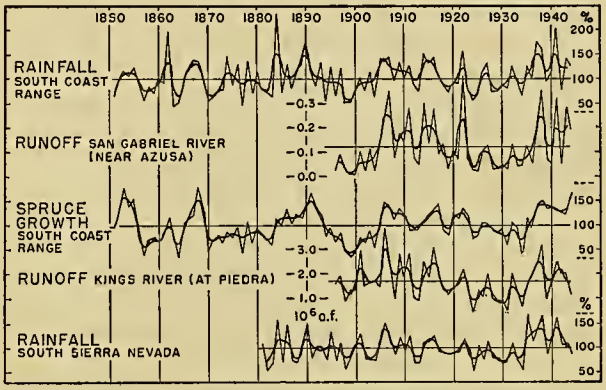

Fig. 4.—Regional tree-ring indices for southern California compared with gage data. Rainfall is expressed in per cent of the mean; tree growth in per cent of the mean trend; runoff in acre-feet × 10^6. (*From University of Arizona Bulletin.*)

The third regional survey of broad character, that of Keen [20] in the ponderosa pines of semiarid eastern Oregon, makes possible some centuries-long comparisons with southern California and the Colorado River Basin. The correlation coefficients of the Oregon index with rainfall and runoff are seen in Table II to be of the same order of magnitude as those in the other two regions.

The analysis by Antevs [3] in the general area studied by Keen is particularly useful in its detailed discussion of the complex of factors influencing the observed growth departures in recent decades. Among other analyses, the study by Hardman and Reil [16] in the Truckee River Basin provides extensive data.

Table II. Correlation Coefficients Between Gage Records and Regional Tree-Ring Indices

Tree index	Correlated with	Period	Interval (yr)	r unsmoothed	r smoothed*
Colorado River Basin	Colorado River runoff	Oct.–Sept.	49	+0.66	+0.81
Eastern Oregon	Eastern Oregon rain	Sept.–Aug.	66	+0.50	—
" "	Columbia River runoff	Jan.–Dec.	57	+0.56	—
Southern California	Coastal Rain	July–June	94	+0.65	+0.75
" "	" "	" "	49	+0.71	+0.85
" "	King's River runoff	Oct.–Sept.	49	+0.52	+0.64
" "	San Gabriel River runoff	Oct.–Sept.	49	+0.61	+0.86

* By formula $b' = \frac{a + 2b + c}{4}$.

Temperature Indices in the Arctic. Tree-ring chronologies in Scandinavia exceed in volume those for any other region outside of the southwestern United States. Two factors seem largely responsible: the major economic importance of forests, and the stimulus of the work begun in 1879 by de Geer [4] on the annual clay layers or varves.

Problems associated with the recognition and dating of false annual or locally absent rings, so important in

the Southwest, are almost nonexistent for the simple though narrow-ringed arctic series discussed by Erlandsson [12], Ording [23], and others. On the other hand, the fluctuations in ring-widths in arctic series tend to be relatively small, and the chronologies vary from site to site more than those in the Southwest.

Almost all arctic studies have noted the relation of ring-width fluctuations to the fluctuations in mean or average maximum summer temperature, particularly that of the June–July interval, the highest correlation coefficients being of the order of +0.7. As one would expect, precipitation is in general not an important limiting factor in growth. The longer tree indices of arctic temperatures are noted in Table I.

Good series for numerous areas in northern Alaska have been developed by Giddings [13, 14], who finds that the more sensitive tree records represent June–July mean temperatures with some fidelity. Extending living-tree records by the use of archaeological beams, he has developed one series almost a thousand years in length.

Indices of Physiological Drought in the Eastern United States. In the absence of a dominant climatic variable, it does not appear possible to derive a simple meteorological index from the ring-growth in the nonmarginal areas, although some correlations of larger growth departures with rainfall or temperature of various spring and summer months are reported by Lyon [21, 22] and others. An example of a fair degree of cross-dating over a considerable area is furnished by the analysis of hemlock growth in New England—an indication that trees in relatively moist areas can provide a significant history representing the resultant effect on plant growth of a complex of climatic conditions.

LONG-TERM CLIMATIC FLUCTUATIONS

Changing Areas of Drought. A sufficient number of ring chronologies of rainfall in the western United States have been developed to permit a preliminary view of this phenomenon over the centuries. The tendency towards a variability in the area affected by drought in different years, a striking characteristic of gage records of rainfall and runoff, applies also to longer drought intervals and is evident over the entire range of the data. Centuries-long chronology transects for 1500 miles or more of the Pacific Slope and the front ranges of the Rocky Mountains reveal no systematic time displacements in maxima or minima from one area to another of sufficient significance to permit their use in long-term weather forecasting. Perhaps the most important element emphasized by this analysis is the need for caution in generalizing, either in time or areal extent, any local indications of cyclic recurrence, drought frequency, trends, and similar phenomena.

Dry and Wet Years and Intervals. The three regional chronologies noted above, for the Colorado River Basin, southern California, and eastern Oregon, each on a broad statistical base of sensitive ring records, may be used to derive long-term statistical parameters of interest to the climatologist. It appears that specially dry winters and low runoff in the Colorado River Basin, of the severity of the "dust-bowl year" 1934, occurred about once in twenty years during the 658 years of ring record (not *every* twenty years!); instances of two successive years of such critically small runoff, of special importance in the management of the reservoir level at Hoover Dam, seem to have occurred only three times during that record. In the Colorado River index, after simple three-term smoothing of the type noted in Table II, the median length of an interval of general excess or deficit is about six years, intervals of deficiency or excess more than three times this length occurring once in about 200 years. In southern California the median length is about 8 years in the 560 years of similarly smoothed record. Intervals of excess and deficit are in general somewhat longer in Keen's Oregon chronology, an effect in part, at least, of the heavier smoothing.

The Colorado Basin index indicates that the interval of greatest deficiency in rainfall and runoff in this region since A.D. 1300 occurred in A.D. 1573–1593, when the average deficiency was well below that in the most severe intervals recorded by modern gages. It is significant that the greatest minimum in the southern California index occurred in 1571–1597, when the accumulated deficit approached twice that of any interval in the century or so of rain-gage records. The eastern Oregon index shows only a weak general deficiency from 1565 to 1599, broken by a short interval of excess near 1587; the most pronounced minimum in that index began in 1917 and was followed by "gradual encroachment of desert conditions into what were once thriving pine stands" [20] during the next two decades.

Relevant to this is the interregional correlation coefficient, computed for the interval 1650–1935, of +0.46 for the Colorado Basin versus southern California, which compares with a coefficient of +0.21 for the same interval between the Colorado Basin and eastern Oregon; very similar results are obtained when winter rainfall data in the three regions are correlated. No significant correlation between British Columbia growth and that in the Colorado River Basin has been noted for the last three centuries or so of data.

No long-term trend has yet been found in any of the major ring indices which could be reliably interpreted as a secular change in climate, though temporary fluctuations of considerable magnitude and duration are evident throughout the records. Beams in Southwestern ruins, which were cut as much as 1700 years ago, show about the same ring sensitivity as living trees on the same sites, a strong hint that no decidedly more moist or dry conditions prevailed at those times.

Cycle Analysis. Douglass has pointed out the persistent tendency of many tree-ring series to show fluctuations of 22–23 years and fractions and multiples of this cycle, which seem related to sunspot or possibly other extraterrestrial phenomena. Cycle lengths of this order are to be found in the ring series in fossil woods and have been reported in the Scandinavian ring chronologies of temperature. The cycles found in tree growth seem, however, to be characterized by variability in length, amplitude, and form, to tend to appear and disappear according to no discernible law, and to occur in almost any combination. A satisfactory physical

explanation of these characteristics has not yet been developed.

LINES OF FUTURE DEVELOPMENT

It is probable that the contributions of tree-ring analysis to meteorological and hydrological knowledge have only just begun to be manifest. Advances will depend on two related developments: the construction of growth indices for new areas and, in areas already studied, the replacement or amplification of indices by others of greater fidelity to the limiting climatic variable. The profound importance of the latter property of ring chronologies cannot be overemphasized.

Reconnaissance has shown that rainfall chronologies of good sensitivity may be found in selected trees in the headwaters areas of the Missouri, Snake, and other major rivers of the western United States; indices for these basins comparable to that already developed for the Colorado River Basin are now being constructed.

Potential sources of rainfall chronologies appear to exist in the mid-latitude Andes Mountains, the Mediterranean area, the northwest provinces of India, and elsewhere. The vast Siberian Arctic is, as far as is known, totally untouched as a source of temperature chronologies.

The refinement of tree-ring data is primarily related to chronologies in semiarid regions. Even the most elaborate index of this type thus far available, that for the Colorado River Basin developed in 1945, is subject to considerable improvement. The last century of this index is based on some 100 Douglas fir trees from 24 stations within the basin, supplemented by two indices in other species from seven and four stations respectively; earlier portions of the index are progressively weaker, the main index at A.D. 1500, for example, representing 10 stations and 34 trees, supplemented by one minor index for one station. Field work since 1945 has shown that at least 50 stations within this basin can yield sensitive records from 500 to 800 years old, in both Douglas fir and pinyon pine, from which it is possible to derive indices of substantially higher fidelity to rainfall and runoff, particularly in the earlier centuries. Such an extension is now in progress.

As the world map of significant tree-ring chronologies of rainfall or temperature becomes more complete, some estimate may become possible of the large-scale fluctuations in the weather year by year for many centuries. Long-term statistical frequencies found in the climatic records in trees of any area should have greater significance in the light of similar data from many other areas. The application of such knowledge to practical problems in such domains as reclamation, conservation, and water power would seem to be immediate. Of great potential importance is the possible bearing of climatic research in dendrochronology on the problems of long-range climatic forecasting.

Hydrometeorology in the United States *by Robert D. Fletcher* 1033

The Hydrologic Cycle and Its Relation to Meteorology—River Forecasting *by Ray K. Linsley* 1048

HYDROMETEOROLOGY IN THE UNITED STATES

By ROBERT D. FLETCHER

U. S. Weather Bureau, Washington, D. C.

INTRODUCTION

Scope of Hydrometeorology. Meteorological forecasts and advices, though varying greatly as to type, tend to fall into more or less identifiable groups. One such group has come to be known as *hydrometeorology*, that branch of meteorology which deals with the rainfall statistics of storms in order to determine, theoretically or empirically, relationships between meteorological factors and the precipitated moisture which reaches the ground. It is especially concerned with those atmospheric processes which yield the water dealt with in hydrology.[1] In practice, the hydrometeorologist develops estimates—usually in terms of the "maximum possible"—of the space-time distribution of rain over specified drainage areas. The hydrologist uses these values in estimating the flood hydrographs which would result.

The boundaries of hydrometeorology are not sharply defined. The hydrometeorologist, like the hydrologist, is concerned with snow melt, since it is intimately involved with meteorological processes. The cloud physicist and hydrometeorologist, on microscopic and macroscopic scales, respectively, deal with the formation of rain and snow in clouds. The weather forecaster and hydrometeorologist both prepare quantitative predictions of precipitation, although the hydrometeorologist usually does not forecast when precipitation of a given magnitude will occur, but rather that certain maximum intensities can occur over particular areas.

Wherever problems concerned with the accumulation of water from rainfall or snow melt are found, there is a need for hydrometeorological advices or forecasts. In recent years, however, systematic hydrometeorological services have been established largely to provide bases for the design of flood-control and water-usage structures. Among the better known of the hydrometeorological services in the United States are those of the U. S. Weather Bureau. That agency's Hydrometeorological Section was organized to provide hydrometeorological advice for the Department of the Army, Corps of Engineers, which is concerned with the design of flood-control structures. The Weather Bureau's Cooperative Studies Section was established primarily to perform a similar function for the Department of the Interior, Bureau of Reclamation, which is concerned with water conservation and irrigation. The regular duties of the Weather Bureau forecast centers include the quantitative prediction of precipitation intensities over specified areas. Such information is applicable to the operations of flood-control and water-usage structures.

1. Consult "The Hydrologic Cycle and Its Relation to Meteorology—River Forecasting" by R. K. Linsley, pp. 1048–1054 in this Compendium.

Maximum Possible Precipitation. For a given area and duration, the depth of precipitation which can be reached, but not exceeded, is defined as the *maximum possible precipitation*. Since the laws governing precipitation rates are not completely known, this figure is an estimate which implies a range of tolerance, the extent of which depends upon limitations in technical knowledge, data, and thoroughness of analysis. The values computed from the analysis are considered to be the maximum possible since, within the confines of current theory and available data, they are derived from the most productive combinations of the factors controlling rainfall intensities.

In general, three steps are followed in the derivation of maximum possible precipitation values. First a storm model is established—usually in the form of an equation —which expresses rainfall as a function of independent meteorological variables which are not only measurable but also well represented as to quantity and length of record. Theoretical meteorology is basic in the establishment of the equation form: empiricism is utilized in the selection of proportionality factors, constants of integration, and the like. Second, the model is tested through the introduction of observed values for the independent variables. Comparison between observed and computed rainfall rates provides a basis for the estimation of the reliability of the model. Third, the independent variables are maximized statistically. Introduction of the maximum values of these variables, or the most effective combination of them, into the successful rainfall equation produces the estimate of maximum possible precipitation.

BASIC DATA AND GRAPHICAL PRESENTATIONS

Rainfall Intensity, Depth, and Volume. The history of hydrometeorological investigation has demonstrated the need by the field, at one time or another, for nearly every element of the standard meteorological observation. Of considerable importance are (1) humidity, to determine the quantity of moisture which can be precipitated, (2) pressure, to determine the mass of air which can enter into the precipitation process, and (3) wind, to determine the rate at which precipitation can take place. The fundamental element, however, is the precipitation itself. This measurement is one of *intensity* of precipitation, or rate of accumulation of precipitation in the measuring device. It is thus a measurement of the average *depth* of precipitation through duration, the minimum length of duration obtainable being a function of the time-sensitivity of the measurement. It is also a measure of the average *volume* of precipitation through duration, the volume equalling the product of the

average depth and the catchment area of the measuring equipment.

Depth-Duration-Area Data. The user of hydrometeorological advices primarily requires information in the form of average depths of precipitation, duration by duration, over the areas of specified drainage basins. The areas may be as large as, for example, the 145,500 square miles of the Colorado River drainage basin above the Bridge Canyon dam site [26] or they may be small as in the case of the design of storm sewers over a few city blocks. For large areas, the total amount of water which can collect over a period of days is the dominant factor in most design problems. For small areas, design is controlled by high intensities for durations measured in hours or even minutes. The hydrometeorologist is, accordingly, required to determine values of average depth over duration for areas of a larger order of magnitude than those of the catchments of rain gages. He deals with what can be considered as the uniquely hydrometeorological "depth-duration-area" (DDA) values derived from the processing of the essentially "point-rainfall" measurements of the rain gage. Because of the peculiarities of hydrologic needs, most DDA data and estimates are either for large areas and long durations or for small areas and short durations. Because the other two types of combinations are rarely needed, few storms critical as to such combinations have been processed.

In each storm of record, for each standard area (*e.g.*, 10, 100, or 10,000 square miles) and for each duration (*e.g.*, 6, 12, 48, or 120 hr), there exists a maximum depth of rainfall. An array of such data is called the set of "maximum DDA values" for the storm. The Corps of Engineers, in cooperation with the Weather Bureau, is conducting a continuing program of developing maximum DDA values for major rainstorms of record in the United States. Approximately 600 storms have been processed up to the present time. Table I contains the greatest depths together with a list of the storms which produced them. Glasspoole [7] has presented similar data for the United Kingdom, processed by a method slightly different from that used in this country.

Mass Curves of Rainfall. Graphs of accumulated precipitation versus time, called "mass curves" of rainfall, may be prepared in considerable detail in the case of data from recording gages. From 24-hr observation stations, or from stations recording only total-storm amounts, mass curves can be synthesized by referring to the records of nearby recording-gage stations, to synoptic meteorological analysis, and to "double-mass analysis" [11]. The set of mass curves for a single storm is basic to the development of the maximum DDA values, and for the construction of isohyetal maps—for increments of six hours, say, as well as for the total storm. Obviously, the more mass curves available, the more accurate the results will be. DDA values may be derived by planimetering of the isohyetal maps, or by employment of area-weighting procedures such as the "Thiessen polygon" method [24]. A combination of the two methods is now in standard use in the United States.

Conversion of point-rainfall to DDA values involves the assumption that each rain-gage measurement is representative of a more or less large increment of area surrounding it. In its report on thunderstorm rainfall, the Hydrometeorological Section [27] has discussed in detail the reliability of areal rainfall determination.

TABLE I. MAXIMUM OBSERVED RAINFALL DEPTHS IN THE UNITED STATES*

Area (sq mi)	Duration (hr)						
	6	12	18	24	36	48	72
	in.	*in.*	*in.*	*in.*	*in.*	*in.*	*in.*
10	24.7*a*	29.8*b*	35.0*b*	36.5*b*	37.6*b*	37.6*b*	37.6*b*

100,000	1.7*h*	2.5*h*,*i*	3.5*e*	4.3*e*	5.6*e*	6.6*f*	8.9*f*

* The letter after the rainfall depth identifies the particular storm which gave that depth according to the following key:

Storm	*Date*	*Location of rainfall center*
a	July 17–18, 1942	Smethport, Pa.
b	Sept. 8–10, 1921	Thrall, Tex.
c	Aug. 6–9, 1940	Miller Island, La.
d	June 27–July 1, 1899	Hearne, Tex.
e	March 13–15, 1929	Elba, Ala.
f	July 5–10, 1916	Bonifay, Fla.
g	April 15–18, 1900	Eutaw, Ala.
h	May 22–26, 1908	Chattanooga, Okla.
i	Nov. 19–22, 1934	Millry, Ala.
j	June 27–July 4, 1936	Bebe, Tex.
k	April 12–16, 1927	Jeff. Plaq. Sta., La.

Figure 1, reproduced from this report, illustrates the variation in isohyetal-pattern analysis which can result from a variation in the number of reporting stations. For large-area and/or long-duration storms, existing rain-gage networks are usually adequate for computations of DDA values. But only rarely can detailed isohyetal patterns—and thus, accurate DDA values—be determined for the intense, local, short-duration bursts of rainfall which sometimes occur in thunderstorms.

PHYSICAL BACKGROUND OF HYDROMETEOROLOGY

Empiricism and Theory. It has long been recognized that maximum intensities of point rainfall decrease as the durations through which they are computed increase. A number of empirical formulas expressing relations between duration and maximum intensity have been developed, differences between them being ascribable to the availability and type of data used in the formulation of the relationships, geographical regions of application, and similar factors. Since it is also recognized that maximum average depths of rainfall decrease as the area over which they are averaged increases, other empirical relations have been derived to include the factor of area.

Empirical formulas can represent, with an accuracy

adjustable by variation of the complexity of the equations, the envelopes of rainfall occurrences. Their extensions to include the maximum possible precipitation require adoption of arbitrary measures—the use of

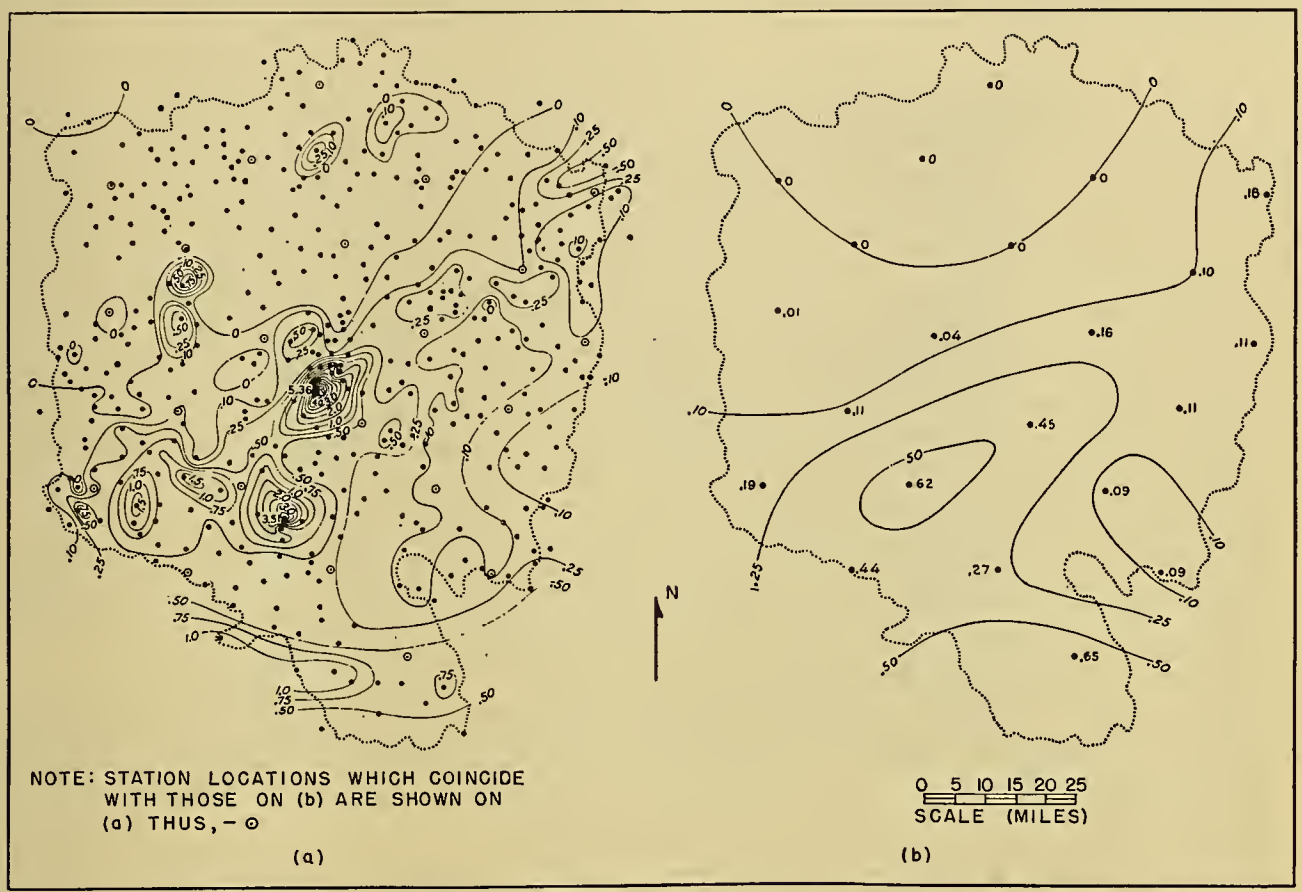

FIG. 1.—Isohyetal maps of storm of August 3, 1939, Muskingum Basin, Ohio; (*a*) 449 rain gages (1 gage per 18 sq mi); (*b*) 22 rain gages (1 gage per 375 sq mi).

safety factors, for example. With methods based upon meteorological theory, it is possible to derive enveloping relationships through the use of meteorological data other than those of precipitation, and to develop the forms of the extensions of these relationships beyond the highest observed depths of precipitation. Such methods have been found to be most suitable for the majority of hydrometeorological problems. Nevertheless, empirical or statistical approaches are still followed whenever theoretical knowledge is not sufficiently complete or whenever available data are inadequate for the test and usage of known theoretical relations. Future advances in hydrometeorology therefore hinge upon further development of basic theory and upon the acquisition of necessary and sufficient data.

Precipitable Water. The immediate source of precipitation is the water-vapor content of the air. For analytical purposes, this quantity is customarily expressed in terms of the depth of "precipitable water" in a column of air,

$$W = \int_0^{p_0} (q/g\rho_w)\, dp, \qquad (1)$$

where g is the acceleration of gravity, ρ_w is the density of water, q is specific humidity, and p_0 is the pressure at the bottom of the air column in which W is the precipitable water. As has been pointed out by Solot [21], when pressure appears in units of millibars, W (in inches) is closely approximated by

$$W = 0.4 \int_0^{p_0} q\, dp. \qquad (2)$$

Increments of W can be computed when the variation of q with pressure is known.

The basic obstacle in the way of general use of the theoretical expression for W is the almost complete absence of upper-air sampling in the major rainstorms of record. Accordingly, hydrometeorologists have been forced to make certain assumptions regarding the relation between W and other meteorological elements, well represented areally and historically. The most common such assumption is that, in major rainstorms, the air in which the rain is formed is saturated throughout its depth and is characterized by a pseudoadiabatic lapse rate. Here, the depth of precipitable water in an air column above a specified pressure surface is a single-valued function of the dew point (or temperature) at that surface. Figure 2 shows the relation, based on this assumption, between W and surface dew point when

the pressure at the surface is 1000 mb. From the graph the depth of precipitable water between any two pressure levels aloft can also be obtained when the potential dew point is known. Precipitable-water tables [32] for combinations of variables involving either pressure or are appreciably reduced in most practical applications. To achieve greater realism, however, refined assumptions can be formulated from synoptic studies of temperature and moisture stratifications, storm type by storm type. For instance, it is apparent that a saturated,

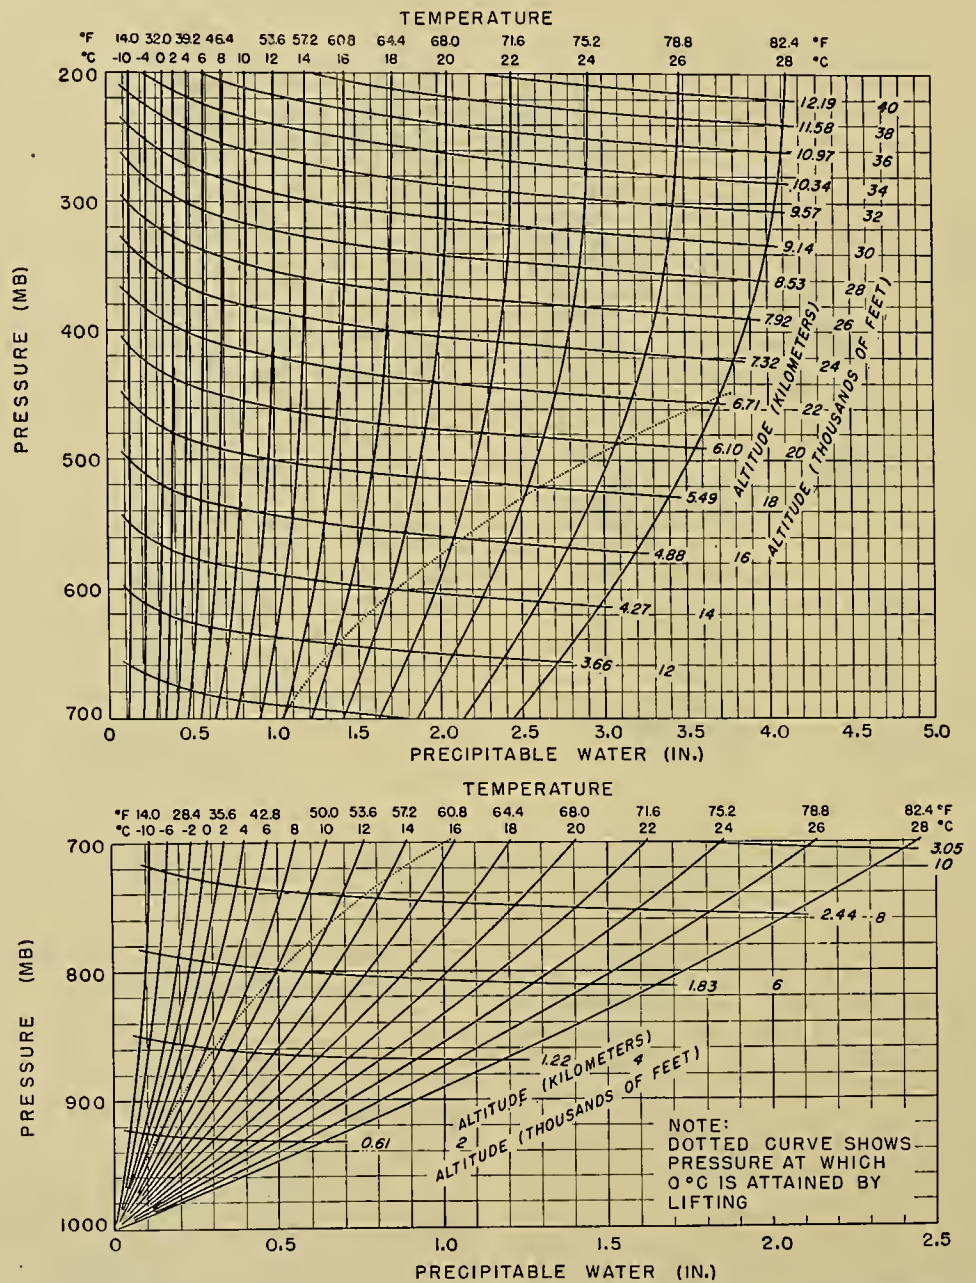

FIG. 2.—Depths of precipitable water in a column of air of given height above 1000 mb, under the assumption of saturation with a pseudoadiabatic lapse rate for the indicated surface temperatures.

height have recently been prepared for hydrometeorological use.

The few tests of this assumption which have been possible in heavy rainstorms indicate that significant deviations may sometimes occur. Since, as will be discussed later, the most common use of precipitable-water values in hydrometeorology involves ratios of W at various dew points, errors inherent in the assumption pseudoadiabatic atmosphere is not particularly close to reality in the case of convective instability, a circumstance which frequently characterizes sizable rainstorms. Whether the maximum possible storm possesses a pseudoadiabatic lapse rate in saturated air has not been established, but this is usually accepted as a reasonable assumption. Investigation is needed to determine whether it is possible to maximize theoretical

relationships to develop optimum distributions of moisture, temperature, and wind.

Vertical Motion. The precipitable-water depth is the amount of moisture available for precipitation in an air column. By itself, however, it does not provide sufficient information for computations of precipitation intensities. Lifting of a saturated column produces a cooling according to the pseudoadiabatic lapse rate, and therefore a decreasing water-vapor content. Thus, if the lift-speed of the column is known in detail, the rate of decrease of W—and hence the rate of condensation—can be computed. If the cloud-particle content of the air column remains fixed, the condensation rate becomes the precipitation intensity. For saturated air with constant cloud-particle content, precipitation intensities can be determined by means of a diagram prepared by Fulks [6], which shows the condensation rate, per unit vertical lift, in 100-m layers of air for various values of pressure and temperature. The equation for intensity of precipitation I, under the same assumptions, is

$$I = \int_{z_0}^{z} V_z \rho \frac{\partial q}{\partial z}\, dz, \tag{3}$$

where V_z is upward velocity and ρ is air density. An integrated form of this equation has been discussed by Showalter [19]:

$$I = V_{z0}\rho_0(x_0 - x_1)/7 \text{ inches per hour}, \tag{4}$$

where V_{z0} is the vertical velocity at the bottom of the air column in which the rain is produced, ρ_0 is the density at the bottom, and x_0 and x_1 are the mixing ratios at the bottom and top, respectively, of the column.

Use of equation (3) requires detailed knowledge of both q and V_z. The volumetric distribution of humidity can be estimated from available aerological soundings or, indirectly, from surface observations in cases of heavy rain. Only under very special conditions, however, can the space distribution of vertical velocity be estimated with an accuracy sufficient for hydrometeorology, and direct measurements of this factor are almost completely lacking. Miller [14] has discussed a number of ways of expressing vertical velocities in terms of quantities more amenable to measurement. Combinations of such expressions with equation (3) can produce various rainfall-intensity equations.

Equations of Continuity. Basic to all theoretically derived rainfall relations used in hydrometeorology is the equation of moisture continuity. This relation states that the average depth R of rainfall through duration D and over area A is equal to the moisture flowing into the space above A, minus that flowing out, plus the moisture above A at time $t = 0$, minus the moisture at $t = D$. The moisture q, to be exact, should be defined as the total number of grams of water in the air per gram of air, whether it be in the form of water vapor, cloud droplets, rain, or snow. Lacking sufficient data as to atmospheric content of liquid- or solid-water particles, hydrometeorologists have assumed that consideration of the water-vapor content, alone, leads to conclusions that are satisfactorily accurate. The assumption may involve important errors in the case of short-duration, small-area rainfall, the errors probably diminishing, however, with an increase of duration and/or area.

The equation of continuity for moisture may be written

$$R = (1/\rho_w A)\left[\int_0^D\int_0^\infty\oint q\rho V_1\, ds\, dz\, dt - \int_0^D\int_0^\infty\oint q\rho V_2\, ds\, dz\, dt + \left(\int_0^A\int_0^\infty q\rho\, dz\, dA\right)_{t=0} - \left(\int_0^A\int_0^\infty q\rho\, dz\, dA\right)_{t=D}\right], \tag{5}$$

where V_1 and V_2 are the horizontal inflow and outflow components, respectively, of the wind normal to a horizontal linear element ds of the vertical wall of the cylinder extending upward from the boundary of area A. The quantities V, q, and ρ must all be forecast if the equation is to be used for the quantitative prediction of precipitation. For purposes of estimating maximum possible precipitation, the most critical combination and values of the independent variables must be determined.

For the horizontal wind, unlike the vertical velocity, measurements are available. Indeed, successful attempts have been made to compute rainfall by direct application of equation (5), although q has had to be considered as a measure of water vapor only, and time and space interpolations of wind between pilot-balloon observations have been necessary. Unfortunately, while several meteorological projects have been undertaken, incorporating dense rain-gage networks and dense coverage of upper-air observations, a near-maximum rainstorm has never occurred when they were in simultaneous operation. As a consequence, investigations of major rainstorms have required approximations of equation (5), with substitutions of available measurements. Furthermore, the choice of elements to be used has necessarily been restricted to those with considerable abundance and length of record in order that methods and results could be comparable.

In some approaches to the problem, the continuity equation for air is used:

$$0 = \int_0^D\int_0^\infty\oint \rho V_1\, ds\, dz\, dt - \int_0^D\int_0^\infty\oint \rho V_2\, ds\, dz\, dt + \left(\int_0^A\int_0^\infty \rho\, dz\, dA\right)_{t=0} - \left(\int_0^A\int_0^\infty \rho\, dz\, dA\right)_{t=D} \tag{6}$$

in which the variables are the same as those appearing in equation (5). When simplifying assumptions are made, the use of equation (6) can bring about elimination of one of the more-difficult-to-measure variables of equation (5).

Storage Equation. Relationships (5) and (6) are quite general. When applied to certain simple flow models, they may be transformed into a rainfall equation which has demonstrated its ability to produce results comparable with observed rainfall amounts. In one such flow model—a two-dimensional one—the wind blows

across a rectangular area of size A and length Y. The inflow wind V_1 blows into the model at low levels, through a depth Δp_1, above which zero wind movement is defined. The outflow wind V_2 blows out of the model at high levels, through a depth Δp_2, above and below which there is no wind movement. There is assumed to be no net accumulation of air or atmospheric water content through duration D. Values used are all assumed to be averages through D. The quantities V_1 and V_2 are taken as averages through the respective Δp's, and the averages with respect to dp are assumed to be equal to the averages with respect to qdp. With these assumptions, equations (5) and (6) can be integrated. Elimination of the outflow wind results in the so-called "storage equation,"

$$R = \frac{V_1 D}{Y}\left(W_1 - \frac{\Delta p_1}{\Delta p_2} W_2\right), \tag{7}$$

in which W_1 and W_2 are the precipitable-water depths at the inflow and outflow ends, respectively. The quantity within parentheses is frequently referred to as W_E, the "effective precipitable water." For each flow model chosen, it represents the amount of rain falling from each unit column processed in the model. In the practical use of the storage equation, the precipitable water is estimated from the surface dew points, and the Δp's are assumed according to the flow model being studied; Y is a function of wind direction and drainage-basin dimensions, and V_1 is estimated from either surface or pilot-balloon observations. For estimation of the maximum possible precipitation that can fall from a given model over a project basin, envelopments of wind-speed and dew-point statistics, for each wind direction, are used in the equation.

OROGRAPHIC RAINFALL

Empirical Approaches. Much of the rain which falls in mountainous regions is due directly to the lifting of moist air up the mountain slopes. For purposes of the present discussion, this percentage of the total rainfall in a storm is defined as the *orographic component*, while the remainder is called the *nonorographic component.*

The orographic component is amenable to fairly simple theoretical derivation since the slope and the elevation of the ground surface—the factors which control the lift of the air per unit wind speed—are fixed and known. For certain noncomplex mountain systems, it is possible to calculate the rainfall with considerable success under the principal assumptions that (1) all of the rain is orographically produced, and (2) the upper-air flow pattern is deducible from surface observations. As the topography becomes more complex, however, not only does the problem become harder to handle mechanically, but also the vertical and horizontal distributions of winds become more difficult to estimate with assurance. Present deficiency in theoretical knowledge of the effects of topography upon the space distribution of wind leads to the conclusion that an empirical approach must serve for many problems involving orographic rainfall until adequate theory is developed. Such an approach may be based upon a rational selection of topographic parameters, for example, slope, exposure, and elevation. Use of multiple-correlation techniques may then produce a regression equation in which rainfall is expressed as a function of the topographic parameters. The equation would also contain a residual term, partly resulting from incomplete selection of parameters and partly giving the nonorographic component of rainfall.

The approach described above is not adaptable to computation of single-storm rainfall unless the meteorological parameters of wind and humidity are also considered. It is well suited, on the other hand, for derivation of long-duration rainfalls over orographic regions of meteorological homogeneity. The method has been used by Russler and Spreen [17] to estimate average seasonal precipitation at points between the relatively sparse network of recording gages in the Colorado River drainage area. Excellent correlations were obtained in this study, in which a graphical multiple-correlation technique was employed.

In a study of rainfall potentialities in the Willamette River Basin, Oregon, Platzman [16] employed an essentially empirical method. Lack of suitable data, in this case, precluded a theoretical investigation. Platzman reasoned that the speed and moisture content of the air passing over the basin from the Pacific were the dominant meteorological factors and, further, that these parameters were representable by observations made at a surface weather-reporting station. He made statistical studies which led to selection of an index station, and from available DDA data from five of the greatest Willamette Basin storms of record, he determined the coefficients in the empirical equation

$$R = (a + bT_d)(c + dV^2), \tag{8}$$

where T_d was dew point and V was wind speed at the index station. Envelopes of the rainy-season wind and dew-point observations at the index station provided values to be placed in equation (8) for estimation of the maximum possible rainfall.

Where theory is inadequate, as in problems associated with highly complex topographic regions, empiricism probably offers the only approach which will produce the required answers. This approach is usually based upon rain which fell in important storms of record and assumes that the model of the average large storm is the same as that of the maximum possible one.

Theoretical Barrier Models. For special, simple topographic regions it is possible to derive expressions based largely upon physical reasoning and yielding computed values which agree well with observed ones. When the outstanding feature of the basin is the existence of one or two mountain barriers which intercept rain-bearing winds, the storage equation (7) may be adapted to the problem. It is usually necessary to make assumptions regarding the vertical distributions of temperature and humidity, since radiosonde observations are inevitably missing in the great storms of record which offer the only checks on the suitability of models to be chosen. Although the assumption of a saturated, pseudo-

adiabatic atmosphere, represented by carefully selected surface index stations, probably does not cause important errors, investigations into the actual structures in major storms may result in significant refinements in the rainfall equations.

The assumption probably open to the most serious question concerns the space-time distributions of wind in the major storms of record and in the maximum possible storm. Observations of upper winds made during periods of both fair and rainy weather are required from stations located near the tops of mountain ranges. Theoretical studies of the structure of air flowing over mountain barriers should continue, special effort being directed toward the theoretical determination of wind structures over barriers during conditions prevalent in major storms. The effects of variations in the geometry of a basin on the wind flow also deserve much study. In other words, the validity of the common assumption of two-dimensional flow should be determined.

The effects of a mountain barrier upon the wind extend not only vertically but also horizontally away from the barrier. In the case of very simple obstacles to wind flow, aerodynamic theory can accurately predict distortions of straight flow. In meteorology, however, the obstacles are irregular mountain peaks, the undisturbed flow pattern is in itself complex, and the fluid is characterized by stratifications of density and humidity. Present meteorological theory is not adequate for the determination of distortions in the wind pattern both upwind and downwind from a barrier except in the qualitative sense that the air begins to rise, on the average, before the barrier is reached, and descends for some time after it has been passed. It is evident that some of the orographic rain must be produced, and must fall, at some distance upwind from the barrier. If a considerable body of rainfall data is available, the "upwind effect" can be treated empirically. Otherwise, assumptions must be made as to the structure of the wind system, whereupon theoretical computations can be made. The upwind-effect problem is only part of the general problem pertaining to flow of air over barriers upon which both statistical and theoretical investigations should be continued. With appropriate modifications of the Reynolds number, laboratory studies with models patterned after typical orographic regions could also lead to valuable results.

Spillover. Since vertical motions which produce rain are inevitably associated with horizontal motions, it is evident that rain formed at a point in the atmosphere will, in general, reach the ground at a spot not vertically below the point of formation. In the case of orographic rainfall, where the wind systems which carry the raindrops along are usually fixed with respect to topographic features, the effect is called *spillover*. The importance of spillover relative to other types of orographically produced rainfall is illustrated in Fig. 3, which contains profiles of rainfall depths in three major storms across the San Joaquin Valley [29]. Theoretical computations of spillover are based upon the following principal assumptions. For each basin two critical raindrop paths can be defined, one at the inflow and the other at the outflow end of the basin, such that all rain formed between them will fall within the basin. Rain formed outside of the space between the two paths will fall outside of the basin. The paths can be based on the assumption of an average raindrop terminal velocity corresponding to that observed in heavy rains, and the horizontal speed of each drop can be assumed to be that of its environment. As with the total orographically produced rainfall, the reliability of the spillover

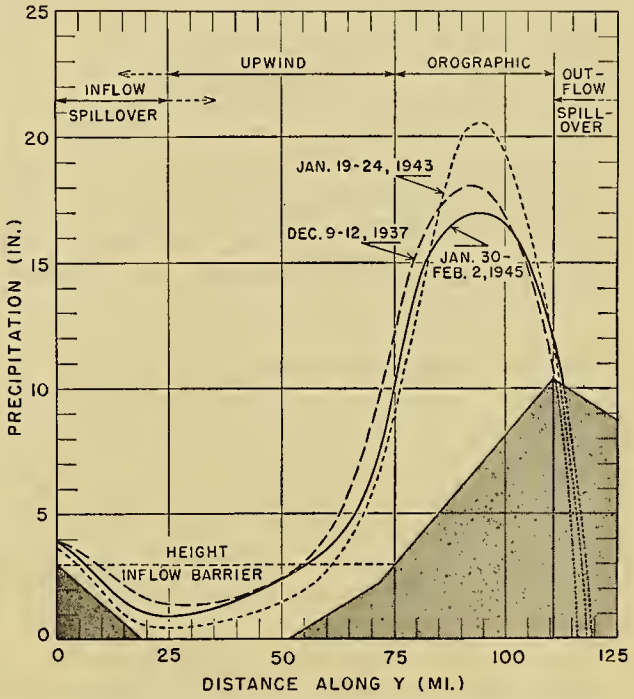

Fig. 3.—Storm profiles, San Joaquin River Basin, California

computations depends upon the accuracy with which the upper-air flow patterns can be reproduced. The importance of spillover increases as the drainage area decreases; for the average small basin of about 100 square miles, spillover may produce a component as high as about 10 per cent of the total rain caused by orography. It is probable, therefore, that errors in the assumptions produce computational inaccuracies of only a few per cent. Spillover can become highly significant for very small basins, however, hence research on this problem is desirable. Refinements in the theory can undoubtedly be attained through application of physical and statistical-mechanical approaches and by collection of data relative to raindrop-size spectra and fall velocities in rainstorms of large magnitudes.

NONOROGRAPHIC RAINFALL

Storm Transposition. In regions of rugged terrain, computations of rainfall are facilitated by an accurate knowledge of the dimensions of the mountain barriers which play such a dominant role in air flow of the lower atmosphere. On the other hand, tests of rainfall formulas for a particular basin may nearly always be carried out through use of precipitation data collected within that

basin only, since the production of rain over other basins is largely controlled by different orographic features. For nonorographic regions as, for instance, the Great Plains of the United States, the fixed controls are absent. Distribution of vertical velocities is, instead, a function of storm type, but the storm type is probably only remotely a function of geographical location within the limits of, say, a half-dozen degrees of latitude or longitude. In nonorographic regions, consequently, while fixed barrier heights are not at hand for use in computation, present meteorological knowledge permits use of data from storms that have occurred not only within the confines of a project drainage basin but also within a sizable area surrounding the basin.

The first estimates of maximum possible precipitation over a drainage basin utilized the highest depths of record within that basin; if no large storms had happened to occur within the period of meteorological history of the basin, use of factors of safety was often adopted. A degree of refinement was then added when the rainfall records of adjoining basins were employed. With the introduction of the process of "transposition" of storm-rainfall values from one region to another came the need for meteorological studies of the major storms of record. Decisions—largely subjective, and based upon the weather-map-analysis experience of trained meteorologists—had to be made as to the area of transposability of each of the great historical storms. In conjunction with other procedures, storm transposition is still in wide use. It will undoubtedly continue to be so until accurate and reliable theoretical rainfall equations can be developed for general usage in nonorographic regions. Use of this procedure obviously requires DDA processing of large numbers of recorded storms.

Moisture Adjustment. The equation of continuity of moisture indicates that rainfall depths increase with water-vapor content of the air, other factors remaining equal. Thus, it can be reasoned that a given storm of record would have produced greater rainfall values had its water-vapor charge been greater, or, in terms of the end product, were a "moisture adjustment" to be applied to the DDA values. Wide usage is made of such a procedure, in combination with that of storm transposition, for regions in which theoretical rainfall equations have not been developed.

Since nearly all of the great historical storms have occurred without available samplings of upper-air humidities, the use of surface indices has had to be adopted. For reasons already pointed out, the surface dew point—reduced to 1000 mb—is usually chosen as the index of the moisture charge of the air in which the rain is formed. In practice, for each storm of record, the dew point is selected at a location, nearest the rainfall center, where tropical air is to be found at the surface. The method of selecting these values is described in detail in a report [30] which also lists the representative storm dew points of about 500 major storms in the United States.

The so-called *maximum possible dew points*, to which the representative storm dew points are adjusted, are derived statistically from the records of first-order Weather Bureau Stations. A close envelopment of the highest values—reduced to the 1000-mb surface—recorded at these stations yields, for each month, a map of maximum possible dew-point isotherms. A detailed description of the process is given in a recent hydrometeorological report [28]. Both the maximum possible and the representative storm dew points are 12-hr values; actually, they are the highest minimum values occurring through any 12-hr duration of the period of record of a station or during the period of a storm, respectively.

Through storm transposition the DDA values of all transposable storms are applied to a project basin and each storm dew point is adjusted to the maximum possible for the season and new location. Envelopment of the transposed and adjusted values of all the storms yields a preliminary estimate of the maximum possible precipitation for the project basin.

Various methods of performing the moisture adjustment have been developed. Of these, only the three which seem to be closest to physical reality will be outlined here. The first, called the *cyclonic-adjustment method*, has frequently been applied to large-area storms. Here, the adjustment is simply multiplication of the rainfall values by the ratio of W at maximum possible dew point to W at the representative-storm dew point, under the assumption of a saturated, pseudo-adiabatic atmosphere. Precipitable-water depths for a layer of air between 1000 and 300 mb are used in the calculations.

The second, the *thunderstorm-adjustment method*, differs from the cyclonic-adjustment method in that the top of the layer for which precipitable-water values are used varies from 100 to 300 mb when the 1000-mb dew point varies from 78F to 50F, respectively. Choice of the range was based upon available data relating to the variation of cumulonimbus cloud tops with surface temperatures and dew points. This method, discussed at length in a hydrometeorological report [28] on generalized estimates of maximum possible precipitation, is intended for use in adjusting storms in which rainfall was mostly from cells of convective action.

The third, or *q-adjustment method*, is intended to apply to the moisture adjustment of storms in which only the magnitude of the moisture charge is to be varied, and all other factors, such as moisture stratification, spatial dimensions of the storm cells, and magnitude and distribution of wind, are to remain unchanged. As described by Fletcher [3], it is possible to factor a mean value of specific humidity from the equation of moisture continuity, and to introduce a factor of proportionality between the mean value and the value of specific humidity corresponding to the surface dew point representative of the storm's moisture charge. For purposes of adjusting storms for moisture only, with all other characteristics to remain unchanged, use of ratios of surface specific humidity is more rigorously correct than use of precipitable-water ratios. However, it has not been established whether the concept that moisture charge can vary without any appreciable change in the rest of a storm's characteristics is physi-

cally tenable. This concept requires considerable theoretical investigation.

Adjustments for Other Factors. In order to reach a project drainage area where rain is to fall, air often must first be lifted over a rise in the ground surface. As in the case of the single-barrier, orographic-rain problem, moisture is removed from the air during its passage over the higher ground. Thus, in treating situations where either a mountain barrier or a long, gentle rise in ground is in the way of air flow toward a basin, it is assumed that a depth of precipitable water contained in a saturated, pseudoadiabatic column of height equal to that of the barrier is removed from the total quantity of moisture initially available for precipitation. The further assumption is made that the barrier—although it may be effective in producing more frequent storms—does not act to alter the wind structure of a transposed storm. It is evident that use cannot be made of the barrier adjustment when a project basin is so close to the downwind side of a barrier that spillover is effective in increasing the precipitation within the basin. The approximate reduction effect of a barrier is one per cent for each 100 ft of barrier height. Statistical tests of the propriety of the barrier adjustment indicate that the adjustment is of the right order of magnitude.

Wind adjustments have been attempted, but the results lack the consistency which marks the moisture and barrier adjustments. Two principal difficulties arise in this connection. First, because minor topographic effects have such a profound influence on the surface wind, it has not been possible to determine reliable wind indices for either the strengths of the currents in storms or the maximum strengths which can be expected in a given locality. Second, it is likely that changes in index-station wind would produce fundamental changes in the nature of a storm by causing important alterations in the space and time distributions of winds.

McCormick [13] has recently shown that there is a significant downward trend of peak rainfall depths as latitude increases. The effect increases as the area over which the depths are averaged increases; for point-rainfall it is so small as not to be statistically significant, but for depths over an area of 2000 square miles the reduction is in the neighborhood of 2 per cent per degree of latitude between latitudes 30°N and 60°N. Variation with rainfall duration was less significant, although there was a tendency for the importance to increase with duration. It is possible that there is a simple physical explanation for the latitude effect. For instance, if the Coriolis acceleration is dominant in the balance of forces in maximum storms, then, since wind appears to the first power in the equation of continuity, rainfall depths should vary inversely with the sine of the latitude.

McCormick also found the quite unexpected, yet statistically significant, fact that the maximum observed depths of rainfall in the United States decrease sharply south of latitude 30°. It is possible that existence of the northern Gulf of Mexico coast—also at latitude 30°—is responsible for this behavior. On the other hand, it is possible that the 30°-peak of rainfall is associated with extreme southward displacements of the meandering jet stream of middle latitudes. Rainfall variations with latitude appear to be important. Thus, with northward or southward transpositions of storms, a latitude adjustment may be in order. The proper nature of the adjustment, however, must await further physical and statistical research.

When allowance is made for latitude and atmospheric moisture content of the major storms of record in the United States, a map of the peak values discloses several meridional maxima, the chief of which extends north-south approximately along the 98° meridian. It may be more than coincidence that the western extremity of the Gulf of Mexico is at about the same meridian. There also may be a certain critical wave length—eastward from the Rockies—of the zonal west winds which, if attained, can be associated with storms which produce greater rainfalls than do storms associated with other wave lengths. The problem of longitudinal variation of maximum rainfall deserves critical attention in the light of its possible use in connection with storm transposition.

Statistical treatments of many other variables should be carried through to determine the existence and probable nature of consistent variations. Hand in hand with the statistics, however, theoretical research should attempt to place the variations on sound physical bases and to determine the degree to which one type of adjustment is dependent upon another. The ultimate objective of the adjustment theory is the expression of rainfall as the product of a number of independent factors, each a function of a particular (measurable) variable, such that all storms can be reduced to a common denominator.

Isobar-Isotherm Relationships. For storms in which the rain-producing air enters at one side of the rainfall area and leaves at the other, it follows that the rainfall depths will be greater the more the inflow winds are confined to low levels and the outflow winds to high levels. Under the assumption that the geostrophic wind-shear equation holds approximately, the wind-stratification system of a heavy rainstorm is such that air entering the system does so with higher temperatures to the left of the current axis and lower temperatures to the right and leaves with the reverse distribution of temperature. A different sort of rainfall-favoring pattern, in which mass convergence takes place at low levels and mass divergence aloft, is characterized, on the inflow side, by anticyclonically curved isobars at low levels and cyclonically curved isobars aloft and, on the outflow side, by anticyclonically curved isobars aloft and cyclonically curved isobars below.

The patterns described above may be combined to form an isobar-isotherm configuration which is theoretically an important rain producer and which has been observed on synoptic maps in varying degrees. For example, combination of a warm, Λ-shaped trough in Texas and a cold cyclone in more northern states meets most of the requirements. With such a configuration, the heaviest rain should fall to the east of the line

joining the warm trough and cold low. It is of interest to note that this example is a storm type which can produce large rainfall depths for long durations. Existence of the warm continental surface (late spring through fall) south of Texas tends to retard movement of a warm trough; in addition, deep cold lows farther to the north are frequently observed to move very slowly. Synoptic studies of variations in this and other types of major storms will without question throw much light on the relationships between rainfall and other measurable variables.

Statistical Relationships. The problem of objective forecasting of rainfall has been attacked—sometimes quantitatively and sometimes qualitatively—by many writers. In the main, the approaches have been statistical, although the choice of independent variables has usually been made on physical grounds. Jorgensen [9] has related upper-air flow patterns to rainfall in California. By means of "composite maps," Solot [22] has developed a method of preparing monthly precipitation forecasts for the Hawaiian Islands. Brier [1] and Penn [15] have made use of upper-air flow patterns in developing objective methods of quantitative precipitation forecasting. Through use of mean maps, Klein [10] has related five-day precipitation amounts to characteristics observed at the 700-mb surface. The statistical approaches, of which the above are a selection, yield results which show appreciable amounts of skill. Especially for the task of quantitative precipitation forecasting, objective, statistical methods display much promise.

As far as hydrometeorological needs are concerned, approaches such as those listed in the previous paragraph constitute only the first step. They tend to deal with average rather than enveloping values of the variables. Forecasts are based on relations derived from rainfall depths of lower orders of magnitude than those with which the hydrometeorologist is concerned. Furthermore, the approaches make no provision for extrapolation of observed to maximum possible values. They have, however, disclosed variables which are important as regards rainfall formation and, consequently, suggest certain directions for future hydrometeorological research.

Enveloping Depth-Duration-Area Relationships. It has recently been shown by Fletcher [4] that maximum observed point-rainfall depths tend to vary with a power of duration so near to 0.50 that the assumption that depth varies with the square root of duration produces a very close envelopment of all recorded values of point rainfall. It was found, in addition to the square root of duration variation, that maximum observed areal rainfall depths vary hyperbolically with area. The equation

$$R = \sqrt{D}\left(0.5 + \frac{266}{19.2 + \sqrt{A}}\right) \qquad (9)$$

was found to be a close envelope of all observed rainfall depths for durations ranging from one minute to one year, and for areas between a point and 200,000 square miles. In the equation, R is depth of rainfall in inches, D is duration in hours, and A is area in square miles.

Equation (9) was derived empirically, and it is entirely possible that future rainfall records may bring about revisions in the constants. On the other hand, theoretical investigations now under way suggest that the form of the equation is correct for maximum possible precipitation.

SPECIAL HYDROMETEOROLOGICAL PROBLEMS

Rainfall Probabilities. Certain design problems require estimates not of the maximum possible precipitation but rather of the greatest precipitation to be expected within a selected number of years. Economic factors might dictate, for example, that the design criteria for a certain structure should be based upon the greatest 6-hr rainfall to be expected once in ten years. For some needs point-rainfall estimates suffice, for others, estimates of average depths over specified areas are required.

From the Weather Bureau's tabulations of excessive rainfall occurrences, Yarnell [34] has published charts of rainfall expectancies in periods of from 2 to 100 years. Such charts can answer many questions as to probabilities of heavy rains. They are confined, however, to point-rainfall depths for durations from 5 min to only 24 hr, and are based upon data which have some variation as to criteria of selection. There is great practical need for an extension of Yarnell's work to longer durations and to averaging of depths over areas.

Other writers have made studies of frequencies of point-rainfall depths and, occasionally, of averages over various sizes of area. When the highest values of rainfall are considered, however, the difficulty arises that such values occur only once in the period of record of the observing station. Thus, the reliability of a "once in a hundred years" value, and similar values, is open to question. Development in statistical theory will undoubtedly assist as regards the probability aspects of high rainfall rates. It is obvious, nevertheless, that accumulation of data through the years is necessary for the development of the probabilities of extremely high rates of rainfall.

Space and Time Distributions of Rainfall. Estimates of maximum possible DDA values do not meet all of the needs of the hydrologist, especially for larger drainage basins. It is also necessary that estimates be made of the isohyetal patterns and their variations with time. As far as river stages at the lower end of a basin are concerned, a heavy burst of rainfall occurring upstream and followed by another downstream is a more significant sequence than one in which the order is reversed.

Heavy storms of record exhibit the characteristic that the highest ratios of observed to maximum recorded DDA values for the United States tend to cluster about only one combination of area and duration, that is, each storm is important only within a restricted range of the durations and areas over which rain actually fell in the storm. Maximum recorded values for the United States are therefore determined by a series of "controlling" storms. Since the greatest storms of record all

possess this characteristic, the assumption has come to be made that all of the maximum possible DDA values will not necessarily fall in one great storm but, rather, that each of several great storms will yield a limited number of maximum DDA values. Until meteorological theory can demonstrate otherwise, such an assumption —based upon data collected for maximum storms of record—appears to be logical.

In practice, the space-time rainfall distributions observed in the greatest storms transposable to a given basin are used to estimate the distribution of maximum possible precipitation for that basin. If major-storm experience for the basin is large, a good selection of distributions becomes available. Regardless of the number of such distributions which have been observed, however, it is apparent that the most critical distribution possible may not have occurred. Accordingly, the dependability of the method necessarily hinges upon the number of data which has been collected during a relatively short number of years. While the method is objective and reasonable within limitations, investigations should be conducted to develop other methods based upon assumptions physically more acceptable.

Studies of intense, short-duration and small-area rainfall such as occurs within a severe thunderstorm have disclosed a very wide variety of isohyetal patterns. For working purposes it is therefore assumed that there is no limit to the kinds of patterns which can result from such localized storms (very roughly, for areas up to one hundred or two hundred square miles and durations up to one or two days). It is possible, nevertheless, that detailed analyses of large numbers of thunderstorm-type isohyetal patterns may reveal certain wide limits as to space and time distributions of rainfall.

Where production of rain is primarily controlled by orographic features, the problem becomes simpler. In an analysis of rainfall over a small drainage basin in Venezuela, for example, Fletcher [5] found a high correlation between patterns of major storms and between the patterns of a major storm and of the mean annual precipitation. Here, meteorological reasoning strongly suggests that the most effective rain-bearing winds come only from one direction, thus that the maximum possible storm would closely resemble the mean annual precipitation as far as the pattern in space is concerned. For other orographic regions, therefore, the analysis in Venezuela suggests that design patterns may be determined for each wind direction.

The assumption is sometimes made that the total rainfall in a storm occurring in a mountainous region may be separated into two mutually independent parts, the orographic and nonorographic components. The orographic rain is assumed to result only from orographic lifting; the nonorographic component is assumed to be that which is due only to the passing meteorological storm. If the occurrences of nonorographic rain are random, the mean seasonal precipitation pattern can be assumed to be produced purely by the topographic configurations of the region. What is known as the *isopercental method* of storm transposition is based on these assumptions. For a major recorded storm, the ratio (expressed in per cent) of the observed precipitation at each station to the corresponding mean seasonal value is plotted on a map. The resulting pattern of isopercentals is transposed from the region of storm occurrence to the project basin, and the percentages, applied to the mean seasonal values of the basin, produce the transposed isohyetal pattern and the magnitude of each isohyet. There is considerable logic to this method. However, there are certain objections which indicate that research should be conducted to estimate the degree to which it may be in error. For instance, there are probably significant inaccuracies in the assumption that the orographic and nonorographic components are mutually independent. It is conceivable that many storms occur in mountainous regions simply because the mountains are there; if the ground had been level, the synoptic situation might have existed as a nonproducer of rain. Again, the mean seasonal pattern may deviate significantly from a pattern derived from only the major rainstorms of record. In the many ordinary rainstorms which are so important in forming the mean seasonal pattern, variation of the condensation level alone could produce a pattern appreciably different from that produced by storms with a uniform condensation level. Furthermore, effects of orography upon rain-bearing winds from various directions can produce profound changes in the isohyetal pattern, such that the orographic-component pattern with one wind direction might only remotely resemble that with another.

Recurrence Interval. In some drainage basins of large area, it is a matter of days for runoff from the upper reaches to arrive at proposed construction sites. It becomes important, for a basin of this sort, to prepare an estimate of the minimum number of rainless days that can occur between two storms of either maximum possible or near maximum magnitudes. Fundamentally, this is the same kind of problem brought up in the previous paragraphs, since it is concerned with space-time distributions of rainfall. The customary DDA analysis of rainfall on the basis of individual storms requires, however, adoption of somewhat different approaches.

The technique usually followed relies upon precedent established in the approximately half a century of United States weather-map analysis. The synoptic type of the storm yielding the critical rainfall depths is first determined. The weather maps of record are then searched for recurrences of storms of the critical type, or types, and the minimum duration between the occurrences is chosen as the recurrence interval.

Application of the form of equation (9) to durations of several days can provide answers for recurrence-interval problems, although it must first be established that this equation is applicable in specific regions. The relation has been developed, basically, from highest available depths of record from storms occurring throughout the world.

Seasonal Distribution of Rainfall. Design and operational problems often require estimates of the way in which maximum possible precipitation varies with

season. Preliminary estimates of the variations may be determined by the processes of storm transposition and adjustment, month by month. Unfortunately, such an approach suffers from a decimation of the number of storms available for processing. Other difficulties with storm samplings arise from the fact that storms are most frequently chosen for DDA analysis because of unusually large rainfall depths which have been observed, and that some seasons are characterized by maximum observed amounts much lower than those of other seasons. The method will become more useful as more storms are analyzed for their DDA values, and as the sampling becomes more nearly equal, season by season.

The estimates will become more reliable when physical bases are established for seasonal variations in the factors appearing in theoretical rainfall equations. It must be emphasized, however, that extreme rainfall depths are being considered, and thus that seasonal variations of extreme rather than average values of meteorological parameters must be developed. Hydrometeorology necessarily deals with envelopes rather than with means.

Snow Melt. When estimates of maximum possible precipitation are made for drainage basins which are located in the more northerly latitudes of the United States, or parts of which lie at high elevations, consideration must be given to the contribution of snow melt to the total runoff. In the spring of 1948, the Columbia River Basin experienced an excellent example of the conversion of a deep blanket of snow, in combination with heavy rains, into a disastrous flood [25].

Basically, determination of potential runoff is amenable to analysis by means of thermodynamic and turbulent-exchange theories. In a detailed treatment of the problem, Light [12] has defined the "effective snow melt" as a combination of (1) melt due to the direct heat exchange which exists when the air is warmer than the snow mantle, (2) melt resulting from the latent heat released when atmospheric water vapor is condensed on the snow surface, and (3) the condensation of such atmospheric water vapor. He gives the simple relationship for the effective snow melt D in centimeters depth per second:

$$D = (Q + 600F)/80 + F = (Q + 680F)/80, \quad (10)$$

where Q is the heat transfer by convection in calories per square centimeter per second and F is the water transfer in cubic centimeters per second. Here, the latent heat of condensation amounts to 600 cal per cc of water deposited, and the latent heat of fusion is 80 cal per cc. It can be seen that the moisture condensed on the snow surface melts 7.5 times its own weight of snow.

The quantities Q and F, in the form given by Sverdrup [23], are expressible in terms of surface wind velocity, temperature difference between air and snow surface, air density and pressure, the surface roughness parameter, and the elevations of the anemometer and hygrothermograph above the snow surface. These expressions may be placed in equation (10) for the derivation of Light's snow-melt formula:

$$D = U_m[0.00184(T - 32)10^{-0.0156h} + 0.00578(e - 6.11)], \quad (11)$$

where D is the effective snow melt in inches per six hours, U_m is the average wind speed in miles per hour, T is air temperature in degrees Fahrenheit, e is vapor pressure in millibars, and h is station elevation in thousands of feet above sea level. The formula assumes a snow-surface temperature of 32F, and reference elevations of 50 and 100 ft for the anemometer and hygrothermograph, respectively. The roughness parameter is assumed to be 0.25 cm.

The snow-melt formula can be refined to take air stability and wind shear into account more accurately through the use of meteorological measurements at more than one level. The net melting effect of incoming and outgoing radiation may also be estimated by a method given by Wilson [33]. Furthermore, the relatively unimportant melting effect of rain may be estimated when assumptions are made as to raindrop temperatures.

The theoretical formula represents the rate of melt of a smooth snow surface over which the wind blows without appreciable retardation due to such obstructions as trees. Project basins usually have sizable tree-covered areas, however, and sometimes are located in mountainous terrain. To account for errors in the assumption of surface roughness, an empirical factor of proportionality—the *basin factor*—is introduced into the formula. Comparisons of observed with computed values of melt are the bases for determination of the basin factor. The latter is normally found to be less than unity since, in most basins, forests exist to such an extent that the turbulent heat exchange occurring at a well-exposed index anemometer station is greater than the average heat exchange over the basin as a whole.

When the basin factor has been determined, synoptic meteorological studies lead to conclusions regarding magnitudes of snowstorms antecedent to the maximum possible rainstorms, and the antecedent temperature regime and its effect upon the antecedent snow cover. The space and time distributions of wind and dew point immediately preceding and during the maximum rainstorm then form the bases for the determination of the wind and temperature parameters appearing in the snow-melt formula. It must be established that a certain critical depth of snow can exist at the onset of the rainstorm. This depth is such that the winds and temperatures of the rain period will melt all of the snow cover. A snow cover which is greater than that which can be melted during the rain period will store some of the snow melt and act to reduce the runoff. Thus it is evident that the critical snow depth is not necessarily the maximum possible.

The snow-melt problem is being systematically attacked by the collection and processing of data at three

field laboratories,[2] operated cooperatively by the Weather Bureau and the Corps of Engineers, in the mountainous regions of the western United States. Studies are currently under way on such features as the effects upon snow melt of varying degrees of forest cover, of elevation and character of the ground surface, and of meteorological factors. Study is also being made of the structure, density, water-storage capacity, and other variable characteristics of snow covers. Data available through the work done at these laboratories will undoubtedly lead to a great increase in knowledge of the processes involved in the melting of snow and, indirectly, of depths of snow critical from the standpoint of runoff.

Wind Tides and Waves in Reservoirs. The hydrometeorologist, because he is primarily a meteorologist, is called upon at times to investigate meteorological problems only indirectly connected with calculations of rates of precipitation. The height of a flood-control structure depends upon the maximum expected water level behind it; such a level will be caused primarily by maximum rainfall occurring with the most critical space-time distribution. If winds are blowing, however, the surface of the water cannot remain horizontal. Instead, a tilting of the reservoir surface results from the stress of the wind blowing across it. On the tilted surface, furthermore, waves develop which may have certain destructive effects.

To computations of maximum possible precipitation, then, must sometimes be added estimates of maximum wind-duration values for critical directions. Information of this sort is usually obtained through a study of long series of synoptic weather charts and through statistical analyses of post-rainstorm wind records of weather stations.

When the surface-wind system of a storm is known in considerable detail, as was the case with the Florida hurricane of August 1949 [31], the process of storm transposition can often be used. The process requires statistical studies of relations between winds at stations whose observations determine the surface-wind system, and winds over the project reservoir. The consistency in such relationships has generally been found to be quite significant. However, the assumption that a windstorm of record could occur without structural change over a project reservoir limits the kinds of transpositions to be made. Theoretical investigations are needed to improve present knowledge of modifications in a wind system (*e.g.*, of a hurricane) due to changes in place of occurrence, in direction of storm travel, and in character of the underlying surface.

A "design" windstorm derived, for instance, by the transposition method, must be converted into terms of water levels and wave heights for the project reservoir. The field of oceanography at present does not provide much information for the solution of such a problem. Relationships between surface winds, wind tides and waves in shallow, inland reservoirs of limited extent, and the effects of a steadily changing wind system, must be known before many important hydrologic design problems can be successfully attacked.

Water Resources. Recent years have seen an increasing need for evaluation of water supply, especially in the western states. To appraise this all-important resource requires the combined efforts of the hydrometeorologist, climatologist, and hydrologist. The problem is multifold, in that it embraces studies of rainfall, evaporation, transpiration, snow melt, runoff, and surface and underground storage. The hydrometeorologist is directly concerned with the association of wind, humidity, and other meteorological elements with factors involved in the water budget of an area.

The process of evaporation exercises much control over the amount of water available for use. However, conversion of evaporation-pan measurements to actual ground- and reservoir-surface evaporation has not yet met with a satisfactory solution. Pan evaporation has been empirically related to such meteorological parameters as wind and humidity, and there are theoretical equations expressing evaporation as a function of vertical gradients of wind and humidity. A great deal of work, theoretical and statistical, remains to be done, however, before statistics of meteorological factors can be combined to determine, with assurance, long-term evaporation losses.

THE FUTURE OF HYDROMETEOROLOGY

Systematic Organization and Use of Existing Data. There exists in the weather archives a wealth of information requiring organization for hydrometeorological appraisal and research. Maximum recorded point-rainfall depths have been extracted from some of the records for some durations. For example, Shands and Ammerman [18] have tabulated maximum values for 207 first-order Weather Bureau stations for a selection of durations from five minutes to one day. It would be desirable for many more durations to be considered. A maximum observed depth-duration curve for each station would be especially well received. Records of stations other than first-order Weather Bureau stations, as well as those of foreign stations, should be similarly processed.

Maximum observed values should not be restricted to those falling between fixed clock hours, days, or months. According to Jennings [8], the world's record 24-hr value was recorded at Baguio, Philippine Islands, on July 14–15, 1911. An accumulation of about 46 in. was observed from noon of the 14th to noon of the next day. It is almost a certainty that a still greater depth could be selected from some other 24-hr interval during the storm period. Unfortunately, records needed for determination of such a greater depth were lost during World War II.

The selection of storms hydrometeorologically analyzed for DDA values by the Corps of Engineers and the Weather Bureau should be greatly augmented. For both theoretical and statistical research, there is

2. The Central Sierra Snow Laboratory at Soda Springs, California; the Upper Columbia Snow Laboratory near Marias Pass, Montana; and the Willamette Snow Laboratory, Oregon.

need for such analyses of storms covering a wide variety of magnitudes, durations, areas, storm types, seasons, and locations. The DDA values, were they placed on punch cards, could be speedily correlated with many factors which have so far not been tested as to their significances to areal rainfall intensities.

The use of punch-card techniques would facilitate extension of the work of Yarnell [34] and other writers, as regards rainfall probabilities. Addition of data from large numbers of DDA-analyzed storms would eventually permit establishment of probabilities of occurrence of areal rainfall intensities.

Augmentation of Existing Rainfall-Reporting Networks. Statistical studies as to correlations between point and areal rainfall depths should be undertaken with the objective, among others, of determining the proper density for rain-gage networks. It is likely that existing networks are acceptable for most purposes in some sections of the United States. In mountainous regions the network is still far too meager for determination of effects of topography on rainfall. Over oceans and other large bodies of water—where special instrumentation is required—there are essentially no observations available for research.

As suggested by Smith and Fletcher [20] in 1946, the use of radar for quantitative determination of precipitation intensities between observing stations may have practical possibilities. Later investigations, such as those of Byers [2], tend to substantiate the idea. Radar has already proved its value in qualitative, short-range precipitation forecasting. Development of electronic equipment to measure areal values of precipitation intensities would be of extreme value for both forecasting and planning.

Physical Research. In theoretical hydrometeorology, the greatest need is for knowledge of the behavior of wind in space and time, over orographic and nonorographic terrain, in synoptic situations favorable for peak rainfall intensities. Wind observations are required in great quantity in this connection, and physical reasoning regarding limiting conditions must be developed.

The equations of continuity and hydrostatics have been the principal theoretical relationships used in hydrometeorology. Exploration into the applicability of others, such as the equations of motion and of energy relationships, is needed.

Results of research in the field of atmospheric turbulence can be turned to great practical use in hydrometeorology. Intimately connected with the theory of turbulence are the problems of snow melt, evaporation, behavior of wind over rugged terrain, and the aggregate behavior of raindrops in convective cloud currents. Some of these and other problems are amenable to treatment by the methods of statistical mechanics.

As far as the field of hydrometeorology is concerned, there are two main goals toward which research should be directed. The first is the development of improved theoretical equations relating rainfall depths, averaged over area and through duration, with measurable independent variables. The other is the establishment of physically reliable methods of maximizing the rainfall through maximization of the variables, in combination, to which it is related.

THE HYDROLOGIC CYCLE AND ITS RELATION TO METEOROLOGY—RIVER FORECASTING

By RAY K. LINSLEY

U. S. Weather Bureau, Washington, D. C.

THE HYDROLOGIC CYCLE AND ITS RELATION TO METEOROLOGY

Hydrology is that branch of physical geography which deals with the waters of the earth exclusive of the oceans. As a central focus for their efforts, hydrologists have adopted what is known as the *hydrologic cycle* (Fig. 1). This concept describes the circulation of water as it evaporates from the oceans and enters the atmosphere, is precipitated to the earth, and ultimately returns to the oceans by surface and underground channels. The interest of meteorology in the atmospheric phase of this cycle is self-evident.

No schematic diagram can do justice to the complexities of the hydrologic cycle. Instead of a simple step-by-step cycle, all phases may occur simultaneously. Large volumes of water may remain in storage at the earth's surface as snow or soil moisture. Some of this stored moisture is evaporated and may be reprecipitated over land. Many writers [4] have attempted to evaluate the quantities of water involved in the meteorological phases of the cycle. From the viewpoint of the hydrologist such evaluations are largely academic, for he is interested in the disposition of the water which reaches a specific area, and its ultimate source is of little concern. There seems little doubt that moisture evaporated from the land is an unimportant source of continental precipitation and, hence, that such activities as land drainage or reservoir construction can have little effect on the precipitation regime of an area.

Because of the importance of water in human life, hydrology in a simple form has been practiced since the dawn of history. Archeological evidence indicates that many successful water-supply and drainage projects were constructed at early dates. Scientific hydrology got its start in the 15th century A.D., when it was demonstrated that precipitation over land areas was adequate to supply the flow of streams. Relatively little further progress was made in the science until the current century, when engineering requirements forced the development of techniques for the design of major water-control projects.

Fields of Hydrology. O. E. Meinzer has suggested the division of hydrology into four fields representing stages in the surface phase of the hydrologic cycle: *potamology*, study of surface streams; *limnology*, study of lakes; *cryology*, study of snow and ice; and *geohydrology*, study of ground water.

Lakes are an important influence on the climate of their immediate vicinity and may contribute substantial amounts of water vapor to the atmosphere. The limnologist is vitally interested in long-term trends in precipitation and evaporative potential, as these factors affect the progressive rise and fall of lake levels. A study of lake-level trends may ultimately prove valuable in interpreting long-period changes in climate.

While the field of cryology is, in the strict sense, limited to snow and ice on the earth's surface, the meteorological conditions during snowfall greatly influence the physical characteristics of the snow which accumulates on the ground. This snow subsequently undergoes a continuous metamorphosis in response to the effects of temperature, humidity, wind, and precipitation. Studies of the influence of meteorological factors on snow may eventually contribute to our knowledge of the changes in air-mass characteristics resulting from passage over extensive snow-covered areas.

Of the four branches of hydrology, geohydrology is probably least closely related to meteorology. The ground-water specialist is interested in precipitation and precipitation trends in the intake areas which feed the major water-bearing formations. Beyond this point, however, the geological features of the ground-water problem are paramount. In turn there appears to be little of interest to the meteorologist in the study of ground water.

Potamology is the largest of the branches of hydrology and to some extent embraces the other three branches. The surface-water hydrologist is interested in lakes as sources of streams or as factors in the characteristics of streams which flow through them. He is greatly interested in snow and ice as an important source of water for stream flow. Finally, the dry-weather flow of most streams is derived largely from ground water and the potamologist must therefore concern himself with the ground-water features of his area. He is more interested in meteorological conditions than are his colleagues, for the flow of surface streams is directly related to the prevailing weather situation. In the material to follow, some of the more important problems in surface-water hydrology in which the meteorologist may be interested, or to which he may ultimately contribute a solution, are discussed briefly.

Precipitation. Since precipitation is the source of all stream flow (and ground water) with the exception of small quantities of water of internal origin, a basic problem in hydrology is the evaluation of the precipitation regime over an area. The hydrologist finds it necessary to deal with areas defined in terms of natural drainage boundaries, that is, river basins. His aim is the quantitative solution of the equation defining the hydrologic balance of the area,

$$P - E \pm \Delta S = R, \qquad (1)$$

where P is average precipitation, E is the water returned to the atmosphere by evapotranspiration, ΔS is the increment of water added to or removed from storage in the basin, and R is the runoff volume leaving the basin via the streams.

To balance equation (1) it must first be possible to determine the true average precipitation over the basin. This immediately involves problems in sampling, unless radar techniques can measure the integrated total over the basin. In level terrain, where the occurrence and distribution of precipitation are more or less random, the planning of an adequate precipitation-gage network depends on an understanding of the structure of storms and particularly of the variations of depth with distance from the storm center. In mountainous regions the effect of topography must also be considered. Spreen [13] has suggested the use of empirical correlations between average annual precipitation and topographic parameters. Maps prepared from such correlations would provide a guide to the proper location of stations for better evaluation of annual or seasonal precipitation. Similar studies of individual storms in rugged terrain are still needed.

Evaporation. The study of evaporation has presented more practical difficulties than most other items in the hydrologic balance. Storage reservoirs are designed to conserve water which would otherwise go to waste during the rainy season and to make it available when needed. There have been numerous instances in which the increased evaporation from the enlarged water surface created by the reservoir has exceeded the volume of usable water gained by storage, thus making the reservoir a liability rather than an asset. Less critical in many respects, but nevertheless preventing the quantitative solution of the water balance, is the unsolved problem of evaporation from land surfaces.

For many years the only attempt to solve these problems at the practical level has been by the use of evaporation pans. Obviously, there is a vast difference between the evaporation from a pan 4 ft in diameter and 10 in. deep and that from a large reservoir. It has been generally accepted, on the basis of experiments by Rohwer [11], that the evaporation from reservoirs averages about 0.7 of that from the U. S. Weather Bureau Class A pan. It is known, however, that there are considerable variations in this coefficient depending on size, depth and exposure of the reservoir, and time of year. Any quantitative application of pan data to soil evaporation is made difficult by the varying evaporation opportunity with variations in soil moisture.

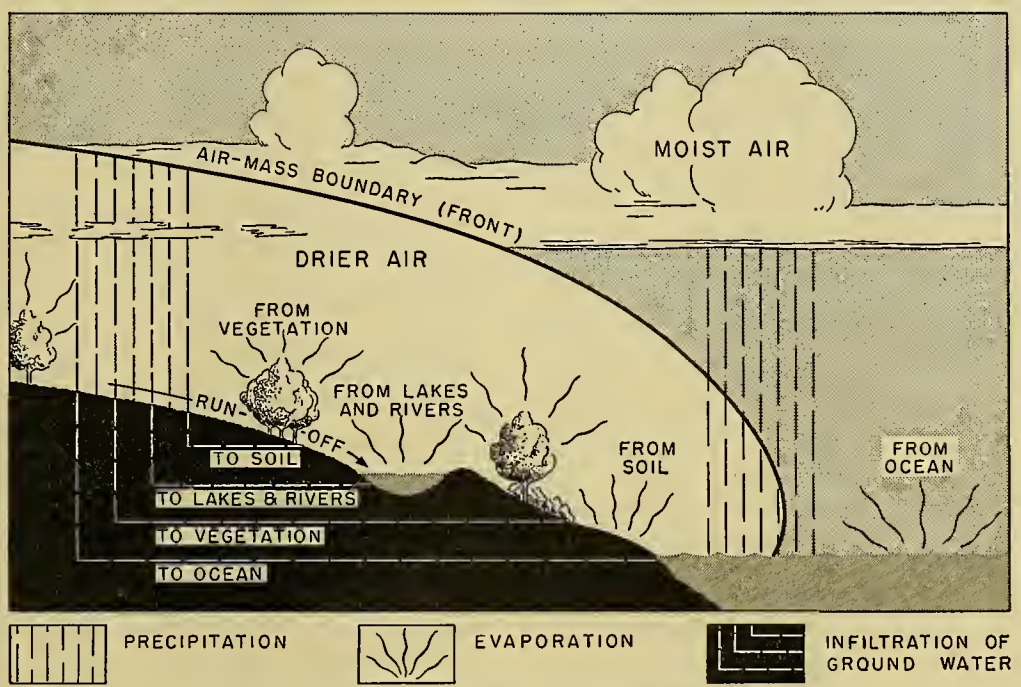

Fig. 1.—Schematic diagram of the hydrologic cycle.

A technique for determining evaporation either by direct measurement of outgoing moisture or by computation from the energy balance [10], turbulent transfer [14, 15], or other theory is urgently needed. However, evaporimeter data cannot be ignored, for they are all that will be available for many years. It has been shown that a good correlation exists between pan evaporation and readily available meteorological data—temperature, dew point, and wind [7, 9]. Through such correlations, available evaporimeter data may serve to guide the extrapolation and application of data collected by other means. A more rational method for adjusting pan data to reservoir conditions may be found if water temperature, wind, and humidity are observed at both the pan and the reservoir site. One difficulty hampering a study of this problem is the fact that almost no completely watertight reservoir

exists—leakage through gates and valves and seepage through the banks accounting for losses of the same order of magnitude as evaporation. In addition, the accurate measurement of all inflow to the larger reservoirs is exceedingly difficult.

In the spring of 1950 the U. S. Navy, Geological Survey, Bureau of Reclamation, and Weather Bureau jointly undertook a study of evaporation at Lake Hefner near Oklahoma City, Oklahoma. This reservoir, selected after a nationwide survey, is considered to be most nearly the ideal experimental site available. Instruments have been installed with a view to testing the turbulent transfer and energy balance concepts and to refine the relationship between evaporation pans and lake evaporation. This study should prove to be one of the most important steps toward the solution of the evaporation problem undertaken in recent years. It is to be noted, however, that almost any relationship developed will involve an empirical coefficient which must be selected largely on the basis of judgment before the method can be applied to any other lake or reservoir.

Snow. The snow pack which accumulates each winter in the mountains of the western United States constitutes a reservoir of such proportions as to dwarf all man-made lakes in this country. With the coming of the spring thaws, this water is delivered to the valleys when it is most urgently needed for irrigation. Occasionally, under the influence of extremely abnormal meteorological conditions, the melt water is released so rapidly that damaging floods result. It is natural therefore that the problem of ice and snow should receive considerable attention from the hydrologist.

The problem of snow melt is not unlike that of evaporation. Melting of snow is the result of heat brought to it from several sources—conduction and convection from air, radiation, condensation of water vapor, rainfall, and the soil. Continued research into the mechanics of turbulent transfer will materially aid studies of snow melt. However, the snow-melt problem involves extensive areas, usually with a wide range of elevation and rugged topography. It is doubtful, therefore, that a theoretical approach will find practical application in most hydrologic work. It is to be hoped that theoretical studies will suggest a more adequate empirical approach to the job.

Design Problems. Another phase of hydrologic work in which meteorology can play an important role is the field of design. Every structure, large or small, designed to control the flow of water, be it a culvert on a secondary road or a major reservoir, must be planned to withstand some maximum flow of water known as the *design flood*. For the smaller structures, economics dictates that the design flood be the probable maximum flood to be expected during the estimated useful life of the structure. For larger structures, where failure may take a large toll of life or cause damage far beyond the value of the structure itself, the design may be based on the maximum flood which can possibly be expected to occur. Cost normally increases with the magnitude of the design flood. Hence, overdesign is costly in terms of wasted material and labor, while underdesign may be equally costly as a result of failure and resulting replacement. Any knowledge which helps to refine estimates of design-flood magnitude is of definite economic value [1].

Generally speaking, the design of smaller structures is based on frequency analysis, and for structures having a useful life of thirty years or less the design criteria may be assumed to be reasonably adequate. For larger structures the situation is not so favorable. Reliable records of stream flow in excess of thirty years are rare. The situation is somewhat better as far as precipitation records are concerned but, even for these data, records in excess of fifty years are scarce. Some writers have proposed the so-called *station-year* technique [3] in which records from a number of stations within a homogeneous area are assumed to be independent and can thus be combined to give a record equivalent in length to the total length of the individual station records. Even if the validity of this approach were beyond question, it fails to satisfy the design problems for intermediate and larger projects whose drainage areas are so large that single-station records cannot be considered representative. A study of the frequency of occurrence of various average depths of rainfall over areas from 100 to 10,000 square miles would be extremely useful. Because of the lack of processed storm data, such a study would involve an immense amount of work. A study of storm morphology with particular reference to the relation between maximum point and average depths would also be of considerable value.

Another problem often encountered involves joint frequency, that is, the question, What is the frequency of rainfalls of various magnitudes with snow cover on the ground? or, What is the probability of a small, intense storm which would overload the drainage works of a leveed area at the same time that a major flood is occurring as the result of general heavy rains several days earlier? [16] Probably these problems cannot be solved by either meteorologists or hydrologists until much longer records exist. However, the considered judgment of the meteorologist can be of material aid to a hydrologist forced to make a decision and adopt a design value, no matter how poor its basis.

The situation reaches an extreme in the case of those major structures whose failure cannot be permitted under any condition. Here it is necessary to adopt the maximum possible flood as a design criterion. Since records are far too short to define such a physical extreme, it is necessary to synthesize it on a theoretical basis. It is therefore logical to turn to the meteorologist for an expression of the magnitude of the maximum possible storm for the project basin. The joint venture deriving from this need—hydrometeorology—is discussed elsewhere in this Compendium.[1]

It would be an easy matter for the hydrometeorologist to protect himself against an underestimate by using

1. Consult "Hydrometeorology in the United States" by R. D. Fletcher, pp. 1033–1047.

a liberal factor of safety. However, such a procedure would result in excessive project costs, and it is necessary to adhere to estimates made on the basis of sound meteorological theory supported by professional judgment. Obviously, the answer to the question, What is the maximum amount of rain which can fall over a given drainage basin in a specified time? requires the entire resources of the science and a considerable body of fact and theory not yet available. Consequently, any fundamental advance into the problems of meteorology will ultimately contribute to the solution of the problems of hydrometeorology.

RIVER FORECASTING

Of all the applications of hydrology, perhaps the one of most interest to the meteorologist is river forecasting. In flood forecasting particularly, meteorology is the outpost which provides a warning of the earliest evidence of possible floods. Many countries have recognized this fact by combining their hydrological and meteorological activities in a single hydrometeorological service. In the United States, where most hydrologic work is assigned to other agencies, the U. S. Weather Bureau bears the responsibility for all types of river forecasts.

The Organization of a River-Forecasting Service. The first essential of a river-forecasting service is a reporting network bringing current river stage and weather data to the forecast office. In terms of instrumentation and types of observations, this network may be much simpler than that used for weather forecasting. River stages, precipitation depths, and occasionally air temperature and the water equivalent of snow are the essential items of data. Because small-scale variations in weather are important in river forecasting, the network of stations must be far denser than is normally required for weather forecasting. The controlling factors for the frequency of reports are the size and the hydrologic characteristics of the river basin. Forecasts at the point of outflow from basins of 20,000 square miles or more can usually be made on the basis of daily reports, while for basins under 100 square miles hourly reports may be inadequate because of the rapid concentration of flow.

In addition to the reporting network, the service must, of course, have forecast offices staffed with an adequate number of trained personnel and equipped with properly developed forecasting relationships. Because of the high peak work load during floods, the staff must be well-organized to accomplish its job in a minimum of time.

Flood Routing. The forecasting operation naturally divides into several categories. In making forecasts along a large river it is necessary to estimate the speed of movement and the changes in shape which the flood wave undergoes as it moves downstream. In terms of theoretical hydraulics, this is a problem in wave motion. However, the equations of wave motion are far too complex for application to natural channels within the time available for forecasting. Hydrologists have therefore turned to a more empirical solution known as *flood routing*.

The simplest flood-routing relation is the *crest-stage relation*, which is a plotting of historical flood crests at one station against the resulting crests at another station downstream. Used in conjunction with a *time-of-travel curve*, which shows the rate of crest travel at various stages, the crest-stage relation is a simple and often effective means of forecasting peak stages. However, considerable flow may be contributed to the flood wave by tributaries entering between the two stations and, unless this flow is always proportional to the upstream inflow (or negligible in comparison to this inflow), large errors may result. Moreover, crest forecasts alone are frequently insufficient. When operation of reservoirs is involved, it is necessary to know the time distribution of all runoff which is to enter the reservoir in order to plan its effective operation. In addition, riverbank interests are almost as concerned with the time at which the river will rise to the critical level at their particular location as they are in the ultimate crest, since this time fixes the interval available to them for evacuation.

Forecasts of the shape of the entire hydrograph may be made by use of *storage routing* based on the storage equation,

$$It - Ot = \Delta S, \tag{2}$$

where I and O are the rates of inflow to and outflow from a section of the river, t is time, and ΔS is the change in volume of water within the reach during time t. If it is assumed that the average of the flows at the beginning and end of the routing period equals the average flow for the period, this equation can be written as

$$\frac{I_1 + I_2}{2}\, t - \frac{O_1 + O_2}{2}\, t = S_2 - S_1, \tag{3}$$

where the subscripts 1 and 2 refer to the beginning and end of the period, respectively. Equation (3) contains two unknowns, O_2 and S_2, but by expressing S as a function of O (and sometimes I) a second equation is available for the solution. One of the more straightforward, analytical solutions of the routing equation is the Muskingum method. This method assumes that the relation between storage and flow in a stream can be written as

$$S = K[xI + (1 - x)O], \tag{4}$$

where K is a storage constant having the dimension of time and x is a dimensionless ratio expressing the relative importance of O and I in determining the storage within the reach.

Introducing equation (4) into equation (3) and solving for O_2, we find

$$O_2 = C_0 I_1 + C_1 O_1 + C_2 I_2, \tag{5}$$

where the several C's are functions of K, x, and t. If values of S are plotted against values of the bracketed term in (4), the best value of x is that which reduces the plotted points most nearly to a straight line, and

K is the slope of this line. More interesting, however, is the possibility of solving (5) by means of least squares in which the C's become regression constants, or by multiple graphical correlation yielding a chart such as Fig. 2. The latter method has the advantage of permitting curvilinear and joint functions without the complexities of the analytical solution.

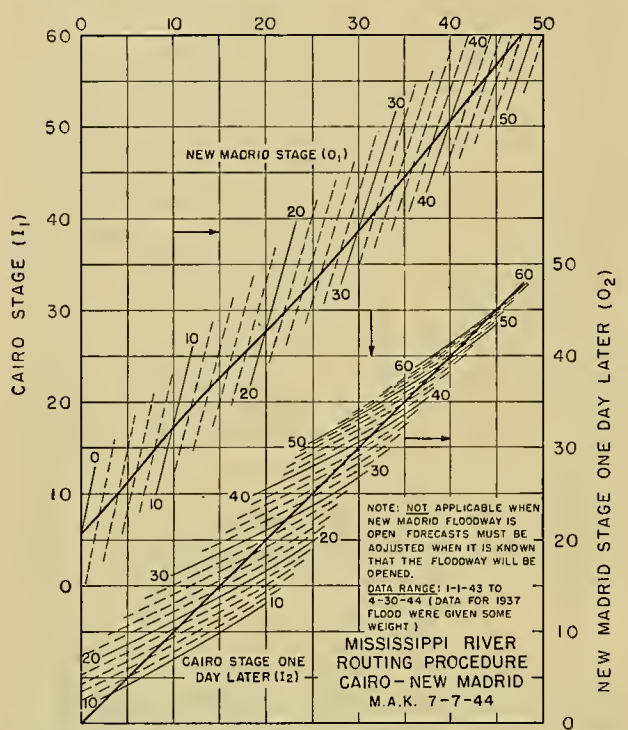

Fig. 2.—Stage routing relation between Cairo, Ill. and New Madrid, Mo. developed by multiple graphical correlation.

Recently an electronic circuit has been devised for the solution of the differential form of the storage equation ($I - O = dS/dt$) by analogy with the flow of electricity in a circuit containing capacitors [6].

Forecasting the Runoff from Rainfall. The forecaster dealing with small headwater basins cannot make use of upstream flows as a basis for forecasts, and he must turn to the ultimate inflow to the basin—precipitation. The first step in headwater forecasting is therefore the determination of the quantity of water which will actually reach the stream. This step is a detailed evaluation of one small portion of the hydrologic cycle. The forecaster must determine the portion of the precipitation which will be held in the basin as interception on vegetation, in puddles on the ground surface, and as subsurface storage (soil-moisture and ground water). The amount of this "basin recharge" in any storm is a function of (1) the moisture conditions in the basin prior to the storm, and (2) the intensity, amount, duration, and distribution of the precipitation. Much has been written on the theoretical considerations which may ultimately lead to a completely rational solution of this problem [7]. For the time being at least, the complexities introduced by superimposing the varying characteristics of a storm with respect to area over a basin which itself has varying soil types, vegetal cover, and antecedent moisture conditions have forced the adoption of empirical techniques.

Many methods have been employed, ranging upward in complexity from a simple correlation between rainfall and runoff, but the procedure which has proven most successful in the experience of the U. S. Weather Bureau is a multiple graphical correlation such as that shown in Fig. 3. Here the moisture condition of the basin is introduced in terms of an antecedent precipitation index, a weighted summation of precipitation for approximately thirty days prior to the storm with the highest weights assigned to the most recent days. The significance of this antecedent index is modified by the introduction of the week of the year to reflect at least the normal evapotranspiration characteristics and the extent of interception by foliage. Storm characteristics are expressed in terms of duration and amount of precipitation. If the variation in depth of precipitation is great, the average over the basin may not reflect the true runoff because of the curvilinear relations involved. In this case runoff may be computed for subareas of the basin and averaged to get the best estimate of average runoff.

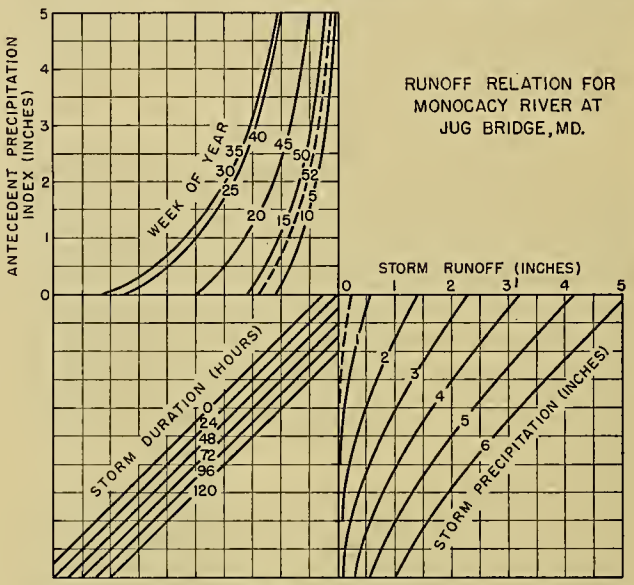

Fig. 3.—Rainfall-runoff relation for the Monocacy River above Frederick, Md.

Runoff Distribution After the total volume of runoff is computed, usually in terms of the depth in inches over the basin, the final step is the determination of the time distribution of this runoff in terms of the stream flow at the outlet of the basin. Sherman [12] observed that the hydrograph shapes for storms of like distribution and equal duration were characteristically similar on any basin. This led to the concept of the *unit hydrograph* which is almost universally used today for determining hydrograph shape. The unit hydrograph (Fig. 4) is a composite of the hydrographs of storms of equal duration and similar areal distribution of rainfall, all reduced to a volume of one inch of runoff by dividing their ordinates by the runoff depth in inches. A series of such graphs must be available for

various durations and patterns of rainfall distribution on each basin. The forecaster then selects the one most nearly comparable to the conditions of the current storm. By multiplying its ordinates by the predicted volume of runoff for the storm, he determines the probable outflow hydrograph. For storms extending over several forecast periods, the predicted hydrographs for each period may be added to arrive at the total flow.

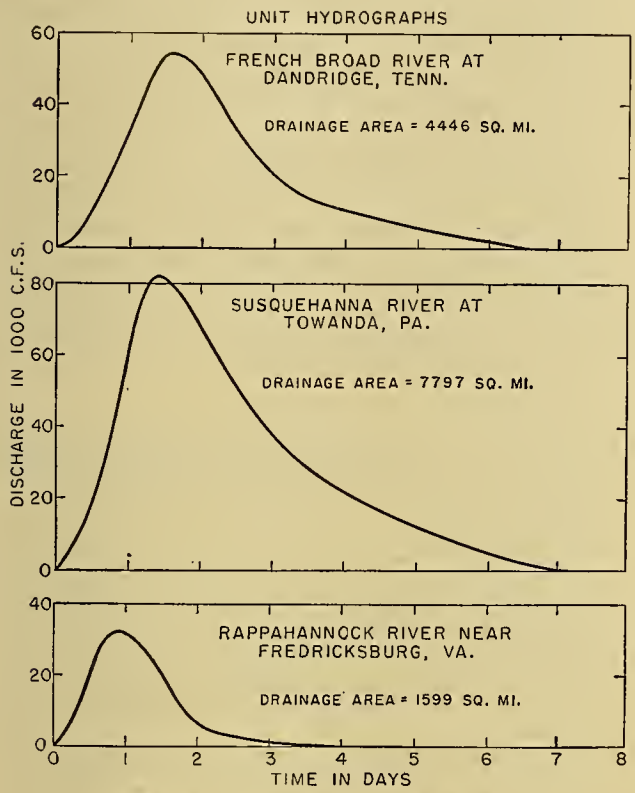

Fig. 4.—Typical unit hydrographs.

The problem of predicting the basin-outflow hydrograph is quite similar in its theoretical aspects to that of routing a flood wave downriver. The ordinary routing procedure makes it necessary to adopt routing periods so short that the computations for a headwater basin would be too time-consuming for forecasting purposes. However, the electronic routing machine [6] makes this approach a practical reality. In fact, the use of headwater forecasting techniques may be extended to areas much larger than can now be successfully treated with the unit hydrograph.

Snow-Melt Forecasting. Forecasting the runoff from melting snow poses many problems which have not yet been solved satisfactorily. In level terrain, the rate of melting of snow has been forecast with reasonable accuracy by use of factors expressing melt per degree day above 32F. If melting is concurrent with rainfall, the water equivalent of the snow may be added to the rainfall and a relation such as Fig. 3 used to compute runoff.

In mountainous terrain the situation is much more difficult. Here the snow pack accumulates in the form of a wedge with its greatest depths at high elevations, tapering to zero depth at intermediate and low levels. Owing to the variation of temperature with elevation, melting normally occurs over a fairly narrow range of elevation immediately above the snow line. The term "snow line" is used to describe the lower limit of the snow pack and does not imply a contour of constant elevation. As this melting zone moves upslope with the annual rise of temperature, the distance to the outlet of the basin increases and the effect of a unit of melt on the outflow changes.

Although it is believed that our understanding of the problem is sufficiently complete to permit a solution by the use of the multiple graphical correlation so effectively used in other phases of forecasting, records of snow-line elevation or area covered by snow have never been kept on a systematic basis and it has been exceedingly difficult to procure data which are adequate for such analysis.

Water-Supply Forecasting. The time lag of several months between the accumulation of snow in mountain areas and its subsequent melting has led to the development of methods for forecasting the volume of stream flow to be expected from a winter's accumulation of snow. Such forecasts make possible the scheduling of hydroelectric operations and the planning of agricultural work in terms of the water which will be available for irrigation.

Two different methods have been used in the preparation of such forecasts. One method uses relations derived by correlation of accumulated winter precipitation with runoff. Both precipitation and stream-flow data must be adjusted to eliminate time trends, and weights are assigned to the various precipitation stations and months of the year in proportion to their significance in the correlation [5]. The other technique makes use of a direct relation between the water equivalent of snow on the ground at the end of the accumulation season and subsequent runoff [2]. Both approaches seem to have about the same level of accuracy, with some advantage in reliability going to the first because of the longer record lengths which permit more careful statistical analysis. In all probability, a technique combining the two types of basic data would yield the most accurate forecasts.

Closely related to the problem of long-range volume forecasts is that of long-range estimates of the seasonal peak flow. Such forecasts have been attempted for the larger basins with moderate success. However, meteorological conditions during the late spring and early summer months play a far greater role in determining the peak flow than in determining the total volume. With the same amount of snow available, continued high temperatures for two or three weeks may cause a flood, while the same temperatures interspersed with short periods of cool weather will result in only moderate flows. Hence, large errors in long-range peak-flow forecasts must be expected in some years.

The Role of Meteorology in River Forecasting. Both short-range flood forecasts and long-range estimates of water-supply volume or seasonal peak flow may be seriously in error if weather conditions differ materially

from those anticipated by the forecaster. Hence, improvement of quantitative weather-forecasting techniques will materially aid the river forecaster, for he can treat weather forecasts in the same manner as observed data to synthesize the stream-flow situation which will develop. The U. S. Weather Bureau uses a statistical approach to this problem in its water-supply forecasts, in which estimates of probable flow volume are given for maximum and minimum of record, quartile, and median precipitation during the late spring and early summer months. A system which would interpret the meteorological situation in terms of an extended-range weather forecast would be much superior to such a statistical evaluation.

Broadly speaking, the river forecaster needs two types of weather forecasts. For flood forecasting he needs a detailed forecast extending from 1 to 10 days into the future, giving the amount, time of occurrence, and areal distribution of precipitation and, if snow melt is involved, temperature. For water-supply forecasting a less detailed outlook for 30 to 90 days ahead, indicating in general terms the precipitation anomalies and temperature trends, is necessary. Such forecasts would, in almost every case, give sufficient advance warning to permit carefully planned action, thus avoiding the waste and inefficiency of emergency methods. This need is highlighted by the existence of flood-control reservoirs which require a foreknowledge of the probable stream flow as much as thirty days in advance for successful operation.

LARGE-SCALE ASPECTS OF ENERGY TRANSFORMATION OVER THE OCEANS

By WOODROW C. JACOBS

Headquarters, Air Weather Service, Washington, D. C.

INTRODUCTION

There has been a recent and encouraging re-emphasis on investigations which involve some phase of the terrestrial heat budget, and the steadily accumulating number of investigations on the subject has brought proof that many meteorological and climatological problems can be wholly or partially solved through a consideration of energy transformation processes. In nearly all cases the purpose of the inquiries has been to ascertain the order of magnitude of one or more of the following components of the heat budget:

1. Radiative balance between the sun, earth, space, clouds, and atmosphere. This includes separate considerations of the solar constant and of the reflection, scattering, absorption, and emission of radiant energy by the earth's surface, clouds, and turbid (moist) atmosphere.
2. Exchange of sensible heat between the surface and the atmosphere.
3. Heat used for evaporation (or melting).
4. Heat realized through condensation (or freezing).
5. Heat produced through dissipation of kinetic and gravitational potential energy in the atmosphere (and ocean).
6. Transport of heat by ocean currents.
7. Lateral and vertical transport of real heat and latent heat (as water vapor) by the atmosphere.
8. Transfer of heat through conduction in the earth's surface (or through vertical mixing and layer transmission in the case of water bodies).
9. Changes in the internal energy of the atmosphere and of the surface layers of land and oceans.

Unfortunately, all of these factors in the energy budget of the earth and atmosphere are highly interdependent, a fact which renders their numerical computation exceedingly laborious. This is especially true if, instead of applying to average conditions, the evaluations are carried out for particular large-scale situations. It is because of this complexity that most of the general solutions to the large-scale problems which have been presented to date are greatly simplified and apply to average annual conditions and most often to global zones rather than to specific geographic areas. Nevertheless, a knowledge of the basic causes of space and time variations in temperature, humidity, pressure, winds, precipitation, and nearly everything else that contributes to the sum total of both weather and climate is obviously of fundamental importance in meteorology. Hence it is imperative that some consideration be given to the heat energy necessary to these conditions, its sources, when and where it is delivered, and how it is distributed.

Because additional details on energy transformation processes are covered elsewhere in this volume, the following discussion is limited to several narrow but important phases of the problem. The field of application covers only the ocean areas of the globe. The discussion is further restricted to cover only the large-scale and more or less long-term (average) aspects of the *convective* transfer of energy between sea surface and atmosphere. Space does not permit consideration of the radiative flux of heat energy between sea and atmosphere, nor are the short-term or "synoptic" aspects covered except as they are mentioned among the recommendations for future research.

Classical meteorological literature is replete with references to the profound effect of the oceans on world weather and climate. The moderating influence of oceans on the climates at high latitudes and particularly on the west coasts of continents has long been recognized, but steps to evaluate the "effects" have consisted largely of attempts to compare or classify the local climates on the basis of "maritimeness" or "continentality." Not until recently have serious efforts been made to evaluate the sea surface as a heat and moisture source and to demonstrate the role of the oceans in supplying energy for initiating and maintaining the general circulation of the atmosphere. When it is considered that the oceans comprise seventy-one per cent of the earth's surface—the surface from which the atmosphere receives by conduction and radiation all but a small fraction of its total heat energy—and that the oceans are the prime source of moisture for all atmospheric processes induced by water vapor, it is not unreasonable to expect that a solution to the problem of ocean-atmosphere energy relationships will carry the meteorologist a long way toward achieving a full understanding of the terrestrial energy budget. Unfortunately, the investigators who have dealt with the large-scale aspects of the problem are few in number, and the meager results of their studies have been presented in something less than a dozen brief papers. For this reason the author hopes he will be forgiven if in the following discussion he appears to make excessive reference to some of his own work along this line.

RATE OF EXCHANGE OF SENSIBLE HEAT BETWEEN SEA SURFACE AND ATMOSPHERE

Most of the earlier attempts to evaluate the rate at which sensible heat is conducted to the atmosphere

from the sea surface were incidental to computing oceanic evaporation on the basis of energy considerations.[1] In these cases very simple assumptions were made as to the magnitude of the ratio R between the amount of surplus heat given off directly to the atmosphere as sensible heat Q_h and the amount used for evaporation Q_e. Schmidt [26], in his determinations of the annual latitudinal evaporation from the oceans, accepted values for R which ranged from about 1.67 to 0.28, but subsequent analysis by Ångström [2] indicated that these values were much too high to represent average conditions over the oceans. Ångström concluded that only about 10 per cent of the heat surplus is given off to the atmosphere by conduction and that about 90 per cent is used for evaporation. Mosby [18], in recomputing the annual latitudinal evaporation over all oceans, accepted Ångström's supposition and considered R to be constant at 0.10 at all latitudes. McEwen [13], on the other hand, assumed R to be constant at 0.20 when determining the annual latitudinal evaporation over the North Pacific.

Up to 1940 none of the investigators had made any attempt to evaluate separately the sea-surface and time variations in Q_h or in the ratio R. Nevertheless, Bowen [3] in 1926 had derived a formula which proposed to establish the relation between evaporation and heat exchange at a water surface and this formula had been applied by Cummings and Richardson [5] in determining the evaporation from lakes. In considering the rates at which heat and water vapor are transported across the lower and upper surfaces of a volume of air in contact with a water surface, Bowen had concluded that the ratio between the heat loss by conduction and that by evaporation can be obtained from the expression

$$R = 0.64 \frac{p}{1000} \left(\frac{t_w - t_a}{e_w - e_a} \right), \qquad (1)$$

where t_w and t_a are the water and air temperatures respectively, e_w is the vapor pressure of the water surface, e_a is the vapor pressure of the air, and p is atmospheric pressure (all pressures in millibars). Bowen's derivation of this formula is quite involved but the same equation has been derived quite simply by Sverdrup [34] and the method will not be repeated here.

Sverdrup [35] subsequently pointed out that the application of the Bowen ratio might be invalidated if it proved necessary to consider the effects of the radiative transfer of heat through the laminar layer next to the sea surface, and if the evaporation from the sea surface is greatly increased at wind velocities high enough to carry spray into the air. However, Sverdrup [36] has more recently presented data to indicate that near the boundary surface the radiative transfer of heat is relatively unimportant. In addition, through a comparison between the observed humidity gradients existing above the sea surface and those derived on the basis of theoretical considerations of the transfer of water vapor within the boundary layer, he has also concluded that the effect of the evaporation from spray is relatively unimportant. He states that "The successful application of the theory of turbulence to the problem of air mass transformation indicates that there exists no large difference in the processes by which heat and water vapor are diffused."

Although the Bowen formula has suffered extensive criticism from meteorologists, the available observations to date indicate that it is capable of giving values for the ratio Q_h/Q_e of the approximate order of magnitude, at least if reasonably correct temperature and humidity observations are obtained near the sea surface and if the computations involve use of data obtained over extensive water bodies where the effects of lateral mixing can be neglected.

The author [6], following a suggestion given by Sverdrup, applied the Bowen ratio to seasonal evaporation values computed for five-degree squares over the North Atlantic and North Pacific and demonstrated that this ratio is a highly variable quantity, both seasonally and with respect to the regional distribution. The ratio proves to be low, or even negative, in regions overlain by dry air and where the temperature differential between sea surface and atmosphere is small (as in the trade-wind areas). High values are found in regions where warm water is overlain by relatively moist (often cool) air (as over the Gulf Stream and Kuroshio during winter). The average seasonal five-degree zonal values are shown to range from -1.5 to $+0.6$, although most values were within the range from -0.4 to $+0.5$.

The seasonal and annual values for the rate of exchange of sensible heat with each five-degree square over the North Atlantic were then obtained by applying the Bowen ratio as follows:

$$Q_h = RL_tE \text{ cal cm}^{-2} \text{ day}^{-1}, \qquad (2)$$

where L_t is the latent heat of vaporization at average sea-surface temperature t, and E is the evaporation rate in centimeters per day. The results of the computations on the basis of the annual data only are given in Fig. 1; the full set of seasonal charts is to appear in a later publication [10]. During all seasons the isolines for Q_h show, roughly, the same configuration as those for E (or Q_e); these values being at their maximum in winter and along the western sides of the oceans in mid-latitudes. However, one important difference is shown. No tropical areas of maximum Q_h appear within the trade-wind regions to correspond to the areas of maximum evaporation found in those areas.

The average seasonal values of Q_h for the various latitude zones are given in Table I. One interesting aspect of these data is the fact that the values are higher in the North Pacific than in the North Atlantic at all latitudes and during all seasons except winter for the areas north of latitude 35°N. From the data so far accumulated it appears that the atmosphere is being directly heated by the sea surface at significant rates only in the middle and high latitudes, along the eastern sides of the continents and principally during the winter

1. Consult "Evaporation from the Oceans" by H. U. Sverdrup, pp.1071–1081 in this Compendium.

season. During summer it appears that over large areas the sea is actually receiving some energy by conduction from the atmosphere.

In connection with the probable accuracy of the author's Q_h values, one phase of which is discussed by Sverdrup elsewhere in this volume,[1] it should be pointed out that all of the computations of evaporation and heat exchange were based on data published by the U. S. Weather Bureau [38] and represent ship observations recorded over the oceans at or very near Greenwich Meridian noon. As a result, most of the observations in the North Atlantic were taken during daylight hours, between 0600 and 1200 LMT, while those in the North Pacific have been obtained largely during night hours, between 2000 and 0600 LMT. Although the diurnal variations in evaporation or heat exchange over the oceans can be assumed to be small [33], the values computed from the *uncorrected* observational data obtained on shipboard might conceivably show significant differences between the two oceans, partly because of a true diurnal variation in the quantity $(t_w - t_a)$ and partly because of an apparent variation created by the daytime heating and nighttime cooling of ship and instruments. The author has previously considered this latter possibility [7] when attempting to account for the very nearly constant latitudinal differences in the annual values for R between the North Atlantic and North Pacific.[2]

The author has more recently re-examined the question of possible errors in the computed Q_h values—errors which might result from the time differences in

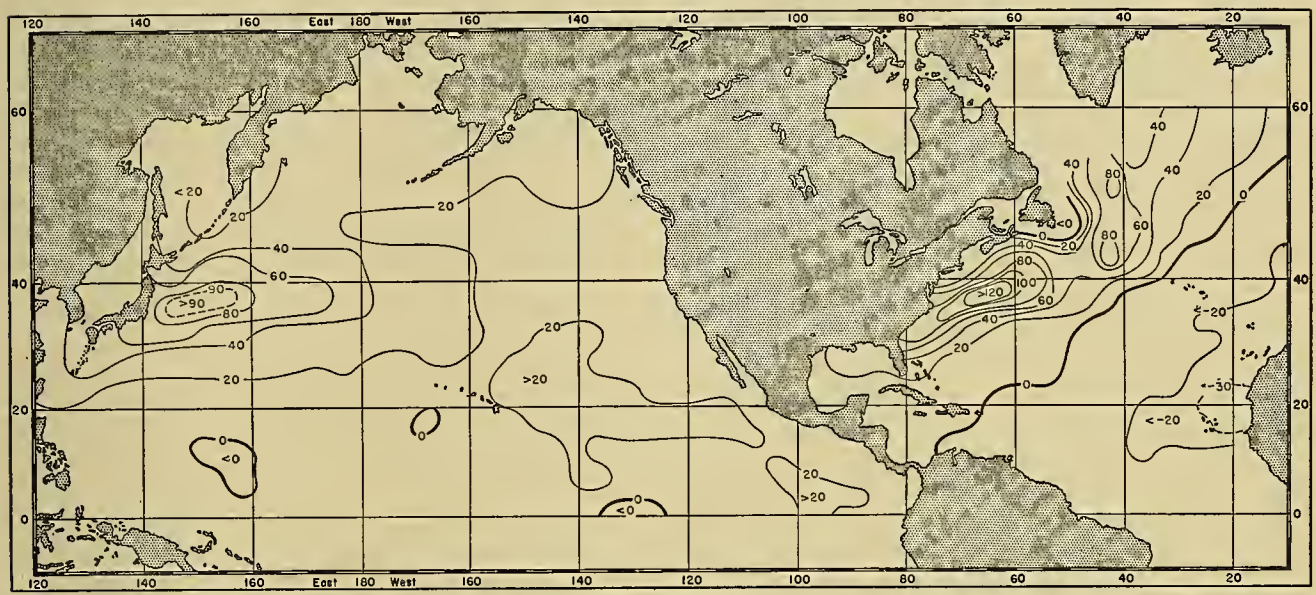

FIG. 1.—The annual values of the rate of exchange of sensible heat between ocean and atmosphere Q_h over the North Atlantic and North Pacific, expressed in calories per square centimeter per day.

* The North Atlantic includes the Gulf of Mexico and Caribbean Sea, within the appropriate latitude ranges for all zonal energy values, in this and succeeding tables.

2. The mean annual values for R arranged by five-degree ranges of latitude show that for nearly every zone in the North Pacific the value for the ratio R is 0.10 or 0.11 greater than for the corresponding zone in the North Atlantic. The seasonal values, however, do not exhibit this relationship.

ship observations. For this purpose a sampling has been made of the extensive hourly sea and air temperature data obtained on the last *Carnegie* Expedition [11]. In order to test the diurnal variation of $(t_w - t_a)$ under conditions such that radiation effects should be at a maximum, the analysis was limited to hourly temperature data collected on 103 days when the *Carnegie* was in the tropics or, during summer months, when it was at the higher latitudes. The hourly values for $(t_w - t_a)$, when t_a was uncorrected for radiation effects (see Table II), varied from a maximum of +0.90C between the hours of 0200 and 0400 LMT to a minimum of −0.24C at 1200 LMT, giving an extreme range of 1.14C. When t_a data corrected for radiation effects were used (see [11] for discussion of correction method), the time and magnitude of the maximum values for $(t_w - t_a)$ remained unchanged, but the hour of occurrence of the minimum was shifted to 1000 LMT and the previous negative value raised to +0.21C, giving a corrected range of 0.69C. If it is assumed that the method of correcting the *Carnegie* data for radiational effects is valid, these differences indicate that about 40 per cent of the apparent diurnal variation in $(t_w - t_a)$ is brought about by daytime heating of ship and instruments.

From the standpoint of the effects of the diurnal variation of $(t_w - t_a)$ upon the published results for Q_h, it appears that the time error should be significant only in those regions where Q_h is small or negative and where the temperature observations were obtained during daylight hours. Fortunately this effect was noticeable on the author's charts only in the eastern and southern North Atlantic where $(t_w - t_a)$ is small or negative and where the observations were recorded during the late forenoon. On the charts for Q_h this correction would serve to restrict the negative areas in the North Atlantic, giving slight positive values to the peripheral portions of those areas which at present indicate negative values. None of the values for the North Pacific should be noticeably affected. In future computation of Q_h, when Greenwich Meridian noon observations are used, particular care should be exercised to remove the diurnal effects from the $(t_w - t_a)$ data which represent ocean areas from about 60°W eastward to 90°E. (See Table II.)

One of the principal objections to the use of the Bowen ratio for establishing Q_h is that it requires both extensive humidity observations and observed or calculated evaporation rates. Neither of these two classes of data are available for the Southern Hemisphere nor do such data exist in any quantity for the higher latitude oceans. A more direct method for determining the sensible heat flux between sea and atmosphere would be desirable, preferably one which does not involve the use of either humidity or evaporation data.

In a recently published article, Miyazaki [15] presents monthly values of Q_h within five restricted areas "along the *Tusima* warm current" (Sea of Japan). The results have been obtained through use of an equation developed by Kuzmin and Saito [12] in which only the quantities $(t_w - t_a)$ and W_a, the wind velocity at height a, are needed.[3] However, the validity of the method is not established by the computation nor is any attempt made to adjust the formula to fit the type of observational materials which were used.

Burke [4] has developed a method for determining the changes in the heat content of continental polar air as it moves out over a warm sea surface. The technique requires a knowledge of the initial air temperature, the initial lapse rate in the air mass, and the distance the air mass has traveled over a sea surface exhibiting a

3. The final equation which was used for the computations is

$$Q_h = \frac{4.15\,(t_w - t_a)W_a}{5.742\left[\ln\left(\frac{a + z_0}{z_0}\right)\right]^2 + 0.16W_a} \text{ cal cm}^{-2}\text{ day}^{-1}, \quad (3)$$

where z_0 is the roughness parameter (given as a function of wind speed after Krümmel and increasing from 0.25 cm at W_a = 100 cm sec^{-1} to 27.00 cm at W_a = 2000 cm sec^{-1}). The thickness of the laminar boundary layer is assumed constant at 0.16 cm.

known temperature gradient. For these reasons the equations are not in convenient form for application in the large-scale climatological sense. This statement is not to be construed as a criticism of the method, however, since it has been designed for use by forecasters and not for the evaluation of large-scale energy transformation processes over the oceans. Nevertheless, the method might prove invaluable for investigations, on a limited areal scale, of the synoptic aspects of heat transfer between sea surface and atmosphere. It might also be applied in the climatological sense within those peripheral ocean areas where, during one or more of the seasons, air trajectories remain fairly constant and the initial continental air-mass characteristics do not show great variation (as, perhaps, over the Sea of Japan in winter).

RATE OF EXCHANGE OF ENERGY IN THE LATENT FORM OF WATER VAPOR

Of the total solar energy absorbed at the sea surface during the course of a year, approximately fifty per cent is used for evaporating sea water and, therefore, is made available to the atmosphere in the latent form of water vapor.[4] In view of this, and considering the relative magnitudes of land and sea areas, it would appear that the latent energy represented by water vapor derived from ocean evaporation constitutes the most important single component of the atmospheric heat budget. It is obvious that any paper which proposes to deal with atmospheric energy transformation processes should give primary attention to the problem of ocean evaporation. The fundamental details concerning this problem are so well covered by another article in this Compendium[1] that it will not be necessary here to expound the theoretical aspects of the processes governing the transfer of water vapor from sea surface to atmosphere. For this reason the present discussion will be limited to consideration of the large-scale and seasonal aspects of ocean evaporation in terms of its energy equivalence.

It has long been known that evaporation is governed by atmospheric humidity, surface water temperature, and wind speed. Nevertheless, empirical methods which have been used in the past to relate evaporation to these factors generally have not been successful, either because the equations contained unevaluated functions or because they were constructed to fit a special limited set of observations. In addition, the several evaporation equations derived on the basis of theoretical considerations have given equally divergent results, and no single theoretical method for computing evaporation has yet been devised which has general application when use is made of temperature, humidity, and wind data obtained under a variety of observational circumstances.

4. According to Mosby [18], 41 per cent of the total solar energy absorbed at the sea surface between the 70th parallels is radiated directly back to space, 53 per cent is used for evaporation and 6 per cent is conducted to the atmosphere as sensible heat. However, on the basis of the author's data, it appears that the last figure should be revised upward.

This state of affairs led Sverdrup in 1940 to suggest to the author that it might be possible to compute the average evaporation over the oceans, using available marine climatic data, by applying an equation of the type:

$$E = K\,(e_w - e_a)\,W_a, \tag{4}$$

where K is an empirical "evaporation factor" arrived at by comparing the long-term annual ocean evaporation computed through the use of the energy equations with that computed for the same period through the use of the several existing equations which involve theoretical considerations of the interchange of water vapor within the turbulent boundary layer near the sea surface. In equation (4), e_w is the vapor pressure at the sea surface, e_a is the vapor pressure at height a above the sea surface, and W_a is the wind speed at height a.

In following this suggestion, the mean annual evaporation was computed for each of four selected areas in the North Atlantic and North Pacific by two methods: first, by using an energy-budget method similar to that employed by Mosby [18] and arriving at values designated as E_1, and second, by using the evaporation equations of Sverdrup [31] and Montgomery [16] and arriving at values for K (and E). Since, as a first step in computing evaporation by the energy equations, it was necessary to disregard the oceanic heat advection term, the areas selected were those within which the latitudinal transport of surface waters is at a minimum and, at the same time, those allowing a rather wide sampling of latitudinal differences in available solar energy (Table III). The marine climatic data which entered into the computations were obtained from U. S. Weather Bureau sources [38].

Of the two theoretical equations which were used to arrive at the final values for K in equation (4), the one presented by Montgomery is in somewhat simpler form than that presented by Sverdrup and for that reason it will be exemplified in the following discussion. According to Montgomery,

$$E = \rho k_0 \gamma_a \Gamma_a\,(q_w - q_a)\,W_a, \tag{5}$$

where ρ is air density, $k_0 = 0.4$ is the Kármán constant, γ_a the resistance coefficient, Γ_a the evaporation coefficient, q_w the specific humidity at the sea surface, and q_a the specific humidity at height a. With all quantities in cgs units, the evaporation is expressed in grams per square centimeter per second. It should be pointed out that equation (5) does not deal with instantaneous values of humidity and wind speed but probably applies to these quantities averaged over a period of not less than an hour.

The coefficients γ_a and Γ_a in equation (5) depend upon the height a at which humidity and wind speed are measured, and also upon the character of the sea surface. The sea surface can be considered hydrodynamically *smooth* at wind speeds less than about 650 cm sec^{-1} (measured at a height of 600 cm) and hydrodynamically *rough* at higher wind speeds [19, 24, 25].

If averages for a smooth surface and maxima for a

rough surface are used, the numerical values of the constants are:

		γ_a	Γ_a
Smooth surface	($W_{600} < 650$ cm sec^{-1})	0.030	0.085
Rough surface	($W_{600} > 650$ cm sec^{-1})	0.059	0.148

With $q = 0.623\ e/p$, where e is vapor pressure and p is atmospheric pressure, and $\rho = 1.25 \times 10^{-3}$ and $p = 1000$ mb:

Smooth surface $E = 0.79 \times 10^{-3}\ (e_w - e_a)\ W_a$, (6)
Rough surface $E = 2.71 \times 10^{-3}\ (e_w - e_a)\ W_a$. (7)

The hourly evaporation in grams or centimeters becomes:

Smooth surface $E = 2.8 \times 10^{-6}\ (e_w - e_a)\ W_a$, (8)
Rough surface $E = 9.8 \times 10^{-6}\ (e_w - e_a)\ W_a$. (9)

However, when climatological data are used, the evaporation should be computed from the equation

$$\bar{E} = 2.8 \times 10^{-6} \{n[\overline{(e_w - e_a)W_a}]_{W_a<650} + 3.5m[\overline{(e_w - e_a)W_a}]_{W_a>650}\}, \quad (10)$$

where n and m represent the fraction of hours with wind speeds less or greater than 650 cm sec^{-1}, respectively ($n + m = 1$), and where the notation $\overline{(e_w - e_a)W_a}$ represents the average of hourly values of the product $(e_w - e_a)W_a$. When dealing with climatological data, only the average monthly or seasonal values $\overline{(e_w - e_a)}$ and $\overline{W}_a$ are known, and even if the percentage of winds of speeds less than 650 cm sec^{-1} (less than force Beaufort 4) is determined, the corresponding value of $\overline{(e_w - e_a)W_a}$ is still unknown. It remains to determine whether evaporation could be computed with a reasonable degree of accuracy, using a simple equation similar to (4), where for hourly values the factor K might be expected to lie between 2.8×10^{-6} and 9.8×10^{-6}, if E is expressed in grams (or centimeters), $\bar{e}$ in millibars, and $\overline{W}_a$ in centimeters per second.

The climatological values for q_w, q_a, W_a, and the computed values (hourly) for E_1 were substituted in equation (5), and the factor K was determined for each of the four areas. The results are given in Table III. A considerable spread in the K values among the four areas is indicated but this is the expected result because it is obvious that the advection term cannot be neglected when computing evaporation by the energy equations for any restricted ocean area. The computed quantities E_1 and E could be expected to be equal only in the absence of lateral heat transport or if the entire ocean surface could be included in their computation.

The average value of K for the four areas proves to be approximately 6×10^{-6}, that is, a value which lies about halfway between that applicable to a smooth surface and that which applies to a rough surface. Thus, if E is the 24-hr evaporation in millimeters or in decigrams per square centimeter and W_a the wind speed in meters per second, equation (4) becomes

$$E = 0.142\ (e_w - e_a)\ W_a. \quad (11)$$

It would be expected that the values for E_1, computed by means of the energy equations, would tend to be too high at the lower latitudes and too low at the higher latitudes because of the neglect of the advection term. This difference should be particularly noticeable in the North Atlantic where the dialatitudinal transport of surface waters from lower to higher latitudes is considerably greater than in the North Pacific. The data in Table III show that this is the case. Sverdrup has

Table III. Values of K, E_1, and E for Selected Areas

Latitude	Longitude	E_1* (10^{-3} cm hr^{-1})	$e_w - e_a$ (mb)	W_a (cm sec^{-1})	K	E† (10^{-3} cm hr^{-1})	E_1/E

* E_1 = evaporation computed on the basis of the energy equations.
† E = evaporation computed by equation (4) with $K = 6 \times 10^{-6}$.

further analyzed the significance of the heat advection term elsewhere in this volume[1] and he points out that the zonal differences in K are of the proper order of magnitude to be accounted for by the zonal differences in the heat advection term. Moreover, the computations of E made for the North Atlantic and North Pacific through use of equation (11), and averaged for the year for the entire area, give results which are in agreement with those previously reached through energy considerations. Nevertheless, there must still remain some uncertainty as to the average value of K. However, the time and space variations in evaporation over the oceans are so large that it is believed that the remaining uncertainty is relatively unimportant.

Through the use of equation (11), which applies only to the particular marine climatic data which were used, computations of the seasonal and annual values of E have been made for each five-degree square in the North Atlantic and North Pacific. The results have been converted into their energy equivalents by taking L_t to be 585 cal g^{-1} and thus letting

$$Q_e = 585\ E \text{ cal cm}^{-2} \text{ day}^{-1}, \quad (12)$$

where E is given in centimeters per day.

The results of the computations on the basis of the annual data only are given in Fig. 2. The full set of seasonal evaporation charts upon which the annual Q_e is based will appear in the publication to which reference has previously been made [10]. The computations show that the regions of greatest energy exchange are on the western sides of the oceans and around the semipermanent high-pressure fields. The values for Q_e on the eastern sides of the oceans are generally smaller. The absolute maximum value for Q_e for all oceans occurs in the North Atlantic in winter within the Gulf Stream between latitudes 35°N and 40°N and about 700 miles east of the Virginia Capes, where the average Q_e is about 670 cal cm^{-2} day^{-1}. The maximum value in the North Pacific, 550 cal cm^{-2} day^{-1}, occurs farther south and nearer the coast within the Kuroshio between latitudes 25°N and 30°N and approximately 300 miles northeast of Formosa. As shown by the data in Table IV, except for equatorial areas, the values for Q_e are nearly everywhere greatest during winter and generally lowest during summer. However, the summer decrease is small within the tropical areas of high evaporation. The quantity Q_e remains positive during all seasons for all areas except in the North Pacific north of latitude 55° and west of 160°W, and in the North Atlantic waters immediately surrounding Labrador, where slight negative values are shown during summer months (where $e_a > e_w$). A comparison between the data in Table I and Table IV indicates that over the oceans as a whole the atmosphere is being directly heated by the sea surface most rapidly in the higher latitudes, but that it is receiving moisture principally in the middle and lower latitudes.

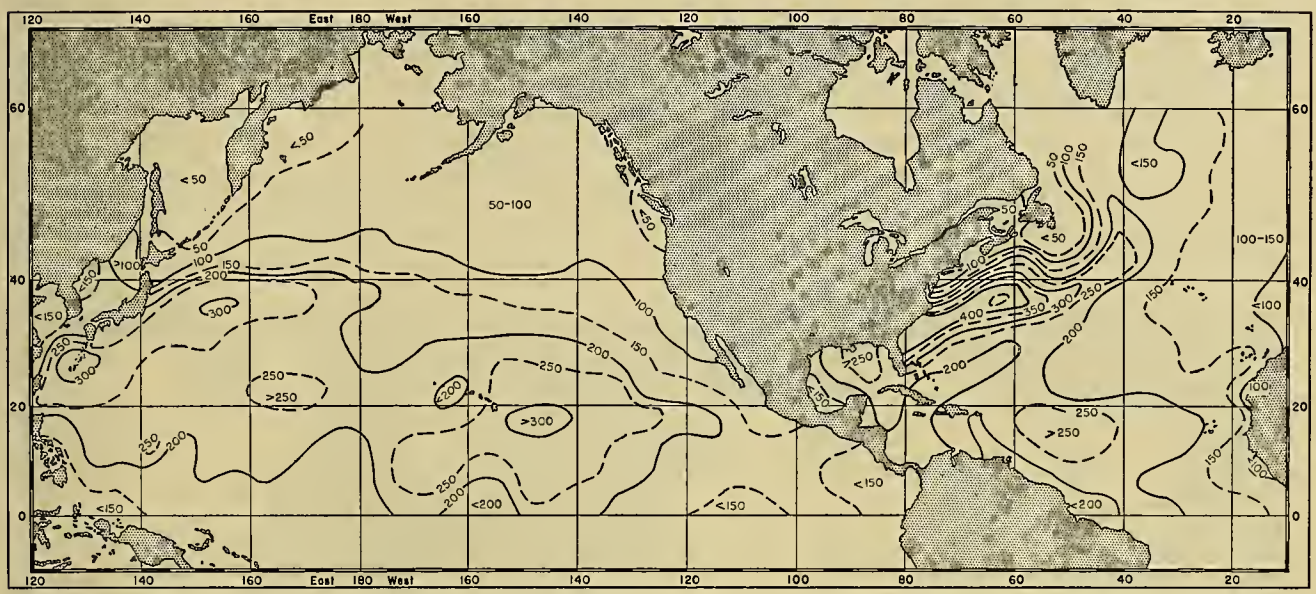

Fig. 2.—The annual values of the rate of energy loss from the sea surface through evaporation Q_e over the North Atlantic and North Pacific, expressed in calories per square centimeter per day. (The values above can be converted into rough evaporation rates by considering that the isometric interval of 50 cal cm^{-2} day^{-1} is approximately equivalent to an evaporation rate of 12 in. yr^{-1}.)

Concerning additional direct methods for determining Q_e over ocean areas, Miyazaki [15] has attempted to apply a modification of the Sverdrup evaporation

equation [32] directly to determine the monthly averages of Q_e within the same five areas for which he determined Q_h.[5] He does not attempt to evaluate the equation empirically against the available observational materials and he resorts to humidity data from land stations as a substitute for observations at sea. His monthly averages for Q_e appear somewhat too large during summer (the three-month summer average for the five areas proves to be 116 cal cm^{-2} day^{-1}).

RATE OF TOTAL HEAT LOSS FROM THE OCEANS THROUGH CONVECTION

The only method for directly estimating the total convective heat loss Q_a from a water surface appears to be the one recently developed by Montgomery [17]. He presents a detailed discussion of methods for estimating the total eddy flux of heat from a moist surface by combining the effects of heat transfer by conduction and heat transfer by evaporation (or surface condensation) and, after deriving several general expressions, he arrives at a more restricted equation which yields good approximations for Q_a under certain conditions. These conditions are that the humidity and temperature observations be obtained within 10 m of the water surface and that the pressure should be within about 10 per cent of standard pressure. He shows that if the *specific enthalpy*, including the latent heat of water vapor, is designated by h_t, and if V_z' is a specially defined fluctuation of the vertical component of velocity, then the unit-area eddy flux of heat is $\langle \rho V_z' h_t \rangle$ and

$$\langle \rho V_z' h_t \rangle = \left(\int_a^b \frac{dz}{k\bar{\rho}} \right)^{-1} c_{pd}(\overline{T}_{ea} - \overline{T}_{eb}), \qquad (14)$$

where k is the *eddy diffusivity* (Richardson), c_{pd} is the isobaric specific heat of dry air, $\overline{T}_{ea}$ is the mean *equivalent temperature* at the surface, and $\overline{T}_{eb}$ is the same quantity at a chosen, short distance above. For this purpose, the *equivalent temperature* of a sample of air is defined as the temperature of dry air having the same enthalpy.

Montgomery's method, however, has not yet been made applicable to the type of observational materials generally available in the marine climatic record. Furthermore, the meteorologist generally is more interested in the separate fractions of the energy exchange, Q_h and Q_e, than he is in their sum. Nevertheless, the method could facilitate computations of the rate of total "contact" heat loss from the sea surface and thus be useful to the oceanographer when he finds it convenient to evaluate the sea-surface heat loss for special analytical purposes and when it is possible for him to obtain controlled meteorological observations.

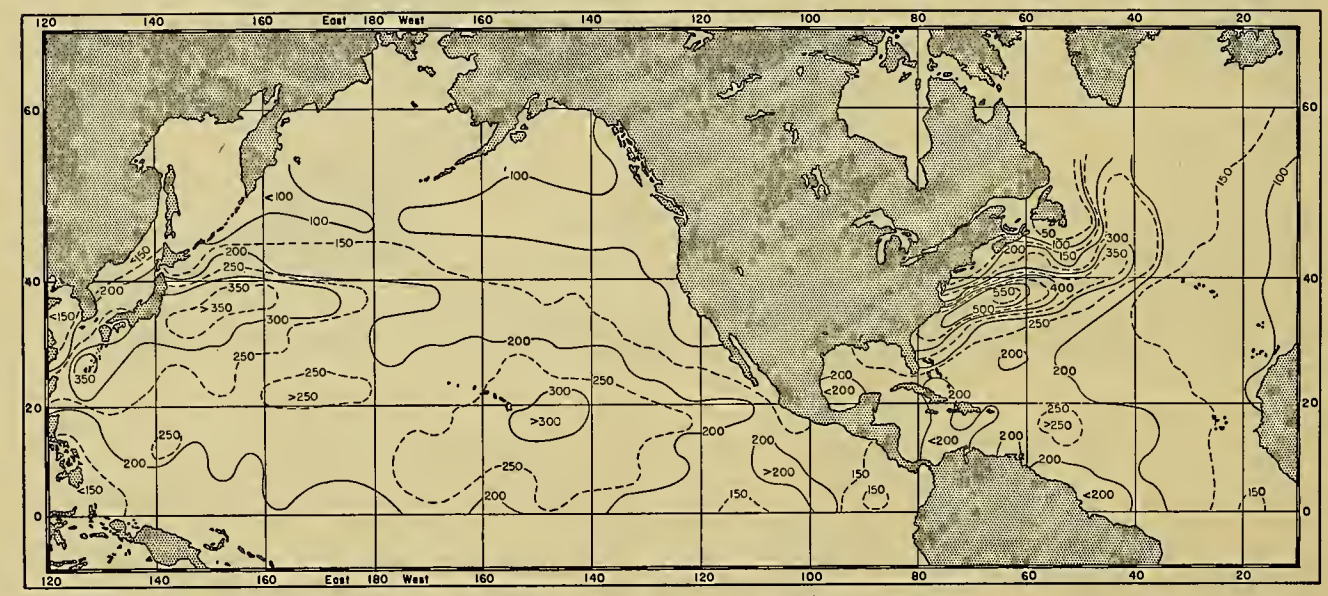

FIG. 3.—The annual values of the rate of total energy loss from the ocean surface through convection ($Q_a = Q_h + Q_e$) over the North Atlantic and North Pacific, expressed in calories per square centimeter per day.

The only available large-scale computations of the total energy exchange between the ocean and atmosphere have been presented in chart form for the North Pacific and North Atlantic [6, 10] and are based on the sum

$$Q_a = Q_h + Q_e. \qquad (15)$$

Therefore, they represent the summation of computations which have already been described in the preceding two sections.

In their general configuration the charts for Q_a are quite similar to the charts for Q_e, except that the

5. The equation used is:

$$Q_e = \frac{590 \times 2.15 \times 10^{-2}(e_w - e_a)W_a}{8.64\left[\log \frac{(a + z_0)}{z_0}\right]^2 + 0.16W_a} \text{ cal cm}^{-2} \text{ day}^{-1}, \qquad (13)$$

where $L_t = 590$ cal g^{-1}.

west-east gradient in Q_a is intensified due to the high values of Q_h over the western sides of the oceans and the low values over the eastern portions. The charts are also, in a qualitative manner, quite similar to those for Q_h except that the latter show no maximum areas of sensible heat exchange within the tropical trade-wind region corresponding to the areas of maximum Q_a in this belt. In the North Atlantic in winter, Q_a reaches values as high as 937 cal cm^{-2} day^{-1} within the Gulf Stream off the Virginia Capes. In the North Pacific the maximum value for Q_a occurs in winter within the Kuroshio northeast of Formosa, coinciding with the area of maximum Q_e, where a value of 728 cal cm^{-2} day^{-1} is computed, with a secondary area of maximum Q_a (718 cal cm^{-2} day^{-1}) between latitudes 35°N and 40°N approximately 350 miles east of Japan. The annual chart for Q_a is given as Fig. 3.

The seasonal values for Q_a arranged by latitude zones are given in Table V. These data show that, except near the equator, Q_a is at a maximum during winter and at a minimum during summer with the quantities tending to be greater during autumn than during spring. The seasonal variations are large in middle and high latitudes but small near the equator. Both oceans show secondary minima in the total energy exchange between latitudes 45°N and 50°N.

The author [6] has previously pointed out that during winter the locations of the principal Northern Hemisphere frontal zones as given by Petterssen [20] appear to correspond quite closely to the zones of maximum Q_a; in every case the zones of frontogenesis lie to the northwest of a zone of maximum Q_a with the major axes of the zones of maximum energy exchange parallel to the principal axes of the frontal zones.

RATE OF TOTAL HEAT GAIN BY THE ATMOSPHERE THROUGH CONVECTION

The quantity Q_a discussed in the preceding section represents the rate of total energy loss (or gain) from the ocean surface by conduction to the atmosphere. From the standpoint of the sea surface, this loss is entirely in the form of sensible heat; but in the case of the atmosphere only that fraction which appears as Q_h is immediately available for heating the air, the remaining energy being latent in the form of water vapor. Therefore, in order to obtain a quantity for the atmosphere which is equivalent to the quantity Q_a for the oceans, it is necessary to consider the heat supplied to the atmosphere through the condensation of the water vapor. The writer has previously shown that the latter quantity can be obtained, completely, from data concerning precipitation amounts over the oceans [9].

The sensible heat equivalent (calories per square centimeter per unit time) of the precipitated water is given by

$$Q_p = L_t P, \tag{16}$$

where L_t is the latent heat of condensation which, in this case, is correctly assumed to take place at the evaporation temperature t, and P is the rate of precipitation. One source of error which may be locally important during the winter season is introduced through the assumption in (16) that all precipitation is in the form of liquid water. However, even if it is assumed that *all* of the water precipitated at the higher latitudes occurs in the form of unmelted snow or sleet, the total error cannot exceed about 12 per cent. Actually, only a fraction of the precipitation occurring over the oceans during winter will appear as snow, even at high latitudes, so the probable error is much less.

Therefore, in order to complete the energy computations for the atmosphere it is necessary to have seasonal data concerning precipitation amounts over the oceans. However, an examination of the literature reveals not only that no seasonal data on precipitation amounts over the oceans exist, but that even the few data on the annual amounts have been subject to considerable criticism. In order to obtain approximately correct annual precipitation values, the published regional data [14, 27, 28, 29, 30] were made compatible and brought into agreement with Wüst's more reliable zonal values [39] by the assignment of simple correction factors for each

of the oceans.[6] Upon this basis an entirely new chart of the annual precipitation over all oceans has been prepared.

Then, through the use of published climatological data on the seasonal frequencies of precipitation over all oceans [38], seasonal precipitation values were computed for each ten-degree square through the use of the expression

$$P_s = \frac{F_p P_a}{\sum_{i=1}^{4} F_{pi}}, \tag{17}$$

where P_s is the seasonal precipitation rate (g cm^{-2} season^{-1}), P_a is the annual precipitation, and F_p is the seasonal frequency of Greenwich Meridian noon observations showing precipitation of any type. The complete series of seasonal (and annual) charts showing precipitation amounts over the oceans, together with details concerning the justification and verification of the method used, is contained in the publication previously referred to [10].

Since the precipitation rates over the oceans are given in centimeters per season (equivalent to grams per square centimeter per season) and since it was desired to have the energy equivalent Q_p given in calories per square centimeter per day, for purposes of convenience equation (16) was put in the form

$$Q_p = n^{-1} L_t P_s, \tag{18}$$

where n is the number of days in the season. Thus, where n is 91 and L_t is 585 cal g^{-1}, (18) becomes

$$Q_p = 6.43\ P_s \text{ cal cm}^{-2} \text{ day}^{-1}. \tag{19}$$

On the basis of formula (18) and the precipitation data arrived at through the use of (17), computations of the seasonal (and annual) values of Q_p have been made for each ten-degree square over the oceans. The seasonal averages arranged by latitude zones are given in Table VI. These data show that, in general, Q_p in the higher latitudes is greatest during the winter season in each hemisphere, while in the lower latitudes it is greatest during summer. In higher latitudes the minima occur during the corresponding summer seasons, and in the lower latitudes during the spring. With respect to time, therefore, the periods of maximum and minimum Q_p in the two hemispheres are exactly out of phase, that is, the zonal maxima in one hemisphere tend to occur during the months when the corresponding zonal minima occur in the opposite hemisphere. This result is hardly unexpected.

More interesting is a comparison between the corre-

sponding zonal values in each hemisphere. It may be noted that, except in the Indian Ocean, there exists no zone of high Q_p values within the Southern Hemisphere to correspond to the equatorial zone of maximum Q_p found in the Northern Hemisphere. This results in an approximate ten-degree poleward displacement of the analogous Q_p zones in the North Atlantic and North Pacific compared to the South Atlantic and South Pacific. In the case of the Indian Ocean, the situation is reversed. In this case the equatorial region of high Q_p values exists south of the equator. Also, the northern part of the Indian Ocean exhibits greater seasonal variations in Q_p than does any other portion of the oceans.

Of greater interest from an atmospheric energy point of view, however, are the data concerning the rate at which total convective energy is acquired by the atmosphere in the Northern Hemisphere, both through the condensation of water vapor and through the exchange of sensible heat with the sea surface. The total energy Q_{ph} is quite obviously the sum of these two quantities, that is,

$$Q_{ph} = Q_p + Q_h \text{ cal cm}^{-2} \text{ day}^{-1}. \quad (20)$$

The annual chart of Q_{ph} is given as Fig. 4 and the seasonal zonal averages are given in Table VII.

The results of the computations indicate that the principal sources of heat energy for maintaining the general circulation over the oceans are in the equatorial regions and at the higher latitudes. The subtropical latitudes appear as regions where very little heat energy is being supplied to the atmosphere. In these latter regions the very large rate of energy transfer which is indicated by the Q_a data does not make itself felt until it is released in the zone of equatorial convergence (or along the polar front at higher latitudes). The principal sources of heat energy for maintaining the circulation

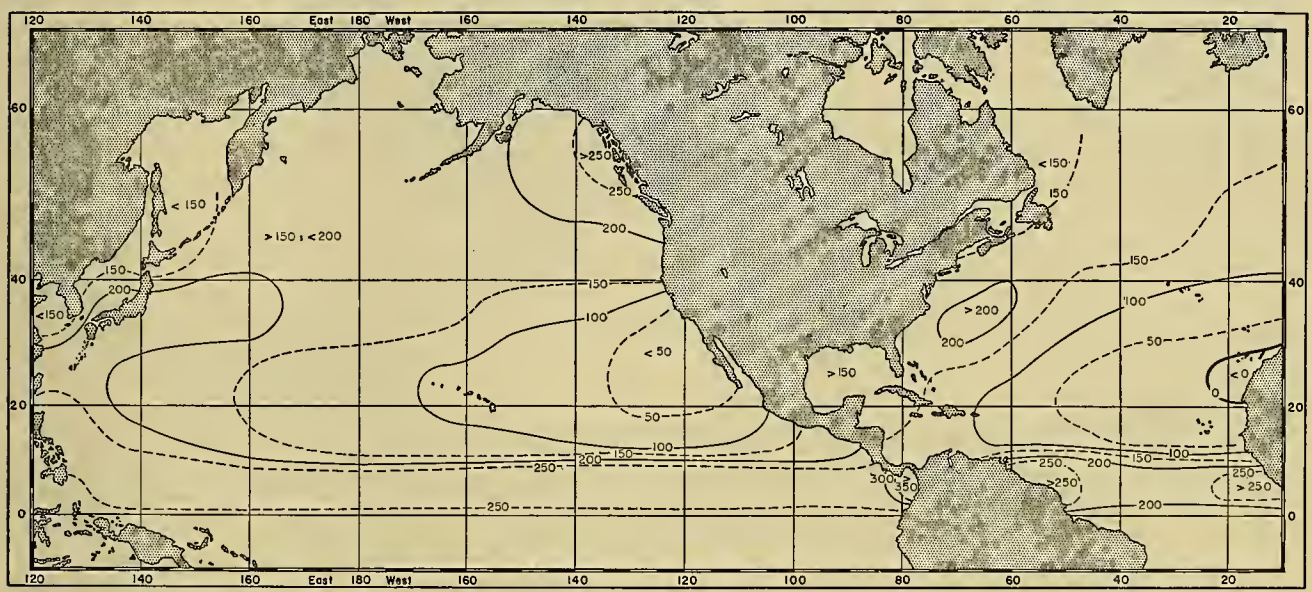

FIG. 4.—The annual values of the rate of total energy gain by the atmosphere Q_{ph}, both through the exchange of sensible heat with the sea surface Q_h and through condensation Q_p. The results are expressed in calories per square centimeter per day.

TABLE VII. SEASONAL VALUES OF Q_{ph} IN DIFFERENT LATITUDE ZONES (in cal cm^{-2} day^{-1})

North latitude zone	North Atlantic				North Pacific			
	Dec.–Feb.	Mar.–May	June–Aug.	Sept.–Nov.	Dec.–Feb.	Mar.–May	June–Aug.	Sept.–Nov.
0°–10°	237	229	330	217	268	249	292	261
10°–20°	85	38	93	97	109	108	171	177
20°–30°	109	55	62	112	157	110	109	104
30°–40°	213	120	52	129	238	151	100	137
40°–50°	268	140	87	164	218	149	119	184
50°–60°	265	135	83	189	246	193	130	202

at the higher latitudes are probably the western portion of the oceans (particularly in winter) and the central and eastern portions of the oceans, poleward from latitude 40°N.

The existence of the seasonal and annual Q_a and Q_{ph} data for the North Atlantic and North Pacific allows the determination of the important quantity represented by their difference. Because

$$Q_a - Q_{ph} = (L_t E + Q_h) - (L_t P + Q_h) = L_t (E - P), \quad (21)$$

the difference $(Q_a - Q_{ph})$, when positive, represents latent energy which is locally surplus and available for transport to the continents or other portions of the oceans where it is made available as real heat through

condensation. When the quantity is negative, it indicates that an excess of latent energy is being locally transformed into sensible heat. However, since the author has already computed the seasonal and annual differences between evaporation and precipitation over the oceans [10], the difference $(Q_a - Q_{ph})$ can be determined very simply through use of these data and by applying the expression

$$Q_a - Q_{ph} = 6.43\ (E_s - P_s)\ \text{cal cm}^{-2}\ \text{day}^{-1}, \quad (22)$$

when $n = 91$ and $L_t = 585$, and E_s and P_s are the seasonal values of E and P expressed in grams per square centimeter per season.

The annual values of $(Q_a - Q_{ph})$ are given in Fig. 5 and the seasonal averages for latitude zones are given in Table VIII. These data show that the surplus latent energy is derived almost entirely from the ocean areas between 10°N and 40°N. The values are greatest in nearly every latitude zone during winter; during summer the quantity $(Q_a - Q_{ph})$, averaged for the entire North Atlantic and North Pacific, is negative, indicating that the Northern Hemisphere oceans are not sources of water vapor as surplus latent energy during this season.

Albrecht [1] has prepared a rough annual chart, showing $(E - P)$ over the oceans, which is based upon a comparison between observed surface salinities and those computed by means of Wüst's formulas [39] which give surface salinities as a function of $(E - P)$. A comparison between Albrecht's chart and Fig. 5 shows that the two agree in the gross features. However, the centers of Albrecht's areas of maximum $(E - P)$ are displaced from the positions indicated on Fig. 5. This displacement would be expected on the basis of the horizontal oceanic circulation which tends to shift the areas of maximum salinity in the direction of surface flow away from the centers of maximum $(E - P)$. Wüst's formulas apply regionally only in the absence of significant horizontal transport. Therefore, any $(E - P)$ chart based upon an examination of the distribution of surface salinities will show important regional departures from the true distribution [9].

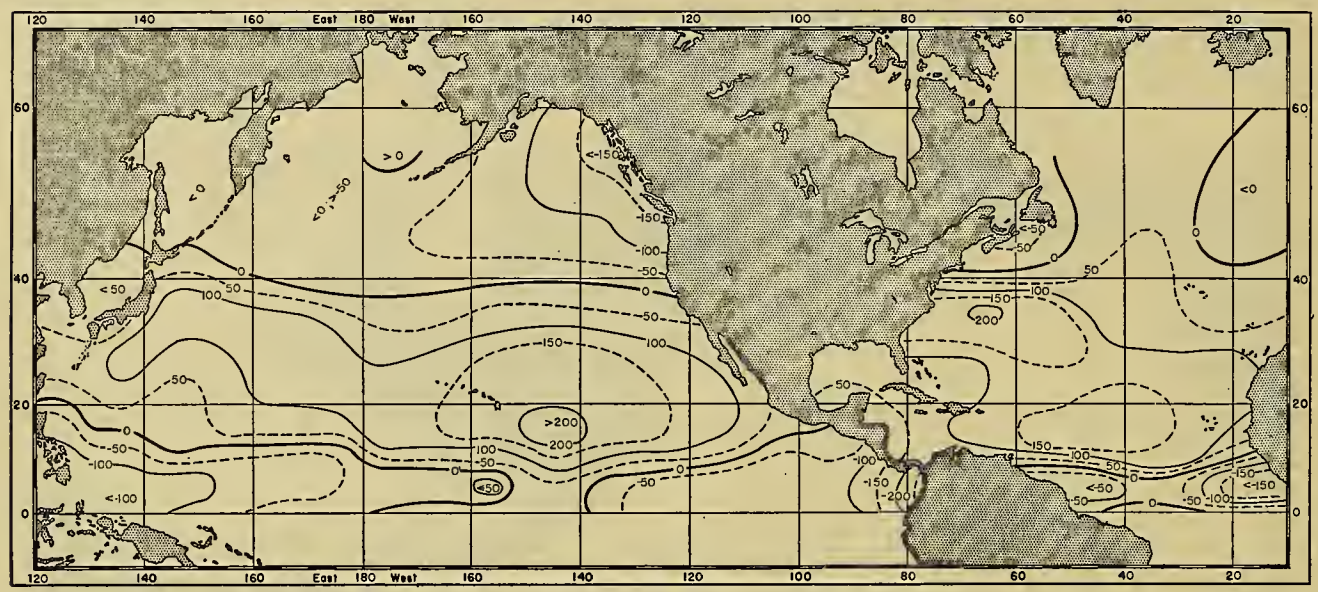

FIG. 5.—The annual values of the surplus of energy available in the latent form of water vapor $[Q_a - Q_{ph} = L_t\ (E - P)]$, expressed in calories per square centimeter per day. (The values above can be converted into rough $E - P$ rates by considering that the isometric interval of 50 cal cm^{-2} day^{-1} is approximately equivalent to an excess rate of evaporation over precipitation of 12 in. yr^{-1}. Negative values indicate a corresponding excess of precipitation over evaporation.)

CONCLUSIONS

It should be emphasized that the mean seasonal and annual distributions of the several ocean-atmosphere energy components which have been discussed here are by no means representative of instantaneous conditions over the oceans. It is to be expected that large nonperiodic variations in the seasonal (and perhaps annual) Q rates will occur and that the areas of maximum and minimum values will vary in both intensity and position. It is quite probable, also, that the *relative* magnitudes of the various Q values will exhibit important regional variations of a nonperiodic nature. The daily synoptic patterns of each energy factor should be as complex and individualistic as are the synoptic patterns of other meteorological elements such as pressure and winds. If the tracks of pressure centers or the zonal circulations show a progressive shifting from decade to decade, as has been pointed out by Petterssen [21], then corresponding shifts in the normal patterns of the several Q values should be expected. If secular variations in the amount of solar energy received at the surface of the earth occur, it is to be expected that similar secular variations in Q_h, Q_e, and Q_p will occur. However, it is not suggested that such variations must be proportional, since the effects of increased humidity, cloudiness, etc., may be important.

For the purpose of filling the gaps in our knowledge of the interrelations between oceanic energy transformation processes and fluctuations in the general circulations of the atmosphere and oceans, the short-term and nonperiodic aspects of the exchange of energy between ocean and atmosphere should be investigated. Furthermore, from the climatic point of view, the seasonal and annual analyses of the exchange of sensible heat and water vapor between sea and atmosphere should be extended to the Southern Hemisphere as soon as the necessary humidity data become available.[7]

In viewing the major unsolved problems associated with the transformation of energy over the oceans it should be pointed out that a consideration of the convective transfer of energy between ocean and atmosphere does not, itself, complete the analysis of the ocean-atmosphere energy cycle. The quantity Q_a discussed on pp. 1065 ff. does not include the large fraction of stored heat that the sea surface loses through direct radiation to space nor does it take into account the smaller fraction of heat that is locally made available to (or removed from) the water mass through the dissipation (or creation) of the kinetic energy represented by current, wave, and tidal motions.

The quantity Q_{ph} discussed in the last section does not include the amount of heat the moist atmosphere receives through the absorption of long-wave sea-surface radiation or through the small absorption of direct solar energy. Neither does Q_{ph} include the regionally important fractions of heat energy locally made available to the atmosphere (or removed) through the dissipation (creation) of kinetic energy of atmospheric motion or the "layer heating" resulting from the reduction of gravitational potential energy through subsidence (or the "layer cooling" resulting from the creation of gravitational potential energy through lifting).[8] The end result, of course, is that the total energy acquired by the whole atmosphere through conduction, condensation, and radiation must exactly balance the radiative loss.

It is the author's opinion that a nonexhaustive list of the more important phases of the ocean-atmosphere energy relationships that need investigation should include:

1. The determination of the nonperiodic and short-term variations in the energy exchange between ocean and atmosphere.
2. The analysis of the seasonal and regional aspects of the radiative transfer of energy between sea surface and atmosphere.
3. The determination of the surplus of solar energy stored in the oceans and transported by ocean currents.
4. The analysis of the large-scale aspects of the transport of internal energy by the atmosphere over the oceans.
5. The analysis of the large-scale aspects of the interconversion of heat and kinetic and gravitational potential energy of atmosphere and oceans.

7. Száva-Kováts [37] has presented charts, which have been rather widely published in climatological texts, showing the January and Jnly distributions of relative humidity and vapor pressure over all oceans. However, an examination of the original paper reveals that the values have been obtained on the basis of simple assumptions as to the average relationship between sea-surface temperatures and the humidities at a standard height in the overlying atmosphere. Obviously, snch data are not suitable for the evaporation computations where no such assumptions are allowable.

8. The author has considered the latter aspects in some detail elsewhere [8].

EVAPORATION FROM THE OCEANS

By H. U. SVERDRUP

Norwegian Polar Institute, Oslo

INTRODUCTION

The problem of evaporation from the oceans has received little attention compared to that directed towards the study of evaporation from lakes and land surfaces. One of the reasons for this is that the results of the latter, being of great interest to the hydrological engineers, are of immediate economic importance. Furthermore, until recently, weather forecasting has been concerned primarily with forecasting over land areas, for which purpose it has been sufficient to know that air which has travelled over the oceans contains a great deal of moisture, but it has not been necessary to ask how this moisture has been added to the air. With the rapid development of air routes across the oceans, accurate weather forecasts for ocean areas are needed, and in this connection the question of how air masses are modified when passing over water becomes important. When dealing with this modification, knowledge of evaporation as a function of the meteorological conditions near the sea surface becomes indispensable.

This development is reflected in the very manner in which the question of evaporation from the oceans has been dealt with during the last seventy-five years. Up to about 1930, most efforts were directed towards establishing the annual evaporation in different latitudes in order to examine the general water budget of the atmosphere, but during the last two decades the emphasis has been placed on examinations of the evaporation under given meteorological conditions. Some advances have been made, but these studies are still in their infancy.

EVAPORATION FROM THE OCEANS DETERMINED BY EXTRAPOLATION OF VALUES FROM LAND

In his discussion of the water budget of the atmosphere, Brückner [3] tried to find the evaporation from the oceans by extrapolating values derived from observations on land. He used observations from coastal regions particularly and obtained an average evaporation from all oceans between 70°N and 70°S of 110 ± 15 cm per year. He suggests that this value may be somewhat high because he has probably assumed too large an evaporation between 10°N and 10°S (see Table I). It is of interest to observe that, besides other material, Brückner made use of Russell's map of 1888 of the evaporation in the United States, from which he obtained the following values at the Atlantic and Pacific coasts:

North Latitude (deg)	Evaporation (cm per year)	Evaporation (mm per 24 hr)
25–30	120	3.3
30–40	98	2.7
40–45	82	2.2
45–50	51	1.4

A comparison with the evaporation data in Table I shows that these values are in remarkable agreement with results that have been obtained by entirely different methods.

DIRECT MEASUREMENTS OF EVAPORATION AT SEA

History. Measurements of evaporation from pans have been carried out on board ship in limited number. The first observations of this type were made by Mohn [15] during the Norwegian North Atlantic Expedition, 1876–78. Mohn used an evaporation pan that floated in a large container and determined the evaporation in 12 hours by adding enough fresh water to the pan, at the end of the time interval, to bring the weight of pan and water back to its original amount.

In subsequent experiments the evaporation has been determined by means of the increase in salinity during the period of exposure; in the earlier ones the salinity was determined by aerometric measurements of density and in the later ones by chlorine titration. In several cases pans have been exposed simultaneously to wind and sunshine, to sunshine only, and to wind only, in order to examine the effects of exposure. However, the results, which have been extensively discussed, have all been derived from observations obtained with the pan placed in as unprotected a position as possible.

Nearly all the measurements referred to in the last paragraph were made in German investigations during the years 1892 to 1914, and most of them between 1908 and 1914. They have been summarized and discussed by Wüst [29], who gives a list of the pertinent literature. Several measurements [10] were made during the last cruise of the *Carnegie*, but it is doubtful if such observations will be continued in the future because the results are difficult to interpret and because other methods of approach have met with fair success.

Discussion. Wüst [29] showed that the evaporation from pans on board ship depended principally on two variables, the wind velocity w, and the evaporation potential defined as

$$P = (T/273)(e_s - e). \tag{1}$$

In (1), T represents the absolute temperature of the water in the pan, e_s the vapor pressure at the water surface, and e the vapor pressure in the air measured on board ship. The wind velocity, w, is the wind velocity measured or estimated on board ship.

Regarding the vapor pressure at the water surface, it should be observed that the vapor pressure over sea water is somewhat lower than that over distilled water. If the latter is represented by e_d,

$$e_s = e_d\,(1 - 0.00053S), \tag{2}$$

where S is the salinity in parts per thousand. Over the oceans the salinity differs so little from 35 per mille that with sufficient accuracy $e_s = 0.98e_d$.

The observed evaporation values could be represented with good approximation by the equation,

$$E = 0.40\,P\,(1 + 0.40w) \qquad (3)$$

where E represents evaporation in centimeters per 24 hours, and e, which enters into the term P, is measured in millibars, and w in meters per second.

reduction factor. Somewhat arbitrarily he selected a height of 0.2 m above the sea surface, calculated what the evaporation from a pan at that height should have been, and assumed that a pan placed 0.2 m above the sea surface would have given values that would represent the evaporation from the sea surface itself. The numerical values are based on only a few series of measurements of wind and humidity gradients carried out at low wind velocity and on assumptions, the validity of which is not obvious. It is therefore not

‡ $Q_e = (Q_s - Q_r)/(1 + R)$.

§ Latent heat of vaporization, taking average sea-surface temperature into account. ($L = 596 - 0.56\vartheta$).

In discussing the accuracy of the evaporation values observed on board ship, Wüst [29] arrived at the conclusion that the values represent the actual evaporation *from the pan* with an accuracy better than ±8 per cent. The pertinent question is, therefore, whether these measurements permit any conclusions as to the evaporation *from the sea surface*. This question was first dealt with by Schmidt [21], who showed that the evaporation from the sea surface was probably only half that from the pans. Later on, the matter was discussed in great detail by Wüst [29, 30] and by Cherubim [5].

In attempting to reduce the pan values to values of evaporation from the sea surface, Wüst points out that: (1) the temperature of the sea surface deviates from that at the surface of the water in the pan, (2) the vapor pressure of the air at a short distance from the sea surface differs from that observed on board ship, and (3) similarly the wind velocity at a short distance from the sea surface differs from the wind velocity recorded on board ship. By means of special observations carried out in the Baltic in 1919 Wüst established the variation of the vapor pressure and wind with height above the sea surface and used the values thus obtained for a computation of a combined

surprising that somewhat different approaches give different results. In 1920 Wüst found a factor of 0.46, in 1931 Cherubim obtained a value of 0.58, and in 1936 Wüst finally adopted the value of 0.53, which, as will be shown, gives evaporation values that agree remarkably well with those obtained on the basis of energy considerations.

Results. From the evaporation measurements which have been carried out on board ship along different routes and by means of climatological data from which the evaporation on board ship can be computed using equation (3), Wüst derived average values of the annual evaporation from all oceans between 70°N and 70°S. These, based on a reduction factor of 0.53, are entered in Table I. Wüst estimates the probable error in his values to be ±12 per cent. The average value is 96 ± 12 cm per year.

Wüst claims only that the *average* values observed on board ship can be reduced to values of evaporation from the sea surface. He does not claim that the relationship between evaporation, evaporation potential (equation (3)), and wind velocity, which was established for the pan measurements, is applicable to the evaporation from the sea surface after multiplication by the factor 0.53. It does not appear probable that the equation

applies, because it gives high evaporation rates at very low wind velocities and, by extrapolation, an evaporation of 0.21 mm per 24 hr in absolutely calm weather. When one is dealing with a pan, the evaporation may indeed be considerable even at very low wind velocities, but the evaporation from the sea surface under this condition must be negligible. The question as to the relation between the evaporation and the meteorological conditions at sea will be discussed later.

EVAPORATION FROM THE OCEANS COMPUTED FROM ENERGY CONSIDERATIONS

Energy available for evaporation. The first attempt to determine the evaporation from the oceans on the basis of energy considerations was made by Schmidt [20]. In principle the procedure is quite simple. During the year the oceans gain energy by short-wave radiation from the sun and the sky (Q_s) and lose energy by effective long-wave radiation to the atmosphere (Q_r), by evaporation (Q_e), and by conduction of heat to the atmosphere (Q_h). Other sources of energy gains or losses, such as conduction of heat from the interior of the earth, energy changes related to chemical and biochemical processes in the sea, and friction losses, are negligible compared to the former. Furthermore, it can be assumed that the average temperature of the oceans remains so nearly constant from one year to another that, to a close approximation, the average energy gain must equal the loss:

$$Q_s = Q_r + Q_e + Q_h. \tag{4}$$

Introducing

$$R = Q_h/Q_e \tag{5}$$

and

$$E = Q_e/L, \tag{6}$$

where L is the latent heat of vaporization, we obtain

$$E = \frac{Q_s - Q_r}{L\,(1 + R)}. \tag{7}$$

Schmidt determined the values of the radiation surplus ($Q_s - Q_r$), using measurements of radiation at sea combined with climatological data as to cloudiness and sea-surface temperature (see Fig. 1).

Mosby [17] undertook a new computation of the radiation surplus, using certain empirical relations between the incoming radiation and the altitude of the sun. On the whole his values agree very well with those of Schmidt (see Fig. 1). The major discrepancy is found between latitudes 20°N and 20°S where Schmidt's results show a minimum of radiation surplus near the equator, whereas Mosby obtains no such minimum. The reason for this is that Schmidt has introduced a considerably greater cloudiness at the equator than at 30°N or 30°S (5.9, 4.2, and 4.0, respectively), whereas Mosby has used nearly the same values of cloudiness in all latitudes between 30°N and 30°S (values between 5.6 and 5.2). It seems probable that Schmidt's values give a more correct representation of the variation of radiation surplus with latitude.

McEwen [13] has computed the radiation surplus between latitudes 20° and 50°N in the eastern North Pacific, using a very elaborate method. His results are in very good agreement with those of Schmidt and Mosby, as is evident from Fig. 1.

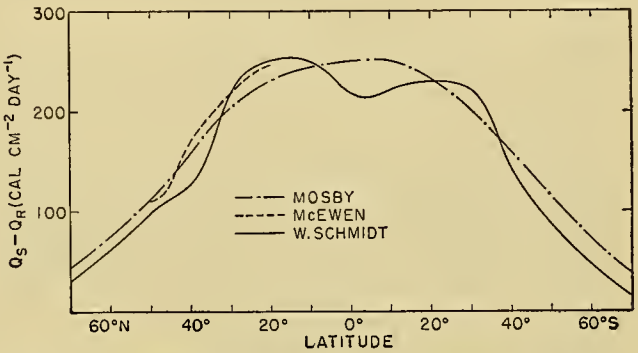

FIG. 1.—Average annual surplus of energy (in cal cm^{-2} min^{-1}) which the oceans receive in different latitudes by radiation processes.

The Bowen Ratio. From the preceding discussion and the results shown in Fig. 1 it appears that the radiation surplus received by the oceans has been determined with considerable accuracy. For computing the evaporation it is in addition necessary to know the ratio $R = Q_h/Q_s$, which is often referred to as the *Bowen ratio* because Bowen [2] has shown that it can readily be computed from meteorological observations on board ship if, in addition, the sea surface temperature has been recorded.

When computing the evaporation, Schmidt [20] did not introduce the ratio R, but a ratio $R' = Q_s/(Q_s - Q_r)$ from which R can be found from the relation $R = (1 - R')/R'$. Schmidt had no means of determining R' directly, but concluded from certain general considerations that it varied greatly with latitude. Expressed as R, the range is from a value of about 0.28 at the equator to a value of about 1.67 at 70°N or S.

Ångström [1] criticised Schmidt's determination of R and pointed out that in middle latitudes Schmidt's values were far too large. From the application of energy considerations to Swedish lakes and from measurements of actual evaporation and of meteorological conditions Ångström concluded that the ratio R was only about 0.1, meaning that, of the net energy received by radiation ($Q_s - Q_r$), only about 10 per cent was given off to the atmosphere by conduction and about 90 per cent was used for evaporation.

Mosby [17] accepted Ångström's estimate of R and used a value of 0.1 for the computation of the average evaporation from all oceans. He was not aware of Bowen's paper, according to which R can be computed if the air temperature ϑ_a and the vapor pressure e_a have been observed at the same height a above the sea surface, and if the temperature at the sea surface ϑ_s has been recorded, from which the vapor pressure at the sea surface is obtained using equation (2). If we antici-

pate part of the following discussion (p. 1075, eq. (12)), the Bowen formula can be derived in a simple manner. If the eddy coefficients for diffusion of water vapor and conduction of heat are assumed to be identical, the upward fluxes of latent energy of water vapor and of heat can be written

$$Q_e = -L \frac{0.621}{p} A \frac{de}{dz}$$

and

$$Q_h = -c_p A \frac{d\vartheta}{dz},$$

where p is the atmospheric pressure, A the eddy conductivity (or diffusivity), c_p the specific heat of the air, and ϑ the air temperature. To be exact, potential temperature should have been used, but near the sea surface, where the vertical temperature gradient is large, only a small error is introduced by using the ordinary temperature. It follows that

$$R = \frac{Q_h}{Q_e} \frac{c_p\, p}{0.621\, L} \frac{d\vartheta/dz}{de/dz}.$$

Replacing the ratio of the differentials by the ratio $(\vartheta_s - \vartheta_a)/(e_s - e_a)$ and introducing the numerical values $c_p = 0.240$, $p = 1000$ mb, and $L = 585$, one obtains R, the Bowen ratio:

$$R = 0.64 \frac{\vartheta_s - \vartheta_a}{e_s - e_a}. \qquad (8)$$

The Bowen ratio has been used extensively by Cummings and Richardson (see, for example, [6]) in the study of evaporation from lakes, and by Jacobs [8] in his examination of the energy exchange between the ocean and the atmosphere.

For the North Atlantic and the North Pacific Oceans, Jacobs determined the Bowen ratio as a function of latitude. In both cases R increased with latitude, but the values found for the North Atlantic were consistently smaller than those for the North Pacific. In the Atlantic even small negative values were found near the equator, indicating that there the average air temperature is slightly higher than the sea-surface temperature. The reality of this feature must be questioned. Careful observations from specially equipped ships have demonstrated that in the tropics of the Atlantic Ocean the air temperature is about 0.8C *lower* than the sea-surface temperature, but the values found on climatological charts show a smaller difference or even a higher air temperature. The reason for this is that the climatological charts are based on routine observations on board ship, in which errors due to the ship's heat or faulty exposure of the thermometer have not been eliminated. In his computations of R, Jacobs [8] used data from climatological charts and, therefore, his R values are probably too small in low latitudes, but in higher latitudes they are more nearly correct.

Taking the average for the two northern oceans one obtains:

North Latitude (deg)	R (Jacobs)	R (Corrected)	R (in intervals of latitude)
70	0.53	0.53	
			0.45
60	0.37	0.37	
			0.31
50	0.25	0.25	
			0.21
40	0.18	0.18	
			0.15
30	0.08	0.13	
			0.11
20	0.02	0.10	
			0.10
10	0.00	0.10	
			0.10
0	0.00	0.10	

The increase with increasing north latitude is in part an effect of the continents from which cold air flows out over the oceans in winter. In the Southern Hemisphere the effect is absent or weak, and therefore we shall assume that R increases only to 0.25 at 70°S.

Results. In revising the computation of evaporation on the basis of energy considerations we shall make use of Schmidt's values of the radiation surplus and of Jacobs' values of R in the Northern Hemisphere after application of an estimated correction in the tropics. For the Southern Hemisphere we shall introduce estimated values. For the latent heat of vaporization, values will be used corresponding to the average sea-surface temperature in the different latitudes. All values used and the results obtained are shown in Table I, which also contains the evaporation observed on board ship reduced to true evaporation (p. 1072) and average values according to Jacobs.

If we take into consideration the ocean areas between parallels of latitude, the average annual evaporation between latitudes 70°N and 70°S is found to be 99 cm per year. The error of this value is probably less than ±10 cm per year.

EVAPORATION FROM THE OCEANS COMPUTED FROM METEOROLOGICAL ELEMENTS

History. In evaporation studies one of the aims has long been the establishment of relationships that would permit computation of evaporation from the meteorological elements recorded on board ship, that is, from air temperature, humidity, wind velocity, and barometric pressure, and from knowledge of the sea-surface temperature. Prior to about 1920 several empirical equations were developed on the basis of pan measurements on shipboard or on land (see for example equation (3)), but these equations give only the empirical relation between the evaporation *from the pan* and certain meteorological elements and they cannot be expected to give correct values of the evaporation from the sea surface. This point of view had not been generally recognized [7, 11] but had been emphasized by Schmidt [21], who strongly recommended the detailed examination of humidity, temperature, and wind conditions in the very lowest layers of the air directly above the sea surface in order to establish a basis for reducing the evaporation measurements on board ship to the sea surface.

Wüst [29] carried out a limited number of such measurements (see p. 1072), but used them only for a reduction of the *averages* and not for the establishment of a new relationship. Recent advances have been made by following the entirely different procedure

of computing evaporation directly from a knowledge of humidity and wind conditions in the lowest layer. A first attempt in this direction was made by Wagner [28], who had to confine himself to general considerations and the use of empirical relations established over land because the type of studies urged by Schmidt had not been made.

Even today there are available only a few series of measurements of temperature, humidity, and wind at various levels in the vicinity of the sea surface. The interpretation of these few observations has, however, helped to throw light on the problem of evaporation, but clear-cut results have not been obtained. It is necessary to review the manner in which the problem has been dealt with by different authors and to evaluate the empirical evidence that supports or contradicts the different conclusions.

Theoretical Considerations. When one is dealing with evaporation, the moisture content of the air is best described by the specific humidity q. The moisture concentration (water vapor per unit volume) is then equal to ρq, and this concentration will be considered a conservative property, that is, a property which is altered locally (except at the boundaries) by processes of diffusion and advection only:

$$\frac{\partial(\rho q)}{\partial t} = \frac{\partial}{\partial x}\left(\frac{A_x}{\rho}\frac{\partial(\rho q)}{\partial x}\right) + \frac{\partial}{\partial y}\left(\frac{A_y}{\rho}\frac{\partial(\rho q)}{\partial y}\right) + \frac{\partial}{\partial z}\left(\frac{A_z}{\rho}\frac{\partial(\rho q)}{\partial z}\right) - \frac{\partial}{\partial x}(\rho q w_x) - \frac{\partial}{\partial y}(\rho q w_y) - \frac{\partial}{\partial z}(\rho q w_z)\,. \tag{9}$$

Here A_x/ρ, A_y/ρ, and A_z/ρ represent the diffusion coefficients (of dimensions $L^2\ T^{-1}$) which are supposed to be different in different directions, ρ is the density of the air, and w_x, w_y, and w_z are the velocity components. The definition implies that the following considerations are not valid if droplets are present in such numbers that condensation on or evaporation from these droplets cannot be neglected.

Equation (9) has been used in very simplified forms. If we assume stationary conditions ($\partial(\rho q)/\partial t = 0$), motion along the x-axis only ($w_y = w_z = 0$), and neglect horizontal diffusion ($A_x\,\partial(\rho q)/\partial x = A_y\,\partial(\rho q)/\partial y = 0$), equation (9) is reduced to

$$\frac{\partial}{\partial z}\left(\frac{A_z}{\rho}\frac{\partial(\rho q)}{\partial z}\right) = \frac{\partial(\rho q w_x)}{\partial x}\,. \tag{10}$$

In this form it has been applied by Sutton [22] to the problem of evaporation from a limited body of water. His theoretical conclusions are in good agreement with the results of experiments in the laboratory and conditions observed in the field. Other similar studies have been carried out and have led to the clarification of experimental results, but they are not applicable to the problem of evaporation from the ocean because the ocean surface must be considered as a water surface of infinite extension, directly above which the horizontal gradients of moisture content are negligible. Very near the sea surface the vertical velocity can be neglected in all circumstances and the density can be considered constant. Equation (9) is then reduced to

$$\frac{d}{dz}\left(A\frac{dq}{dz}\right) = 0$$

or

$$A\frac{dq}{dz} = \text{const}, \tag{11}$$

which simply expresses the fact that near the boundary surface the vertical flux of water vapor, expressed in units of mass per area and time, is independent of height. In the cgs system the flux is expressed in g cm^{-2} sec^{-1}.

If the vertical flux is directed upwards, dq/dz must be negative. In this case the flux must equal the evaporation from the water surface, and therefore

$$E = -A\frac{dq}{dz}\ (\text{g cm}^{-2}\ \text{sec}^{-1}). \tag{12}$$

Thus the problem of evaporation is reduced to the problem of finding the vertical flux of water vapor.

This may appear to be an easy matter, because in the air the eddy diffusivity A can be considered to be practically known from wind observations. However, difficulties arise because, very close to the surface, diffusivity and viscosity are *not* identical, and because different assumptions as to the character of the diffusivity close to the surface lead to widely different results.

The eddy viscosity increases with height and, furthermore, depends upon the stability of the stratification and the character of the sea surface, whether hydrodynamically smooth or rough. At indifferent stratification or slight instability, conditions which prevail over the sea, the eddy viscosity is a linear function of height.

In anticipation of material which follows, it can be stated that at some distance from the surface

$$A \approx \rho k_0 w_* z, \tag{13}$$

where k_0 and w_* are defined as below. Since $A\ dq/dz = \text{const}$, it follows that q must vary with the logarithm of height, and Montgomery [16] has therefore introduced an evaporation coefficient Γ, defined by

$$\Gamma \equiv -\frac{1}{q_s - q}\frac{dq}{d\ln z}\,. \tag{14}$$

Introducing (13) and (14) into (12) we obtain

$$E = k_0 \rho w_* \Gamma\,(q_s - q). \tag{15}$$

It is this expression which we shall attempt to evaluate for smooth and rough conditions; that is, we shall determine the evaporation coefficient Γ which is the unknown factor.

Over a *smooth* surface there exists, next to the surface, a thin boundary layer in which the flow is laminar and where ordinary viscosity acts. Above this laminar layer the turbulent layer begins. Placing the origin of the vertical axis at the top of the laminar layer, we have in

the turbulent layer

$$A = \rho(\nu + k_0 w_* z), \tag{16}$$

and in the laminar layer

$$A = \mu = \rho\nu. \tag{17}$$

Here μ is the viscosity and ν the kinematic viscosity of the air, k_0 is von Kármán's universal turbulence constant ($k_0 = 0.4$), and w_* is the "friction velocity" which is defined by the equation

$$w_* = \sqrt{\tau/\rho} \tag{18}$$

where τ is the shearing stress. This is defined as $\tau = A\, dw/dz$ and is supposed, near the sea surface, to be independent of height and equal to τ_0, the wind stress at the sea surface. The friction velocity can be expressed by the wind at any level w:

$$w_* = \gamma w, \tag{19}$$

where γ is the resistance coefficient which, according to von Kármán, can be obtained from the equation

$$\frac{1}{\gamma} + \frac{1}{k_0} \ln \frac{1}{\gamma} = 5.5 + \frac{1}{k_0} \ln \frac{w_* z}{\nu}. \tag{20}$$

The thickness of the laminar layer δ is supposed to depend on the viscosity and the stress as expressed by the friction velocity:

$$\delta = \lambda \frac{\nu}{w_*}, \tag{21}$$

where λ is a constant for which von Kármán found the value 11.5, whereas Montgomery [16] obtained 7.8. In the following applications we shall use von Kármán's value, $\lambda = 11.5$, but the choice is not of great importance.

The picture given above of the variation with height of the eddy viscosity appears fully applicable when turning to the eddy diffusivity. We must indeed expect that next to the sea surface there exists a layer through which the flux of water vapor takes place by molecular diffusion, and it seems reasonable that the thickness of this layer equals that of the laminar layer. In the turbulent layer the eddy diffusivity must then be

$$A' = \rho(\kappa + k_0 w_* z), \tag{22}$$

where κ is the coefficient of diffusion of water vapor through air. For values of $z >> \delta$ this eddy diffusivity differs only imperceptibly from the eddy viscosity.

The flux of water vapor through the two layers is then

$$E = -\rho\kappa \left(\frac{dq}{dz}\right)_l = -\rho\,(\kappa + k_0 w_* z) \left(\frac{dq}{dz}\right)_t, \tag{23}$$

where the indices l and t indicate that the differentials apply to the laminar and the turbulent layer, respectively. By integration, remembering that $z = 0$ at the top of the laminar layer where $q = q_\delta$:

$$q_s - q_\delta = \frac{E}{\rho\kappa}\delta = \frac{E}{\rho w_*}\frac{\lambda\nu}{\kappa}, \tag{24}$$

$$q_\delta - q = \frac{E}{k_0 \rho w_*} \ln \frac{\kappa + k_0 w_* z}{\kappa}. \tag{25}$$

Adding and considering that κ is small compared to $k_0 w_* z$ for $z >> \delta$, we obtain:

$$q_s - q = \frac{E}{k_0 \rho w_*}\left[\lambda k_0 \frac{\nu}{\kappa} + \ln \frac{k_0 w_* z}{\kappa}\right], \tag{26}$$

or, introducing w,

$$E = k_0 \rho\gamma w \frac{q_s - q}{\lambda k_0 \frac{\nu}{\kappa} + \ln \frac{k_0 w_* z}{\kappa}}. \tag{27}$$

Therefore:

$$\Gamma_a = \left[\lambda k_0 \frac{\nu}{\kappa} + \ln \frac{k_0 w_* a}{\kappa}\right]^{-1}. \tag{28}$$

Here the ratio ν/κ is independent of temperature ($\nu/\kappa = 0.602$), but κ increases a little with temperature (at 0C $\kappa = 0.22$, at 20C $\kappa = 0.25$ cm^2 sec^{-1}). With $\kappa = 0.24$ cm^2 sec^{-1} and $a = 800$ cm, Γ_a is shown in Fig. 2 as a function of w.

According to Rossby [19], the sea surface has the character of a hydrodynamically *smooth* surface at wind velocities up to 6–7 m sec^{-1} as measured at a height of about 8 m. At wind velocities exceeding 7–8 m sec^{-1} the sea surface appears to be hydrodynamically rough.

Over a *rough* surface the eddy viscosity increases linearly with height and has, at the surface itself ($z = 0$), a value which is much larger than that of the ordinary viscosity:

$$A = k_0 \rho w_* (z + z_0). \tag{29}$$

Here z_0 is the "roughness length" of the surface. The resistance coefficient γ is determined by

$$\gamma = \frac{k_0}{\ln \frac{z + z_0}{z_0}}. \tag{30}$$

When this concept is applied to conditions over the ocean the question arises as to where to place the zero level. No wind profiles have been measured at high wind velocities when large waves have been present, and we have, therefore, no knowledge of the wind distribution very close to the sea surface.

Using other features—the angle between surface wind (*e.g.*, wind at about 8 m) and pressure gradient, the ratio between surface wind and gradient wind—Rossby arrived at the conclusion that over the ocean the roughness length is independent of the wind velocity and equal to about 0.6 cm. This result is substantiated by the facts that with $z_0 = 0.6$ cm and with 800 cm $< z <$ 1500 cm, equation (30) renders γ values in agreement with those found by entirely different methods, and that these γ values have been applied

successfully to such problems as the generation of wind waves and the maintenance of the equatorial currents [25].

We may therefore state that at wind velocities above 6–7 m sec^{-1} the eddy viscosity in the lower layer above the sea surface behaves *as if* the sea surface were a rough surface (z_0 = 0.6 cm) located about 8 m below the level at which ship observations are ordinarily made. The next question is then, How does the eddy diffusivity behave? If z is not small, the eddy diffusivity must be practically equal to the eddy viscosity, but what happens when z approaches zero? It appears quite probable that in this case, as well, we must introduce a layer next to the boundary surface through which the flux of water vapor takes place by ordinary diffusion. In 1937 the present writer argued as follows [23, p. 4]:

> One can conceive that for a short time a mass of air comes to rest in one of the hollows of the surface. This mass of air will immediately give off its momentum to the surface, but the vapor pressure will not immediately attain the value which is characteristic of the surface. As long as this mass remains at rest, its vapor contents will be increased by processes of ordinary diffusion, supposing that it originally was lower than the equilibrium pressure corresponding to the temperature and salinity of the surface. After a short time the air mass will be removed and replaced by another, and similar processes will be repeated. In order to describe these processes one can introduce a boundary layer, the thickness of which is a statistical quantity representative of the average conditions and within which the transport of water vapor takes place through ordinary diffusion.

A much more extreme view has been advanced by Millar [14] and Montgomery [16], who assume that even over a rough surface the laws pertaining to a smooth surface apply to a distance Z from the boundary surface, but that at that height an abrupt transition to "rough" conditions takes place.

So far, five different attempts have been made to discuss the evaporation from a rough surface, based on different assumptions as to the character of the diffusivity close to the surface. These assumptions can be described as follows:

1. Next to the surface there is a true diffusion layer followed by an intermediate layer of thickness Z in which the eddy diffusivity corresponds to that over a smooth surface, $A = \rho(\kappa + k_0 w_{*s} z)$, where w_{*s} is obtained from equation (20). At Z the eddy diffusivity suddenly increases to the value of the eddy viscosity over a rough surface, and for $z > Z$, $A = k_0 \rho w_{*r} (z + z_0)$ where w_{*r} is obtained from equation (30) [14, 16].

2. Next to the surface there is a true diffusion layer of thickness $\delta = \lambda\nu/w_{*r}$, where w_{*r} applies to a rough surface. From the top of this layer the eddy diffusivity increases at the same rate as the eddy viscosity above a rough surface. These assumptions agree with those of Bunker and others [4] if their notations are made to correspond to those that apply to conditions above a rough surface.

3. Next to the surface there is a true diffusion layer of thickness $\delta = \lambda\nu/w_{*r}$, where w_{*r} applies to a rough surface. At the top of this layer the diffusivity increases abruptly from the molecular value to the value over a rough surface: $A = k_0 \rho w_{*r} (\delta + z_0)$, and for $z > \delta$: $A = k_0 \rho w_{*r} (z + z_0)$ [23].

4. There exists no layer of true diffusion. The eddy diffusivity is at all levels identical with the eddy viscosity, $A = k_0 \rho w_{*r} (z + z_0)$ (Sverdrup [24]).

5. The character of the diffusivity corresponds to that assumed under (1), but at the top of the intermediate layer, at $z = Z$, the vertical flux of water vapor increases abruptly from E_0 to E where $E_0/E = (w_{*s}/w_{*r})^2$ [18].

On the basis of these assumptions it is possible to compute Γ_a. The results are:

$$1.\quad \Gamma_a = \left[\ln \frac{a}{Z} + \frac{w_{*r}}{w_{*s}} \left(\lambda k_0 \frac{\nu}{\kappa} + \ln \frac{k_0 w_{*s} Z}{\kappa} \right) \right]^{-1}, \tag{31}$$

$$2.\quad \Gamma_a = \left(\lambda k_0 \frac{\nu}{\kappa} + \ln \frac{k_0 w_{*r} a}{\kappa} \right)^{-1}, \tag{32}$$

$$3.\quad \Gamma_a = \left(\lambda k_0 \frac{\nu}{\kappa} + \ln \frac{a}{\delta + z_0} \right)^{-1}, \tag{33}$$

$$4.\quad \Gamma_a = \left(\ln \frac{a}{z_0} \right)^{-1}, \tag{34}$$

$$5.\quad \Gamma_a = \left(\ln \frac{a}{z_0} - 1.76 \frac{w_{*r}}{w_{*s}} \right)^{-1}. \tag{35}$$

In Fig. 2 five Γ_a curves, referred to a = 800 cm, are shown as functions of the wind velocity, corresponding to the five sets of assumptions. The curve marked (1) is plotted according to values given by Montgomery [16], taking into account that here we refer Γ_a to a height of 8 m, whereas he used 4 m. When computing Γ_a in cases (2) and (3), the question arises as to what value to assign to λ. It is not obvious that the value for a smooth surface (λ = 11.5) is applicable, but lacking means of determining a better value, we have used it. It may be observed that, on the basis of Montgomery's humidity measurements, Sverdrup [23] found λ = 27.5, but this value seems doubtful because it was derived

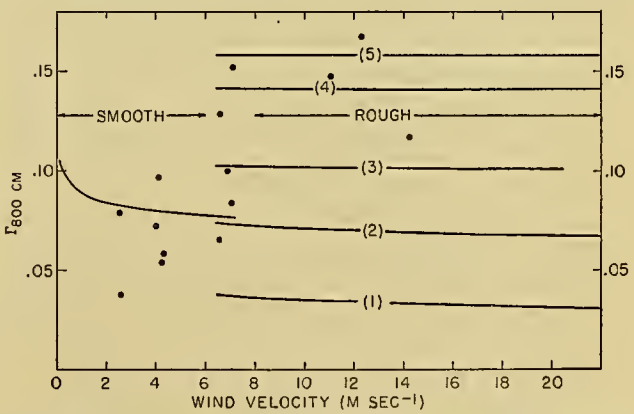

FIG. 2.—Theoretical values of the evaporation coefficient as function of the wind velocity at 800 cm, computed on the basis of different assumptions, and observed values shown by dots.

from observations that included many cases of flow over a smooth surface. With $\lambda = 27.5$, curve (3) would nearly coincide with curve (2).

The wide spread of the curves (2) to (5) clearly demonstrates the importance of the assumptions as to the diffusivity near the boundary surface. Assumptions (1), (4), and (5) appear too extreme, but none can be rejected offhand since we have no basis for describing what actually takes place, but are trying to introduce a model which gives results in consistent agreement with observed conditions. In order to advance a step further we have to compare the theoretical conclusions with the empirical results. Our empirical data are of two kinds. On the one hand we have available a few series of measurements of humidity at different heights above the sea surface from which Γ_a can be found, and on the other hand we have series of accurate ships' observations of meteorological conditions and sea surface temperatures from which we can compute evaporation, using different Γ_a values, and we can compare the results with those derived from energy considerations. In order to facilitate computations and comparisons we shall use vapor pressure instead of specific humidity. Approximately, $e = qp/0.621$ or with $p = 1000$ mb, $e = 161q$. We then write equation (15) in the form

$$E = K_a (e_s - e_a) w_a, \tag{36}$$

and shall call K_a the evaporation factor. We shall use units such that with pressure in millibars and wind velocity in meters per second we obtain the evaporation in millimeters per 24 hours. The curves for K_a ($a = 800$ cm) are shown in Fig. 3. The heavy curves

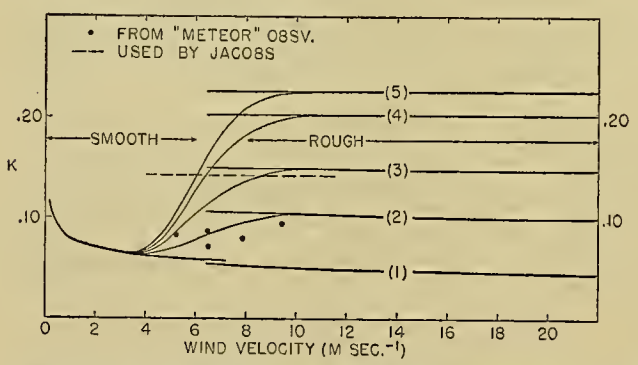

FIG. 3.—Theoretical values of the evaporation factor K as function of the wind velocity at 800 cm, computed on the basis of different assumptions, and empirical values shown by dots and a dashed line.

should be used for computing evaporation from single observations. If climatological averages are available, we must use some transition curves in an interval of velocities around 6–7 m sec^{-1}, the width of which depends upon the spread of values upon which the averages are based. In Fig. 2, arbitrary transition curves are indicated for the interval 2–11 m sec^{-1}.

Discussion. The theoretical considerations lead to such different evaporation factors that the theoretical approach is useless until there can be advanced adequate arguments for accepting one of the many models which at present can be used to describe the character of the eddy diffusion of water vapor close to the sea surface. The theory apparently leads to consistent results at wind velocities up to 6 m sec^{-1} for individual cases, or up to 4 m sec^{-1} for average conditions, but it should be emphasized that this consistency arises because it has been accepted that the sea surface is smooth at low wind velocities. The empirical evidence for this feature is, however, so meager that its reality is badly in need of confirmation. Should it not be confirmed, we must admit that the theoretical computation of the evaporation factor fails at all wind velocities. The only remaining conclusion is that such a factor can probably be established, either on a theoretical basis (if a new foundation for the development of a theory is found) or on an empirical basis.

In trying to do the latter we may follow one of three courses: (*a*) the evaporation coefficient Γ may be determined from measurements of humidity gradients over the sea; (*b*) where accurate meteorological observations are available, and where evaporation can be computed from energy considerations, the evaporation factor may be determined; or (*c*) where climatological charts are available, based on observations that may contain small systematic errors, such as temperature observations on shipboard, the procedure under (*b*) can be used. We shall examine these procedures more closely.

In Fig. 2 the values of Γ have been plotted which have been derived from observations of humidity gradients. Most of the observations were made at wind velocities below 6 m sec^{-1} and agree fairly well with the theoretical values for a smooth surface. The few observations at high wind velocities agree quite well with curve (4) for a rough surface, and this feature led the writer [24] to accept that approach although he previously [23] had adhered to different concepts. It will be shown here that the agreement between the empirical Γ values and the theoretical curve (4) must be accidental because the evaporation factor K, based on curve (4), gives far too high evaporation values.

The second method (*b*), can be used only if very accurate meteorological observations are available for a large area and a sufficiently long time. The *Meteor* observations in the Atlantic [12] satisfy this requirement, and from these the data in Table II have been obtained. The factor K, which has been plotted in Fig. 3, lies between 0.07 and 0.09, and agrees fairly well with values derived from curve (2). The result is in sharp contrast to that derived from examination of humidity gradients and indicates that of the different theoretical assumptions number (2) is the most nearly correct. It should be borne in mind that the computation of the evaporation factor on the above basis is somewhat uncertain, because the meteorological observations are extended over only from 1⅓ to 3 months in summer whereas the "energy values" apply to the whole year. The errors that may be introduced because of this circumstance should, however, not be serious, because in the tropics the annual variation in

evaporation is small and the same probably applies to the South Atlantic down to latitude 55°S.

The third approach has been used by Jacobs [8, 9] in computing the evaporation from the data contained in the *Atlas of Climatic Charts of the Oceans* [27].

TABLE II. EVAPORATION FACTOR K [$K = E/w\ (e_s - e_a)$] (Computed from the meteorological observations on board the *Meteor* and the evaporation rates determined by Wüst)

Region	Latitude range	Number of days	w (m sec^{-1})	$e_s - e_a$ (mb)	Evaporation (Wüst) (mm day^{-1})	K
NE—trade	10°–25°N	67	6.5*	6.4	3.58	0.086
Calm belt	10°N–0°	40	5.2	7.6	3.20	0.082
SE—trade	0°–25°S	107	6.5	7.6	3.48	0.071
Transition	25°–35°S	56	7.9	4.9	3.05	0.079
Westerlies	35°–55°S	86	9.4	2.0	1.75	0.093

* Reduced to the probable average value. The observed value was 8.3 m sec^{-1}, but observations were made in midwinter.

Data of this character may contain small systematic errors in sea-surface and air temperatures, and in humidities and wind velocities. It is, therefore, best to establish the evaporation factor on a strictly empirical basis, requiring that evaporation computed from meteorological data shall agree with that obtained from energy considerations. Jacobs followed this procedure. By undertaking a comparison between results from four limited areas he found

$$K = 0.142$$

and could show that by using this value the total evaporation from the North Atlantic and North Pacific Oceans agrees with that computed on the energy basis. It should be observed that the value 0.142 has no general significance, because it applies to the specific data used by Jacobs and may not apply if other climatological compilations are used. Also it should be mentioned that the factor K used by Jacobs may not be a constant, but may depend on the wind velocity. If so, some of the details of Jacobs' results are possibly in error, but the main conclusions can be expected to be correct.

Results. Using the equation

$$E = 0.142\ (e_s - e_a)w_a \qquad \text{(mm per 24 hr)}, \quad (37)$$

where e is in mb and w in m sec^{-1}, Jacobs has by means of the data in the *Atlas of Climatic Charts of the Oceans* [27] computed regional and seasonal values of the evaporation from the North Atlantic and North Pacific Oceans.

The average values between 0° and 60°N are entered in Table I. The average evaporation in this latitude range agrees with the corresponding average from the energy relations, indicating that a correct value of the factor K was obtained by means of results from four limited areas. Between 0° and 30°N they are *higher*. The observed evaporation rates (Table I, Wüst) display the same feature, which indicates that in low latitudes part of the radiation surplus is stored as heat in the water, is carried north by ocean currents, and is used for evaporation in middle and higher latitudes. The energy that is transported by the ocean currents across the parallel of 30°N amounts, according to Jacobs' values, to 1.4×10^{16} cal min^{-1}. The observed evaporation rates give a similar transport to the north, and at the same time they show no consistent transport in the Southern Hemisphere.

It is well known that the earth receives a radiation surplus in lower latitudes and a deficit in higher latitudes [26]. In order to maintain a steady average temperature distribution, heat must therefore be transported from the equator towards the poles across the parallels of latitude, and at 30°N this transport amounts to 3.6×10^{16} cal min^{-1}. It has been generally assumed that this transport takes place mainly by means of the air currents, but the results referred to above indicate that in the Northern Hemisphere about one-third of the transport takes place by means of ocean currents and two-thirds by means of air currents, whereas in the Southern Hemisphere the transport by ocean currents is negligible. This conclusion seems reasonable because currents that carry warm water into higher latitudes are far better developed in the Northern than in the Southern Hemisphere.

From the preceding discussion it is evident that the computation of evaporation from meteorological observations has so far not rendered an independent check on results obtained by other methods because energy considerations have been used to establish the evaporation factor to be applied. Still, the approach has greatly increased our knowledge as to the evaporation from the oceans because it has furnished a basis for a detailed examination of the energy exchange between the ocean and the atmosphere. This question is dealt with in an adjoining article in this Compendium, which also presents the available information as to the evaporation from different ocean areas in different seasons.

CONCLUSIONS[1]

The problem of evaporation from the oceans has been attacked by three different methods: (1) observations of evaporation from pans on board ship; (2) computations on the basis of the available energy; and (3) computations of vertical flux of water vapor.

1. Observations of evaporation from pans on board ship have rendered fairly consistent values, but the reduction of these values to true rates of evaporation from the sea surface is so uncertain that the two other methods of approach appear to be superior.

2. Different computations based on energy considerations have given similar results as to the average annual

1. When the present article was in press the author received a copy of the paper: Anderson, E. R., and others, *A Review of Evaporation Theory and Development of Instrumentation.* (Lake Mead Water Loss Investigations.) Interim Rep. Navy Electronics Laboratory, Rep. No. 159, pp. 1–70, February 1950. This report includes considerations applicable to a limited body of water and deals with effects of stability. Where the problems are similar, the conclusions agree with those in the present paper. The report contains a long list of references.

evaporation between parallels of latitude. Still, in order to place the results on a firmer basis, it is very desirable to obtain further direct measurements at sea of incoming radiation from sun and sky and of nocturnal radiation. Measurements of the reflectivity of the sea surface under different conditions are also needed, as well as further examination of the Bowen ratio (the ratio between heat losses from the sea surface by conduction and by evaporation). Even with improved knowledge of these conditions, the energy approach cannot render information as to evaporation rates under given meteorological conditions or seasonal and regional values of the evaporation. In order to compute such values the third approach has to be adopted.

3. For the computation of the vertical flux of water vapor from the sea surface several assumptions have been introduced as to the character of the eddy transfer processes near the sea surface. These assumptions lead to different formulas from which the evaporation rate can be obtained from observations of humidity and wind velocity at a standard level above the sea surface and observations of the sea surface temperature from which the vapor pressure at the sea surface can be derived.

These theoretical equations all presuppose indifferent stratification or slight instability. This restriction is not very serious, because stable conditions are not common over the open ocean and when they occur, evaporation is small.

The different approaches have been reviewed and it has been shown that they lead to widely diverging results. Furthermore, it has been shown that the available empirical evidence is far too scanty and too inconsistent to indicate what assumption may be acceptable.

In order to advance our knowledge, it is necessary to carry out a large number of detailed measurements of conditions directly above the sea surface. These should comprise measurements of wind profiles in order to examine the validity of the concept that at low wind velocities the sea surface is hydrodynamically smooth, measurements of humidity in order to examine the validity of the logarithmic law for the decrease of water vapor with height, and measurements of temperature in order to establish the stability under which the observations are made. It is possible that such extended observations may show that one of the suggested theoretical equations is applicable, but it is also possible that new concepts have to be introduced and more variables considered in order to arrive at a satisfactory basis for the computation of evaporation during short time intervals.

The problem is somewhat different if seasonal and regional values are to be computed from climatological data. In this case it may be assumed that the evaporation can be computed by means of an equation that is based on theoretical considerations, and the unknown factor in this equation may be established by means of evaporation values that are derived from energy considerations. Such an equation cannot be expected to give accurate results before the correctness of the character of the formula has been more firmly established, and before it has been shown that the unknown factor is a constant.

FORECASTING OCEAN WAVES[1]

By W. H. MUNK and R. S. ARTHUR

University of California, Scripps Institution of Oceanography

Introduction

One result of the interaction of wind and ocean is the generation of surface waves. Prior to 1940 a few inadequate empirical rules formed the only basis for the prediction of wind-induced waves. A concentrated effort under the stimulus of wartime demands has resulted in the development of relationships which make possible the forecasting of ocean waves from synoptic meteorological data.

As an introductory example, reference is made to the meteorological situation north of the Hawaiian Islands in early January 1947. An intense low-pressure center remained virtually stationary 1000 miles to the northeast of the islands for a period of more than 72 hours (Fig. 1). On January 1 and 2, the winds in an area extending from 500 to 1200 miles north of the islands were force 8–10 and direction N-NNW for a period of 36 hours. This area comprised the *fetch* and computations based on wind velocity, duration, and the forecasting relationships give a wave height of 38 ft and a period of 11.3 sec at the southern boundary [1]. The characteristics of the wind waves which are in the process of generation in such a fetch are referred to as *state of sea* or simply *sea*. After the wind waves left this particular area of direct influence of intense winds, they continued onward as *swell* through a region of relatively weak winds, and reached Hawaii in 28 hours after having traveled a distance of 600 nautical miles. Over this *decay distance* the height of the significant waves decreased and the period and length increased. Computations yield a swell of height 22 ft and period 14 sec, and available observations compare favorably with these calculations. Further computations show the swell reaching Palmyra Atoll, which is 900 miles south of Hawaii, with a height of 12.5 ft and a period 17 sec after an additional travel time of 29 hours.

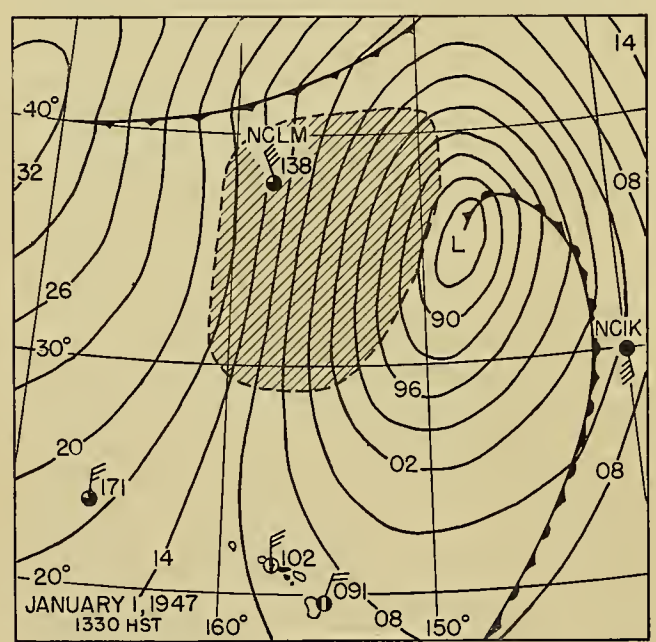

FIG. 1.—Weather map for 1330 Hawaiian Standard Time, January 1, 1947. The shaded area represents the fetch.

The damage in Hawaii was estimated at between one and two million dollars. Three waves are reported to have inundated low-lying Cooper Island in the Palmyra group. Although these wave conditions are extreme for Hawaii and Palmyra, wave damage in general is by no means rare. Damaging waves may even move from one hemisphere to another. In April 1930, more than 20,000 tons of superstructure stone were displaced from the Long Beach, California, breakwater by the action of swell which in all probability had its origin in the "Roaring Forties" of the South Pacific Ocean. The "rollers" of St. Helena and Ascension, which cross the equator after moving from the North Atlantic, have been famous since at least 1846, when thirteen vessels were driven from their moorings and wrecked on the shores of St. Helena. Reports of the disaster indicate that waves broke seaward of the vessels at a depth of around 20 m which denotes that breaker height was approximately 50 ft.

The primary motivation for the development of a wave-forecasting method has been the fact that waves are a nuisance. This problem came into particular prominence during the planning in 1942 of the invasion of North Africa. In that year, Instructor Commander C. T. Suthons, R. N., began an investigation of wave-forecasting techniques in England, and the same problem was studied in the Oceanographic Section, Directorate of Weather, Headquarters, Army Air Forces. The study was continued at Scripps Institution of Oceanography under Air Force and, later, Navy support, and in 1943 the method which was used throughout the war had in essence been developed [8]. Although oceanographers played an important role in the development of forecasting methods, the application is best carried out by meteorologists.

Since waves represent the effect of the wind integrated over time and distance, forecasts of waves can be made from a knowledge of only the large-scale features of the wind distribution. Such forecasts are likely

1. Contribution from the Scripps Institution of Oceanography, New Series No. 511. Many of the results discussed here are based on research supported by the Office of Naval Research, Navy Department, under contract with the University of California.

to be made more easily and with greater certainty than most types of meteorological forecasts.

The present status of wave forecasting is that there are available methods which permit useful predictions of certain wave characteristics from synoptic meteorological observations. The theoretical basis of the methods does not adequately explain the physical mechanism of wave generation and decay. We shall consider wave forecasting, the deficiencies of the methods, and some of the unsolved problems.

Sea, Swell, and Surf

The categories *sea*, *swell*, and *surf* form a natural division of the topic of wave forecasting. The latter, or more generally, the transformation of waves in shallow water, is dealt with by methods which are somewhat different from those used in the study of sea and swell. The essential features of the surf problem have been accounted for physically, whereas this is not the case for sea and swell, as previously mentioned. Sea is determined by the nature of the winds, and the forecasting of sea depends therefore upon the current and predicted synoptic meteorological situation. Swell depends to a lesser extent upon the synoptic situation, but its characteristics can still be altered by a following or an opposing wind during the course of decay. Surf is determined by factors which are largely nonmeteorological, and we confine our consideration of surf to this section, where we note some of the important physical factors in the problem.

As waves move into shallow water the wave length and wave velocity decrease. Waves moving at an angle to the bottom contours are subject to refraction. The wave crests tend to orient themselves parallel to the bottom contours. Changes in wave-crest orientation are associated with convergence and divergence of energy along the crest [11]. As a result, waves over a submarine canyon are relatively low compared to waves on either side of the canyon; the pattern is reversed for a submarine ridge. These changes can all be quantitatively accounted for by the linear-wave theory, assuming conservation of energy and constancy of wave period [22]. An exception occurs where the waves travel over great stretches of shallow water such as exist along the coast of the Gulf of Mexico and the shelf east of Long Branch, New Jersey. In such cases the effects of bottom friction [14] and percolation [13] should be taken into account.

As the waves approach the breaking point the height increases rather suddenly, and the wave breaks at a depth approximately equal to $\frac{4}{3}$ the wave height. Adequate predictions can be based on the application of the solitary-wave theory [12]. Waves breaking at an angle to the shore set up longshore currents whose average velocity can be roughly estimated when bottom contours are straight and parallel [15]. In the case of nearly normal wave approach, longshore currents are variable in direction and form an integral part of a system of currents, called *rip currents* [19], which include narrow zones of fast flow away from shore. Active research is being conducted on the near-shore circulation [19], including rip currents, on orbital velocities, and on the important role played by waves, particularly breakers, in beach erosion and in the design of engineering structures.

Although a number of characteristics of surf are predictable if the deep-water wave characteristics and the bottom topography are known [9], it must be noted that the basic relationships apply only approximately, and even large deviations are to be expected. More research on surf is indicated, particularly on the problem of the mechanism of breaking.

Forecasting Significant Waves

The notations given below will be used in the discussion which follows.

F—length of wind fetch (subscript F denotes value of variable at end of fetch);
D—decay distance (subscript D denotes value of variable at end of decay distance);
H—wave height;
C—phase velocity of wave;
T—wave period;
L—wave length;
δ—H/L (wave steepness);
E—mean energy of wave per unit area;
x—horizontal distance coordinate;
t—time;
t_d—duration time of wind;
U—wind velocity at about 8 m above surface;
β—C/U (wave age);
τ—tangential stress of wind on sea surface;
u_0'—mean surface mass transport velocity;
R_N—mean rate of energy transfer to wave as a result of normal wind pressure;
R_T—mean rate of energy transfer to wave as a result of tangential wind stress;
g—acceleration of gravity;
s—sheltering coefficient;
ρ—density of air;
γ^2—resistance coefficient applicable to wind.

The outstanding characteristic of sea and swell is its irregularity, and a complete description of the sea surface requires the introduction of statistical terms. Nevertheless, a practical purpose can be served by dealing only with the most prominent, or "significant," waves. A definition of the term "significant" is given in the following section. One of the major achievements of wartime wave forecasting was the development of operationally useful methods, one with a theoretical-empirical basis [24], and the other primarily empirical [20]. We next consider the results and basis of the first method, and make a brief comparison with the second.

Observers have noted that as the wind blows over a limited fetch, the wave height and period over the upwind part of the fetch reach a steady state after a limited interval of time. As time passes the steady-state region expands over the whole fetch. The wave height and period at the end of the fetch are determined from the wind velocity, fetch, and duration. The relationships given below, in terms of nondimensional parameters, follow from the forecasting theory.

Steady state:

$$gH_F/U^2 = f_1(gF/U^2), \tag{1}$$

$$C_F/U = f_2(gF/U^2); \tag{2}$$

Transient state:

$$gH_F/U^2 = f_3(gt_d/U), \tag{3}$$

$$C_F/U = f_4(gt_d/U). \tag{4}$$

Height and period of swell at the end of the decay distance and travel time are determined from the decay distance and the period at the end of the fetch according to:

$$H_D/H_F = f_5(D/gT_F^2), \tag{5}$$

$$T_D/T_F = f_6(D/gT_F^2), \tag{6}$$

$$t_D/T_F = f_7(D/gT_F^2). \tag{7}$$

Relationships (1)–(7) are translated into practical graphs for use in forecasting[2] (examples are presented in Figs. 2 and 3).

The basis of the theory is the development of equations which express the energy budget between wind and waves. Use is made of results from two hydrodynamical theories of irrotational waves: (1) the Airy theory of waves of small amplitude, and (2) Stokes' theory of waves of finite amplitude. Certain constants which occur in the solution are evaluated empirically.

2. R. S. Arthur, "Revised Wave Forecasting Graphs and Procedures." *Scripps Institution of Oceanography Wave Report No. 73*, March 1948 (unpublished). These forecasting relationships, as revised according to [24], are to be included in a forthcoming manual on wave forecasting to be issued by the Hydrographic Office.

The assumption is made that energy is transferred from wind to waves by normal pressure and tangential stress. Following Jeffreys, the expression used for the mean rate of energy transfer per unit area as a result of normal wind pressure is

$$R_N = \pm \frac{\pi^2}{2} s\rho(U - C)^2 \delta^2 C, \tag{8}$$

where the sign is positive for $U > C$ and negative for $U < C$. Thus, a transfer expression which depends upon variations in pressure along the surface is introduced, although use is made of hydrodynamical theories which assume constant pressure along the surface.

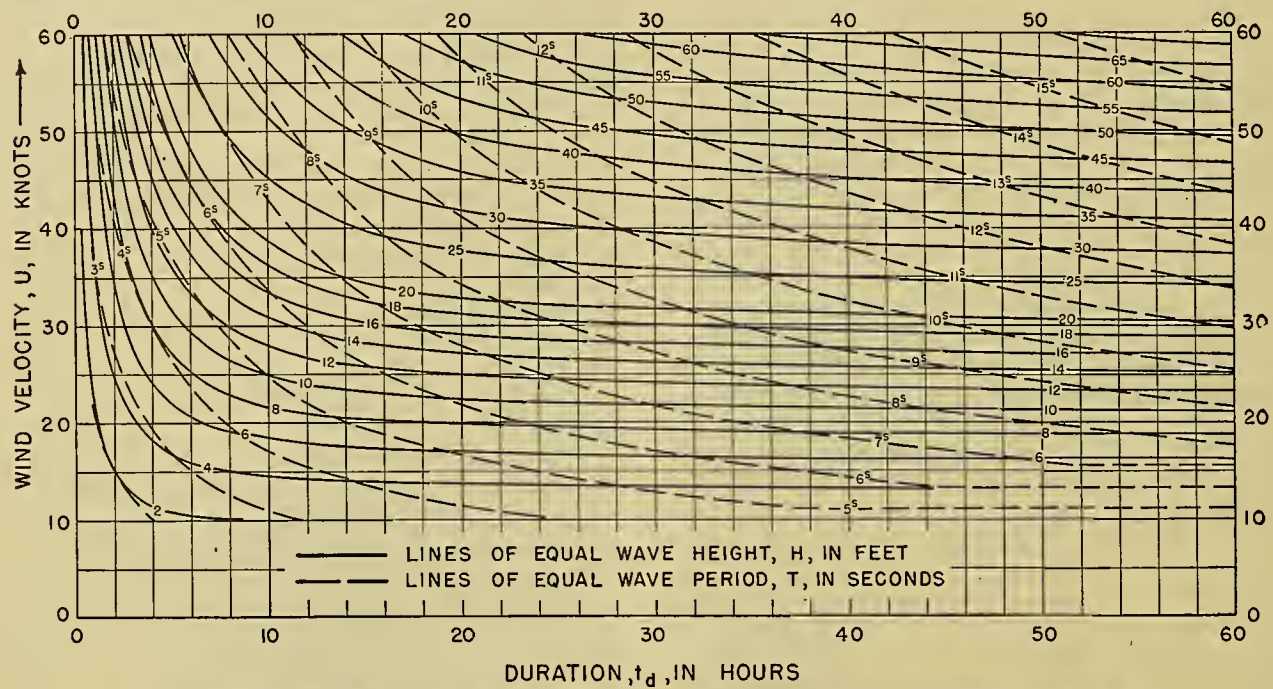

Fig 2—Transient state wave-generation relationships in practical form for use in forecasting.

For the tangential stress, the form

$$\tau = \gamma^2 \rho U^2, \tag{9}$$

where $\gamma^2 = 2.6 \times 10^{-3}$, is introduced with the understanding that wind velocities are great enough so that the sea surface is hydrodynamically rough. The expression for R_N is derived using the horizontal component of particle velocity at the surface from the Airy theory, but on this basis no energy is transferred by tangential stress. However, if the average surface mass transport velocity, $u_0' = \pi^2\delta^2 C$, from the Stokes theory is utilized, the mean rate of energy transfer per unit area by tangential stress is

$$R_T = \frac{1}{L}\int_0^L \tau u_0' \, dx = \pi^2 \rho \gamma^2 \delta^2 C U^2, \tag{10}$$

and on the basis of this expression a transfer of energy from wind to waves is possible even if the waves move faster than the wind. Further investigation of this point is indicated because if the difference between the wind velocity and the horizontal component of particle velocity is introduced in the expression for τ, seemingly

a more accurate formulation of the transfer expression, no energy is added on the basis of either the Airy or the Stokes theory if the waves move faster than the wind. The validity of Stokes' expression for mass transport in the case of waves on a rotating globe has also been questioned.[3]

If the waves are conservative, that is if they maintain their identity, the knowledge from theory of the way in which energy advances with the wave form leads to the following differential equations:

Steady state:

$$\frac{C}{2}\frac{dE}{dx} + \frac{E}{2}\frac{dc}{dx} = R_T \pm R_N; \qquad (11)$$

Transient state:

$$\frac{dE}{dt} + \frac{E}{C}\frac{dC}{dt} = R_T \pm R_N \qquad (12)$$

where the positive sign is used for $C \leqq U$ and the negative sign for $C > U$. Actually the waves comprising sea cannot be conservative and the equations apply at best only approximately.

Since the wave energy is related to the wave height, the two unknowns in the equations above may be considered as wave height and wave velocity and the knowns as distance and time. An additional equation is obtained by assuming that the energy transferred from the wind is divided in a certain fixed manner between the energies required to increase wave height and wave period. The solution of the resulting system of differential equations leads to a relationship between wave steepness and wave age,

$$\delta = f(\beta) \qquad (13)$$

and, finally, to the relationships (1)–(4) above.

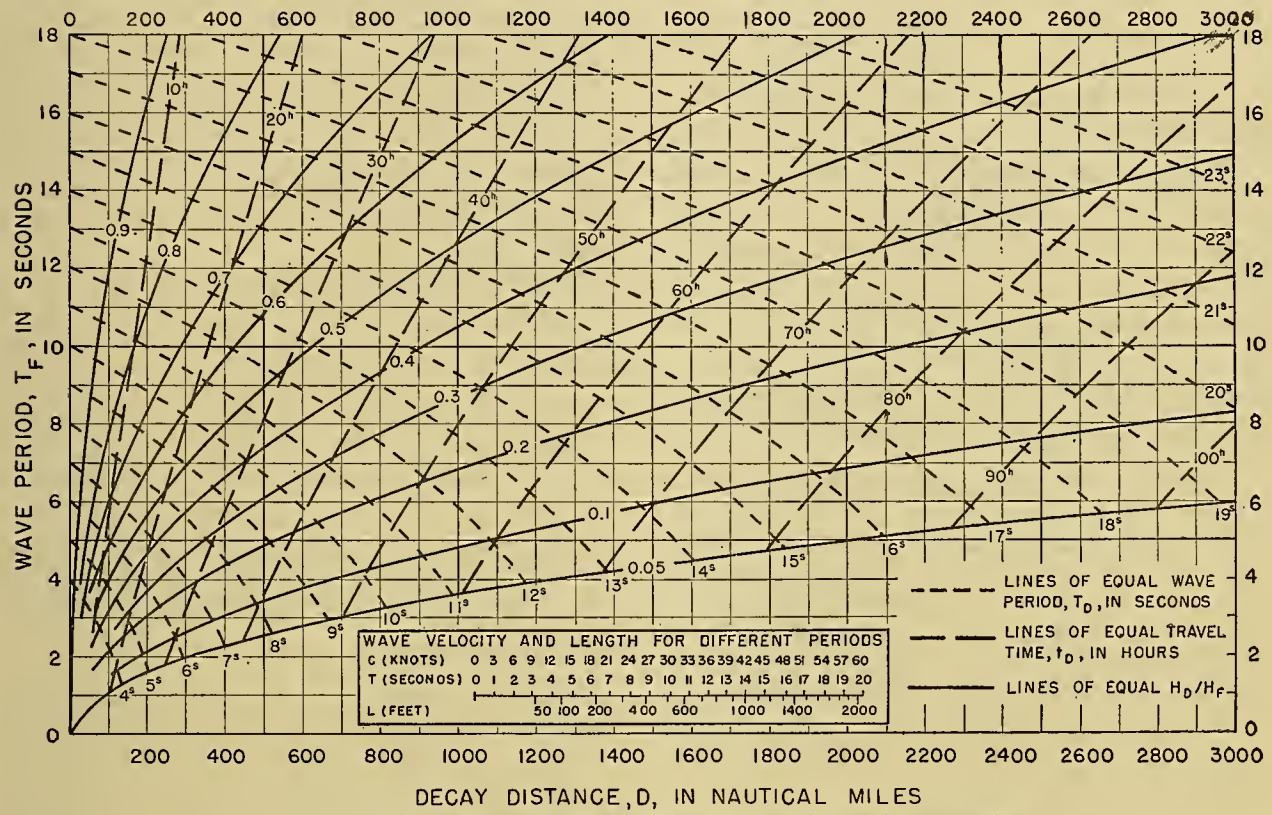

FIG. 3.—Wave-decay relationships in practical form for use in forecasting.

The relationship between δ and β is particularly useful in comparison with wave observations. Many of the observations available for the first checking of the forecasting relationships were inadequate in that either duration time or fetch or both were missing. Most observations are sufficiently complete for the computation of wave steepness and age. Certain constant parameters appearing in the equation are evaluated by fitting the analytical expression (13) to the available observations. The resulting relationship (solid line curve, Fig. 4) gives a satisfactory fit.

Waves leaving the fetch and advancing as swell through a region of calms lose energy by the normal pressure effect of air resistance, but no effect of tangential stress need be considered. The solution of the equation expressing the energy budget of swell yields an increase of wave period during decay and a decrease of wave height, and these facts are in agreement with observations.

Sverdrup [21] compares the decay of swell to the advancement under the influence of air resistance of a train of impulsively generated waves and shows that the period increase is explicable as a result of selective

3. F. Ursell, "The Theoretical Form of Ocean Swell on a Rotating Earth." Admiralty Research Laboratory, A.R.L./R.6/1.03.41/W, February 1947 (unpublished).

attenuation. The comparison suggests that travel time be computed on the basis of the decay distance and the group velocity of the swell at the end of the decay distance. The effect of a following wind during decay is to give lower swell arriving earlier, and the effect of an opposing wind is the opposite. The results for travel

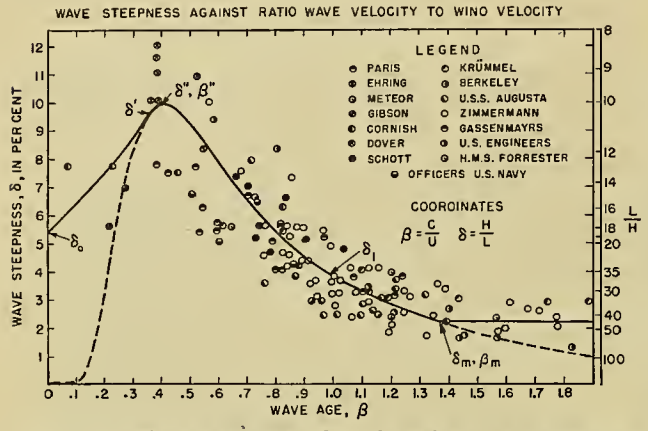

FIG. 4.—Wave steepness plotted against wave age. The dashed lines represent the part of the theoretical relationship which must be modified to conform to empirical evidence.

time, following wind, and opposing wind are incorporated into the forecasting method.

Groen and Dorrestein [7] attribute the decay and the period increase of swell to a selective damping by eddy viscosity. The eddy-viscosity coefficient used depends on the size of the systems under consideration, and the coefficient is larger for long waves than for short ones. Groen and Dorrestein point out that it is improbable that the values of the sheltering coefficient would be the same for swell and wind waves as Sverdrup and Munk [24] have assumed.

TABLE I. PREDICTED AND OBSERVED WAVE CHARACTERISTICS

	Per cent of cases
Predicted height within 1 ft of observed height	53
Predicted height within 2 ft of observed height	80
Predicted period within 2 sec of observed period	63
Predicted arrival time within 6 hr of observed time	69

Isaacs and Saville [10] have compared forecasts made according to the method in its present form with records from wave meters at Point Sur, California, and Heceta Head, Oregon. The results of the comparison for a total of more than 200 forecasts for each station during the period April to December, 1947, are given in Table I. The predicted heights are appropriately corrected for the transformation from deep water to the position of the wave meter. They do not show any tendency to be higher or lower than the observed heights. The predicted arrival times, however, show a tendency to be too early and the periods to be too low.

According to Isaacs and Saville, "97 per cent of the recorded significant *increases* in wave height were forecast, but 23 per cent of the forecast wave trains failed to arrive. The rather large proportion of non-arrivals apparently resulted from the erroneous selection of fetches. . . ." They conclude that the forecasting technique "results in a high degree of reliability for forecasting the arrival of significant increases in wave height, and prognosticating the wave heights," but that "the forecast of wave period and arrival time of the peaks of the wave trains does not display the same degree of reliability. . . ." Bates [3] reviews the forecasting of sea, swell, and surf for landing operations in World War II and concludes that the forecasts were basically correct.

Suthons [20] presents graphs for the forecasting of sea and swell, but the empirical data on which they are based and the exact methods of preparation are not indicated. Predicted wave periods for sea are longer from these graphs than from the first method, and wave heights lower. If a δ,β-relationship is derived from Suthons' graphs, the agreement with the observational data mentioned above (Fig. 4) is not good over a wide range of β values. Suthons attributes the increase in wave period to the downward transport of wave energy by molecular and eddy viscosity, but no quantitative discussion of the mechanism is presented.

The Wave Spectrum

The great complexity of the waves in the sea obscures the exact meaning of earlier wave observations which form the empirical basis for the forecasting methods discussed in the preceding section. Only recently has it been possible, by analyzing records from pressure-type wave meters, to clarify the relation of the predicted wave height and period to the irregular pattern actually recorded.

An individual wave record shows a wide range of heights and periods. For many practical applications, such as the landing of craft, wave action on structures, and sand movement, only the heights and periods of the higher waves in the record are significant. The terms *significant wave height* and *significant wave period* have accordingly been defined as the average height and period, respectively, of the highest one-third of the waves, after ripples and waves of height less than one foot are eliminated from consideration [23].

Experience shows that observers who attempt to determine visually the characteristics of waves tend to record heights and periods which are approximately those of the significant waves rather than of the average waves. Since the forecasting method is based on such visual observations, one might expect that the predicted wave heights and periods are to be considered significant heights and periods. This expectation has subsequently been confirmed [10].

The characterization of a wave record in terms of the

significant waves gives a useful description of the record.[4] Wiegel [25] finds that the daily average height of the highest ten per cent of the waves bears a relatively constant relationship to the significant height at the locations on the Pacific Coast of the United States. This fact is of practical importance because less time is required to compute the average for the highest ten per cent. A good correlation between the maximum waves recorded each day and the significant waves is also noted, and Seiwell [17] finds at Cuttyhunk and Bermuda that the ratio of the daily average height of all waves to the highest one-third is relatively constant. These results (Table II) taken collectively indicate that in general a similar *distribution* of wave heights prevails in the waves generated in different storms although the absolute magnitude varies.

Table II. Ratios of Mean Wave Height and of Average of Highest 10 Per Cent to Significant Wave Height

	Observation Point					
	Scripps[4] (swell)	Point Sur [25]	Heceta Head [25]	Point Arguello [25]	Cutty-hunk [17]	Ber-muda [17]
Interval over which averages formed	46 waves	three 20-min intervals per day			2-min intervals	
Ratio of mean to significant	0.67				0.64	0.64
Ratio of highest 10% to significant		1.27	1.30	1.30		

A more detailed interpretation is obtained by subjecting the records to harmonic analysis. Barber and Ursell [2] have pioneered in the development of instruments for obtaining the Fourier amplitude spectrum. The spectra are taken to indicate that a storm produces a mixture of trains of waves of all lengths up to a maximum which depends on the greatest wind strength. The component trains act independently during decay, and each travels at the group velocity appropriate to its period. In an individual spectrum at a very distant station the swell covers a narrow range of periods, but at a closer station the wave band is wider and broadens rapidly toward shorter periods. Seiwell and Wadsworth [18], on the other hand, take issue with such an interpretation of the component periods in the Fourier amplitude spectrum. From a computation of the autocorrelation function they reach the following rather surprising conclusions which are quoted from their summary:

(1) Periodogram analyses performed on oceanic wave records do not appear to give correct geophysical information. The numerous wave periods, and bands of periods, indicated by this type of analysis do not necessarily possess physical significance.

(2) Application of the hypothesis of generalized harmonic analyses to western North Atlantic wave records indicates that ocean wave patterns are not complex interference patterns resulting from combinations of many wave frequencies, but frequently consist of a single sinusoidal wave on which is superimposed an oscillatory component. . . .

This question of the interpretation of records is fundamental in the consideration of wave generation and propagation, and it merits further study.

Problems in Forecasting

Three main stages in the study of forecasting ocean waves from storms can be recognized. In the earliest stage the forecasting was based on empirical "engineering rules," mutually inconsistent and often incomplete. The well-known Stevenson's law, for example, relates wave height to fetch without regard to wind speed. The second stage was the development during World War II of consistent, dimensionally correct relationships. These relationships have made it possible to forecast the significant waves to an accuracy sufficient for many practical applications. Most of the foregoing discussion deals with this stage of the development. The relationships are strengthened by the application of hydrodynamic theory, although the theoretical basis is not at all secure. The third stage, and one which we are now entering, centers about the British studies of the wave spectrum [2, 5], and some recent attempts to forecast the entire spectrum [4].

According to Deacon [4],

> The width of the spectrum when waves are being generated by a rising wind suggests that the energy begins to be distributed over a range of wave lengths as soon as the waves are formed, some being communicated to the longer wave lengths before the shorter ones are fully energized. Each spectrum has an *optimum band* in which the waves are highest. Waves shorter than this optimum period are lower, presumably because they have a smaller capacity for absorbing energy without becoming unstable; and longer waves are lower, probably because their speed, which is nearly equal to that of the wind, allows them less opportunity of absorbing energy. . . . The period of the highest waves is approximately 25 per cent less than the period of the longest waves.

From this point of view the forecasting of significant waves is closely related to the forecasting of the optimum band. An increase in significant wave height with fetch, or with wind speed, corresponds to an increase in the maximum energy contained in this band, and an increase in the period of the significant waves represents a shift of the optimum band towards longer periods. Since the characteristic of this optimum band depends closely on the character of the component wave trains longer and shorter than those of the band, it is not possible to develop a satisfactory physical theory for forecasting the optimum band without regard to the remaining portion of the spectrum. Nor is it desirable to do so, for there are many practical problems for which the character of the optimum band is only incidental. In the study of the acoustic and optical properties of the sea surface the short-period portion of

4. W. H. Munk, "Proposed Uniform Procedure for Observing Waves and Interpreting Instrument Records." *Scripps Institution of Oceanography Wave Report No. 26*, December 12, 1944 (unpublished).

the spectrum is the important one. In the problem of storm tracking we are most interested in the longest periods present, as those travel most rapidly.[5] It is therefore desirable to divorce from the problem of wave forecasting the selection of that particular portion of the spectrum which happens to be important to a definite application.

The derivation of the physical laws governing the growth of the component wave trains under wind action remains the outstanding theoretical problem in the development of a method for forecasting the wave spectrum. The problem promises to be a difficult one for at least two reasons: (1) the limitations on the growth of the shorter waves imposed by stability considerations introduce a nonlinearity into the problem; (2) to the extent to which the lower, shorter waves are sheltered from the wind by the large waves, the energy budgets of the component wave trains are not mutually independent.

The problem of forecasting the transformation of the swell traveling through the region of decay also resolves itself into the problem of forecasting the change in the spectrum of the swell. The observed increase in the period of the significant swell is the result of the relatively rapid attenuation of the short-period components. One possible mechanism is provided by the viscous effects of the water, according to which the dissipation of energy is inversely proportional to the fourth power of the wave period. It can, however, easily be demonstrated that the effect of viscosity is several orders of magnitude too small to explain the observed transformation. Sverdrup [21] has, however, demonstrated that the selective attenuation resulting from the air resistance on waves traveling through regions of calm (equation (8) with $U = 0$) provides a possible mechanism for selective attenuation. Groen and Dorrestein suggest that selective damping by eddy viscosity is the mechanism. Further study is indicated.

It should also be noted that laws governing the generation of waves at low wind speed can be expected to differ from those governing the generation at moderate and high speeds. The reason lies in the character of the sea surface, which appears to be hydrodynamically smooth at wind speeds less than 6 m sec^{-1}, and hydrodynamically rough at wind speeds exceeding 7 m sec^{-1} [16]. Equation (9) and all subsequent development is based on the assumption of a rough sea surface.

In addition to the more fundamental problems mentioned above, there remain many problems of practical applications. Among the more important ones is the prediction of waves and swell from a tropical storm. The rules of thumb which have been established[6] do not in all cases lead to adequate forecasts.

Most of the actual testing of wave forecasting methods has been carried out for west-coast situations. Forecasting for an east coast offers some special problems, and these are being investigated by the Department of Meteorology, New York University, under the sponsorship of the Beach Erosion Board, and by the Woods Hole Oceanographic Institution [6].

OCEAN WAVES AS A METEOROLOGICAL TOOL[1]

By W. H. MUNK

University of California, Scripps Institution of Oceanography and Institute of Geophysics

Introduction

Since ancient times seafaring men have recognized the significance of ocean waves as a sea-borne storm warning. However, their interpretation was intuitive, based upon the experience gained in a lifetime at sea.

The first attempt to apply this ancient art as an aid in weather forecasting appears to have been made in New Zealand around the turn of the century.[2] Yet no *quantitative* methods were developed until World War II. We shall describe the three general methods which present themselves at this time. Each of these has its advantages and disadvantages, but it is too early to state whether these methods will find widespread application.

The Height-Period Method Applied to Visible Swell

This method is based on the relationships established for forecasting sea and swell from weather maps [15, 16].[3] It consists of computing the wind speed U in a storm area, the distance D from the storm area, and the travel time t_D of a swell, making use of measurements of the swell height H_D and period T_D. A discussion of these quantities is found in another paper.[3] Wave height and period refer to deep water, and to the *significant* waves, that is, the average of the highest one-third of all waves present.[4] Observations from shipboard can therefore be taken without further modification. In the case of land-based observations the wave *period* can be determined at any depth since it does not change as waves enter shallow water. Along steep coastlines or exposed beaches with simple bottom topography the deep water wave *height* can, for practical purposes, be taken as the wave height one or two wave lengths outside the breaker zone. Otherwise it is necessary to take into account, by means of specially constructed "refraction diagrams" [7, 12], the effect of bottom topography and of the configuration of the coastline.

The nondimensional relationships given below follow from the forecasting theory [16]:[5]

$$\frac{U^2}{gH_D} = \frac{1}{2\pi}\frac{1}{\delta_F\beta_F^2}\left(\frac{\delta_F}{\delta_D}\right)^{.57}, \tag{1}$$

$$\frac{D}{gT_D^2} = 1.72 \times 10^3\left[1 - \left(\frac{\delta_D}{\delta_F}\right)^{.429}\right], \tag{2}$$

$$\frac{t_D}{T_D} = 2.16 \times 10^4\left[1 - \left(\frac{\delta_D}{\delta_F}\right)^{.429}\right], \tag{3}$$

$$\delta_D = \frac{2\pi}{g}\frac{H_D}{T_D^2}, \tag{4}$$

$$\delta_F = \delta_F(\beta_F), \tag{5}$$

$$\beta_F = \beta_F(gt/U), \tag{6}$$

where g is gravity, and t the storm duration. The relationships (5) and (6) are very complicated analytically, and are here presented in graphical form (Fig. 1). Equations (1) to (6) contain seven unknowns, and the quantities U, D, and t_D are therefore not uniquely determined from measurements of swell height and period. To obtain a complete solution a relation

$$t = t\,(U) \tag{7}$$

will be assumed between the duration of the storm and its intensity, based on the common experience that high winds are usually of short duration. For two specific relationships, a storm of unusual duration (line A in Fig. 2 inset), and a short-lived storm (line B), equations (1) to (7) have been solved and the results shown graphically (Fig. 2), using practical units. The examples in Table I illustrate that D and t_D do not depend very critically upon the nature of the relationship $t(U)$ and can be determined with greater certainty than U. To obtain greater accuracy the forecaster may attempt an interpolation between Cases A and B, based on his experience with the duration of storms over particular regions. It should be noted that the results ob-

1. Contribution from the Scripps Institution of Oceanography, New Series No. 512. Many of the results discussed here are based on research carried out for the Hydrographic Office, the Office of Naval Research, and the Bureau of Ships of the Navy Department, under contract with the University of California.

2. Prof. C. E. Palmer, in a letter to the author, writes, "In the early days of weather forecasting in New Zealand (towards the end of the last century) no information from Australia was available, consequently the only meteorological warning of storms coming from the west was the local fall in the barometer. In an endeavor to get more advanced warnings, Captain Edwin, who was then in charge of a very small weather forecasting organization in the Marine Department, used the observations of sea and swells from light houses to supplement the data on the synoptic maps. These old maps are still in the archives of the New Zealand Meteorological Service and I have studied them with some interest because the reconstruction of the storm positions and tracks by means of the ocean observations seems remarkably good."

3. Consult "Forecasting Ocean Waves" by W. H. Munk and R. S. Arthur, pp. 1082–1089 in this Compendium.

4. In estimating wave heights from visual observations there is a tendency to arrive at values well in excess of the mean heights for all waves present. The definition of significant waves given above has been found in accord with the estimates of most observers.

5. Equation (3) has been revised according to equation (1) in R. S. Arthur, "Revised Wave Forecasting Graphs and Procedure." *Scripps Institution Wave Report 73*, March 1948 (unpublished).

tained become increasingly uncertain as the distance between storm and observer becomes greater.

For a discussion of the assumptions underlying the foregoing equations the reader is referred to the original paper [16]. The advantage of this method is that for

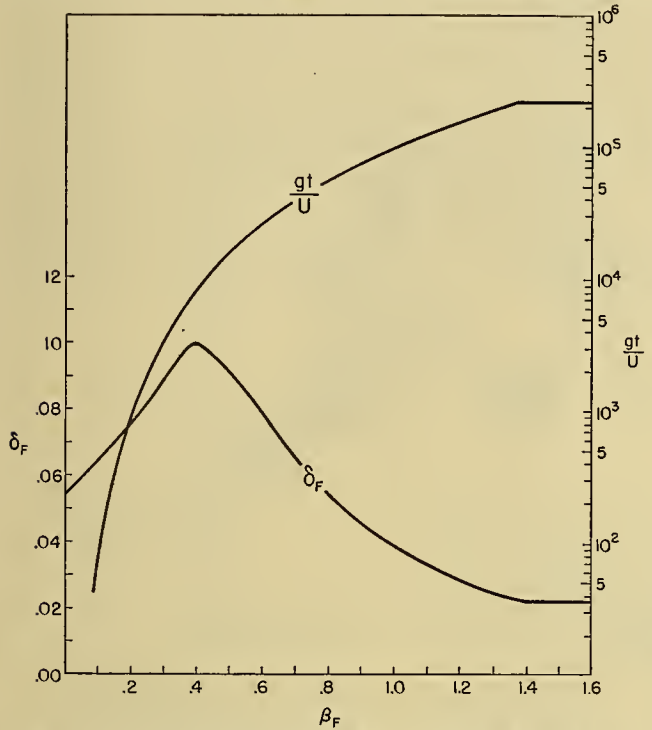

FIG. 1.—Plot of equations (5) and (6) relating wave steepness δ (height/length), wave age β (wave velocity/wind velocity), wind speed U, and wind duration t. Subscript "F" refers to values at end of feteh. (*From Sverdrup and Munk* [16], *Figs. 5 and 7.*)

shipboard observations, or for exposed and steep coasts, it permits a rapid determination of the storm distance and a rough estimate of the storm intensity without the need of special wave-measuring equipment. In this sense the method was first used during World War II by Capt. D. F. Leipper, AAF, as an aid in forecasting the arrival of intense storms in the Aleutian area. In many instances the arrival of heavy swell preceded all other indications of the storm. From a climatological point of view this method can be applied by "mapping" on an H_D,T_D-diagram typical meteorological situations associated with wave conditions in certain areas (Fig. 3).

The principal disadvantage of this method is the slow velocity of the significant waves. As a result the information concerning storm location and intensity may be several days old before the waves reach shore.

The Frequency-Spectrum Method Applied to Forerunners of Swell

The limitations outlined above can be overcome in part by dealing with the low, long, imperceptible waves which precede the visible swell. Since these waves are only a few inches high it is not possible to apply simple, visual methods of observation, but the advantages involved often appear to justify the use of special instrumental techniques.

In the first place, the forerunners travel considerably faster than the visible swell. On the basis of instrumental observations now available [1] the period of the forerunners may reach 25 sec, compared to 12–13 sec

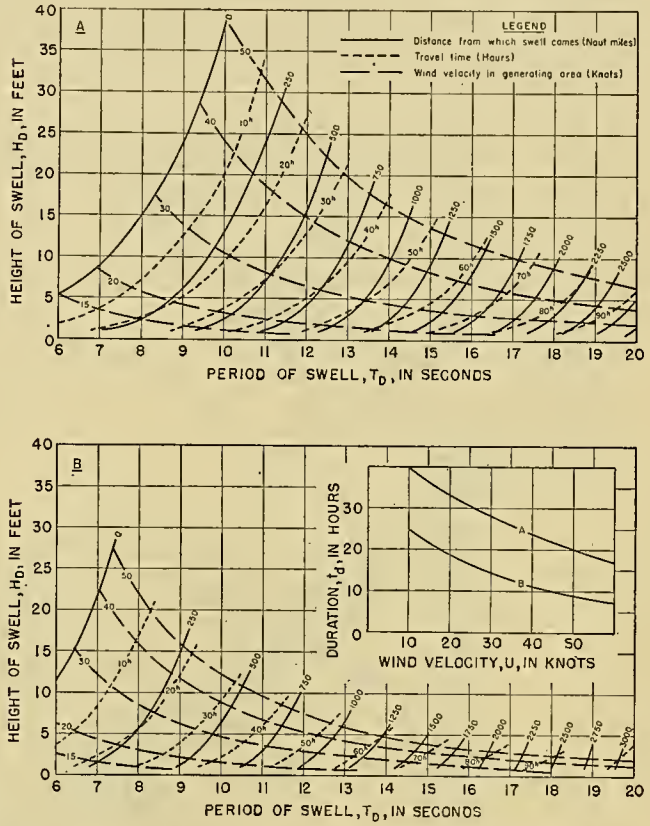

FIG. 2.—Distance from which swell comes, travel time, and wind velocity in generating area as functions of observed height and period of swell. The upper figure is drawn for a long-lived storm, the lower figure for a short-lived storm. The assumed relation between wind speed and duration for these two cases is shown in the inset. (*From Sverdrup and Munk* [16].)

as a typical maximum period for the swell. The corresponding group velocities with which the disturbance created by a storm is effectively propagated by surface wave motion are of the order of 900 nautical miles per day for the forerunners, in constrast with 400 miles per day for the swell.

TABLE I. SAMPLE CALCULATIONS FOR A STORM OF UNUSUAL DURATION (CASE A) AND A SHORT-LIVED STORM (CASE B)

H_D (ft)	T_D (sec)	Storm duration (see inset, Fig. 2)	D (naut. mi)	t_D (hr)	U (knots)
6	12	Case A	700	38	30
		Case B	825	45	45

A second advantage of the "frequency-spectrum method" over the "height-period method" is that travel time and storm distance are *uniquely* determined from a knowledge of wave periods. The need for measuring wave height is eliminated.

Instrumentation. Shore-based instruments for recording ocean waves have been in existence for many years.

Most of the older instruments recorded the elevation of the sea surface against time by some suitable arrangements of floats. During World War II very effective methods were developed which derive from the underwater pressure fluctuations induced by the surface waves. It is curious that this mode of attack should have been initiated independently in Great Britain and the United States. An early model developed by the

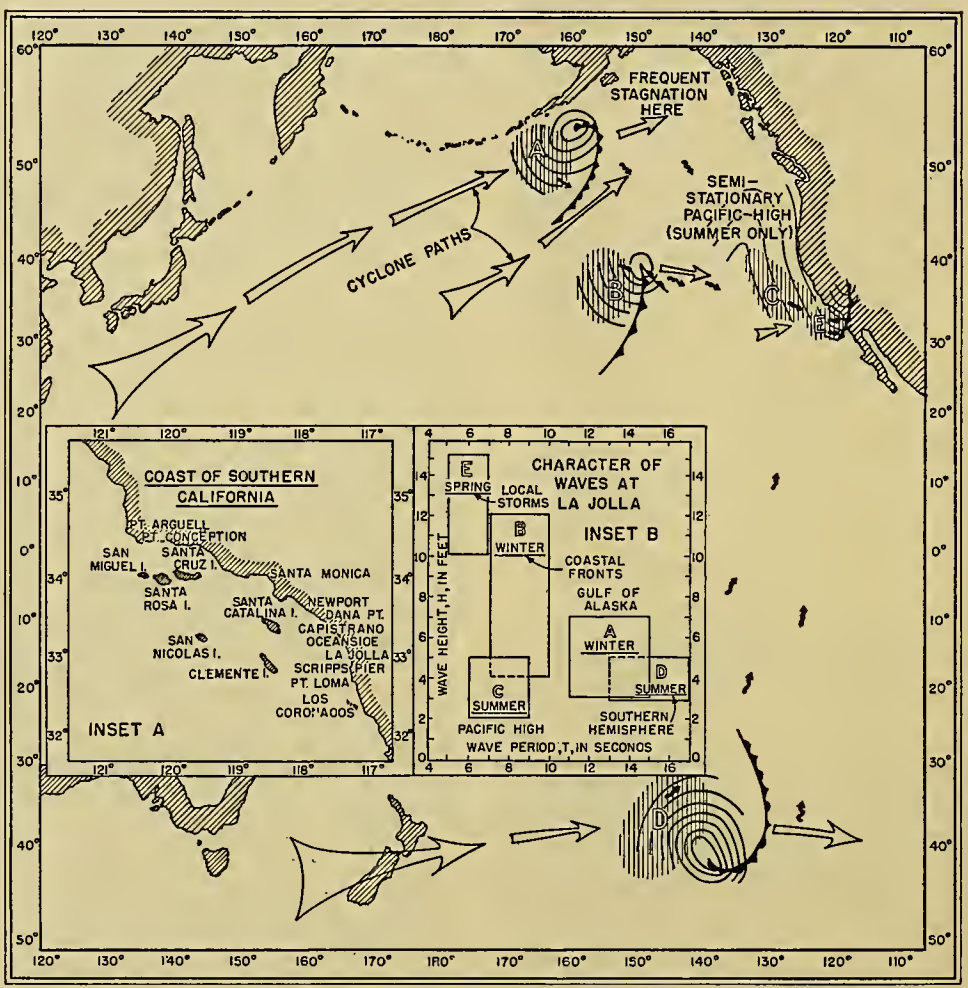

Fig. 3.—Origin of waves reaching La Jolla, California. The capital letters on the large chart represent typical meteorological situations, which give rise at La Jolla to waves of heights and periods shown in inset B. Inset A is a chart of the region near La Jolla on an enlarged scale. The shaded areas on the large chart represent typical fetches, that is, areas where the waves are generated. The isobaric pattern and the nature of the meteorological fronts are also indicated. The large open arrows represent typical paths of the storm systems. The wavy arrows indicate the direction of the waves leaving the storm systems. The figure cannot represent the nature of the meteorological situations with any degree of accuracy, but it is supposed to illustrate how different meteorological situations can be identified by the height and period of the waves with which they are associated. (*From Munk and Traylor* [12].)

Mine Design Department, British Admiralty, has been in operation at Pendeen, near Lands End, England, since 1944. In the United States the development of wave instruments has been carried out chiefly at the Woods Hole Oceanographic Institution and at the Department of Engineering of the University of California. In an early model designed by M. Ewing the recording apparatus was contained directly in the underwater unit. Later, units recording on shore were installed near Cuttyhunk, Massachusetts, and on the island of Bermuda [8]. A number of shore recording models have been developed at the College of Engineering, University of California [6], and these have been installed at Quillayute River, Washington; Heceta Head, Oregon; Point Cabrillo, Point Sur, Point Arguello, Oceanside, and La Jolla, California; and on the island of Guam.

Although the various instruments differ in many important aspects, the following principles are common to most wave instruments of the underwater pressure type and should be understood for a proper interpretation of the records. Surface waves induce pressure fluctuations in the entire column of water between the surface and the sea bottom (Fig. 4). For any given wave height and depth of water, the amplitude of these fluctuations depends on the wave period in such a manner that waves of very short period are virtually eliminated. The underwater unit measures the deviation of the fluctuating pressure at the sea bottom from the mean hydrostatic pressure. A "slow leak" in the underwater unit elimi-

nates the effect of tides and other very long waves. The pressure fluctuations are converted into electrical modulations, which are transmitted through a cable to a shore recorder. Finally the records are subjected to a harmonic analysis by a special instrument [2]. The natural wave spectrum is therefore modified in three stages: (1) waves of short period are removed by hydrodynamic filtering; (2) waves of very long period are removed by the slow leak in the underwater unit; (3) the remaining record is broken down further by harmonic analysis.

Hydrodynamic filtering is particularly adapted for extracting the low forerunners from the complex pattern of the sea surface. The response characteristics of this filter can be expressed by the ratio $\Delta P/\Delta P_0$ of the amplitude of the pressure fluctuation at the bottom to

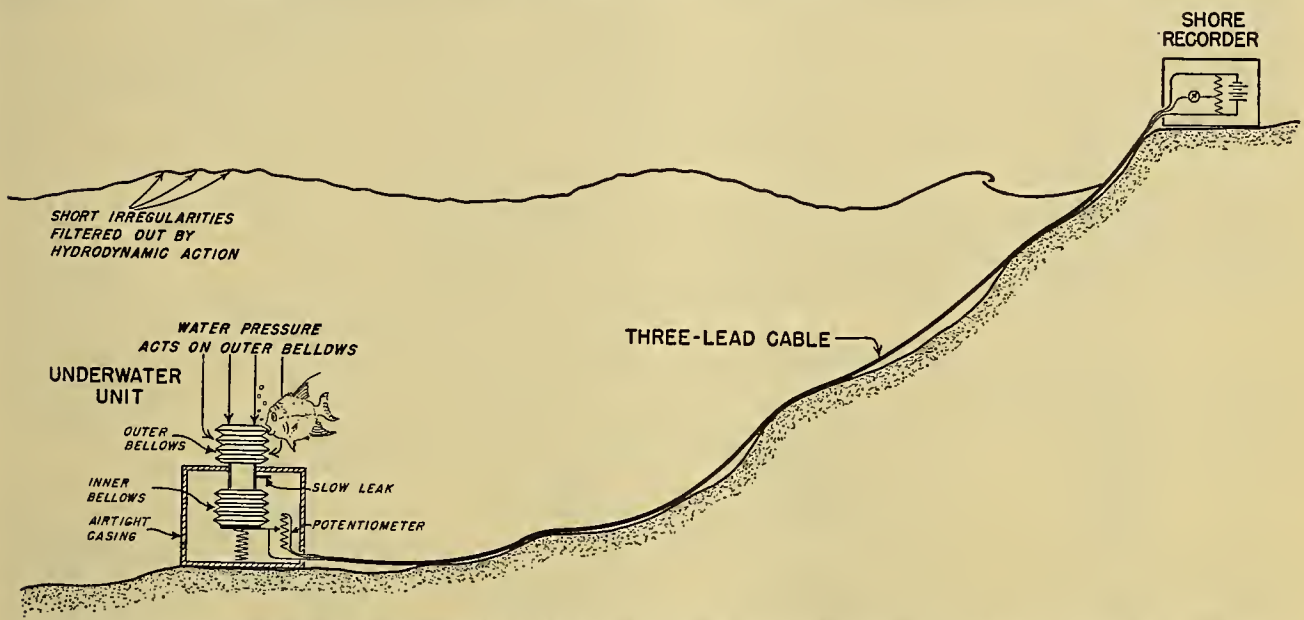

Fig. 4.—Recording mechanism. The pressure is transmitted through an outer bellows into a second bellows inside the instrument casing, so that the pressure of the air inside the two bellows always equals the pressure in the water outside. The air inside the bellows can pass through a slow leak into the instrument casing, and the *average* pressure inside the casing equals the *average* pressure in the water, that is, the hydrostatic pressure. The leak is so slow that the pressure inside the instrument does not change appreciably during one wave period, yet it permits pressure equalization related to tides. The total displacement of the inner bellows depends on the *difference* in pressure between the inside and the outside of the bellows and therefore measures the deviations of pressure (amplitude ΔP) from the hydrostatic mean.

that just beneath the surface. Let h designate the water depth, L the wave length, T the wave period, and g the acceleration due to gravity. The length L can be eliminated between the equations

$$\frac{\Delta P}{\Delta P_0} = \frac{1}{\cosh\,(2\pi h/L)}, \tag{8}$$

$$\left(\frac{2\pi}{T}\right)^2 = \frac{2\pi g}{L}\tanh\frac{2\pi h}{L}, \tag{9}$$

so that the hydrodynamic filtering effect $\Delta P/\Delta P_0$ can be computed as a function of depth and wave period. For instrument depths (on the bottom) of 40, 150, and 600 ft, the pressure fluctuations for wave periods of 4, 8, and 16 sec, respectively, are reduced to 10 per cent of their surface value ($\Delta P/\Delta P_0 = 0.10$).

Measurements by Seiwell [13] would indicate that equations (8) and (9) are in error by approximately 20 per cent.[6] Ewing and Press [4] have suggested that this discrepancy might be related to the nonrigidity of the sea bottom. Folsom [5] obtains about half this discrepancy in laboratory experiments employing metal wave tanks, thus indicating that the discrepancy might also be related to other factors.

Two methods for determining *wave direction* are being investigated. At the Department of Engineering, University of California, Berkeley, J. D. Isaacs has measured wave direction by means of a Rayleigh disk attached to the underwater unit. The orientation of this disk is recorded ashore by means of a Selsyn motor. In the case of a simple wave train the disk will align itself normal to the plane of orbital motion. In the case of an interference pattern the records are difficult to interpret. At the Scripps Institution, R. S. Arthur is investigating the determination of wave direction from a comparison of the phase relationships of records from two underwater instruments placed roughly parallel to shore. The development of a reliable method for measuring wave direction is an essential requirement in making use of wave records for tracking storms.

Interpretation of Records. In order to overcome the almost prohibitive labor involved in carrying out harmonic analysis by numerical computations, a very effective instrument for frequency analysis has been developed at the Admiralty Research Laboratory in Teddington, England [2]. Figure 5 shows a set of period

6. Seiwell uses the deep-water formula $(2\pi/T)^2 = 2\pi g/L$ rather than equation (9) (see discussion by Ewing and Press [4]).

analyses obtained by the methods discussed above.[7] The first indications of the storm on the wave record were some "low-frequency noises" at 1400, 14 March 1945. At that time visual observations at Pendeen revealed only the presence of 10-sec and 12-sec waves from another source; the long forerunners of the swell were too low to be visible.

The band of gradually diminishing periods was the result of an intense storm which formed on 10 March off the coast of Cuba, 3000 miles from Pendeen, and

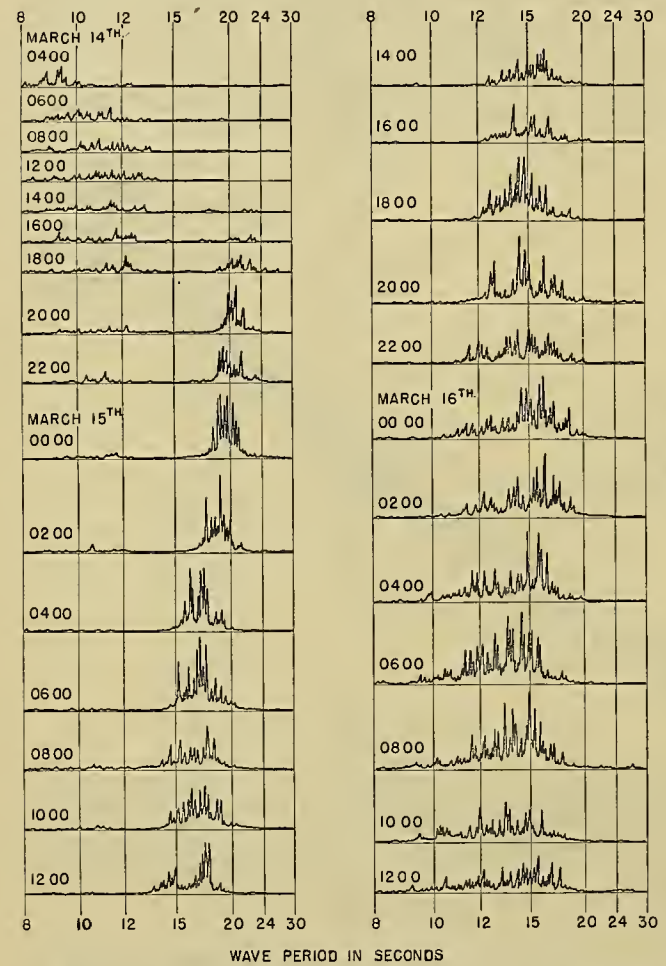

Fig. 5.—Spectrograms of waves recorded during 14–16 March 1945 at Pendeen, England [1]. Each spectrogram gives the distribution of energy among wave periods for a 20-minute record. The records were taken at 2-hourly intervals.

traveled in a general northeast direction, passing west of the British Isles. Four representative weather maps are shown in Figs. 6–9. The positions indicated for the "fetches" were determined according to the rules developed for wave forecasting.[3] It should be noted that the fetch lengthened during the time interval between 1830, 11 March, and 1830, 12 March.

The spectrogram in Fig. 5 can be interpreted in terms of the classical wave theory, according to which component wave trains travel independently with the group velocity appropriate to their period:

$$V = \frac{gT}{4\pi} = \frac{x_w - x_s}{t_w - t_s}. \tag{10}$$

Here x_w and x_s represent the location of a point disturbance and the wave station, respectively; t_w and t_s the time of the disturbance and the time at which waves of period T arrived at the wave station. Equation (10) has a simple geometric interpretation on a time-distance

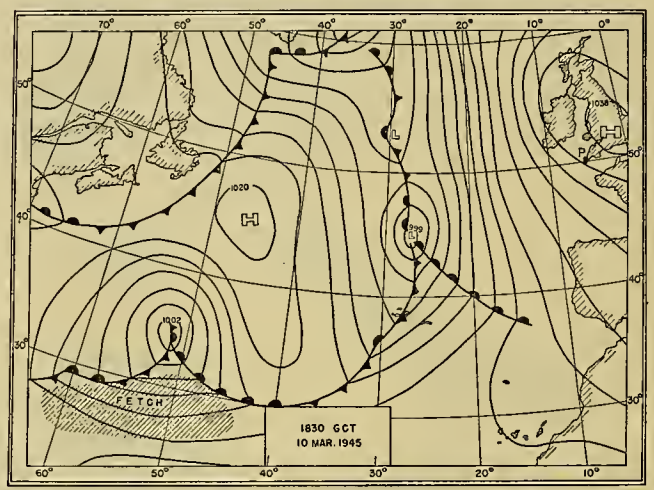

Fig. 6.—Surface weather map for 10 March 1945. Fronts are represented in the conventional manner, and isobars are labeled in millibars. Point P denotes the wave station at Pendeen, England. Figs. 6–9 show the passage across the Atlantic Ocean of the storm for which the wave spectrograms are shown in Fig. 5. (*From Munk* [9].)

diagram (Fig. 10): Rays through the point source represent the paths of wave periods, the value of each period being determined by the slope of the ray. The measurement of two periods, T_1 and T_2, arriving at times $t_{w,1}$ and $t_{w,2}$, suffices to determine distance and time of the source.

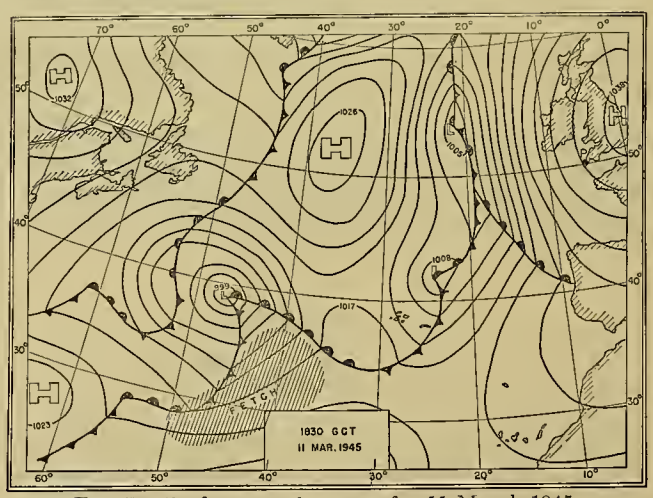

Fig. 7.—Surface weather map for 11 March 1945.

Figure 11 shows the *propagation diagram* used by Barber and Ursell [1]. For each spectrogram (Fig. 5) the maximum and minimum periods were determined, and

lines of appropriate slope drawn. It is apparent from the figure that the foregoing interpretation of the wave observations is consistent with the meteorological observations. The author has found it convenient to use a graph [9, Fig. 5] with a special coordinate system on

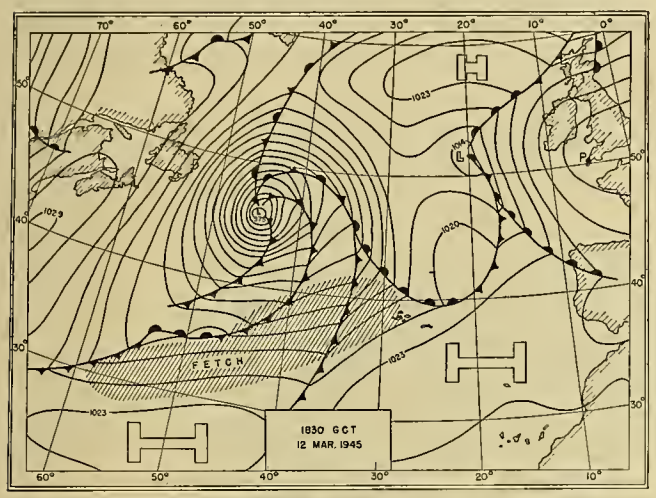

FIG. 8.—Surface weather map for 12 March 1945.

which periods from a single disturbance fall along a straight line. In this manner certain outstanding features on the spectrogram (such as the upper and lower limits) were used to determine the distance and time of the source region with which they are associated.

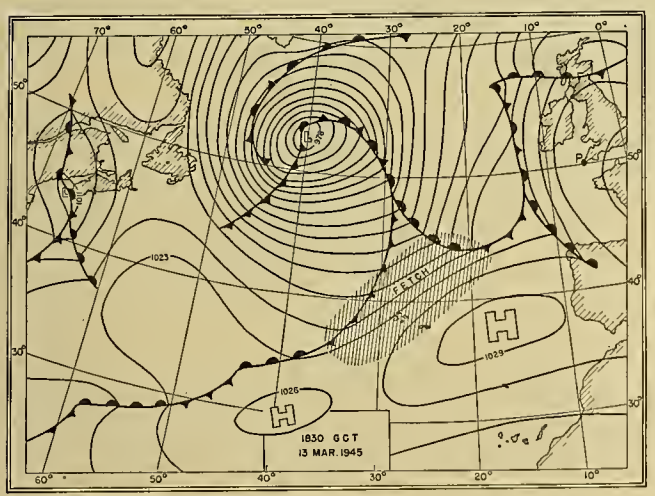

FIG. 9.—Surface weather map for 13 March 1945.

The information taken from the weather maps and the periods recorded at the wave station have been replotted in Fig. 12 to emphasize the similarity, with regard to both shape and width, between the storm path and the period band. The computed positions, designated by A, B, . . . F, agree fairly well with the information on the weather maps, especially if it is remembered that these "foci" were obtained from theory without the introduction of any arbitrary constants. The foci A, B, and C were computed from the lower limit of the period band and seem to correspond to the forward edge of the fetch; D, E, and F were computed from conspicuous features near the upper limit of the period band and give the approximate position of the rear edge of the fetch. It can be seen, however, that focus A in the upper part of Fig. 12 is located 500 miles

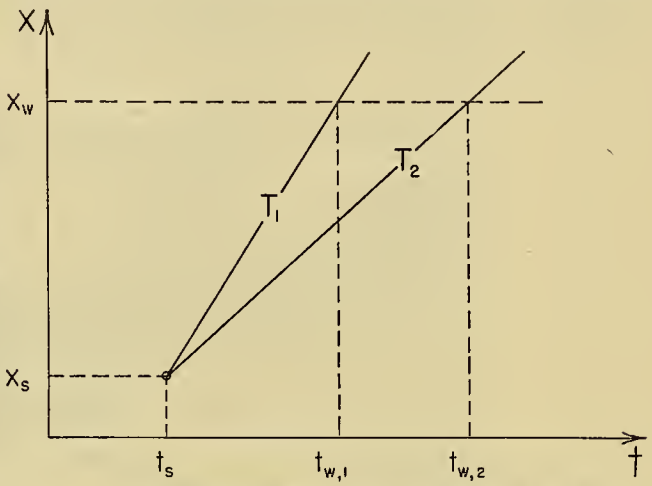

FIG. 10.—Schematic presentation of propagation of wave periods on a time-distance diagram. x_s and t_s represent the position and time of a point disturbance; x_w is the position of a wave-recording station, showing the arrival of waves of periods T_1 and T_2 at times $t_{w,1}$ and $t_{w,2}$, respectively.

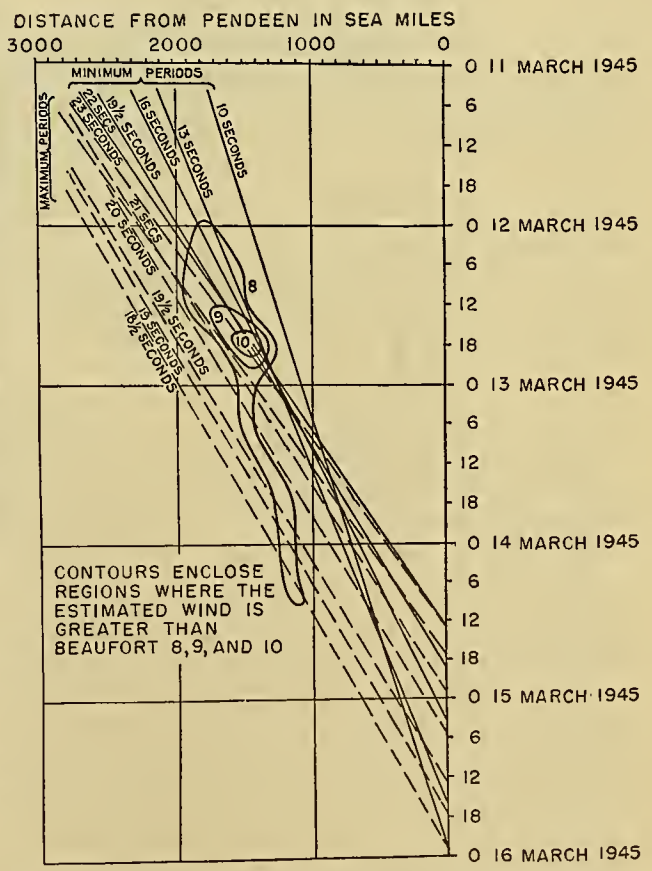

FIG. 11.—Propagation diagram for 11–16 March 1945, using winds estimated from the pressure distribution, flowing within 30° of a line of the recording station. (*From Barber and Ursell* [1].)

behind the storm front, and the other two foci about 200 miles behind the front. These discrepancies must be expected, since waves generated at the front itself could not gather sufficient energy to be perceptible at the wave station; furthermore, the distance between the point of wave origin and the storm front must be larger for the farthest disturbance, which is almost 3000 miles from Pendeen.

Iceland, Pendeen came under the influence of the fetch in the cold sector, which remained at about the same distance from Pendeen. In the meantime the fetch in the warm sector of the second storm moved slowly eastward, and on 18 February this and the fetch remaining from the first storm appeared as a single generation area. By 19 February the first storm had undergone complete frontolysis. The only remaining fetch was that

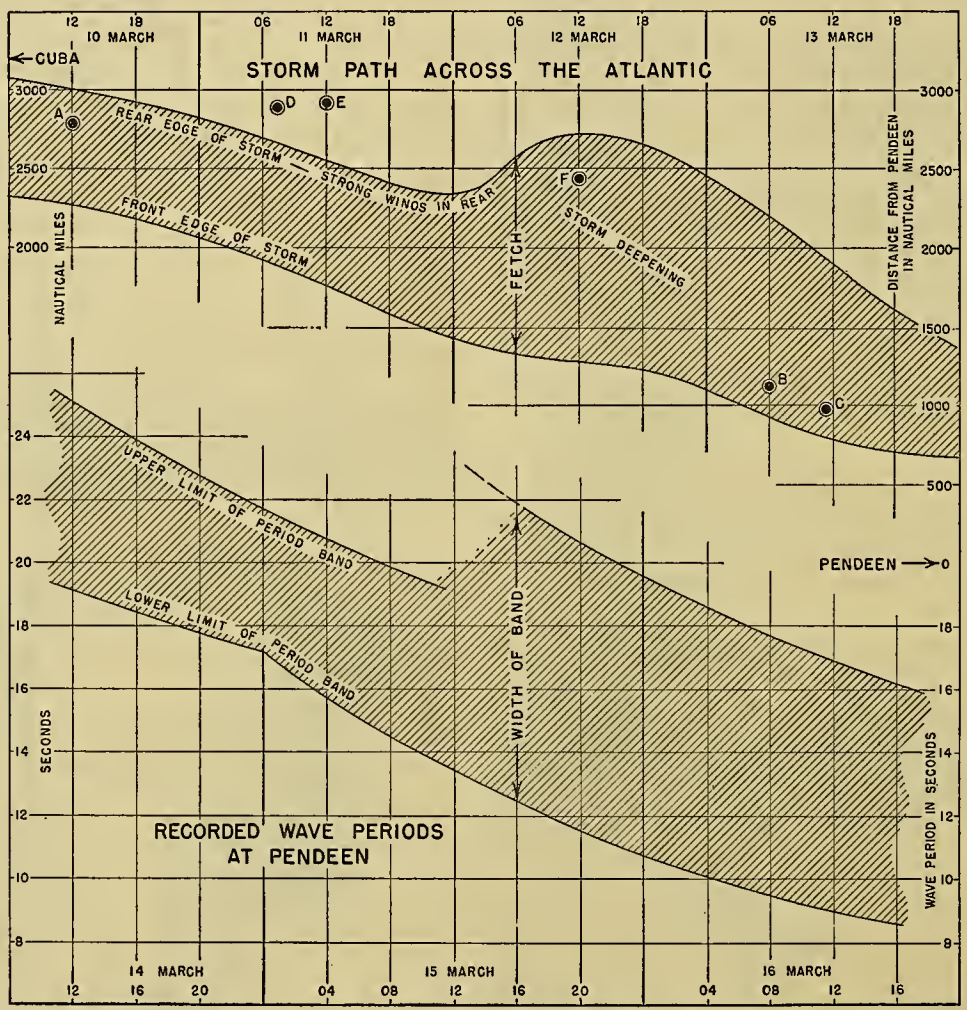

FIG. 12.—Comparison of storm path with period band. The shaded band in the upper part shows the movement of the storm system toward the wave station. The forward and rear edges of the storm were determined by 6-hourly weather maps, of which every fourth map is shown in Figs. 6–9. The computed storm positions (foci) are marked *A*, *B*, . . . *F*. The limits of the period band in the lower part were determined from the wave spectrograms shown in Fig. 5. (*From Munk* [9].)

Figure 13 illustrates the application of the method to a more complex meteorological situation. Two storm systems which existed simultaneously could be identified and traced separately. On 15 February 1945 the development of a cyclone started off the east coast of the United States. On 17 February the center of the cyclone had reached mid-Atlantic, and an unusually well-defined 1000-mile fetch in the warm sector was pointing directly toward the wave station. At the same time a new low-pressure area had just moved off the east coast of the United States and formed a second fetch immediately north of Bermuda (Fig. 13, upper right). As the first storm stagnated and veered northward toward in the cold sector of the second storm, which was moving northward toward Iceland.

The spectrograms shown in Fig. 13 are more complicated than those in the preceding examples, and the interpretation is much more difficult. The first three foci fall in the first storm as it moved across the Atlantic. Foci *D* to *H* are associated with wave trains that were formed as the first storm veered northward and its fetch was joined with the fetch of the second storm. Only by that time had the main-period band moved sufficiently into the lower periods to permit identification of a wave train, *F*, from the distant second storm. Foci *J* to *N* originated from the joint fetch existing from

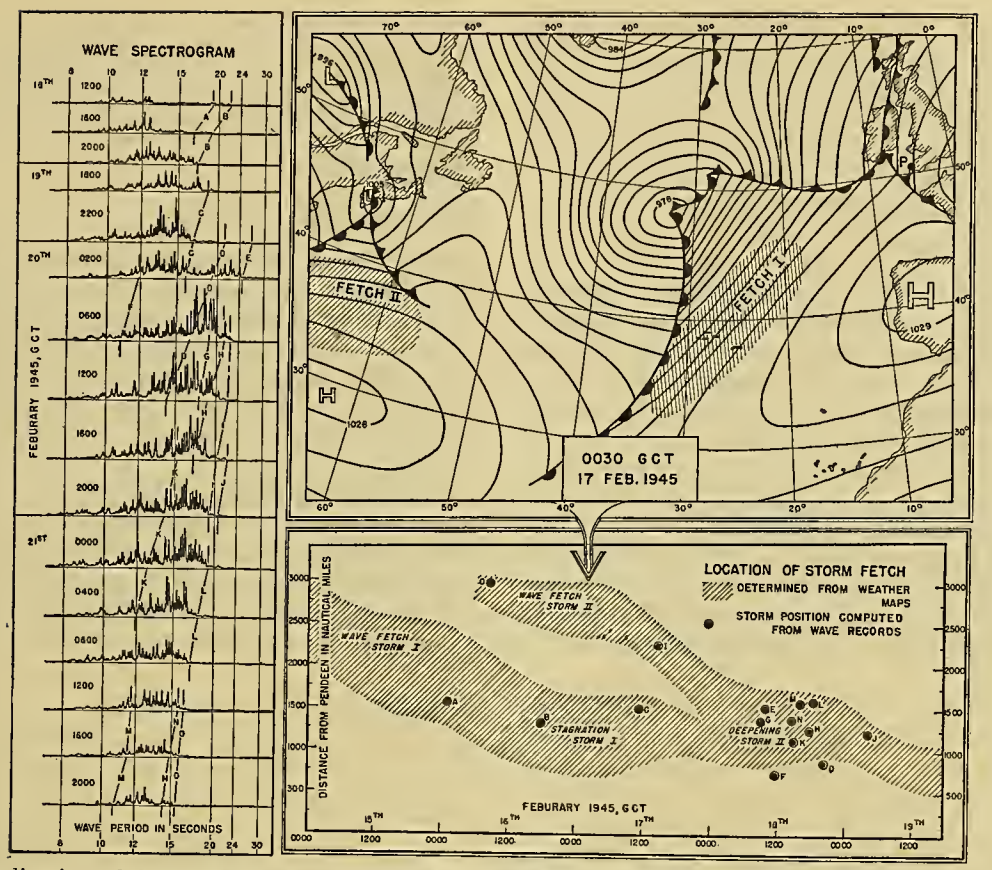

FIG. 13.—Application of storm-tracking method to wave records of 18–21 February 1945. The period spectrograms recorded at Pendeen are shown to the left. Significant features on adjoining records are connected by dashed lines, marked *A, B, . . . O*. The corresponding foci are shown by the circles in the diagram at the lower right, where the shaded band gives the path of the storm determined from weather maps. One of these weather maps is shown at the upper right. (*From Munk* [9].)

18 to 19 February, but focus *O* had its origin in the second storm system when it was still 3000 miles from the wave station.

Discussion. A considerable number of meteorological sequences have been studied by means of the Pendeen wave records, and in all instances the agreement between computations based on the wave records and the information on the weather maps was encouraging. In one instance, 26 June 1945, waves from a hurricane off the coast of Florida were faintly recognizable above the disturbance caused by a moderate local storm. To the author's knowledge, attempts based on wave records taken along the coasts of the United States have not been equally successful. This can be attributed at least partly to instrumental difficulties.

At one time the author had hoped that by shifting the range of maximum response of the instruments toward longer periods (by placing recording units of greater sensitivity in deeper water) it should be possible to record even longer forerunners, with periods, say, up to 60 sec, and correspondingly high velocities. Experience in England [1] does not support this expectation. Figure 14, based on thirteen well-substantiated storms, shows a correlation between maximum wind force of *distant* storms and the maximum recorded swell period. A possible explanation is contained in the forecasting theory [16] according to which waves gain energy from the wind only if the wave age (wave velocity/wind velocity) is less than 1.37. The dashed line in Fig. 14 corresponds to values of the wave age ranging from 1.26 to 2.26. The preliminary conclusion

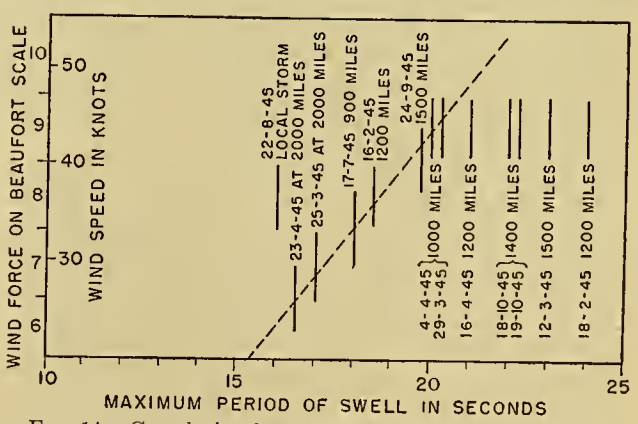

FIG. 14.—Correlation between the maximum wind strength and the maximum period of swell generated for thirteen storms. (*From Barber and Ursell* [1].)

is that fore-runners with periods longer than 25 sec, or perhaps 30 sec, are so low compared to other types of wave motion in that period range [10] that they would be associated with an unfavorable signal-to-noise ratio. Accordingly, the highest group velocities which one may

hope for are of the order of 1000 nautical miles per day. Not until many more situations have been analyzed will an evaluation of the usefulness of the method be possible. The results so far obtained demonstrate the feasibility of locating and tracking storms at distances exceeding 3000 miles and of making rough estimates regarding the size and character of these storms.

The Storm Surge Method

The preceding discussion has indicated that the swell spectrum, visible or invisible, is limited by the maximum velocities of the winds in a storm area. This conclusion is in accord with the hypothesis that swell was originally caused by the normal and tangential stresses applied by the wind to the sea surface, but it does not preclude the existence of other types of waves from storm areas of much longer period than those of the swell. To explore this possibility an instrument [11] has been built which is sensitive to waves whose periods lie between those of the swell and tides. It is essentially a modified tide gauge, and the filtering of the swell and tides is accomplished by means of capillaries and air volumes. The instrument does not require the expensive and troublesome underwater cable and is therefore simpler and much less expensive than the underwater pressure recorder described in the preceding section. One such unit has been installed at the end of the Scripps Institution pier at La Jolla, California; a second unit has recently been installed in Hawaii.

During the spring of 1948 five severe storms passed off the coast of California. In each of the five cases, waves of periods of approximately 15 min (storm surges) were received from 24 to 36 hours prior to the arrival of the heaviest surf and the strongest winds.

Some of the data are summarized in Table II, giving the height H and period T of the storm surges, and also of the swell as it was recorded on the underwater recorder at a depth of 40 ft. The mean height of the storm surges was only 1 in. and it is quite clear that these waves could be detected only by special instruments. According to Table II the earliest arrival of the storm surges preceded the heavy swell by one and one-half days on the average.

It must be emphasized that the study of these storm surges is in a preliminary stage, and that the manner in which they are generated is not at all understood. Should it be possible to use storm surges in locating storms at sea, they would have the advantage of relatively high speed, $\sqrt{gh}$ in water of depth h, or 10,000 nautical miles per day in mid-ocean. It is hoped, therefore, that they may eventually provide a tool to the synoptic meteorologist.

Discussion and Conclusions

The relative merits of the three methods involving the propagation of ocean surface waves are summarized below. We shall also point out some of the disadvantages and advantages of these methods as compared to methods involving the propagation of sound waves through the sea bottom (microseisms) and electromagnetic waves through the atmosphere (radar and spherics).

Instrumentation. The height-period (HT) method requires no special instrumentation. The frequency-spectrum analysis (FA) method requires an underwater recording unit connected by a cable to a shore recorder. Along rocky coasts and coral reefs the chafing of the cable may create quite a serious problem and the use of expensive and unwieldy armored cable may be required. A frequency analyzer must be available at each location if the method is to be used synoptically. The storm surge (SS) method involves a much simpler installation, provided a pier or breakwater is available for securing the instrument.

Storm Location. The bearing and distance of a storm can be located by the HT and FA methods from a single station. In the case of the HT method a visual estimate of wave direction should suffice in view of the uncertainties regarding the determination of distance. The theory underlying the method is insecure, and it is also necessary to make assumptions regarding the duration of the storm. Furthermore, an estimate of deep-water wave height from shore observations may be subject to considerable error. The HT method has the advantage that it permits some estimate of the storm location from a single set of simple observations.

The FA method, on the other hand, depends upon the determination of a *shift* in the frequency spectrum and requires therefore (intermittent) observations extending over a minimum period of perhaps six hours. The determination of distance is based on sound physical theory, and furthermore does not involve the deter-

Table II. Data for Five Severe Storms off the California Coast

Date (1948)	Earliest storm surges			Maximum storm surges			Maximum swell			
	Date and time	H (ft)	T (min)	Date and time	H (ft)	T (min)	Date and time	H (ft)	T (sec)	Warning period (hr)

mination of wave height. In the determination of wave height the response characteristics of the instrument enter as an important factor, and it may be necessary to take into account, by means of specially constructed "refraction diagrams" [7, 12], the effect of bottom topography and of the configuration of the coastlines. Wave periods, on the other hand, are relatively easy to ascertain from wave records and are not subject to the complex changes in wave pattern that occur as waves come into shallow water. Determination of wave direction by means of a Rayleigh disk or a two-unit wave station are being investigated.

It is not likely that the SS method will make it possible to compute the storm distance from records at a single station. The distance determination for the FA method depends upon the high dispersiveness of ocean swell, and storm surges are almost nondispersive. In view of the great length of storm surges they will also be subject to considerable refraction. The principal hope lies in the determination of the arrival time of identical phases at two or three stations, and the location of storms from special charts based on the propagation at $\sqrt{gh}$ velocity.

Range. It is estimated that the HT method can be used to distances up to 3000 nautical miles, the FA method to distances exceeding 3000 miles. The range of the SS method is not known. The values given above are in excess of those that have been obtained by seismic and electromagnetic methods.

Group Velocity. The group velocities applicable for the HT, FA, and SS methods are of the order of 400, 900, and 10,000 nautical miles per day respectively. The relatively long interval between the time the waves are generated and the time they are recorded at the wave station is a disadvantage in the application of the HT and FA methods. Their practical use will, therefore, be largely to verify or modify the interpretation already made on the basis of meteorological information. In the case of compact meteorological disturbances, such as young hurricanes, these waves may well provide the first clue as to the existence of the storms. The methods should be particularly useful over the southern oceans [3] and for other regions where the network of observing stations is widely spaced. The group velocity of the storm surges, although slow compared to the seismic and electromagnetic waves, is sufficiently large to permit synoptic application.

Storm Intensity. The HT method gives an estimate of the storm intensity. In the case of the FA method an estimate of wind speeds from the maximum recorded period is suggested by Fig. 14. It is also hoped that studies dealing with the propagation of *energy* by the forerunners will lead to an interpretation of the spectrogram *ordinate,* which has received no attention so far but must be related to the storm intensity. The relationship between storm intensity and storm surges has not been studied.

Other Storm Characteristics. The application of the methods employing ocean surface waves is further enhanced by the possibility of determining not only the location and intensity of the storm, but also its size, type, acceleration, and other characteristics. In view of the close "coupling" between the wind pattern and the sea surface waves one might expect a better chance for success by the methods described in this report than by those based on seismic and electromagnetic waves.[8]

Desirable Future Studies. With regard to the HT method the research requirements coincide with those pertaining to the problem of forecasting ocean waves and are discussed in another paper.[3] Of particular importance is a better understanding of the decay of swell traveling through an area of calm or cross winds. In this connection it is planned to establish a wave recorder in the equatorial Pacific, possibly on the Marquesas Islands. These islands lie 2400 miles and about 6 days "up-swell" from California, and a comparison of wave records obtained there with those at Oceanside, California, would give information concerning the attenuation of swell over large distances. It is hoped that these studies may help to bring about, on a scientific basis, a revival of the ancient art of judging weather from the appearance of the sea surface.

The FA method appears to have reached a stage of development where it will be possible to work with records from a network of stations, rather than from a single station. We may expect marked progress as a consequence. Our present experience is almost entirely confined to stations in the eastern Atlantic *toward* which the storms were moving.[9] Development and standardization of suitable recording and analyzing equipment is urgently needed. The determination of wave direction is an essential requirement in making use of wave records for tracking storms.

The SS method is at such an early stage of development that further work along instrumental and theoretical lines is required before it is possible to make any definite recommendations. An improved instrument has been installed at the end of the Scripps Institution Pier, in La Jolla, California, and similar units will be installed during 1950 at Oceanside, California, 30 miles north of La Jolla (for direction determination) and in Hawaii. By means of this network of long-period-wave stations it is hoped that research on the generation and propagation of storm surges can be vigorously pushed.

In conclusion it must be emphasized that it would be most unfortunate if study were to be limited to the three methods with which we have been chiefly concerned here. A systematic exploration of the spectrum of ocean waves is likely to lead to surprising new developments. In this connection it should be remembered that the sea surface wave pattern provides a complete picture, though a distorted one, of the entire wind distribution over the ocean, and our interpretation of this

8. Recent evidence [3] indicates that some of the microseismic activity is caused by the interference pattern of the surface waves in the storm area. Apparently a second-order effect inherent in such a pattern is associated with pressure fluctuations which do not disappear at great depth.

9. Lt. R. L. Miller, USAF, has successfully applied the method to a storm over the Bering Sea, using wave records taken at Guam, located to the *rear* of the moving storm (*Scripps Institution Wave Report No. 90,* unpublished).

picture should improve with the advance of instruments, of theoretical studies, and of empirical experience.

AEROBIOLOGY

By WOODROW C. JACOBS

Headquarters, Air Weather Service, Washington, D. C.

INTRODUCTION

The field of extramural aerobiology is concerned with the distribution of living organisms by the exterior atmosphere and with some of the consequences of this distribution. It includes within its sphere of interest a study of the dispersion of insect populations, fungus spores, bacteria, viruses, molds, and pollens—in fact, all forms of life, both plant and animal, that are borne aloft and transported wholly or in large part by the atmosphere.

The present-day field of aerobiology had its origin in the pioneer experiments of Spallanzani in 1776, and in the work of Pasteur, Tyndall, and others who used the method of the aerobiologist in combating the theory of the spontaneous generation of life and in developing the germ theory of disease. It has been only within the last fifteen or twenty years, however, that aerobiology has emerged as a specialized field of investigation. An examination of the very extensive literature on the subject accumulated during these later years reveals that activity in the field has been largely confined to the biologist and has seldom included the meteorologist. Few of the biological data appear to have been analyzed from the standpoint of fluid mechanics which leaves the quantitative meteorological approach, based on theory and supported by meteorological-biological observations, as something that remains largely for the future.

The biologist has directed his attention primarily to the problems of entrapment, identification, and enumeration of organisms carried by air, but has more recently become interested in the atmosphere as the medium for the dispersal of the organisms. The meteorologist, on the other hand, has as yet shown comparatively little interest in the results of aerobiological investigation as a possible means for acquiring new knowledge on the nature of mixing processes in the atmosphere and on the movements of air masses. Nevertheless, the ever-increasing concern of the botanist, zoologist, geneticist, agriculturist, allergist, the general public, and, more recently, the militarist, in the results of the atmospheric dissemination of organisms, whether the latter be injurious insects, allergens, or pathogens, shows clearly that the subject is one of great importance and of wide general interest.

BIOLOGICAL FACTORS

Methods and Problems of Sampling and Counting. From the standpoint of the biologist the ultimate quantitative goal of atmospheric biological research is the determination and/or prediction of the type and number of viable organisms suspended in a given volume of air. For those microorganisms which may be readily identified by their shape or superficial surface characteristics and which cannot be grown on culture media, the adhesive-coated slide is widely used as a sample trap. A glass collecting slide is normally exposed horizontally to the air and, although particles are deposited by the combined action of turbulent air motion and by gravity, the technique is commonly referred to simply as the "gravity slide" method of collection. The method has several important disadvantages from the meteorological point of view. First, comparatively long exposures are required—24 hours being the time unit commonly used. The method, therefore, does not afford a means for determining the degree of atmospheric contamination at a given moment or through a given short time interval which, of course, limits the use of the data in the "synoptic" sense. The second, and principal, criticism of the gravity method, however, lies in the fact that the catch does not represent recovery from a definite volume of air. Attempts to convert gravity slide figures into volumetric terms have not been too successful. In spite of the obvious disadvantages of the method, a large proportion of our present statistics on pollen and fungus-spore distribution has been obtained from these gravity slide samples.

For the study of mold spores and bacteria which are too small for convenient direct microscopic examination, it is necessary to examine cultured specimens and count the colonies of each type of specimen. This type of sample is obtained by exposing standard Petri dishes containing suitable culture media to the air for periods ranging from two minutes to one-half hour. This is the so-called "plate method" of collection and suffers from the same disadvantage as the gravity slide technique in that the results cannot be interpreted in volumetric terms. The samples obtained by this method represent organisms released from the air during the brief period of sampling and no record whatsoever is obtained during the long gaps between exposures. The method is also time-consuming and expensive, and to secure reasonably complete data from only a few collecting locations requires the support of a large staff of laboratory technicians.

Because it is necessary to identify and count the microorganisms after they have been captured, it appears that some sort of impingement-slide method of collection offers the greatest promise of adaptability to aerobiological work. For surface collecting the equipment should be economical, simple to operate, and capable of sampling known volumes of air. Above all, the equipment, the techniques of its use, the method of counting, and the units of measure for reporting results

should be standardized among observers and technicians as far as is practicable.

Several types of volumetric sampling devices (such as the Owens dust counter) are available in some quantity, but most of them handle an insufficient volume of air to be adaptable to aerobiological investigation. While Durham [8] has reported the development of an apparatus which impinges the particles from a measured quantity of air on a slowly moving slide, thus affording both a record of organisms and of the volume of air sampled throughout the 24-hour period, the results of collections by this method have not been reported upon in detail. In a study of various types of air filters for trapping microorganisms, DallaValle and Hollaender [5] found that the relative efficiency of a viscous impinging surface tested was approximately 70 per cent. They report that the highly efficient Greenburg-Smith impinger, used as a dust-sampling apparatus by the U. S. Public Health Service, is not particularly adaptable to aerobiological work. It is the opinion of the writer, however, that the efficiency of the collector, itself, is not nearly so important as the condition that the relative efficiency be a known factor and approximately a constant.

For sampling the upper atmosphere the collecting equipment should be compact, light in weight (particularly if it is to be supported aloft by balloon, parachute, or special atmospheric sounding device), and fully automatic in operation; it should be designed to exclude the possibility of contamination[1] and to provide for the multiple sampling of measured volumes of air at known temperatures (and humidities) between specified small pressure intervals (or at known altitudes).

Proctor [23] has perfected an apparatus for upper-air sampling by aircraft which, in addition to securing operation independent of the pilot, simultaneously records certain meteorological data. In addition, variation in air flow is recorded to permit comparative counts in known volumes of air. As in his previous models of collecting instruments, provision is made for photomicrography and subculture of the microorganisms with the exclusion of contamination or cross innoculation of the separate samples.

As would be expected, the problem of collecting and identifying the larger organisms and insects is simpler than the sampling and counting of air-borne microorganisms. The most common methods for collecting these larger forms at or near the surface involve the use of nets, flight or baited traps of some sort, or simply entail the visual counting of insects on the wing or as they alight on some object. None of these methods, however, serve to give the true population of organisms in the air at any given time, although it is possible, under certain conditions, to convert flight-trap collections into rough volumetric terms.

Kites and balloons were naturally the earliest devices used for sampling insect populations in the upper air, but few of the results of collections by either method appear to have been published. The most successful collections appear to have been obtained through the use of aircraft. Perhaps the most extensive study made of the insect population of the atmosphere was conducted at Tallulah, La., during a five-year period between 1926 and 1931 by the Bureau of Entomology and Quarantine of the U. S. Department of Agriculture. The results have been reported upon in considerable detail by Glick [9, 10]. In these collections some 28,739 specimens were taken, from altitudes as low as 20 ft above the ground to as high as 15,000 ft with specially designed traps fitted to the wings of several types of aircraft. The results are given in volumetric terms (average volume of air per insect) although desirable details concerning the testing and calibration of the collecting instrument are lacking. It is unfortunate that similar data are not more generally available for other regions.

Methods and Problems of Identifying Organisms and Locating Sources. Perhaps the greatest difficulty that confronts the aerobiologist in sampling the atmosphere arises from the fact that many species of organisms are so similar in appearance that important differences which serve to separate species defy description or pictorial representation. Even in the cases of some economically important plant pathogens, the spores cannot be identified by morphological characteristics alone. In the cases of other forms, such marked variations in size, shape, and septation exist within the species that identification is impossible unless many spores are examined. Because it is certain that many closely related species within the same genus differ greatly in cultural characteristics, allergenic or biochemical effects and pathogenicity, the solution to the problem of rapid and precise identification of organisms is an essential step toward the full development of an applied aerobiology.

The greatest difficulty that confronts the meteorologist in his investigations of the local and long-distance dissemination of organisms lies in his lack of knowledge concerning the exact (or even approximate) sources of the collected specimens. In the case of the more commonly collected spores and pollens, the parent plants or fungi may be so universally distributed that it is wasted effort even to attempt speculation as to the origin of the air-borne forms. In the case of bacteria in the atmosphere the problem is even more difficult, for here the entire earth's surface (including the oceans) must be considered as a potential source. It is unfortunate for the meteorologist that the organisms most frequently collected and identified are those whose sources are most cosmopolitan.

It is true that the surface of the earth itself can be considered the source of specimens collected in the upper atmosphere but this is far too broad a classification of origin to allow anything beyond gross analyses of the atmospheric factors involved in the vertical and horizontal transport of organisms. By the same line of reasoning, the shore line of a large body of water may be considered a *line source* for land forms

1. The element of contamination is an important consideration when sampling the upper atmosphere, the air over the oceans, or in other situations where population densities of microorganisms are low.

collected over water or for aquatic forms collected inland. The latter technique has been successfully employed by ZoBell and Mathews [40], Rittenberg [26], and Jacobs [14] in their analyses of data on the microbial populations of marine air.

In the investigation of the local dissemination of organisms the problem of identification of origin is usually less difficult. In such cases the collections can frequently be made near or above a source which is readily identified because of a local anomaly in surface cover or because the spore formers or pollinators can be isolated with a reasonable degree of fineness. Proctor and Parker [24] have suggested the artificial introduction into the atmosphere of an easily identified organism for studying dispersion but, because of the rapidity with which small organisms are dispersed throughout large volumes of air and the concurrent impracticability of introducing sufficiently large numbers of organisms to allow reasonable chance for a sample recovery, it appears that such a method would be limited to studies of purely local transport. The use of stained insects has been employed for the latter purpose with some success [30].

From the standpoint of the meteorologist, who is primarily concerned with the atmospheric processes involved in the dissemination of organisms and less interested in the results of such dissemination, it appears that the most pressing need in aerobiologic research is the establishment of a standard list of "biological indicators" or "markers" (as they are called by Stakman [31]). This list should contain properly described and representative spores, pollens, molds, bacteria, and, perhaps, insects that can be easily identified and whose local sources have been determined. The sources represented by the type specimens should be mutually exclusive as to character of surface and/or geographic location. In the case of fungi, considerable care must be exercised in selecting species that produce a vast number of spores in a relatively short time; they should not multiply on dead vegetation or survive in a given region from one year to another [3].

From the standpoint of agriculturists, medical researchers, and workers in related fields, who are more interested in the results of dissemination than in dissemination processes, the primary need in aerobiology is the perfection of techniques for collecting and identifying organisms of pathogenic importance and in the determination of circumstances governing their survival and multiplication after they cease to be airborne. This segregation of interest is meant as no reflection upon the attitude of the meteorologist, for it is taken without question that the physical processes governing the distribution of pathogenic and allergenic forms by the atmosphere are identical to those governing the distribution of the nonpathogenic and nonallergenic species.

The Atmosphere as an Environment for Organisms. From the pathological standpoint the viability of organisms transported by air currents is as important a consideration as is the distance to which they are carried. As stated by Stakman [31], "To show that propagative bodies of pathogens are disseminated by the wind is only the first step in finding out what needs to be known. Are they viable at the end of their trip; how long will they remain viable, even if on the host plant, if conditions are not favorable for germination and entrance into the host soon after their trip; do they belong to a virulent race; is the host plant in susceptible condition; are [meteorological] conditions favorable for rapid multiplication and spread if initial infection occurs? These are only a few of the most important questions that must be answered if the problem is to be studied in its broadest aspects."

It is, first of all, obvious to the meteorologist that the organisms must be able to withstand great extremes of temperature, pressure, humidity, and solar radiation if they are to survive transport over great distances. From the standpoint of temperature it may be argued that because solid particles (thus all organisms) in the air radiate and absorb very nearly as a black body, they must undergo extreme temperature changes which are not represented by temperature changes within the air mass. However, the heat capacity of the organism, or a particle with which it is associated, must be very small, thus it can be assumed that the temperature of the organism at any instant must be very nearly the temperature of the ambient atmosphere. It is therefore doubtful if such organisms are ever subjected to excessively high temperatures. Certain organisms probably succumb to the very low temperatures that exist at high altitudes [34] although there are some forms which survive temperatures approaching absolute zero [39].

Bacteriologists have shown that exposure to ultraviolet radiations for short periods is lethal to most bacteria. In this connection, however, it is of particular interest to note that bacteria which are killed when suspensions (or agar plates streaked with suspensions) are exposed directly to sunlight are the same organisms which have been recovered from air by exposing agar plates for different periods of time. It appears that at least the air-borne parent cells are relatively resistant to sunlight. Whether this resistivity is due to extrinsic or intrinsic conditions is not clear. Some results [29] indicate that certain individual bacteria within a species survive dosages of ultraviolet radiation which are ordinarily lethal to the species, but that the resistivity of the individual bacterium does not persist in the subculture progeny. On the other hand, the writer will show later that many bacteria suspended in the atmosphere must be associated with a dust particle of some sort (such as surface debris or sea salt) or a water droplet, and this particle may afford sufficient protection against the lethal type of radiation. Nevertheless, the bacterial counts should show a diurnal variation due to this cause.

There is the possibility that desiccation of the organism in dry air may render it nonsusceptible to ultraviolet radiations because of its reduced water content. There appears to exist, however, a marked difference of opinion among investigators concerning the effect of humidity. Rentschler [25] concludes from

laboratory experiments that high relative humidity of the air does not increase the resistivity of air-borne bacteria. Wells [35] and Whisler [36], on the other hand, maintain that ultraviolet radiations are ten to twenty times more germicidal in dry air than in humid air. These antithetical results strongly suggest that the differences in germicidal effects were in some way related to differences in the number or character of condensation nuclei present in the several experiments.

In this connection it should be stressed that soil or sea-salt particles play a possible dual role in the maintenance of viability in the organism. In addition to containing aggregates of microorganisms they may, under certain circumstances, act as condensation nuclei (if hygroscopic) for water vapor in the atmosphere and in so doing provide favorable conditions of moisture for the persistence of organisms in the viable state. If this reasoning is valid, then the consideration of variations of atmospheric moisture should be important.

Wellington [34] has reported upon a series of laboratory experiments designed to determine the effects of substantial decreases in pressure, temperature, and humidity upon certain species of insects common in Canada. Attempts were made to simulate those combinations of pressure, temperature, and humidity that an organism might experience upon being lifted from the surface to a height of around 20 km. He concludes that the decrease in atmospheric pressure may be safely neglected as either a limiting or lethal factor among the elementary environmental changes experienced by insects distributed at higher levels; he does show, however, that most of the species tested become insensible at pressures below 120 mb. He found, also, that the flight activity of the insects varied somewhat with pressure, remaining constant for most insects up to simulated altitudes of about 7.5 km, then decreasing to zero at about 16 km. In the cases of *Coleoptera* and *Diptera*, however, there was a distinct increase in activity down to a pressure equivalent to 1.5 km where it again approached normality. This latter finding is significant from the standpoint of the actual vertical distribution of these orders. That the responses are barotactic and not due to distress occasioned by the lowered oxygen pressure was also proved by the experiment. The effects of reduced pressures on microorganisms appear not to have been similarly investigated but, because of their small size and simple internal structure, it is assumed that the effect can be neglected in the cases of these groups also.

There appear to be few, if any, actual quantitative data concerning the fraction of organisms that are able to survive significant transport. Proctor [21], in his investigation of the number of bacteria at high levels, also collected and counted the number of dust particles. He found the ratio of microorganisms (bacteria and molds) to dust particles to be 1 to 108 for all levels and 1 to 118 above 9000 ft. As the writer has previously pointed out [14], this would show about eight per cent fewer bacteria per particle for the higher levels, which might indicate that this proportion was killed, since the physical factors governing their removal from the air would be the same as for the dust particles. Proctor did not give average values for the layer below 9000 ft; it can therefore be assumed that the proportion that did not survive was somewhat greater than eight per cent.

METEOROLOGICAL FACTORS

The Mechanics of Exchange of Organisms Between Earth and Atmosphere. It is assumed that nearly all surfaces, whatever their nature or composition, will contribute organisms to the atmosphere; but that some surfaces, because of greater populations of organisms, more extensive vegetative cover, greater mobility of surface materials, or more intensive atmospheric turbulence, will contribute far more than others. In the case of bacteria, it is a statistically remote possibility that any single organisms in the soil will be lifted by themselves into the air; in all probability they are most frequently associated with debris of some kind, such as bits of organic matter, dust motes, or, in the case of marine forms, with salt particles or droplets of concentrated sea water. These organisms must therefore exist most frequently as colonies rather than as individuals. The laboratory method of plating and counting the bacteria and molds permits of no distinction between individuals and groups. Because the number of bacteria in a cubic centimeter of soil may be numbered in the millions or hundreds of millions, the potential supply of these organisms must be considered almost unlimited.

By this reasoning, the processes governing the exchange of soil bacteria between the earth and atmosphere are the same as for the exchange of other terrigenous materials. The quantity of material exchanged will be greatest in those areas where ample supplies of loose particles exist on the surface, surface winds are strong enough to stir up these materials, and steep lapse rates exist in the atmosphere to favor the vertical transport of the particles. The supply of microorganisms should be greatest where the surface is dry due to deficient rainfall, where there is an abundance of organic matter in the soil, where intensive cultivation is practiced, and in and near wooded areas. A spring maximum of dust in the atmosphere is noted in the solar radiation measurements in the United States. This is to be expected since the soil is driest at this season, cultivation is most extensive, surface winds are strongest, and the vertical temperature lapse rates are steepest. It can be assumed that the population of soil microorganisms in the atmosphere will be greatest during this season for the same reasons.

It has previously been pointed out that Proctor [21], during his determinations of the number of bacteria at high levels, also collected and counted the number of dust particles. Although he made no volumetric calculations, rough computations by the writer indicate that he collected approximately 510 visible and collectable dust particles per cubic meter of air averaged for all levels. Above 9000 ft there were approximately 25 per cent fewer particles than the general average. His ratio of 1 microorganism to 108 dust

particles as an average for all levels gives a figure of only 4.7 collectable bacteria (or molds) per cubic meter of air. If one considers the great number of bacteria that must exist in the lowest layers of air, these results show that either a very small percentage of the organisms survive or that the original number is dispersed rapidly throughout exceedingly large volumes of air. It is, perhaps, also possible that the processes governing the removal of organisms from the atmosphere are more effective than has previously been assumed.

The processes governing the exchange of spores and pollens between the earth and atmosphere are not wholly analogous to those governing the exchange of bacteria and molds between soil and air. The pollens and spores of fungi present a wide range of types with respect to their morphology, physiology, and mode of production and liberation [15]. Consequently they vary greatly in adaptation to aerial dissemination. In the case of certain fungi, very elaborate mechanisms exist for the forcible ejection of the fungus spores from their sporophores or spore mother-cells into the air. The force with which the spores are ejected varies greatly with different species, the most common ejection distances being of the order of one or two millimeters to several centimeters. Although many fungi produce an almost incomprehensibly large number of spores,[2] none of the latter appear to be provided with special adaptations for flotation as is the case with some seeds and insects.

Of the various classes of organisms so far discussed, only the insects are capable of aerial locomotion. Their initial presence in the lower layers of the atmosphere and, to some extent, their vertical distribution and local dissemination are due to the flight activity of the insects themselves. Even here, however, the activity of the insect is dependent in some degree upon such meteorological factors as temperature, wind, and humidity [10, 20, 33, 37]. Some nonflying insects are specially adapted to aerial dissemination, good examples being several species of spiders whose young spin webs from some elevated object to be later carried with the wind. Glick reports that at times great masses of such webs are found floating in the air, even at altitudes of 7000 to 10,000 ft.

A large number of seeds are particularly well adapted to aerial dissemination through very effective structures that increase their frictional resistance to air. Because of the size of the seeds and their very common occurrence, knowledge regarding them is more general than is true of smaller organisms.

Viruses which are produced within the tissues of plants or animals do not appear particularly well adapted to aerial dissemination except as they may be carried by insect vectors or birds. There is the possibility, however, that such virus material may occasionally be associated with bits of organic matter or microorganisms in the atmosphere. Additional research on the possible (free) aerial dissemination of virus substances is needed.

In the case of marine bacteria, it is only when the sea surface is stirred sufficiently to produce spray that a mechanism exists for the introduction of the sea-surface organism into the atmosphere. The spray droplets will, of course, include any bacteria present in the sea water and subsequent evaporation of the droplet will leave the organism associated with a salt particle or droplet of concentrated sea water. Since such particles are extremely effective nuclei for the condensation of water vapor in the atmosphere, they are more readily removed than are the nonhygroscopic dust particles which may contain soil bacteria. Since the number of marine bacteria in a cubic centimeter of sea water seldom exceeds 500, it can be computed (on the basis of data concerning evaporation from spray)[3] that the populations of marine bacteria in the air must be sparse everywhere except, perhaps, at times of rough sea or in the vicinity of a coastal "breaker zone."

An understanding of the physical processes which serve to remove organisms from the atmosphere once they have become air-borne is as important to the aerobiologist as is a knowledge of the mechanism governing the lifting of the organisms into the atmosphere in the first place. Most investigators in the field of aerobiology have taken great pains to point out the usual small size and mass of air-borne organisms, and data concerning the computed or observed free rates of fall under the influence of gravity (in still air) appear in almost every analytical paper.[4] The present author has no desire to minimize the importance of small size and mass in furthering the dissemination of microorganisms for those are their primary adaptations to aerial transport. It should be pointed out, however, that of all the forces tending to move the single microorganism vertically, the gravitational factor is merely another component of force additive to others usually of greater magnitude. The possibility that a single pollen grain, spore, or bacterium carried through convection to an altitude of several kilometers will ever be allowed to settle back to earth through the effects of gravity alone is exceedingly remote. Some organisms of near colloidal dimensions could be considered to remain almost permanently in the atmosphere were they not brought down to the surface again through turbulence or through capture by condensation or precipitation products.

Many investigators have made note of the fact that rainfall is an extremely effective mechanism for clearing

2. Christensen [3] cites as an example of the remarkable power of reproduction of many plant pathogens, that *Ustilago zeae* (corn smut) in two weeks may produce a gall of 20–40 cubic inches, each cubic inch of which contains about six billion spores. One acre of corn with 10 per cent infection would produce 5×10^{13} spores during the same period.

3. On the basis of determinations of the sea-salt content of marine air [13], the author has previously computed that the number of marine bacteria near the sea-surface source averages about five per cubic meter of air [14].

4. The free rates of fall of the largest fraction of bacteria, spores, and pollens (at sea-level air densities) are within the range of 0.1 to 20 mm sec^{-1}. In some cases the velocities approach those predicted by Stokes' law and in other cases substantially reduced velocities are indicated.

the atmosphere of organisms. The comparatively large number of microorganisms found in rain water by various investigators is further evidence that at least a sizeable fraction of the air-borne organisms have been captured and removed from the atmosphere by falling raindrops. While it has not been definitely proved that microorganisms ever act directly as condensation nuclei in the atmosphere, at least one investigator has noted that the rate of fall of spores in moist air is several times greater than in dry air, presumably because the organism has increased its mass through the absorption of water vapor.

It would thus appear that the condensation and precipitation of water vapor are the important mechanisms for removing microorganisms from the atmosphere. The transport to the surface through the effects of turbulence with subsequent settling or impingement appears to be the secondary process. This reasoning, of course, does not apply to the larger organisms whose free rates of fall are appreciable and which are supported aloft only within strong convective currents or through their own flight activity.

Vertical and Horizontal Transport of Organisms. Turbulence in the atmosphere tends to create a uniform distribution of properties throughout the air mass. This action, however, is of far greater magnitude than the mere diffusion of properties between layers; apparently the mixing takes place through the motions of eddies or discrete parcels of air which are pushed from their original surroundings at irregular intervals. Thus, it would be expected that air-borne microorganisms, whose source is at the surface of the earth, would be distributed throughout the entire depth of at least the troposphere,[5] but that the density of organisms would decrease the greater the distance from the source. Biological work to date shows this to be true. Proctor [21] notes a general decrease in both dust particles and bacteria with elevation and an increase in the bacterial count in the vicinity of wooded areas, while Rittenberg [26] has presented data which show a general decrease in the mold count over the oceans with increasing distance from shore. It would appear that the horizontal distance over which the individual microorganism may be transported is almost limitless and is largely determined by its ability to survive the atmospheric environment.[6] The meteorologist, of course, is interested in the total distribution of microorganisms; the biologist, on the other hand, concerns himself only with what he terms the *effective* distribution. The effective distribution is a function of the virulence and concentration of organisms and of the conditions bearing upon their multiplication and spread at the *place* and *time* of deposition.

As an example of the sometimes complex meteorological circumstances that must precede the effective long-distance dissemination of important plant pathogens, Stakman and Christensen [32] cite the spread of stem rust on wheat through the North Central States during 1942 and 1943. In both years, barberry bushes (the secondary host) in the Virginias became heavily infected about May 15 because of favorable weather circumstances during the preceding period of development. Throughout the first half of June, southeast winds, accompanied by rains (favoring multiplication), carried the rust spores west-northwestward, causing heavy infection through much of Ohio and Indiana and as far as southern Michigan and northeastern Illinois. While the south-to-north air movement was not unusual, the destructive epidemics resulted only when all meteorological factors favorable for rust development operated in conjunction.

Supporting evidence on the long-distance dissemination of plant pathogens is given by data collected in Canada which show that urediniospores of leaf and stem rust of wheat are regularly introduced each spring into Manitoba by spores from the United States. These rusts do not overwinter in Canada, but the urediniospores are invariably found in the air in advance of the infection of the wheat crop. Of even greater interest is the fact that the rusts do not survive the hot summers of the south and every fall must be reintroduced by wind-borne spores from the north. The meteorologist cannot help but note how the maintenance of such a biological cycle is favored by the normal seasonal change in the general atmospheric circulation over these areas.

Numerous similar examples of the long-distance dissemination of organisms appear in the very extensive literature on aerobiology. A large fraction of the papers contain aerobiological data which should be further analyzed by the meteorologist.

Although turbulence tends to create uniformity of properties throughout an air mass, at any given instant this air mass must contain variously large and small masses (eddies) with somewhat different properties from those of the surrounding air. This no doubt accounts for at least part of the extreme variability in bacterial counts within small areas, or over short intervals of time, which has been noted by various investigators. The more intense or prolonged the turbulent action, however, the more nearly will uniformity of properties be approached. At the same time, however, there must be a general decrease in the density of the property relative to the total air mass as the distance between the observation and the source area increases.

If this "uniformity of properties" were actually attained in a given region (which would be the case were the process one of pure diffusion), the spatial distribution of microorganisms would approximate a frequency distribution of the Poisson type, and the ratio of the variance (*i.e.* mean squared deviation) of the counts to the mean of the counts made in the region should approximately equal 1.00. A higher ratio indi-

5. Living spores of several common molds were caught in a spore trap released from the balloon *Explorer II* at 72,500 ft and set to close at 36,000 ft [27].

6. Living spores of various fungi have been caught from aeroplanes above the Caribbean Sea 600 miles from their nearest possible source [17], while allergens have been identified at least 1500 miles from their probable origins. In spite of the usual low concentrations at the source, marine bacteria have been collected 80 miles inland from the nearest seacoast [40].

cates the presence of eddy masses which still retain the properties derived from their sources. However, the longer the elapsed time since such an eddy mass left its source, the more completely will its population become equalized with that of its surroundings because of diffusion and small-scale turbulence; hence, for any class of microorganisms, the ratio referred to above should diminish with distance from the source.

The writer has previously analyzed data obtained by Rittenberg [26] on the distribution of molds[7] over the ocean from shore to a distance of 400 miles westward from the Southern California coast. The mold samples represent collections made on shipboard at oceanographic stations at approximately equal distances along courses normal to the coastline. The region off the coast of California presents unusually stable conditions throughout practically all months, therefore it is not expected that the mixing processes are as effective here as in some other areas. Nevertheless, the data accumulated by Rittenberg show the reasoning in the preceding paragraphs to be valid. His collections give an average mold count per hour of 155.6 for the region from 0–100 miles off the coast and a count of 29.0 for the region from 100–400 miles off the coast. If the mean of the differences in count between individual collecting stations is taken as a measure of the variability, a value of 250.1 molds per hour is found for the coastal region and 30.8 molds for the region beyond the 100-mile zone. These figures are interesting in that they give ratios between the mean differences in count and mean counts of 1.61 for the first region and 1.06 for the second. However, the actual mixing processes are probably best represented if the ratio of the variance to the mean of the counts is taken. In this case, the ratio is 402.0 in the first region and 32.7 in the second. As suggested, if the mixing were accomplished solely by pure diffusion, the ratios would approach 1.00 in both areas. Approximately the same number of counts were obtained in each of the areas under consideration.

One may speculate as to the origin of the molds. The prevailing winds in the Southern California area are from the sea, and thus the air masses usually present over the coastal region are essentially marine in character and may have passed over several thousand miles of sea surface without contact with land. Since the mold collections were made by Rittenberg at intervals of varying length and on several cruises, it may be assumed that a large fraction of the counts were made within truly marine air masses. If the molds are primarily of land origin, they must have originated either over the continental land masses to the east or over the far removed land areas bordering the North Pacific Ocean on the west or north. The fact that Rittenberg notes a decrease in the mold counts from shore seaward appears to rule out the latter possibility which indicates that these organisms actually originated from the land surface of the United States but were transported westward across the prevailing wind stream through lateral mixing. Whether the effect is the result of a more or less continuous mixing process or is brought about by sporadic incursions of continental air masses over the ocean is a matter for further speculation.

Considerations such as these suggest the use of bacterial counts in the identification of air masses and in the study of large-scale mixing processes in the atmosphere. The identification of the origins of species of organisms found in the atmosphere should give information concerning the origin of the air masses, while the study of the ratios (at the surface and aloft) between organisms representing two or more source areas should give additional information concerning the nature and effectiveness of lateral and vertical mixing. Few of the available aerobiological data, however, are complete enough to allow this type of analysis.

Many observers have reported great irregularities in concentrations of organisms collected at different levels in the atmosphere, often finding heavier concentrations at higher altitudes than at lower levels. In some cases the investigators have reported encountering clouds of spores or bacteria several thousand feet above the surface of the earth, seemingly borne along by the wind as more or less discrete, sharply bounded units. However, it should be pointed out that such collections have been obtained through the use of aircraft, and it is quite probable that in many cases the variations in samples merely represent the passage of the aircraft from and into convective (rising) columns of air which would be expected to have greater populations of organisms than the surrounding (and perhaps descending) portions of the atmosphere. Wellington [34] has suggested the use of the helicopter for the purpose of "selective sampling"—a technique which could be used to obtain more meaningful data on the vertical distribution of organisms in the atmosphere.

Several investigators have noted that increased counts of microorganisms are obtained in airplane collections upon entering clouds and have ascribed the condition to the fact that the cloud is a more favorable environment for the organisms than is clear air, although Durham [7] ascribes the increase to the loss of electrostatic charge and the consequent dislodging of particles which adhere to the plane. It does not seem to have occurred to the investigators that the vertical cloud boundary probably also represents the vertical boundary of a rising air column which should contain a heavier concentration of organisms than the surrounding clear (nonconvective) area.

The discussion so far is intended to indicate the importance of the horizontal and vertical mixing in distributing organisms throughout the atmosphere. The height to which the organisms may be transported depends upon the degree of stability (or instability) near the surface and upon the height of the turbulent or convective layer of air. The presence of a stable layer at the surface will prevent or retard the introduction of surface organisms into the upper atmosphere but will,

7. Rittenberg assumes that all the molds are of land origin regardless of whether they develop on sea-water media or tap-water media, although it is admitted that at least a portion of the molds collected may have had a temporary sojourn in the sea.

at the same time, maintain higher concentrations of organisms in the surface layers; the presence of a discontinuity surface in the upper air will limit vertical transport in either direction resulting in the concentration of organisms above or below such a surface. There are several recorded instances of such biologic stratification. For example, Durham [8] has noted that abrupt spore ceilings are often marked by a cloud layer or by a visible haze line. He noted one instance in which a detached cloud of fungus spores, almost 100 per cent *Alternaria*, was encountered about 1000 feet above a visible 4000-ft haze line that marked the ceiling for ragweed and the ground cloud of other spores. An analysis of the meteorological conditions that existed near New Orleans on September 12, 1940 (the date and place of collection), might prove interesting, particularly if the source of the "cloud" of *Alternaria* could be identified.

Nearly all investigators who have studied the vertical distribution of organisms in the atmosphere have noted the importance of thermal convection in increasing the populations at higher altitudes. Thermal convection over a region is a diurnal phenomenon and is usually at a maximum in the early afternoon; as a result, the maximum altitude populated by organisms should be highest at this time of day. Nearly all the data on insect populations verify this conclusion.

In general, the horizontal transport of organisms will be determined by the general stream flow in the atmosphere, but lateral mixing will transport the organisms laterally away from the trajectories indicated in the general wind observations. In temperate latitudes, the greater transport will be from west to east and, considering the greater carrying power of polar air masses, from north to south. As an example of the latter, Durham [8] calls attention to a remarkable mold-spore shower that occurred October 6–8, 1937, over the eastern half of the United States. During this period, extremely high slide counts of *Alternaria* and *Hormodendrum* were recorded at all collection points between southern Minnesota and Louisiana with somewhat increased counts in the tier of states between North Dakota and Texas. He presents a map of the area which shows, for each of the three days, the line along which the concentration of the organisms was a maximum. The writer has referred to the synoptic charts for those dates and finds it interesting to discover that Durham's lines of maximum spore concentration on each date coincide almost exactly with the daily positions of an extensive and rapidly-moving dry cold front.

A number of investigators have attempted to describe mathematically the vertical and horizontal distributions of organisms as functions of space or time but none appear to have been too successful. Wolfenbarger [38] has prepared regression formulas for the plots of a very large number of series of data on the spatial variations in organism counts; all are based on the form

$$E = a + b(\ln x), \text{ or}$$

$$E = a + b(\ln x) + c(1/x),$$

where E is the calculated number or concentration of organisms, a is the position on the graph and b and c are factors determining the slope of the curve as influenced by the logarithm or reciprocal of the distance x from the source. He presents the completed formulas for 251 separate plots of data. For example he finds, from one set of data, that the number of codling moths caught at a distance of x feet from an infested orchard can be given approximately by the expression:

$$E = 5.2904 (\log x) + 20114.0849 (1/x) - 18.0628.$$

Since the formulas nowhere take into account meteorological conditions or other factors governing distribution, the writer fails to appreciate the great amount of effort that must have gone into their preparation.

CONCLUDING REMARKS

No attempt has been made in these pages to cover in detail the list of specific possibilities for research in the field, either from the standpoint of the biologist or of the meteorologist. The principal gaps in the research programs conducted by aerobiologists have been pointed out, and suggestions for general lines of research have been offered in the several sections. The writer hopes that the discussion will serve as an added stimulus toward future investigations in the field by both groups and that it will, in some measure, give guidance to the biologist. It is the problem of the biologist to develop certain and rapid methods for identifying the organisms with respect to type and place of origin; it will be the problem of the meteorologist to apply the results of the biological investigations to a study of the atmosphere.

The author is indebted to Drs. B. E. Proctor, E. C. Stakman, J. J. Christensen, R. P. Wodehouse, G. W. Keitt, and P. A. Glick for their assistance in locating recent materials on the subject of aerobiology and to Mrs. Marguerite Gleeck of the Air Weather Service, for her careful reading of the manuscript. The writer also wishes to acknowledge his extensive use of the volume *Aerobiology*, published by the American Association for the Advancement of Science, as a source for biological information.

REFERENCES

No attempt is made here to cover the list of important papers concerned with aerobiological subjects. Care has been taken to include the more recent titles, those which, themselves, contain extensive bibliographies, and all titles which have been specifically referred to in the text. A valuable bibliography, which was published after this list of references was prepared, is that by Miss H. P. Kramer, "Cumulative Annotated Bibliography on Aerobiology and Its Applications to Meteorology." *Meteor. Abstr. & Bibliogr.*, 1: 119–135 (1950).

PHYSICAL ASPECTS OF HUMAN BIOCLIMATOLOGY*

By KONRAD J. K. BUETTNER

Randolph Field, Texas

According to the classical definition by Humboldt [50], the term *climate* designates all changes in the atmosphere that noticeably affect human physiology. With this definition, upon which the present article is based, the meteorological elements must be evaluated in a manner different from that used, for instance, in connection with an airway meteorological service or with plant geography. Thermal elements of the climate become the most decisive, specific radiations come next, whereas pressure, wind direction, and similar basic weather data play only an indirect role.

HEAT BALANCE

Heat Production. The body gains the energy necessary for maintaining its internal temperature by combustion of converted food. This energy is given off by conduction, convection, radiation, and evaporation from the skin, as well as by advection to, and evaporation from, the respiratory organs. A maximum of 20 per cent of the heat produced (less basal metabolism) may be used for external work. The excretion of stool, urine, etc., merely presents a decrease in the body's heat capacity. Unfortunately, metabolism, which is essential for the life of every cell, takes place in both hot and cold environments; however, it cannot be regulated beyond certain limits.

An adequate oxygen supply to the blood through diffusion in the lungs' surface requires a certain partial pressure of oxygen in the lungs. This partial pressure is determined almost exclusively by the atmospheric pressure because the fraction of oxygen in the air is very nearly constant. Pressure variations caused by weather, however, are too small to be significant in this relation. Consequently, only the well-known variation of pressure with altitude needs to be considered.

The combustion end products, CO_2 and H_2O, are removed by breathing and metabolism. Excessive CO_2 content of the inspired air is harmful; it occurs only near volcanoes and in artificial climates (crowded rooms, submarines, etc.), but in such cases the coexistent sultriness is often more important than the presence of CO_2.

The base value of heat production (at rest, "comfortable" climate) is about 40 Cal m^{-2} hr^{-1}. Exercise, fever, or cold increase this value up to a rate larger by more than one order of magnitude.

If, starting with "comfortable" conditions, the room temperature decreases by 10C, the heat production of the body increases by about one half. This heat production would have to double if the skin temperature were to remain constant. Actually, however, the latter decreases by about 7C because of a decrease in the advection of warm blood to the skin, particularly to that of the extremities whose temperature then drops almost to that of the air. The thermal conductance (taken between the interior of the body and the average skin) decreases from about 50 to 10 Cal m^{-2} hr^{-1} (deg C)$^{-1}$. On the other hand, it may rise to 120 Cal m^{-2} hr^{-1} (deg C)$^{-1}$ for portions of the skin heated separately and may drop almost to zero for cold extremities [7, 19, 84]. This complex of phenomena corresponds to variations in blood circulation which, in both extremes, constitute a severe load on the heart: since the temperature gradient between heart and skin is small in the case of warm surroundings, the heart must pump large quantities of blood to the periphery in order to rid the body of the heat it produces. In the case of cold surroundings, on the other hand, the necessary heat must be produced by arduous muscular activity which, again, strains the heart.

Rapid variations of the thermal environment produce temperature fluctuations first in the skin, then in larger portions of the body, until a new equilibrium is established. This involves a stock-piling of heat, using the body's heat capacity. The values of specific heat are:

Skin	0.77	Cal kg^{-1} (deg C)$^{-1}$
Fat	0.55	"
Muscle	0.91	"

Roughly, the entire body can lose j Cal m^{-2} without discomfort if its heat metabolism amounts to j Cal m^{-2} hr^{-1} [8]. The corresponding drop in the true body temperature is composed of 65 per cent core temperatures (rectum) and 35 per cent skin temperature [24]. This ratio may vary; nevertheless, the mean body temperature is usually not equal to the rectal temperature.

Heat Loss by Convection. In the simplest case, the temperature of a room may be used as a measure of its climate. However, thermal environments are rarely as simple as that; usually wind, radiation, and humidity act simultaneously. The total rate of heat loss can be determined only synthetically from these weather elements.

The known laws of heat transfer by convection have successfully been applied to the human body [13, 16, 19, 49]. The skin is surrounded by a laminar boundary layer several millimeters thick (in the case of calm air). At the inner portion of this layer, heat transfer takes place by pure conduction. A steady transition to turbulent austausch takes place towards the outside. The dependence of surface conductance h_a on wind velocity v, diameter d, and density of the air ρ is expressed by the following formula:

$$\frac{h_a d}{k} = CU^n, \qquad (1)$$

* Translated from the original German.

where k is the thermal conductivity of the air; $U = v\rho d/\mu$, Reynolds number; μ is the viscosity of the air, and d is the diameter of the cylinder or sphere, or the trunk width of the human body. The exponent n depends on the structure of the air flow. For the range which is of interest to us ($10^3 < U < 10^5$) the following values have been found:

	C	n	References
Cylinder, normal to axis	0.35	0.56	[72]
Sphere	0.70	0.52	[13, 16, 19]
Human body, supine, nude	1.0	0.54	[13, 16, 19]

(1a)

Under normal conditions, for the supine adult, we find approximately [13]:

$$h_a = 6.3\sqrt{v}\ \text{Cal m}^{-2}\ \text{hr}^{-1}\ (\text{deg C})^{-1}, \qquad (2)$$

where v is expressed in kilometers per hour and is greater than 2 km hr^{-1}. In these measurements [13], the exposed surface is taken as fifty per cent of the geometrical surface. More recent measurements made for sitting persons [84] and standing persons [63] showed values of $5.5\sqrt{v}$ and $3.9\sqrt{v}$, respectively. The scatter in the factors (6.3, 5.5, and 3.9) is caused by differences in the methods used for determining the area from which heat is lost.

Siple [27, 79] used the heat of fusion of water to determine the "wind chill" which, actually, is the cooling power at sub-zero temperatures. In his antarctic experiments he found the formula,

$$h = 10.9\sqrt{v} + 9.0 - v. \qquad (2a)$$

He used as a measuring device a cylindrical vessel which contained the water to be frozen. The plastic wall, one-eighth of an inch thick, has to be considered as a thermal insulator, or the whole instrument may be thought of as a clothed cooling device. Therefore, equation (15) (see below) should be applied with $S = 0$ and $h_r = 5$ Cal m^{-2} hr^{-1}. Best agreement with the measurements [27, 79] can be found by writing equation (15) in the form:

$$h = \frac{1}{(h_a + h_r)^{-1} + h_c^{-1}}, \qquad (2b)$$

where $h_r = 5$, $h_a = 9.0\sqrt{v}$, and $h_c = 80$, all in Cal m^{-2} hr^{-1} (deg C)$^{-1}$ (v in km hr^{-1}). The values of h_a and h_c thus extracted from the experiments fit the data to be expected for a cylinder of this size and a plastic wall of this thickness.

According to equation (1), the local value of h_a is large for highly curved surfaces such as the fingers. Moreover, h_a decreases with decreasing atmospheric pressure.

In the absence of forced flow, the higher surface temperature in itself produces convection. From the law of similarity and from experiments we obtain

$$\frac{h_{a0}\,d}{k} = c\sqrt[4]{G}, \qquad (3)$$

where $G = d^3 g\rho^2(\vartheta_s - \vartheta_a)\,\mu^{-2}\,T^{-1}$,
$T = 273 + (\vartheta_s + \vartheta_a)/2$,
g = acceleration of gravity,
ϑ_s = skin temperature,
ϑ_a = air temperature.

Values measured in calm air give
$c = 0.37$ for cylinders [72],
$c = 0.44$ for spheres [13].

Because of body motion and other sources of air flow, the human body is rarely surrounded by completely calm air, and hence equation (3) is rarely applicable. Actually, in rooms of normal size and in calm air, a value of $h_a = 3.3$ Cal m^{-2} hr^{-1} (deg C)$^{-1}$ was found for recumbent adults and $h_a = 3.9$ Cal m^{-2} hr^{-1} (deg C)$^{-1}$ was found for recumbent children [13, 16]. A value of $h_a = 2.0$ Cal m^{-2} hr^{-1} (deg C)$^{-1}$ was found for seated persons, on the basis of the geometric instead of the projected surface [84]. In narrow containers, such as calorimeters designed for human subjects, even smaller values have been observed [64].

Heat Transfer by Evaporation. Analogous laws are applicable to the evaporation of moisture from the skin to the air. The numerical values for boundary layer and austausch may be applied here. For the vapor transfer coefficient

$$h_w \equiv V/(e_s - e_a),$$

where V is the heat loss (in Cal m^{-2} hr^{-1}) by evaporation, and e_s and e_a are the vapor pressures of skin and air, respectively, theory and measurements [10, 11] yield the value:

$$h_w = 1.63\ h_a\ \text{Cal m}^{-2}\ \text{hr}^{-1}\ \text{mb}^{-1}. \qquad (4)$$

Experiments reveal that either the skin becomes wet, owing to active secretion of sweat glands, or water diffuses through a slightly permeable membrane at the surface (presumably the *stratum granulosum*). The second process, the so-called *perspiratio insensibilis*, is almost independent of wind, since the diffusion resistance is considerably greater in the skin than in the boundary layer of the air [19]. On the other hand, this portion of heat transfer by evaporation apparently increases with increasing E_s, the saturation vapor pressure at skin temperature. If f denotes the wet portion of the total surface, and c is a constant, then

$$V = [fh_w + c(1 - f)]\,(E_s - e_a). \qquad (5)$$

Equation (4) applies only at sea-level pressure. According to equations (1) and (1a), h_a is nearly proportional to $\sqrt{\rho}$ and thus decreases with altitude. However, since equation (4) contains the diffusion constant, which increases as $1/p$, we find $h_w \propto 1/\sqrt{\rho}$. We thus find an *increase* of the vapor transfer coefficient with height. In view of the fact that the *perspiratio insensibilis* is independent of h_w, the well-known desiccation at high altitudes must be attributed less to this factor than to the decrease in e_a.

Heat Transfer by Radiation. Radiation from the sun and sky, and solar radiation reflected from the surroundings (S) cover the spectral range between 0.3 μ and 3 μ; radiation of the skin and terrestrial objects (R), that between 3 μ and 50 μ. The optical constants for the skin differ widely for S and R: the mean energy albedos are 0.35 and 0.04, respectively [16, 42]. The mean absorption coefficients for incident solar and terrestrial radiation are 7 cm^{-1} and 100 cm^{-1}, respectively.

The reflection and absorption spectra in the solar region are complicated and depend upon pigmentation (race, suntan), congestion of blood vessels (erythema), etc. In the yellow and red bands, noticeable fractions of the radiation penetrate deep layers, whereas in the region from 0.5 μ to 0.9 μ, reflection is particularly strong. As far as its own radiation R is concerned, the skin acts nearly as a black body, its emission constant being $\epsilon = 0.96$ according to [16], or 0.99 according to [42]. We may write

$$R = 4.96\epsilon\left[\left(\frac{T_s}{100}\right)^4 - \left(\frac{T_r}{100}\right)^4\right] = h_r(\vartheta_s - \vartheta_r)\ \text{Cal m}^{-2}\ \text{hr}^{-1}, \quad (6)$$

where, approximately,

$$h_r = 19.84\epsilon\left(\frac{T_s + T_r}{2}\right)^3,$$

and ϑ_r is the radiation temperature of the surroundings, which in the case of a room is identical to the mean wall temperature (T_r and T_s are in degrees absolute). This identity applies also to specularly reflecting walls, as long as they are sufficiently far removed. In the open, the following approximation is usually adequate for a man or a sphere just above a plane surface:

$$R = \frac{h_r}{2}(\vartheta_s - \vartheta_r) + \frac{h_r}{2}(\vartheta_s - \vartheta_a) + R_h\ \text{Cal m}^{-2}\ \text{hr}^{-1}, \quad (6a)$$

where ϑ_r is the mean temperature of the solid surroundings, and R_h is the radiation to the sky by a sphere having an air temperature ϑ_a. Data on R_h are given after the calculations of Poschmann in [69]. The radiation R_h depends on cloud conditions, ϑ_a and e_a, and may rise to 100 Cal m^{-2} hr^{-1}. Its effect on human heat loss may be considerable, for example, during clear winter nights.

Total Heat Balance. The heat balance for the nude body is

$$Q - C\dot{\vartheta}_b + \epsilon_H S F_H = h_a F_a(\vartheta_s - \vartheta_a) + h_r F_r(\vartheta_s - \vartheta_r) + [h_w f + c(1 - f)]F_a(E_s - e_a). \quad (7)$$

In this expression the subscript H refers to the sun (Helios), Q is the heat production of the body (less loss in breathing), C is its heat capacity, and $\dot{\vartheta}_b$ is the change of the average body temperature with time.

At least three different surfaces have to be considered in the discussion of heat balance, namely, the projected surface for the solar radiation (F_H), the surface for the heat loss to the air (F_a), and the surface for the heat loss by outgoing radiation (F_r). All surfaces are smaller than the geometrical surface F which has been measured frequently because of its dependence on the height, weight, age, sex, and clinical factors of the subjects. For adults, F amounts to 1–2 m^2. The values of F_a and F_r are smaller for the recumbent person because of mutual contact between certain skin areas and contact with the insulating bed. For a standing person $F_a \approx 0.8F$, and for a person supine on an insulating bed it may be as low as $F_a \approx 0.5F$. For the average of all possible positions, $F_H \approx F_a/4$. Sky and reflected solar radiation might require special consideration. Usually, $F_a = F_r$.

Sultriness and Heat. In an ordinary room, $S = 0$ and $\vartheta_a = \vartheta_r$. In calm air at sea level, the value of h_a has been found to be close to that of h_r. With this simplification in mind (which should not be generalized), we write $h_{a0} = h_r = h$. In order to maintain the body temperature at a steady state ($\dot{\vartheta}_b = 0$), equation (7) becomes

$$\frac{Q}{2F_a h} = \left[\vartheta_s + \frac{h_{w0} f + c(1 - f)}{2h} E_s\right] - \left[\vartheta_a + \frac{h_{w0} f + c(1 - f)}{2h} e_a\right]. \quad (8)$$

According to experiment [17], $c \approx 0.2h_{w0}$. If equation (4) is used, the physiological quantities ϑ_s and f, skin temperature and wetness factor, are thus related to the environmental values ϑ_a and e_a.

We may now introduce certain standard data such as $Q/F_a = 120$ Cal m^{-2} hr^{-1}, $2h_{a0} = 8.4$ Cal m^{-2} hr^{-1} (deg C)$^{-1}$, and $\vartheta_s = 34.5$C. We find from equation (8) that $f = 1$ when

$$\vartheta_a + 0.815e_a = 63,$$

in which ϑ_a is expressed in degrees centigrade and e_a in millibars. When the wetness factor f equals unity, thorough wetness and consequently unbearable heat conditions are indicated. This has been proved by different observations. The majority of deaths during military maneuvers in the United States [78] or caused by heat waves in the United States[1] have occurred with values greater than those approximated by the formula: $\vartheta_a + 0.75e_a = 61$. In general, similar climatic strain in the range of sultriness (*i.e.*, high temperature and high humidity combined) is given by equations of the form

$$\vartheta_a + ae_a = b, \qquad (a \leqq 0.815). \quad (8a)$$

The more comfortable the surroundings, the smaller the values of ϑ_s and f, and the smaller the values of a and b according to equation (8). Such systems of physiologically equivalent combinations of (ϑ_s, e_a) correspond to the "effective temperatures" [49] of the American Society of Heating and Ventilating Engineers. From equation (8) we can readily interpret them as lines of constant (ϑ_s, f).

Evaporative cooling devices for homes and automobiles leave the equivalent temperature of the cooled and moistened air,

$$\vartheta + 1.5e = \vartheta' + 1.5E', \quad (8b)$$

approximately constant (psychrometric equation). Comparison of equations (8*a*) and (8*b*) shows that relief from heat may be expected only in the case of low relative humidities.

Overheating of the body ($\dot{\vartheta}_b > 0$) occurs for corresponding values of S, e_a, ϑ_a, etc., particularly when $\vartheta_a > \vartheta_s$ and $\vartheta_r > \vartheta_s$, so that only evaporation has a cooling effect. This becomes inadequate either if h_w is too small and e_a too large (jungle climate), or if the

1. T. Düll and B. Düll, personal communication.

body is not capable of supplying sufficient water to make $f = 1$. This is known to occur in hot deserts, that is, wind no longer produces cooling. The average person is rarely capable of filtering more than 1 kg hr^{-1} of water through the skin; in certain morbid conditions, for instance prior to heat prostration or after prolonged thirst, the rate of filtering is even less. The subsequent overheating is associated with desiccation of the skin and the formation of a salt crust.

Since f as well as ϑ_s represents a physiological variable, the total effect of ϑ_a, ϑ_r, e_a, and v can be determined only by calculations of the type referred to above, but hardly by means of instruments which seek to simulate actual conditions. The problem of defining climatic strain in one unit becomes even more difficult in the case of sunshine ($S > 0$). A solution of this problem seems more promising in the region between sultriness and cold.

Cooling. Perspiration ($f > 0$) is an emergency function of the body; ϑ_s values should stay between certain limits. We feel comfortable when $\vartheta_s \approx 33$C and $f \approx 0$, that is, when $a = 0.2$ and $b = 26.4$ (equation (8a)). This corresponds to an effective temperature of approximately 22C, which is the "summer comfort" standard of the American Society of Heating and Ventilating Engineers for lightly clothed persons. For $a = 0.2$, the effect of atmospheric humidity on skin temperature is already negligible; however, values of relative humidity above 70 per cent and below 20 per cent are undesirable for secondary reasons (effect on clothing and microorganisms, or desiccation of the skin, respectively). If the last term (evaporation) is omitted and $\vartheta_b = 0$, equation (7) can be used to derive a numerical criterion describing the total effect of several climatic elements in one index:

1. *Température résultante* [58] and *operative temperature* [38]. These quasi-temperatures comprise the radiation and air temperature if $S = 0$ and $v = 0$:

$$\text{op. temp.} = \frac{h_r \vartheta_r + h_{a0} \vartheta_a}{h_r + h_{a0}}. \qquad (9)$$

2. *Cooling power.* The problem here is to determine the (artificial) heat supply Q of a device required to keep its temperature ϑ_s constant (usually at 34C). The quantities ϵ_h, ϵ, F_H/F_a, and the constants of equations (1) to (3a) are supposed to have the values corresponding to those of the human body. Instruments of this type are the katathermometer of L. Hill and the frigorimeter of C. Dorno (see [13, 16, 69, 74, 80]).

3. *Standard operative temperature.* Calculation [38] permits the comparison of two rooms ($v \geqq 0$, $S = 0$), considering the skin temperature ϑ_s constant:

$$\text{std. op. temp.} = \frac{h_r \vartheta_r + h_a \vartheta_a - \vartheta_s (h_a - h_0)}{h_r + h_a}. \qquad (10)$$

4. *Cooling temperature* (ϑ_s'). This is the fictitious skin temperature of a sphere, heated with $Q = \text{const}$, whose constants correspond to those of a blond human. In this case,

$$\vartheta_s' = \frac{h_r \vartheta_r + h_a \vartheta_a + Q/F_a + \epsilon_H S/4}{h_r + h_a}. \qquad (11)$$

The value ($\vartheta_s' - 12$C) is the "temperature of equal effectivity," that is, the temperature of a "normal room" ($v = 0$, $S = 0$, $\vartheta_a = \vartheta_r$), which is physiologically equivalent. (For existing instruments by Pfleiderer and Buettner [13, 16, 69, 80] the constants are $Q/F = 96$ Cal m^{-2} hr^{-1}, $\epsilon_H = 0.60$, $\epsilon > 0.90$, and $d = 15$ cm (sphere).) For an additional, smaller model, the "Frierkoerper": $Q/F = 120$ Cal m^{-2} hr^{-1}, $d = 7$ cm [19].

Numerous other forms may be reduced to those given above. We give cooling temperature preference over cooling power and standard operative temperature, since in the mean cooling range the human body tends to achieve a constant Q with variable ϑ_s, rather than to keep ϑ_s constant.

The purposes of establishing and observing these combination elements are as follows:

1. Establishment of a comparative physiological climatology for nonhumid regions. The thermal load on a human body may be calculated from the elements v, ϑ_r, ϑ_a, and S, if these are known at the location of the body; unfortunately, this is rarely the case. On the other hand, series of cooling measurements are available only sporadically.

2. Evaluation of artificial climate and clothing (see below).

3. Determination of the dosage for exposure to the open air in sanatoriums in moderate and cool climates. The tonic effect of the change from indoors to a veranda increases with the deviation from the comfort climate and with the duration of outdoor exposure. The ϑ_s value recorded by the frigorigraph serves as a measure of comfort or load; values are to be measured at the patient's bed or calculated by means of equation (11); $\vartheta_s' = 37$C is comfortable. A formula found successful in a sanatorium on the North Sea coast (calculated from data in [68]) is

$$(|\vartheta_s' - 37|)t = BD, \qquad (12)$$

where t is the exposure time in minutes, $B = 8$ for $\vartheta_s' < 35$C, $B = 20$ for $\vartheta_s' > 40$C, and $t = 4D$ for $35\text{C} < \vartheta_s' < 40$C. The dose D increases from 5 for hypersensitive persons to 60 for healthy persons. Because of possible damage from ultraviolet radiation, the exposure time must be limited on the basis of special measurements or tables (see Table II).

Clothing. The main purpose of clothing is to produce a bearable skin temperature through thermal insulation. Let us assume that the incident radiation S is absorbed at the surface of clothing having a temperature ϑ_x; outside, $\vartheta_a = \vartheta_r$; underneath the clothing, which has the thickness d, the skin temperature ϑ_s prevails. The quantity h_c is the "thermal conductance" of the fabric and $1/h_c$ is its "insulation value" (as a measure of this, one also uses 1 Clo = 1.715 deg C m^2 hr Cal^{-1}). The values of h_a and h_r are practically the same for clothed and for bare sections except perhaps in the case of thickly clothed fingers. The increase of the surface area has to be taken into account. In the

case of clothing such as fur, the true surface is difficult to determine.

We then have, for the surface concerned,

$$Q + \epsilon_H S F_H = F_a(h_a + h_r)(\vartheta_x - \vartheta_a), \qquad (13)$$

and

$$Q = F_a h_c(\vartheta_s - \vartheta_x); \qquad (14)$$

hence

$$\frac{Q}{F_a h_c} + \frac{Q + \epsilon_H S F_H}{F_a(h_a + h_r)} = \vartheta_s - \vartheta_a . \qquad (15)$$

The following conclusions can be reached from equation (15):

1. Above certain wind speeds (large h_a), solar radiation S becomes ineffective.

2. For $h_c \ll (h_a + h_r)$, that is, for good insulation, the effects of wind (assuming h_c to be invariant with respect to v) and of solar radiation vanish.

3. Protection against solar radiation by reflection (small ϵ_H) is particularly effective in the case of thin fabrics (large h_c), deep penetration of the radiation being undesirable, of course. Solar rays are best reflected by white surfaces; those originating from sources below 1500C (fire), by shiny metals [20].

4. The insulation value $1/h_c$ necessary to maintain the Q and ϑ_s of the body constant can be determined experimentally or by calculations on the basis of the frigorigraph values ϑ'. Let Q, ϵ_H, and ϵ be the same for the body and for the frigorigraph. For the body, $F_a = 4F_H$. Finally, let $\vartheta_a = \vartheta_r$. It then follows from equations (11) and (15) that

$$\frac{1}{h_c} = \frac{F_a(\vartheta_s - \vartheta_s')}{Q} \text{ deg C m}^2 \text{ hr Cal}^{-1}. \qquad (16)$$

For clothing comprising several layers ($i = 1, 2 \ldots n$),

$$h_c = \frac{1}{\sum d_i/k_i + \sum \dfrac{1}{k_a/d_a + h_r}} + f(v), \qquad (17)$$

where d_i and k_i denote thickness and thermal conductivity of the clothing layers, respectively; d_a and k_a are the corresponding values for the intermediate layers of air. (Since convection would occur in thick air layers, equation (17) is valid only for $d_a < 0.01$ m.) The factor d_a is particularly sensitive to pressure and body motion. The function $f(v)$ represents symbolically the total effect of wind pressure on insulation (wind penetration through porous fabrics and openings; flapping, etc.).

The conductivity of cloth (k_i) is determined by three elements: (1) conduction by the interstitial air, (2) conduction along the component of the fabric fiber oriented in the direction of heat flow (the same component is responsible for resistance against compression) which becomes undesirably high for dense, compressed, and wet fabrics, and (3) radiation from fiber to fiber, a process which has hitherto not been considered, but which becomes noticeable in the case of large fiber separations. With increasing temperatures, the two conduction terms rise only slightly, but the radiation term increases considerably [21]. Table I lists several values to illustrate the foregoing considerations.

Table I. Heat Conductivity and Density of Different Materials

(*According to Buettner* [14, 18])

Material	k (Cal m^{-1} hr^{-1} (deg C)$^{-1}$)	ρ (kg m^{-3})
Air	0.023	1.3
Water	0.52	1000
Wool cloth, dry	0.030	100
Wool cloth, wet	0.092	250
Wool cloth, dry, under pressure	0.035	170
Asbestos	0.079	860
Glass fabric, 20C	0.027	210
Glass fabric, 350C	0.081	210
Human skin, upper layer, excised	0.18	—
Human skin (0–2 mm deep), *in situ**	0.32	—
Human skin (2 mm deep), *in situ*, cool*	0.47	—
Human skin (2 mm deep), *in situ*, warm*	3.60	—

* After [14]. They include the effect of blood advection.

Rain or perspiration increases k_i; water in the cloth may even freeze, thus causing even higher k_i. These processes might make the cloth windproof; consideration must be given to the question when and where this water or ice can be eliminated.

The question of how the extremities should be protected in extreme cold is difficult to answer. If the body as a whole produces enough heat, even poorly protected extremities are safe [40]. On the other hand, for geometrical reasons, clothing for the hands and feet would have to be prohibitively thick.

In the case of hot desert winds, loose clothing affords protection against overheating and dehydration resulting from the inadequate water supply to the skin [1, 19].

Breathing. In breathing, a heat exchange A takes place which depends on the transferred volume M (m^3 hr^{-1}), the heat capacity and density of the air, and the difference in the equivalent temperatures of the inhaled and exhaled air.

The mechanism by which the exhaled air is heated and humidified may be conceived of as follows [70]: Incoming air having the equivalent temperature J_i cools the mucous membranes of the upper respiratory organs (nose, mouth, throat) by convection. During this process the air itself is raised to blood temperature and saturated with moisture. The air, returning after a brief pause in the lungs, is cooled by the still relatively cool, mucous membranes. As long as the mucous membranes are moist, the air remains saturated and emerges from the mouth or nose with the equivalent temperature,

$$J_e = \vartheta_e + 1.5E_e.$$

The process may be treated schematically by assuming a constant mean membrane temperature. We introduce as fictitious quantities the equivalent temperature of saturation at blood temperature J_b and at the average temperature of the mucous membrane J_s, as well as the thermal conductance of the membrane h_s, the sur-

face conductance of the passing air h_a, and the effective surface area of the membranes F. Then the heat transferred to the inhaled air during its passage into the lungs is given by

$$h_a F(J_s - J_i) = M\rho c_p(J_b - J_i), \qquad (18)$$

and the total heat loss of the body by respiration,

$$A = M\rho c_p(J_e - J_i) = h_s F q(J_b - J_s), \qquad (19)$$

in which q is a relative time factor depending on the

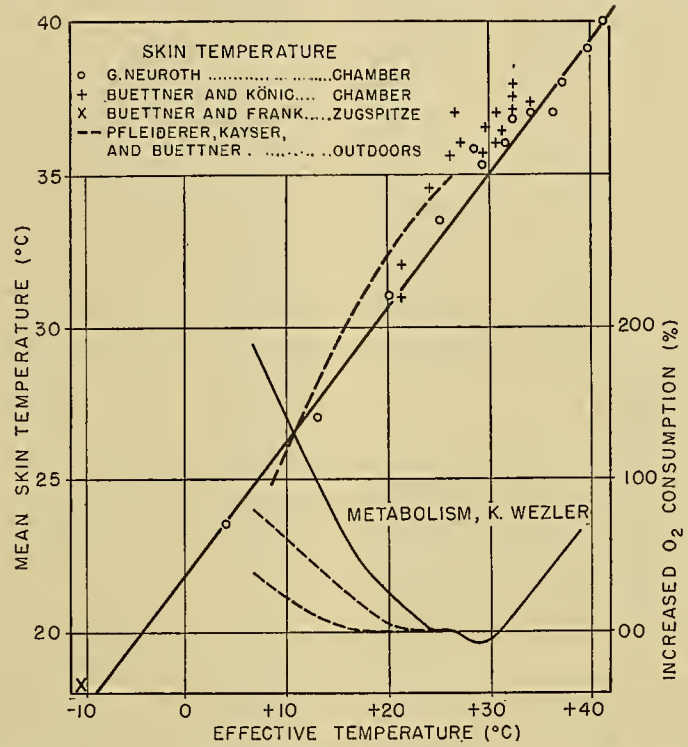

FIG. 1.—Mean skin temperature of supine, nude persons at rest, in terms of "effective temperature." Data are partly from a climatic chamber and partly from various climates in the open air (North Sea coast, Alps, central Africa). The abscissa has been converted to "effective temperature" on the basis of original values (temperature and humidity) according to the method of the A.S.H.V.E. for unclothed persons. In the case of cool and windy conditions, which prevailed for the most part at "effective temperatures" below 20C, the "temperature of equal effectivity" [18, 19] was used instead of the ordinary air temperature. Only in the central range were climatic conditions such that they could be withstood for several hours. The duration of experiments in the two extremes was about ½ hr. The metabolism curves (*after Wezler* [83]) in the lower right show the heat production measured by oxygen consumption of supine, nude persons as a function of "effective temperature." Data were obtained from four persons in a climatic chamber and show noticeable differences at the lower temperatures.

rhythm and relative length of the breath pause; hence

$$\frac{J_e - J_i}{J_b - J_i} = P(h_s, q, M, h_a, F). \qquad (20)$$

This calculation may be considered as a first attempt to find a connection between the observed temperatures without knowing J_s.

A comprehensive study of all available measurements for the case of normal mouth or nose breathing (not yet published; see [11, 17, 19, 70]) reveals a drop of J_e from 125C (mouth) and 125C (nose) down to 82C (mouth) and 65C (nose), respectively, if J_i changes from 100C to −40C. The average $M = 0.6$ m^3 hr^{-1} in these experiments. The variation of the function P with J_i is remarkably small: it drops from 0.84 to 0.75 (mouth) and from 0.84 to 0.62 (nose) if J_i changes from 100C to −40C. The slight dependency of P on M may be explained by a compensatory effect of M and F (cooling of deeper tracts with a deep breath). When the inhaled air is very warm and dry, the exhaled air is no longer saturated [11]. In any case, J_e is by no means constant but decreases with J_i.

At higher altitudes, A becomes an important part of the total heat loss: If M increases to compensate for the decreased partial pressure of O_2 ($M\rho = M'\rho'$), then the "dry" loss $M'\rho'(\vartheta_e - \vartheta_i)$ remains the same (observations in a pressure chamber have yielded the same values of temperature and saturation as at sea level). However, the "wet" portion $M'C(E_e - c_i)$ increases with M'/M. (C includes the heat of vaporization and the conversion from e to absolute humidity.) Exercise, fever, etc., have little influence on the relative amount of heat loss by breathing because increased internal combustion requires a higher M.

In general, the heat transfer due to breathing may be considered as small compared to the transfer through the skin.

The General Effects of Climate. Let us consider on the basis of our formulas how the body stabilizes its temperature, that is, how it balances its gain and loss of heat. In the "comfort" range, Q is at a minimum, ϑ_s is about 33–34C, and $f = 0$. If ϑ_a or c_a rises, Q at

first remains constant; increasing ϑ_s and f makes the removal of heat possible. In addition to the "dry" climatic factors, e_a becomes ever more important. With even higher values of ϑ_a and e_a, f finally reaches unity, and $(\vartheta_b - \vartheta_s)$ becomes too small to produce a sufficient "radiator effect." To remove a constant Q through the skin, a peripheral blood flow proportional to $1/(\vartheta_b - \vartheta_s)$ is necessary. This value becomes unbearably high. In addition, the increased blood temperature and work done in internal circulation raise Q [83] (see Fig. 1).

Cold restricts the peripheral blood circulation and thereby decreases ϑ_s and thus also E_s. By physiological regulation the decrease in skin temperature finally causes an increase in Q, varying considerably from individual to individual, as a consequence of shivering, conscious muscular activity, or thermally excited, purely physiological control (Fig. 1).

In spite of these effects, the core temperature remains constant in tropical as well as in arctic climates (except for extremes) after a brief adaptation period. The most important climatic elements in the tropics are humidity and temperature; in the Arctic, temperature and wind. In each case they are modified favorably or unfavorably by solar radiation. Exercise increases Q and thus makes warm climates less bearable and cold climates more bearable.

In a cool and moderate climate, variation in peripheral blood circulation and the stimulation to increased heat and food metabolism represent beneficial stimuli for healthy people, but a considerable strain for those with circulatory diseases. Metabolic and cardiovascular diseases as well as mental exhaustion or instability, chronic respiratory diseases and rheumatic afflictions occur frequently in the area of maximal stimulation, for instance, west of the Great Lakes [51, 56]. In these same areas we also find the earliest onset of growth and sexual maturity in adolescents.

In the warm, humid Tropics, a small amount of human activity accompanies a low Q. This condition is further augmented by the absence of diurnal, interdiurnal, and annual fluctuations of weather elements. The uniformly high values of temperature and humidity of the skin decrease its resistance to diseases. This decreased resistance, together with the abundance of microorganisms and a low social standard, increases the number of skin diseases; there are in addition innumerable internal tropical diseases. These illnesses might have influenced previous tropical cultures more than the climate proper could have done.

The dry, hot climates and the tropical highlands assume a position between the two extremes noted above, since they show a high variability of the weather, although at times the heat stress is great. The number of microorganisms is small. The dryness of the air is favorable to the cure of tuberculosis of the lungs. Cultures in these areas (Egypt, Near East, Inca) are outstanding and old.

Survival and culture in the Arctic seem to be a matter of providing only food, shelter, clothing, etc.

Medical geography and climatology [51, 56, 57] may have to be rewritten in the next few decades because a large number of the indirect effects of climate, especially the infectious diseases (malaria, sleeping sickness, food poisoning) can be eliminated. New means of transportation and storage will eliminate unbalanced diets; air conditioning can alleviate peaks of heat stress. The sociological situation can thus be changed. The Pygmy in the primeval forests of the Congo, the Bedouin in the Sahara, and the Eskimo in the Arctic are influenced not only by climate, but also by such factors as seclusion and the poverty of the country.

RADIATION

The caloric effect of solar radiation was discussed above in connection with the over-all heat metabolism of the human body. The heat radiation from the clear sky is slight. The differences in spectral composition between direct solar radiation and sky radiation, each considered for various solar elevations, cloudiness, and turbidity, are of little importance for the caloric effect.

On the other hand, a number of photochemical processes are connected with shorter wave lengths and are thus highly variable with regard to weather. The most important of these processes are vision by means of the spectrally selective, sensitive retina and the formation of erythema, pigment, and vitamin D in the skin (for a summary see [12, 16, 69]).

For measurements in the biologically important range below 0.32 μ one uses, in addition to spectrographs, special instruments such as the cadmium cell of which C. Dorno made excellent use, the special photocell of Coblentz [26], and the UV-Dosimeter of IG-Farben [37] (for a summary see [60, 69]). Measurements of the ultraviolet sky radiation are indispensable in all biological investigations since more than half the total incoming ultraviolet radiation is scattered by the sky.

Erythema solare, erroneously referred to as sunburn, is produced by the direct action of ultraviolet radiation below 0.32 μ upon the cells of the skin, perhaps directly on the nucleic acid of the cell nuclei (Fig. 2). In this process the photochemical sensitivity curve is modified by absorption in the uppermost layers of the skin. The primary cell damage is followed after about one-half hour by reddening of the skin, subsequent swelling, and in the case of excessive doses, by the formation of blisters and epidermic defects after several days. In the case of skin with a certain predisposition, the same cell damage causes the formation of "delayed pigment." This occurs after two to three days and consists of a migration of melanin particles to the surface. By a different photochemical process, the "immediate pigment" is formed even more rapidly than the erythema. This process is caused by long-wave ultraviolet radiation (Fig. 2). It consists of a darkening of already present melanins [12, 43, 44, 46].

In the case of erythema and of both kinds of pigment, one can measure the threshold and also the degree of discoloration; the latter is determined by the difference in reflectivity at a wave length typical for the particular discoloration (green in the case of erythema) [16]. The threshold dose required for erythema is essentially a value depending on the individual. The threshold

dose D of white persons is $50 < D < 600$ (D = ultraviolet intensity in units of the IG-Farben Dosimeter $\times$ time in minutes) [16, 54]. The mean value of all persons examined (mostly blond) was $D = 200$, a value which corresponds to a 15-min exposure to sun and sky at 60° solar altitude in middle latitudes. In all persons the reddening measured by means of a reflectometer increased by about 1 per cent for each 80 D units above the threshold value of D. Different climates (arctic to tropic), the temperature of skin or air, the origin of the radiation (sun or sky), wind, etc., do not influence the relation of D and the erythema produced [16, 64].

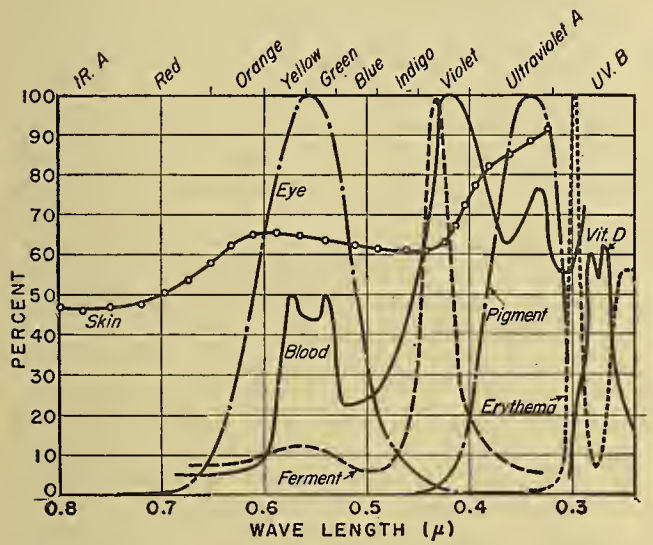

Fig. 2.—Threshold and absorption spectra for the human body. *Blood*—decrease in light intensity when passing through a layer of blood corpuscles 7.8 μ thick (about equal to the diameter of one blood corpuscle). *Skin*—loss in passing through a light-brown layer of skin 0.8 mm thick. *Ferment*—breathing ferment, according to Warburg, which is held responsible for the effect of violet light. *Vitamin D*—absorption coefficient of nonirradiated ergosterin. *Eye*—sensitivity curve of the normal eye, adapted to daylight. The outer limits lie at 800 and 320 mμ. *Pigment*—the curve of direct pigmentation due to long-wave ultraviolet, the so-called "immediate pigment," according to Henschke and Schultze [46]. *Erythema*—skin-reddening curve plotted according to the reciprocal values of the excitation threshold. In the curves "blood," "skin," and "ferment," light depletion is represented; 100 denotes opacity. In the case of "vitamin D," the numbers, which have been divided by 100, represent the absorption coefficients. All other curves are referred to the maximum of the curve in question. (*After Pfleiderer and Buettner* [69].)

Immunity against erythema can be attained by the "delayed pigment," by thickening of the epidermis, or by both. Ointments which do not transmit at $\lambda < 0.32\ \mu$ afford protection against erythema without preventing the formation of "immediate pigment." A light erythema may be a desirable stimulus for a healthy person; on the other hand, an acute form is associated with a dangerous activation of tubercular lung processes and may, in rare cases, even cause skin cancer. The cosmetic value of the pigment is a matter of fashion.

Vitamin D, which is indispensable for the formation of bones, is produced from the ergosterin of the skin by almost the same radiation (Fig. 2) and at about the same superficial skin layer as erythema. Since this vitamin nowadays can also be taken orally, rickets can no longer be considered a climatic disease.

The ultraviolet radiation below 0.32 μ varies more than that of any other part of the solar spectrum. It is absorbed by the atmospheric ozone, highly scattered by air and aerosol, and reflected by snow. The effect of dust above large cities is frequently overestimated; the loss for Boston [41] and Berlin [16] amounts to less than 20 per cent for the noontime sun, and even less for the sky. In Berlin the loss is no greater for the ultraviolet than it is for the other wave lengths.

Table II. Ultraviolet Intensity of Sun and Sky*

Region	Sun's elevation							
	10°	20°	30°	40°	50°	60°	70°	90°
Northern and central Europe, and central Africa, altitude < 500 m	1	3	6	8	11	14	—	—
Oceans in tropical latitudes	2	4	7	12	17	22	27	37
Central Europe, altitude 1150 m	—	4	8	12	16	20	—	—
Central Europe and central Africa, altitude approx. 3000 m	—	5	11	16	21	26	31	42

* Measured with the IG-Farben UV-Dosimeter, 1938 model, during the warm season and with a clear sky (summarized in [69]).

Table II shows measurements made with the IG-Farben Dosimeter (1938 model) from Lapland to the hills of the Belgian Congo. Table III shows the effect of clouds of medium thickness on the ultraviolet radiation of sun plus sky.

Table III. Effect of Cloudiness on Ultraviolet Radiation*

Cloudiness	0/10	3/10	5/10	9/10	8/10	10/10
Percentage of ultraviolet radiation transmitted	100	90	75	65	55	45

* For clouds of medium thickness, with average elevation of sun.

The brightness and color of the surroundings produce a number of psychological and physiological effects via the eye. The greatest change in this field, the introduction of electric illumination at the beginning of this century and the resulting elimination of biological darkness during the winter, is held responsible for the more rapid maturing of adolescents observed since that time.

Glare is typical of two climates: the arctic and the subtropic, where bright snow or sand, abundant sunshine (subtropic), and the scarcity of natural shadow coincide. Temperate and tropical zones have less sunshine as well as a darker background and numerous sources of shadow. Glare increases the contrast threshold of the eye, impairs space perception, and makes landscapes appear flat. Snow blindness may be due to glare as well as to an ultraviolet erythema of the eye.

The beneficial or, in the case of an excess, harmful effect of the natural radiation encountered in the open

is usually combined with thermal climatic stimuli, such as cold, wind, water, and snow. Good and bad physiological effects thus depend frequently on the totality of all climatic stimuli.

METEOROTROPISM

The preceding sections present information on the current status of *physical bioclimatology:* measurable weather factors produce measurable changes in man by biologically understandable mechanisms [16]. Such clear, causal relationships are rarely encountered in bioclimatology except in the fields of thermal and photochemical effects. Not even the effects of changes in the chemical composition of atmospheric air (CO_2, O_3, N_2O, I) fall into this category.

The deleterious effects of harmful industrial effluents are felt by the population only if the wind has the proper direction, or during prolonged stable air stratification, especially in winter. All our knowledge of micrometeorology and austausch has to be applied to check this disgraceful aspect of modern artificial climate. Hay fever is connected with the blossoming time of certain species of grass, as well as with dryness and wind direction. All of these phenomena can, to a certain degree, be reproduced in the climatic chamber; however, in the case of head colds, headaches, and associated diseases of doubtful origin, this is no longer entirely true. In considering daily and seasonal rhythms (except for those caused by radiation and dietary conditions) and the numerous "trigger" diseases initiated in the sympathetic nervous system, we have entirely left the field of physical bioclimatology for the field of "statistical bioclimatology."

The Effect of Periodic Weather Processes. Nearly every biological component from the rectal temperature to the mental disposition has a daily and a seasonal rhythm. Correlation of these biological elements with any meteorological factor proves nothing a priori, except that weather and human life take place on the rotating earth. Changes in personal climate caused by night work or work in a mine apparently fail to cause an immediate change in the phase of biological curves; on the other hand, in case of sudden change of longitude (such as by air travel) the biological phase seems to adapt itself within a few days (H. Strughold).

The nature of the seasonal rhythm can be illustrated by two diseases whose causes have been recognized. The high infant mortality rate during summertime, which was formerly observed in all temperate climates, was due to overheating as a result of an excess of blankets and clothing [31] and to a lack of cleanliness causing an increase of the number of all kinds of microorganisms. Many of these microorganisms find optimal living conditions during summer weather. Lack of ultraviolet-produced vitamin D, accompanied by dietary deficiencies, leads to a wintertime peak of rickets. If exposure to the sun from February to April (central Europe) causes excessively rapid healing, that is, calcification of the bones, the calcium level in the blood decreases, possibly resulting in tetany of infants [31, 61, 69].

Many infectious diseases show yearly variations that are due either to changes in the daily contact among people or to alterations in living conditions of microorganisms. Circulatory diseases are more frequent during the season of greatest stress owing to sudden weather changes. Certain skin diseases have their peak during the month of maximum perspiration. The sex ratio of births and the pH of blood vary with the season [67]. The number of deaths from heart failure, suicide, blood pH, and the ratio of births to deaths reveal a weekly as well as a lunar period, according to Petersen [67].

The Effect of Aperiodic Weather Processes. Many nonepidemic diseases begin abruptly, that is, with a well-defined onset. Some of them have a tendency to begin suddenly in number, that is, the distribution of initial manifestations over all days of the year is by no means statistically random. A trigger cause must therefore be present, and this has long been sought in the weather. The numerous attempts to hold individual weather elements (p, e, v, ϑ_a, or their time derivatives, or oxygen content of the air, precipitation) responsible must be considered as having failed. Even in the case of head colds which may perhaps be caused partly by thermal effects, it has not been possible to find a correlation with the daily temperature fluctuations, except perhaps for a decrease in frequency for very slight temperature fluctuations and for strong winds [36]. Extremely low temperatures have usually failed to produce colds in heroic self-experimentation or in the case of entire armies [59]; however, a sudden onset of thawing weather or rain may be coincident with an onset of colds. On the other hand, it has been made possible by the methods of Linke [55] and de Rudder [31] to find a correlation between the incidence of diseases and weather fronts, prefrontal subsidence, and orographic foehn.

The meteorotropic diseases have in common the prerequisite of a constitutional or acquired predisposition of the individual. The predisposition may be a latent infection or a permanent defect such as a scar. They may also be partly initiated by the sympathetic nervous system. The weather frequently served only as a trigger which numerous other stimuli could provide equally well. Some of these diseases are "pains due to the weather," laryngeal croup, thrombosis and embolism, acute glaucoma, hemoptysis, the onset of diphtheria, herpes, stroke, and attacks of asthma [9, 31]. Variations in the healthy body caused by weather (blood pressure, flushing of the skin, and a drop of the leucocyte count upon administration of $NaCl$) have also been observed. Experiments [32] have revealed correlations of psychological conditions with weather fluctuations as well as with solar activity.

However, it must be noted that not every front acts as a trigger and that, in addition to fronts, other factors may act in the same way. Sometimes cold and warm fronts and occlusions act alike; sometimes their consequences are diametrically opposed. For many diseases

correlation with a weather phenomenon is difficult to detect because the time lag between the given phenomenon and the first manifestation of the disease is unknown and perhaps variable; furthermore, almost all investigations have been made in central Europe and in the northern United States, that is, in regions where changes of air masses are too frequent to correlate one onset of illness with one front only. A number of the pertinent investigations have failed to meet statistical requirements.

According to Petersen [65], different fronts have different effects: cold fronts cause "anabolism," contraction of blood vessels, spasms, and biochemical reduction; warm fronts produce the opposite effects. Similarly, Curry tried to classify his patients into those sensitive to warm fronts and those sensitive to cold fronts [10, 29, 30]. A premonition of the weather, together with the foehn sickness, was explained [36] by the theory that descending air currents produce triggering action, particularly in the case of rheumatic attacks. The weather effect demonstrated by fronts may be nonspecific [69]; it may be a remote effect or, most probably, it may be caused by admixtures to the air. Pressure variations of all frequencies were found to be without effect [81]. On the other hand, the foehn illness could be avoided by purification of the air [81]. The decisive agent was assumed to be the oxidizing power of the air, the "*Aran*" [29, 30] (essentially ozone), which is brought down from high altitudes by descending air currents and perhaps produced by electric discharges. According to this, one could expect no causal relationship with fronts, but only a statistical relationship. The "*Aran*" hypothesis remains to be verified.

The vast number of publications in the past on effects of the static electric field of the atmosphere and of the terrestrial magnetism on man have not survived more recent critical tests. The daily occurrence of contact and friction electricity during extreme dryness, such as in heated rooms in winter, causes uncomfortable electric discharges and may occasionally cause an explosion of gasoline or ether vapor.

Theoretical calculations and some clinical results instigated the hypothesis of certain effects of inhaled atmospheric ions on man. Beside enhancement of specific electrochemical effects of the inhaled nucleus, a charge of the alveolar wall by unipolarly charged and absorbed ions may be anticipated. Open-air tests did not yield a reliable correlation coefficient between the number and unipolarity of large atmospheric ions or any other electrical factor of the inhaled air and the human health.

The very interesting correlation between sunspot activity and mental diseases, suicides [32–34], gestation eclampsia [6], the sedimentation rate of the healthy male blood serum [82], cholera in Russia, and meningitis (for a summary see [67]) belong in the field of bioastrophysics unless a meteorological agent can be found as an intermediate factor.

Aviation Medicine [3, 39, 48, 76]. At high altitudes, or on mountains, man is subject to specific effects of oxygen partial pressure and of changes of air pressure. Additional effects stemming from heat or cold, radiation, stress of flying or mountain climbing, acceleration, etc., might be aggravated by the effects of pressure. The blood, as the carrier of fuel and oxygen, must attain at least an 80 per cent saturation with oxygen in passing the lungs. To accomplish this, an oxygen pressure of 80 mb must prevail within the lungs, a fact which in turn presupposes a 133-mb oxygen pressure of the inhaled air. Ordinarily, 63 mb of H_2O, 53 mb of CO_2, as well as the N_2 pressure, have to be added to account for a real picture of the air inside the lungs.

At an average height of 3.5 km, the external O_2 pressure assumes the value of 133 mb. Above this level, a nearly complete physiological compensation is provided through various countermeasures: increase in breathing, increase in the amount of the oxygen-carrying vehicle (blood), and decrease in the alveolar CO_2 pressure.

Below 96 mb O_2 pressure (above 6 km of height), these compensations fail in a nonadapted man and the "engine" stops owing to lack of oxygen.

If pure oxygen is breathed, the afore-mentioned critical partial pressures of oxygen are reached at altitudes as high as 11.8 km and 14 km, respectively. For this reason, pressurized cabins are indispensable above these heights, even for a crew breathing O_2 by use of masks.

The reduction in barometric pressure in itself may cause discomfort and distress due to the expansion of gases trapped in body cavities (intestines, dental cavities, sinus).

Nitrogen is physically dissolved in the blood according to the existing partial pressure (Henry's law). Subsequent to a fast ascent to heights above 8 km, this N_2 tends to degasify from the blood, forming small bubbles which provoke pain in the joints and may even affect the brain. Owing to the hydrostatic pressure, the lower organs are usually less affected. These symptoms are known under the name "aeroembolism." The N_2 in the blood may be replaced by O_2 or *He* to prevent aeroembolism [48, 79].

A sudden drop of pressure may be caused by rupture of a pressurized cabin at great heights. This drop causes rapid expansion of the air in the lungs. This "explosive decompression" may even damage the walls of the lungs.

Space Medicine [4, 5, 23, 47, 52, 53, 77]. Space medicine comprises the human factor involved in flights beyond the lower stratosphere and in flights along trajectories equivalent to those of a celestial body. The main problems of this new field are:

1. With increasing altitude the protective atmospheric filter will gradually be lost. First solar X-rays are encountered at 100 km, but the existence of hard components, able to penetrate the hull of a craft, is dubious. Effects of cosmic-ray showers and of cosmic radio waves on man are being considered, but they are not very likely. Biological effects of cosmic-ray primaries prevalent above 25 km may be of prime importance. In passing through tissue, they produce very

thick and heavy ionization tracks which, compared with effects of alpha rays, should be strong enough to endanger lives exposed for more than one hour [53, 77].

2. The cabin climate of a craft at an altitude of more than 150 km, coasting along a celestial orbit after power shutoff, would be characterized by radiation equilibrium of the hull and lack of air convection inside. The surface temperature depends on the following radiations in addition to interior heating: sun, solar radiation reflected from the earth, and the radiation from the earth and cosmos. The main material constant is the ratio of the absorption coefficient at $\lambda < 3\,\mu$ to that of $\lambda > 3\,\mu$. This ratio equals 1.0, 0.1, and 6.0 for ideal black, white, and metallic surfaces, respectively. With a solar constant of 1200 Cal m^{-2} hr^{-1}, an average earth albedo of 0.42, and an average earth radiation of 174 Cal m^{-2} hr^{-1}, equilibrium temperatures are found [23] for a sphere, a plate always facing the sun, and a plate always facing the opposite direction (Table IV). The temperatures are higher than one might expect.

Table IV. Equilibrium Temperature of a Solid Surface Outside the Atmosphere but Close to the Earth

Form of surface	Day			Night
	black °C	white °C	nickel °C	all °C
Sphere	+63	−42	+239	−68
Plate facing the sun	+122	−51	+347	−29
Plate facing the opposite direction	+68	−13	+231	−270

If the earth's gravity is balanced by the centrifugal forces of the flight trajectory, gravity within the craft is absent and convection consequently ceases (see equation (3)). Exchange of heat, water vapor, respiratory gases, settling of dust, etc., can take place only by processes such as artificial ventilation and filtering. The thermal insulation of thick air layers would be equivalent to that of stagnant air of this thickness.

3. Lack of gravity may influence the human sensory system in a way and to an extent which cannot be predicted.

Effects of Extreme Heat and Cold [22, 45, 62, 73]. All the formulas on heat exchange of the human body, described in the first section, are based upon the assumption of a steady state. The skin and rectal temperature changes are too small to cause additional factors in our equations, except the simple one concerning any slow, temporal, linear increase of the body temperature as a whole.

If, however, heat transfer to the skin surpasses 500 to 1000 Cal m^{-2} hr^{-1}, the simplification of a steady state no longer holds, and the differential equation of heat conductivity has to be applied in full.

When heat or cold is applied during a short period of time, generally less than one minute, the skin temperature changes according to the amount and kind of heat transfer (Newtonian, constant nonpenetrating heat, constant penetrating radiant heat, contact heat, etc.) and according to the material and initial temperature of the skin. The temperature change of the surface proper generally depends on only one constant, the product of three characteristics (heat conductivity × density × specific heat) of the skin at the surface. This product was shown experimentally to lie between the values of water and fat, and not to depend on the blood flow. With this experimental fact sudden temperature changes of the skin can be calculated (formulas in [22, 25, 45, 62, 73]), for example, for the rapid cooling in very cold wind, according to measurements of Siple [79] and Buettner [22], or heating by solar radiation [73].

PROBLEMS FOR FUTURE RESEARCH

Bioclimatology is essentially an applied science. As such, it can be expected to experience changes in its major problems as a consequence of progress made in related fields. Taking tropical medicine as an illustrative example, we may note that it may one day find itself in the position of being confined to problems of sultriness and sunstroke as soon as progress in epidemiology will have eliminated the major objectives currently being pursued. From this point of view, heat and cold merit serious considerations as basic and isolated problems. Few thermal measurements have been made on clothed people exposed to the actual environment of various climates, whereas ample data exist for nude subjects under the artificial conditions of a climatic chamber. These conditions fail to account for the variation of some important factors, chief among them being rapid changes in the wind speed. These variations may cause variations in the skin temperature, but to a varying degree, depending on the situation, because cooling power depends on $\sqrt{v}$, air transport on v, and wind pressure on v^2. Temperature and radiation are also subject to rapid meteorological changes.

It is believed that there exists a pronounced disproportion between competitive formulas and instruments designed to determine the "dry" cooling and their application in the practice of physicotherapy, comparative climatology, clothing design, and building construction. In fact, the excellent work carried out on clothing by the Office of The Quartermaster General, U. S. Army, had to be accomplished mainly without the use of "cooling power." There is much left to be done in the study of the effects of strong winds on clothed bodies. More open-air studies can be expected to yield stress data, integrating the effects of heat and humidity.

Even if all these formulas were on hand, their climatological use would be impaired by the lack of data on wind velocity near the ground, radiation, vapor pressure, and soil temperature. Typical climatological data are more useful to a botanist than to a physician. On a climatological map the summer climate of, say, El Paso and San Antonio, Texas, look nearly alike. But the difference in vapor pressure makes the two localities very different in their habitability.

As far as solar ultraviolet radiation is concerned, it is still uncertain whether it is beneficial in all cases or not. Its absence has sometimes been observed to coin-

cide with uncleanliness, malnutrition, darkness, cold, and similar conditions. A simple recording ultraviolet radiation meter might further the use of sharply defined ultraviolet doses in climatotherapy.

Pollens and industrial aerosols are well known and frequent forms of noxious constituents of the air. Detailed studies, especially of the dependency of air pollution on weather, would facilitate the protection of the community.

In contrast to the situation outlined above, outdoor experiments made in the field of "statistical bioclimatology" are far more numerous than those made in the climatic chamber. The solution of these problems might not be found by additional simultaneous observations of the outbreak of illness and weather elements or of weather complexes such as fronts. There are too many unknown factors which might influence the result. If one single element, such as ozone, is thought to be responsible, every effort should be made for the study of its effects, using physiological methods and climatic chambers. Generally, we urgently need physiological methods indicating small discomforts from weather and clinical methods for the detection of the slightest and earliest traces of the various illnesses referred to above. With such data available, a statistical correlation of meteorological and medical phenomena could become fruitful.

After completion of this manuscript the excellent monograph, "Physiology of Heat Regulation and the Science of Clothing" [64], appeared. It describes in full the field of research which is briefly discussed here. The monograph is based mainly on the large number of investigations in laboratories in the United States during World War II.

SOME PROBLEMS OF ATMOSPHERIC CHEMISTRY*

By H. CAUER

Institute for Chemical Climatology, Hohenberg a. d. Eger, Germany

INTRODUCTION

Although a good basis for chemical investigations in the atmosphere was established during the past century by Smith [53], and individual investigations such as those by Schmauss and Wigand [51] have been of great value, a full incorporation of chemical concepts and procedures into the consideration of meteorological phenomena has not, up to the present, become general. This is due primarily to the fact that satisfactory methods for the chemical analysis of air do not yet exist, and furthermore that none of the available methods lend themselves to the routine procedures which have been possible in the measurement of physical phenomena. At present, experimental work of this kind requires a good chemical-analytical knowledge and many years of experience if passably reliable results are to be obtained. Since the pertinent methods consist of special techniques for detecting traces, their mastery cannot be expected by physicists, even those whose minor field is chemistry or physical chemistry. On the other hand, although the analytical chemist has the necessary specialized knowledge, including the requisite information in the physico-chemical field, he lacks a fundamental insight into the problems of physical meteorology.

Therefore, the most important task in the development of chemical meteorology and climatology appears to the author to be the training of analytical chemists who study physical chemistry and physical meteorology as secondary fields. A second requirement, and one which will necessitate the active participation of the analytical chemist, is the further development of methodology. Not until the development has been more or less completed will it be possible to undertake a third major task, that of making many parallel investigations in micrometeorological as well as world-wide networks under the most varied atmospheric conditions and at various heights above the ground.

METHODS

As a survey of the chemical methods available today, two groups of methods developed in Europe will be discussed briefly: (1) the absorption-tube method for detecting the presence of secondary gaseous substances, and (2) the condensation method for the analysis of water-soluble constituents of the air which form condensation nuclei.

Absorption-Tube Methods for Detecting Traces of Gaseous Materials. The iodine of the air is determined, in principle, according to the method developed by von Fellenberg [25], that is, by absorption in a very dilute aqueous K_2CO_3 solution and final determination by colorimetric or titrimetric techniques. This method has been greatly simplified by the author with the apparatus shown schematically in Fig. 1. It consists of a motor-driven pump, dry-gas meter, and Cauer absorption tube. As a result of control investigations by Quitmann [44], this equipment has been simplified and can be used for serial and uninterrupted tests. It is made in three sizes [7]: an apparatus mounted on a stand equipped with an absorption tube (circulation capacity 10 m^3 hr^{-1}); a readily portable apparatus provided with an absorption tube (circulation capacity 0.6 m^3 hr^{-1}); and a smaller apparatus for measuring small amounts. The use of this equipment has been described elsewhere [5]. The chemical analysis requires 60–90 min.

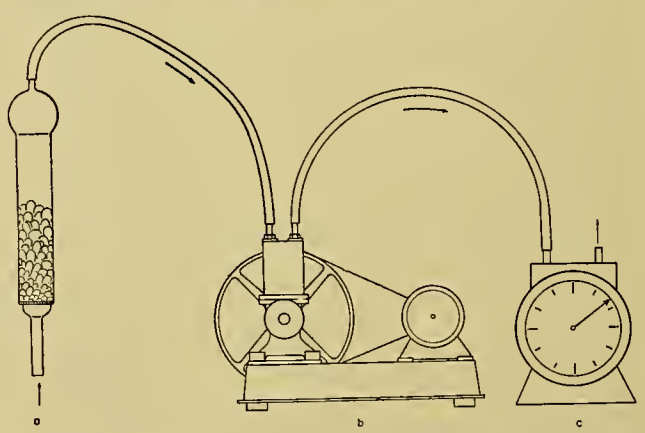

FIG. 1.—Schematic representation of apparatus for detecting traces of gaseous materials; (*a*) Cauer absorption tubes without separate charging vessel; (*b*) motor and pump; (*c*) dry-gas meter.

Depending on the concentration present, the total chlorine (chloride, free chlorine, chlorine dioxide) is determined, according to Cauer [6], with one of the devices mentioned above, using a 1.5 per cent solution of KOH. Final determination is made by titration with $AgNO_3$. According to the data given by Nitschke [41], best results are obtained in alcoholic solution after the method of Bang and Blix. One-sixth of the free chlorine escapes analysis. The air sampling requires 10–60 min, the chemical analysis about 1 hr.

The sulfuric acid or the sulfates and sulfites are determined by two methods. The first is a nonquantitative standard method developed by Liesegang [38], which measures the quantity of sulfates plus sulfites precipitated during a period of 100 hr on a porcelain bell equipped with an extraction thimble. The end determination is made gravimetrically as $BaSO_4$. The method

* Translated from the original German.

gives an insight into the distribution of the sulfate up to 50 km leeward of intense sources of gaseous effluents. Exact instantaneous measurements can, of course, be made only with the apparatus discussed above in the paragraph on the determination of iodine. For this purpose from 0.05 to 20 m^3 of air (depending on the concentration) are washed in aqueous solutions of alkali hydroxides or carbonates, a process which requires 5–120 min. Subsequent analysis requires about 60 min.

Hydrogen sulfide is determined, according to Quitmann [45], by absorption in 2–3 cc of acetic cadmium acetate solution, with the smallest Cauer apparatus. For this measurement, 300–500 l of air are washed in about 60 min. The end determination is performed with *KI* solution in approximately 30 min.

Nitric acid is determined in the same way as sulfuric acid, in dilute aqueous solutions of alkali hydroxides, using the same equipment. After reduction with metallic zinc, the nitrate is determined as nitrite with Griess's reagent [47]. The time required corresponds to that needed for the determination of H_2SO_4.

Ozone is determined, according to Cauer [6], with the aid of the intermediate-size apparatus described previously, which is provided with an absorption tube (circulation capacity 0.6 m^3 hr^{-1}). The classical method of detection, based on reaction with *KI* in a neutral aqueous solution, is used. From 100 to 300 l of air are washed within 10–30 min in 10 cc of 0.2 to 0.6 per cent aqueous $NaC_2H_3O_2$ solution (*p*H 6.7–7.1) which contains 50 μg iodine ions as *KI*. The iodide is oxidized to I_2 by O_3 and the I_2 is removed by the air stream. Therefore, in the end determination the residual nonoxidized iodide is analyzed according to the method of von Fellenberg [25], and the difference is computed in terms of O_3. For experienced chemists, this analysis requires 20 min, but necessitates great care, and is difficult for nonchemists. By working in shifts, four trained operators can make two or even three parallel series of hourly measurements for several weeks at a stretch. The method is inapplicable if the air contains relatively large quantities of nitrite and of free halogens which, because of their acidic character, nullify the buffer effect. Unpublished experiments, made on the North Sea, have shown that even at a high natural content of total Cl_2 the buffer effect is not impaired, because the dilute free chlorine present is evidently converted very rapidly into chlorine dioxide. A corresponding absence of significant errors has also been noted in the presence of large quantities of natural nitrite [13]. A similar method, published later by V. Regener [49], must be considered a close parallel to the foregoing technique because of the addition of the buffer effect contributed by Ehmert. Unfortunately, because of difficulties inherent in the apparatus, this procedure is even more awkward to carry out than Cauer's method.

Simplification of the method for O_3 determination appears to be an important problem. In the author's opinion, the approach to this problem is hardly to be found in deep cooling and absorption in silica gel (because of increased possibility of error), but perhaps in the oxidizing effect of O_3 on aldehydes, as attempted by Briner and Perrottet [4]. The approach used by Dirnagl [22] and Curry [19] for developing automatic recording of the *KI* method has much to recommend it. This apparatus is a development of the automatic recorder for the determination of H_2S, according to Kraus [32]. According to their technique, a large unmeasured quantity of air is blown mechanically on a filter paper soaked with a neutral *KI* solution. At stipulated time intervals a fresh portion of the filter paper is exposed by clockwork. The resulting coloration can be calibrated by the exact methods discussed previously. An improvement of this method and a reduction of its cost would offer new possibilities for more extensive comparative investigations. In this respect, to be sure, technical deficiencies cannot be justified by assuming that an additional oxidizing factor, such as O_x, might be present, or even that the total oxidation value is being measured [22]. The latter is certainly unlikely, for NO_2 and ClO_2 oxidize in acidic solution at the *p*H value used, but by no means completely.

The total oxidation value is determined, according to Cauer [6], in the same way as is O_3; not in neutral solution, but in H_2SO_4 solution (0.05 per cent) having a *p*H below 2.8. The oxidized I_2 is calculated in terms of active *O*, in which two iodine atoms correspond to one oxygen atom. The time required for sampling and analysis is the same as for O_3.

The total reduction value, according to Quitmann [44], is determined with the aid of the smallest of the Cauer absorption tubes, by washing 20–50 l of air in 3 cc of a concentrated $K_2Cr_2O_7$–H_2SO_4 solution for 15–30 min. The final determination consists of the addition of *KI* and titration of the liberated iodine with thiosulfate. The difference between this iodine value and the one which would have been determined if no chromate had been reduced by substances in the air corresponds to the reduction effect of the air and can again be computed (according to the formula: 2 iodine = 1 oxygen) in terms of the active oxygen missing for the oxidation of the reducing substance (see Table III). In this way the total oxidation values can be compared directly with the reduction values. If the reduction value is divided by the oxidation value, the quotient represents the *Redox value* of the air. During World War II a simple, rapid method for determining the reduction value, designed for hygienic purposes, was developed by the author. For meteorological purposes, this method, as yet unpublished, might also be applicable to air that is not too humid.

Condensation Method for Determining Traces of Substances Which Form Condensation Nuclei. Condensation nuclei are obtained, according to Quitmann and Cauer [47], or according to H. Cauer and G. Cauer [15], by cooling the highly polished metal surfaces of a Cauer condensation sphere below the dew point but not to the freezing point. The water in the thin layer of air very close to the metallic surface is rapidly attracted by chemical substances suitable as nuclei, and droplets are

subsequently deposited.[1] As a result of thermal convection, this process is continuous in the newly advected air, and fog particles, proportional in number to the mass of air flowing close to the metallic surface, adhere to it and finally drip off into a graduated tapered vessel. The condensation apparatus (Fig. 2) consists of an egg-shaped dew-cup which is plated with *Cr* or *Ni*, is well-polished, and has a capacity of two liters of ice water.

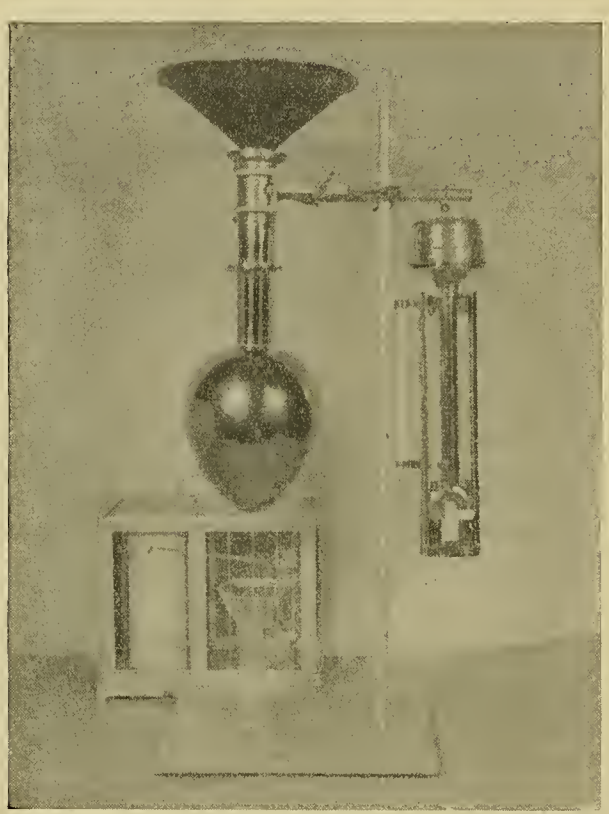

FIG. 2.—Apparatus for the analysis of traces which form condensation nuclei. Center, Cauer condensation dew-cup; at right, Assman psychrometer; below, thermohygrograph.

During the time required for the dew deposit, 20 min in most cases, the mean absolute water content of the air must be determined in the immediate vicinity with the aid of an Assmann psychrometer or a thermohygrograph. Depending on the number of analyses and the substances to be investigated, amounts of condensate ranging from 1 to 20 cc are collected. During ventilation the sphere must be shielded from direct sunlight and dust. Hence it cannot be used during storms; likewise, it cannot be used when the absolute humidity of the air is small. During cold weather a coating of hoarfrost is produced by charging the sphere with a refrigerant.

Insofar as possible, the chemical substances are analyzed by the methods usual in water analysis [47]. For other substances special trace-detection methods are used, for example, spot analyses [15, 24]. The number of analyzable substances can be increased greatly with the help of a spectrograph. For this purpose a measured quantity of dew is carefully evaporated in a platinum dish and the residue is picked up with the heated carbon rods of the spectrograph. Several standard solutions of different concentration are treated in the same way. The subsequent spectrophotographs show the presence and order of magnitude of substances in the dew by the spectrographic lines and their intensity. From the measured concentration of substances in the dew, and on the basis of the simultaneous measurement of the mean absolute humidity, the quantity of chemical substances capable of forming condensation nuclei is computed for one cubic meter of air. It was unexpectedly found that the highly hygroscopic compounds can be determined more accurately in this way than by the absorption-tube methods mentioned previously. When frost deposits are used, however, the results must be multiplied by a factor of three [15], a fact which was still unknown at the time of the first publication of the method [47], and for which no adequate theoretical explanation has been found.

By this method the halides, sulfates, ammoniacal substances, soluble alkali compounds, and alkaline-earth compounds as well as organic materials such as formaldehyde can be quantitatively determined. Metals can be determined particularly well with the aid of the spectrograph. Other substances such as nitrates and nitrites can also be determined with the aid of the condensation sphere, but only that portion of the substance which can act as condensation nuclei, depending on the relative humidity and pressure in a given case. The physico-chemical reasons for this phenomenon are still unexplained. The nonpolar gaseous components of the air, such as the two principal components, O_2 and N_2, cannot be analyzed by this method.

RESULTS FROM ABSORPTION-TUBE METHODS

Iodine of the Air. Contrary to previous assumptions, the iodine in the air over central Europe [10] does not originate directly from the ocean but comes principally from the combustion of iodine-containing ocean products for the extraction of iodine and for domestic heating in coastal towns. The principal sources of the iodine in the air over Europe consequently are Brittany, Scotland (Shetland Islands), Scandinavia (Stavanger region), and to a minor extent Spanish Galicia (Finisterre).

The iodine is lifted off the ground by convection cells and is transported in the air masses as far as the Carpathians; in the case of intense storms this distance is occasionally covered in less than twenty-four hours. The dilution occurring during this process is at first very marked, but later it proceeds at a continuously decreasing rate. Under normal conditions, the mean iodine content along the coast of Brittany is 0.4 $\mu g\ m^{-3}$; during the combustion of seaweed (*laminaria* and *fucus*) it runs to 6000 $\mu g\ m^{-3}$. In central Europe it

1. The direct condensation of steam on cooled, polished, metal surfaces without the existence of condensation nuclei amounts to almost one per cent of the total possible precipitation, according to Mayer [39] (this percentage also includes the direct condensation on the surface of the water). This occurrence is so low that the validity of the following chemical analysis is not affected.

normally ranges up to 0.05 $\mu g\ m^{-3}$, but during the intrusion of air masses from districts where the smoldering of seaweed is practiced it is 0.6 $\mu g\ m^{-3}$ (von Fellenberg's mean [25]). In eastern central Europe (Szepes, Slovakia) the normal is 0.08 $\mu g\ m^{-3}$, but the intrusion of air from seaweed-burning regions raises this value to 0.13 $\mu g\ m^{-3}$. If air from the interior of the continent (Russia) reaches central Europe, the mean there drops to only 0.1 $\mu g\ m^{-3}$. If the natural mean, that is, that quantity of iodine which directly and solely originates from the sea, is calculated, the value found for central Europe is 0.0025 $\mu g\ m^{-3}$. The higher values actually found reveal the effects of industrial processes, of coal combustion, and of decomposition processes on the earth's surface.

Under the influence of light, and to a lesser extent of O_3, or by autocatalytic processes, there exists an iodine cycle between the gaseous phase and a state wherein the iodine is dissolved in droplets. If the iodine is dissolved as iodide ion, it is easily oxidized to molecular iodine, escapes as gas from its solution, and when further oxidized forms iodine pentoxide (which is intensely hygroscopic and nucleogenic). However, by reduction of the free iodine to hydrogen iodide and subsequent formation of condensation nuclei, the iodine can again return to the dissolved state.

Ozone of Air Strata near the Ground. Repeated measurements [8, 9, 13, 14, 50, 54] show that the concentration of O_3 in the air near the ground is, on the average, independent of the height of the sampling point above sea level. Means and deviations shown in Table I support this conclusion. Only a mean of individual measurements made by Ehmert [23] during flights at altitudes from 1000 to 8000 m above the ground is essentially higher than the other means. The peak values were found by Ehmert at the level of the cumulus and stratus cloud cover. By using optical methods, E. Regener [48] also found a few high values at greater heights in the troposphere during thunderstorm conditions, that is, at a time when air was not only being transported downward from above, but also upward out of the thunderstorm region where electrical equalization processes between clouds were taking place. For this reason, O'Brien, Mohler, and Stewart [42, 43] were unable to confirm these findings for stable anticyclonic conditions. These authors found smaller concentrations of O_3 in the lower stratosphere than at the ground. In such cases, Regener visualizes a damming effect of the O_3 flow at the ground, a phenomenon that, however, would be possible only if the reducing substances in the air were present in far smaller quantities, and if the oxidation power of O_3 were small enough to resemble that of O_2. In the "pure" mountain air of Ober Schreiberhau, Cauer [12] found reduced substances to be in excess by a factor of 160, that is, there was an active oxygen deficiency. Laboratory experiments have shown that the O_3 from a limited O_3 source does not decompose rapidly, but reacts almost instantaneously with the reducing substances of the air so that after a brief time nothing further can be detected save the odor, which evidently characterizes the reaction products rather than the O_3. Since the reducing substances originate principally from anaerobic decomposition processes of organic material in soils and waters whence they rise upward almost continuously, the O_3, assuming its exclusively stratospheric origin, could appear at ground level only at intervals and for short periods during conditions of subsidence from greater altitudes. Likewise, an accumulation of O_3, whatever its source, can occur only where the reducing substances in the air or the decomposing organic substances in the soil are lacking. This would probably be the case in extended desert regions, such as the Atacama Desert.

Table I. Surface Ozone Concentrations in Europe

Location	Altitude msl (m)	Mean ($\mu g\ m^{-3}$)	Range ($\mu g\ m^{-3}$)	Number of analyses
Friedrichshafen, Lake of Constance	1000–8000	38*	23.8– 77.8*	14
Jungfrau, Switzerland	3450	11.9	4.0– 30.0	20
Weszterheim, Tatra, Slovakia	1010	30.0	5.0–102.0	412
Ober Schreiberhau, Riesengebirge	750	16.8	0.3– 36.0	351
Glatzer Bergland, Silesia	400–800	14.5	0.0– 40.0	448
Koenigstein, Taunus:	400			
More than 20 m from lightning rod				
General		15.9	0.0– 99.9	472
Cloudy weather		18.3	1.3– 99.9	339
Fair weather		10.6	0.0– 35.0	133
Not more than 0.02 m from lightning rod				
General		31.7	1.9–189.1	128
Cloudy weather		46.9	5.2–189.1	77
Fair weather		11.4	1.9– 87.5	51
Island of Norderney, North Sea:	20			
General		24.8	5.5– 73.4	181
Near a grounded conductor tip (~0.02m)		35.5	3.1–126.1	48
Berlin, radio antenna mast	175	6.0	0.0– 20.0	50

* Approximate values.

Therefore, it is hard for a chemist to conceive of the generally assumed presence of an "ozone flow" from the stratosphere, whose richest O_3-bearing strata at 22–26 km altitude contain no more than about 200–300 $\mu g\ m^{-3}$, especially because the short-wave insolation causes, in addition to O_3 formation, an almost equally intense dissociation at high altitudes. Hence, the chemist is compelled to seek other continuously active and especially more copious O_3 sources than that which the stratosphere can offer, even under optimum conditions (except in the case of foehn). Moreover, the results of a series of measurements made in the Riesengebirge [50, 54] and in the Taunus [13] agree with these considerations. According to these results, strong fluctuations are usual even for stable weather conditions without high-reaching turbulence; unusually low or even zero values were found for air that had subsided from a considerable altitude (above 3000 m) during foehn conditions or as a consequence of subsidence in an anticyclone over the plains. In other words, the zero values occur in air with few large nuclei, but with relatively considerable quantities of motile small nuclei, that is,

during conditions of sharply increased conductivity or low electric potential. This phenomenon is strikingly parallel to the low O_3 values in air that has been enriched by radioactive emanations, that is, the highly conductive air at radioactive spas [9, 19]. The objection could be raised here that O_3 is produced during the decay of radium. This is, indeed, the case for the principal members of the decay series, or rather, O_3 is produced by their electrons which are either not decelerated or decelerated only slightly. However, the quantity of O_3 thus produced is extraordinarily small, although numerous excited and ionized atoms and molecules will simultaneously be formed by secondary radiation. Therefore the principal effect of the emanations from the ground is probably not an increase of the O_3 content but an increase of the ionization of the air. The strongly decreased values observed during foehn can thus be explained by the fact that air subsiding from greater altitudes is already deficient in O_3 as well as by the fact that the O_3 is almost completely eliminated by reduction processes in strata near the ground because, as a result of the high conductivity, no electron accelerations sufficiently great for local O_3 formation can occur from grounded point dischargers in the air near the surface, or between clouds. Equally low values of O_3 are observed at the inception of condensation phenomena during the formation of fog and protracted precipitation with mist, and likewise in the presence of tobacco smoke and cooking vapors indoors. The reaction mechanism for the elimination of O_3 in such cases is still unexplained. It must be assumed that O_3 during fog formation reacts with reducing substances such as ammoniacal compounds. This appears to be the reason for the low values and small fluctuations of O_3 in forests, where particularly intensive exhalations of reducing anaerobic decomposition products occur.

During fair weather, the mean values increase. The air behind a cold front, which has few middle- and large-sized nuclei because of their removal by rain, is frequently still poor in O_3. The O_3 values increase only when the number of small nuclei decreases and that of the large nuclei increases, or, in other words, concurrently with the intermittent increase of the potential occurring frequently during such weather. Similar phenomena may be observed when rather low clouds or high fogs move by and when brief precipitation sets in (Lenard effect). The abrupt increase of the values during subsidence phenomena from *lower* altitudes (height of the lower clouds) is also very informative. This increase, in the author's opinion, is caused by O_3 which originated during electrical discharge processes in nonhomogeneous fields between clouds. However, in addition to this, the formation of O_3 at grounded point dischargers might be of considerable local importance. In fact, it has been shown by investigations on lightning rods [13] that, even in fair weather, values are found around these devices which are three times larger than those recorded farther away. Thus, the quantities of O_3 that emanate from such discharger tips into the surrounding air are considerable as compared with the average total O_3. Ozone from grounded dischargers was recently found by the present author in investigations over a limited measuring field in Wyk on the island of Föhr. In these investigations it was particularly striking to note that considerable absolute differences occurred over distances of a few meters, but that the trend in the fluctuations was everywhere the same without exception. At constant wind the values were consistently higher at one measuring station than at the other, a behavior pattern which was sometimes reversed when the wind changed. From the foregoing observations one gets the impression that sometimes the one measuring station and sometimes the other was subject to the effect of O_3 from a more intense source in the field.

A rough calculation by Reiter,[2] based on findings by Schottky, shows that, with a potential of 130 v m^{-1} on a hemispherical conductor tip of 0.5 cm^2 surface area one meter above the ground, the potential may reach 1,000,000 v m^{-1} over partial conductor points (microscopically small elevations). However, a potential of only 500,000 v m^{-1} is sufficient to produce electrons having the acceleration of 8 ev required for O_3 formation, assuming an average of 10^5 electron impacts before adhesion to gas molecules. The formation of O_3 at grounded conductor tips such as on lightning rods therefore appears possible even in a normal electrostatic field. To what extent this occurs at less elevated conductor tips has not been investigated sufficiently to permit any definite statements. However, chemical measurements indicate that O_3 is formed even with lower points during rather brief intensive fluctuations of the electric field. It is not possible with our present knowledge to appraise the significance of such O_3 formation near the ground as compared with the O_3 production in nonhomogeneous electrostatic fields between clouds, augmented perhaps by O_3 from the stratosphere, although the subsidence of O_3 from great heights has never been satisfactorily demonstrated. For the solution of this problem extensive investigations of O_3 are needed, involving not only measurements from field stations and aircraft, but also analyses with respect to the companion reactions and the reaction products of O_3. Furthermore, the rapid fluctuations (within seconds) of the electrostatic field, and the change of the number of nuclei must be measured simultaneously, as was done in the extensive work by Landsberg in collaboration with Amelung [1].

Total Oxidation of the Air. Fluctuations of the oxidation values are preponderantly parallel to those of O_3, but opposing trends may also occur. In the Taunus region [13] the mean was 15 μg active oxygen per cubic meter, in Norderney [14] it was about 24 $\mu g\ m^{-3}$. Previous oxidation values [11, 12] were always lower as compared to the values derived from the deficiency in active oxygen, or from the reduction values. Where reducing substances are lacking, as in desert regions or in the Arctic, the total oxidation values are probably large and effective. The total oxidation values are produced by the oxidizing effects of O_3, NO_2, ClO_2, Cl_2, Br_2, I_2, and oxides of the latter two halogens. Despite thousands of analyses by means of titanium sulfate,

2. Personal communication.

hydrogen peroxide could be detected only in the immediate vicinity of fireplaces and therefore cannot be considered an oxidizing factor of practical importance.

RESULTS FROM THE CONDENSATION METHOD

This method takes into account merely those condensation nuclei around which water droplets form by condensation, not only during the slight water-vapor supersaturations and pressure fluctuations possible in the free atmosphere, but also even before saturation is attained. The condensation nuclei thus represent distinctly hygroscopic substances, that is, those secondary constituents of the air which possess the most intense molecular attractive forces (capillary forces). Their radii range in order of magnitude from 10^{-7} cm to 10^{-4} cm. In the following discussion the averages and fluctuations obtained thus far will be considered; the data are given in Table II.

Table II. Surface Concentrations of Nuclei-Forming Substances in Europe

Substance	Region	Mean ($\mu g\ m^{-3}$)	Range ($\mu g\ m^{-3}$)
Mg	Mainland and coast	3.1	0.0– 65.2
Cl	Mainland and coast	32.2	0.0–964.8
SO_4	Mainland and coast	2.6	0.0–732.0
NH_3	Mainland	7.9	2.5– 54.4
NH_3	Island of Norderney	5.5	0.0– 25.0
NO_2	Mainland	1.0	0.0– 21.6
NO_2	Island of Norderney	0.14	0.0– 1.2
H_2O_2		0.0	0.0– 0.0
$HCHO$	Mainland	0.5	0.0– 16.0

Chlorine of the Air. Contrary to previous concepts, it is not the sulfates but the chlorides that represent the principal mass of nuclei-producing substances in Europe, except in the more populous regions.

In contrast to the spray theory, according to which sea salts are transported chemically unchanged in droplets of sea water, lose their water in dry air, and function subsequently as condensation nuclei far inland, it was possible to determine that a sharp chemical disintegration of the droplets takes place very soon after lifting from the ocean surface [16, 17]. The ratio of the Cl^- to the Mg^{++}, K^+, and Na^+ on the high seas, as determined during submarine voyages, does not correspond even approximately to the ratios in the sea water, where, for example, a constant weight ratio, $Mg/Cl = 1/15$, is found. The chlorine in the gaseous phase apparently escapes rapidly from the droplets by autocatalytic processes and under the influence of O_3 [6]. However, the chlorine evidently remains in this state only a short time [16, 17]. Under the influence of light quanta it is partly converted with hydrogen into HCl, which, being hygroscopic, produces condensation nuclei, and is partly oxidized to ClO_2, according to data obtained on islands in the North Sea. This ClO_2 is likewise productive of condensation nuclei and dissociates in the dissolved droplets to form $HClO$, or HCl and $HClO_3$. These alternations between the dissolved and gaseous phases probably occur in the air in the nature of a continuous cycle. In the eastern regions of central Europe Cl_2 is occasionally absent from the air, even in the form of chlorides. The invasion of maritime air into these regions (Tatra and Riesengebirge) can often be detected by the fact that chlorides appear and that their amounts increase rapidly. The alkali ions and alkaline-earth ions, which are enriched by the liberation of Cl_2 from the droplets, do not show such a cyclic phenomenon. They combine with CO_2 and diminish rapidly by precipitation.

Nitrogen Compounds of the Air. Nitrites and nitrates appear to be quantitatively dependent on electrical discharge phenomena, on the heating and humidity of the ground (bacterial activity), and on pressure fluctuations [11, 12]. In the air of high mountains they represent important condensation nuclei (nitrite production from rock formations in the Andes or in the Atacama Desert). In contrast, they exist only to a minor degree in maritime air.

Ammonia or ammoniacal compounds appear to depend quantitatively on anaerobic processes of decomposition, combustion processes, and periods of inflorescence (*e.g.*, of the *Prunus* genus) [12], and, next to chlorides, represent the largest group of substances which form condensation nuclei over the European continent. They occur over the entire continent without exception. Only on sand islands having sparse vegetation and human population are zero values found in maritime air. In the case of land winds that have traversed the sea, low values are also encountered.

Formaldehyde of the Air. Formaldehyde was found to be an index of the presence of incomplete combustion processes. No indication of a transportation by subsidence from high altitudes, a process assumed by Dhar and Ram [21] and by Groth and Suess [27], could be found up to the present time. Some of the results have been published elsewhere [28].

Table III. Average *p*H Value of the Aerosol and Mean Reduction Values of the Air

Location	Altitude msl (m)	Mean *p*H value	Mean reduction value (active oxygen deficiency in $\mu g\ m^{-3}$)
Nebelhorn, Alps	1000-2000	3.4	—
High Tatra, Slovakia	>1000	4.0	—
Ober Schreiberhau, Riesengebirge	50	4.7	160
Berlin	25	6.2	1600
Island of Norderney, North Sea	10	4.6	—
Diesel engine rooms	—	5.2	18,800

The *p*H Value of the Aerosol. The mean *p*H value of the condensation nuclei seems to be a function of the mass ratio of the hygroscopic acidic and basic secondary constituents in each case (see Table III). In high mountains (1000 m above sea level), the strongly acidic average *p*H value (bactericidal for pathogenic bacteria) is due to the decrease in ammoniacal substances, so that without the attendant buffer effects the nitrite present in the droplets is able to dissociate strongly. In the mountains at an altitude of only 700 m the mean is forced into the weakly acidic range (which

arrests virulence), because of the increase in the concentration of ammoniacal substances in the nuclei, whereas in Berlin the mean *p*H value is forced almost to the neutral point (which promotes virulence). Conversely, the mean *p*H value on the Island of Norderney again lies in the weakly acidic range, because of the lack of ammoniacal substances. In this case, however, the weakly buffered acids are not nitrites but hydrogen compounds of the halogens originating from the sea.

WORKING HYPOTHESES

Significance of Molecular Forces for Condensation. The unexpected results of quantitative analyses obtained by the condensation method gave the first stimulus to the theoretical consideration of condensation [12]. If gaseous substances subsequently dissolve in suspended drops of pure water, an equilibrium must occur between the gaseous and the dissolved portion of the gas. This precludes a total quantitative determination by analysis of the dissolved portion only. The adequacy of a quantitative determination rests therefore on the assumption that prior to the condensation a certain orderly arrangement exists between the corresponding gaseous chemical substances and the water-vapor molecules. The hygroscopic substances accordingly represent an integral component of numerous condensation nuclei, owing to their attractive forces which are inherently stronger than those which the water molecules exert upon one another. Wilson [59] and Wegener [57] were aware that the laws of thermodynamics are insufficient to explain cloud formation. According to contemporary concepts, as treated by Wolf [60], a gas (water vapor) is not condensable at finite temperatures if only elastic impact forces exist between its molecules in accordance with the Boyle-Mariotte law. To explain condensation (cloud formation), the chemist must therefore have recourse to intermolecular forces and, in the last analysis, to processes of atomic energy. This approach was initiated by Lenard [37] prior to 1914. He was followed by Volmer [56], who, however, did not recognize as clearly as Lenard the great significance of the short-range forces manifest in the nuclei formation *before* water-vapor saturation (*e.g.*, fog formation by NH_4NO_3 produced by O_3 and other factors, or even by artificial acidic fogs $Cl \cdot SO_2 \cdot Cl$). He believed that it was possible to explain water-vapor aggregation and condensation into droplets by relatively strong supersaturation alone without the aid of nuclei. The four types of short-range molecular forces will now be discussed in the light of our present knowledge.

Polar Forces. These forces, which are of electrostatic nature, give rise to mutual orientation of the molecules, particularly that between electrical charge carriers and the dipole. As in the case of the ion atmosphere in solutions treated by Debye [20], it is obvious to assume that neutral dipoles of the water vapor become attached in a more or less oriented manner to charged gas molecules and form a "cluster." At any rate, this clustering can be considered as the origin of the so-called "small ions" in air (water-vapor molecules, $r = 1.4 \times 10^{-8}$ cm; small ions, $r = 7 \times 10^{-8}$ cm). Spatial considerations may require a certain supersaturation before the small ions can grow sufficiently large to become visible. There is room around the ion for only a restricted number of oriented water molecules. Only when supersaturation occurs, or in the course of an increased number of collisions, is it possible for additional, similarly oriented dipoles to penetrate this configuration. In this process the centers of the molecules approach each other and as a result the induction forces, discussed below, become effective and further increase the attractive forces of the molecules. The free rotation due to the thermal motion is thereby considerably diminished and is even nullified during sufficient, say adiabatic, cooling. If charged gas molecules were to adhere to varyingly large groups of water-vapor molecules scarcely, if at all, affected by molecular forces, the so-called "small ions" would increase in size irregularly and at a much lower supersaturation. In the free atmosphere the majority of the small, charged nuclei do not grow into large ones, since small ions vanish by recombination and by association with medium and large nuclei which are produced by more strongly hygroscopic substances (tangling of chains and rings of dipolar substances with water-vapor molecules, resulting in condensation—see below) and which possess an electrical double-layer.

Dipole Forces. These forces, which are also of electrostatic nature, orient the neutral, permanently dipolar water-vapor molecules with respect to each other. This orientation is achieved without the aid of extraneous ions and solely by the polar attractive forces between dipoles. As the temperature of the system is lowered, the free rotation ceases here also. Depending on whether the water dipoles come in contact with each other or with different dipoles (1) a simple super molecular formation may occur with dipoles nonpolarly parallel to each other, (2) a ring formation may occur, or (3) a chain formation may occur when the dipoles are in polar arrangement with subsequent tangling. Tangling phenomena involving dipoles of supercooled liquids (rubber) were observed by Debye. In a conversation with the present author, Hückel and Eucken advanced the idea that water-vapor molecules unaffected by an ion and not in combination with hygroscopic substances occur principally in groups of eight (rings), which are in equilibrium with groups of four (rings) and with single molecules. Because of their closed form, the pure water rings, in the present author's opinion, are probably less suited to formation of nuclei than are the chains having admixtures of foreign substances. In the latter, a more rapid growth and tangling can occur as a result of the greater proximity of the centers of the molecules. Furthermore, for the same reasons, these chains probably resist dissolution from an addition of heat somewhat more strongly than do the ring-shaped, readily dissolvable, pure water rings. Naturally, dipoles of the most varied types, such as NH_3, HCl, H_2SO_4, and H_2CO, unite with the dipole H_2O. The decisive factor for the foregoing process is the dipole moment (the unit of which is 1 "debye" (D) $= 10^{-18}$ electrostatic units) of the two substances, since the attraction at sufficient proximity is propor-

tional to the product of the two values of the dipole moment. The effect of two dipoles upon each other is one of attraction, repulsion, or relative cancellation, depending on their mutual positions. It could be assumed that in gases with freely rotating molecules (thermal motion) these forces mutually cancel in the mean. Actually, however, according to Wolf [60], the rotation is not uniform when dipoles move past each other, since the positions of attraction (smaller potential energy) are preferred to those of repulsion. In addition the dipole movements are probably somewhat affected by the electrostatic field, since by means of X-ray techniques Német [40] found a relatively large effect of the electrostatic field on the structure of ice.

The behavior of azeotropic mixtures is further evidence for the approximate correctness of these concepts. For example, if *HCl* of any concentration is allowed to evaporate at normal pressure, an equilibrium at a concentration of approximately 20 per cent acid is reached in which the ratio of acid molecules to water molecules is 1/6, that is, the same ratio as for an hydrochloric acid hydrate which has been arranged by dipole forces. In effect, therefore, all the molecules that were not retained by a small excess of attractive forces are vaporized. For the condensation of water molecules on *HCl* it is significant that the recombination at normal pressure takes place in the same molecular ratio 1/8, regardless of whether a concentrated or a dilute acid is subjected to distillation. According to our present knowledge, this constancy of molecular ratios can be explained only by short-range forces pre-orienting the dipoles prior to condensation.

Computations from the relatively small Cl^- values in dew and hoarfrost at the North Sea by Köhler [31], and in Ober Schreiberhau by the author, showed that the hydrochloric acid nuclei—which were still assumed by Köhler to be *NaCl* nuclei—could have originated from a few molecules of *HCl* with eight times as many molecules of water.

Induction Forces. These forces, which are of electrostatic nature, originate when one pole induces a dipole moment in a neighboring pole; this dipole moment points in the direction of the inducing pole so that an attraction results between the inducing and induced molecules. The attraction is proportional to the product of the exciting pole moment (either a permanent dipole or an ionized gas molecule) and the induced dipole moment. This type of attraction, however, is far less significant than the dipole forces of permanent dipoles. These induction forces are probably important in condensation on walls by inducing a mirror dipole and are important for a similar reason in the case of condensation on solid suspended particles. However, for meteorological phenomena this is not too important, since many types of solid particles require a higher water-vapor saturation to produce condensation than is customarily encountered in the atmosphere. Other particles, such as ash dust with its hydrophilic compounds, for example, K_2CO_3 or freshly powdered quartz crystals, which are characterized by a highly active surface, possess readily inducible dipoles.

Dispersion Forces. These forces, which are of electromagnetic plus electrostatic nature, are based on the fact that alternating electric fields are produced as a result of the motion of electrons in an excited state. Under the influence of these fields, dipole moments, whose interaction produces a net attraction, are induced in each of two or more mutually approaching molecules. Their effect is far greater than that of induction forces. The dispersion forces are not a function of temperature; they are effective for relatively large molecules, at rather high temperatures, and also for nonpolar molecules. Their lifetime is extremely short. However, with adequate stimulus (ultraviolet radiation), the same atoms and molecules can be continuously re-excited.

Importance of the Order of Hydration for the Mode of Charging Nuclei. The electrical double-layer, a consequence of the hydration order, was recognized clearly for the first time during the observation of the chemical separation in the spray of salt sols already mentioned [18]. A description of a separation experiment of this type follows.

The mother liquor used for the atomization in this experiment contained *Mg*, *Cl*, and *K* in the following proportions: $Mg/Cl = 1/440$; $Mg/K = 1/4$. The *p*H value was 7.6. Fine droplets (of the magnitude of condensation nuclei) were produced by a jet of compressed air; at various distances from the nozzle they had the mean values given in Table IV.

Table IV. Aerosol Characteristics in a Spray Experiment

Distance of droplets from nozzle (m)	0.30	1.50	3.00
Cl/Mg	83	30	37
*p*H	6.9	6.3	6.3
Concentration*			
Cl	9	2.72	2.72
Mg	48	40	32
K	25	15	10

* In per cent of concentration in mother liquor.

At 1.50 m from the nozzle, after 45 min of atomization, 15 per cent of the total chlorine dissolved in the droplets was still present in the form of condensation nuclei, and 85 per cent in the gaseous phase, probably predominantly as ClO_2, Cl_2, and *HCl*.

The results show a strong escape of the Cl_2 (produced autocatalytically), as well as a separation of the Cl_2 component which has remained dissolved from the nonvolatile alkalis, and a lower *p*H value (more acidic) in the far-drifting, atomized component. This is possible only if there is an excess of cations in the interior of the coarse drops and an excess of *Cl* anions in the outermost molecular layer. In the atomization process, portions of this layer are removed as most finely divided, far-drifting water droplets, while the coarser drops containing the bulk of the mass fall to the ground near the nozzle. Such an arrangement of the chemical substances in the solution can be explained only by hydration, according to Born [3]. That is, neutral water molecules are attracted by the chemical ions; moreover, this

attraction increases as the size of the ion decreases. Water molecules thus attracted form the so-called water coating. Owing to the particular spatial conditions which cause a stronger pull of the large ions toward the interior, the hydrated ions now become arranged toward the center in the order of increasing size of their coating, whereas the "bare" ions (in this case the Cl^-) accumulate on the surface. Jebsen-Marwedel [30] states that for similar phenomena in fluid glass the "bare" ions, that is, those with smaller molecular forces, are squeezed into the surface. According to Benson [2], this surface activity as a preliminary stage of molecular separation is a familiar phenomenon in the case of foam. However, according to Whitney and Grahame [58], it also represents the basic reason for the occurrence of the electrical double-layer. Undoubtedly, this surface activity is also the basis for the electrical double-layer of droplets suspended in the atmosphere.

Ballo-Electricity. The precipitation electricity (Lenard effect, that is, negative charge of the fine particles and positive charge of the somewhat coarser ones) must also be affected by the order of hydration, according to the discussion above, because of its dependence on the double-layer. To prove this, experiments with atomization of drops in thunderstorm updrafts and experiments with falling drops (rain) were undertaken using dilute aqueous solutions of $MgCl_2$ and $[Mg(NH_3)_6]Cl_2$, corresponding to the concentration in raindrops. The atomized droplets were chemically analyzed and tested for charge at various distances up to 3 m from the nozzle. These tests were made in the same way with the falling of the central drops and the small secondary drops [12]. The investigations yielded the following information:

In addition to the appearance of the Lenard effect, a chemical separation occurred in the atomized drops such that the fine particles, which drifted to some distance after being torn from the bulk surface, were enriched with Cl^- ions and showed a decreased pH value (more acid), whereas the coarser particles which settled more rapidly were enriched with cations and showed a higher pH value. In the case of the falling drops the same difference could be found between the coarse main drop and the fine secondary drop which represents the outermost shell of the total drop.

Therefore, the separation of pairs of ions is to be regarded as an almost confirmed cause for the balloelectric charge in the case of the Lenard effect. According to the concepts of Simpson [52] and the presentation of Israël [29], the repeated breakup of the water drops in the cloud by updrafts is, indeed, the fuel of the storm machine. However, the then unknown electrical agent which is effective during this drop disintegration and which is responsible for a continuously renewed occurrence of the Lenard effect, can now be considered as recognized in the order of hydration that repeats itself after each drop breakup. The mechanism of the processes has not yet been explained in all its details, nor is the significance of this effect for thunderstorm formation completely understood.

Electrical Charge by Adhesion. In continuation of the concepts outlined above, this process is also linked to the order of hydration. This process takes place on suspended droplets and hence is not associated with drop disintegration, but is produced by the adhesion of a gas molecule, ionized by cosmic radiation, secondary radiation, etc., or by adhesion of a small ion. The adhesion to droplets is in all probability a selective process. If positive chemical ions are accumulated in the boundary layer of the droplet, negative particles are attracted and positive ones are repelled. If some other type of chemical phenomenon is responsible for the accumulation of negative ions in the boundary layer, the reverse occurs. This concept of the control of the charging process by chemical phenomena leads also to the explanation of the unipolarity of clouds. According to this working hypothesis, droplets of like origin and hence of like chemical composition must assume charges of the same sign. A selective association of small charge carriers was observed by Tyndall [55]. According to him, alcoholic gases capture principally negative carriers and this effect increases with an increase in the length of the carbon chain. If the dipole group OH is removed from such compounds, any effect on carriers ceases. Thus, one can imagine that clouds whose elements are of uniform chemical composition act like a filter on the smallest charge carriers of one sign. If, for example, over extended areas of blossoms (*Prunus*), heated air cools adiabatically as it rises to a greater altitude and forms droplets with an excess of the NH_4^+ cation in the surface layer, these droplets must become negatively charged. Conversely, droplets suspended directly above (as in inversions) with an excess of NO_2^- in the surface layer (condensation on nitrites) would become positively charged. Observations pointing in this direction (specifically, data from chemical experiments) were obtained in the High Tatra (Szepes, Slovakia) during the development of areal thunderstorms [11, 12]. Perhaps such a phenomenon is the explanation for the fact that frequently the upper portions of the thunderheads were positively charged while the bottom portions were negatively charged. During the penetration of droplets into clouds having a different type of chemical make-up, or opposite charge, electrical balancing processes and coagulation result. The consequence of this, in turn, is a different chemical make-up of the new droplets and thus new, rapid, layerwise coagulation. It is possible that the rapid fluctuations of the electrostatic field are correlated with such filter and coagulation processes. If this is true, perhaps these processes also control the stronger or weaker production of O_3 at the tips of grounded conductors as well as in nonhomogeneous fields between clouds. Their possible significance for thunderstorm formation cannot yet be evaluated from the available experimental data.

Ice-Particle Charging. This process was recognized as one of the most important sources of thunderstorm electricity in the informative studies by Findeisen [26] and might, in the final analysis, have no other origin than a chemical separation. Although in the case of ice a hydration equal to that in droplets cannot exist, at least a boundary layer arrangement with a double-

layer may occur. Particularly in the production of graupel, in which the liquid phase of the water customarily occurs in conjunction with the solid phase, such behavior must be expected, as is attested to by the very valuable physical experimental work of Lange and collaborators [33–36] on the Volta potential between the phases. They refer repeatedly in their papers to the significance of the molecular forces and the traces of chemicals in the orientation processes which run parallel to the crystallization and the melting. The orientation processes consist of wandering of ions, formation of double-layers, hydration, and dehydration. Exhaustive analyses of trace elements, especially concerning the chemical difference between broken-off crystal tips and the main mass of the crystal, might lead a step further in this case. In this connection, the information reported by Wall at the Geophysical Institute of the University of Frankfurt a. M. in 1948 is also important. With the aid of rotating mirrors he was able not only to ascertain the dipole character of snow crystals but also to observe, even at a low temperature, a liquid layer in their interior. The latter phenomenon is possible only if the liquid consists of a highly concentrated salt solution whose substances serve as condensation nuclei. An explanation of the physico-chemical phenomena at the interface between ice and mother liquid should, in the opinion of the present author, give more fundamental information concerning the charging of the particles than does the usual assumption of the presence of piezoelectricity.

CONCLUSION

The scope of research in the field of atmospheric chemistry could only be sketched in this highly compressed survey. Several promising lines for research in the immediate future have been suggested, with a brief discussion of modern methods, results, and working hypotheses to serve as a general background. The overall development of a practical "applied atmospheric chemistry" is an undertaking which will require two or three research teams of not less than eight or nine scientists well schooled in analytical and technical methods, equipped with first-class laboratory facilities, and working in collaboration. They could within a reasonable time develop experimental methods of a high degree of accuracy and speed. Simultaneous serial observations of various interrelated chemical substances in the atmosphere are badly needed, but very small groups will not be in a position to undertake the work required. Complementary physical measurements, such as nuclei counts and the measurement of ultraviolet radiation, should be undertaken simultaneously.

It is not unreasonable to expect that in a few years chemical concepts and techniques will not only be available for atmospheric hygiene, but will also be useful in general weather forecasting. The first rapid and usable techniques, important in the field of dynamic meteorology, possibly may not be connected with the determination of O_3 but with determinations of the pH value of aerosols and the reduction power. Such uses would be particularly valuable in that they would provide a rapid and accurate indication of the motion of air masses and equally reliable information about such factors as the degree of turbulence.

ATMOSPHERIC POLLUTION

Atmospheric Pollution *by E. Wendell Hewson* 1139

ATMOSPHERIC POLLUTION

By E. WENDELL HEWSON

Massachusetts Institute of Technology

INTRODUCTION

Contamination of the atmosphere by human activities has occurred in many countries and from early times [86]; with increasing industrialization such pollution is becoming more widespread and severe. Atmospheric pollution presents a problem the solution of which requires contributions from many fields, such as chemistry [60], city planning [87], legislation [93], public health [46, 93, 99], mechanical engineering [77, 93], meteorology [9, 19, 24, 39, 104], and plant physiology [45, 93, 97, 106]. Thus the analysis, measurement of concentrations, and methods of removal at the source of certain offending contaminants are chemical problems; city planning, by locating industrial plants most advantageously relative to population centers, makes its contribution; legal authorities draw up enforceable codes; industrial hygiene and public health authorities may specify acceptable upper limits to contaminants; mechanical engineers play their part through development of more efficient combustion processes and design of dust collectors; meteorology describes the manner in which contaminants are transported and diffused by the atmosphere and offers methods of alleviation; and plant physiology examines the effects of pollution on vegetation. General discussions of atmospheric pollution are available, either brief [1, 8, 34, 36, 51, 63], or comprehensive [56, 93]. For a very complete bibliography of meteorological literature on atmospheric pollution, see [48].

Before launching into the discussion of the strictly meteorological aspects of atmospheric pollution, it is desirable to survey briefly several closely related topics, namely types of atmospheric contaminants and methods of measuring them.

TYPES OF CONTAMINANTS

Man-made contaminants in the atmosphere may be divided broadly into two categories, particulate matter and gases.

Particulate Matter. The largest of the atmospheric impurities are certain of the dusts, which tend to settle out in a relatively short time. Grinding for size reduction is a prolific source. Dusts are also frequently formed by industrial combustion processes and ejected into the atmosphere by flue gases of sufficiently high velocity to carry heavier particles up the stacks; such high stack velocities are characteristic of industrial furnaces. These impurities consist of coal and coke dusts and fly ash. The smaller particles tend to remain suspended and are frequently termed "aerosols." Fumes, formed by volatilization and condensation of solids, and smokes are typical; many of these smaller particles are composed of tar and other combustible matter; some of them are hygroscopic and act as condensation nuclei [50]. Finally, there are the mists, consisting of liquid droplets which are often of a permanent nature. For detailed discussions, see [24, 36, 56, 98, 102].

Gases and Vapors. The presence of such contaminants, although invisible, may be revealed by their smell, or by a stinging or burning, as of the eyes, or by their corrosive effect on materials or damage to vegetation, or, in special cases, by the radiation emitted by them. Sulfur dioxide is one of the most prevalent of such gases. Acid vapors have a corrosive action and certain organic compounds in extremely small concentrations are malodorous [36, 80, 81, 98]. Radioactive waste gases from nuclear reactors present special features [8, 76]. Radiation hazards from such gases decrease with time because of their decay, argon-41, for example, having a half-life of 110 minutes.

MEASUREMENT OF ATMOSPHERIC POLLUTION

Various methods of measuring pollution have been devised: some of these methods, along with an extensive bibliography of 120 references, are given in [13]; the basic considerations which should be kept in mind when designing instruments are described in [35]. The more widely used methods of measuring pollution are described briefly below; fuller treatments are available elsewhere [24, 93], and suggested improvements in instrumentation have also been outlined [24, pp. 132–136].

The Deposit Gauge. This instrument, designed for the purpose of collecting the total amount of material deposited on a given area during a given time, is one of the first widely used for the measurement of atmospheric pollution [66]. One form is similar to a rain gauge, and consists essentially of a funnel with a collecting bottle below; the impurities and rainwater collected are analyzed by chemical methods. Its limitations are also similar to those of the rain gauge [61], since its "catch" is very sensitive to exposure, and depends not only on pollution present but also on rainfall, wind direction, and turbulence [4; 25, pp. 18–21; 59]. A detailed description of the significance of deposit-gauge measurements has been given [25, pp. 8–11]. Other more refined deposit gauges have been designed, but they all suffer from the above-mentioned limitation.

The Smoke Filter. Samples of the solid matter suspended in the atmosphere may be obtained by drawing a measured volume of air through a filter paper by means of a pump. The solids are filtered out, leaving a gray stain on the paper; their amount is determined by visual comparison with a standard scale of shades or by photometric methods. An automatic filter, which has been widely used, was designed by Owens

in 1918 [26]; a modified design more suitable for the North American climate has been produced [18]. A variety of more elaborate instruments for the study of particulate matter have recently been used [98]; these include the condensation-nuclei counter [94], the midget impinger [15], the cascade impactor and the electron microscope [57].

The Ringelmann Chart. In the United States the emission of solids from stacks has been estimated by the Ringelmann chart. The observer compares the shade of grayness of the smoke with a series of shade diagrams consisting of black horizontal and vertical lines on a white ground; the thickness of these lines increases progressively through the series. The method is highly subjective and open to criticism, the results obtained being influenced by such factors as background, illumination, etc. [33, 55].

Sulfur Dioxide Apparatus. Two methods are widely used. In one, air is drawn through a bubbler containing dilute hydrogen peroxide. Sulfur dioxide in the air combines with the hydrogen peroxide to form sulfuric acid. The acidity of the solution is determined either by titration [24] or by measuring its electrical conductivity [89, 90, 91]; the concentration of the sulfur dioxide is then computed from the measured acidity of the solution. A recording instrument utilizing the titration principle provides a measure of materials, such as sulfur dioxide, that exert a reducing action on an acid solution of bromine [96, 98].

The other method, developed by Wilsdon and McConnell [105], depends on the corrosive action of sulfur dioxide. A prepared surface of lead peroxide is exposed to the atmosphere for a specified period of time, usually a month; sulfur dioxide reacts with the peroxide to form lead sulfate. The yield of sulfate is proportional to the mean concentration of sulfur dioxide. Of the various meteorological elements, only rainfall influences the reaction rate [24].

The Ultraviolet Daylight Integrator. The amount of ultraviolet light from the sun cut off is a measure of pollution by particulate matter and is significant for the health of human and plant life. A number of methods of measuring ultraviolet radiation received at the earth's surface have been devised [56], the best of which consists of two coaxial translucent fused silica bulbs, one inside the other, and with necks downward. With this arrangement, a nearly constant intensity of diffuse light passes down the neck of the inner bulb for any position of the light source over a hemisphere; a silver filter transmits only ultraviolet radiation; the intensity of the ultraviolet light is varied by an optical wedge; and finally, the light falls on suitable photographic paper [24].

Visibility. Visibility data permit a determination of pollution by solid and liquid particles [27]. Objective methods of measuring the attenuation of light by particulate contaminants in the atmosphere have been devised [29, 78, 79, 98], and laboratory studies have been made. In one important laboratory study [10] two types of suspensoids were used, one consisting of transparent liquid drops produced by burning phosphorus, and the other of black opaque carbon particles produced by burning camphor. For the carbon particles, the glare and diffusion were negligible, and the logarithm of the transmission was proportional to the total amount of carbon. For a water cloud there was considerable scattering of light and the transmission did not fall off with concentration nearly so rapidly as for carbon. Mixed clouds showed intermediate properties. In another laboratory study [98], measurements were made of the opacity of pollutants such as sulfur trioxide which combine with water to form sulfuric acid mists. Studies of the interrelationship of visibility and various parameters have been made; in one, it was deduced that the product of the number of particles per unit volume, the relative humidity, and the visibility is a constant [47]; in another, that visibility is inversely proportional to smoke concentration [24, pp. 118–119]. A start has been made in the application of theory to the problem [10, 30, 78], but there are uncertainties involved. For example, since some of the particles are hygroscopic, their size at higher relative humidities may increase by condensation, thus decreasing the visibility even though there may have been no increase in pollution [62]. The contribution of visibility studies has to date been strictly limited.

POLLUTION BY SINGLE SOURCES

Atmospheric pollution by a single source is frequently of importance, as in the case of an industrial plant emitting contaminants from its stack. A number of theoretical studies of this problem have been made.

Basic Equations. One of the first theoretical treatments was that by Roberts [70] in 1923. He developed an equation for the concentrations downwind from a continuous point source using as a parameter the coefficient of eddy diffusivity. Subsequent studies [69] have indicated the inadequacy of an approach based on the assumption that the coefficient is constant and suggest that other parameters are required.

In 1932, Sutton [82] developed an equation for a point source at the earth's surface by assigning an expression, deduced from dimensional considerations, to the correlation coefficient introduced by Taylor in his theory of diffusion by continuous movements.

Using statistical concepts fundamentally very similar to those of Taylor and Sutton, Bosanquet and Pearson [12] and Bosanquet [11] developed a number of useful expressions for the pollution from a point source. One such expression gives the concentration which is effective in cumulative processes, such as the blackening of a neighborhood by soot and the attack of structures by acid constituents of the stack effluents. Thus, if the fraction of the year during which the wind direction falls within an arc θ is $a\theta$, then the average value of the concentration for the whole year is given by

$$\bar{\chi} = \frac{Qa}{pux^2} e^{-h/px}, \tag{1}$$

where Q is the mass of contaminant emitted per unit time, u is the wind speed, x is the distance downwind from the source, h is the height of the stack, and p is a

numerical parameter with an average value of 0.05 and a range from a minimum of 0.02 for low turbulence to a maximum of 0.15 for very turbulent air flow. Bosanquet and Pearson also give a formula for the ground-level concentration χ_0 during a brief interval of time due to a continuous point source, in the form

$$\chi_0 = \frac{Q}{\sqrt{2\pi}pqux^2} \exp\left(-\frac{h}{px} - \frac{y^2}{2q^2x^2}\right), \quad (2)$$

where y is the distance crosswind from the axis of the smoke cloud, q is a second numerical parameter with an average value of 0.08, and the other symbols are as defined for equation (1).

In 1947, Sutton [84] extended his treatment to cover elevated point sources and assigned values to the various parameters involved. The general expression derived is

$$\chi = \frac{Q \exp\left(-y^2/C_y^2x^{2-n}\right)}{\pi C_y C_z u x^{2-n}} \cdot [\exp\{-(z-h)^2/C_z^2x^{2-n}\} + \exp\{-(z+h)^2/C_z^2x^{2-n}\}], \quad (3)$$

where z is distance upward; C_y and C_z are virtual diffusion coefficients for the crosswind and vertical directions, respectively; n is a numerical parameter whose value, lying between 0 and 1, is related to the diffusing power of the turbulence; and the other symbols are as given above. With $z = 0$, (3) gives the concentration at the surface as

$$\chi_0 = \frac{2Q}{\pi C_y C_z u x^{2-n}} \exp\left\{-\frac{1}{x^{2-n}}\left(\frac{y^2}{C_y^2} + \frac{h^2}{C_z^2}\right)\right\} \quad (4)$$

and its maximum as

$$\chi_m = \frac{2Q}{e\pi uh^2}\left(\frac{C_z}{C_y}\right), \quad (5)$$

which occurs at a distance x_m from the source, given by

$$x_m = (h^2/C_z^2)^{1/(2-n)}. \quad (6)$$

The parameter n, obtained by fitting the theoretical profile $u = u_1 z^{n/(2-n)}$ to the observed change of wind speed with height, has the value ¼ under average conditions of lapse rate, with a range from ½ for a large inversion to ⅕ for a large lapse. For average conditions, Sutton gives values of C_y varying from 0.21 for a source at the surface to 0.07 for one at 100 m and values of C_z from 0.12 to 0.07 for the same range of heights of sources; for sources at 25 m and higher the values of C_y and C_z are the same. For inversions the coefficients are smaller; for large lapse rates they are greater. The values of the numerical parameters n, C_y, and C_z given above have been obtained by Sutton from basic meteorological data, but their validity has been checked through measurement of concentrations from surface sources only. Their use does not give instantaneous values of concentrations, but rather the average at a fixed point for a period of not less than three minutes; Sutton states that in the absence of systematic changes in wind direction near the surface the time-mean values for longer intervals are not significantly different. The validity of the numerical values of the parameters for elevated sources has not been established. Figure 1 gives maximum concentrations at the ground and the distance from the stack at which such maxima occur as functions of stack height and of groups of vertical temperature gradients; the curves are derived from equations (5) and (6) above.

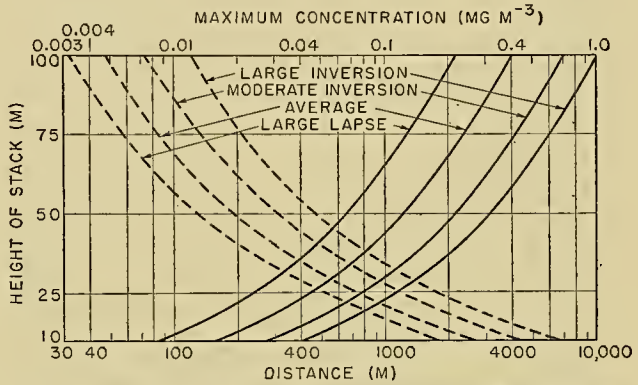

FIG. 1.—Maximum ground concentrations (dashed curves) and distances from stack base (solid curves) at which they occur with various vertical temperature distributions for stacks of different heights, according to Sutton. Rate of emission: 1 g sec^{-1}.

Lowry [52] has given an equation for maximum surface concentrations which embodies features of both (1) and (5). It has the form

$$\bar{\chi}_m = \frac{2Q}{e\pi h^2}\left(\frac{a_m}{u}\right), \quad (7)$$

where $\bar{\chi}_m$ is the time-mean concentration at a fixed point for a period of one hour; a_m is the frequency during the hour of the most frequent wind direction at the top of the stack; and the other symbols are as defined previously. The location of the maximum ground concentration is also specified: its direction from the stack is given by the most frequent wind direction at the top of the stack during the hour; its distance is given by the empirical expression

$$x_m = h \csc \sigma, \quad (8)$$

where σ is the standard deviation of the wind direction in degrees during a period of 10 or 15 minutes. Equation (8) applies only for sources at a height of the order of 100 m and when the range of direction is greater than 10 or 15 deg. The general validity of equations (7) and (8) has been verified by measurements of surface concentrations of oil-fog emitted from the 108-m experimental stack at Brookhaven National Laboratory. For further details and a suggested use of these two equations in climatological planning, see page 1152.

An equation for concentrations under very stable conditions has been given by Barad [5]. His approach derives generically from Roberts' work [70], but incorporates certain modifications. Barad assumes that in the horizontal layer of air near an elevated source, the variation with height of the eddy coefficient for vertical transfer is sufficiently small in very stable

conditions to warrant treating the coefficient as a constant with a value equal to the mean for the layer; similarly, a mean value for the eddy coefficient for horizontal transfer is also taken. Instead of assuming, as in previous treatments, a point source of infinite concentration, an area source of finite concentration is postulated. The source is taken to be an elliptical area whose major axis lies horizontally crosswind and whose minor axis is vertical; the area is located in the vertical plane at which the effluent flow first becomes horizontal after leaving the top of the stack. With these assumptions and specified boundary conditions the fundamental differential equation is solved. Computed concentrations are substantially smaller near the source than those obtained from Roberts' equation, but the difference becomes progressively less with increasing distance from the source. As the size of the vertical areal source increases, appreciable differences occur for greater distances downwind. The theory has not yet been checked by measurements of concentrations under inversion conditions. The emphasis on areal rather than on point sources is valuable, and further investigations of diffusion from such sources under various atmospheric conditions may well lead to significant advances of a general nature. Barad's analysis suggests that studies of the effluent from industrial stacks of large diameter, considered as vertical areal sources, should be made under inversion conditions.

Relatively few measured values of concentrations from individual elevated sources are available to permit a comparison with theory; those taken in the course of the Trail investigation [19] are of limited applicability because they were taken in the Columbia River valley; those taken at Brookhaven National Laboratory [53] have not been generally available long enough to permit a full analysis of them; the publication of other analyses [16, 92] is in such a form that it is difficult to apply the results in an evaluation of the several equations which have been proposed, as given above. It is thus possible at the present time to make only a few tentative remarks concerning the relative merits of the various approaches.

A comparison of the equation of Bosanquet and Pearson, (2), with that of Sutton, (4), brings out the fact that the expressions are similar in form but different in detail. The numerical parameters p and q are closely related to Sutton's C_z and C_y, a point emphasized by the fact that under average conditions $p = 0.05$ and $q = 0.08$ whereas $C_y = C_z = 0.07$ for a source at a height of 100 m. On the other hand, Sutton's equations involve an additional parameter n which gives them a greater flexibility for portraying faithfully the diffusion in complex meteorological conditions. Sutton [84] points out that his treatment supports a number of the main conclusions of Bosanquet and Pearson.

It is stated by Lowry [52] that, in the light of measured concentrations at Brookhaven National Laboratory, Sutton's equation (5) gives concentrations which are too high if a time-mean of an hour is used. It appears that the measured concentrations may be less than one-tenth of the values predicted from (5) using Sutton's values of the parameters, although generally the discrepancy is less marked. If we take (5) as applying for a time-mean of an hour, then a comparison of (5) and (7) indicates that $a_m = C_z/C_y$. Sutton assumes that, at heights of 25 m and above, turbulence is isotropic, in which case it should follow that $a_m = 1$, but Lowry finds that $a_m < 1$. Thus it appears that when time-means of an hour are taken, rather than those of several minutes, as considered by Sutton, the effective turbulence is not isotropic but $C_y > C_z$. It has been pointed out by Barad [5] that under very stable conditions at Brookhaven the plume of oil-fog travels nearly horizontally for miles with very little increase in vertical thickness but with a gradual lateral widening and a meandering as of a river. It is not yet clear whether the predominance of lateral spreading of the smoke is primarily a result of greater horizontal than vertical turbulent mixing or a result of the variation of the mean wind direction with height, a factor mentioned by Church [16]. The fact that the rate of variation of mean wind direction with height in the surface layers is a maximum in slowly moving and very stable air suggests that this factor should be taken into account under such atmospheric conditions. Further investigation on this point is required. The observed meandering of the smoke plume in an approximately horizontal plane recalls to mind the work of Parr [67], who suggested that the intensity of vertical mixing decreases and that of lateral mixing by large eddies increases as the vertical stability increases. When such meandering is marked, it is clear that the time-mean concentration for a period of the order of an hour at a fixed point relative to the earth will in general be substantially smaller than that for a period of a few minutes or the instantaneous maximum value. The work of Lowry and Barad at Brookhaven indicates that the magnitude of time-mean concentrations is a function of the length of the sampling period, and that such time-mean concentrations have limited significance unless the periods are specified.

It is not yet possible to compare the analysis of Barad [5] with other treatments, because observational data are lacking. However, it may be that an adequate analysis of the behavior of smoke from an elevated source in very stable air will require an assessment of the influence of the variation of mean wind direction with height, mentioned above.

To summarize briefly, each of the proposed equations must be used with caution, and applied only when certain conditions are met. When, under average conditions, a general estimate of the mean concentration for several minutes is sufficient, either Bosanquet and Pearson's equation (2) or Sutton's expressions will be adequate. On the other hand, if mean concentrations for a similar period under other meteorological conditions are required, where quantities such as the vertical temperature gradient differ markedly from the average, then Sutton's equations are to be preferred. When mean concentrations at a point for longer periods are required, Lowry's expression will be more reliable. With strong inversions, Barad's analysis merits atten-

tion. It must be emphasized, however, that although the above analyses are the best available, they still await experimental verification. Only Lowry's treatment has any direct experimental backing, and further verification of it is needed. Many more measurements of concentrations and of the associated meteorological variables are required in order to check the forms of the expressions and, more particularly, to evaluate the various parameters under a wide range of conditions. Furthermore, under certain atmospheric conditions described in the next two sections, the expressions given above break down completely.

Concentrations Near the Source. Whether or not significant concentrations of suspended impurities occur at the surface near a stack depends largely on the stability of the atmosphere. Etkes and Brooks [21] have described the behavior of smoke from a stack during various conditions of stability and wind speed. Their analysis indicates that smoke comes to the surface near a stack only with light winds and a superadiabatic lapse rate. Such conditions occur often on clear summer afternoons or occasionally after the passage of a cold front, especially during the early autumn over continental areas. This behavior of the smoke near the source is confirmed in a study by Church [16], who classifies it as "looping," a descriptive term for the oscillating motion of the narrow plume of smoke. He finds that the large convective eddies which produce looping occur only with winds of 20 mph or less. On the average, the plume first reaches the ground 80 ft away from a 200-ft stack with a wind speed of 1 mph; the distance is proportionately greater for higher speeds up to 20 mph. For a 200-ft stack, Church gives the following tentative average values of the dilution at the surface during unstable conditions: 2000 at 450 ft; 4000 at 900 ft; and more than 10,000 beyond 1700 ft. The dilution is defined as the number of volumes of air with which a unit volume of stack effluent has been mixed; a dilution figure of 500, for example, signifies a concentration $\frac{1}{500}$ of that in the stack. Lowry [52] gives three stack heights as the approximate distance at which maximum concentrations occur in unstable air and with light winds. Bosanquet and Pearson [12] point out that under such conditions mean surface concentrations for periods from a few minutes to an hour are given by equation (1) if a suitable value of a is used.

Large particles, such as fly ash, will be deposited near the source irrespective of weather conditions; the lighter the wind the nearer to the source will the deposit occur.

Some general conclusions concerning the occurrence of high concentrations at the surface near a stack may be reached by inference. The diurnal variation of such concentrations will show a maximum frequency of occurrence during the early afternoon and a minimum during the night and early morning. The annual variation will consist of a maximum during the summer and a minimum during the winter and early spring.

A considerable amount of atmospheric pollution comes not from stacks but from sources at or near the earth's surface as a result of various operations near industrial plants. The most reliable data available are measured concentrations downwind from point and line sources taken during average meteorological conditions on downland on Salisbury Plain, England [83]. Sutton's theoretical expressions [83] for such concentrations are in satisfactory agreement with these data, but measured values neither of concentrations nor of Sutton's parameters are available for extreme conditions, such as large temperature lapses or inversions, or for various types of terrain. The solution of a number of pollution problems thus awaits further measurements of concentrations from known surface sources and of the various meteorological parameters required for an evaluation of theoretical approaches. Such measurements would be most valuable if made at various locations and heights among and around typical industrial plants under both average and extreme meteorological conditions.

Concentrations Distant from the Source. The general picture of concentrations distant from a stack is given by the theoretical and semitheoretical analyses of Bosanquet and Pearson, Sutton, Lowry, and Barad. Church's empirical analysis [16] also provides information of interest, especially concerning the physical behavior of the smoke under various conditions and the degree of its dilution as related to wind speed and stability. The latter for a 200-ft stack is portrayed in Fig. 2; the degree of stability is expressed by $1/\theta \times d\theta/dz$. It will be noted from the figure that the smallest dilutions (greatest concentrations) at the ground occur with light winds and unstable air, as indicated in the previous section. The least dilutions increase with the wind speed for a specified degree of stability. For a given wind speed, the least dilutions diminish with decreasing stability until a minimum is reached and then increase; the minima occur at progressively greater values of the stability as the wind speed increases.

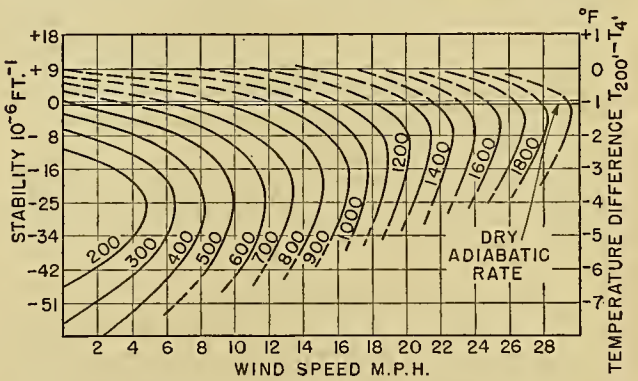

Fig. 2.—Least dilutions (maximum concentrations) at the ground as related to stability and wind speed, according to Church. A dilution of 800 denotes a concentration which is $\frac{1}{800}$ of that in the stack. Stack height: 200 ft. (*Reproduced by permission of the American Chemical Society.*)

When considering the range of usefulness of these approaches, the assumptions on which they are based should be kept in mind. These approaches provide a picture of the diffusion of smoke or gas from a stack under any one of a given set of conditions, with the

implicit assumption that the controlling meteorological conditions do not change significantly during the period under consideration; these treatments may be termed then, in a certain sense, static. But the atmosphere is a dynamic entity whose characteristics may and often do change radically within short periods of time. These changes sometimes lead to surface concentrations which are not predicted by current theories. Several examples may be given. Dean, Swain, Hewson, and Gill [19] describe concentrations of sulfur dioxide found in the Columbia River valley in the vicinity of the smelter at Trail, British Columbia. During the summer the highest surface concentrations occur with considerable regularity at about 8 A.M., the surprising feature being the fact that the onset and progressive development of these fumigations occur practically simultaneously at stations as far as 35 miles downvalley from the smelter. Bosanquet and Pearson's discussion was available at the time of the investigation, but it provided no assistance in this case. The probable explanation was given by Hewson [38]. During the early morning hours the gas flows downvalley in a thin layer which does not reach the valley floor because turbulence is inhibited

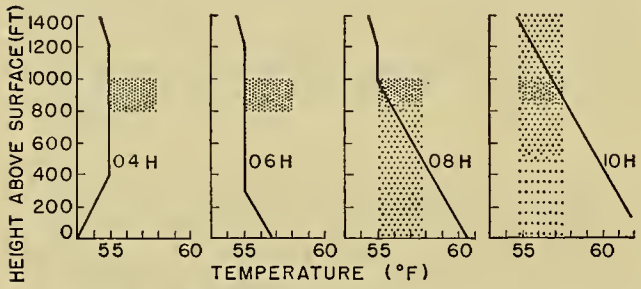

FIG. 3.—Various stages in the process by which contaminants from an elevated source reach the ground in high concentrations during a summer morning, according to Hewson [38].

by the stability of the air. After sunrise, solar radiation heats the surface which in turn heats a layer of surface air, producing in it a superadiabatic lapse rate and marked turbulence. The thickness of this turbulent layer increases with time; when its upper boundary reaches the layer of highly concentrated gas aloft, the gas diffuses rapidly downward producing sudden, high, and nearly simultaneous fumigations along the valley floor. As the upper boundary of the turbulent layer continues to rise, upward diffusion of the gas proceeds, leading to exponentially decreasing surface concentrations thereafter. The several phases involved are illustrated in Fig. 3. From the theoretical standpoint a simplified two-stage mechanism may be visualized. Stage one: concentrations aloft during the early morning are those appropriate for a continuous point source (the top of the stack) and a highly stable atmosphere. Stage two: subsequently the plume of smoke or gas acts as an instantaneous line or narrow area source in a highly turbulent atmosphere, with diffusion occurring initially downward and sideways but not upward; since the instantaneous line source moves with the wind, there is no net component of air flow normal to the line source. Investigations near other smelters on level terrain have shown that such simultaneous fumigations during the morning in summer are of frequent occurrence; the effects noted above are therefore not confined to valleys. According to Lowry [52], experiments at Brookhaven show that the average surface concentration during the fifteen-minute period with peak values is twenty times the maximum specified by Sutton's equations. The findings at Trail, that the greatest concentrations at the surface during the summer occur several hours after sunrise, are thus confirmed. The fact that high concentrations of gas or smoke may come to the surface in this manner miles from the stack must be borne in mind when peak values likely to be reached are of interest.

The effect of an isothermal or inversion layer a short distance above the smoke plume is a second factor which is not allowed for by the general theory. On June 3, 1939, a quasi-stationary frontal surface was located in the Columbia River valley near Trail [19, 38]. As shown by airplane soundings, there was a frontal isothermal layer at a level below the top of the valley sides but well above the top of the stacks, with a large lapse rate below the isothermal layer. Measured turbulence near the surface was large, but unusually and unexpectedly high surface concentrations of sulfur dioxide were measured at stations downvalley from the smelter. The low level of turbulence in the isothermal layer aloft prevented significant upward diffusion through it from occurring, and as a result the gas flowed downvalley as in a giant pipe. Over level terrain the result would not be so serious, since the gas would be free to diffuse laterally. However, there is little doubt that the presence of frontal or subsidence inversions and isothermal layers just above the smoke stream causes pollution conditions of serious concern which are not considered by present theories.

It is clear that there is a great need for both theoretical and experimental investigations of such special conditions which often lead to the most serious instances of atmospheric pollution.

The Influence of Topography. If the terrain in the vicinity of a source of pollution is not essentially level, the difficulty of specifying what the concentration of a contaminant will be at a given point under various meteorological conditions is greatly increased. The problems encountered when the source is in a valley have been fully described [19], and are twofold. When the winds are moderate or strong, local eddies caused by the configuration of the land produce a distribution of smoke which is well nigh impossible to predict from theoretical considerations. An evaluation of this factor requires a detailed investigation, the results of which can rarely be extrapolated to apply to other sites. Secondly, when the winds are light, local winds such as mountain and valley winds predominate, and even the prediction as to whether the wind will be up- or downvalley presents a major problem. The problem is further complicated if a number of side valleys and ravines lead into the main valley. The same factors, but to a

lesser degree, provide complications over any area of irregular terrain. Near a shore line, land and sea breezes occur and must be taken into account when considering the probable areal distribution of airborne pollution. The effect of topography will be considered further in the next section.

The Deposition of Particulate Matter. Calculations of the rate of deposition on the ground of particulate matter from a continuous point source have been presented by Baron, Gerhard, and Johnstone [6]. The rate of deposition is given by the product of the concentration of particles adjacent to the laminar layer and their free settling velocity through this layer, that is, by $\chi_0 w_s$. The quantity χ_0 is given by appropriate forms of either Bosanquet and Pearson's or Sutton's equations, and w_s by Stokes' law for small spheres with a specific gravity of 1.0, in air at 70F. An expression for the fraction ϕ of the total cloud which is deposited per unit time per unit distance downwind is obtained by integrating the product in the crosswind direction from $-\infty$ to $+\infty$. Thus, for example, for Bosanquet and Pearson's equation, the authors obtain

$$\phi = \frac{w_s(1.78h/p)^{w_s/up}}{pux^{(1+w_s/up)}} e^{-h/px}. \tag{9}$$

For Sutton's equations a more involved analysis is used. The values computed with Sutton's equation agree well with those for Bosanquet and Pearson's equation for lapse conditions only, since the latter use an average value for the vertical diffusion coefficient. The essential results may be summarized as follows: a decrease in turbulence increases the maximum rate of deposition and shifts the point at which it occurs downwind from the source; an increase in stack height decreases the rate of deposition and shifts the point of maximum deposition downwind—the maximum rate of deposition is approximately inversely proportional to the stack height. A similar analysis for continuous line sources is available [44].

The Coagulation of Particulate Matter. If smoke particles coagulate at all rapidly in the atmosphere, the effect will be important in increasing the rate of deposition as the particles grow in size. It is known that coagulation by molecular movements is small [101]. The coagulation of smoke particles in the surface layers of the atmosphere has been studied both experimentally and theoretically by Teverovsky [88]. By means of ultramicroscopes the change in the size of smoke particles in a plume was investigated: the number of particles and the mass concentration of the smoke were measured at several points along the plume and the average radius of the particles was calculated from the values obtained. It was found that with 10^4 to 10^6 particles per cubic centimeter the average radius increased from 0.2 μ to 0.4 μ while the smoke traveled a distance of 1 km. This coagulation is attributed to the action of microeddies which causes neighboring particles to converge. Teverovsky gives the orders of magnitude of various diffusion coefficients as follows: the coefficient for molecular movements is 10^{-6} cm^2 sec^{-1}; the coefficient for the microeddies to which coagulation is ascribed is 10^{-3} cm^2 sec^{-1}; and the coefficient for large eddies which are negligible as coagulating agents is 10^4 cm^2 sec^{-1}. The application of theories based both on dimensional analysis and on considerations of energy dissipation leads to results in good agreement with the observations made. These conclusions suggest that the possible effect of turbulent coagulation on the accuracy of photoelectric measurements of smoke concentrations should be examined.

Wind-Tunnel Investigations. Two types of wind-tunnel studies have been made, those to determine the effect of eddies induced by the stacks themselves and by nearby buildings [40, 58, 73, 74], and those to determine the distribution of a contaminant in undisturbed flow [58]. Because the effect of large-scale semipermanent eddies induced by buildings may be much more significant near the source than that of the prevailing field of turbulence in the atmosphere, experiments of the former type can be counted on to give information that is, in the main, reliable. Wind-tunnel studies of undisturbed flow are open to more serious question, however; in these it is assumed that the effective diffusing agency is the turbulence induced by the jet itself, and no allowance is made for the variations of the natural turbulence of the ambient atmosphere, which may be considerable for a given wind speed. Even near the stack the distribution of a contaminant will be significantly affected by the degree of natural turbulence present. The main objection to studies in present-day tunnels is that the degree of turbulence cannot be varied so as to simulate the range of natural turbulence in the atmosphere which is associated with a wide range of stability conditions.

It is possible that various actual stability conditions could be simulated by using a wind tunnel in which the lower surface of the tunnel could be heated and the upper surface cooled and vice versa. Because of the bounding surfaces above and below and the small vertical extent of the air flowing in the tunnel, it is probable that a lapse rate such as the dry adiabatic would not have the basic significance that it exhibits in the atmosphere. However, a lapse rate in the tunnel such that the air density increases with height, that is, a lapse rate greater than 0.034C m^{-1}, might simulate a superadiabatic lapse rate in the atmosphere and produce marked thermal turbulence in the tunnel. Similarly, by cooling the bottom of the tunnel and heating its top, strong inversions could be produced which would reduce turbulence to a degree characteristic of lesser inversions in the atmosphere. The technical difficulties in such a study are considerable, but do not appear to be insuperable. Thus, inversion conditions have been obtained in the Göttingen "hot-cold" tunnel by heating the roof of the tunnel by steam and cooling the lower surface by running water. Detailed comparisons of concentrations from a given stack under various atmospheric conditions with those obtained with exact replicas of stack and surrounding terrain in such a wind tunnel should serve to put model studies on a firm basis. An excellent discussion of wind-tunnel

techniques as applied to meteorological problems, including those posed by atmospheric pollution, is available.[1]

POLLUTION BY MULTIPLE SOURCES

The problems of pollution by multiple sources include those of single sources and a large number of others as well. The interplay of meteorological and other factors is extremely complex in the most important instance, that of a city, and only a start has been made in the study of such factors and their various roles. The main conclusions of the few studies of city pollution which have been made are set forth below.

Effect of Wind. The role of the main air currents of the atmosphere's circulations in transporting pollution is an obvious one. The effects of large-scale features of the general circulation and of local winds on pollution in the Los Angeles area have been described in detail by Beer and Leopold [7]. Of the latter type, both land and sea breezes and mountain and valley winds play a part in alleviating or contributing to the nuisance in the Los Angeles region. More detailed studies of the effects of wind on city pollution have been made, such as that at Leicester, England [24]. There the average effect of wind in shifting the center of surface pollution was surprisingly small. Pollution was naturally greater downwind from the center of the city, but the points of maximum surface concentration of smoke and sulfur dioxide never moved more than half a mile from the city's center as a result of wind; as the wind speed increased, the nearly circular contour lines of equal average pollution at the surface moved downwind by distances up to one mile, without any change in their radii. These results suggest that the upward diffusion of pollution by turbulent mixing is a major factor in limiting surface pollution, a conclusion confirmed by Fig. 4, which shows the effect of winds of various speeds on ultraviolet daylight in Leicester during the winter. The figures in the circles give the loss of ultraviolet light, expressed in logarithmic units, as a percentage of that received in the country districts around. Since the loss of ultraviolet light will be an approximate measure of the smoke above that portion of the city, the diagram indicates that the maximum of total smoke in winter may be found as far as two miles downwind from the city's center. The surface maximum was never more than half a mile downwind. A comparison between daily mean smoke and daily mean wind speed at Leicester was also made. In general the pollution decreases with increasing wind speed, the decrease being progressively more marked with increasing stability, and more pronounced in winter than in summer.

Less elaborate studies of city pollution have been made, such as that of Davidson [17] for New York City. The main meteorological conclusion of this investigation is that dust concentrations at the surface vary inversely as the square root of the wind speed. Other studies suggest that surface smoke concentration varies inversely as the wind speed [31, 47].

1. Consult "Model Techniques in Meteorological Research" by H. Rouse, pp. 1249–1254 in this Compendium.

Effect of Atmospheric Stability. The immediate effect of stability on surface city pollution depends on whether the stable layer is at the surface or aloft. At Leicester the connection with surface stability was studied. It was found that daily mean smoke increases with stability, the increase being small with winds of 10 mph but becoming progressively more pronounced with decreasing winds. The increase was more marked in winter than in summer. There is evidence that diurnal variations of stability, and hence of turbulence, influence the pollution from multiple sources. An investigation of pollution in fourteen of the largest cities in the United States [42] showed a low level of contamination in the early morning, followed by a peak in the forenoon, which occurs earlier in summer than in winter, at a

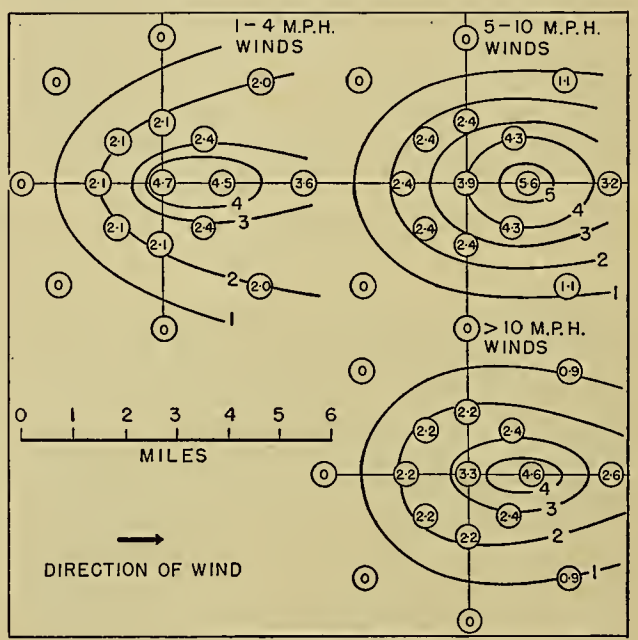

FIG. 4.—The effect of wind speed on ultraviolet daylight losses during winter weekdays in Leicester. Logarithmic units: one unit represents a loss, due to smoke, of 9.4 per cent of the possible ultraviolet daylight. (*Reproduced by permission of H. M. Stationery Office.*)

time ranging from about 6:30 to 8 A.M.; this maximum is followed by a rapid fall to a minimum about 2 P.M. when there is another rise to a peak about 8 P.M. The afternoon minimum is as low or lower than the early morning one. Similar results have been found in studies of pollution in British cities. These observations suggest strongly that the pollution which causes the morning maximum is carried downward from aloft by increased turbulence associated with increased lapse rates caused by solar heating, in much the same manner as described in the preceding section for elevated single sources [38]. The seasonal shift in the time of the morning maximum is clearly related to the seasonal variations in the solar heating.

The stability of air aloft has a considerable influence on summer pollution in the Los Angeles area, as pointed out by Beer and Leopold [7], and by Magill [54]. During that season the air at higher levels is relatively warm as

a result of subsidence occurring over the eastern portion of the Pacific anticyclone. Near the surface the air is relatively cool because of its recent oceanic trajectory, and mechanical turbulence has produced in it a marked lapse rate. Between these two bodies of air an inversion is usually present, extending perhaps from 2000 to 4000 ft. Thus, although there may be turbulence and convection near the surface, the inversion aloft inhibits the upward diffusion of contaminants by eddy processes, and extensive pollution develops.

Effect of Rain. It is not yet clear whether rain tends to alleviate surface pollution by washing impurities out of the air. At Leicester it was found that from 27 to 37 per cent of dissolved matter deposited on the surface and from 16 to 19 per cent of insoluble matter deposited there was brought down by rain. It is not known, however, whether these materials were present in the cloud particles from which the rain developed or whether they were washed out of the contaminated atmosphere by the rain drops as the latter fell. An investigation in fourteen large American cities [42] indicated that rain had no effect in cleansing the air, but rather that it tended to increase the concentration of smoke near the ground. The evidence at Leicester indicates that rain does not reduce the concentrations of sulfur dioxide in the air at all rapidly.

The Annual Variation. Near cities in extratropical latitudes there is a marked annual variation, with a maximum in winter and a minimum in summer. A large proportion of the winter pollution is due to products of combustion released from heating plants in buildings, but industrial contaminants emitted are not subject to the same degree of annual variation. Because of this complication, the effects of the annual variation of atmospheric conditions on pollution are not at all well known. The winter maximum and summer minimum are well marked at New York City [17] and at Leicester. At the latter, smoke has the largest range of annual variation, and insoluble deposit the smallest.

The Weekly Variation. This is due, not to meteorological factors, but to the shutting down, partially or completely, of industrial plants during the week end. It will therefore not be discussed here.

The Daily Variation. Surveys of smoke and dust in American cities, such as those for New York [17] and for a group of fourteen large cities [42], and in British cities, such as London, Glasgow, Blackburn, and Stoke-on-Trent [28], show a maximum at times ranging from 6:30 to 9 A.M. and a secondary maximum in the late afternoon. Increased industrial activity and home and office heating in the morning taken in conjunction with increasing turbulence associated with solar heating, as outlined earlier, account for the morning maximum; decreasing turbulence in the late afternoon before industrial emission of pollution has been reduced causes the secondary maximum.

Effect of Topography. As with single sources, the pollution from multiple sources, as represented by an industrial city, is markedly affected by topographic features. In a valley, for example, under stagnant atmospheric conditions, serious concentrations may and sometimes do develop; the valley sides act as physical barriers which prevent the lateral diffusion which normally occurs over more level terrain. Two extreme examples may be quoted. During the period December 1–5, 1930, severe pollution occurred in the Meuse valley in Belgium [22]. Anticyclonic conditions prevailed during the period, with fog and very light winds which carried pollution from the city of Liége and from industrial plants nearby into a narrow portion of the valley; an inversion accentuated the pollution. The conditions were so severe that several hundred persons suffered from acute respiratory troubles and sixty-three died on December 4 and 5. A similar disaster occurred at Donora, Pa., during the last few days of October, 1948 [23, 99]. Donora lies in the relatively deep and narrow valley of the Monongahela River at a distance of about twenty miles from Pittsburgh. During the five-day period of light winds associated with anticyclonic conditions, the pollution became severe and twenty persons died and hundreds were stricken in and near Donora. It appears from these instances that if stagnant anticyclonic conditions persist for four days or more, an occurrence most probable in middle latitudes in the autumn, fatal concentrations of pollution may develop. Topographic effects on pollution near some great cities are important. For example, the mountain ranges near Los Angeles are a factor at certain times in increasing the pollution problem there [54].

Because of the proven danger of lethal concentrations of contaminants to valley communities, there is an urgent need for both theoretical and observational programs of study of valley pollution. Given a knowledge of certain meteorological quantities in and just above a valley, of the rate at which contaminants are entering the valley, and of the topography of the valley, it should be possible to compute from approximate expressions the rate of accumulation of impurities in a given section of the valley during prolonged stagnant atmospheric conditions. Such data would forewarn of approaching critical concentrations and of the necessity for preventive action. As outlined in a later section, the climatological use of such data would also be most valuable.

Serious accumulations of contaminants are more likely to occur at inland locations where, in general, surface winds are lighter than near the coast line [104].

Further Research. There is a need for many more measurements of pollution in, near, and above industrial cities and of the associated pertinent meteorological parameters. Relatively little attention has been paid to concentrations at large distances from industrial cities; in the Leicester report [24, p. 126] it is suggested that downwind from a city the size of Leicester the smoke diminishes as the distance for the interval 4 to 10 miles; farther from the city, from say 10 to 100 miles, it diminishes as the square of the distance; and beyond about 100 miles it diminishes more slowly again, and ultimately as the distance. Such a tentative formulation of large-scale aspects is useful, but observations are needed to permit confirmation or modification

of the thesis. An analysis by Brunt [14] of surface dust counts for one year taken over a distance interval of ten miles downwind from the center of Norwich, England, shows that the pollution is approximately inversely proportional to the distance from the center of the city and that it diminishes with increasing wind speed. Suggestions as to research on various aspects of the problem of pollution by cities have been made [24, pp. 139–145]. Studies of the following are suggested: the three-dimensional distribution of pollution under various meteorological conditions; the distribution and characteristics of country pollution, including the heights reached by it; the processes of natural removal of pollution; atmospheric turbulence in its association with pollution; pollution in city parks, where there is no emission of pollution, for the detailed information to be gained; and special aspects of the problem which could readily be investigated by local authorities without the services of a highly trained staff.

The theoretical aspects of pollution by multiple sources have as yet received little attention. The problem to be solved is essentially that of the pollution caused by a large number of point sources of a widely varying nature. A start has been made by Sherwood [75], who applied Sutton's concepts to study theoretically the screening produced by the smoke emitted from a number of equidistant continuous point sources arranged along a line lying across wind. The problem presented by an industrial city is of course extremely complex: the point sources are irregularly located over an area, at varying heights, are emitting a variety of contaminants at differing rates, which also vary with time, into an atmosphere whose diffusing properties vary with both periodic and aperiodic components. Such a statement may merely induce deep pessimism, but it also suggests that an attempt to handle the problem of pollution from such an array of point sources by statistical combinations of individual point sources may prove fruitful. It is obvious that a complete theoretical treatment cannot be expected in the near future, but a start could be made by singling out one of the numerous variables and determining, if possible, the patterns of pollution resulting from various statistical representations of the chosen variable. Some of the other variables might then be handled by other appropriate statistical simplifications, leading gradually to a theory of increasing scope and validity. The measurement of the distribution of tracer substances emitted according to plan from a number of suitably chosen sources would be invaluable for checking theoretical distributions.

SECONDARY EFFECTS ON METEOROLOGICAL ELEMENTS

The possibility that atmospheric pollution has an effect on some of the meteorological variables and on the microfeatures of weather must be considered. For example, the question of the influence of a pall of smoke over a city under stagnant atmospheric conditions on both solar and terrestrial radiation is an interesting one which merits attention. It is possible that under such conditions differential heating or cooling between the polluted city air and the cleaner air over surrounding country districts leads to local convergence or divergence which in itself may act so as to increase concentrations over certain areas and at certain heights while causing decreased concentrations elsewhere.

Rainfall. Climatological studies of rainfall at Rochdale, England, indicate that both the average amount and average rate of rainfall are slightly smaller on Sunday than on other days of the week [2, 3]. Since the factories were closed on Sunday, it is inferred that condensation on the nuclei produced by industrial processes leads to the increased rainfall on the other days of the week. It has been shown that the Ruhr region of Germany gets measurable rain or drizzle on twenty more days per annum than do nearby less industrialized areas [103].

Fog. Measurements of relative humidity in fog often give values substantially less than 100 per cent, particularly in industrial areas. From this we may infer that atmospheric pollution increases the incidence and duration of fogs. There is also direct evidence: a long series of observations in Prague, Czechoslovakia, show that there were, on the average, about eighty-two days with fog per year in the period 1800–1880, and that since that period the number has nearly doubled [41]. The observations were made continuously at the same point and by the same rules. The effect of increasing industrialization and its attendant pollution is thus marked. It has been suggested [43] that sulfur dioxide may contribute directly to fog formation under certain conditions when photochemical oxidization by ultraviolet light is sufficient to produce sulfur trioxide, which is highly hygroscopic. On the other hand, there are indications [62] that such combustion nuclei alone cannot be responsible for the difference between relative humidities in fog in industrial and rural districts. The possibility that radiational cooling of contaminating particles, and thus of the ambient air, is a significant factor has been considered [49]. Other phases of the behavior of fog in a polluted atmosphere have been discussed [20]: in industrial cities it has been observed that a dirty fog at, say, 9 P.M. changes to a clean one by about 5 A.M. next morning, without a clearing of the fog, suggesting that the dirty particles fall out and are replaced by clean ones; fog droplets in town air dissolve the sulfur dioxide present, forming sulfurous acid which will oxidize to sulfuric acid which in turn acts to retard the clearing of such a fog. In a laboratory study of artificial fogs [65] it was found that, as pollution increases, a corresponding increase of fog density occurs only until the pollution attains a value characteristic of a small town. On the other hand, there is a continuous increase in fog duration with increasing air pollution. Further laboratory investigations [64] have shown the relative effectiveness of various combustion products and of the quality of the combustion process in prolonging the fog and in increasing its density. Incomplete combustion tends to increase both fog den-

sity and duration. From the foregoing brief discussion it will be obvious that the processes of mutual interaction between pollution and fog need further study.

LIMITATION AND CONTROL OF ATMOSPHERIC POLLUTION

There are in existence various laws whose purpose it is to limit pollution at the source [32]. Thus, in the United States, California has an air-pollution-control law and several counties and many municipalities have ordinances. This regulation of pollution is being undertaken by the following methods: by the sampling and inspection of discharges, in the case of smoke mainly through the use of the Ringelmann chart; by permits to operate existing equipment; by permits to build or install new equipment from which atmospheric contaminants may be emitted; and by control of the quality and kind of fuel used. Limitation of sulfur dioxide emission has in a few cases been specified. Thus the regulations of the Los Angeles County Air Pollution Control District permit a maximum emission of 2000 parts per million. In Great Britain the limitation tends to be more restrictive: the London County Council permits a maximum concentration of 35 ppm. Some of the possible means of limitation are mentioned below.

Limitation of Contaminants Emitted. There are two possibilities: to change plant processes so as to reduce contaminants in effluents to acceptable levels; or to remove or treat contaminants before they reach the atmosphere. Since the latter procedure usually involves less dislocation of plant facilities and less expense, it has been much more widely adopted. Methods of removing sulfur compounds and dust and fumes from waste gases have been described by Johnstone [43] and elsewhere [1].

Effect of Stack Height. It is clear from the discussion of the theory that high stacks are useful in alleviating surface pollution. However, it has been pointed out by Bosanquet and Pearson [12] that any increase above a reasonable height [68] has no practical effect. In other words, the use of high stacks leads to amelioration up to a certain point; to obtain further improvement, other methods must be used.

Effect of Stack Temperature. When effluent gases are warmer than the ambient air they have a buoyancy which causes them to rise. Their ascent ceases when, or shortly after, their temperature drops to that of the surrounding air. In this connection adiabatic cooling is of secondary importance in comparison with turbulent transfer of heat from the effluent gases to the air through which they rise. For given temperatures of effluent and atmosphere, the height to which the gases rise depends on the volume emitted per unit time, on the turbulence of the surrounding atmosphere, and on the wind speed. With low turbulence and low winds the eddy transfer of heat is relatively small and the gases rise nearly vertically to considerable heights, the height attained being greater with greater volume emitted per unit time. With large volumes emitted the gases may rise 400 to 600 ft; with even greater volumes they may rise 1000 to 1200 ft. With a highly turbulent atmosphere and higher winds the initial rise may be only one or two hundred feet or less. The height to which gases rise before leveling off has been called the "effective stack height" by Beers [8].

The problem has been discussed theoretically by Schmidt [71] and by Sutton [85]. Schmidt used approximate methods of solution involving infinite series, whereas Sutton postulated that if temperature differences between the vertical jet and the surrounding air are not too large, the spread of a vertical stream of hot gas must bear a close resemblance to the diffusion in the atmosphere of a cloud of cold smoke from a continuous point source. No wind and a dry adiabatic lapse rate are assumed, and the turbulence of the general environment is considered negligible in comparison with that induced by the jet itself. For the upward velocity w of the warm effluent Schmidt obtains an expression of the general form

$$w = \text{const}\, z^{-1/3}, \tag{10}$$

the constant being evaluated in terms of infinite series, whereas Sutton's corresponding equation is

$$w = \left(\frac{7gQ}{3\pi c_p \rho C T}\right)^{1/3} z^{-0.29}, \tag{11}$$

where g is the acceleration of gravity, Q is the heat supplied at the source per unit time, c_p is the specific heat of dry air at constant pressure, ρ is the air density, C is a diffusion coefficient with an approximate value of 0.3 $cm^{1/8}$, and T is the mean absolute temperature of the undisturbed air. Strictly speaking, since the actual source will not be a point, but an area, the height z is not measured from the mouth of the stack but from some lower level whose position depends on the size of the orifice. Both theories give results of the correct order of magnitude, but detailed checks with actual observations are required. Furthermore, the important case of calm conditions associated with an inversion is not covered by the theories. Sutton also obtains an approximate solution of the problem when there is a wind but, as he points out, the uncertainties then are much greater.

Meteorological Control. The possibility of alleviating pollution by varying the emission of contaminants as the diffusing power of the atmosphere varies has as yet received relatively little attention. Such a procedure has been used successfully by the smelter in the Columbia River valley at Trail, British Columbia. There, in order to prevent damage to vegetation downvalley (to the south) in the state of Washington, an upper limit to emission of sulfur dioxide has been set: with marked turbulence and hence rapid diffusion of the sulfur dioxide the maximum permissible rate of emission is much greater than when turbulence and diffusion are small; the upper limit is also a function of wind direction and speed [19, 37, 38]. The upper limits as specified by the Trail Smelter Arbitral Tribunal are given in Table I.

The degree of turbulence is specified in terms of the bridled-cup turbulence integrator [19], as developed by Gill. This instrument may be described as a gust accelerometer. Each change of wind speed of 2 mph causes a deflection in the trace made by a moving pen. The degree of turbulence is specified as the number of deflections per half hour; if this number is multiplied by four, the horizontal gust acceleration in miles per hour per hour is obtained. The turbulence integrator thus measures a basic parameter of the turbulence field. It has been found that winds at Trail from the north, east, south, southwest, and intermediate directions, and with a speed of 5 mph or more, generally do not carry the smoke downvalley and into the state of Washington, and so are considered favorable. Winds from directions other than these and a wind in any direction with a speed of less than 5 mph are unfavorable. Because the degree of susceptibility of vegetation to damage by sulfur dioxide varies with the time of day and the season of the year, the permissible maxima have corresponding variations—high maxima for low susceptibility and vice versa. Overriding safeguards are provided in other clauses of the control regime. Because of the great difficulty of forecasting winds and turbulence in a valley such as that in which the smelter is located, the control is based on contemporary, not forecast, conditions. Over more regular terrain it should be possible to forecast the pertinent parameters to a satisfactory degree of accuracy.

Table I. Maximum Permissible Sulfur Emission
(tons of contained sulfur per hour)

Time	Season	Turbulence*							
		0–74		75–149		150–349		≥350	
Midnight to 3 A.M.	Growing	2	*6*	6	*9*	9	*11*	11	
	Nongrowing	2	*8*	6	*11*	9	*11*	11	
3 A.M. to 3 hr after sunrise	Growing	0	*2*	4	*4*	4	*6*	6	
	Nongrowing	0	*4*	4	*6*	4	*6*	6	
3 hr after sunrise to 3 hr before sunset	Growing	2	*6*	6	*9*	9	*11*	11	
	Nongrowing	2	*8*	6	*11*	9	*11*	11	
3 hr before sunset to sunset	Growing	2	*5*	5	*7*	7	*9*	9

	Nongrowing	3	*9*	6	*11*	9	*11*	11	

* Deflections of turbulence integrator per half hour. Sulfur emission for unfavorable winds (left columns) and for favorable winds (right columns).

Methods of forecasting smog for the Los Angeles area, to permit control of the amount of contaminating substances discharged into the air when smog is imminent, are being developed [54, 98]. A study of the relationship between past occurrences of smog and past weather conditions has led to the development of a smog index S which is expressed in terms of meteorological variables.

$$S = \frac{10(T_D + 10)}{RW}\left(\frac{I}{V}\right)^{1/2}, \tag{12}$$

where: T_D = deviation in degrees Fahrenheit of the 24-hour mean temperature from the mean temperature for that particular day of the year;
R = relative humidity at noon;
W = total 24-hour wind movement in miles;
V = noon visibility in miles; and
I = inversion intensity from the equation

$$I = \frac{(\Delta\theta)^2}{3 + z\Delta z}, \tag{13}$$

where: $\Delta\theta$ = change in potential temperature in degrees Kelvin through the inversion layer;
z = height of the inversion base, in hectometers; and
Δz = thickness of the inversion layer, in hectometers.

Agreement is marked between days for which the smog index is large (indicating smog conditions) and days on which more than the minimum of four complaints of smog were received by the Los Angeles County Air Pollution Control District. The success of this index led to a method of forecasting smog in terms of the relationship between the presence or absence of smog and upper-air pressures and air movements. Smog occurs only when the three-day sum of the deviations from the normal height of the 700-mb surface lies within the limits 0 and +1000 ft (700-mb surface higher than normal) and the three-day sum of the daily average wind speeds at 10,000 ft is less than 80 mph (light winds at 10,000 ft). When the two parameters lie outside these limits there is a high probability that smog will not occur on the day for which the computation was made nor on the two following days.

Investigations made by Smith [76] and associates at Brookhaven National Laboratory have laid the foundation for a program of meteorological control of effluents from the nuclear reactor there. Predominant gustiness is classified according to types denoted by the symbols A, B, C, and D, corresponding to marked thermal turbulence, a combination of thermal and mechanical turbulence, marked mechanical turbulence, and turbulence with small vertical components of motion, respectively. These four types are illustrated in Fig. 5. The occurrence of each type in terms of gradient wind speed, vertical temperature distribution, time of day, and season of the year is specified; such specifications simplify the forecasting of the gustiness. The effluent to be controlled is argon-41, with a half-life of 110 minutes; the stack concentrations are so low that no health hazard is encountered from instantaneous maximum concentrations. Rather, it is mean radiation dosage over a number of days which has been selected as the operating criterion. A series of templates, each giving contours of mean hourly radiation dosage at ground level for a particular combination of wind speed and gustiness, were prepared on the basis of experimental data on oil-fog concentrations. The forecast radiation dosage, obtained from the templates, is added to the accumulated dosage over a period of days obtained by use of the templates in conjunction with the

known past meteorological conditions. By this procedure the forecaster is able to determine whether or not there is any likelihood that continued operation of the reactor would result in a radiation dosage higher than that specified as the maximum operating level.

increasing production costs; or by the construction of auxiliary plants for the recovery and processing of commercially valuable materials now in the effluents, to which plants varying amounts of the effluent could be diverted in accordance with prevailing meteorological

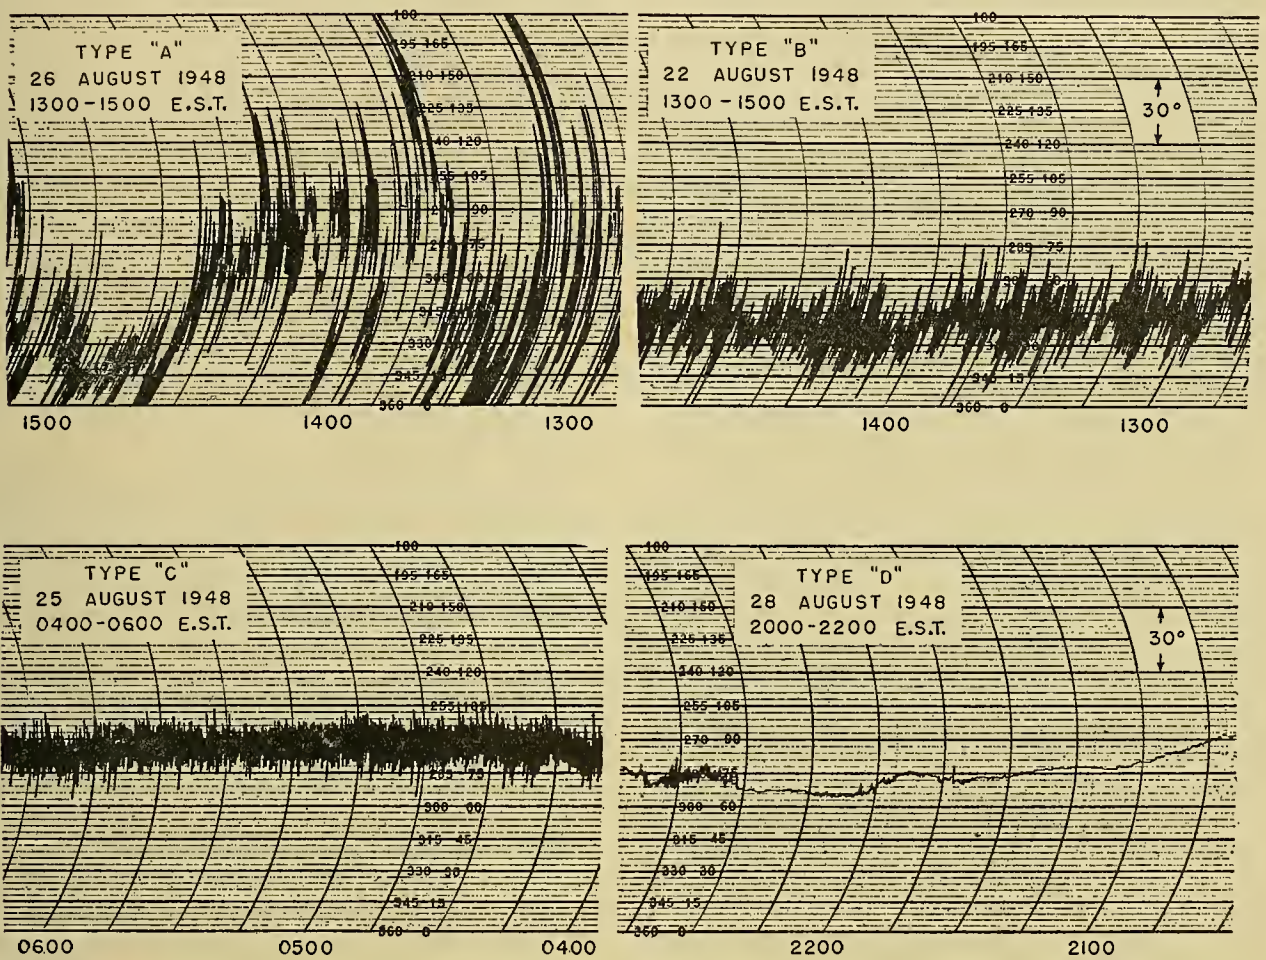

FIG. 5.—Four types of gustiness shown by the variability of wind direction as indicated by a wind vane at top of experimental stack at Brookhaven, according to Smith. *A*—great instability; *B*—moderate instability; *C*—moderate stability; and *D*—great stability.

In the report on the Donora investigations [99], it is recommended that production in local and nearby industrial plants be curtailed when stagnant atmospheric conditions develop in the valley. Such conditions are to be anticipated when an extensive, slowly moving anticyclone approaches the eastern United States and gives indications of stagnating; and when, in addition, the stability of the air in the valley exceeds a specified value, valley and upper winds are light and less than specified values, and moderate to dense fog in the valley continues for some time past noon.

The examples given above are sufficient to indicate the possibilities of forecasting future diffusion conditions. Such meteorological control as outlined above requires flexibility of plant operations. The requisite flexibility might be attained in several ways: by modifying plant processes so as to permit some variation of the rate of emission of contaminants but without unduly

conditions. It is probable that the cost of such a program applied to existing plants would in most cases be prohibitively high, but if the possibilities of meteorological control were seriously considered in the design of new plants and in the extensive modernization of older ones, a gradual amelioration of atmospheric pollution would be achieved over a period of years.

In urban areas the pollution by domestic heating units presents a serious problem. A wider use of central heating plants in new housing developments would be helpful. Such plants, with high stacks and a design which permits some degree of meteorological control, would reduce pollution. Such possibilities, and those of industrial control, should receive serious consideration by city planning commissions.

Although the alternative of removal of contaminants at the source has many attractive features, the problem of the disposal of such collected wastes may well become

increasingly acute; most rivers already receive more wastes than is desirable, and the dumping of wastes out-of-doors in large piles mars the landscape and raises other problems. However, these are not the only possibilities. For example, the problem of the disposal of economically worthless smokes and fine dusts collected at the source could be alleviated by turning off Cottrell precipitators or other precipitating equipment when atmospheric turbulence is high and thus allowing the atmosphere to disperse the contaminants in very low concentrations over a wide area. A possible extension of this method is to collect the fine particles during periods of low turbulence and then reintroduce them into the flue gases during periods when the diffusing action of the atmosphere is very high. A successful development of this method would thus permit atmospheric disposal of all but the large particles.

For a substantial fraction of the time the atmosphere is an excellent diffusing agency, spreading gases and aerosols over such wide areas in such low concentrations that they present no problem. It seems only reasonable to use this natural diffusing agency in the disposal of industrial wastes whenever possible.

Climatological Planning. Although the problem of waste disposal in the atmosphere is only one of a number to be considered when selecting a site for a new plant, considerable alleviation of pollution could be achieved if more weight were given to this factor. It is obvious that, if at all possible, a new plant should be located so that the prevailing winds will carry contaminants away from, not toward, populated areas, fertile agricultural land, valuable timber stands, etc. The prevalence of calm conditions, both persistent and transient, which lead to small lapse rates and inversions near the surface, taken in conjunction with local orographic conditions, should also be considered [104]. Thus, in the Los Angeles area, the records show that, on the average, inversions occur 260 days a year, of which 65 days are characterized by marked inversions. The persistence of such inversions is important in assessing the probable pollution nuisance. If it is found desirable to locate industrial plants in areas where natural diffusing conditions are poor, a knowledge of that fact would permit the design of plant equipment for the effective mitigation of the potential nuisance.

If a system of meteorological control is to be established, a study of the pertinent climatological data would provide information on the degree of curtailment of emission of contaminants desirable at various times of the year, the duration of periods of curtailment, and other facts of value in designing the requisite plant equipment. If substances are to be removed from the effluent and used in the manufacture of by-products, climatological data would permit an estimate of the required plant capacity and of its probable utilization throughout the year.

Methods of using climatological data for the solution of certain problems have been developed. Down-wash of contaminants in large-scale eddies in the lee of buildings may be marked when winds are high. Sherlock [72] has described a method of using wind data to determine how frequently such down-wash is likely to occur over a period of years. Lowry [52] has developed a basis for a pollution climatology. The necessary data are obtained from an anemometer and a wind vane at the proposed level of the top of the stack. Maximum ground concentrations are obtained from equation (7); the wind vane gives the appropriate value of the quantity a_m and the anemometer gives the value of the mean wind speed u, both for the period of one hour. The quantity σ in (8) is obtained from the wind vane. The two equations then give the mean maximum ground concentration for one hour and the distance from the source at which this mean maximum occurs. The longer the exploratory observations are continued the more accurate and reliable will be the results. To facilitate the use of the method, mean values are given of a_m and σ appropriate for the four types of gustiness shown by the wind vane and illustrated in Fig. 5. Allowance has been made for the high morning concentrations which often occur in summer, but the method is subject to the other limitations of current theories which have been described earlier.

Climatological planning is especially urgent in connection with industrial installations in valleys, as demonstrated by the disasters in the Meuse River valley in Belgium and at Donora in the Monongahela River valley which have been described earlier. Climatological studies of the relevant meteorological parameters would reveal how often dangerous accumulations in the valley are likely to occur, at what seasons of the year, and their probable duration. Such studies would also provide data for industrial plants in the valley to permit them to design units of the necessary capacity for collecting contaminants at the source.

THE PRESENT POSITION AND FUTURE REQUIREMENTS

A survey of atmospheric pollution studies indicates that advance in the meteorological aspects of the problem has been most rapid in Great Britain and the United States.

Systematic studies began earlier in Great Britain when, in 1912, a conference of delegates of municipal authorities and others was held in connection with the Smoke Abatement Exhibition in London. At that time a committee was appointed to "draw up details of a standard apparatus for the measurement of soot and dust and standard methods for its use." The committee's first report covered operations during the period April, 1914, to March, 1915. Since that time systematic measurements of contaminants in a number of cities have been made. However, detailed studies of the relationship between city pollution and meteorological conditions were not made until 1937, when a three-year survey of the city of Leicester [24] was commenced. Important experimental and theoretical contributions to the solution of problems presented by point and line sources have been made independently by Sutton and the group which worked under him at the Chemical Defence Experimental Station, Porton.

Uncoordinated work on a smaller scale has gone on for a number of years in the United States, but with a great increase in interest and activity during the past five years. Increased industrialization and, in particular, the problems of disposing of wastes from atomic energy installations have led to fresh attacks on atmospheric pollution. The former has produced such acute conditions in the Los Angeles area that a major investigation of all phases of the problem is now in progress. The latter have led to valuable studies of the behavior of effluents from experimental stacks.

Having considered the present position, it may be worth while to devote a little attention to some of the problems which may have to be faced in the future. In particular, general methods of procedure are worth discussing. For present purposes, possible future investigations may be classed either as extensive or intensive.

An extensive program of investigations is defined here as one in which a variety of problems are studied by a number of small and independent groups, coordination of effort among the different groups being limited to that achieved as a result of voluntary mutual consultation and discussion. The writer believes that such a program, because it provides the widest scope for individual initiative and inspiration, is in most cases the more desirable. Studies which have been made of pollution from single sources may be thought of as comprising an extensive program. The nature of the single-source problem is such that substantial progress may be made by such groups: the problems chosen for study may be delimited without sacrificing the essential usefulness of the results; relatively small groups of research personnel are sufficient, a few specialists in several fields at most being needed; instrumental requirements for gaining limited objectives are not excessive; and support and sponsorship by several interested organizations will be adequate. Furthermore, for these reasons the necessary financial support is not too great and can be obtained without undue difficulty.

However, there are other phases of the atmospheric pollution problem the successful solution of which requires resources and facilities of a higher order of magnitude. The outstanding example is that presented by multiple sources, as represented by an industrial city. Here the problem is one of great complexity and it should be studied simultaneously from a number of points of view if results of value are to be achieved. Such an investigation requires the services of groups of specialists and technicians equipped with facilities for measuring a variety of variables and for analyzing the observations in detail. In addition to substantial financial backing, the successful prosecution of such an intensive investigation of pollution in an industrial city requires the wholehearted cooperation of a number of organizations, such as municipal and county authorities, federal agencies, research institutions, and various industries whose plant operations contribute to the general city pollution. To give a specific example, the cooperation of radio stations in allowing meteorological instruments to be installed on their transmitting towers would be most helpful. Such an intensive program requires a higher degree of coordination and integration of effort than do the extensive studies with limited objectives referred to above.

The writer believes that both extensive and intensive programs of research will in the future make their contribution. The need for more coordination of effort in certain areas was clearly recognized at the U. S. Technical Conference on Air Pollution, held in Washington, D. C., on May 3–5, 1950. A Steering Committee was set up by the Conference to explore ways and means of extending the areas of cooperation; the meteorological representative on this Committee is Dr. H. E. Landsberg. During the meetings of the Meteorology Panel of the Conference the need for more research of both the extensive and intensive types was expressed. A report of the discussions of the Meteorology Panel was prepared by a group consisting of Dr. H. E. Landsberg and Dr. H. Wexler, the panel co-chairmen, Dr. E. W. Hewson, the panel chairman, and, by invitation, Dr. O. G. Sutton, chairman of the British government's Atmospheric Pollution Research Committee. This report was presented to the plenary session of the Conference [93]. Because of the fundamental nature of the problems considered, the report is reproduced in full below.

The panel meetings have revealed how extensive and how varied is the attack on the meteorological phases of the problem of air pollution. We are encouraged by the evidence of great activity and effort.

The present position may be summarized as follows. The distribution of pollution from a single source, either elevated or at the ground, has been studied both theoretically and experimentally for various meteorological conditions. Valuable information has been gained concerning the influence of special factors such as the following: diurnal variations of atmospheric diffusion; frontal surfaces and subsidence inversions aloft; deposition and coagulation of particulate matter in the atmosphere; and topography. Progress has been made in the study of pollution from multiple sources, such as represented by a city. The average distribution of contaminants in a city is governed by wind, rain, atmospheric stability, and topographic features. The contaminants in their turn influence rainfall and fog occurrence and persistence. However, our knowledge of city pollution and its dependence on weather conditions is less complete and detailed than that of pollution from a single stack.

Meteorological studies will aid in programs for minimizing pollution. The effects of increasing stack heights and temperatures have been determined. Rates of emission may, in cases where plant operations permit, be varied in accordance with clearly defined and precisely stated meteorological criteria. Methods of using climatological data to aid in determining the optimum location of a new industrial plant are available.

In short, there is a substantial fund of meteorological knowledge available for use in meeting present problems.

However, we find we are hampered in several ways. Our efforts are not as fruitful as they should be because of: a lack of coordination of effort; a lack of a basic theoretical doctrine by which to orient our efforts; and a lack of standardization of instruments and terminology. Our review of the present position has revealed a number of weak spots which require

attention and a number of lines of attack along which valuable progress may be anticipated.

The following are our recommendations for future action:

RECOMMENDATIONS

1. That standardization in methods of handling several aspects of the problem be achieved at the earliest possible moment. In particular, standard instruments and procedures of evaluation should be evolved and adopted for use. Such standardized instruments, *e.g.*, for direct measurements of turbulence, are required both for routine and research investigations. If it is necessary to use non-standard instruments, a full description of the operating characteristics of the equipment should be given. There is also an urgent need to adopt a standard terminology to ensure precision in presenting and conveying information.

2. That the theoretical development of the subject be promoted in every way possible. The development of basic turbulence theory is a prerequisite for fundamental advance in the study of atmospheric diffusion, and must be fostered.

3. That the problem of diffusion of effluents in a city be investigated intensively, since the pollution nuisance reaches the ultimate there. A program in which experiment and theory are both fully developed toward a common end is required. For example, it is suggested that intensive surveys of pollution and the associated meteorological conditions be made by a team which would survey ten cities well distributed over the country in annual succession, the team spending a year in each city. Each city would be chosen as characteristic for certain features of terrain and climate. At the end of the ten-year period ten cities would have been studied in sufficient detail to permit a classification of diffusion conditions in each in terms of specific quantities. It may then be possible to extrapolate the detailed conclusions to other cities with the aid of only routine measurements in the latter for comparison.

4. That micrometeorological and microclimatological surveys of cities and their suburbs be undertaken by local authorities with the assistance of a professional meteorologist. Instruments of standard type should be mounted on existing radio masts at standard heights with measured values presented for standard times in standard units. A detailed outline of the suggested procedure to be followed by local authorities in establishing such a survey should be prepared and distributed. Such a local survey would be relatively inexpensive.

5. That whenever a meteorological survey is in progress, a continuous record of the magnitude and location of pollution should be provided to permit correlation with meteorological variables. This will require the establishment of a standard pollution index so that different cities can be compared.

6. That the United States Weather Bureau be encouraged to take more observations of micrometeorological significance at its stations. Emphasis should be placed on obtaining regular observations of gradients of temperature and wind in the lowest 500 feet of the atmosphere.

7. That the organization be undertaken of existing and current literature on all phases of atmospheric pollution so that everyone may be aware of the work of those in other phases. Publication might be in toto or in abstract form.

CONCERNING SPECIFIC PROBLEMS TO BE ATTACKED

8. That, if possible, the relationship between wind-tunnel flow and natural atmospheric flow be established.

9. That the means by which contaminants are removed from the atmosphere be studied in detail. Is the natural cleansing process rapid enough to warrant increasing the rate of disposal of wastes in the atmosphere? At times the atmosphere is an extremely efficient disperser of gases and aerosols. In the long run, it may prove to be preferable to use this natural diffusing agency rather than removing contaminants at the source; with atmospheric dispersal the problem of disposal of economically worthless substances does not arise.

10. That an aerial survey of the distribution of inversion fog be undertaken. Atmospheric pollution tends to accumulate over terrain where such radiation fogs are of frequent occurrence.

11. That atmospheric electricity be measured more widely. The conductivity of the air depends on the degree of pollution, and affords a convenient method of studying the secular trends of the latter [95, 100].

With serious attention given to the above and related problems, meteorology will continue to make an increasing contribution to the solution of the problem of atmospheric pollution.

PROMISING LINES OF FURTHER RESEARCH

In portions of some of the preceding sections the writer has outlined his ideas on promising lines of attack on various aspects of the problem of atmospheric pollution. He is greatly indebted to a group of specialists in the field who have, at his request, stated briefly their ideas on how we may best advance our knowledge of atmospheric pollution. These suggestions will be most valuable as guideposts to give direction to future research. The statements are given below.

N. R. Beers. It is important that one be able to determine the significant turbulence by using the ordinary weather map and simple and inexpensive observations at his own station. The principles involved in sound refraction may be applied to investigate inversion conditions with both source and receiver on the ground.

Fixed base observations along a horizontal line, as between the meteorological towers at Brookhaven, may be made to investigate the structure of eddies. I have suggested specifically the possibility of hanging some 100 to 200 small balloons between the towers, to be fastened to the 900-foot-long "horizontal" cables. Motion pictures will illustrate the air movement between the towers at desired heights up to 100 feet above ground.

A general investigation should be made respecting trajectories of the air over a station, and nuclei of various kinds, such as sea salt, radon, pollen, dust, etc. The investigation must be carried out at several stations and at several elevations above ground.

Phil E. Church. I believe that man has the right to breathe pure, clean, unpolluted air as well as to drink unpolluted water. It is not likely, however, that the time will soon come when no man-made pollutants of any type will be discharged into the atmosphere or when atmospheric pollutant sewage systems will be constructed. Until such time, the concentration of contamination reaching the level where man lives is largely at the mercy of the characteristics of the air into which the contaminant is ejected. Hence, we must know more about these atmospheric characteristics, particularly in and near large and growing industrial centers. Especially important characteristics which must be thoroughly known at all levels into which contaminants are or will be ejected are duration, frequency, and magnitude of stable and unstable lapse rates, and wind direction, gustiness,

shear, and speed. These may in turn, after experimental work to determine quantitatively the amount of dilution a contaminant undergoes under various meteorological conditions, determine how much contaminant may be released without nuisance or physiological harm.

G. M. B. Dobson. As a result of much work in recent years, we now have a fair knowledge of the distribution of pollution within a town and the mechanism of its removal from the air at street level. On the other hand we know very little about the travel of the smoke cloud down wind from a large town though its effect is clearly seen in reduced visibility 50 or 100 miles away. A survey, possibly using aircraft, of the spreading, vertically and horizontally, and the change in concentration of the smoke at different distances would be of much interest. The results would need to be correlated with the meteorological conditions.

A. R. Meetham. Ventilation of towns. The concentration of smoke and gaseous pollution at street level is only partly determined by wind, being less closely correlated with wind speed than with other factors related to atmospheric turbulence. There is no orthodox method of measuring ventilation by turbulence; but it can be studied in towns where there is a large central park or smokeless zone by measuring the ratio of pollution in the center of the park to that a short way upwind. In Hyde Park, London, the ratio varied from 0.27 in high turbulence to 0.85 in low turbulence [24, p. 71].

M. E. Smith. Progress in meteorological research associated with atmospheric pollution requires the accumulation of certain data which are currently difficult to obtain without elaborate facilities. It is therefore desirable that relatively inexpensive equipment and simple techniques be developed to obtain these data. A thorough investigation of the usefulness of radio-wave propagation for the measurement of vertical temperature and humidity structure is particularly promising, since the equipment presumably would not involve the use of fixed towers or masts.

The determination of the extent to which wind tunnels can be used to simulate atmospheric turbulence by variation of vertical density structure, as well as other parameters, is also worthy of consideration. Such an investigation would establish more clearly the significance of numerous tests which have been made, and might provide an invaluable research tool for the investigation of proposed industrial installations.

O. G. Sutton. The situation in Great Britain at present is as follows. There is in existence a well-coordinated system of observations in the vicinity of sources of pollution, using standard instruments (deposit gauges, lead peroxide cylinders, etc.) which are provided by the Fuel Research Station of the Department of Scientific and Industrial Research and operated by the local authorities (town and borough councils). This procedure ensures that observations taken in different localities are comparable, a very important point for the subsequent statistical investigation. The results are analyzed by the Fuel Research Station and the final statistics, with maps of distribution, are issued in an official publication.

The main effort of the past decade, apart from research on instrumentation, has been the study of pollution at a selected site. The best known example is the Leicester Survey [24]. Although attempts were made in this survey to investigate the underlying physics of the distribution of pollution, it is probably fair to describe this work as primarily concerned with establishing the facts (in a statistical sense) of the distribution of pollution around a center of industry. The nature of the raw data and the heterogeneous character of the source made any really detailed physical study impossible.

It is hoped that it will now be possible to make more individual studies. The mathematical theory, although incomplete and by no means fully established, is now sufficiently advanced to give direction to the necessary experimental work. This should take the form of wind-tunnel investigations, supplemented by full-scale observations, of the distribution of pollution from a specific source, such as a power plant. This technique should be useful, for example, in revealing any tendency towards dangerous pockets of pollution in heavily contoured areas, by employing relief maps of the district with chemical indicators. Secondly, it should prove possible to establish a technique of experimentation for the prior investigation of a proposed factory or power plant layout to ensure that the effluent has a reasonable chance of getting away without being caught in some local eddy system and thus brought down to ground level in a high concentration.

To sum up, attention should now be directed more towards the mathematical-physical and experimental study of individual sources, and less towards the statistical survey of a polluted area. The routine observations should continue at all costs, since they form the essential factual basis of the problem.

THE CLASSIFICATION OF CLOUD FORMS

By WALLACE E. HOWELL

Blue Hill Meteorological Observatory, Harvard University

Introduction

If clouds occurred in a naturally limited number of forms, like regular polyhedrons, the problem of classifying them would be simple. Such, however, is not the case. Clouds occur in an infinite variety of forms, and the classifications that have been devised to describe them bear the stamp of human and fallible notions about their appearance, origin, and structure. Order in clouds is the product of man's will, and man's will can change it.

In its present status, cloud classification comprises not only classifications now in use, but also notions and concepts abandoned in the past that are still valid and may be given new value in the future. In taking stock of our present position, therefore, valid notions from the past must not be overlooked. A review of the present status may properly take the form of an historical summary of selected developments.

Assessment of our present position has two aspects, logical and pragmatic. How completely and logically has nature been described? How suitable are the classifications for the uses to which they are put, and wherein lie their shortcomings? Thoughtful answers to these questions will point the way toward future progress.

The encoding of cloud forms for purposes of transmission or recording of observations must not be confused with classification. Encoding is a sequel to classification; once classes are established, a code may be devised by assigning to each class a number, or, if there are not enough numbers to go around, by grouping two or more classes under a single number. However, classification should never be artificially restricted to meet the demands of a numerical code. Natural phenomena, fingers and toes excepted, do not occur by tens, and the attempt to force them into such a mold will usually be wrong. In the present work the problems of encoding are not treated.

The Present Position

The classification of cloud forms has been developed from two main points of view. One, beginning in the early 19th century, concentrated on the appearance of clouds as seen from the ground; its latest stage is the international classification of cloud forms. The other viewpoint stressed the processes that form clouds. It began in the early 20th century, and is still in a rudimentary stage. No general agreement has been reached and no international codification attempted. In the following paragraphs an attempt will be made to point out the accomplishments from each viewpoint that appear to have value now and for the future.

A beginning has been made towards what may eventually become a classification of clouds based on their physical constitution, *i.e.*, drop-size spectrum, liquid-water content, form and size of ice crystals, etc. The factual basis for this approach is still far from complete, and few classifications based on it have yet been formulated.

The International Classification and Its Antecedents. The first classification that is still vital was that proposed by Luke Howard [11] in 1803. He recognized three simple modifications, which he named *cirrus*, *cumulus*, and *stratus*. The definitions he gave would pass as current today, except for minor details. He next defined two intermediate forms, *cirro-cumulus* and *cirro-stratus*, and two combined forms, *cumulo-stratus* and *cirro-cumulo-stratus* or *nimbus*. His intermediate forms survive today as the middle clouds and the cirrocumulus and cirrostratus, but his combined forms have been largely lost except for surviving traces of Howard's theory that rain, both of frontal and thunderstorm origin, is caused by the electrical interaction of two cloud layers. His definition of the nimbus therefore embraced both cumulonimbus and nimbostratus. It is worth noting that Howard did not call his system a classification nor claim that it embraced all clouds, but intended it only "to impose names on such of them as are worthy of notice."

Howard's work became the standard reference; but the authors of general meteorological texts, which began to appear in the middle 19th century, often paraphrased it carelessly and erroneously. It was through careless copying of Howard's definitions by various authors that the stratus gradually came to be described as "a cloud above the ground," whereas Howard clearly applied the term to fog lying on the ground as well as to low layer clouds. The only concrete contribution during that period was made by Kaemtz, who differentiated stratocumulus from stratus, recognizing only the cumulonimbus half of Howard's nimbus and defining the former broadly enough to include most rain clouds.

The initial success of the French meteorological bureau in the late 1850's stimulated the study of clouds as well as other branches of meteorology. It opened a period when many new ideas were advanced, a fertile if somewhat febrile period marked by originality in the invention of new classifications more than by perfection and consolidation of existing ones. Noteworthy because of its later influence was the system of Poëy [16] who regarded cirrus and stratus as the only fundamental cloud forms, the one being of ice and the other of water. He anticipated Bergeron [3] by ascribing the origin of rain to the coexistence of these two clouds which, when coexisting, he called "pallium." Clayton [7] suggested stratus and cumulus as the two fundamental forms, a

notion that has persisted strongly to the present day in many popular works on meteorology although it never was given any official recognition internationally.

The confusion resulting from a variety of irreconcilable classifications led, late in the nineteenth century, to steps towards international agreement. A classification into principal cloud types, devised by Abercromby and Hildebrandsson, illustrated in a cloud atlas by Hildebrandsson, Köppen and Neumayer in 1890, was recommended for international use by the International Meteorological Congress at Munich the following year. It became the basis for the first International Cloud Atlas [10]. The ten principal cloud types recognized were cirrus, cirro-stratus, cirro-cumulus, alto-cumulus, alto-stratus, strato-cumulus, nimbus, cumulus, cumulonimbus, and stratus, in that order.

Almost immediately after the appearance of this classification came proposals for a more detailed one following the same framework. Although successive editions of the International Atlas appeared in 1905 and 1910 without significant changes, official recognition of terms that were coming into widespread use could not be indefinitely postponed. In 1922 an international commission for the study of clouds was formed to rewrite the Atlas.

Two new guiding principles were adopted by this group. The first was acceptance of the formal framework of classification, first laid down by Linnaeus, which had become standard in many fields of science. This meant the division of *all forms* of cloud into families and their further subdivision into genera, subgenera, species, and varieties. The second principle was one suggested by Shaw, who noted that several of the forms were defined in terms of separate "unit clouds" and that several others were in terms of aggregations of these unit clouds.

The work of the commission resulted in the publication in 1929 of a revised International Cloud Atlas [1]. The new Atlas established four families on the basis of cloud height: high, middle, and low clouds, and clouds of vertical development. Within these four families the ten previously recognized forms were distributed as genera, stratus being moved from tenth place to seventh so as to place it in the correct family. Following Shaw's suggestion, three "forms" of clouds were recognized: isolated clouds; sheets of clouds divided into filaments, scales, or rounded masses; and more or less continuous sheets. These forms, however, were not given formal standing as families or genera. A number of subgenera, species, and varieties were defined on the basis of what was by then current usage acquired gradually during the preceding half century without any great changes being made. The latest edition of the Atlas [13], appearing in 1932, did not change any of the important concepts of its predecessor.

A different set of fundamental forms was suggested by Bergeron [4]: the cumuliform (*Cu, Sc vesp, Cb, Ac cast*), the wave-form (*St, Sc, Ac, Cc*), and the stratiform (*Cs, As, Ns*).[1]

1. An explanation of abbreviations is given in [13].

Genetical Classifications. The rapid advances made during the early years of the 20th century in the study of the upper air led to an increasing appreciation of the role of cloud forms as indicators of atmospheric processes. This gave rise to progress along the second principal road in the classification of clouds, namely what have been called *genetical classifications.* Because there has been no international codification of genetical classifications, meteorologists are less likely to be familiar with all the principal ones that have been proposed, and this article will therefore describe them in some detail.

One of the first of the genetical classifications was proposed by J. Bjerknes and Douglas in a memorandum that was later amplified by Douglas [9]. It divides clouds into four types on the basis of "the physical processes involved in the formation of clouds." These are:

A. Cloud systems due to slow upward motion over a large area, usually associated with continuous precipitation (*Ns, As, Cs,* and some forms of *Ci*). The main feature is the great horizontal and vertical extent of the cloud system.

B. The cumulus and cumulonimbus group (including *Ci* or broken *As* formed from anvils), due to smaller air masses rising through their environment. Of great interest in this group are the layers of stratocumulus or altocumulus which develop turreted tops and eventually may grow into cumulonimbus.

C. The clouds due to turbulent motion, which may be either irregular (*Fs*) or arranged in definite layers (*St, Sc, Ac, Cc*). These eddy sheet clouds result from unstable motion within the cloudy air. Genuine stratus clouds are due (according to Douglas) to cooling of the air at the earth's surface combined with air movement which sets up turbulence and raises the cloud off the ground.

D. Lenticular clouds and cloud patches of smooth appearance, indicating local ascent of a damp stratified layer.

To this classification Douglas appends the note that *Ci* clouds could not be completely classified from a physical point of view at that time.

At about the same time Stüve proposed a much more detailed subdivision of cloud forms in a genetical classification that he revised for a later publication in 1937 [18]. An outline of his classification follows:

A. Clouds formed outside the space they occupy.
   1. Fluid or solid (amorphous or crystalline): *virga.*
   2. Crystals: *Ci, Ci unc.*

B. Clouds proper to the space they occupy.
   1. Clouds of convection. Cumuliform clouds.
      a. Formed through thermal convection.
         (1) Having no connection with a surface of discontinuity; their bases determined by the condensation level of air rising from the ground and therefore horizontal; the tops perhaps governed by an inversion: *Cu.* With strong development resulting from marked instability: *Cb.*
         (2) Formed from *Sc* or *Ac* through lifting of

the layer until latent convective instability is released: *cast.*

b. Formed through dynamic convection. Always lying beneath a surface of subsidence, their bases parallel to it.

(1) Fluid. Distinguished according to height: *Sc*, *Ac.*

(2) Solid: *Cc.*

2. Clouds of advection.

a. Formed by active upglide over an inversion.

(1) Without precipitation: *As.*

(2) With virga: *As* with *virga.*

(3) With precipitation reaching the ground: *Ns.*

b. Formed through passive upglide over an inversion.

(1) Without precipitation: *mam.*

(2) With precipitation: *Cb.* (In its upper portion this becomes a cloud of thermal convection.)

c. Formed through upglide over a free upglide surface (*i.e.*, one not resting on the ground): *St mam.*

d. Through upglide beneath an upglide surface alone no clouds are formed, but rather this upglide favors the formation of forms under B, 1, *b*, and otherwise leads with the help of thermal and dynamic convection to the formation of *St* and *fog* beneath a surface of subsidence, if this bounds a homogeneous air mass that lies directly on the ground.

3. Clouds of lifting. Whenever a maximum of relative humidity is brought into being beneath an inversion by dynamic convection, lifting of the whole air mass can produce condensation there.

a. Water.

(1) Lifting above upthrusting *Cu: pil.*

(2) Lifting through advection at a lower level: *lent* (and also, according to the preponderance of eddy diffusion before and during the lifting, either more stratiform or more cumuliform).

b. Ice.

(1) Lifting above upthrusting *Cb: Ci pil.*

(2) Lifting of the upper layers through upglide of an air mass over an upglide surface: *Cs*, *Ci.*

4. Clouds of turbulence. They arise through eddy diffusion in a manner similar to the forms produced through dynamic convection. In this case, however, the eddy diffusion originates through friction with the ground.

a. Formation made possible through evaporation from precipitation falling into the zone of turbulence: *Fs.*

b. Formation made possible through a nearly adiabatic lapse rate: *Fc*, *Cu.*

C. Orographic clouds. Landforms and the conditions of ground friction they establish do not lead to new forms of cloud, but localize the regions of their formation.

1. Cloud formation because of mountains.

a. More or less homogeneous clouds that cling to mountains, mostly on the windward side.

b. Banner clouds, forming in the lee.

2. Coastal cloudiness resulting from changed friction.

3. Localization of cloud formation through the differing thermal properties of the earth's surface.

A genetical classification introduced by Petterssen [15] approaches the problem from the point of view of air-mass properties. His classification of four categories follows:

A. Internal clouds that characterize the stability conditions of the air masses to which they belong.

1. Clouds that form in unstable air masses: *Cu hum*, *Cu con*, *Cb cal*, *Cb inc*, *Cb cap*, *Cb mam*, and certain detached high clouds such as *Ci den* which originate from the anvils of *Cb.*

2. Clouds that form in stable air masses: *St* and *fog.*

B. Clouds that characterize the discontinuities within or between air masses.

3. Clouds that form in connection with quasi-horizontal inversions. These are most frequently related to category 2: *Sc* and certain types of *Ac.* A great variety of clouds belong to category 3 but show signs of instability and are therefore related to category 1: *Sc vesp*, *Sc cast*, *Sc cug*, *Cu und* and certain types of *Ac cast.*

4. Frontal clouds that are formed because of upglide movement along frontal surfaces. When the air is stable these are of a stratiform type: *As.* When it is completely unstable they may be of the cumulus type: *Cb arc.* When it is conditionally unstable, the lower part of the cloud system may be stratified, and *Cu* or *Cb* towers project from the upper part of the frontal cloud layer.

Although not generally called such, the international classification of states of the sky is actually a *genetical classification* which takes as its basis three main origins of clouds: in cyclones, or in particular extratropical cyclones; in regions of convection or thunderstorm activity; and in regions of turbulence. The cyclonic cloud systems are treated in greatest detail, being divided into emissary, front, central, lateral, rear, and connecting zones. In the thundery systems, pre-thundery, thundery, and rear zones are recognized. The details of the classification are published in standard references [13, 5], and need not be repeated here. It may be pointed out, however, that the codes for states of the sky, C_L, C_M, C_H, are designed specifically to describe the most significant aspects of nephsystems as they are manifest in the sky.

A genetical classification put forward by Kähler [14] corresponds quite closely to the principal divisions of Stüve's classification, adding but one new notion. This is the separate recognition of clouds formed through mixture of warm, moist air and cold air at an interface between them. The resulting cloud forms are described as being weak and of the *As* type.

Physical Classification. The only classification that has so far been advanced from the point of view of the

physical constitution of clouds is that proposed by Bergeron [2] on the basis of his investigation of colloidal instability of clouds. His classification is made in tabular form as follows:

Group	Cloud element	Characteristic precipitation	Cumuliform cloud	Stratiform cloud
I	Complete crystals	Ice needles	*Cc* with halo	*Cs neb*,
II	Complete crystals and skeletons	Dry powder snow	*Ci unc*	*Cs fil*, *Cc* without halo
III	Skeletons and fog droplets	Snowflakes and/or rime-graupel or frost-graupel	*Cb* (winter)	*As*
IV	Fog droplets	(Dry fog)	*Cu*	*St*, *Sc*, *Ac*
V	Drizzle droplets	Wet fog, drizzle	*Cu*	*St*, *Sc*, *Ac*
VI	Raindrops	Rain or hail	*Cb* (summer)	*Ns*

According to Bergeron, Groups I and IV (only complete crystals or only droplets) are colloidally stable, Groups II and V exhibit slight colloidal instability, and Groups III and VI are wholly unstable.

Assessment of Adequacies and Inadequacies

The international classification of clouds has behind it nearly a century and a half of development, and a half a century of experience has been gained with it in essentially its present form. Many great meteorologists have devoted their attention to perfecting it. It would seem to represent a high degree of perfection and refinement. However, there are serious criticisms that can be leveled against it. Intended to permit accurate classification of any observed cloud form, its genera are not mutually exclusive and many cloud forms fit none of the genera defined. Intended to bring about uniform usage, observers still fail by a wide margin to agree on the classification of common forms of cloud.

Two examples will serve to illustrate this unsatisfactory status. In 1942 the author showed a set of color pictures of clouds before a group of meteorologists all of whom had had at least three years of professional training in synoptic meteorology. The slides were selected to illustrate common states of the sky and no attempt was made to select either the most typical appearances of the cloud genera or the most ambiguous. Every person in the group was asked to write down, as each slide was shown, the genus of the principal cloud form illustrated. When the results were tabulated it was found that only 56 per cent of the group, on the average, agreed on the principal genus, 27 per cent preferring a second genus and the rest of the group scattering their selections among as many as six additional genera.

It may be argued that the group test showed only that the training in cloud recognition of the subjects was insufficient and nonuniform, and indeed this may have been the case. Nevertheless, if the classification is so ineffectual in the hands of meteorologists, regardless of its intrinsic quality it fails in an important part of its intended purpose. It must be so fitted to the demands that meteorologists will find it easy and natural to use accurately.

The second example is the result of a review the author made of more than thirty books appearing between 1938 and 1942, comprising both standard meteorological texts and training materials on meteorology intended for aviators. Nearly half of the books take no notice of the 1932 International Cloud Atlas, but retain the terms and definitions of the earlier editions. A sizeable number mention cirrus, stratus, cumulus, and nimbus as the four fundamental cloud forms—a notion that has no basis in the international classification or its antecedents. A few reduce the number of basic forms to two, cumuliform and stratiform, disregarding the occurrence of cirrus which conforms to neither. Another book explains that "nimbus" means "head," and that therefore a nimbostratus is a stratus with a head on it! Nor are these examples of divergences by any means all drawn from nonmeteorologist authors.

The day is past when meteorological terms were practically the private property of professional meteorologists. The airmen who use meteorological terms now outnumber the meteorologists, and their use of the word "stratus" to describe any low cloud that forms an extensive low ceiling, or "cumulus" to denote the most spectacular thunderhead, is an example of word usage that we cannot ignore.

At this point let us review the nature of a classification as such. A classification as conceived by Linnaeus corresponds to the geometric concept of a partition; that is, a whole that is divided into a finite number of mutually exclusive parts, the sum of all the parts constituting the whole. Application of this concept to the classification of clouds would require that every conceivable form of cloud be allocable to one and only one family; within that family to one and only one genus, species, etc. The problem of defining the classes is that of drawing the lines between them.

An attempt to subject the international classification to rigorous tests of logic meets with difficulty. For example, the definition of cirrus gives only three characteristics as belonging unequivocally to this genus: that they are detached clouds, have a delicate and fibrous appearance, and are without shading. No other genus is open to detached clouds of delicate and fibrous appearance. What is to be said, then, of a detached, delicate, fibrous cloud that is thick enough to show shading? Plate 6 of the International Atlas shows just such a cloud and the explanatory text even calls attention to the shading. Yet it is classified as cirrus. The example would be trivial if it were unique; it is the multiplicity of such ambiguities that makes the classification open to grave criticism. No matter how strictly the definitions are made mutually exclusive, the human element of observation necessarily blurs the boundary between them in actual use. No effort should be spared to eliminate indefiniteness from the definitions themselves.

Brooks [6], taking cognizance of the same problem, questions whether it is not too much to expect that the definitions of the genera could be made completely in-

clusive and exclusive without overloading them unduly. To some extent this is a matter of degree, as to how lengthy and detailed a definition may be without being so clumsy as to defeat its purpose. But it is also one of purpose, whether the definition is framed to describe a typical form or to delimit a class. A very suggestive result is obtained if one strips from the international definitions of the genera all characteristics that do not explicitly serve to distinguish one genus from another. The remainders are:

Cirrus: a detached high cloud that shows no shading.

Cirrocumulus: a layer (or groups) of cloud masses in regular arrangement, the elements of which show no shading.

Cirrostratus: a continuous sheet of high cloud not showing relief and not thick enough to blur the outlines of the sun or moon.

Altocumulus: a layer (or groups) of cloud masses in regular arrangement, or a continuous layer showing relief on its lower side, the smallest elements of which have a diameter less than ten solar diameters, and the thickest elements of which show shading.

Stratocumulus: a layer (or groups) of cloud masses in regular arrangement, or a continuous cloud sheet showing relief in its lower side, the smallest elements of which have a diameter of more than ten solar diameters.

Stratus: a uniform layer of low cloud, from which, if precipitation falls, it falls as drizzle.

Nimbostratus: a nearly uniform layer of low cloud, from which, if precipitation falls, it falls as continuous rain or snow.

Cumulus: a cloud of vertical development whose upper portion is not fibrous in appearance.

Cumulonimbus: a cloud of vertical development whose upper portion is fibrous in appearance.

The altered character of these definitions is at once apparent. They are less vividly descriptive than the international definitions, but emphasize more clearly the elements that distinguish one genus from another.

Genetical Classifications. The present situation of the genetical classifications somewhat resembles that of the classifications based on appearance shortly before the first efforts at international agreement. In the several classifications, major processes are universally recognized: the overturning of air by through-going thermal convection, the stirring that characterizes turbulent layers, and the widespread lifting that accompanies horizontal convergence of the lower air layers in the forward portion of a cyclone. The manner in which the processes are arranged and subdivided, the relative weight given to different manifestations of a process, the number of additional processes thought worthy of mention, and to some extent, the nomenclature of the resulting clouds are matters on which full agreement has not yet been reached. Some aspects do not come clearly to the fore in any of the classifications, notably the difference between forced turbulence and thermal circulation in sheets of air, the manifestations of shearing motion, and the part played by radiation. The descriptions of cloud forms resulting from the various processes are somewhat incomplete, especially with regard to the dissipative stages in the life of the clouds.

Physical Classifications. Bergeron's classification of clouds according to their constitution, whether composed of complete crystals, skeletal crystals, or water droplets, covers only a single aspect of cloud constitution, namely colloidal instability. Before a comprehensive physical classification can begin to take shape, the collection and assimilation of a more adequate factual basis is necessary. A start in this direction has been made by Nakaya[2] with regard to the laws that govern the crystalline structure of ice crystals and snow, and by Diem [8] and others with regard to the drop sizes characteristic of the various cloud forms. Information about the drop-size distribution and its origin [12] should also find application here.

A View into the Future

It is of course easier to criticize than to improve. Nevertheless, it is possible to foresee and outline certain steps that will contribute toward progress in the field of cloud classification.

Classification According to Form. One of the most pressing needs is an approach to a more rigorous logical treatment of the international definitions, making each category of the classification (family, genus, species, etc.) as nearly as possible a geometrical partition. The problem presents serious difficulties if the definitions are not to become cumbersome. It can be simplified, however, if the definitions, particularly those of the genera, are stripped of all provisional statements (*i.e.*, those including "sometimes" or "usually," etc.) and all statements that do not contribute to rigorous distinctions between classes. A further simplification may be achieved by abandoning the arbitrary restriction of the number of genera to ten and defining additional genera. For example, if detached lenticular clouds were given status as a genus, the definition of altocumulus (or other genera) would not have to be stretched to include these clouds.

The effect of eliminating nondefining elements from the definitions of the genera would be to decrease the emphasis now placed on the genus category and increase the importance of the species category. Such a change conforms with the increased emphasis placed on species in the formulation of the codes for states of the sky.

Toward Uniform Practice. As long as the materials and practices used in the training of meteorologists, meteorological observers, and other users of meteorological information remain as divergent as they are today, it will be very difficult to attain uniformity in the use of the international classification. The publication of an authoritative atlas and its distribution to libraries and similar repositories is not adequate as a means of achieving even a reasonable degree of uniformity.

The situation would be helped by the republication of an official abridgement of the International Atlas in a form suitable for wide distribution, so that it would find its way more generally into the libraries of weather-

2. Consult "The Formation of Ice Crystals" by U. Nakaya, pp. 207–220 in this Compendium.

conscious people. With the collaboration of the directors of national meteorological services, it might be possible for such an atlas to be distributed to every weather station in place of the several different publications now so distributed.

Another pressing need is for adequate, uniform training materials and outlines of study. At present, cloud classification is taught not from the International Atlas, which is too bulky and expensive for use in the classroom or for purchase by individual students, but from textbooks that usually accompany brief extracts from the international definitions with introductory and explanatory material that may differ substantially from the Atlas. Training material and courses should be designed to meet the individual needs of introductory, intermediate, and advanced stages in the training of meteorologists and meteorological observers, and appropriate special training material should be provided for the use of student aviators and other students of applied meteorology in its many branches. In order to spread uniform training as widely as possible, the publications should be realistically designed for inexpensive production. Film strips and if possible time-lapse motion pictures should be prepared as auxiliary teaching aids and given the widest possible distribution.

Genetical Classifications. Although the international classification of states of the sky (nephsystems, as distinguished from the C_L, C_M, C_H code) has not gained widespread use in synoptic meteorology, the need for an internationally recognized genetical classification is growing, rather than diminishing. The time is near when our body of information about the relation of cloud forms to the atmospheric processes that form them will be adequate for the purpose and a definitive genetical classification will be achieved.

In the steps toward a comprehensive genetical classification, it will be necessary to broaden the basis of nephanalysis and make the connection between the structure of nephsystems and cyclones more specific. The notion of an idealized cyclone that moves steadily across the country without changing its structure has given way to the concept of a cyclone that passes through a definite life cycle of wave development and occlusion. The development of the nephsystem should be related to that of the cyclone and the connection between them should be clarified by an analysis of the atmospheric processes that are common to both.

A Unifying Principle. The form and appearance of clouds, which is the basis for the international classification, is the product of the genetical processes that formed the clouds, and is influenced by their physical constitution. This forms a compelling basis for interrelation between the different kinds of classification so far discussed. Since the international definitions have intentionally avoided mention of genetical processes as much as possible and refer only to aspects of physical constitution that are visibly apparent, recognition of the interrelations have mostly taken the form of references in the genetical and physical classifications to corresponding international cloud types.

There is nevertheless an inviting possibility that the different classifications may benefit mutually through the development of closer correspondences. There are already many instances of almost perfect correspondence between a cloud form as internationally defined and the genetical class into which it falls. For example, cirrocumulus is associated with only a single subdivision of Stüve's classification, and it is the only form that belongs in that subdivision. The establishment of more correspondences of this sort in the course of revising the international classification and framing an authoritative genetical classification should materially assist in the improvement of both classifications. It provides a powerful principle for eliminating the omissions and ambiguities now troubling us and for broadening the field of general agreement in all aspects of cloud classification.

THE USE OF CLOUDS IN FORECASTING

By CHARLES F. BROOKS

Blue Hill Meteorological Observatory, Harvard University

Introduction

A storm may be described as precipitation surrounded by clouds and usually accompanied by wind. The essence of forecasting is in telling when precipitation will occur and when it will not. Since rain or snow does not occur without advance notice in the form of clouds, we conclude that clouds are a prime element in forecasting.

Weather proverbs from long ago [52, 55] indicate attempts at spot forecasting from cloud observations. The professional forecaster, while less dependent upon scanning the local sky, cannot neglect the synoptic reports of cloud systems and their motions and development. Cloud observations supplement the more direct and quantitative aerological data from balloons, airplanes, and mountain stations, which, moreover, are not always available.

The very presence of a cloud indicates condensation in the atmosphere and hence the occurrence of some cooling process. Cooling in the free air is most commonly caused by ascent and expansion of air; therefore, a cloud usually indicates ascending air. If the cloud is cumuliform, the ascent is localized; if it is stratiform, the ascent is general, probably from broad lifting, such as convergence on a large scale or the upglide of one air layer over another. The sharpness, density, and form also indicate lapse rates, vertical currents, wind shear, and turbulence. The progressive motion provides the wind velocity at or immediately below the cloud height. Better observations and greater attention to interpretation of clouds and their sequence are therefore urged in the interest of improved local and general forecasting.

For comprehensive discussions of aerological interpretations of clouds, the reader may refer to books by Stüve [93], Süring [95], and Kähler [56], to Brooks' systematic article [13], to Möller's review of the literature from 1939–1946 [71], and to relatively recent detailed treatments of special phases such as the studies of *Ci*[1] by Ludlam [62], the studies of *Sc* and *St* by Raethjen [78], Schwerdtfeger [89], and Neiburger [72], of convective phenomena by Bleeker and Andre [10], and of convective clouds in the tropics by Craddock [28–30] and Deppermann [35].

Cloud Observing

Cloud observing presents many problems: separating the levels, observing the forms, extents, and positions, and determining the heights and motions. Summaries of methods of determining cloud heights and motions have been published by Middleton [68], Süring [96, 97], and Eredia [43], and a brief evaluation of the accuracy of different methods of determining cloud heights, by the International Meteorological Organization [54]. Discussions of cloud observing have recently been prepared by Brooks [12], emphasizing the range-finder and dew-point methods for determining cloud heights, and by Fergusson [44], and Conover, Fergusson, and Brooks [26], emphasizing the nephoscope method of obtaining cloud motions. It appears that a coincidence-type of range finder with a base of at least 1½ m is by far the quickest means of getting cloud heights within an accuracy of 5 per cent when there are sharp, well-lighted clouds within 15 km in any part of the sky other than the zenith (where the ceilometer is better). However, the cloud-range meter, of radar type, described by Moles [70], may have some advantage over the range finder within its limit (7000 yd), since sharpness in cloud outline and illumination are not required. The dew-point method is good within 8 per cent, Clayton found [24], when care is exercised to apply it only to clouds forming by the convection of fair-sized parcels of air likely to have the same temperature and dew point as at the observer's station. Large deviations result under sea-breeze or morning-inversion conditions. Heights by the single-theodolite, pibal method were found by Rossi [82] to differ from double-theodolite heights by 5 per cent under stable conditions and by 16 per cent under labile ones; Berg [3] found them to differ from those by airplane by 4 per cent for *Ac* and *Sc*, 8 per cent for *Cu*, and 13–20 per cent for other clouds.

The quickest way of getting cloud motions is with a window-sill nephoscope consisting of a plane, black, horizontal mirror of eight to ten inches diameter, without markings on the mirror other than a depression at the center, and a peephole eyepiece through which the observer can watch the motion of the image of a cloud and follow it with a small marker. When followed for a standard period (or easy fraction or multiple), the direction and relative speed are determined with a single placement of a ruler [12, 26, 44].

Clouds in Short-Term Forecasting at a Single Station

Application of the Diurnal Cycle to Observed Clouds. Early on a calm, clear morning, the occurrence of low clouds moving rapidly from any direction, but particularly from northwest or north, is a good indication of a day with strong winds from the direction from which the clouds are moving. Diurnal convection will soon bring this wind down to the ground.

Early-forming, thermal-convection *Cu* or *Sc* on a winter morning give promise of a generally cloudy day with little rise in temperature, for thermal convection will increase as the sun becomes effective, and the cloud masses will spread under the inversion responsible for the flattening already observed.

1. The international abbreviations of cloud genera will be used throughout

Morning *St* from the south is usually a prognostic of a marked rise in temperature, for it is formed by the mixture of warm, moist air at a low height with colder, surface air, and the mixing layer will soon work through to the ground. This is true especially if there is sufficient insolation to warm the surface layer to a temperature high enough to engage it in turbulent or convective interchange with the warm layer above. Insolation thus favors daytime arrivals of warm fronts at the surface. Unless the advection is raising the dew point rapidly, the mixing through a deeper layer and the rise in temperature tend to reduce the cloudiness by mid- or late morning, changing it from *St* to *Sc* or even *Cu*.

Altocumulus clouds observed in the evening are more likely to last all night, and to increase, growing upward and downward, when the surface wind is south than when the wind is northwesterly. In the first case it is usually the southerly wind, with its transport of heat and moisture, that is responsible for their formation, while in the second, such clouds may be merely the leftovers of flattened tops of convectional clouds formed during the daytime convection from the surface. Radiational cooling from the top of either type, however, favors growth and continuance.

The occurrence of sharp-topped *Cu* or *Sc* at sunset, when the wind is westerly or northwesterly, is a prognostic of a marked fall in temperature, for the sharpness, due to strong convection, indicates the steep lapse rate which is characteristic of a fresh cold air mass. At night radiational cooling as well as advection strengthens cold air masses and, indeed, favors nocturnal arrivals of cold fronts.

Interpretation of Observed Trends in Cloud Transformations. An increase in cloudiness will flatten the diurnal variation of temperature.

A wind-shift line at the earth's surface is usually marked by some forced ascent of air; thus the appearance and approach of cloud forms due to forced ascent indicate coming change, in anywhere from a few minutes to a few hours, depending on the distance and speed. This change may often be accompanied by rain. If there is a well-defined cloud base, the height of which is estimated, successive measurements of the angular altitude of the base as it approaches will give a reasonably accurate estimate of the time of arrival of the wind shift.

On a dull day we expect clearing if it becomes lighter, and vice versa. It is chiefly a change in light which attracts attention. A pall of forest-fire smoke which darkens the sky often brings out the umbrellas. Indeed, a solar eclipse has brought in washing off the line!

A meteorologist can intelligently make up any number of qualitative rules for short-term forecasting at a single station [*cf.* 14; 45; 47, p. 213; 58; 101]. The foregoing remarks must suffice as samples.

The expectancy of *any* rain following the first appearance of various cloud forms was worked out by Clayton [23], apparently in more detail than by anyone else. Sweetland [98] added *St nimbiformis* (=*Ns*) and Palmer [75], halos.

Clayton's analysis of cloud sequences by layers before 135 rainstorms [23] showed that the pre-rain sequence of *Ci* or *Cs* to *As* to *Nb* or *Cb* occurred in 84 per cent of the cases. The average expectancy of rain at Blue Hill, including cases when rain was falling at the zero hour, was 43 per cent in twenty-four hours; but when, as in the cases in Table I, precipitation was not already in progress, the average expectancy was 36 per cent. Only in the case of *Cs* with halos, *As*, and *Nb*(=*Ns*) is the expectancy substantially above average.

Table I. Expectancy of Rain at Blue Hill, Milton, Mass., Following Various Cloud Forms

Genus	Cases	Per cent of cases in which rain follows within 24 hr	Most frequent interval to precipitation† (hr)
Ci	159	33	26
Cc	137	36	22
Cs	160	44	13
Ac	84	45	8
As	142	68	6
*Ns**	70	73	4‡
Halos	569	<57	16‡

* *St nimbiformis.*

† Cases when precipitation began at an unknown hour during the night have been omitted; intervals are therefore somewhat weighted toward daytime conditions. Since rain occurs more readily at night, the intervals would probably have been somewhat less without these exclusions.

‡ Average interval.

Halos Before Rain. The Zuñi Indians say, regarding halos, "When the sun is in his house, it will rain soon." Several tabulations of the occurrence of rain after halo-producing *Cs* are summarized in Table II.

In most of the studies, solar and lunar halos are separated, but the differences are mostly small—frequency of precipitation is 1 per cent greater after lunar halos at Wauseon and 5 per cent greater at State College, but 9 per cent less at Blue Hill and 10 per cent less in London.

Differences between summer and winter are given by Mikesell [57], Neuberger [73], Palmer [75], and Russell [83], the precipitation being decidedly less in summer: Wauseon, 54 per cent vs. 62 per cent, and State College, 42 per cent vs. 78 per cent at twenty-four hours; and Blue Hill, 61 per cent vs. 70 per cent, at thirty-six hours. In London, the frequency in December is as high as 83 per cent (vs. 68 per cent for the year) at twenty-four hours.

Mikesell [57] found that the prognostic value of halos at Wauseon varied markedly with the pressure and pressure tendency (see Table III). The marked concentration of halos with high but falling pressure is in line with the typical position of *Cs* on the back slope of a high.

A few other points from studies of halos and *Cs* follow. Martin [65, 66] reports that at Fort Worth a halo with an east wind is followed by precipitation within thirty-six hours in 87 per cent of the cases, and within forty-eight hours in 95 per cent of the cases. At Columbus, when the wind at the time of the halo or soon after is from the southwest, the precipitation prospect in forty-eight hours is 88 per cent, according to

Martin [65]. Whittier [101, p. 4] urges that more reliance be placed on halos as prognostics of precipitation when they end owing to the thickening of the *Cs* into *As*. Reeder [79] cites the brilliant halo of Sept. 27, 1906, at Columbia, Mo., as the first indication of a tropical cyclone moving northward in the Gulf of Mexico. Dole [39] has cited colored sunsets at a coastal station as a valuable clue to the existence of a tropical storm. According to Neuberger [73, 74], the prognostic value of noncircular halos is greater than that of circular ones, being 85 vs. 77 per cent in Pennsylvania and 73 vs. 68 per cent in northwest Germany; bright halos are better than moderate or weak ones: 72 vs. 66 or 61 per cent in Pennsylvania but the reverse in Germany, 65 vs. 68 slightly higher than Palmer's 69 per cent for *Cs* carrying solar halos. The small difference is probably not significant. We cannot say the halo has no value of its own, however, for the presence of a halo identifies *Cs* as a thin ice cloud and is one of the chief criteria for differentiating *Cs* from the thicker *As*.

Double Cirrus. Süring [95, pp. 24–25], following Mylius' lead that bad weather, especially precipitation, is preceded a short time by multilayered clouds, found that double-layered *Ci* (usually the feathery type) and *vertebratus* are followed by warm-front precipitation, mostly of thunderstorm or squall characteristics, in 90 per cent of the 37 cases observed. These are characteristic of secondaries, particularly on the right front

Table II. Frequency of Any Precipitation Within a Given Number of Hours after Halo

Place	Compiler	No. of halos	No. of yrs.	Interval after halo						Freq. of precip: general average	
				12 hr (%)	18 hr (%)	24 hr (%)	36 hr (%)	48 hr (%)	Average (hr)	24 hr (%)	48 hr (%)
Fort Worth, Tex.	Martin [66]	168	6	—	26	36	48	59	24	—	—
Columbia, Mo.	Reeder [79]	40	2	—	—	24	—	49	—	—	—
Wauseon, Ohio	Mikesell [57]	2918	40	—	—	58	—	—	—	—	—
Columbus, Ohio	Martin [65]	185	12	—	54	65	75	86	26	—	—
State College, Pa.	Neuberger [73]	497	6	37	50	58	69	77	15	—	50†
Blue Hill, Milton, Mass.	Palmer [75]	569	10	—	—	<57	67	—	16	50‡	70‡
York, N. Y.	Stewart [91]	317	7	—	—	64	—	83	20	—	—
London, England	Russell [83]	977	7	—	—	68	—	—	—	—	—
NW Germany	Neuberger [74]	316	—	58*	—	68	—	—	8	44†	—

* Frequency of halos followed by precipitation on the same day.
† Nonhalo days.
‡ Eight-year average.

or 69 per cent, and short-lived ($\leq$15 min) are better than long-lived ($\geq$120 min) halos: 80 vs. 60 per cent in Germany, by the end of the following day. These are to be compared with the chance of precipitation within forty-eight hours when no halo is observed, which is 50 per cent at State College. Brooks [17] found precipitation within thirty-six hours after each of seven complex halos, and after a 46-degree halo Reeder [79] said that precipitation [always] occurred in from twenty-four to thirty-six hours in Missouri, while Neuberger found a 78 per cent probability in Germany.

Table III. Halos, Pressure, and Precipitation

Pressure and tendency	Cases	Per cent of halos followed by precipitation within 24 hr
Below normal and falling	334	83
Near the lowest point	205	66
High but falling	893	64
About normal	572	58
Low but rising	199	53
At about highest point	495	42
Above normal and rising	220	37

In evaluating the halo as a prognostic, in comparison with *Cs* without halo, it is of interest to note that Clayton's tabulation of all daytime *Cs*, whether halo-producing or not, shows a rain probability of 73 per cent (interpolated) within thirty-six hours, which is of a general cyclone. Sometimes these clouds are seen after the end of the warm-front precipitation. Double-layered *Ci* occur in 16 per cent of all cases of *Ci*.

Undulated Sheet Clouds. Sweetland [98, p. 39] found that, at Blue Hill, undulated sheet clouds at all levels are more likely to be forerunners of warmer weather and rain than the more indefinite cloud types (Table IV). Sharp contrasts between over- and under-running

Table IV. Undulated Clouds and Precipitation at Blue Hill [98]

	Ci, Cs	*Cc*	*Ac, As*	*Sc*	*St*
Cases	42	16	24	36	6
Precipitation within 24 hr (per cent)	50	66	67	53	67

winds usually result in sharp cloud markings and striking wave formations and produce a maximum tendency toward forced ascent. Martin [67] has presented records of a "mackerel sky" at Columbus, Ohio, which may be compared with Sweetland's undulated *Ac* (Table V).

Mammatus Clouds. According to Sweetland [98], these are followed by some precipitation within twenty-four hours in 51 per cent of 51 cases. Angot [2] remarks that *Cu mam* mean rain without wind in cold air masses below a warm front surface in the lowlands of Lancashire, but indicate a gale in the exposed Orkneys. Whittier

[101, p. 4] says they are an almost sure precursor of rain.

Altocumulus and Rain. In addition to the observations on mackerel sky, other studies of *Ac* have been made. After *Ac* at the morning observation at Podersdam in northwest Bohemia, Schindler [86] found that rain followed on the same day (14 hours) in 42 per cent of the 700 cases and by the end of the following day in 68 per cent.

Table V. Mackerel Sky and Precipitation

	Cases	Cases with precipitation within				
		12 hr number	24 hr		48 hr	
			number	per cent	number	per cent
Mackerel sky (Martin [67])	17	10	15	(88)	17	(100)
Undulated *Ac* (Sweetland [98])	16	—	10	(62)	—	—

Altocumulus Castellatus as a Prognostic of Rain and Thunderstorms. Ley [60] seems to have been the first (1882) to note that morning *castellatus* is commonly followed by afternoon showers, and afternoon *castellatus* by night thunderstorms when, as he said, radiation from *Ac* tops favors convection. A tabulation of subsequent investigations is given in Table VI.

Table VI. Altocumulus Castellatus and Thunderstorm

Region	*Acc*	Thunderstorm on same day (per cent)	Thunderstorm on same or following day (per cent)
Lake Constance (Peppler [76])	Strong	Nearly 100	—
England (Douglas [41])	Strong	—	69*
Bohemia (Schindler [86])	In morning	—	67
N. of Alps (de Quervain [37])	46 cases	74*	87*
Blue Hill Observatory (Sweetland [98])	12 cases (Apr.–Sept.) 1894–1896	66†	—
Blue Hill Observatory (Brooks [19])	51 cases (May–Sept.) 1946–1949	24†	—

* At station or within 100 mi.
† At station or nearby, no rain in some cases.

In the rainier climates of western and central Europe, higher percentages of storms are noted. The greater frequency of *Acc* observations now than fifty years ago seems to indicate that many *Ac*, formerly not designated *castellatus*, are now thrown into that class, diluting the apparent prognostic value that is logically attached to this indicator of a steep lapse rate. In the more recent Blue Hill study, the thunderstorm expectancy for *Acc* days (24 per cent) was nevertheless greater than the expectancy for all days of the period involved (14 per cent). Schinze and Siegel [87, Figs. 67*a* and *b*] have indicated by cross-section diagrams and charts of temperature and humidity vs. height how *Acc* and *floc* are formed and precede *Cb*.

Altocumulus Lenticularis—A Sign of Wet Weather. The appearance of *Ac lent* usually means an increase in humidity in middle levels commonly owing to the advection of moist air in a wind of increasing speed. Such clouds appear first over mountains where the obstructing masses locally force the wind to ascend. Thus it is that new caps on mountains or lenticulars in their lee are early signs of coming wet weather. Rink [80] describes a striking case of the "Moazagotl Wetterwolke," a standing foehn cloud in a horizontal whirl in the lee of the Riesengebirge, that indicated rain inside twenty-four hours.

De Quervain [37] found that *pileus* was accompanied on the same day or followed on the next by *Cb* in 15 out of 21 cases.

Cirrocumulus. Various indications by *Cc* are cited by Angot [2], who says it means fine weather in Britain (and, he could have added, New England [23]), but the opposite in southern Europe, especially Italy. In the tropics, he says, it has no significance. Schindler [86] found *Cc* more a fair- than a foul-weather cloud in Bohemia, with rain on the same day 33 per cent of the time and by the end of the next day 59 per cent (both 9 per cent less than for *Ac* there). Clayton's figure for twenty-four hours was 36 per cent. Bruckmayer and Seiler [20] corroborate Angot's findings.

Directions of Motion, Point of Convergence. Ley [60, pp. 120, 125, 126] early systematized the prognostics of directions of cloud motion, presenting them in qualitative terms in two groups—for *Ci* and for *Cs*. For the latter, he used only *Cs rad* and the direction of the convergence, or V point on the horizon, which he found was an average of 15 degrees to the right of the direction from which the clouds move. Clayton [23] found that 50 per cent of the motions are within 5 degrees of the V point. Rules are given for each of the eight directions. Thus, "Cirrus from N.W., when not tending to form Cirro-filum, is an indication of temporary fine weather, especially in summer"; and "A V point N.W. is an unfavourable symptom, and when it occurs with or just after an increase of barometric pressure, is an indication of a sudden decrease of the same with rain and wind."

Henry, Bowie, Cox, and Frankenfield [49, p. 287] found four helpful rules: (1) *Ci* from the southwest in the lower Mississippi Valley and Texas indicate that precipitation is likely to occur in that region or to the northwest 24–48 hours after their first appearance; (2) *Ci* from the southwest over Arkansas and Oklahoma, changing to *Cs* overcast, indicate that rain will probably soon extend into the middle Mississippi Valley; (3) *Ci* from the northwest in the southeast quadrant of a high seem to indicate that the high will increase in strength and move slowly; and (4) when *Ci* stripes lie northwest to southeast [probably indicating usual prestorm motion from the northwest], the chance of rain is greater than when their direction is northeast to southwest [the usual orientation at the rear of a storm].

Brooks and Harwood [18] showed that heavy snowstorms at Blue Hill are generally preceded by *Ci* from either north or south of west, but not from straight west.

Guilbert [48], in France, found that *Ci* come from the centers of depressions, that their speed indicates the strength but not the speed of the depression, and that *Ci* observations must be used in conjunction with the weather map. Peppler [76], in southern Germany, however, found that the relation between direction of motion of *Ci* and subsequent weather is not very close, but best when taken in conjunction with the pressure tendency.

Deppermann [34], at Manila, warns that striped *Ci* usually arise from the so-called *false Ci* tops of *Cb*, strung out into lines by a strong upper-air stream.

Table VII. Direction of Densest Clouds and of Cloud Motion, and Frequency of Precipitation within 24 hr

		Cs	*As*	*Ac*	*Sc*
(*A*) Direction in which clouds are densest	Direction	SW or N	W	W	S
	Cases	56	16	80	30
	Frequency of precipitation (per cent)	68	81	66	80
(*B*) Direction from which clouds are moving	Direction	NW	SW	SW	S
	Cases	45	16	52	11
	Frequency of precipitation (per cent)	62	69	75	91
Best combinations of (*A*) and (*B*)	Direction where densest	SW	W	SW or W	S
	Direction of motion	SW or W	SW or W	W	S, SW, or W
	Cases	30	13	24	23
	Frequency of precipitation (per cent)	67	92	88	87

Parallel *Ci* give an appearance of convergence at the horizon. He says, "in quite a few cases where the writer thought he had convergent *Ci*, careful observation showed that there were generally two sets of parallel *Ci* of different altitudes meeting near the horizon."

Direction of Motion and Direction Where Densest. Clayton [23] noted that direction of motion and direction of maximum density when considered jointly have better prognostic value than either alone (Table VII).

The Motions of Cirrus as Prognostics of the Movements of Cyclones. The speed of *Ci* is usually a good index of the changeableness of the weather. Since the wind at the *Ci* level is usually dominated by the gradient of temperature in the troposphere, and since this gradient is a large element in the strength of the zonal circulation, there is, necessarily, a relation between the speed and direction of the *Ci* and the movement of cyclones and anticyclones. The *Ci* usually move from the west and so do the pressure systems, and the faster the average movement of the *Ci*, the faster the pressure systems move. When the temperature gradient of the troposphere is small, however, cyclones and anticyclones may dominate the pressure gradients up to great heights, including the *Ci* levels. Under such conditions, the *Ci* may move from easterly directions and vary considerably in short spaces of time or distances [38].

Pick and Bowering [77] related 162 nephoscope observations of *Ci* at Sealand and Holyhead (Britain) to storm tracks and tabulated the difference in degrees between *Ci* motion and the direction of advance of the depression center. More than half fell between 0 and 60 degrees difference; a few exceeded 90 degrees.

Clayton [23] and Pick and Bowering [77] have made statistical studies of *Ci* motions showing a fair, but not sharp, relationship to the progress of cyclones. Clayton analyzed two years (1887 and 1888) of hourly observations of high clouds at Blue Hill, 1821 in number, in relation to the speed of movement of cyclones, using mean monthly speeds of each (see Table VIII). When he grouped the mean monthly *Ci* speeds by classes of 10 m sec^{-1} and with them the storm movements, he found a fairly regular increase of the latter coordinated with that of the former, with ratios of the *Ci* movement to cyclone movement rising from 2.4 in the 15–25 m sec^{-1} *Ci* speed class to 4.5 in the 65–75 m sec^{-1} class. It seems probable, however, that Clayton's ratios are too high, because he compared average monthly *Ci* motion at Blue Hill Observatory with average monthly storm movement for the entire United States. Most of the storms, however, pass through the northeastern section of the country.

Pick and Bowering, 1929 [77], using individual cases (162 cloud observations), found no regular relationship, though their tables (summarized in Table VIII) indicate

some connection between the speed of *Ci* and the speed of cyclones (British Isles).

Cirrus moving at high speed, even if associated with a fast-moving storm, do not necessarily mean prompt arrival of a storm center. Usually the faster the *Ci*,

TABLE VIII. CIRRUS SPEED AND STORM SPEED

(*Adapted from Clayton* [23, p. 463])

Cirrus speed		Storm speed (mph)	Ratio *Ci*/storm
Range (mph)	Average (mph)		
34– 56	49	20	2.4
56– 79	70	25	2.8
79–101	90	29	3.1
101–123	106	32	3.4
146–168	152	34	4.5

(*Adapted from Pick and Bowering* [77])

Number of cases	*Ci* speed (mph)	Storm speed		
		Range (mph)	Per cent of total cases	Per cent probability
20	<26	<25	85	35
		<45	100	81
52	26–50	25–45	52	46
		<45	96	81
74	51–100	>25	82	65
		>45	34	19
16	>100	>25	75	65
		>45	25	19

the greater the ratio of their speed to that of the storm, and therefore, the farther they will have advanced ahead of the storm center.

Another of Clayton's tabulations [23] relates *Ci* motions to temperature changes (Table IX). Observations

TABLE IX. CIRRUS MOTIONS AND TEMPERATURE CHANGES, BLUE HILL

Direction from which *Ci* moved	Temperature change	All year 410 cases (per cent)	Winter hf yr 205 cases (per cent)	Fast *Ci* 71 cases (per cent)
NW	*Rise* in 12 hr	60	64	76
W	*Rise* in 12 hr	58	69	74
SW	*Fall* in 12 hr	57	66	63
NW	*Rise* in 24 hr	43	48	35
W	*Rise* in 24 hr	34	34	32
NW	*Fall* in 24 hr	48	46	59
W	*Fall* in 24 hr	57	61	61
SW	*Fall* in 24 hr	70	83	75

of *Ci*, totaling 410, all made at 8 A.M., were used and frequency of rises and falls in the subsequent twelve and twenty-four hours noted. Cirrus from the west and northwest were usually followed by a rise in twelve hours and then a fall. The rise could be partly discounted as normal diurnal variation, 8 P.M. being somewhat warmer than 8 A.M. In other cases, falls predominated.

If indications of this type were strengthened with more cases and related to other features, they might be of more value.

Brooks and Harwood [18] noted that fast *Ci* occurred before twenty-four out of thirty-two heavy snowstorms (75 per cent) but before only fourteen of twenty-five very heavy ones (56 per cent). While a fast-moving storm favors precipitation in the form of snow, because of the lack of time for advection of warm air, it also passes so soon that the precipitation is more likely to be moderately heavy than very heavy.

The relationship of *Ci* velocities to weather changes is summarized in Table X (after Clayton [23]).

TABLE X. COMPARISON OF CIRRUS VELOCITIES AND WEATHER CHANGES

Ci velocity range (mph)	Average *Ci* velocity (mph)	Mean daily change in pressure (in.)	Mean daily change in temperature (F deg)	Rain variability* (per cent)
34–56	49	0.11	3.8	19
56–79	70	0.12	4.2	37
79–101	90	0.18	5.3	39
101–123	106	0.19	6.4	31
146–168	152	0.23	7.8	51

* Rain every other day would be 100% variability.

Showers. Cloud observations are particularly useful in forecasting the occurrence and locations of showers. Showers developing from pre-warmfrontal instability at middle levels are usually merely punctuations to general upglide precipitation. Their occurrence, however, can sometimes be anticipated from *Acc* or *Ac densus mammatus*, which reveal the presence of strong convection in middle levels. Longer in advance, *Ci floccus* and *Ci densus*, and especially *Ci nothus*, will indicate the approach of showery weather. If these are seen in the front zone of an open-wave cyclone, it is fair to surmise that they are related to pre-warmfrontal convection rather than simply to cold-frontal overturnings.

Cloud Motions and Shapes as Indicators of Wind, Wind Shear, Vertical Currents, and Turbulence. The progressive motion of a cloud, turbulence on its periphery, and deviations of tall clouds from the vertical indicate actual and relative winds aloft. When cumuliform clouds lean or *Ci* trails depart from the vertical, it is obvious that the wind at one height in the cloud is not the same as that at another height. In a rapidly growing cloud, the amount of deviation from the vertical is the resultant of the rate of fall of the cloud particles and the rate of change of wind velocity with height, both of which may vary. Mrs. Malkus [63, 64] has recently described the process for *Cu*, and Ludlam [62], for *Ci*. Ludlam has presented evidence of a more rapid fall of crystals in *Ci* when they grow in passing through moist layers. When crystals begin to melt they will fall faster. In other words, the up-and-down shape of a cloud represents simple or complex streamlines of the rising or falling air columns the motion of which is rendered visible by the cloud material [13; 62, pp. 48–49]. Strong shear, adverse to thunderstorm development, may be recognized in advance on days otherwise favorable for thunderstorms and used accordingly in forecasting, as Brooks pointed out in 1922 [15, p. 283],

and as recently discussed quantitatively by Byers and Battan [22, p. 173; 99].

The development of *Cu congestus* in the morning is to be used with caution in forecasting afternoon showers; because a strong inversion may stop them short of sufficient vertical development. Or, dry air aloft, usually revealed by fraying tops, may be tapped by the convection, thereby raising the cloud base and lowering the temperature and consequent vertical reach of the clouds. Similarly, as noted above, *Acc* frequently do not indicate a shower.

Altocumulus Direction and Speed and Thunderstorm Movement. In a period when afternoon thunderstorms are occurring or are expected, the direction of motion and the apparent speed of the *Ac* should be noted. If, for example, the motion is from the west, any large cloud heaps or arched tops of thunderstorms in that direction should be watched closely. If the *Ac* have been moving fast, shelter should be sought soon, but if they have been going slowly, a distant storm may not arrive for two hours. Furthermore, if a growing thunderstorm is seen approaching apparently from the northwest, even if the *Ac* have been moving rapidly from the west, the storm is not likely to break as soon as might be expected, for the nearest portion of the storm is not coming toward the observer. Under such conditions, however, the squall will come from the west-northwest or northwest, and is likely to prevail for an appreciable interval before rain begins.

Wind-Shift Line Marked by Clouds. When this condition is noted at either a squall line or a cold front, showers are likely. A wind-shift line at the earth's surface is usually marked by some forced ascent of air; the appearance and approach of cloud forms due to forced ascent thus indicate coming change, often rain, within a few minutes to a few hours, depending on the distance to which the clouds can be seen and the rate of approach. If there is a well-defined cloud base, the height of which is estimated, successive measurements of the angular altitude of the base as it approaches will give a reasonably accurate estimate of the time of arrival of the wind shift.

The approach of a strong wind-shift line may be detected an hour or more in advance by observing the thin white arch of the *Ci* border to the anvil top of the approaching *Cb*. Prefrontal weather is so hazy that only this whitish arch will reveal the presence of a moderately distant *Cb*, for the shadowed air under the heavy anvil will be invisible behind the sunlit hazy blue air near the observer. Thus this part of the sky will appear to be clear and will resemble the blue sky above the *Ci* arch.

When a cold front has passed, the lifting effect of the invading cold air mass continues to make clouds form in middle and upper levels. Though the bank of clouds marking the rainy area associated with the front continues to recede in the east or southeast, new clouds, in bands parallel to the front, continue to form. These new bands will usually not form as rapidly as the general movement of the front carries the whole cloud system away. Indeed, in the daytime, solar heating may throw the western or northwestern edge more rapidly eastward or southeastward than the rate of progress of the front. In the late afternoon and evening, however, the cooling of the moist layers by radiation may, in the case of slowly moving fronts particularly, make the cloud edge retrograde, giving an apparent threat of renewed precipitation which, of course, is quite possible if the front is not far away and if it has some waves in it.

A daytime phenomenon of the clearing-off zone, which Dr. Aili Nurminen has told the author not infrequently makes airport forecasts of improving ceilings fail, is the formation of an abundance of very low *fractocumulus* as soon as the middle and upper clouds permit moderate insolation to reach the wet ground. Fortunately, these soon break, for they so reduce the insolation that convection is weakened. Though more clouds will then form owing to renewed insolation, their bases will be higher.

Difficulties in Forecasting Fronts in Tropics. In the tropics, where fronts are usually slow-moving and often stationary for long periods, the forecasting of frontal passages, which are the chief elements of change in those latitudes, is difficult, as Deppermann [34] very reluctantly admits. Fronts at Manila come mainly from the north, and the upper-air changes due to the overriding of the northers by the trade will occur north of the front and not near Manila. The rare returns of fronts from the south may be heralded by changes in the trade wind aloft. The equatorial front has little overrunning, for the temperature differences between the trades and the southwest monsoon are slight. Even the pre-typhoon sequence of clouds is not perfectly regular, and almost all the cloud forms found in typhoons can also appear on days of strong northers or of many thunderstorms.

Synoptic Types of Sky: How Synoptic Cloud Data May Aid Weather Forecasting

We in the United States pay less attention to states of the sky and cloud sequences than do meteorologists of western Europe, because, except on the Pacific Coast, we have a fairly adequate network of stations, and so do not have to depend upon cloud forms and relationships to give us an idea of weather conditions to the west. Nevertheless, if we do not use the cloud portion of the weather picture, we are depriving ourselves of this considerable advantage in analyzing the weather situation and in following current trends. Schereschewsky [84] emphasized this strongly, as did Bigelow [7] and Ley [60] before him.

The forecaster's situation is still happier, however, when the usual synoptic surface and upper-air data are supplemented with accurate and frequent cloud observations. Of the nineteen elements plotted on the U. S. Daily Weather Maps, seven relate to cloud conditions, and three of these are devoted to thirty separate indications of clouds and their trends at various levels.

The thirty indications are divided into three groups of ten, C_H, C_M, and C_L, each roughly representative of conditions at high, middle, and low levels. The sequence of numbers in each group is generally that from better to worse weather as a storm approaches, ending with the

breakup of the storm clouds as the center or front passes. The various types of sky indicated by the combination of the current C_H, C_M, and C_L have been related to the different portions of cyclones, anticyclones, and frontal systems and to their intensification or weakening. Thus the synoptic maps of types of sky will, by themselves, give a fairly complete picture of the positions and intensities of the cyclones, anticyclones, and fronts of a weather map. Moreover, the diurnal sequence of cloud forms characterizes the type of air mass so well that other features of air mass weather can often be forecast.

An Historical Summary of Cloud Synoptics. Ley, in England, was the first (1872) to show *Ci* motion on a synoptic chart [61], and the first (1878) to make a composite chart of cloud distribution in a typical cyclone [60], which included forms and motions and showed the open sector clear to the center on the south and southwest, with the storm as a whole moving northeastward. Hildebrandsson, in Sweden, was the first (1883) to make a systematic study of the distribution of meteorological elements, including the kinds of clouds and their motions, about barometric minima and maxima [50]. In the United States, Davis [32], in 1894, published a generalized, dynamic cloud cross section of a tropical cyclone and a generalized map of *Ci* and other clouds and rain, winds and isobars of a well-developed low; in 1896 Clayton [23] published a monumental study of the distribution of cloud forms and their motions in cyclones and anticyclones at Blue Hill as compared with Europe, including tables, cross sections, and maps of averages and frequencies; Sweetland [98] followed in 1897 with the cyclonic and anticyclonic distribution of special cloud forms, and in 1900 Bigelow [7] published a detailed 747-page study of the cloud observations at stations throughout the country. The works of Ley, Hildebrandsson, Clayton, and Bigelow were outstanding contributions to our knowledge of the characteristics and circulations of cyclones and anticyclones. These (except Bigelow's) and other researches have been brilliantly analyzed and collated by Hildebrandsson and Teisserenc de Bort [51]. Brooks [11] interpreted, with a cross-section diagram, the cloud details observed at Washington during the passage of a strong cyclone in 1919. During World War I, the French and Norwegians were handicapped by a lack of weather data from the west, and had to base their weather forecasts largely on synoptic interpretations of the cloud systems they observed coming in from the Atlantic. Indeed, this led to the development of air-mass and frontal analysis in Norway.

Bjerknes, in 1919, first related the cloud pattern to frontal systems, with diagrammatic maps and cross sections [8] and, in 1922 with Solberg, added occlusions [9]. Though Guilbert [48] had laid the groundwork in 1922, Schereschewsky and Wehrlé [85] developed the mapping of cloud systems in France in 1923. In developing the dynamics of air masses and fronts, Bergeron in 1928 [4] found clouds helpful. He and Wehrlé, as the most active members of the International Commission for the Study of Clouds, from 1926 to 1932 worked cloud synoptics into the relatively simple pattern presented verbally and diagrammatically in the *International Atlas of Clouds and States of the Sky* [53]. This pattern was amplified by Dedebant and Viaut in 1936 [33] and more clearly depicted by means of cloud cross sections along five lines through an occluded cyclone, and a map of two cloud systems in western and central Europe on February 21, 1935. Viaut [100] has recently improved the idealized pattern and combined the five cross sections into four. Other sections of single storms have been made, giving the details of growing winter cyclones. Photographs from an airplane were taken by Conover [25] to illustrate a cold front, by Douglas [42] to show a cold front and squall line, and diagrams were drawn by Simon [90] to show fronts in Egypt.

Alpert [1] and Berkofsky [6] report the use of low- and middle-cloud sky-cover charts over the easternmost tropical portion of the Pacific Ocean during World War II. These were based on information obtained from patrol flights. In some cases, isolines were drawn for every 0.2 of cloud cover. Such charts proved to be "exceedingly helpful in locating the intertropical convergence zone." Though not strictly synoptic, this was only a slight drawback, for the zones were quasi-stationary.

In 1948, Deppermann [34], after a study of *Ci* stripes in the Philippine Islands, wrote, "Since upper-air currents are themselves subject to considerable changes of path as they proceed, it is evident that an intelligent use of striped *Ci* to indicate the seat of frontal action or a typhoon center demands a good network of upper-air wind and velocity data."

Cloud Cross Sections. In 1926 and 1928, respectively, Stüve [92] and Kopp [59] used Lindenberg data (non-instrumental and range-finder observations of clouds in detail, and records from kite, balloon, and airplane meteorographs) as bases for very detailed representations of temperature inversions, of circulation, cloud, and precipitation cross sections of a warm front, of primary and secondary cold fronts (Stüve), and all the way from anticyclone center to anticyclone center across an occluded front (Kopp). Stüve [94] improved the details of his warm-front section in 1937 and added a cross section through a cold air tongue. In 1943 Schinze and Siegel [87, Figs. 61, 62, 64, 65, 75, 76] published detailed cross sections of warm, cold, and occluded fronts, in which the composition of the clouds (ice, supercooled water, ice and water mixed) and type of precipitation (five types) are shown.

Schneider-Carius [88] has just published a critique of cloud systems, stating that "with the vast experience gained from meteorological flight observations Stüve's cloud system, as a sequel to that of Bjerknes, is considered as antiquated, [while] retaining their importance are the cloud systems of Schinze-Siegel, Schwerdtfeger, and Wehrlé." He finds a "ground layer" the types of which have definite relations to the various states of the low-cloud types of sky of the *Atlas of Clouds* and apply in the tropics as well as in middle latitudes.

Detailed studies of clouds in a particular cyclone are

an aid in interpreting cloud sequences. A cross section showing the clouds and their movements as a storm passes a single station [11] indicates trends but is not synoptic. Conover and Wollaston [27] have recently prepared a detailed study of the cloud systems of a winter cyclone based on a large amount of data from all reporting stations, both surface and upper air, which was reduced to maps of the eastern United States at 3-hour intervals throughout several days. These give a true picture of the cloud development from the origin through the various stages of growth of a cyclone into a full-fledged snowstorm.

Cloud Indications of New Developments. Cloud observations, synoptically mapped, are particularly valuable for indicating the intensification of a low before this trend is apparent in the isobars or surface winds. Often middle clouds afford the first sign of the formation of secondaries, as Miller [69] and George [46] have indicated. Miller points to the sequence of C_M3, C_M5, or C_M7, then C_M2 (*As* becoming *Ns*) in the earliest stages of the development of middle or south Atlantic coastal storms. This cloud development is easily recognizable in Type A storms (new lows, off the coast, usually) but in Type B (secondaries) the new development will be superposed on the lateral sky of the primary, but will be recognizable either by being separated from clouds of equal development nearer the center of the primary or by the apparent progress of this cloud development at a greater rate than the actual advance of clouds into the region.

Cloud and Weather Types. Deppermann [36] has classified Manila weather types more or less directly according to cloud types. His major divisions are Pure Trade, Trade, Northers, Convective Trade, Mild SW Monsoon, Frontal SW Monsoon or SW Monsoon Sector (with typhoon quite distant), and Typhoon types, each with one to seven subdivisions, making twenty-seven altogether. These he has related to an elaborate classification according to frontal types of eighteen main divisions, each with one to seven subdivisions. The map gives the frontal type for the day and the reference table then presents the cloud and other weather features to be expected.

In 1894, Ley [60, see pp. 202–204] proposed something of this sort: that chart books be prepared, showing the distribution of weather, and probabilities for each of a number of synoptic situations. These chart books, he proposed, should be distributed to users of the forecasts and be consulted when the synoptic type was identified by telegram from the forecaster.

Besides the cloud photographs of the various states of the sky in different parts of a cyclone published in the *Atlas of Clouds* [53], an excellent set of such pictures has been published by Miss Douglas [40, see Figs. 142–162, pp. 108–116], and a set of drawings by Brooks [16].

Cloud Indications of How an Approaching Low Will Pass a Station. As the clouds of an approaching storm gather, how can the observer apply the knowledge gained by statistical studies and the idealized or actual charts and cross sections of the distribution of cloud forms mentioned above? The problem is to forecast the track the center will take to one side or the other, the nearness of approach of the center, and the general intensity of the storm. As the clouds thicken steadily from *Ci* to *Cs* and from *Cs* to *As*, an observer naturally expects further development to *Ns* with its rain or snow. There are usually counterindications if such will not be the case, or if the precipitation will come late, amount to little and end soon, or will come in two brief periods separated by several hours of mild, more or less sunny weather. If the northern horizon remains clear until *As* overspreads most of the sky, the storm will probably be passing to the south without bringing precipitation. If the northern horizon is slow in clouding up but becomes covered by the time the cloud sheet is principally *As*, there will probably be some precipitation but not much. In both cases, the temperature will stay low.

If the cloud sheet after increasing to *As* breaks into *As* and *Ac* or *Ci den* and the sky above is seen to have lost most of its *Cs*, the storm is either weakening or passing on the north. In the latter case, the east or northeast wind will veer to southeast and south, unless a secondary is developing to the southwest or south, in which event a new cloud system will appear and go rapidly through the north-of-the-center sequence, already described.

Through the southern margin of a storm, the *Ci* appear first in the west or northwest. They increase hesitatingly. The wind blows from the southeast and does not become strong. The *Ci* thicken to broken *Cs* and these to broken *As*, with local patches of *Ac*. There may be a little rain, and then the wind will turn to south as the warm front passes. The warm, muggy, sometimes showery weather that follows will last for some time before the cold front sweeps over from the northwest or even north-northwest, perhaps with a thunderstorm, but, except for the squall, with less wind afterward. If the low has already occluded, there will be but one brief rain, if any.

The approach and passage of a squall line or cold front is the most spectacular phenomenon of a trip through a low south of the center when the action is strong. A typical sequence is as follows. In the northwest, there appears a long bank of dense, towering clouds, with *Ci*, *Cs*, and *As* in front. The bank soon stretches from west to north, then from west-southwest to north-northeast, and rises higher in the sky. The wind is still increasing. Thunder may now be audible. The high clouds cover most of the sky. The wind begins to weaken as a long, low arch of gray cloud appears across the northwestern sky, which is darkening and growling ominously. The arch rises and lengthens at an alarming rate, as the wind dies to a calm. Now, stretching from the northeastern to the southwestern horizons, the storm collar, with ragged pendants, reaches the zenith as the thundersquall strikes suddenly from the northwest. A downpour follows, with lightning and sharp thunder, and the squall diminishes. After half an hour or more, the sky lightens in the northwest, and the rain soon ceases. As the massive cloud bank retreats in the southeast a cool, dry northwesterly wind begins

to blow. (For another account of the cloud sequence through a storm, see Rossby [81].)

After the low has passed north of the observer, if the wind continues to shift to north or even northeast, and if the high clouds do not clear away, and especially if middle clouds continue, a wave is probably forming on that portion of the front to the southwest, now quasi-stationary and developing into a warm front, and precipitation may be expected again soon, particularly if the clouds are moving rapidly.

Though we cannot agree with Schneider-Carius [88] that it is naive to think one can forecast from clouds alone, it is desirable to emphasize, as did a recent reviewer of Douglas' *Cloud-Reading for Pilots* [40], that an attitude of caution should be adopted towards forecasts deduced solely from cloud structures, since the actual sequences of weather are extremely variable. Knowledge of cloud characteristics of air masses and fronts on the part of the user of forecasts enhances the value of the official forecasts. Brunt [21] wrote: "The greatest difficulty which meets the official forecaster is probably that of timing. . . . The recipient of the forecast can learn, by careful study of the clouds, to check for himself whether the timing of a forecast is correct or not, and in many cases can make use of the forecast when the timing is wrong. . . ."

Desirable Lines of Development

Though cloud systems are already used in professional forecasting, closer attention to clouds should improve both local and general forecasting. For better interpretation of cloud data we need more detailed cloud charts, such as those already mentioned [1, 6, 11], and many more detailed studies of the sequences of clouds in relation to the development and movement of pressure systems and their fronts.

For better observations we need more nephoscopes and more ceilometers and range finders. Nephoscopes should be available at all regularly reporting synoptic stations, to facilitate accurate reports of cloud motions. This would provide a reliable areal continuum for upper-air conditions between the rather openly spaced balloon stations. Ceilometers and range finders, as well as nephoscopes, should be installed at all aerological stations, to supplement the six-hourly pibal and twelve-hourly radiosonde or rawinsonde observations, and to provide a continuous picture of aerological changes.

Wood [102] has suggested that, in the future, automatic radio weather stations might be equipped with television to provide the distant forecaster with a view of the types of sky over his synoptic area. For the time being, we shall have to be content with photoelectric registration of the intensity, degree, and rapidity of variation of light from a small spot of sky overhead to give a rough representation of cloud type (Falconer [43*a*]).

By means of photographs taken from a V-2 rocket, Bergstrahl [5] has shown the distribution of *Cu* in distinct areas, and Crowson [31] has obtained a composite picture of an area of over 500,000 square miles in the southwestern United States and northern Mexico. This comprehensive view made it possible to correlate clouds with atmospheric structure on a large scale. The use of guided missiles to gather atmospheric data has tremendous potentialities, he believes. If television is used instead of conventional photography, complete coverage can be obtained without the problem of film recovery.

Although rocket photography technique is well adapted to desert areas where clouds are thin, it could not do justice to the many layers of damper climates. Perhaps the answer here is television both from above and below!

FOG

By JOSEPH J. GEORGE

Eastern Air Lines, Atlanta, Ga.

Introduction

Fog. The chapter entitled "Fog" in Byers' *General Meteorology* [2] begins with the simple sentence, "It is unwise to attempt an exact definition of fog." It is difficult to find a more adequate beginning.

When a cloud consisting of minute water droplets or ice crystals envelops the observer and restricts his horizontal visibility to 1000 m or less, the international definition of *fog* has been satisfied. Under similar conditions, but with visibility greater than 1000 m the condition is described by the word *mist*, although in the United States this term is popularly applied to the condition meteorologists know as *drizzle*.

Few other meteorological phenomena depend so much upon the location of the observer. A motorist may on one occasion encounter dense fog in the valleys of a hilly terrain and perfectly clear air as he tops the ridges. On another occasion when there is a very low stratus cloud, he may be in clear air only in the valleys and in fog on the ridges. Petterssen [20] points out these inconsistencies clearly and George [6] goes as far as to recommend classing together all types of low clouds forming under conditions which produce fog. The latter course has much to recommend it from the restricted viewpoint of aviation forecasting, but it is completely inadequate for many ordinary uses and impossible for observing practice. The conclusion seems inescapable that with all their clumsiness the present definitions are the most practical solution.

Smoke and Haze. Any discussion of fog must include mention of the related phenomena of smoke and haze. Smoke is considered to be atmospheric pollution caused by the products of imperfect combustion, usually finely divided carbon. Haze consists of very tiny dust particles. Against a dark background such as mountains, haze presents a blue appearance while mist or fog has a gray tone. It will be pointed out later that under many conditions it is impossible to tell when dry haze becomes moist haze, due to the action of hygroscopic nuclei, and when moist haze becomes fog, except for arbitrary visibility limits. The process is a continuous one.

During stagnant anticyclonic conditions, when stabilizing influences are extremely marked, industrial pollution is added to the atmosphere in a normal amount but is confined to the lowest layers of the air rather than being dissipated throughout a deep layer and thus at times produces a high concentration of foreign particles in the air. The combination of fog and smoke under such conditions may remain day and night in a greater or lesser degree. This condition is popularly called *smog*.

Physics of Fog Formation

Since fog is a cloud which happens to form at or near the surface of the earth, the physics of its formation should not be very different from that of a true cloud. Accordingly it is not the purpose of this section to deal with cloud physics except for those features of it which are unique to the formation of fog, or which may differ from their counterparts in cloud above the ground.

The Role of Condensation Nuclei. Through the works of Wilson, Aitken, Wigand, and others, it has been known for many years that condensation under atmospheric conditions requires the presence of some sort of nuclei if it is to take place at any reasonable humidity. At first it was concluded that ordinary dust furnished these nuclei, but it is now believed that only special types of hygroscopic nuclei are really effective. Among these are (1) salt particles which apparently have become airborne from sea spray and have been carried long distances by the wind, and (2) hygroscopic products of combustion such as sulfur trioxide and possibly nitric oxide. According to a description by Landsberg [15], condensation does not take place in the absence of ordinary nuclei until about fourfold supersaturation is attained, and it is believed that this condensation takes place with ions as nuclei. Spontaneous condensation apparently begins at about eightfold supersaturation and takes place as droplets "so fine they resemble a cloud or fog."

In the presence of the hygroscopic nuclei mentioned above, condensation begins at humidities well below saturation. During the formation of a fog, the relative humidity is observed to increase gradually, and correspondingly the amount of suspended liquid water increases as more and more nuclei attract condensation or as already existing droplets grow larger. It is known that many fogs, especially those in industrial areas, form and exist with humidities well below 100 per cent and humidities as low as 80 per cent have been reported. Accordingly the process of fog formation is a continuous one, in which the time required for formation is governed by the rate of increase of relative humidity and the quantity and type of nuclei present. Figure 1, adapted from Neiburger and Wurtele [16], illustrates this point with data gathered at the Los Angeles Airport under conditions in which sea salt was presumed to supply the nuclei. The authors point out that the visibility becomes approximately constant below a humidity of about 67.5 per cent. At this point they consider that the drops become crystalline and the obstruction to vision becomes essentially a dry haze. It is well known that there are nearly always sufficient numbers of active nuclei present to form fog when the humidity reaches saturation. Supersaturation in the production of fog is therefore generally considered to be limited to the order of one per cent or less when it exists at all.

Willett [24] points out the fact that fogs produced at unusually low humidities are particularly dense and

dry, and consist of an unusually large number of very fine particles. These fogs are slow to be dissipated and very disagreeable to people living in regions where they occur. Of course a substantial part of such a fog must be solid particles of combustion.

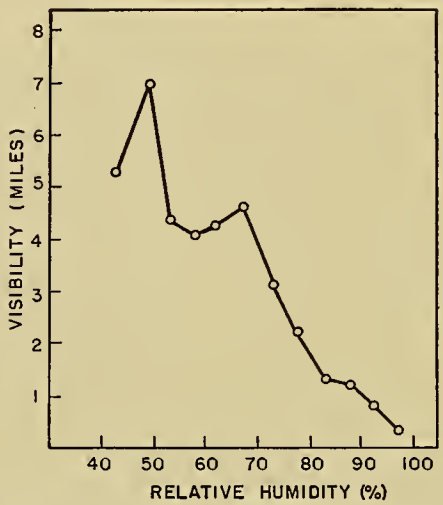

FIG. 1.—The relation between visibility and relative humidity at Los Angeles Airport. (*Adapted from Neiburger and Wurtele* [16].)

Drop-Size Distribution and Liquid-Water Content. Among the most important physical characteristics of fog are the size distribution and water content of the particles comprising it. Although various indirect methods which gave some idea of the drop-size distribution had been known for a considerable time, it remained for Houghton and Radford [13] to perfect a direct method for examining these droplets microscopically. They found that the maxima of the volume distribution curves obtained from forty sets of data taken in sixteen fogs (all of an advection nature, since the location was near the Atlantic Ocean) ranged from 12 to 90 μ. An average of about 30 per cent of the liquid water contained in the fog fell within a 10-μ band centered about the peak of the curve. Individual drop diameters were measured between the extremes of 2 and 130 μ. It should be particularly noted that these figures refer to volume of water and not to frequency of drop diameter. For example, in a given fog the arithmetical mean of drop diameters observed was about 12 μ while the volume mean diameter amounted to 40 μ.

More recently, Heverly [10] has found droplet diameters (in fogs probably purely radiational in character) markedly less than the figures given by Houghton and Radford. In one particular case he cites a range of only 1.5 to 15 μ for drop diameters while in practically every case they examined Houghton and Radford found drops ranging as high as 60 or 80 μ. Heverly [10] observes,

> It appears that coalescence in drop measurements has been overlooked or, at least, underestimated by a number of experimenters. In one instance, when an especially high density of the droplet field was obtained, a great deal of coalescence was microscopically observed. Coalescence took place instantly whenever droplets of water in the vaseline came into contact with one another. Unless the droplets are separated by a distance equivalent to several drop diameters, coalescence appears to be a serious factor and is, probably, the reason for some of the high medians of fog-droplet sizes reported in the literature.

Neiburger and Wurtele found that the most frequent drop diameter for Los Angeles stratus was 14 μ, a value which seems to be in agreement with Houghton's results. Furthermore, these investigators found drops up to 75 or 80 μ, particularly near the base of the stratus, which would presumably correspond with the surface measurements in a fog at ground level. This small but quite possibly important difference in drop-size measurements could of course be due to a difference in techniques as was suggested by Heverly, but it seems more likely that there is a fundamental difference in the characteristics of the fogs examined. Houghton's measurements were made almost entirely in pure advection fog uncontaminated by industrial pollution, while Heverly's apparently were made in the Pennsylvania mountains where industrial pollution is strong and where fogs are almost entirely radiational in character.

The liquid-water content of fogs is one phase of the physical aspects of the matter which appears to be open to little question. Radford's diagram [13, p. 29], reproduced here as Fig. 2, relates the measurements of several independent investigators at various locations to the horizontal visibility, both on logarithmic scales.

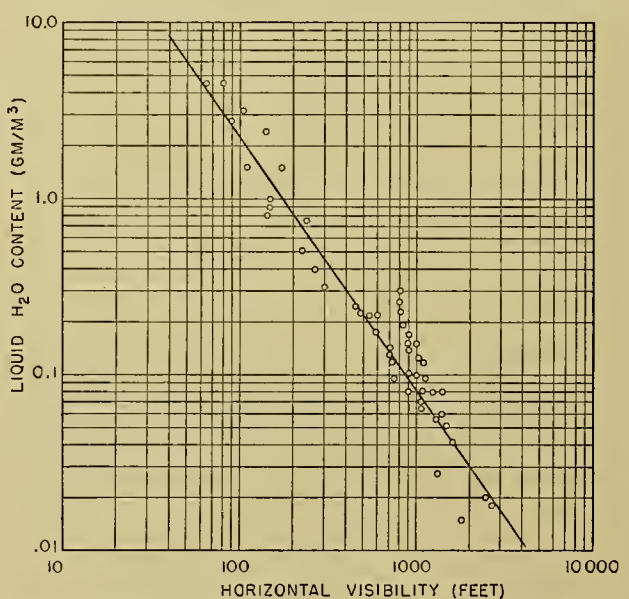

FIG. 2.—Relation between liquid-water content of fogs and visibility. (*After Radford* [13].)

The fit of the curve is surprisingly good for this type of data. It is of interest to note from this curve that visibility will be reduced to less than 1000 m, thus creating fog, by as small an amount of liquid water as 0.02 g m^{-3}.

It seems likely that visibility in industrial areas would be considerably less for corresponding liquid-water contents than is shown by this graph. Willett [24] remarks,

The smaller number of particles is characteristic of the wet and less dense type of fog which consists of relatively large particles. The larger number is the characteristic of the very dense and dry type of low level industrial fog which consists of a great number of very small particles. The wet fog with 10^2 particles per cc may contain more condensed water per cc than the dry fog with 10^4 particles, but for the same amount of liquid water per cc the dry fog of numerous particles is much more effective in reducing the visibility.

Fog over Snow Cover. The formation of fog over snow introduces considerations which are not present in the absence of snow cover. The principal effect is that the snow cover acts as a fog-inhibitor. Petterssen [19] cites climatological evidence to the effect that fogs are rare over snow-covered areas in winter, just when radiational conditions are nearly perfect. His evidence, however, indicates that for temperatures below −40C fogs increase again and are frequent during such low temperature conditions when they are ordinarily composed entirely of ice crystals. Byers [2] comments on the frequency of fog particularly at very low temperatures and quotes from Frost's *Climatological Review of the the Alaska-Yukon Plateau*, "At Fairbanks dense fog always accompanies temperatures of −45F or lower . . . ."

However, important recent evidence is presented by V. J. and M. B. Oliver [18] to the effect that these low-temperature fogs form only around settlements and are almost nonexistent in regions only a few miles removed from them. Pilots accustomed to flying in the arctic winter confirm this, and it seems that many of the accepted statistics concerning arctic fogs at low temperatures are impeached by this evidence. The Olivers offer the hypothesis that smoke particles from the towns act as sublimation nuclei and are the necessary element for the formation of fog under these conditions. They suggest that the smoke contains sublimation nuclei not present in sufficient numbers otherwise. They also point out, however, that the sources of smoke are also sources of moisture which may be of primary importance.

The reasons for the low incidence of fog over snow cover are completely treated by Petterssen [19]. Briefly, for temperatures above freezing he considers that the temperature of the snow surface remains near 0C and that the usual condition of an increase of specific humidity with elevation causes an eddy flux of moisture toward the surface, with the result that condensation takes place on the snow. This removes moisture from the air and acts as an inhibitor of fog but does not entirely prevent it. The higher the temperature above freezing, the greater the dissipating effect. (Although it is not mentioned by Petterssen, it is apparent that this process would have no such dissipating effect upon low stratus clouds.) At a temperature of exactly freezing for both air and snow surface no dissipating influences exist, since the saturation vapor pressure is the same over water and over ice at this temperature. For temperatures below freezing, Petterssen ascribes the dissipating process to the difference between the saturation vapor pressure over water and over ice.

The Olivers [18] mention another dissipating influence on supercooled water fogs.

A mixture of water fog and ice fog occasionally forms at temperatures between zero and freezing, when clearing skies permit rapid cooling by radiation. This condition lasts for only a few hours, during which period the water fog rapidly changes to ice fog or rime and the ice fog thins out and disappears even though temperatures continue to fall. This general weather situation also produces rapid accumulation of hoar frost on trees, wires, and other exposed surfaces. Apparently, the snow surface, trees, wires, etc., are much better radiators than air, and so become much colder than the air, thereby permitting rapid frost deposits, rapid drying of the air, and lowering of the dew point.

It is well known that fogs contain supercooled water down to temperatures of −20C to −40C. The recent work of Schaefer [22] indicates that at −39C fog particles of 10- to 15-μ diameter will freeze without outside stimulus. Köhler [14], some time ago, found that large drops became ice at higher temperatures than small ones, and Heverly [11] has recently produced quantitative results which seem to show that fog droplets with diameters of 50 μ would begin to freeze spontaneously at about −28C or −30C. Even if it is argued that fog droplets are much smaller than this at these temperatures and consequently would have a spontaneous freezing point nearer to Schaefer's −39C, there is still another effect which would lead to a mixture of ice and water particles below −28C. For example, if saturated air at a temperature of −28C is cooled further, as by radiation or upslope movement, the further condensation resulting will [11] "produce relatively fewer and smaller water droplets and more ice crystals." Accordingly we may conclude that nearly all fogs in air at −28C will contain some ice crystals and that the proportion of ice crystals to supercooled droplets will increase rapidly for lower temperatures.

Bergeron [1] has shown that a mixture of supercooled water and ice crystals is "colloidally unstable." Due to the difference in saturation vapor pressure over water and over ice, the vapor pressure over the water droplets would be appreciably greater than that over the ice particles, and a flux would be set up causing evaporation of water particles and an increase in size of the ice particles. There is a tendency for mixed water and ice fogs to change over entirely to ice fogs by this process. Figure 3 is particularly interesting in the light of the above discussion. It is from the Olivers' paper [18] on Alaskan fogs. The almost complete absence of fog at temperatures above −33C and the very rapid increase at lower temperatures seems to add credence to the hypotheses discussed above. All authorities agree that for temperatures below −39C fogs are composed entirely of ice crystals which are in equilibrium with a snow surface and therefore have no tendency to dissipate due to the surface condition.

Physical Processes. The classical concept of the radiative and heat balance of fog situations is about like this: After nightfall, on calm clear nights, the radiational cooling of surface objects is much more rapid than that of the air. Consequently the surface layers of

the air are cooled by conduction, and if this process is carried far enough, dew forms. If there is an increase of specific humidity with altitude, an eddy flux of vapor

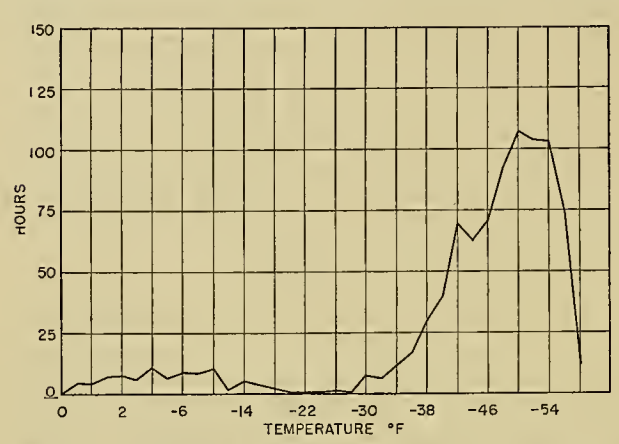

FIG. 3.—Number of hours of fog for various temperatures at Fairbanks, Alaska 1942–1947 inclusive. (*After V. J. and M. B. Oliver* [18].)

downward is established to replace that which has condensed. At the same time, if there is any amount of turbulence at all, heat is conducted toward the surface layers along with the moisture, and some of the cooled air is forced aloft and slightly cooled still further by adiabatic expansion. This process, if continued, is supposed to cool the entire surface layer of air to saturation and thus fog forms. If there is no turbulent interchange of air or if the moisture content decreases vertically, then there will only be a deposition of dew. Obviously the presence of a cloud cover will offer counter radiation to that of the earth and permit so little cooling of the surface layers of air that the possibility of fog is practically eliminated. Likewise if the movement of air is sufficiently rapid for the surface roughness of the area concerned there will be established a turbulent layer deep enough so that more cooling will be required than is available. The intermediate condition between fog formation at the ground and no fog at all (given fog conditions with varying wind velocity) is that in which a stratus cloud deck forms.

Recently, Emmons and Montgomery [5] have pointed out that there is another factor which has not been thoroughly considered. In their words,

> What has not previously been considered in explanations of fog formation is that air with dew point higher than the temperature of the cold surface necessarily loses water vapor by eddy diffusion and real diffusion toward the surface and condensation on it regardless of the nature of the surface. Under the conditions existing when fog forms, eddy diffusion is equally effective in transporting both heat and water vapor. In the laminar layer next to the cold surface, the losses depend on conduction and diffusion, which are effective to nearly the same degree; actually the ratio of thermometric conductivity to diffusivity of water vapor in air is only 0.84. Therefore temperature and dew point both decrease, and although their difference decreases, they cannot become equal, *i.e.*, saturation cannot result, by this process alone.
>
> It must be concluded that fog can form next to a cold surface only when there is further cooling by radiation directly from the air or when saturation is not required.
>
> Likewise, in the opposite case of air in contact with warmer water (whether a water surface or falling precipitation) . . . air receives heat as well as water vapor, so that saturation does not necessarily result. However, in this case three circumstances help bring about saturation and fog; (a) Because diffusion is slightly more effective than conduction, the air gains relatively more water vapor than heat. (b) There may be some heat loss by radiation directly from the air (*e.g.*, when warm raindrops fall through air over cold ground). (c) If the temperature contrast is very large (as in the case of sea smoke), mixing of unmodified air with air modified by the water may produce greater water concentration than is required for saturation at the temperature of the mixture.

Strangely enough, radiation, the most important single element in the formation of fogs, requires less discussion than almost any other aspect of the subject. The reason for this seeming anomaly is not that radiation is of little importance, for without it the only fog formations would be sea fogs, fogs occurring on mountains due to upslope winds (really clouds), and perhaps a few isolated cases of fogs over snow cover. The explanation is, of course, that the difference between various radiative conditions usually amounts to only a very few degrees, and the other factors in the formation of fog make this difference so small that it may usually be neglected.

Suggestions for Research. Deficiencies in our knowledge of the physical processes of fog formation are present at all stages. Beginning with the nuclei, it is apparent that our knowledge of what constitutes them and how they operate is rudimentary. For example, the questions raised by Neiburger and Wurtele [16] concerning the role played by industrial impurities in lowering the relative humidity in fogs appears to cast doubt on at least one accepted idea. The submicroscopic size of these particles makes it difficult to suggest any direct avenue of attack, but perhaps it might be possible to devise laboratory experiments which would answer some pertinent questions concerning the effects of various atmospheric contaminants.

The matter of drop-size distribution appears to be fairly well answered, but the question raised by Heverly should be cleared up, perhaps by a series of observations taken at a number of locations such as mountain valleys and flat areas at some distance from water surfaces of any kind. Furthermore, it might be very instructive to have a series of such measurements made during the formation and dissipation of pure radiation fogs of shallow nature. A series of vertical measurements not only of drop size but of humidity and liquid-water content would also help to reveal the nature of fogs, particularly if the fog area were shallow enough to obtain a complete cross section from dense fog at the base to clear air at the top of the observations.

The question of the number of fog droplets per unit volume has never been accurately answered. Estimates as low as 1 drop cm^{-3} and as high as 1000 drops cm^{-3} have been made. Of course it is true that droplet count varies with the amount and kind of nuclei and with different kinds of fog; however, exact knowledge is

entirely lacking. Probably entirely new techniques will be required to resolve this question satisfactorily.

The formation of fogs over snow cover at very low temperatures probably can be adequately described from available knowledge. However, it would be desirable to have confirming data as to whether ice crystal fogs form over regions remote from human settlements and whether these settlements cause the formation of fog by the addition of otherwise absent sublimation nuclei or in some other way.

The vertical gradient of water vapor in the lowest thousand feet of the atmosphere is something which almost all authorities treat as of considerable importance in the formation of fog. Yet quantitative knowledge of the subject is limited. Some pertinent questions concerning vertical moisture gradients are (1) Exactly what kind of gradient is required for the formation of various densities of fog? (2) How high above the surface do moisture inversions usually extend during fog formations? (3) What rate of flux attends various stability conditions, wind flow, etc.?

It should not be too hard to answer some of these questions at least in part by using existing observation towers with perhaps simple additions to equipment, although the location of these towers with respect to sufficient quantities of fog appears doubtful. It would seem that such observational data might easily be a key not only to broader concepts of the physical process of fog formation but to better methods by which to forecast it.

Synoptic Aspects of Fog

Practically all treatises on fog begin with the author's idea of a classification of fog, usually according to causes. Most such classifications are eminently logical and serve the purpose for which their author intends them adequately and well, and they should be considered according to the user's needs. Willett's table [25], slightly modified by Byers [2, p. 509], is given below and serves as an adequate model, despite the fact that the original version appeared as long ago as 1928.

A. Air-mass fogs.
   1. Advection types.
      a. Types due to the transport of warm air over a cold surface.
         (1) Land- and sea-breeze fog.
         (2) Sea fog.
         (3) Tropical-air fog.
      b. Types due to the transport of cold air over a warm surface.
         (1) Steam fogs (arctic "sea smoke").
   2. Radiation types.
      a. Ground fog.
      b. High-inversion fog.
   3. Advection-radiation fog (radiation over land in damp sea air).
   4. Upslope fog (adiabatic-expansion fog).

B. Frontal fogs.
   1. Prefrontal (warm-front) fog.
   2. Postfrontal (cold-front) fog.
   3. Front-passage fog.

In addition to the classes listed by Willett, the following types appear in Petterssen's scheme [19]: (1) isobaric fog, (2) isallobaric fog, and (3) fog formed by horizontal mixing. All of them (except the last one, under special conditions) are designated by the author as rather unimportant.

If a classification such as these is to be used for forecasting, then it is not only desirable but necessary to eliminate all of the causes listed which are not of direct forecasting value. If this simplification is not made, the forecaster must continually concern himself with rules for the forecasting of various kinds of fog whose causes overlap and which cannot be anticipated by any clear-cut methods. Furthermore, in the case of many types of fog the frequency of formation is so low that any attempt to forecast their occurrence results in continual errors on the side of forecasting a phenomenon which does not occur.

If all of the nonessential types of fog (for practical purposes) are eliminated or modified, only the following classes remain:

A. Air-mass fogs.
   1. Advection types.
      a. Sea fog.
   2. Radiation types.
      a. Restricted heating fog.
      b. Air-drainage, including marsh fog.
   3. Advection-radiation fogs.

B. Frontal fogs.
   1. Pre-warmfrontal fog.
   2. Mixing-radiation fog.

This list is restricted to only six categories of fog, compared with the eleven given in the Willett-Byers classification; fourteen, if the extra types described by Petterssen are added. If the reduction (which is usually made in forecast offices whether or not it is officially recognized) is justified, it simplifies the forecasting problem. Accordingly, a brief consideration of the categories modified or eliminated seems desirable.

Land- and Sea-Breeze Fog. This type of fog is conceded by most authorities to be essentially the same as sea fog. Furthermore its occurrence is distinctly unusual except perhaps in restricted areas of certain sea coasts. Its influence is seldom felt more than two or three miles inland. For these reasons it does not seem that fog of this type merits a separate forecasting division except possibly in very special instances which are better handled as exceptions.

Steam Fogs. Although these fogs, which occur over open water in very cold temperatures, are extremely interesting, they are always shallow and usually do not restrict the visibility to very low values. Furthermore, they are confined mostly to the edges of open water. Byers ascribes them entirely to a difference in vapor pressure between the open water and the air above it of the order of 5 mb. Again, the basic requirement of forecast need is not likely to be present for this type of fog and it is therefore omitted.

Upslope Fogs. Almost every textbook on meteorology

lists this as an important classification of fog. One of the requisites for the formation of this type of fog has been listed by Petterssen as conditional stability of the air mass. If it is not stable, then vertical mixing as the air is lifted will add drier air from above, thus lowering the humidity of the surface air and destroying the chances of fog formation. But it is just in these stable cases that the air flow in the surface layers is most nearly laminar. In this type of flow the mixing of the different layers is at a minimum and consequently, in a typical case, the air arriving at some higher elevation upslope will be far more likely to consist of air which was originally well above the surface, consequently much drier at a point upwind (and downslope) and far from being in prime condition for fog to form. If we take the case in which the wind velocity causes a homogeneous turbulence layer to form, we still must find some method which will cause this layer to gain an abnormal amount of moisture, and strong upslope areas do not usually contain sources of moisture at the surface.

At least in the United States, there is no source of air-mass properties which produces a stable, moist air mass of the proper qualities to form fog by being blown up a geographic slope. Either the air mass is too dry, though stable, or it is moist and unstable. An example of the first type is Canadian *Cp* air, and an example of the latter is *mT* air from the Gulf of Mexico. The region in the United States most noted for upslope fog is the Cheyenne area. Yet, even in 1938, Clapp [3] wrote,

> The importance of humidification and even saturation of the surface air by falling precipitation is emphasized by the fact that only 16% of all fogs studied occurred with a twenty-four hourly precipitation preceding the fog, both at Cheyenne and in surrounding territory, of less than .01 inch. In fact, the majority of fogs occur with precipitation of some form falling before and during the fog.

Clapp also mentions the importance of cloud cover, and it seems reasonable to suspect this factor of being the source of much of the 16 per cent mentioned which occurred without precipitation.

Despite the hallowed spot which the so-called upslope fogs have attained in the minds of most meteorologists, it seems clear that as a primary cause of fog this factor may be completely eliminated from consideration. This is not meant to minimize the importance of upslope cooling in the production of low visibility in pre-warm-frontal precipitation areas, for this is frequently an important factor.

The only place at which this category should receive serious consideration is along the higher portions of a mountain range or even of an isolated mountain. Here, clouds form purely by upslope motion and certainly the resultant fogs, to the comparatively few who experience them, must be classified as pure upslope fog.

Postfrontal (Cold-Front) Fog. As Byers points out, this type of fog is rare and occurs almost entirely when the cold front has become nearly, or quite, stationary, and resembles a warm-front condition in most respects. There are exceptions caused by geography, as might be expected, and they may be important to individual forecasters, but there is little profit to be gained from a detailed consideration of this fog classification other than to recognize the fact of its existence.

Advection-Radiation Fog. One of the biggest sources of confusion to forecasters has always been the breadth with which the term "radiation fog" has been treated. For many years it was the custom of meteorologists to term a fog "radiation" if it formed at night and consequently required the air to lose heat by radiation. George [6] has pointed out the fallacy of this practice. Consider most locations within a hundred or so miles of a temperate latitude seacoast. When conditions are such that air blows from the sea to the land the formation of fog over wide areas of the coastal plains is common and, aside from the immediate seacoast, it forms only at night. When the air flow is from land to sea, under clear skies, no fog forms even under perfect radiative conditions. Which factor is more important, the advection of moist air from the sea, or the loss of heat by radiation at night? Both of these factors are necessary for the formation of fog.

It was for this very common type of fog that the classification *advection-radiation* was established. It is defined as fog occurring in any air mass which has been over an extensive water surface during the daylight hours preceding the night of its formation. Obviously, this definition includes air which was originally colder than the water surface as well as air which was warmer. In the first case, the process of fog formation involves the rapid addition of moisture to the air by its passage over the water and requires strong nocturnal cooling over land to stabilize the lower layers before fog can form. In the latter instance of warm air passing over cold water, evaporation is slow or nonexistent, but the combination of negligible heating by solar radiation while over the water, together with the cooling and stabilizing effect of the cold water surface on the lower layers of air, prepares these layers for fog by requiring little or no nocturnal cooling over land.

It is apparent that, following a strict classification according to causes, two different processes are represented here. For the purpose of scientific investigation it would be necessary to recognize two types, but for forecasting purposes they may conveniently be grouped together in one category and called advection-radiation fog.

Radiation Fog. The question next arises as to exactly what types of fog should be called "radiation." From the same source as the preceding discussion it seems reasonable to adopt the convention that pure radiation fog is that which forms in air that has been over land during the daylight hours preceding the night of its formation. Furthermore, there are two main conditions favorable for radiation fog: (1) The air has been under a cloud cover with or without precipitation falling through it during the day previous to its formation. (2) Pools of air cooled to an excessive degree have collected in valleys, causing air-drainage fogs. Although they are not quite the same, it appears reasonable also to place in this category those fogs which form in low marshy land and along river valleys on calm, clear

nights. This definition of radiation fog carries with it the implication that such fog does not form unless one of the two conditions mentioned above is present.

Some misunderstanding of these principles has appeared; for instance, O'Connor [17] specifies a nonconvective cloud cover, and states that fogs formed as a result of this type of restricted heating are usually post-coldfrontal. In reality, a large proportion of cloud covers which result in radiation fogs are strictly convective in origin, and although practically all fogs in clear air behind cold fronts are formed from this cause, they are very few indeed when compared with the total number of radiation fogs caused in this way.

For forecasting purposes there is little point in distinguishing between ground fog and stratus as two different types of fog, for in nearly all cases the forecasting problem is identical. Whether ground fog or stratus results is entirely dependent upon (1) the terrain, (2) the characteristics of the air mass, and (3) whether the wind velocity exceeds a certain value. Accordingly, in the forecasting classification "ground fog" and "high inversion fog" are replaced by "restricted heating" and "air drainage fog."

Forecasting Methods

The forecasting of fog is, above all other considerations, a local problem. There are many instances in which airport sites which have been moved only a few miles required definite revision of methods for forecasting fog. This is especially true of locations at which an advective element is present. Each season usually requires a new technique, and the duration of the season must be determined from local data.

Advection Fog (Sea Fog). As the name implies, fog of this type forms over the open water as a result of the advection of warm moist air over colder waters. This process obviously stabilizes the air and if continued long enough cools the air to its dew point and fog is formed. The forecasting of these occurrences for sea areas can best be done by combining a computation of future trajectories [2, 7] at various points with a careful plot of mean sea-surface temperatures.

Radiation (Restricted Heating) Fog. There is only one type of fog which can be forecast by using a single tool for most localities, and even this type must be hedged with restrictions. The tool is George's restricted heating radiation fog graph. This method has been tested at various locations in the eastern United States and found to be valid at all locations tested which (1) were not within about 50 miles of a seacoast or other large body of water (including some large rivers) or (2) presented no severe air drainage problems. Figure 4 shows the general form of the radiation graph from Roche's study [21] of Carolina stations. It is not entirely clear why a locality near a seacoast does not experience fog caused by restricted heating in the same degree as inland stations, but it seems likely that land-breeze effects at night added to the normal divergence caused by decrease in friction as the air moves from land to sea may very well thin the moist layer enough to overcome all but the most ideal situations.

The presence of precipitation as a primary element in the formation of fogs has been recognized for some time. Counts [4] cites it as a basic precept in forecasting

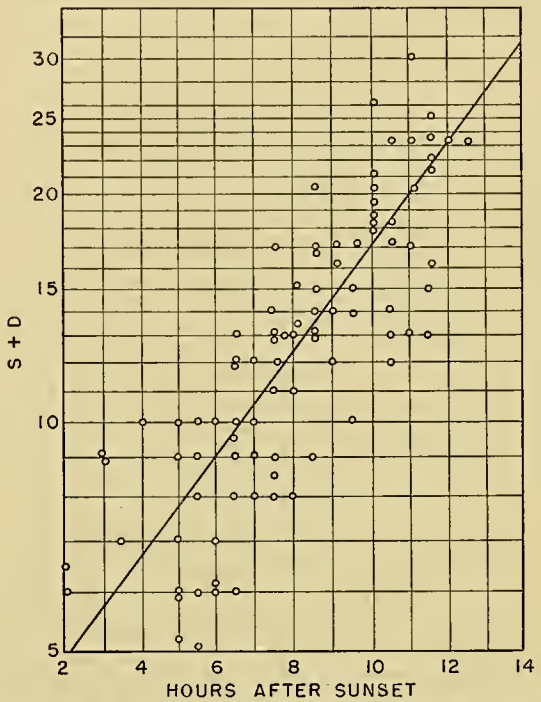

FIG. 4.—Radiation fog graph devised by George and Bradley. Data are by Roche, for Carolina stations. S + D (ordinates) are the sum of the number of sunshine hours during the day plus the number of degrees between temperature and dew point at sunset. The units are mixed but retained in this inaccurate form for practical convenience. Abscissas give number of hours after sunset that fog should form.

fog in California's San Joaquin Valley, and earlier in this article it was pointed out that Clapp found it an almost essential factor for the formation of fog at Cheyenne, Wyoming. Precipitation occurring during the day aids in the formation of fog in two ways: (1) it adds moisture to the lower air layers, and (2) the attending clouds act to prevent the normal diurnal rise in temperature.

At one location (Atlanta, Ga.) a study [8] has been made of the difference in fogs and stratus clouds caused by daytime precipitation conditions and those formed when only cloudiness (without precipitation) was present. Figure 5 illustrates this difference. For geostrophic winds of 15 mph, the resulting stratus clouds in rain situations have an average minimum ceiling of about 200 ft (Fig. 5*a*) and not infrequently they may lower to the surface as dense fog. For the same wind velocity, Fig. 5*b* shows the minimum ceiling in "no rain" situations to be about 700 ft. For geostrophic winds below 12 mph the "no rain" graph indicates that the fog forms and remains a true fog, that is, one at ground level. According to these data, the effect of rain is to add enough moisture to the lower layers to offset to some extent the dissipating effect of higher wind velocities.

Radiation (Air-Drainage) Fog. At various locations, unusual geographic conditions exist which cause the

formation of fog under circumstances that otherwise would not produce fog. The air-drainage fogs which cause the valleys of the Allegheny chain to have one of the highest incidences of fog in the United States [23]

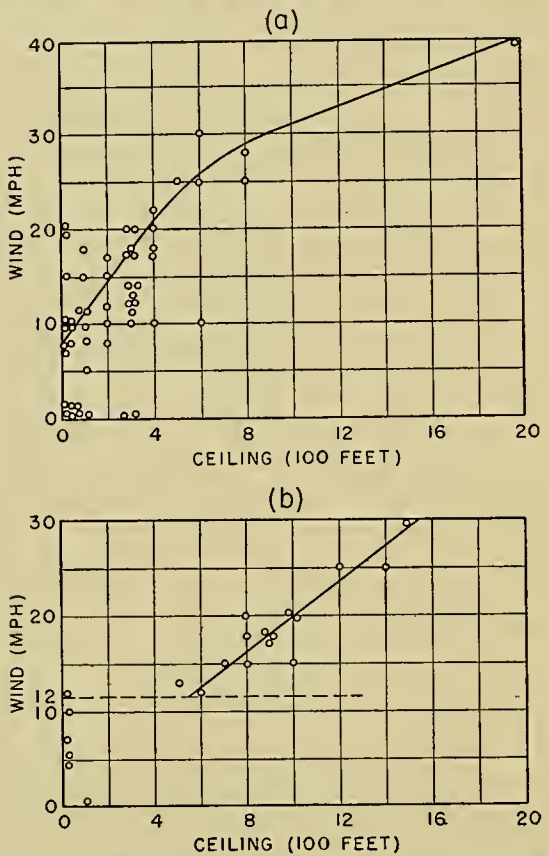

FIG. 5.—(*a*) Forecasting graph for restricted heating fog with rain in the trajectory (for Atlanta). Ordinates are geostrophic wind velocities scaled from the noon chart prior to the night of fog formation. Abscissas give the minimum ceiling attained the following morning. (*b*) Same as (*a*) but no rain in the trajectory.

are caused by geographic conditions. Another example is Charleston, W. Va., which is in a river valley opening to the Ohio Valley toward the northwest. Fog results when anticyclonic conditions prevail in such a manner as to prevent flow of air down the river valley and consequently make air drainage the paramount feature. In many cases, no restriction of heating is concerned; it may be, and frequently is, clear all day at the station and to windward. Methods of forecasting involve the use of the gradient wind direction and the moisture content.

River valleys, especially low-lying marshy ground immediately adjacent to the river, are frequently subject to fogs on calm nights despite a lack of cloud cover during the day or any special air-drainage characteristics. Such areas require special treatment for forecasting, but so far as is known no location of this sort has received much study.

Advection-Radiation Fog. Stated simply, advection-radiation fog is a fog which requires both factors before it may form. The description which follows is, with a few modifications, that given by George [6].

The area over which advection-radiation fogs may form is immediately and clearly defined as that portion of the coastal plains which the lower air layers may reach in one night's travel from the water. A practical limit to gradient winds which allow fog to form is about 30 mph but almost never will this value exist both for the full distance inland and the entire time consumed in traveling this distance; the average transport of air will also be much less because of surface friction. In practice, about 200–250 miles during winter and 150 miles in summer were found to be the inland limits. This allows a maximum average transport of air amounting to 14–18 mph.

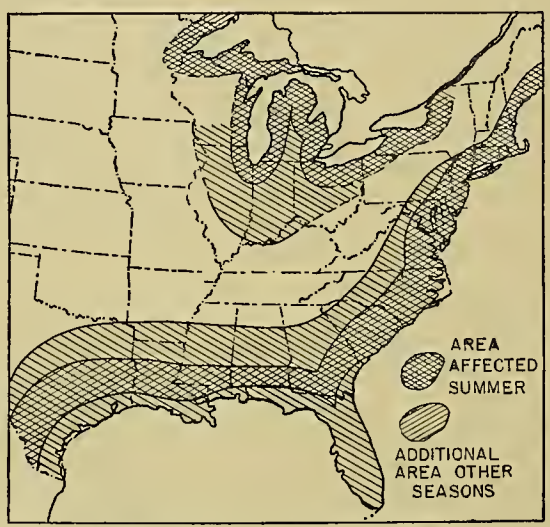

FIG. 6.—The distribution of advection-radiation fog in the eastern United States, showing how the areas affected increase during the portion of the year which has longer nights.

In Fig. 6, the double hatching indicates the area along the Great Lakes and the eastern coast of the United States which is subject to advection-radiation fog in summer and the single hatching indicates the additional area affected during the remainder of the year. During summer, there is a strip 30–50 miles wide along the Gulf and Florida coasts in which no fog forms. The reason this exists is probably because gradient winds from sea to land, sufficient to overcome the tendency for land-breeze formation, allow insufficient time for stabilization caused by radiational cooling to take place. If the land breeze does develop, the accompanying subsidence and other effects are sufficient to prevent the formation of fog. During the colder months, and even in summer farther north, the colder shore waters precool the air, and fog may form even along the coast with reasonable wind velocities. During winter, fall, and spring, the area which is subject to such fog is considerably extended, but it should be noted that this area has nothing to do with the frequency of formation, and, for instance, north of latitude 37°, advection fogs are rare in winter.

The accurate forecasting of advection-radiation fogs is difficult and varies markedly from place to place. Figure 7 illustrates how the gradient wind, no doubt controlled by irregular land and water surfaces, varies

during fog conditions at New Orleans Airport [12]. Other localities require more complicated treatment than this. For instance, Figs. 8*a*, *b*, and *c* show the

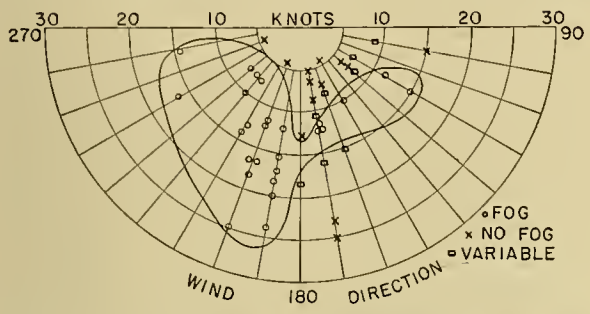

FIG. 7.—A typical method for forecasting advection-radiation fog for New Orleans Airport during winter (*after Hilworth* [12]). The data are gradient winds taken from the afternoon upper-wind sounding.

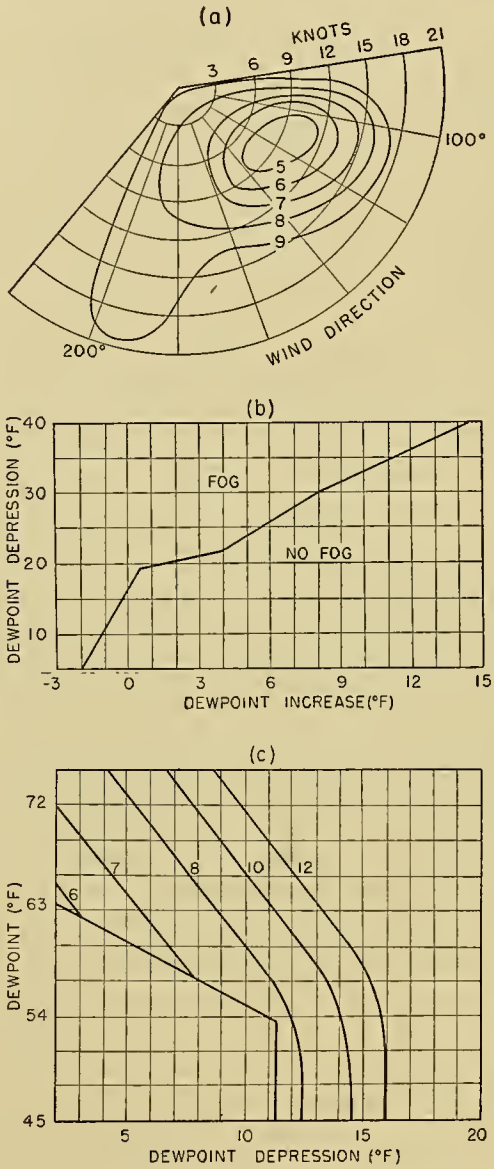
steps required with present methods for forecasting this type of fog at Charleston, S. C., during the fall months. Other and still different methods are used for the remaining seasons.

Pre-Warmfrontal Fog. The forecasting methods for this class of fog usually given in textbooks are rather general in nature and sometimes they are omitted altogether. It is difficult to find much literature on the subject which would be of real assistance to an investigator wishing to learn how to forecast these occurrences. Perhaps the biggest difficulty is the vaguely recognized fact that local geography again plays a dominant role. For example, pre-warmfrontal fogs occur very rarely at Cleveland, probably due either to downslope compressive heating in the cold air or to the frictional divergent effects caused by the proximity of Lake Erie, or to both. At this locality, the clouds consistently remain well above the ground in pre-warmfrontal situations, while at Atlanta, Washington, D. C., and Chicago, fogs formed in this way are common.

Some rather ingenious methods have been utilized for forecasting the formation of low stratus in warmfront situations. An example is Roche's graph [21] for Charlotte, N. C., shown in Fig. 9. In nearly all such methods, however, the authors have used synoptic material which was readily available in a practical sense. Not much effort has been made to apply quantitatively any relationship between temperature of falling precipitation and the surface air layers, which Petterssen has pointed out to be very important to the problem. Also, consideration of the stability of the cold air has remained largely a qualitative problem.

Mixing-Radiation Fog. This is not at all a usual type, but it is important to recognize the significant role played by dissolving fronts at many locations. Particularly in late spring and summer there are many areas which have little or no fog not associated with a weak frontal condition. Whether the formation of this kind of fog involves actual mixing of two dissimilar air masses is open to considerable question, but nocturnal radiation is certainly a requirement. Furthermore, there are many occasions when fog does form in a narrow band along a dissolving front even when no daytime clouds attend it. Forecasting methods are very general for this unusual class and depend largely upon climatology and the individual experience of the forecaster.



FIGS. 8*a*, *b*, *c*.—These graphs indicate a representative solution for advection-radiation fog a little more complicated than most. They are for winter cases at Charleston, S. C. (*after George*). Figure 8*a* takes care of the gradient wind requirement as well as giving a preliminary estimate of time of formation from the numbered contour lines (in hours after sunset). Figure 8*b* eliminates certain instances which would otherwise produce an erroneous forecast for fog. Ordinates are dew-point depressions at maximum temperature and abscissas are obtained by subtracting the temperature of the dew point at maximum temperature from that at sunset. Figure 8*c* provides the humidity element and another estimate of timing.

Timing the Clearing of Fog or Stratus. Several methods have been devised to aid in estimation of the time required to dissipate fog or stratus. Probably the simplest and most direct method is the relationship between thickness of the stratus and time required to clear, given by Wood [26] and reproduced here as Fig. 10.

This method, of course, has reference only to stratus clouds and requires nothing except a knowledge of the cloud thickness, which is usually available to the fore-

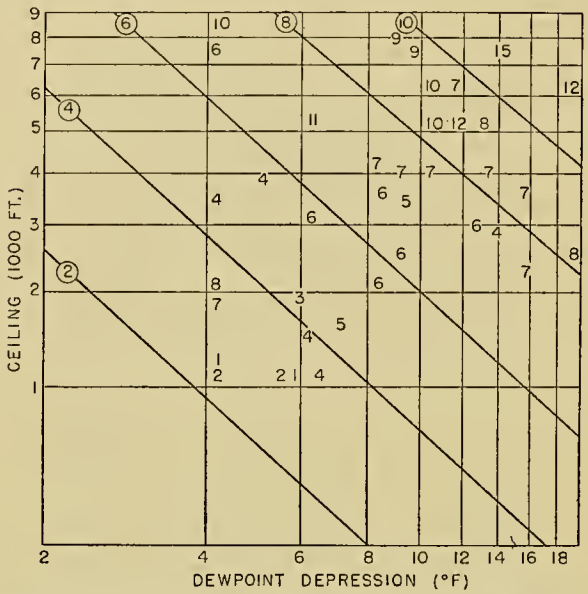


Fig. 9.—A method of forecasting pre-warmfrontal fog or low stratus (*after Roche* [21]). The graph is entered with the dew-point depression and the ceiling at time of beginning precipitation. Sloping lines give time in hours before the stratus forms below 600 ft, as designated by the circled numerals.

caster. Krick has devised a method based on the use of (1) a recent sounding in the vicinity for which the information is desired, and (2) normal surface-heating curves during stratus conditions. The requirement of having both the sounding and the heating curves prevents very widespread adoption of what would otherwise be a reasonably precise method.

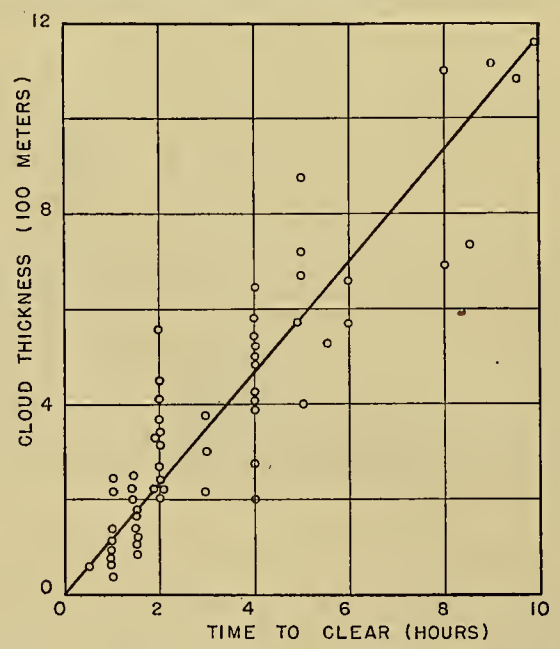

Fig. 10.—The relation between time required for stratus clouds to clear and their thickness (*after Wood* [26]) with data from several coastal stations.

Still another method (Fig. 11) has been used as an approximation for forecasting the dissipation of fog [9]. This is an indirect method of taking into account the

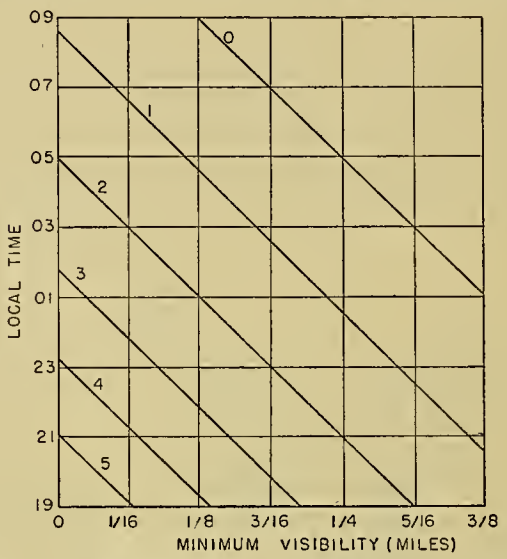

Fig. 11.—Another illustration of method for predicting the clearing of fog. Sloping lines are the number of hours after sunrise required for clearing. (*After George.*)

amount of liquid water which must be evaporated (see Radford's visibility scale, Fig. 2), and the total amount of foggy air measured by the length of time the fog has been present. This method has the advantage of being extremely practical and dealing with easily obtained data, but possesses the disadvantage (which may be inherent in all methods) of requiring the clearing forecast to be made at a time when complete information about the fog is available, or may be anticipated. In none of these methods is any account taken of the nuclei characteristics; it generally is presumed that industrial pollution is not present to a marked degree.

Evaluation and Recommendations. In perspective, it seems clear that our knowledge of the synoptic conditions under which fog forms is far from complete. It is almost as clear that the framework of classification of fog by causes is laid on a solid foundation of knowledge. This is fortunate indeed, for classifications must be accurate before the various causes can be isolated and objectively examined. Fog is so intimately connected with local geography that its forecasting must remain on a local basis. Much progress has been made in the past decade toward the establishment of local synoptic studies in fog, but much more remains to be done and refinements of existing studies are easily possible and highly desirable.

In addition to continued work with local studies, which seems to offer the greatest immediate return for effort expended at present, there are several courses of investigation which should be pursued if any really new techniques in dealing with this phenomenon are to be developed. Of primary interest is the desirability of studying in great detail the vertical structure of the lowest layers of the atmosphere to determine the distribution of temperature and humidity and their

changes during the formation of fog. It is true that good work has been done along these lines at the University of California at Los Angeles, but it has dealt with a very specialized type of fog—the Southern California stratus. Elsewhere, the almost universal rule is that no use whatever is made of these elements either in understanding the causes of, or in forecasting, fog. It is highly significant that radiosondes are almost never used by workers in this field, yet this approach must offer rich possibilities. Perhaps, however, such use would require a method of obtaining more detailed information in the lowest 100 mb of the atmosphere.

Winds in the lowest few thousand feet have been used extensively in synoptic fog research and are of obvious importance. Yet our knowledge of the diurnal changes in wind direction and velocity and, what is really the same problem, the relation of vertical wind sheer to stability considerations, is still far from a practical solution.

A field that might be productive to some extent is that of surface characteristics. The different radiative properties of various ground covers and the day-to-day variations in lake and ocean temperatures, while certainly not neglected, have never received the attention which they perhaps merit.

It is particularly true of fog, as it is generally of most phases of meteorology, that no great discovery is about to solve all the problems, or even cause any sensational advance. Continued work on the physical aspects of the problem will be necessary for advancement and, at the same time, a great deal of so-called "pick and shovel" work in applied synoptic meteorology is absolutely essential if real progress is to be made.

PHYSICAL AND OPERATIONAL ASPECTS OF AIRCRAFT ICING

By LEWIS A. RODERT

National Advisory Committee for Aeronautics

Introduction

When aircraft are exposed to certain meteorological conditions, ice forms on exposed areas in a manner that impairs the efficiency of the components and reduces the usefulness of the craft. Because most aircraft are vulnerable to such ice formations, one of the limiting conditions for all operations is that ice protection must be provided or flight must be restricted to non-icing weather conditions.

Icing conditions vary widely in intensity. Fortunately, the conditions that create a serious hazard are not frequently encountered except in limited geographical locations. The problem thus presented by the formation of ice on aircraft has been met by extensive research and development of means whereby ice protection may be afforded and by meteorological investigations conducted to improve the accuracy of weather forecasting and to aid pilots in avoiding local regions of serious icing conditions. The results of research on ice-prevention methods are extensively reported in aeronautical engineering literature to which reference will be made in the text which follows. Results of the meteorological research have also been reported. They are analyzed and summarized elsewhere in this Compendium.[1]

An analysis of the physical phenomena of ice formations on vulnerable components of the airplane under various atmospheric conditions is presented in this paper. This analysis deals with the atmospheric states and aerodynamic and thermodynamic phenomena in or near functioning airplane components during commonly experienced icing occurrences. The analysis is limited to subsonic flight conditions at altitudes below the tropopause. A description of the effects of ice on the airplane components is also presented with limited quantitative evidence and reference sources. Data relating to the impairment of military equipment by icing are omitted for security reasons. Significant research and development work yet to be accomplished on the airplane-icing problem are enumerated in the closing discussion.

Although the collection of snow in ducts or other frontal openings and the impact of hail cause the impairment of certain components, and even structural damage, these problems are not discussed in this analysis.

The preparation of this report has been made possible by the results of extensive ice-prevention and meteorological researches conducted by the National Advisory Committee for Aeronautics, the U. S. Weather Bureau, other governmental agencies, private industrial and university laboratories, and the laboratories of several foreign governments.

Analysis of Aircraft Ice Formation

The formation of ice on an airplane requires that water come in contact with the surface of the vulnerable airplane component when the surrounding temperature is below 32F and under conditions that provide for the dissipation of the heat of fusion liberated during the phase change to ice. The subsequent analysis concerns the presence or formation of liquid water in the atmosphere near the airplane, the impingement of water droplets on the airplane surface, and the droplet environmental temperature and thermal dissipation required in the phase change to ice. Although most occurrences of icing are explainable on the basis of these factors, several unique types of icing involving other considerations are treated as individual cases.

Availability of Liquid Water. The natural existence in the atmosphere of cloud droplets at temperatures below 32F is responsible for most of the external ice accretions on aircraft. Observations in the atmosphere [11] show that water will remain in the liquid phase in clouds over a wide range of temperatures below the normal freezing point.

Liquid-water droplets existing at temperatures below 32F are commonly called supercooled droplets, the degrees of supercooling being the difference between the melting point of ice and the ambient temperature. It is tacitly assumed that the droplet temperature is substantially the same as the surrounding air temperature. It is probable that liquid cloud droplets can occur at all temperatures found in the normal atmosphere below the tropopause. Observations have also shown [11] that cloud droplets effective in producing icing are usually no greater than 50 μ in diameter; in fact, the typical cloud droplets during icing conditions are from 8 μ to 20 μ in diameter.

Water droplets at temperatures below 32F may also be generated by normally operating airplane components. Consider clear air expanding rapidly along an imaginary stream tube from a condition of near water-vapor saturation. Such a condition may be found in the air stream that enters an engine carburetor when the throttle is partly closed. The geometry and flow pattern for this condition are illustrated in Fig. 1.

As nearly saturated air moves along the stream with decreasing pressure, the temperature decreases according to the adiabatic process, and the total temperature at region 1 (Fig. 1) on the downstream side of the throttle is substantially the same as that of the ambient region 0 until the temperature of water-vapor saturation is reached.

1. Consult "Meteorological Aspects of Aircraft Icing" by W. Lewis, pp. 1197–1203.

Where the flow degenerates to a turbulent condition, such as at regions 2 (Fig. 1), the temperature of the gas particles is substantially equal to that of the fluid

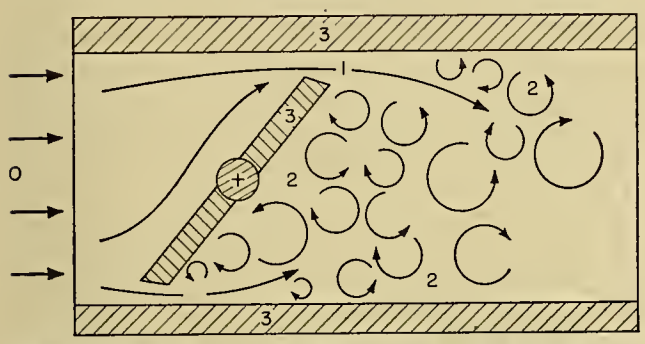

FIG. 1.—Flow through a partially closed carburetor; 0—ambient region, 1—laminar flow at high velocity and low pressure, 2—separated turbulent flow, 3—solid boundary.

in the moving free stream at region 1. The relations between pressure, temperature, and the liquid water precipitated because of expansion along the stream tube are given in a practical and usable form in the pseudo-adiabatic chart as developed by the U. S. Weather Bureau. Because of the velocity of the stream in region 1 and the time interval required for a droplet to grow to a significant size, visible condensation may not occur near the throttle in the moving stream but may be seen at some distance downstream. Droplets may reach sufficient size to cause an icing problem, however, in the separated turbulent regions 2 because of the comparatively stagnant movement through these regions and the greater time interval consequently available for droplet growth. Under certain conditions, vorticity may develop in the standing regions. This will be conducive to the precipitation of more water because of the reduced stream temperature within a vortex. It can be assumed that the temperature of the droplets so formed conforms closely to the stream temperature and that in most cases, including the example of the engine carburetor, the contents of the air-borne droplet do not undergo the phase change to ice until mechanically disturbed as when the droplet strikes the walls of the carburetor.

The expanding flow of clear saturated atmospheric air over an airfoil such as illustrated in Fig. 2 will result

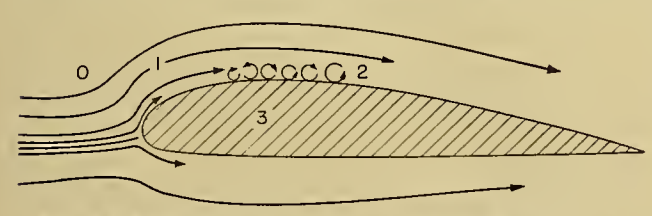

FIG. 2.—Flow over an airfoil; 0—ambient region, 1—low-pressure region, 2—turbulent flow, 3—solid boundary.

in a supersaturated condition in region 2 for the same reasons as those given in the discussion of the carburetor; however, the comparatively high velocity in the turbulent regions over exterior aerodynamic forms prevents droplet growth to a significant size. In wing and propeller tip vortices, visible condensation does form, however, because of the length of time a gas particle remains in the vortex and because of the low temperature which probably exists at the vortex core.

It is therefore evident that supercooled water droplets from which ice may form are found in nature and may also be generated by the aerodynamic and thermodynamic processes of stream flow over the airplane components. Ice is also formed from cloud droplets at temperatures above 32F, although under a combination of operating and weather conditions not often encountered. Snowflakes also are intercepted by airplane surfaces to a very limited extent, and ice formations are thereby accumulated. These special cases of icing and the precipitation of moisture on airplane surfaces from the gaseous state and the subsequent formation of frost are briefly discussed below.

Water Impingement. As an airfoil moves through a cloud, some of the droplets in the volume of space swept through by the airfoil are intercepted by the moving body. The analysis and explanation of the droplet impingement on an airfoil are made for the hypothetical condition in which air passes over a stationary airfoil. In such a flow pattern (Fig. 2), gas particles of the atmosphere follow streamlines past the airfoil. Those passing near the forward stagnation region of the body have small radii of curvature. The inertial effect tending to keep the droplet moving straight in such a curving flow field will provide the force necessary to overcome the viscous forces which tend to hold the droplet motion to that of the air streamlines. The result is that droplets will cross streamlines in the direction of the solid boundary of the airfoil and some will actually strike the surface in the vicinity of the leading edge. In the preceding description of cloud droplets it was noted that the average droplet size is very small, that is, of the order of 8 μ to 20 μ. Furthermore, the velocity of the droplets across the streamlines is small. It follows that the Reynolds number of the droplet motion in the air will be small and that the droplet path can therefore be analyzed by the equations of Stokes' flow, from which it follows that the resistance to motion is proportional to the velocity across the streamlines.

The development of the theory of cloud-droplet interception by airfoils is given in [7, 10], from which quantitative impingement rates and area of catch for particular conditions may be calculated. A method of determining the rate of droplet impingement on an airplane windshield is given in [6]. A discussion of the ingestion of water droplets into the carburetor of an engine is discussed in [9]; however, no attempt has been made to analyze the efficiency or the location at which ingested water comes in contact with the walls or throttle plate of a carburetor.

The area over a component on which the droplets impinge is determined by the liquid-water content of the atmosphere, the range of droplet sizes in the cloud, the velocity, and the shape and size of the airplane component. As the radius of curvature of the entering

surface increases, the percentage of the droplets caught in the swept-out volume decreases and the percentage of the total body area wetted decreases. Increases in the radius of the leading edge also have the effect of limiting the impingement area to the region near the forward stagnation pressure point.

Conditions for Ice Formation. When supercooled droplets impinge upon the surface of an airplane component, the formation of ice follows at a rate determined by the temperature gradient in the immediate environment and the thermal conduction through the gaseous and solid boundaries. It is apparent that the average environmental temperature must be below the melting point of ice. If the droplet freezes quickly upon impact, the shape of the formation will be determined by the droplet impingement pattern; however, if freezing is delayed somewhat after impact, part of the droplet will flow along the solid surface and freeze at a point farther in the rear. The time required for the droplet to freeze therefore determines the shape and the location of the ice, both of which are significant factors in determining the effect of ice on airplane performance.

The temperature of the air particle on the surface of an airplane differs from that of the ambient region because of the velocity of the stream; this departure is a function of the second power of the velocity in addition to other factors. Factors in the boundary layer that determine the temperature of the air particle on the surface include the conversion of the kinetic energy of the gas particle to thermal energy, the conversion of mechanical energy or work to thermal energy in the viscous boundary layer, and the conduction of heat through the gaseous boundary layer. The combined action of these factors determines the recovery temperature of an air particle on the surface of a body in an air stream; however, it should be noted that the heat involved in the phase changes of the water droplet on the surface and conduction through the solid boundary have thus far not been considered.

When the supercooled water droplet strikes the solid boundary, the mechanical disturbance to the droplet causes the phase change to ice. If it is assumed that there is no exchange of heat with the environment and that the droplet temperature rises to 32F during the freezing process, the percentage of the droplet undergoing the phase change will be proportional to the ratio between the degrees of supercooling of the droplet when it struck the surface and the latent heat of fusion.

After impingement, evaporation from the droplet starts. The rate of evaporation is determined by the difference between the vapor pressures at the droplet-air interface and in the ambient region. The evaporation of water from the droplet after impact absorbs heat. (It is to be noted that the temperature and vapor pressure at the droplet-air interface are interrelated and that calculations for one must start with an assumed value for the other from which increasingly accurate evaluations may follow by successive approximations.)

The flow conditions that may exist along the surface of an airplane component such as a wing include the stagnation region at the leading edge, a laminar region also near the leading edge, a turbulent region following the laminar one, and in some cases, a turbulent separated-flow region. It may be concluded from the foregoing discussion that the temperature on the air-water interface of a droplet is affected by frictional heating, by conduction through the boundary layer, and by heat absorbed in evaporation. These effects differ in magnitude and in relation to each other in the different flow regions. It therefore follows that the temperature of the air-water interface differs for various points on the surface of a component along a line parallel to the stream flow, because the only other factor arising from the moving stream—the conversion of kinetic energy to thermal energy—remains constant at all points on the body. It may be further concluded, therefore, that the rapidity with which the water is converted to ice varies for various locations on the surface of an airplane. Inasmuch as all the factors involved in these variations are functions of the velocity, increasing the velocity increases the variations. It is further apparent that if different points on a component move at different velocities (*e.g.*, the points along the radius of a propeller or helicopter blade), still another factor exists that causes surface-temperature variations and therefore variations of freezing conditions.

The discussion has been presented without a consideration of the flow of heat through the solid boundary. Obviously, if heat is applied or taken away through the solid boundary, the conditions for icing will be affected. When the solid boundary is a thermal conductor, which it usually is, variations in the departure from ambient temperature on the air-water interface or on a component surface produce thermal gradients in the solid boundary layer and a flow of heat from the hottest region to the coldest. Thus heat flows from the tip of a metal propeller blade to the hub region. Likewise, because the recovery temperature on the leading edge of an airfoil at the stagnation point is higher than in the laminar region, heat will flow rearward in a metal skin, and icing will be more rapid at the leading edge than would be explainable by the conditions of that local region.

Although of minor importance, the heat from the sun and other sources of radiant thermal energy and the kinetic energy of the impinging water droplet when converted to thermal energy also affect the conditions for icing on the surface of an airplane.

Because not all of the droplet will freeze immediately in most encounters with icing, the liquid water will be subject to abrasion by the air stream, which may blow away in the boundary layer a part of the droplet remaining in the liquid phase or move some of the liquid along the airfoil surface in the direction of the moving stream. The smoothness of the surface will affect this factor. Also, part of a droplet, particularly if it is a large droplet, may bounce away from the solid boundary (in part or entirely) upon impact and re-enter the boundary air. It is possible that droplets contained in the laminar streamlines of the boundary layer and near the leading edge which have zero or negative

velocity components in the direction of the solid boundary may be brought back into contact with the wing surface on the areas that are adjacent to the region of turbulent separated flow (region 2 in Fig. 2). Experimental evidence on the path and history of individual droplets after the first impingement has occurred, however, has not been obtained and discussion of this part of the subject must remain speculative.

The conditions for ice formation are therefore made more favorable for rapid freezing by the following factors:

1. The degree of supercooling with which the droplet strikes the component surface.
2. The conduction of heat through the boundary-layer air.
3. The evaporation of water from the wetted component surface.
4. Conduction of heat away from the vulnerable region through the solid boundary.

On the other hand, conditions for ice formation are made less favorable for freezing by the following factors:

1. The conversion of kinetic energy of the gas particle to thermal energy on the airplane surface.
2. The generation of frictional heat in the boundary-layer air.
3. Conduction of heat to the vulnerable region through the solid boundary.
4. Minor factors such as the conversion of kinetic energy of the water droplet to thermal energy upon impact, and radiant thermal energy from the sun and surroundings.

It is apparent that the velocity and ambient-air temperature are important parameters in most of these factors.

In addition to the aforementioned factors, the rate at which ice forms on an airplane is determined by the following parameters:

1. Liquid-water content of the icing cloud.
2. Droplet size.
3. Shape of airplane component.
4. Size of airplane component.
5. Relative humidity of the atmosphere.

Additional considerations upon which the formation of ice on aircraft depends are:

1. Loss of liquid water from component surface due to abrasion of air stream.
2. Component-surface smoothness.

The analysis of the flow of heat from the surfaces of an airplane wing, with consideration of most of the factors just discussed, has been reported in [4, 13, 17].

Special Cases of Ice Formation. When an airplane moves from a very high altitude at which the temperature of the ambient air is very low to a lower altitude at which the temperature may be above the freezing point of water, the structure of the airplane and therefore the surfaces of the vulnerable components may be below 32F. If at the lower altitude the airplane passes through liquid-water clouds, ice may form over all the wetted areas. Although such an encounter may have annoying consequences for a short time, as soon as the structure gains heat from the atmosphere the temperature will rise and the ice will be shed. The case is of interest in that the solid body is for a short time a heat sink for the heat of fusion.

If the surface temperature of the vulnerable components on a rapidly descending aircraft falls below the saturation temperature of the boundary air, condensation will occur. For this reason fog or frost may form on an airplane windshield even in the absence of visible moisture in the atmosphere. The greater the specific heat and mass of the component, the longer the loss of vision will persist.

A serious operational problem is presented by the formation of frost which is caused by the loss of heat by radiation from the airplane surfaces to the surrounding environment. In this case both the heat of condensation and the heat of fusion are dissipated from the vulnerable area. The formation of frost occurs most commonly at night with the airplane at rest on the ground.

The addition of a nonmiscible volatile liquid, such as aviation gasoline, to a region of droplet-air interface (*e.g.*, in a carburetor) will have the effect of increasing the heat lost from the droplet environment owing to evaporation of the volatile material. The addition of the volatile liquid in this instance causes an increase in the amount of water frozen. If a volatile liquid is added, however, which is miscible and also acts as a freezing point depressant when added to water, the ice formation will be reduced or prevented under some operating conditions.

Effects of Ice on Operation of Airplane Components

The effect of the formation of ice on the function of an airplane component is determined by the magnitude of the formation and the vulnerability of the component to icing.

Wings and Control Surfaces. The formation of ice on an airfoil, whether the airfoil is used as a wing or as the fixed stabilizing component of a control surface, reduces the maximum lift coefficient and increases the drag coefficient. The shape of the ice formation, as determined by the rate of freezing of the droplet and the area of impingement on the airfoil leading edge, has an important effect in the deleterious results of the formation. Wind-tunnel research has shown that a protuberance of a given height on the surface of a wing produces the maximum loss in aerodynamic efficiency when the protuberance is located near the region of minimum local pressure. For many airfoils the minimum local pressure region may be at about the 5 per cent chord point [5]. A protuberance located in the vicinity of the stagnation pressure point has comparatively little effect on the acrodynamic characteristics. It follows that ice forming on the forward extremity of the airfoil will not impair flight as much as will formations located 5 per cent from the leading edge and on the upper surface of a wing. Icing conditions resulting from large droplets that strike over a wide area on the leading edge therefore cause a more serious effect than do small droplets. Ice formed under

droplet environmental conditions that do not result in sudden phase change but allow a part of the liquid to move slightly rearward on a wing is a more serious problem than ice that freezes where the droplet strikes near the leading edge.

The formation of ice on the wing of an airplane has been observed to increase the drag of the airplane by 35 per cent [14] during flight in natural icing conditions. The formation of ice on the control surfaces of an airplane not only increases the drag but also may adversely affect the control of the craft [15]. The nature of the problem of icing on airfoils is such that protection equipment is considered to be necessary on craft expected to operate in inclement weather.

The formation of frost on the wings causes a serious loss of lift and an increase in drag. It is considered to be extremely dangerous to undertake a take off with an airplane on which even a small frost formation exists.

Propeller Blades. The formation of ice on propeller blades, the blade being an airfoil, has an aerodynamic effect similar to that previously described for wings and control surfaces. Furthermore, during operation without icing protection, the ice formation remains on some blades but is shed by others. The rotation of blades, some with ice, others without ice, creates asymmetry in both the centrifugal and aerodynamic forces on the propeller and, therefore, will produce serious propeller vibrations. A further problem arising from ice formations on propellers is due to fragments of the ice leaving the blade during flight and striking other airplane components with damaging effect. Flight observations made during natural icing conditions [14] show that the efficiency of a propeller may be reduced by as much as 19 per cent because of the formation of ice on the blades; however, most encounters with icing do not reduce the efficiency by more than 10 per cent. Ice protection for airplane propellers is provided for aircraft that are to be operated in inclement weather.

Engine Induction System. The formation of ice in the air-induction system of aircraft engines impairs the engine operation by reducing the air flow to the engine and, in certain instances, alters the operation of the fuel-metering system. Ice forms on the inner walls of the air-inlet duct, screen, guide vanes, impact pressure tubes (part of the fuel-metering system), throttle plate, and all protuberances exposed to the air stream; in fact, this part of the icing problem presents the most serious hazard to the airplane. During cruising operations the manifold pressure may be gradually reduced because of the closing of the air inlet to the engine, or the engine may stop suddenly when changes in the fuel metering result in noncombustible charges being drawn into the engine cylinder. When the engine power is reduced for a glide to a landing, the formation of ice in the throttle area may be accelerated and prevent full power should it be needed for further cruising or climbing. If the glide path undershoots the landing area, therefore, an accident is almost unavoidable, because the power for extending the glide will not be available and a landing must be made in an unprepared area outside the airport. Ice protection is provided for the induction system in all practical aircraft. The extent to which special devices are needed to protect the induction system is largely determined by (1) the internal aerodynamic smoothness of the induction system, (2) the extent to which the entrance excludes water droplets and still admits air, (3) the manner in which fuel is delivered to the cylinder (in a mixture with air or liquid injection), and (4) the air- and fuel-metering arrangements [3, 9]. By attention to these fundamentals some recently developed designs have demonstrated increasing invulnerability to icing.

Windshield. The formation of ice on an airplane windshield or other exposed transparent area impairs the vision through the area within a few seconds after icing conditions are encountered [6, 12]. Protection for the essential areas is provided on aircraft that are to be operated in inclement weather. The location of the windshield in the forward areas of the fuselage surface and the extent to which the exterior surface of the transparent area and its frame are faired in with the fuselage contours determine the rate at which ice forms on the glass and therefore the degree of protection required.

Pitot-Static Head. The formation of ice on the exposed total-pressure pitot tube and static vents by which the airspeed indicator and altimeter are operated renders these instruments inaccurate or inoperative within a few seconds after icing conditions are encountered. Protection against such formations is provided on all aircraft in which flight in inclement weather is to be undertaken. It is possible to locate the static pressure vent in a substantially nonvulnerable position on the airplane. The pitot head must be exposed; however, the designer has some latitude in the possible shape of the component within which the quantitative need for protection may be minimized [2].

Radio Antennas. The formation of ice on radio antennas causes the exposed structures to fail because of the increased drag forces or violent vibrations induced by the flow of air over the distended shapes formed by the ice. The communication system for the airplane is guarded against such failure by submerging the antenna, by placing it in a sheltered area, or by making the structure sufficiently strong to withstand the increased loads or vibrations. The shape, location, and orientation of the antenna determine the severity of the icing problem on this type of component [8].

Vents and Air Inlets. The formation of ice on a wing leading-edge region that is forward and in the vicinity of a vent from a fuel tank will cause a loss of pressure in the ventilation system which may result in fuel-system and engine failure [16].

The formation of ice at the opening to air-duct inlets will impair the flow of air through the duct, and the severity of this aspect of the problem is aggravated by the need for a screen in the duct [1].

Protuberances and Other Vulnerable Components. The formation of ice on protuberances such as radio-antenna masts and on the forward areas of the fuselage, engine nacelles, propeller hub, and other exposed parts results in an increase in the airplane drag of as much as 25 per cent [14]. When large formations of ice which

have accumulated on forward regions of the airplane, such as engine nacelles or propeller hub, become dislodged, as will be the case when the airplane encounters air temperatures above 32F, they move with the air stream in a rearward direction. If they strike other components of the craft, serious structural damage is inflicted. Protection for areas on which the formation of ice does not seriously impair the safety of flight is not provided for in current airplane design. The need for such protection varies over a wide range depending on the aerodynamic cleanliness with which the designer is able to render the general design layout. By eliminating protuberances, by the use of flush inlet scoops and sheltered vents, and by the arrangement of the main airplane components so as to eliminate, insofar as possible, leading-edge areas having small radii of curvature, the deleterious results of icing may be significantly minimized.

Topics Needing Further Study

The hazards and nuisances presented by the airplane-icing problem have in part been met by the development of ice-protection devices and by refinements in airplane design which make the components less vulnerable. Of the various methods of removing or preventing ice—mechanical, chemical, and thermal—the thermal method has given the greatest promise of providing a solution that can be adapted to practical transport or military airplanes without undue penalty in weight, added complication, or airplane cost. It should not be construed, however, that the other methods are unworkable or impracticable. The suggestions for further research that follow pertain to the extension of knowledge on the thermal ice-prevention system, to several atmospheric studies, and to an instrument-development program which is related to meteorological observations.

Heat-Transfer Relationships. The validity and accuracy of the relationships at present employed for determining heat transfer, mass transfer, recovery temperature, and droplet interception should be examined for the full range of values of velocity, shape, and size of aircraft now under design or likely to be designed in the near future. The recovery temperature at various flow conditions on a wetted airfoil at velocities near and above the speed of sound may be of interest in future aircraft; data on this factor should be established. Of interest in this problem is the comparative significance of viscous dissipation, conductive effects, and evaporation in the regions of laminar, turbulent, and separated flow for the high-speed range. An understanding of the nature of thermal ice prevention in greater detail than now exists is needed in order that effective protection may be provided without prohibitive penalities in added equipment to operating aircraft.

Variations in the Icing Problem with Altitude. An attractive speculation is that by flying very high the icing problem may be avoided. It is therefore of interest to learn what icing conditions are to be encountered at altitudes such as in the tops of cumuliform clouds, and with what degree of severity and frequency icing is apt to be encountered. Almost all the data thus far collected have been obtained at comparatively low altitudes. In consideration of the probability that extensive future operations will be conducted at high altitudes, the altitude range of the data should be extended. Data should be collected at altitudes above 25,000 ft on the dimensions and frequency of icing conditions and on the liquid water content, droplet size, and temperature range occurring with icing at these altitudes.

Critical Geographical Areas. Reports from military and commercial transport operations supply evidence that some geographical areas are attended by unique icing conditions of severe intensity; therefore, factual data on and a theoretical basis for the variations in the icing problem with geographical locations should be established.

Physics of Icing-Cloud Stability. Inasmuch as water normally freezes at 32F, it is of prime interest to understand why the droplets in an icing cloud have not undergone the phase change to the solid state and become snow or hail. An effort should be made to identify and analyze the full range of conditions which must be met in order that water droplets may change to ice. When this topic is more thoroughly explored and understood, the very interesting problems of modifying the weather artificially can be evaluated more adequately.

Forecasts of Icing. If airmen could receive accurate and complete forecasts of icing conditions, many operations could be routed around the hazardous locality, thus eliminating the need for special flight equipment and greatly extending the usefulness of aircraft in which ice protection is not installed. Improvements in the forecasting of icing are needed as are the means for effectively communicating the forecast to flight-operation centers.

Instruments for Collecting Atmospheric Data on Icing. The understanding of the phenomenon of icing, the design of efficient anti-icing equipment, and the development of reliable techniques of forecasting the occurrence of icing require that accurate and comprehensive data on the factors that produce icing be collected. Although instruments have been developed whereby data of considerable value have been obtained [11], still further instrumental research is needed.

In the study of the physics of the icing cloud, instruments that will reveal the existence and size of nuclei, water droplets, and snow crystals are needed. Data on such particulate substances need to be collected in order to reveal their variations with space and time.

In the study of the operational aspects of the icing problem, instruments are needed with which data on the occurrence of icing over wide ranges of geographical location and altitude can be collected.

METEOROLOGICAL ASPECTS OF AIRCRAFT ICING

By WILLIAM LEWIS

U. S. Weather Bureau, Washington, D. C.

Introduction

The formation of ice on airplanes has long been recognized as a serious problem affecting the regularity and safety of aircraft operations. With the improvement of instrument-flying techniques and navigational aids and the resulting increase in regularity of operations in inclement weather, the problems associated with icing conditions have become of prime importance to airline operators, airplane manufacturers, and meteorologists.

Until recently, very little quantitative data was available on the actual physical characteristics of icing conditions. Most of the available information on the meteorology of icing was based either on studies of pilots' reports [3, 11, 16, 17] or on theoretical inferences regarding cloud composition. In particular, the ideas of Bergeron on the composition of precipitating stratiform clouds in a warm-front situation have been used as a basis for a model of icing zones in a warm-front cloud system which has been presented in several textbooks on aeronautical meteorology (*e.g.*, [5]). A somewhat different model, later proposed by Findeisen [6], contained a more accurate representation of the typical composition of precipitating stratiform clouds. The importance of orographic effects in the geographical distribution of icing conditions was emphasized by Riley [16].

With the development of thermal methods of ice protection, the need for quantitative information on liquid-water concentration, cloud-drop diameter, and temperature in icing conditions was recognized and projects were undertaken to obtain the necessary data. The first of these was the Mount Washington Project, conducted by the Mount Washington Observatory, Harvard University, the U. S. Air Force, and the U. S. Weather Bureau. This project has resulted in the collection of a large amount of data on the composition of clouds at the summit of Mount Washington, N. H., at an elevation of approximately 6300 ft [7].

Flight measurements of liquid-water concentration and drop diameter in clouds have been made by the National Advisory Committee for Aeronautics [13–15], the Air Materiel Command of the U. S. Air Force [4], and other groups. As a result of these researches the probable range and relative frequency of occurrence of various values of the significant variables have been tentatively established and values have been chosen to be used as a basis for the design of thermal ice-prevention equipment [9]. This work has also led to a more complete understanding of the composition of clouds in general and the type and severity of icing conditions to be expected in various weather situations.

The Physical Characteristics of Icing Conditions

For most practical purposes, the physical characteristics of icing conditions may be regarded as determined by the values of three basic parameters: liquid-water concentration w, drop diameter d, and temperature T. The necessary and sufficient condition for ice formation upon a small object moving through the air with a velocity V is that w be greater than zero and T be below freezing by an amount equal to or greater than ΔT, where ΔT is the wet-air kinetic temperature rise at the velocity V. Although the value of ΔT is influenced to a slight extent by several factors, including the shape and thermal conductivity of the moving object and the value of w, it is given with sufficient accuracy for most practical purposes by the following expression:

$$\Delta T = 0.8 \left(\frac{V}{100}\right)^2 \frac{\gamma_m}{\gamma_d}, \tag{1}$$

where γ_m and γ_d are the saturated- and dry-adiabatic lapse rates, V is in miles per hour, and ΔT is in centigrade degrees. The rate at which water is intercepted by an object, expressed in grams per second per square centimeter of projected area, is given by

$$I = EwV \times 10^{-6}, \tag{2}$$

where w is in grams per cubic meter and V is in centimeters per second. This equation defines the quantity E, called the *collection efficiency*, the value of which depends upon V, d, and the size and shape of the object. In general, the collection efficiency is greatest for small objects, high air speeds, and large drops.

The variation of the kinetic temperature rise with air speed, and the dependence of collection efficiency upon drop size, air speed, and size and shape of the object, furnish an explanation of the importance of temperature and drop size in determining the severity of icing for particular components of an airplane. In the case of wings, the sizes and curvatures of the wing sections commonly used on modern airplanes, and the speeds at which these airplanes operate, are such that the values of collection efficiency vary from zero or near zero for the smallest cloud drops to 70 to 80 per cent for large cloud drops and virtually 100 per cent for freezing drizzle or freezing rain. The drop size is therefore nearly as important as the liquid-water concentration in determining the severity of wing icing.

In the case of propellers, the small cross sections and high blade speeds result in very high values of collection efficiency for almost the entire range of cloud drop sizes; hence, drop size is relatively unimportant for propeller icing. Because of the large values of the

kinetic temperature rise associated with the high speeds of propeller blades, the free-air temperature is an important factor in determining the extent of ice formation. For propellers of the size and speed ordinarily used on transport airplanes, ice formations which occur at free-air temperatures of −5C or higher do not extend far from the root of the blade and have only a very slight effect on propeller efficiency. With decreasing air temperature, the extent of ice formation gradually increases, reaching almost to the blade tips at −15C. At temperatures below −15C, serious propeller icing may occur even with low values of liquid-water concentration and small drops.

In the case of windshields, the configurations most commonly used, such as the familiar V-type, are ordinarily affected by icing conditions with average-sized drops; however, in the special case of a windshield which is flush with the fuselage contours, the collection efficiency may be so low that icing occurs only in the presence of exceptionally large drops.

The shape of the ice formations is influenced greatly by the rate of freezing. Under conditions of low temperature, low water concentration and small drops, the water freezes as it strikes without forming a liquid film, thus producing rather narrow, smooth, pointed ice accretions. On the other hand, temperatures near freezing, and larger values of water concentration and drop size, result in the formation of a film of liquid water which spreads as it freezes, giving rise to irregular ice formations with flat or concave surfaces facing the air stream. These two types of ice are generally called *rime* and *glaze*, respectively.

The Definition of Icing Intensity. The preceding discussion shows that the intensity of icing is dependent on liquid-water concentration, cloud-drop diameter, and temperature. Since the relative importance of these factors is different for different airplane components, no single function of these quantities can be used to define a scale of icing intensity that will apply equally to all components of all aircraft. The only scale now in use which defines light, moderate, and heavy icing in quantitative terms is that used by the U. S. Weather Bureau in reporting the intensity of icing observed at Mount Washington. This scale is based on the rate at which ice would form on a cylinder three inches in diameter moving at a speed of 200 mph, which represents a reasonable compromise among the various aircraft components. Because of the fact that this scale was designed to describe conditions on mountain summits, which are usually more severe than those encountered in the free air, conditions defined by it as "moderate" or "heavy" are substantially more severe than conditions described in the same terms by pilots. In fact, experience with pilots' reports suggests that the conditions defined as "trace," "light," and "moderate" according to the Weather Bureau scale would ordinarily be reported by pilots as "light," "moderate," and "heavy," respectively. For this reason some misunderstanding has resulted from the application of this scale to icing conditions encountered in flight. Accordingly, it is suggested that the scale be modified for use as a basis for quantitative definitions of icing conditions encountered in flight by assigning different descriptive terms to the four degrees of icing intensity defined by the scale. Table I shows the scale now used by the Weather Bureau for reporting icing conditions at mountain stations and the scale suggested for flight use. The definitions are given in terms of the rate of accretion on a cylinder three inches in diameter; corresponding values of liquid-water concentration for four values of drop diameter are also included.

Measurement of Liquid-Water Concentration and Cloud-Drop Diameter. Although several methods have been employed for measuring liquid-water concentration and drop diameter in clouds [10], nearly all of the reliable observations now available have been made by the rotating-multicylinder method devised by Arenberg [1]. As used in flight, this method employs a series of rotating cylindrical collectors (usually four) of different diameters which are mounted coaxially and exposed with the axis at right angles to the air stream for a measured time interval. The weights of ice collected on the cylinders are used to determine the liquid-water concentration and the average drop diameter. The calculations are based on values of the collection efficiency of cylinders calculated by Langmuir and Blodgett [12]. This method yields reliable and fairly accurate values of liquid-water concentration. The determination of drop size is reliable and reasonably accurate for values of drop diameter below 20 μ, but becomes increasingly inaccurate and unreliable for larger drops. Values of drop diameters around 30 μ are subject to considerable error and values over 40 μ are highly unreliable.

The value of drop diameter obtained in this way is called the *mean-effective diameter* and is believed to represent approximately the volume median size; half of the water is contained in larger drops, half in smaller

Table I. Icing-Intensity Scales

ones. By assuming the form of the drop-size distribution, it is theoretically possible to determine approximately the degree of homogeneity of drop sizes from the rotating-cylinder data. In actual practice, however, it has been found that determinations of drop-size distribution made in flight by this method are not reliable [14], although satisfactory results have been reported from Mount Washington [7]. Comparisons of values of maximum drop-diameter, obtained from the width of the area of drop impingement on a stationary cylinder, with values of the mean-effective diameter simultaneously determined by the rotating-cylinder method indicate that most clouds do not contain significant amounts of liquid water in the form of drops appreciably larger than the mean-effective diameter. For practical purposes, therefore, in the study of icing conditions, most clouds may be regarded as composed of uniform drops.[1]

The Concentration of Liquid Water in Clouds

In general, the formation of clouds is brought about by cooling due to the adiabatic ascent of air. For a strictly adiabatic process, without mixing or precipitation, the concentration of liquid water at an altitude z is given by the following equation:

$$w_z = \rho_z (x_c - x_z), \tag{3}$$

where w_z is the liquid-water concentration (g m^{-3}) at altitude z, ρ_z is the density of dry air (kg m^{-3}) at altitude z, x_c is the saturation mixing ratio (g kg^{-1}) at the condensation level, and x_z is the saturation mixing ratio (g kg^{-1}) at altitude z. Calculations from this equation indicate that the most important factors determining the liquid-water concentration in adiabatically lifted air are the temperature at the condensation level and the vertical distance above the condensation level. The actual altitude of the condensation level is of minor importance. Values of w, calculated by equation (3), are presented in Table II. These values are

Table II. Liquid-Water Concentration in Adiabatically Lifted Air*

Vertical distance above condensation level	Temperature at condensation level

* Condensation pressure = 850 mb.

based on a condensation level at a pressure altitude of 4780 ft. In actual clouds the processes of precipitation as well as the entrainment and mixing of drier air both act to reduce the liquid-water concentration below the values based on adiabatic lifting; hence these values should be regarded as maxima which may be approached under certain conditions but are very unlikely to be exceeded.

In a study of the physical factors which influence the amount of liquid water in clouds, it is convenient to consider three classes of clouds, based on the three principal processes by which air may be lifted, namely, convection, turbulence, and horizontal convergence of the velocity field.

Clouds Formed Primarily by Convection (Cumulus and Cumulonimbus). As long as no precipitation occurs, the concentration of liquid water in cumulus clouds is determined mainly by the temperature of the cloud base, the vertical distance above the base, the amount of entrainment and mixing, and the humidity of the environmental air. Recent studies [2] indicate that the lapse rate in cumulus clouds is usually very close to that of the environment, and that the amount of entrainment increases as the lapse rate exceeds the moist-adiabatic. The conditions for maximum liquid-water concentration are, therefore, a lapse rate only slightly in excess of moist-adiabatic and high relative humidity in the environmental air. Under these conditions the liquid-water concentration sometimes closely approaches the value based on adiabatic lifting.

In general, the effect of entrainment is to reduce the liquid-water concentration below the adiabatic value, and this effect increases from the base to the top of the cloud. The result is that the greatest values of liquid-water concentration occur at a distance above the cloud base of from one-half to three-fourths the height of the cloud, instead of at the top. The horizontal distribution of liquid-water concentration across cumulus clouds has not been accurately determined because instantaneous measurements have not been made. However, it would appear reasonable to suppose that the central portions of an updraft would be least affected by entrainment and would therefore have higher liquid-water content than the outer portions.

The effect of the formation of ice crystals in cumulus clouds, as in all other types, is a rapid reduction in the liquid-water concentration. The transformation from liquid drops to snow usually proceeds quite rapidly once it begins, frequently reducing the liquid-water concentration from over 1 g m^{-3} to about 0.1 g m^{-3} in twenty minutes or less. The formation of ice crystals is one of the most important factors limiting the icing hazards in cumulus clouds. Careful observation of cumulus cloud development indicates that individual cumulus congestus towers seldom remain in that stage longer than ten to fifteen minutes; they generally either subside and evaporate or change to ice crystals within that time.

Clouds Formed Primarily by Turbulence (Stratus, Stratocumulus, and Altocumulus). Clouds of this type are formed in the upper portions of certain layers of air which are mixed by turbulence. This may be the surface turbulence layer, as is usually the case with stratus or low stratocumulus, or a higher layer which becomes unstable as a result of lifting, differential advection, or some other process. In the ideal case, in which the

1. This conclusion is based on data taken in flight. Observations on Mount Washington indicate a considerable frequency of nonuniform drop-size distributions [7, 8].

entire layer is thoroughly mixed adiabatically, the liquid-water concentration would be given by equation (3). In actual clouds, however, the observed values of liquid-water concentration are less than the calculated values, usually averaging from one-fourth to one-half and rarely exceeding three-fourths of the calculated value. In most cases the liquid-water concentration increases approximately linearly from near zero at the cloud base to a maximum just below the top. The difference between the observed and theoretical values of liquid-water content may be attributed to incomplete mixing within the layer and to the downward mixing of some dry air from above the cloud.

Ice crystals may form within a turbulent layer cloud or may fall into it from an overlying altostratus cloud. In the former case, the precipitation is usually light and the concentration of liquid water decreases quite slowly near the top and more rapidly in the lower parts of the layer. This process leads to a gradual dissipation of the cloud, proceeding from the bottom upward. In the latter case, the intensity of precipitation is frequently great enough to cause the rapid dissipation of the entire cloud layer.

Clouds Formed Primarily by Horizontal Convergence (Altostratus, Altocumulus, and Altocumulus-Altostratus). Horizontal convergence in the wind-velocity field at low altitudes is accompanied by relatively slow lifting of large masses of air. This is the type of lifting which ordinarily takes place in the forward and central portions of moving cyclones and leads to the formation of very deep and extensive cloud systems predominantly of the altostratus type. Observations have shown that supercooled liquid-water is ordinarily almost completely absent from the main altostratus portions of such cloud systems, since these are composed almost entirely of ice crystals. Around the edges of these cloud systems, however, a complex pattern of altocumulus layers at various levels frequently occurs, composed predominantly of liquid water. When these layers form in stable air, they are lenticular and usually rather low in water content. When certain layers become unstable as a result of the lifting process, altocumulus of the turbulence type, resembling high stratocumulus, may be formed. The concentration of liquid water in these clouds depends on temperature and cloud thickness, as noted in the preceding paragraph.

Freezing Rain and Freezing Drizzle. The meteorological conditions ordinarily required for the formation of freezing rain are an inversion, usually frontal, with temperatures above freezing in the warm air above the inversion and temperatures below freezing in the cold air below the inversion. The temperature range of the occurrence of freezing rain is rather small, since the raindrops freeze and become sleet (U. S. Weather Bureau definition) at temperatures only a few degrees below freezing. Unfortunately, measurements of the concentration of liquid water in freezing rain are not available. Estimates can be made, however, since it is known that freezing rain generally consists of relatively light, uniform precipitation over a fairly large area. If a precipitation rate of 0.1 in. hr^{-1} and a drop diameter of one millimeter are assumed, the liquid-water concentration would be about 0.15 g m^{-3}, which is less than is usually found in clouds.

Because freezing drizzle is only rarely encountered and the methods used to measure drop size in flight are not reliable for drops of drizzle size (thus making the correct identification of drizzle difficult), very little information is available concerning its liquid-water content. Unlike freezing rain, freezing drizzle is not limited in its occurrence to frontal conditions but may form in a variety of meteorological situations and over a wide range of temperature and altitude. The fact that large values of cloud drop size tend to occur only with small values of liquid-water concentration would suggest that low values of liquid-water content would be expected in freezing drizzle.

Statistical Data on Liquid-Water Concentration. A substantial amount of data on liquid-water concentration and drop size in clouds in the United States is available as a result of flight measurements by various organizations. Most of these observations were made by the National Advisory Committee for Aeronautics [13–15]. A considerable number were also made by the Air Materiel Command Aeronautical Ice Research Laboratory [4], and a limited number by United Air Lines, American Airlines, and the Douglas Aircraft Company. All these measurements were made by the rotating-cylinder method and represent average values over time intervals varying from about 30 sec to 10 min. The average exposure interval was about 1 min in cumuliform clouds and 3–5 min in stratiform clouds. Data from all the above-mentioned sources have been included in Tables III and IV.

Table III gives frequency distributions of values of liquid-water concentration observed in three principal cloud types: cumulus and cumulonimbus, stratus

and stratocumulus, and altocumulus and altostratus-altocumulus. This last group includes all middle cloud types containing liquid water since typical altostratus clouds are composed of ice crystals.

It can be seen from Table III that the average and extreme values of liquid-water concentration in cumulus clouds are much greater than in other cloud types. This is due to the much greater vertical extent of cumulus clouds. A compensating factor is their limited horizontal extent. It is noted that the concentration of liquid water is considerably lower in altocumulus and altocumulus-altostratus than in stratus and stratocumulus clouds. The difference is due to the lower temperature and smaller vertical thickness of altocumulus and also to the frequent occurrence of ice crystals in altocumulus when associated with altostratus.

The Size of Cloud Drops

Important inferences concerning the sizes of cloud drops to be expected from various conditions of cloud formation can be drawn from a theoretical analysis of the mechanism of cloud-droplet formation and growth. A detailed and quantitative treatment of the physics of cloud-drop formation has recently been given by Howell [8]. According to this study, for the case of uniformly lifted air, "the numerical concentration of drops is determined primarily by the rate of cooling during the initial stage of condensation. It depends, as a rule, only slightly on the concentration of condensation nuclei. With continued uniform cooling, the drop concentration diminishes slightly toward a fixed constant value." It is also shown that uniform lifting leads to a rather uniform drop-size distribution. The effect of evaporation, owing either to warming in descending portions of a cloud or to entrainment of dry air, is a decrease in the concentration of drops, since the smaller drops evaporate most rapidly. On the basis of these considerations, the highest concentration of drops would be expected in rapidly formed cumulus clouds and the lowest concentrations in altocumulus clouds formed slowly by convergence in stable air.

Actual measurements of cloud-drop diameter made in flight indicate wide variations for clouds of all types. Frequency distributions of observed values of mean-effective drop diameter are given in Table IV for three principal cloud types and two geographical areas. The classification on the basis of location was made because it was observed that the largest values of drop size were found mostly along the Pacific Coast. The data in Table IV are from the sources listed previously for Table III. Representative values of drop concentration were calculated from the median values of liquid-water concentration and drop diameter and are also included in Table IV.

It can be seen from an examination of Table IV that there is a slight variation of drop size with cloud type and a greater variation with geographic location. The occurrence of larger drops in the Pacific Coast region is believed to be due to the prevalence of maritime air masses with little pollution from combustion sources, and hence a very low concentration of effective nuclei. The small average drop concentration in altocumulus clouds was to be expected from condensation theory. Larger values for stratocumulus and cumulus clouds are believed to be due to greater turbulence and hence more rapid lifting at the time of condensation. The fact that cumulus clouds have smaller drop concentration than stratocumulus may be due to the greater effectiveness of such modifying factors as entrainment and precipitation, which promote evaporation and thus reduce the drop concentration.

The Problem of Forecasting Icing Conditions

For the purposes of this discussion, it will be assumed that satisfactory forecasts of the type, location, thickness, altitude, and temperature of cloud masses, and the occurrence and type of precipitation can be made. It is fully realized that this assumption is frequently not valid, but it is made here in order to separate the problems peculiar to forecasting icing intensity from the general problem of weather forecasting. In other words, the problem to be treated here is that of estimating the icing intensity to be expected within a cloud of known type, dimensions, and temperature. If this can be done satisfactorily, a forecast of icing can be derived from any good forecast of weather and cloud conditions. However, regardless of whether satisfactory forecasts of cloud conditions can be made, reliable estimates of the presence of icing in the currently observed and reported cloud conditions may be of considerable value.

The importance of a consideration of cloud type in estimating icing conditions cannot be overemphasized, since entirely different icing conditions prevail in different types of clouds. A brief discussion of the icing conditions likely to be found in clouds of various types is given in the following paragraphs.

Cumulus and Cumulonimbus Clouds. Icing conditions in cumulus clouds are sharply limited in horizontal extent, highly variable, and occasionally very severe.

The most severe icing conditions occurring anywhere are found in the upper half of tall cumulus congestus clouds just before they reach the cumulonimbus stage. Ordinarily, such clouds comprise only a small portion of the total air mass and therefore they can usually be circumnavigated. Also, the limited horizontal extent of cumulus towers limits the amount of ice that can be collected during a single passage through a cloud. Because of the removal of liquid water by precipitation, icing conditions in cumulonimbus clouds are usually much less severe than in cumulus congestus clouds; however, conditions in cumulonimbus are extremely variable, and sometimes very heavy icing may be encountered for short distances.

Stratus and Stratocumulus Clouds. Stratus and stratocumulus clouds ordinarily contain moderate to low concentrations of liquid water, although fairly high values sometimes occur near the tops of unusually thick layers. These clouds are rarely characterized by large values of drop diameter. Although the icing conditions in stratus and stratocumulus clouds are usually light to moderate in intensity, they present one of the chief icing hazards to aircraft operation, since the cloud layers frequently cover large areas and it is not possible to ascend or descend without flying through them. Also, traffic control procedures may occasionally require prolonged flight in a stratocumulus layer. The intensity of icing usually increases from near zero at the base of the cloud layer to a maximum just below the top, the maximum intensity being proportional to the thickness of the layer. The factor which limits the intensity of icing is the limited thickness of the cloud layers. Individual layers of stratus or stratocumulus clouds seldom exceed 3000 ft in vertical extent. For layers of a given thickness, the liquid-water content is greater in warmer clouds, hence the greatest rates of ice accretion will be found at temperatures only a few degrees below freezing. This relation does not apply to individual clouds, however, since in any particular cloud layer the icing is most severe in the upper, colder portions.

When light or very light snow falls from a stratus or stratocumulus layer it is an indication of decreasing liquid-water concentration and icing intensity; when moderate or heavy snow occurs, the liquid water disappears very quickly and little or no icing is to be expected.

Altocumulus Clouds. Icing conditions in altocumulus clouds are generally similar to, but milder than, those in stratocumulus clouds, as the temperatures are usually lower and the average cloud thickness is less. Large values of drop diameter occur more frequently in altocumulus clouds with the result that icing conditions are occasionally considerably more severe than would be expected from the thickness of the layer. Ordinarily, however, only light and occasionally moderate conditions are encountered in altocumulus clouds and these are usually not difficult to avoid by a change of altitude.

Altostratus Clouds and Altocumulus Associated with Altostratus. Altostratus clouds usually consist of thick and extensive cloud masses which are composed almost entirely of ice crystals and therefore do not cause icing. This fact is of the greatest importance in forecasting icing conditions. The failure of forecasters to realize that altostratus clouds and the large precipitation areas usually composed predominantly of altostratus contain little or no supercooled liquid water is probably responsible for more errors in forecasting icing conditions than any other factor.

Around the edges of altostratus cloud systems, especially on the side where air is flowing upward into the system, there is frequently found a rather complex grouping of altocumulus layers. These usually merge with the altostratus, losing their liquid water as they become impregnated with ice crystals. Frequently, rather large cloud areas of mixed composition are formed in this way, for though a mixture of ice crystals and cloud drops is an unstable condition and therefore transient, a continuous supply of freshly formed altocumulus clouds is often available. Usually only light icing occurs in mixed clouds of this type.

Flight Planning and Dispatching in Relation to Icing Conditions. The consideration that should be given to icing in flight planning is largely a function of the ice-protection equipment on the airplane. Aircraft without deicing equipment of any kind should avoid all subfreezing clouds if possible. Aircraft equipped with rubber-boot deicers should avoid prolonged flight in continuous stratus or stratocumulus layers by a suitable change in altitude and should circumnavigate heavy cumulus clouds whenever practicable. Aircraft having thermal ice-prevention systems can safely fly in a great majority of icing conditions, but if exceptionally severe or prolonged icing conditions are encountered, some changes in altitude or flight path may be advisable. It should not be necessary to postpone or cancel flights because of reported or expected icing conditions when adequate thermal ice protection is available.

Because the occurrence of icing conditions is usually quite variable both in space and time, the practice of prohibiting flights in certain areas as a result of reported icing conditions is of doubtful validity. Such restrictions should not be applied to aircraft with adequate thermal ice-prevention systems.

Problems Requiring Further Research

One of the outstanding problems in the study of icing conditions is that of obtaining satisfactory measurements of the meteorological quantities involved. Much effort has been applied to this problem and noteworthy results have been achieved, but much still remains to be done. For example, there is a need for a more convenient and dependable means of determining the distribution of drop sizes in clouds, and also for a more accurate means of measuring mean-effective and maximum drop diameters when these exceed 30 to 40 μ.

There is also a need for simple and dependable automatic instruments for recording liquid-water concentration and average drop size, instruments suitable for use during routine flights to obtain statistical data.

One aspect of the icing problem in which our present

knowledge appears to be inadequate concerns the conditions under which ice crystals form in clouds. Meteorologists have been keenly interested in this problem since the advent of the Bergeron-Findeisen theories of precipitation. Thus far, however, no adequate explanation is available for the observed facts that certain types of clouds usually contain ice crystals while other types do not, nor is there a satisfactory explanation of the mechanism of the formation of ice crystals in liquid clouds.

The discovery by Schaefer [18] that liquid clouds could be converted to ice crystals by seeding with dry ice has resulted in investigations of the effects of cloud seeding by various agencies. At present there is a wide difference of opinion among investigators in this field, but there is good reason to expect that these experiments will eventually make an important contribution to a fuller understanding of the formation of ice crystals in clouds.

The modifications of clouds that have been accomplished by seeding suggest the possibility that this technique may provide a practicable means of reducing the icing hazard in limited areas, for example in the vicinity of busy airports. Further experiments will be required to establish the practical possibilities and limitations of seeding as a means of locally controlling icing conditions.

The data now available on liquid-water concentration and drop size in clouds, while sufficient to define in general terms the ranges of values usually encountered, are still inadequate to determine the frequency and severity of icing conditions to be expected in various areas under the influence of various synoptic situations. It is expected that if and when automatic recording instruments come into general use, a large body of statistical data will be accumulated which can be analyzed from a synoptic-climatological standpoint to provide information which may be of considerable value to airplane operators and practicing meteorologists.

INSTRUMENTS AND TECHNIQUES FOR METEOROLOGICAL MEASUREMENTS

By MICHAEL FERENCE, Jr.

Evans Signal Laboratory, Signal Corps Engineering Laboratories

INTRODUCTION

During the past several years a number of authors [15, 19, 24] have adequately and critically discussed meteorological equipment commonly employed for weather observations. The purpose of this article, therefore, is to examine the more recent equipment and techniques and focus attention on the degree of reliability of this equipment. Three things will become apparent from this discussion: first, that the major effort during recent years has been devoted to improving upper-atmosphere sounding systems; second, that electronic techniques are playing an ever-increasing and important role in equipment design; and third, that with the manyfold increase in information now possible for weather centrals an urgent need exists for a more efficient utilization of data transmission and presentation systems.

The pattern that will be followed in this article is to present a functional description of equipment or technique, followed by a more detailed examination of the major components of the equipment, with the view of analyzing errors and presenting an over-all evaluation of the system. In an article of this length it will not be possible to present all the data employed in the evaluation, but an effort will be made to supplement the discussion with appropriate references to the literature. No mention will be made of aerographs, sferics equipment, and radar storm-detection equipment, since they are described elsewhere in this Compendium.[1]

RADIOSONDE-RADIOWIND SYSTEMS

General Description. Within the past ten years more time and effort have probably been expended on the development of radiosonde-radiowind systems than on any other single meteorological system. Many systems have been proposed and several have been successfully developed and put into operational use [12, 20, 27, 32]. However, the major portion of the present survey will be devoted to the latest equipment development, and in particular to the redesigned radiosonde-radiowind system just being introduced in this country. The design features of this system are such as to lend themselves to mass-production techniques.

A complete radiosonde-radiowind system consists of a number of major components—flight equipment, including the meteorological sensing elements, radio transmitter, and balloon; a ground direction finder for precise angle measurements; and ground recorders or data-presentation equipment. As constituted at present, the system will yield information on temperature, relative humidity, pressure, and the magnitude and direction of the wind.

One of the earliest successful radiosonde-radiowind systems (placed in widespread use during World War II) is the now familiar Radio Set SCR-658. This set, operating at 400 megacycles per second (mc sec^{-1}), and now being used by the United States Weather Bureau and the United States military services, represented the best design compromise between the availability of inexpensive and efficient radio-frequency oscillators for radiosonde use and the requirement of a narrow antenna pattern. However, it became evident that two sources of error were present in this system: (1) the very broad antenna pattern which limited wind determination to within 15 degrees of the horizon, and (2) the presence of the human link in the tracking system. Both sources of error have been considerably reduced in the design of the new radiowind system operating at 1680 mc sec^{-1} and incorporating automatic tracking features. To take advantage of the increased accuracy possible in wind determination, the sensing elements of the radiosonde have also been improved. A brief, qualitative description will be given here of the over-all operation of the system, followed by a more detailed analysis. The block diagram of Fig. 1 will aid in this description.

The flight equipment of this redesigned radiosonde is basically that first introduced by Diamond and Hinman [10]. Resistance changes of the temperature and humidity elements control the audio modulation frequency (10–190 cps) of a blocking oscillator which in turn deletes 65-microsecond segments from the 1680-mc radio-frequency carrier at the audio rate. This modified 1680-mc carrier is transmitted to the ground and received by a parabolic antenna of the automatic direction finder which thus tracks the airborne transmitter (see Fig. 2). The received signal, suitably modified by the direction finder, is then divided into two parts—one used as an error signal for tracking purposes and the other (containing the meteorological message) fed to a recorder. A record is also made of the azimuth and elevation angles of the direction finder at prescribed time intervals. From these basic data, temperature, pressure, relative humidity, and wind velocity as a function of altitude may be computed. In order to analyze the errors present in this new radiosonde-radiowind system it is necessary to discuss its major components in some detail.

Radiosonde Flight Equipment. A typical radiosonde now in general field use by the Weather Service of the United States Air Force is illustrated in Fig. 3. This instrument consists of a meteorological modulator, a radiosonde transmitter, and batteries. The modulator

1. Consult articles by A. C. Bemis, M. G. H. Ligda, R. Wexler, and R. C. Wanta.

unit includes a selector switch activated by a pressure-sensitive aneroid capsule (Fig. 4). In the present design the selector switch has 150 silver conducting-reference signals for pressure measurements, and all other conducting strips up to the 104th are associated with humidity measurements. Humidity is not meas-

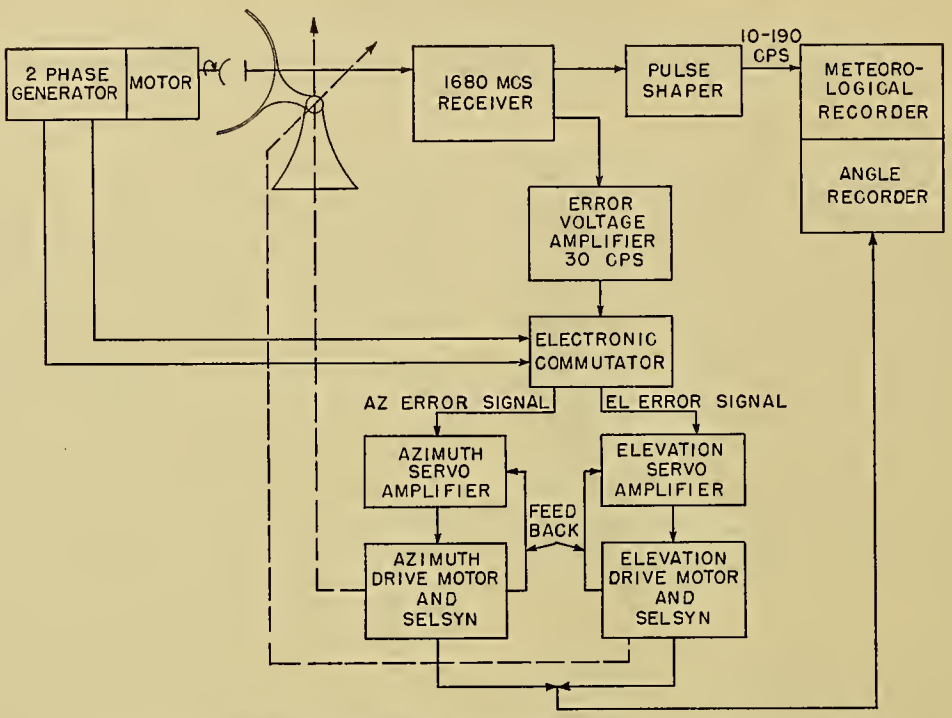

Fig. 1.—Block diagram of the latest automatic balloon-tracking direction finder.

strips, each separated by an insulating segment. Every fifth conducting strip is 0.0065 in. wide; all other conducting strips are 0.004 in. wide; while the insulating

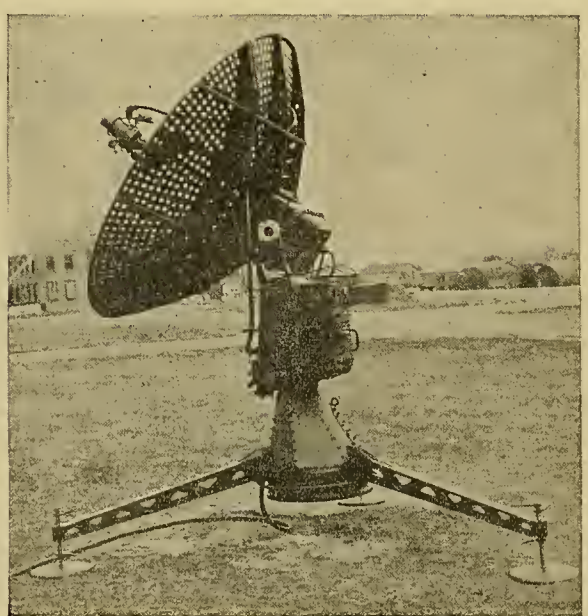

Fig. 2.—An automatic balloon-tracking direction finder set up for operation. Rawin Set AN/GMD-1.

segments are about 0.008 in. in width. Each insulating segment is associated with a temperature measurement, each 5th and 15th conducting strip is associated with

ured after the 104th contact, the remaining conducting strips being used for reference signals. The 150 conducting strips are printed on a polystyrene block to reduce fabrication costs, to avoid complicated wire connections, and to increase the uniformity of the segment alignment.

Pressure Capsule. The pressure capsule employed in this new design is temperature compensated and constructed so as to give approximately logarithmic response over the operating range—the deflection per millibar at 50 mb being approximately five times the deflection at 1000 mb. Without affecting the useful sensitivity and accuracy at high pressure, these capsules provide an appreciable increase in accuracy and sensitivity at low pressures.

The precision of pressure measurements depends upon such factors as repeatability of the mechanical motion of the aneroid and its lever system, the temperature compensation, the precision with which the surface pressure can be set on the commutator, and the reliability of the switching operation. It is estimated that the over-all probable error in pressure measurement of the present modulator units is:

±1	mb at	1000 mb
±3	mb at	500 mb
±1.5	mb at	100 mb
±1.5	mb at	10 mb

However, it should be emphasized that the incremental accuracy between contacts is very much

better than the figures quoted above; a probable error of ±0.5 mb between contacts can be assumed.

Temperature. The temperature-sensing element is a rod of ceramic material, 0.020 in. in diameter and 1 in.

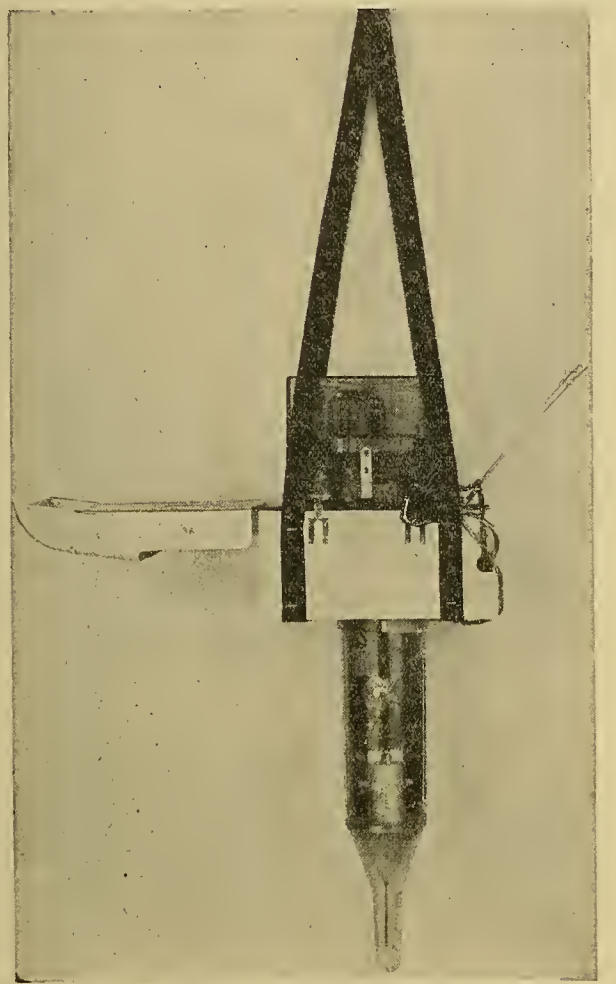

FIG. 3.—Complete radiosonde showing the meteorological modulator, the exposed temperature element, the humidity shield, and the 1680-mc transmitter.

in length. These thermistors possess very high negative resistance coefficients, the resistance varying from approximately 20,000 ohms to 2,000,000 ohms for the temperature range of from +60C to −90C. In order to decrease errors due to solar radiation, the elements are coated with a suitable lead carbonate pigment which has a reflectivity coefficient of about 0.92. The coating increases the diameter to about 0.035 in. The experimental results of Brasefield [6] indicate that such elements may be directly exposed to solar radiation without introducing an error in excess of 0.5C, except at altitudes above 80,000 ft where errors from 1.0 to 1.5C may occur. For these altitudes, however, corrections can be applied. If such corrections are applied, it is estimated that the probable error of the residual is approximately ±0.2C.

Another important parameter of a temperature element is its lag constant, defined as the time required for the element to respond to approximately 63 per cent of the interval between an initial temperature and a final stable value. For the new white temperature element this constant is about 3.5 sec at sea level and for a ventilation rate of 1000 ft min^{-1}. At an altitude

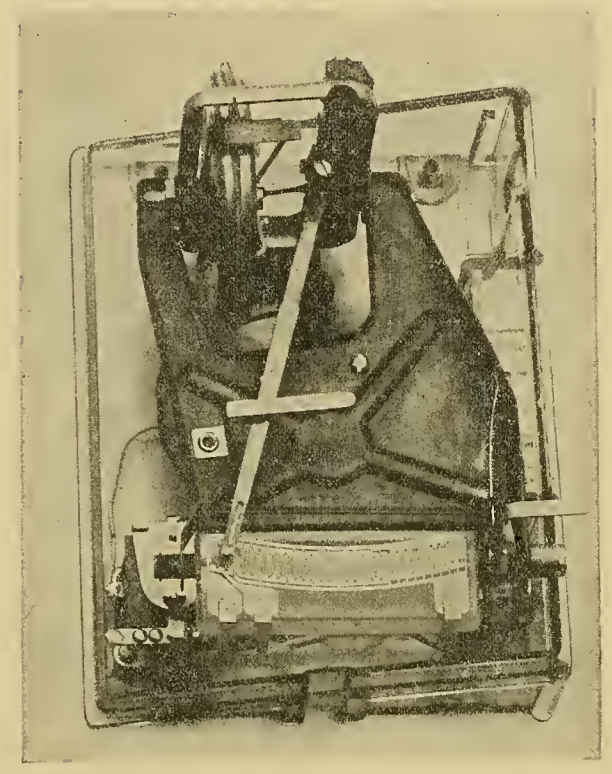

FIG. 4.—The selector switch with pressure capsule.

of 100,000 ft the lag is about 22 sec proportional to $\rho^{-0.4}$, where ρ is the density. If the temperatures are corrected for lag, then the residual lag error introduces a probable error of about ±0.2C in the temperature determination.

To obtain a reasonable estimate of the over-all probable error in determining temperature, it is necessary to consider the following sources of random error: solar radiation (±0.2C), residual lag (±0.2C), transmitter error (±0.2C), lock-in error (±0.1C), calibration error (±0.2C), recorder error (±0.2C), and finally, evaluator error (±0.2C). From the theory of the propagation of errors, it follows that the over-all probable error in temperature measurement is about ±0.5C.

Humidity. Unquestionably the weakest link in the present radiosonde is the humidity element. The element employed is a modification of the original Dunmore [13] design and consists of a polystyrene strip 4 in. long, 2 in. wide, and $\frac{1}{16}$ in. thick, coated with an electrolytic film of lithium chloride dissolved in polyvinyl acetate or alcohol and provided with two electrodes along the two long edges. At room temperature the resistance of the strip varies from approximately ten million ohms to five thousand ohms for a relative-humidity change of from 15 per cent to near saturation. In addition, the resistance of the humidity strip varies with temperature as well as vapor pressure, and ac-

cordingly corrections must be applied for the temperature effect.

As in the case of the temperature element, the absolute values of the humidity-resistance relation may vary over wide limits between elements, provided the shape of the humidity-resistance curves remains reasonably unaltered. This latter requirement permits use of a simple evaluator similar to that employed for temperature reduction.

The humidity strip is subject to several serious errors, some of which can be evaluated and corrections then applied. Others are not easily evaluated, and corrections are therefore difficult to apply. The more important sources of error are polarization, "washing out effect," variation in the shape of the humidity-resistance curve, effect of direct exposure to moisture, lag, insensitivity to humidity changes at very low temperatures, and insensitivity to humidity changes at very high humidity.

Polarization is a phenomenon exhibited by the strip whenever direct current passes through it. The effect is an increase in the resistance of the strip and a consequent lower humidity indication. In the early design of humidity elements, polarization was a rather serious source of error. However, with the use of wide strips (2 in. wide) and consequently higher resistance, polarization has been all but eliminated. For example, a change of less than 1 per cent relative humidity takes place during a 30-min continuous exposure of the element to constant humidity and temperature.

Humidity elements exposed to near-saturation (96 per cent relative humidity) for 30 min and then to air at 70 per cent relative humidity retained their calibration within 1 per cent relative humidity. However, the effect of direct exposure to moisture is far more serious. At this writing there is no unanimity of agreement among investigators as to the extent of damage caused by water droplets on the strip. This point certainly requires more detailed treatment.

A very important characteristic of any humidity element is its lag constant. According to Wexler [33] this constant for the lithium chloride strip (4 in. by ¾ in. by 1/16 in.) depends upon the magnitude and direction of the relative-humidity change and upon the relative humidity from which the change was made, in addition to the marked dependence upon temperature. Although the response characteristics of the strip do not follow an exponential law, for convenience the lag constant will be given for a 63 per cent change in humidity, for the range of 50 to 70 per cent relative humidity. This procedure will give low lag constants.

For ascensional rates of 1000 ft min^{-1}, the lag constant of the present element is approximately 4.0 sec for a temperature of 25C, increasing rapidly with a decrease in temperature, reaching values of 15 sec at 0C and values in excess of 120 sec at −30C. Although these high lag constants of the electrolytic elements leave much to be desired, they are superior to the hair hygrometer in this respect.

Under proper conditions the electrolytic strip can be quite reliable. If the element is not subjected to moisture condensations, it will give relative-humidity measurements with a probable error of ±2.5 per cent for temperatures to −10C and a humidity range of 15 to 96 per cent.

Radiosonde Transmitter. A diagrammatic sketch of the radiosonde transmitter is shown in Fig. 5. This

FIG. 5.—Circuit diagram of the present 1680-mc transmitter. V-1 is the new cavity oscillator.

transmitter consists of a radio-frequency oscillator operating at 1680 mc sec^{-1} and an electronic modulator for imposing intelligence onto the radio frequency carrier. As shown in the diagram, the radio-frequency oscillator is of the cavity type and is capable of yielding ½ watt of radio-frequency power.

The electronic modulator is basically a blocking oscillator whose repetition rate of 10 to 190 cps is controlled by the variable resistance of the meteorological sensing elements. From basic considerations, it can be shown that the oscillation time of the blocking oscillator should be as short as possible. To meet this requirement, the time constants have been adjusted so that the oscillation time is about 65 microseconds. While the blocking oscillator is on, the radio frequency carrier is quenched, and thus the radio signal reaching the ground has 65-microsecond segments deleted at an audio rate of 10 to 190 cps. To the direction finder, this represents an essentially continuous wave.

The basic reason why the Diamond-Hinman radiosonde lends itself so successfully to mass production is the fortunate relationship that exists between the audio frequency and resistance parameters of the blocking oscillator. It can be shown from an analysis of the circuit that the audio frequency f is given by the following general relation:

$$f = \frac{1}{\tau + bRC}, \qquad (1)$$

where f is the audio frequency, τ a constant proportional to the pulse width, b a constant, R the grid-circuit resistance, and C the grid-circuit capacity. By reducing the pulse width to 65 microseconds and maintaining the product bRC constant, τ was made quite small compared with bRC. Thus, the inverse proportionality between audio frequency and resistance was markedly improved. The accurate evaluation of the meteorological data is based upon maintaining a strict proportionality between two frequencies for two values of R.

The power requirements for this transmitting unit are supplied by a newly developed cuprous chloride-magnesium battery, whose capacity and discharge characteristics are superior to the lead acid cells. When required, the battery is actuated by the addition of water. Considerable internal heat is generated during discharge, hence the usual precautions of thermal insulation for protection against low ambient temperature are unnecessary. A battery pack of sufficient capacity to operate the radiosonde for three hours weighs less than 600 g. The "A" portion of the battery can supply 6.8 v with a 250-ma drain and the "B" section 115 v with a 30-ma drain. A comparison of the discharge characteristics of the lead acid cell and the new cuprous chloride-magnesium cell is shown in Fig. 6.

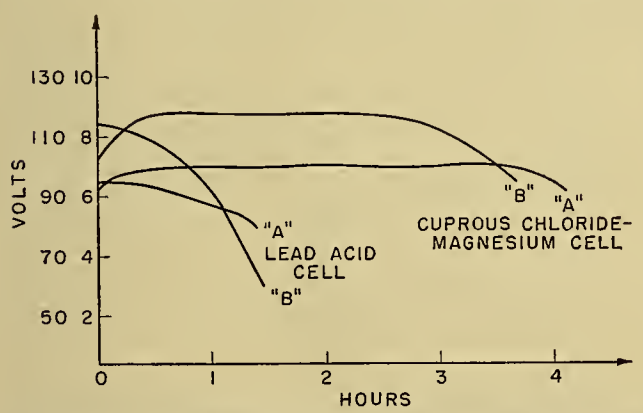

FIG. 6.—A comparison of the discharge curves of the new cuprous-chloride magnesium cell and the standard lead acid cell.

The ambient temperature of the cell was changed during discharge from room temperature to −58F.

The radio transmitter represents an important link in the radiosonde-radiowind system, for serious errors may occur in the meteorological measurements if extra precautions in design are not exercised. For example, it is necessary to keep the frequency drift of the 1680-mc oscillator to within a few megacycles in order that direction finding should not be impaired. In the present design, this drift is maintained in the range of −2 to 4 mc sec^{-1}. Also, changes in the blocking-oscillator rate due to causes other than true changes in the meteorological elements must be kept to a minimum. Audio-frequency shifts of 2 cps on release of the radiosonde and a gradual change of 2.5 cps during an hour flight have been noted. Compensation for these shifts can readily be made in the ground recorder. However, it is estimated that random variations in the blocking-oscillator rate will introduce probable errors in temperature measurement, for example, of about ±0.2C. These newest radiosonde transmitters are quite efficient and reliable and represent a real advance in the telemetering art.

Radiosonde Ground Equipment. The ground direction-finder shown in Fig. 2 serves the dual role of an electronic theodolite [18] and a receptor for radiosonde data. These two functions are discharged by the direction finder in this manner. The essentially continuous waves from the radiosonde transmitter are received by the seven-foot parabolic antenna and its scanning system. As indicated in the block diagram of Fig. 1, the scanning mechanism places a 30-cps modulation on the carrier, the amplitude and phase of the modulation being a function of the vectorial deviation of the target from the axis of the parabola. For radio signals arriving along the axis, the amplitude of the modulation is zero. The modulated carrier is amplified by the receiver, detected, and passed through a band-pass filter to an electronic commutator which yields a pair of d-c voltages, one indicating an elevation error and the other an azimuth error. These error voltages are then applied to their respective thyratron amplifiers for control of the elevation and azimuth drive motors. The receiver also detects the pulses that contain the meteorological data and passes them along to special circuits that amplify and shape the pulses suitably for the remote meteorological frequency-meter and recorder.

As an electronic theodolite [18], the direction finder measures elevation and azimuth angles as basic data. To determine wind speed and direction, it is necessary to know either the height of the radiosonde above a ground plane or the slant range. In the present system, the height of the radiosonde is computed by means of the hydrostatic equation from data obtained during flight. Given the height above the ground for prescribed time intervals and the corresponding elevation and azimuth angles, the horizontal wind velocity may be computed by following the standard theodolite procedure.

In analyzing the sources of errors present in wind measurement, it is necessary to consider the internal precision of angle measurement of the theodolite under dynamic conditions, the errors introduced through the radio transmitting link, and the errors introduced through height determinations. It is estimated that the over-all probable error in elevation and azimuth angle measurements is ±0.05 degrees. This figure takes into account random errors due to the swinging of the radiosonde, propagation errors, dynamic errors in angle measurements at the ground, and errors present in the angle recorder. In estimating this error it is assumed that the elevation angle is in excess of 6 degrees and that a line-of-sight range of approximately 125 miles is not exceeded. Tracking accuracy deteriorates rapidly for elevation angles less than 6 degrees due to ground reflections. For distances in excess of 125 miles, the

signal-to-noise ratio at the receiver becomes unfavorable.

To describe the error in wind-velocity measurement, use will be made of the standard vector-error σ_v. This quantity is defined by the equation

$$\sigma_v = \sqrt{\sigma_s^2 + |V|^2 \sigma_\alpha^2} \text{ (mph)}, \qquad (2)$$

where σ_s is the standard wind-speed error, $|V|$ the wind speed, and σ_α the standard wind-direction error. The standard vector error then represents the radius of the error circle associated with each wind-velocity measurement. Errors in speed and direction are thus conveniently combined. The measurement of σ_s, however, requires knowledge of azimuth elevation angle and height errors, and is influenced by the time interval used for averaging the wind speed $|V|$. With the present equipment, 2-min time intervals are used up to 40,000 ft, 5-min intervals up to 70,000 ft, and 10-min intervals up to 100,000 ft.

It is clear that to ascribe a single standard vector-error to the wind-measuring system is not meaningful unless considerable auxiliary knowledge is also available. Sufficient information for vector-error computation is given in the two graphs of Fig. 7. These graphs represent two wind cross-sections observed at Belmar, New Jersey, Fig. 7(*A*) during December, and Fig. 7(*B*) during July. For ease in computation, only the gross features of this wind structure are shown. In each example the wind speed and direction are shown, together with the computed slant range of the radiosonde. It was assumed that the rate of rise of the balloon was 1000 ft min^{-1}, that the probable incremental error in pressure measurement was ± 1.0 mb (a very conservative estimate), and that the probable error in angular measurement was ± 0.05 degrees. These data are sufficient for computing the standard vector error by equation (2). The numbers at the side of the wind-speed curve represent standard vector errors in miles per hour. Figure 7(*A*) represents an unfavorable situation for wind measurement, Fig. 7(*B*) a favorable one. In (*A*) very strong westerly winds were prevalent, reaching speeds of 100 mph at 40,000 ft. The balloon burst at approximately 120,000 ft nearly 65 miles from the direction finder. The sudden decrease in error from 40,000 to 60,000 ft is due principally to the use of 5-min rather than 2-min averaging intervals. Above 80,000 ft, the errors in height determination become critical. By a judicious use of the rate of rise of the balloon, this error can be reduced by a factor of two or three.

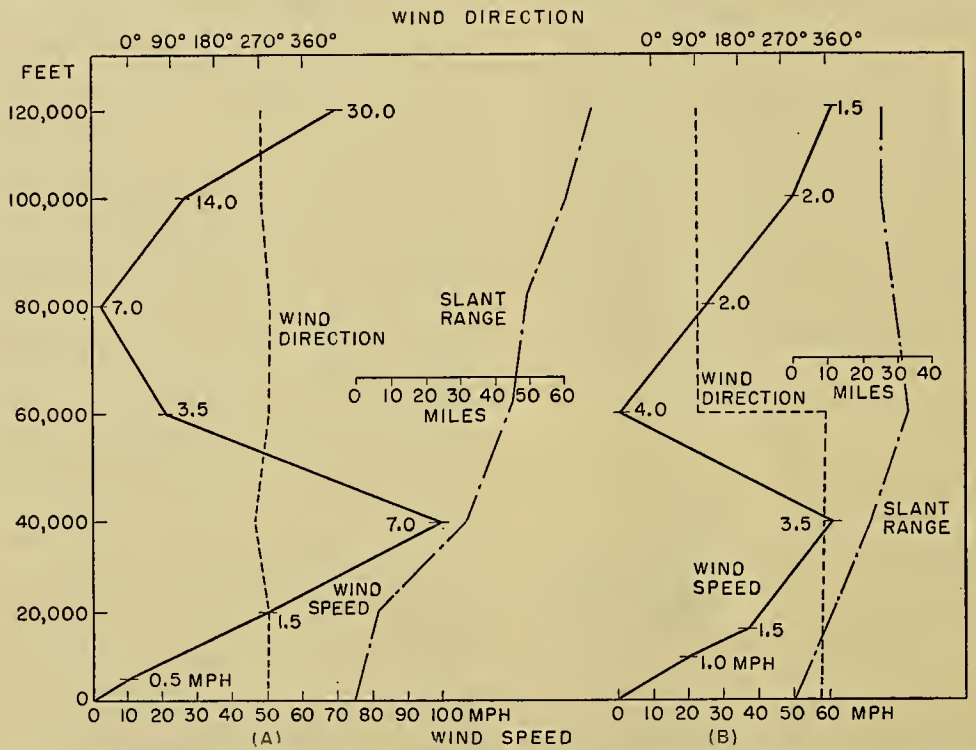

FIG. 7.—To compute the standard vector error expected from the radiosonde-radiowind set, two wind structures observed at Belmar, N. J., in December and July, are shown. In *A*, a strong jet is present at 40,000 ft, with the winds predominantly westerlies up to 120,000 ft. In *B*, the winds from 60,000 to 120,000 ft are strong easterlies. Computed standard vector errors are placed alongside selected height intervals of the wind-speed curves.

In Fig. 7(*B*), the winds were from the northwest, increasing in magnitude to 40,000 ft, then decreasing to nearly zero at 60,000 ft. Above this level the winds steadily increased, blowing from the east and returning the radiosonde to the vicinity of its launching point. The balloon burst at approximately 120,000 ft. For this case the elevation angles for the high altitudes were in the vicinity of 80 degrees, and errors due to height inaccuracies did not predominate; hence the rather low standard vector-error above 80,000 ft.

To improve the accuracy of wind measurements above 80,000 ft, it will be necessary either to improve the accuracy of pressure measurement at these altitudes and take advantage of the rather uniform ascensional rates of the balloon, or to resort to transponder techniques and obtain accurate slant ranges. It is still too early to determine which method is more economical.

Meteorological Recorder. As described above, the properly shaped pulses containing the temperature, pressure, and relative humidity data are fed to a frequency meter which converts the incoming frequency, over the range from 8 to 200 cps, to d-c voltages linearly proportional to frequency. These voltages are measured by a modified Leeds and Northrup-type recording potentiometer. The unit includes circuits for automatic range adjustment. Drifts occurring in the airborne transmitter are automatically corrected by this adjustment. The equivalent frequency is printed on a 10-in. strip chart that covers the range from 0 to 200 cps. The chart can be read within 0.1 of a division, producing an error in temperature of about ±0.2C.

Miscellaneous Accessories. In order to improve the reliability of base-line checks, a portable chamber has been designed to maintain reasonably constant values of temperatrue, pressure, and relative humidity. These quantities are known within 0.1C, ¼ mb pressure, and 1 per cent relative humidity. A circular evaluator that permits the simultaneous lock-in of both temperature and relative humidity is also available. This important innovation was made possible by recognizing that the shapes of the resistance-humidity curves of the humidity strips are nearly identical. The dew-point temperature for any relative humidity may be read directly off the scales. By use of this evaluator the efficiency and accuracy of humidity computations have been significantly increased.

General Remarks. In appraising the over-all performance of this radiosonde-radiowind system, it is important to bear in mind that the design features are such that no individual calibration of the radiosonde after leaving the factory is neccssary, and furthermore that each of the components can be mass produced—on the order of 100,000 per year. The manufacturing tolerances placed on the individual components are indeed quite severe. If the radiosondes were to be used for research purposes, where individual calibration of a small number could be justified, the over-all accuracy of the measurements would be greatly improved—the temperature error reduced to approximately ±0.2C, the pressure errors to ±0.5 mb, and the wind errors for altitudes above 40,000 ft to about one half (or less) of those computed in Fig. 7.

Because of the uncertainties of the solar radiation correction, the effects of moisture condensation, and the lag, it does not appear that temperature measurements with the present thermistors can be made with probable errors less than ±0.2C up to altitudes of 100,000 ft. Very little data are available on the accuracy of temperature measurements within clouds, using the exposed thermistors. The problem has not received the attention that its importance merits.

In order to improve the pressure measurement at high altitudes, serious consideration should be given to the use of the hypsometer. Preliminary measurements on hypsometers, designed for radiosonde use, indicate that in the range of from 50 mb to 1 mb an accuracy of about 0.1 mb should be expected. Furthermore, the use of the hypsometer for the entire pressure range is feasible, provided pressure measurements at 1000 mb to within 7 mb are acceptable. Pressure measurements at the lower pressures would be made with the same percentage error. Some modification of the meteorological recorder would also be necessary.

The problem of humidity measurements in the free atmosphere is indeed the most difficult one. As outlined above, the three major objections to the present lithium chloride strip are (1) the deterioration of the element on direct exposure to water droplets, (2) the very high lag constant at low temperatures, and (3) the insensitivity at very high humidities. Although various salts have been suggested as substitutes for lithium chloride to improve the performance of these elements, it does not appear that the use of electrolytes will overcome the basic difficulties of low-temperature hygrometry and of irreversible dilution when exposed to water droplets. One encouraging development on the horizon is the possible use of a carbon humidity strip. Although very little information is available at present, it does appear that the carbon elements have lag constants of the order of 0.4 sec at 25C; furthermore they are not subject to the dilution difficulties of the electrolytic strips, and are quite sensitive to humidity changes at high relative humidity. The opportunities for research in hygrometry are still very great.

Radar-Wind and Radarsonde Systems. In the preceding paragraphs a description has been given of a wind measuring system that required a knowledge of azimuth angle, elevation angle, and height. Another system in use, capable of accurate wind measurement, employs a microwave radar. Measurement is made by automatically tracking a balloon-borne passive target, in the form of a corner reflector, with a suitable ground radar set operating at either 3000 or 10,000 mc sec^{-1}. Measurements are then made of azimuth angle α, elevation angle θ, and slant range r. In addition, the time derivatives of these quantities, $\dot{\alpha}$, $\dot{\theta}$, $\dot{r}$, are available. With this information, wind velocity can readily be computed. The accuracy of the angular measurement is comparable to that of the direction finders; however, the accuracy in range measurement is greater than the corresponding accuracy in height determination, especially at high altitudes. Furthermore, in the radar system the cosine of the elevation angle is used to compute horizontal distance; in the radio direction-finding system, the cotangent is used. For low-elevation angles, therefore, the radar system is capable of greater accuracy in wind measurement than the radio direction-finding system. The possible limitation of this system for wind measurement is that of range. However, by replacing the passive target with an active transponder or beacon, this limitation can readily be over-

come. The British [17], for example, have developed such a transponder system, and a similar system has been developed for the Navy [22] by the National Bureau of Standards. Wind measurements have been made by the British to ranges of 100 miles and altitudes of 70,000 ft, the latter limitation being that of the balloon. Although no accuracies have been quoted, an analysis of the basic system suggests that the errors in measurement of wind should be less than those of the radiosonde-radiowind system.

Although measurement of wind alone is an important function, the value of a sounding is increased if the temperature, pressure, and relative humidity are also known. In the British [17] system, the incorporation of meteorological sensing elements into the flight equipment in such a manner that the pulses are used as the telemetering channel is now contemplated. Although no entirely satisfactory system has so far been described, there is no basic reason why such a system cannot be developed. The author is of the opinion that an all-electronic radarsonde system with meteorological computers will represent another major step forward in the radiosonde art.

The radiosonde-radiowind system described previously is capable of modification to an equivalent radarsonde system by the addition of a ranging unit. Whether such a modification is desirable, or whether a complete redesign starting with a basic radar set is necessary, will be determined to a great extent by economic rather than technical difficulties.

METEOROLOGICAL BALLOONS

A full description of meteorological balloons and their uses, from the time of the first balloon in 1783 until 1935, has been given by Reger [19]. In these early years, balloons were fabricated from a variety of materials, such as oiled silk, paper, goldbeater's skin, and sheet rubber. The use of rubber latex was restricted to the smaller balloon sizes, such as pilot balloons.

With the advent of the modern radiosonde, tremendous strides have been made in the manufacture of large balloons (350–10,000 g). Two methods have been developed for fabricating these large balloons. In the first method, a rubber gel is formed by introducing latex into a hollow spherical mold immersed in hot water, and then automatically rotating it in such a way that the latex is deposited rather uniformly on the interior wall of the mold. In the second method, a suitable form made of plastic or aluminum is dipped into a coagulant and then into the latex. The latex solidifies and forms a gel on the mold. In both methods the gel is inflated while still wet and soft, and then carefully dried, deflated, and cured. From a wet gel pulled off a 20-in. dipping mold, it is possible to produce a finished balloon 60 in. in diameter that in turn can be inflated to a diameter in excess of 25 ft before bursting. It appears from the rather sparse data available that balloons made from a hollow mold are somewhat stiffer than those produced by the dipping process. Recently, plastic materials such as polyethylene have been successfully fabricated into balloons. It is still too early, however, to evaluate this balloon development properly.

Altitude Performance. The present standard meteorological balloon used to carry radiosondes aloft is made of a synthetic rubber called *neoprene*. The exact ingredients and the technique of fabrication, including curing times and temperatures, are considered trade secrets by the balloon manufacturers. Therefore, it is not possible to correlate these important factors with such balloon parameters as ascensional rates and bursting altitudes. It can be stated, however, that the balloons now supplied in this country for radiosonde work are of remarkable quality. The average daytime performance of these balloons, based on several hundred flights, can be summarized as follows:

Weight of balloon	1000–1400 g
Pay load	1700 g
Free lift	1000–1500 g
Amount of H_2 used	120 ft^3
Approximate initial diameter	6$\frac{1}{4}$ ft
Approximate diameter at 90,000 ft	25 ft
Unstrained thickness	0.004 in.
Thickness at burst	0.0002 in.
Ascensional rate	1000 (+100 ft min^{-1})
	(−50 ft min^{-1})
Altitude attained	90,000 ft (80% of the time)
	100,000 ft (37% of the time)

Very large balloons, fabricated of synthetic rubber, have reached altitudes of from 120,000 to 140,000 ft during the daytime. These experimental balloons, carrying a pay load of about 2000 g, weigh approximately 10,000 g and require nearly 700 ft^3 of gas. The balloons are only partially inflated at the ground and become fully extended at about 30,000 ft. The rate of climb is about 800 ft min^{-1} to 30,000 ft, and then 1100 ft min^{-1} to bursting altitude. However, the performance of these few experimental balloons has been extremely erratic. If fabrication techniques can be developed that will yield balloons of uniform thickness and quality, it is estimated that altitudes of about 150,000 ft can be attained. Balloons of such altitude performance will open up new frontiers for upper-atmospheric research.

Temperature Effects. In the course of testing balloons for performance, it has been observed that differences in temperature between the inside and outside of the balloons for daytime flights may reach values as high as 40C at 50,000 ft, and remain sensibly constant to the bursting altitude. At night, the temperature within the balloon remains about 1C warmer than the outside up to altitudes of 50,000 ft. The temperature gradient then reverses, the inside becoming progressively cooler and reaching temperature differences of about 10C at altitudes around 90,000 ft. Natural-rubber balloons were used for these nighttime flights.

Although the daytime performance of the neoprene balloons can be considered excellent as far as altitude is concerned, the nighttime performance of the synthetic balloons leaves much to be desired. The average height that can be expected is from about 55,000 to 60,000 ft; this limitation is due principally to the freezing of the balloon. By using natural rubber latex,

altitude performance comparable to the daytime performance of the neoprene balloons has been attained.

A curious variation of the average bursting height of the natural rubber balloons with the seasons has recently been noted. During the summer and autumn about 55 per cent of the balloons reached altitudes of about 90,000 ft. During the winter and spring, only 8 per cent reached this altitude. Whether or not this variation in balloon performance can be attributed to the seasonal variation in ozone remains to be determined.

Ascensional Rates. One important way of improving the over-all performance of the present radiosonde-radiowind system is to increase the ascensional rate of the balloons to about 2000 ft min^{-1}. With values of this order, very favorable elevation angles can be attained for wind determination. This objective should be attained without sacrificing the bursting altitude of the balloon and without using an excessive amount of hydrogen. This latter consideration is of practical importance. To date, the use of rubber balloons to attain high ascensional rates has not been entirely successful. However, the use of balloons made of polyethylene material 0.0015 in. thick, and designed to conform to an optimum aerodynamic shape, has given rather interesting results. Teardrop balloons, 22 ft long and 5½ ft maximum width, have attained stable rates of climb in excess of 2000 ft min^{-1} up to altitudes of 45,000 ft.

In studies of the ascensional rates of the 2000-g balloons for varying free lifts Sharenow [29] has found that the ascensional rates of spherical rubber balloons do not continue to increase with increasing free lift. The optimum free lift for the 2000-g balloon is roughly 5000 g, providing the maximum average ascensional rate and a high bursting altitude. Greater free lifts reduce the average rate of ascent and also the bursting altitude. In analyzing the reasons for these effects, Sharenow concludes that the back pressure of the balloon controls in part the initial ascensional rate of a given balloon and thus the over-all average rate.

According to Väisälä [24, p. 151], the back pressure of a balloon of thickness d and unstretched radius r_0 is given by

$$\Delta p = \frac{2d}{r_0} P(n), \tag{3}$$

where $P(n)$ is characteristic of the material and $n = r/r_0$, with r the radius at any time during inflation. In order to improve Δp appreciably, it appears necessary to change the characteristics of the material, since the thickness d and unstretched radius r_0 are reasonably fixed by pay-load and altitude requirements. Sharenow suggests investigating the effect of cure on back pressure.

Summary. These basic problems in balloon development are in need of solution: (1) substantial increase in ascensional rates of balloons without impairing other desirable performance characteristics, (2) design of a balloon to reach heights of about 150,000 ft economically and with a high degree of reliability and, (3) improvement of the nighttime performance of the synthetic balloon.

PARACHUTE RADIOSONDES

Introduction. The parachute radiosonde was designed to be launched from a weather-reconnaissance plane, operating at a maximum altitude of 30,000 ft and with a maximum speed of 300 mph. The basic data of temperature, pressure, and relative humidity, obtained from the flight level to the earth's surface, are transmitted in Morse code signals back to the plane. The equipment consists of the telemetering device, sensing elements, transmitter, and parachute assembly.

Telemetering System. One of the early requirements of this type of radiosonde that greatly influenced its design was that the telemetered data must be received in the plane with the minimum amount of recording equipment. A very simple telemetering system using phonograph-type disks was suggested by J. M. Brady and developed into a practical parachute radiosonde by Brailsford [5]. In the present system, a vinylite disk with 200 grooves is used. Each groove in turn is engraved with a unique set of Morse code letters, so that the exact position of a set of pickup arms can be determined from the code letters. The three pickup arms, arranged around the circumference of the disk at about 90-degree intervals, are mechanically linked to an aneroid capsule, a bimetal, and a hair hygrometer. As the sensing elements respond to changing meteorological conditions, their respective pickup arms sweep across the disk.

Only an 85-degree sector of the disk contains the coded information. As the disk rotates, this sector comes into contact with each stylus of the pickup arm successively, so that the transmitted signal will consist of three code groups representing pressure, temperature, and humidity, followed by a pause. In order that each pickup arm can move freely in accordance with atmospheric changes, the 85-degree sector is raised about 0.62 in. above the rest of the disk. By this device, all arms are free except the one transmitting a signal.

The over-all sensitivity of the coding system is dependent on the number of grooves and the range of the sensing elements. For this instrument, the pressure sensitivity is 5 mb per groove width, the temperature sensitivity is 0.8C per groove, and the relative-humidity sensitivity is 2 per cent per groove. The self-starting unidirectional motor drives the disk at a rate of 12 rpm, so that with a descent rate of 1200 ft min^{-1}, the atmosphere is sampled once every 100 ft.

Temperature. In designing the various components of the radiosonde, it is important to bear in mind the transient shock of $20g$ to which the instrument is subjected at release. This is particularly true of the sensing elements. The bimetal used for temperature measurements is in the form of an elliptical spring, with the inner surface of each leaf as the high-expansion side. With this construction it is possible to use quite thin materials for low temperature lags and at the same time retain a reasonably stiff structure. In addition, it turns out that the element possesses linear

response characteristics over the temperature range of +40C to −70C. The temperature lag constant of the radiosonde is about 15 sec. The over-all probable error in temperature measurement of this instrument is ±1.5C.

Pressure. The aneroid pressure-cell will operate over a pressure range of from 200 to 1060 mb. The probable error in pressure measurement is ±5 mb.

Humidity. The humidity measurements are subject to the inherent limitations of hair hygrometers. Unfortunately, in most operations the hair is exposed very quickly to low temperatures, with the result that the lag constant becomes prohibitively high. Under these conditions the humidity indication can only be considered as qualitative.

Transmitter. The radio transmitter used in this equipment is a one-tube standard continuous-wave crystal-controlled oscillator, operating at specific frequencies in the range of from 2 to 12 mc sec^{-1}. The oscillator is interrupted by a keying relay actuated by the vibrating styli of the pickup arms. The radio frequency output is about ¼ watt, ample for the operational range of the airplanes. The transmitting link introduces no appreciable errors in the meteorological message.

Parachute. The parachute assembly contains a 5-ft nylon parachute with a 135-ft load line. The transmitting antenna is woven into the load line. In addition, the parachute is provided with a time-delay release mechanism to delay the opening of the parachute from 3 to 5 sec. The over-all dimensions of the "parachute radiosonde," including parachute and batteries, are about 10 in. by 6 in. by 19 in., and it weighs approximately nine pounds.

General Remarks. The equipment described above represents a first attempt to design a parachute radiosonde to meet rather severe operating conditions. In spite of the fact that the humidity response is disappointing, as it is in most equipment, the radiosonde does give reliable and meaningful data on temperature and pressure. In addition, the simplicity of data transmission and reception has much to commend it. To improve the humidity response, the use of the lithium chloride strip, or better still the new carbon element, appears as a possibility. The new white-coated thermistors would improve the temperature measurements. However, use of these electrical elements would necessitate either an electrical-mechanical adapter kit, a very undesirable solution, or a complete redesign of the telemetering system. There are many elegant telemetering schemes available today and possibly a suitable one can be adapted for this use.

WIRE SONDES

Introduction. The wire sonde is a specialized piece of meteorological equipment designed to provide temperature and humidity data from the ground to a height of approximately 1000 ft for micrometeorological purposes and, more particularly, for microwave-propagation studies. The typical system includes sensing elements for temperature and relative humidity, ground recording devices, and captive-balloon equipment. Although several systems [1, 2, 28] have been developed and are in use at present, basically they have much in common and differ only in details. The typical system that will be described and used to illustrate sources of error is one that was developed for the Signal Corps.

Airborne Unit. The airborne unit consists of the sensing elements, radiation shields, blower, and batteries; the entire unit weighing approximately ¾ lb. Temperatures are measured by means of a small ceramic bead, similar to that employed in the standard radiosondes. Relative humidity is measured in two different ways, depending on the ambient temperature. For temperatures above freezing, the wet-bulb temperatures are read. A thermistor bead identical to that used for dry-bulb measurements is covered with a light cloth wick immersed in a well of water. For temperatures below freezing, the lithium chloride electrolytic element, previously described, is used. Proper ventilation for these elements is supplied by a small blower, powered by a six-volt cuprous chloride-magnesium water-activated battery.

Recording Unit. The recording device consists essentially of a Wheatstone bridge with the balancing dials calibrated to read either the temperature directly or, by throwing a switch, the wet-bulb temperature or relative humidity. The resistance network of the bridge is compensated for the resistance of the cable leads. In operation, the bridge is electrically connected to the thermistors through a nylon-encased three-conductor cable, 2000 ft long and weighing about 4.5 lb.

Balloon. To maintain the airborne unit at a reasonably constant height during observations, a kite-type balloon called the "kytoon"[2] is used. The kytoon is streamlined and combines the aerodynamic properties of a balloon and a kite. The balloon is approximately 6½ ft long and 39 in. in diameter. During a strong wind, the kytoon lifts like a kite and is not driven downward as easily as a captive spherical balloon. Under average conditions the kytoon has a lift of about three pounds. Calculation of the height of the balloon is made by measuring the length of cable payed out and the angle of the cable leaving the reel. Difficulties in computation arise if a variable wind is present.

Accuracy of Measurements. With the proper exposure and ventilation of the elements, temperature may be measured with a probable error of about ±0.1C over the temperature range of from +40C to −40C. The wet-bulb reading can be made with a probable error of ±0.2C for temperatures above 0C. The lithium chloride strip will yield values of relative humidity to within ±2 per cent for temperatures to −10C and for humidity ranges of 15–96 per cent. Below this temperature, the element rapidly becomes sluggish and its accuracy will strongly depend on the rate of humidity change as indicated earlier in this survey.

General Comments. As stated above, many variations have been suggested for wire-sonde equipment. Investigators at the Naval Electronics Laboratory [1]

2. The kytoon is manufactured by the Dewey and Almy Chemical Co., Cambridge, Mass.

use the lithium chloride strip for humidity over the entire temperature range. At the National Bureau of Standards [28] a wire sonde has been completed that will give accurate heights through the use of a sensitive pressure-altimeter in the airborne unit. This latter development will ease the serious problem of height determination. Practically all of the systems in use today will yield useful information within the lag-constant limits of a few seconds.

AUTOMATIC WEATHER STATIONS

Introduction. Although the need for automatic weather stations has been recognized by meteorologists for a good many years, it has not been until rather recently that developments in radio communications, telemetric techniques, and power units have advanced sufficiently to insure a practical system. In general, a system can be considered practical if it can operate unattended for at least three months and preferably six months under a variety of climatic conditions and furthermore be reasonably transportable.

Several successful automatic weather stations have been designed to meet particular needs [7, 25]. However, for general use in isolated regions where standard meteorological data at the surface are required, two systems have been developed sufficiently to warrant discussion here. One system uses the telemetric technique, now extensively employed in the audio-modulated-frequency radiosonde [9]. The other is based on the "comb" principle of coding, originally suggested by the work of Moltchanoff [27]. The audio-modulated system has recently been described in some detail by Wood [35]. The present discussion will be centered around the code-type station which will be used to illustrate the accuracy of the data obtained from unattended stations and the problems peculiar to this type of research.

Code-Type Automatic Weather Station. The essential components of any unattended station are programming and coding devices, sensing elements, power supply, and communications equipment. Most systems differ in the coding device employed.

In the present system, measures of temperature, pressure, relative humidity, precipitation, wind speed and direction, and light from the sky are transmitted via a two-letter Morse code. In order to accomplish this coding, each indicating element has been so designed that changes in meteorological conditions are translated into angular positions of an arm. To measure the angular position of the arms, use is made of the "comb" principle. The freely moving arm ranges over a series of contacts insulated from each other and arranged in the arc of a circle. Two sets of combs in juxtaposition are utilized, one containing 100 narrow contact pins, and the other containing 10 contacts sufficiently wide for each to subtend 10 of the narrow pins. Associated with each wide contact, therefore, are the 10 narrow contacts, so that a total scale of 100 unique units is provided by the combs. During the measurement of temperature, for example, a depressor bar is actuated and forces the freely moving temperature arm into the teeth of the comb, necessarily touching one wide contact, say, number 30, and one of the narrow contacts associated with it, say number 6. The number "36" then represents a measure of temperature in arbitrary units. At the instant the arm touches the contacts, an electrical circuit through the depressor bar is closed, so that keying of the transmitter with the two-letter Morse code, characteristic of "36," is made possible.

Programming of the station is controlled by a marine chronometer, electrically wound. About two minutes before transmission time the clock turns on the power through a series of relays. While the gasoline engine used to power the station is warming up, various other electrical devices, such as radio tubes, are placed in operational readiness. At the end of two minutes a series of motor-driven cams for switching the sensing elements into the keying circuit are started. During the time the depressor bar keeps the arm of a sensor element in the teeth of the comb, coded signals at the rate of 12 per min are transmitted. The total transmission time required for the meteorological message and station identification is about two minutes. The station transmits once every three hours. The received signal may be taken down by a trained radio operator or fed into a tape recorder of standard design.

The power required to operate this station is supplied by a gasoline-engine-driven generator having a capacity of about 7½ kilowatts. The engine employs a four-cylinder four-cycle liquid-cooled system. The liquid that circulates through the engine is part of a 30-gallon heat-ballast tank required to maintain the temperature of the weather station at about 40F. For operations in cold regions, about one gallon of gasoline is consumed each day.

Conventional radio-transmitting equipment has been adapted for this use. However, since the transmitting ranges may vary between 100 and 1000 miles and since transmitting conditions vary with location and season, the selection of appropriate radio gear has been on an individual station basis. It is expected that 75- and 500-watt transmitters, covering the frequency range of from 2 to 20 mc sec^{-1}, will provide satisfactory ranges for most applications. Provisions are available in the programming unit for converting automatically to appropriate daytime or nighttime frequencies in order to obtain optimum results.

Measurements of temperature, pressure, relative humidity, winds, and precipitation are made with standard weather-station equipment, slightly modified for the coding device. A Bourdon-tube measuring element is employed for the measurement of ambient temperature. The element itself is exposed in a standard instrument shelter. Two sets of combs in series are used to cover the temperature range of from +110F to −60F. The probable error of the temperature measurement is about ±1F.

The pressure unit is a sensitive one-cell aneroid barometer whose indicating arm travels through 720 degrees for a pressure range of from 1050 to 700 mb. For this pressure range, three sets of combs are

combined in series in a circle. Because of the frequency of measurement, no ambiguity will arise in using the same contacts for each 360 degrees of motion of the pressure arm. Probable error in pressure measurement is ±0.5 mb.

For humidity indications, a standard hair hygrograph has been modified by replacing the clock and chart drum with the coding device. For the range of from 10 to 100 per cent relative humidity only fifty contacts are used. Although humidity changes in increments of 2 per cent can be recorded, the accuracy of the measurements is about ±7 per cent for temperatures above freezing, due principally to drift errors of the hair. It should be noted that for all these measurements lag constants are not as critical as they are in radiosonde observations.

A tipping-bucket type of rain gage is employed to determine the accumulated rainfall between transmission times. Accumulated rainfall up to 3 in. can be measured in steps of 0.03 in. Standard rotating-cup anemometers and wind vanes have been adopted for surface-wind measurements. Over the range of from 2 to 150 mph, values are transmitted in increments of 1.5 mph and wind direction in increments of 3.6 degrees. As soon as the equipment is available, measurements of the visibility and of the amount of light from the northern sector of the sky will also be made.

General Remarks. To utilize the full potential value of an automatic weather station, the installation should be operable unattended for as long a time as possible. The design goal of this equipment is from six months to one year. As a matter of fact, this equipment has operated unattended for a little over six months. This achievement, however, should be taken merely as an indication of the possibilities of the newly developed automatic weather station.

One serious problem has always been that of an adequate power supply—a reliable source of power that can operate automatically, intermittently, and under a wide variety of climatic conditions for a long period of time. To date, the best results are obtained with gasoline-engine-driven generators, especially where large amounts of power are required. Wind-driven power plants offer promise for locations where the average winds are high enough to operate the wind generators efficiently and maintain the storage batteries fully charged. Also, for systems with modest over-all power requirements of several hundred watts, the use of banks of Edison primary cells in underground vaults is possible.

For locations where icing is prevalent, serious problems of instrument design arise, particularly for wind measurements. Most rotating-cup anemometers and wind vanes can become totally inoperative and permanently damaged when subjected to severe icing. A specially designed heated Pitot-tube anemometer and wind vane have been designed and are satisfactory, except that excessive continuous power is required to keep them deiced. In addition, the Pitot-tube anemometers are rather insensitive to low wind speeds.

A properly designed instrument shelter is required for the arctic use of unattended weather stations. Rime ice and wind-blown snow can cause havoc with instruments exposed in present standard shelters.

To expand the usefulness of unattended stations, additional instrument research is necessary. There is a need for a reliable humidity indicator for the temperature ranges encountered. A pressure-tendency indicator, a snow gage, a cloud-base indicator, and a visibility meter that are readily adaptable to automatic weather station techniques would collectively expand the importance of the unattended weather stations manyfold.

CEILOMETERS—PULSED LIGHT AND RADAR

Introduction. The general requirement for the measurement of the base of clouds during the daytime as well as at night has been satisfied with the development of the elegant ceilometer by Laufer and Foskett [21]. The problem of the overwhelming background light scattered by a cloud during daytime observations, with the standard light projector, was solved by utilizing a modulated light beam in the projector and a specially designed photoelectric pickup device in the telescope. The projector and telescope were separated by a 1000-ft base line. These ceilometers are in widespread use by the United States Weather Bureau, Navy, and Air Force.

There are, however, two other important requirements in meteorology for cloud height measurements. One is a method for measuring the base of clouds from a single station. The second is a method for measuring the tops as well as the bases of clouds from the ground. In this section, a brief description will be given of two pieces of experimental equipment that show great promise of meeting these additional requirements. One is a pulsed-light cloud-base indicator and the other a microwave radar set capable of depicting cross sections of cloud systems.

Detection of Clouds by Pulsed Light [17, 26]. The principle of operation of this British [17] device is briefly this. Light pulses of about one-microsecond duration are produced by a high voltage spark placed at the focus of a good quality 36-in. Cassegrain mirror. The light pulse reflected from a cloud deck is then received by a second mirror which focuses the light on a photocell. The output of the cell is placed on a cathode-ray tube, using the usual radar techniques of display.

The electric spark produced between aluminum electrodes has a peak power of about 11 megawatts. It is estimated that a flux of about four million lumens is placed on a cloud deck. With the first experimental model, clouds up to 18,000 ft were detected in daylight. It is expected that this device, designed at the Telecommunications Research Establishment in England, will be modified to incorporate a means for recording on paper the height of the base of clouds.

Radar Cloud-Base and Cloud-Top Indicator. It was concluded from theoretical studies [34] that with a radar set operating on a wave length of about one centimeter and with sufficient, though reasonable, peak

power and receiver sensitivity it should be possible to detect and locate clouds and cloud layers. These studies were based on the concept that the microwaves are scattered by water droplets of radii between 10 and 30 microns.

These results were strikingly verified with an experimental radar set designed to operate on a wave length in the one-centimeter region. The equipment was designed so that the radar beam was directed vertically and the returned cloud echoes were presented on a standard "A" type cathode-ray tube. According to Gould [16], clouds were detected to heights in excess of 45,000 ft. It has also been possible to locate clouds through several thousand feet of light rain. However, the minimum altitude that can be detected is about 800 ft, this limitation being due to the length of the pulse and the finite recovery time of the radar receiver.

In order to obtain continuous records of the cloud tops and bases, a conventional-type facsimile recorder has been modified to record the cloud echoes. The recording device gives a plot of altitude of the cloud versus time. In this way a good cross section of the clouds that go by overhead is obtained.

Figure 8 is a typical record made with this radar set. At the top of the photograph is shown the fine structure of a cloud resolved by the equipment. At the bottom of the photograph is a record of a thunderstorm of 23 July 1948. This cumulonimbus built up to approximately 45,000 ft before it gave rise to an intense rainfall. The white vertical lines are due to instrumental difficulties of detuning. The very deep hole to the right of the white lines is probably due to excessive attenuation by the rain. An example of a recording showing two distinct cloud decks is illustrated in Fig. 9. The development of the radar cloud-base and cloud-top indicator represents one of the most significant advances in meteorological instrumentation of the past fifteen years.

GENERAL TRENDS

During the past ten years many new and clever experimental techniques have been developed and made available for the solution of meteorological problems. For example, a few of the more obvious advances the last decade has seen are (1) the introduction of radar capable of radiating megawatts of electromagnetic peak power and detecting micro-microwatts of scattered power, (2) basic advances in electro-mechanical systems, (3) basic advances in sensitive infrared devices, (4) development of versatile and rapid analogue and digital

computers, and (5) introduction of new concepts in communication theory. Some of these techniques have already markedly influenced the design of meteorological equipment and increased our understanding of the atmosphere. An even greater use of this fund of knowledge will, of course, be made in the future. In the following paragraphs, a few experimental problems that lie within the scope of this survey will be discussed and possible approaches for their solution suggested.

grometer and have placed it in the forefront as a low-temperature humidity indicator. Dobson, for example, has successfully used this instrument for measurements of water vapor from high-altitude airplanes, and recently Barrett and Herndon [4] have flown the hygrometer to 100,000 ft using the newly developed plastic balloons. Although the equipment used by Barrett weighed approximately 46 lb, there is no reason why this weight could not be materially decreased by the

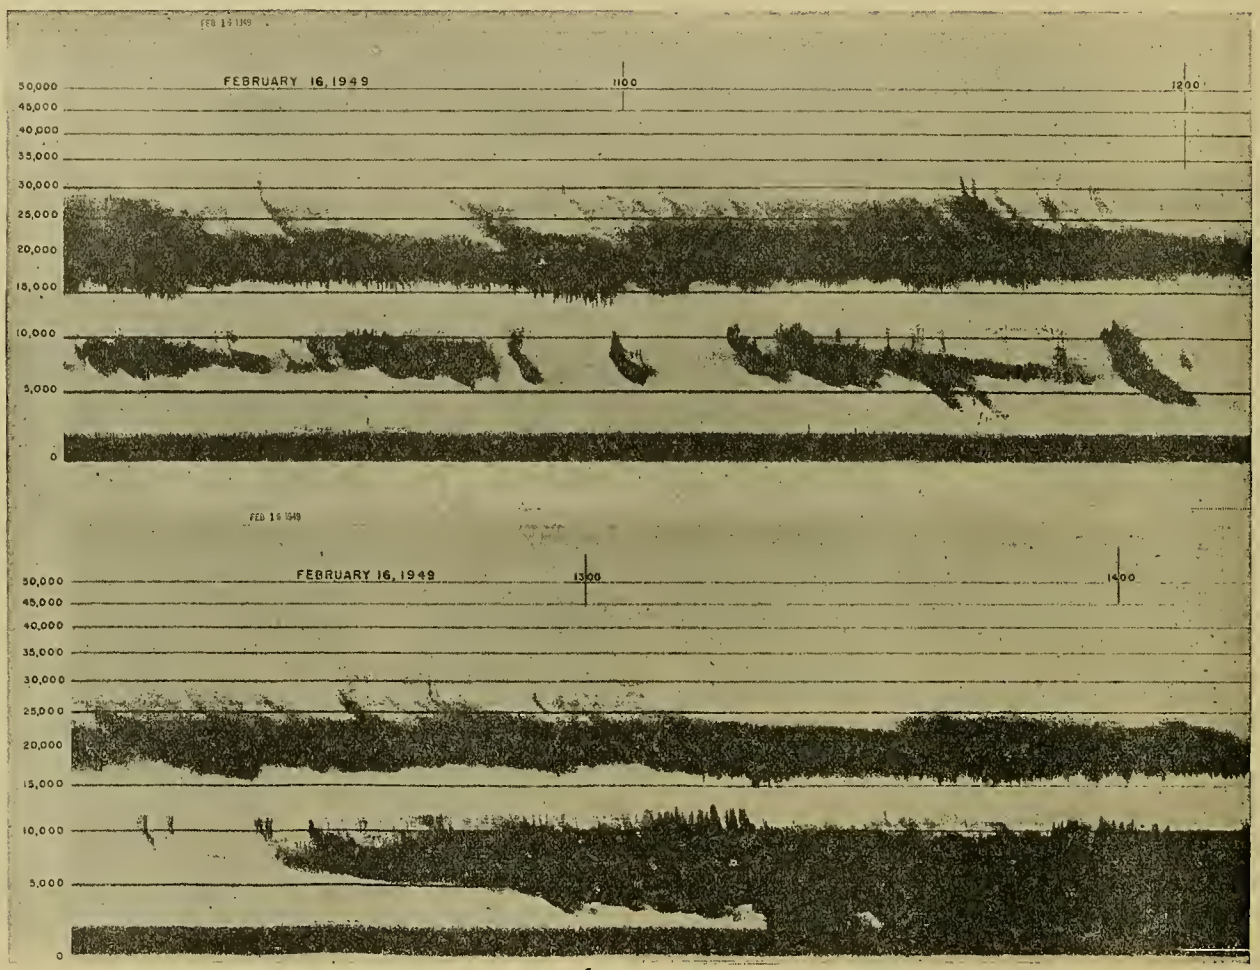

Fig. 9.—An example of a recording showing two distinct cloud decks. (*Courtesy, Signal Corps Engineering Laboratories.*)

One of the most exasperating if not the most important experimental problem in need of a fresh approach is that of low-temperature hygrometry—the measurement of water vapor to temperatures as low as −80C, accurately, rapidly, and economically. As is well known, such standard devices as the hair, goldbeater's skin, electrolytic strip, and wet-bulb thermometer are inherently poor indicators of humidity at these low temperatures. There are, however, two quite promising techniques that should be more fully exploited, namely the dew-point hygrometer and the infrared spectral hygrometer. Such investigators as Dobson [11], Thornthwaite and Owen [30], and the University of Chicago group [31], have contributed significantly to the development of the dew-point hy-

use of printed circuits, light-weight cuprous chloride-magnesium batteries, and a refrigerant such as Freon 13, and thus make possible flights to 140,000 ft, using rubber balloons. The Freon may also be used as a hypsometer. With properly employed surface-temperature measuring techniques, frost-point temperatures to −80C can readily be measured with a probable error of about ±0.5C. In addition to research requirements, the dew-point hygrometer should find wide-spread use for aerographs and for arctic station observations.

Although a spectral hygrometer using the 6.5-μ water-vapor band would appear to be an ideal instrument for humidity measurements, it has not to date been sufficiently practical for field use, due in part to the lack of

sensitivity and ruggedness of the infrared detectors and in part to the lack of precise water-vapor absorption coefficients for low temperatures and humidity. However, this former difficulty should be somewhat eased with the use of the newer photoconductive cell and especially the nonselective pneumatic cell. Both of these detectors can readily be incorporated into stable electronic amplifiers and should result in a quite sensitive and accurate hygrometer.

The possibility of probing the troposphere and middle stratosphere without the use of expendables is taking an encouraging turn, particularly through the use of radar techniques. Experimental equipments have been devised to probe cloud structures and locate the zero degree isotherm within the clouds whenever present. The location of precipitation areas through radar is also well known, and there are data on hand to suggest that some temperature inversions can be detected through the use of radar. For example, the work of Friend [14], using radar of frequencies ranging from 100 to 10,000 mc sec^{-1}, points to the real possibility of discerning air-mass boundaries, surfaces of water-vapor transitions, and other fine structures associated with dielectric changes of the atmosphere, such as turbulence. Furthermore, Jones [17] has made a most interesting suggestion of utilizing pulsed-light techniques for deducing the density field as a function of height.

Recent advances in the art of balloon fabrication and in techniques of radio direction finding will practically insure measurements of winds to about 35 km. Studies of the motion of noctilucent clouds in northern latitudes has given some information on wind velocities from 70 to 90 km. In addition the possibility of estimating winds in the vicinity of 160 km through doppler studies of meteor trails has been reported by Manning and Villard [23]. Recently, Crary [8] outlined a method of obtaining wind estimates from 30 to 60 km by the study of the anomalous propagation of sound. However, in spite of these most interesting techniques, a real need exists for a method of measuring winds on a semiroutine basis at the critical altitudes of 35 to 80 km. The use of smoke trails from V-2 rockets has not been successful at these very high altitudes.

In an earlier section of this article it was stated that the white thermistor element could measure temperatures with an accuracy of ± 0.5C. Two of the important corrections that must be applied are those of lag and radiation, these errors becoming increasingly important at very high altitudes. According to Barrett and Suomi [3], one method of suppressing these sources of errors is to use a sonic thermometer. These investigators have described a very clever sonic thermometer based on a pulse feed-back principle and have claimed such improvements as absence of radiation error and freedom from lag errors. In addition to these advantages, it is emphasized that a sonic thermometer permits space integration of air temperatures as a means for obtaining air temperatures more representative than is possible with point measurements. The question of space integration versus point measurements of temperature and winds is in need of clarification.

The time has perhaps arrived to give serious consideration to the important problem of data-presentation schemes. The amount of raw data presented to the forecaster for analysis and study is truly staggering. He may now have available to him for consideration, in addition to standard surface observations, complete radiosonde and radiowind data to 100,000 ft, detailed data on bases and tops of clouds from various strategic observation stations, sferics data from a world-wide network, detailed radar storm information, and other miscellaneous data. From these raw data he may draw a multitude of thermodynamic diagrams and charts, wind trajectories, velocity fields, acceleration fields, etc., for a variety of pressure levels, for an entire hemisphere, and for several time intervals. Presumably the forecaster would want a three-dimensional presentation of the current state of the atmosphere and of significant variations therein. There appears to be general agreement that atmospheric changes are sufficiently complex that a simple representation of them is not feasible at best.

It is suggested, therefore, that a careful over-all study of systems be undertaken at the earliest possible moment. Such a study would include an analysis of methods of obtaining raw data, of systems for data transmission, of possible utilization of analogue and digital computers, and finally a recommendation of an integrated data-presentation scheme. In the opinion of this writer such a cooperative study between system engineers and meteorologists is necessary to insure continuing progress in forecasting techniques.

It is a pleasure to acknowledge the many valuable criticisms and suggestions given to the author by his colleagues in the Meteorological Branch of the Evans Signal Laboratory.

AIRCRAFT METEOROLOGICAL INSTRUMENTS

By ALAN C. BEMIS

Massachusetts Institute of Technology

INTRODUCTION

The first scheduled weather flights were made in the early 1930's and were essentially vertical soundings. The airplanes carried simple meteorographs which recorded temperature, pressure, and humidity in much the same manner as the balloon-borne meteorographs of that period. Radiosondes being as yet undeveloped, the use of airplanes was the most practical method of obtaining vertical measurements promptly for forecasting purposes. At present the airplane, with its greater speed and cruising range, is more commonly used for measurements aloft along a chosen horizontal line, and it is for flights of this type that most instrumentation is now designed.

Much of the instrumental development to date has been carried out in connection with highly specialized research programs of various sorts. The study of aircraft icing, for example, has required an extensive program of instrumentation, much of it designed for important meteorological quantities never before measured in the free air [4, 27, 41, 52]. For such a program it is often practicable to use very complex laboratory instruments, expensive to build and operate. The author believes we now suffer from a serious lack of simple, well-engineered instruments, which might be relatively inaccurate, but nevertheless of great value when commonly available. For example, the Thunderstorm Project [5] operating in 1946–47 was unable to make any in-flight measurements of liquid-water content because the only available instruments for the purpose were still experimental. Even temperature measurement was a problem, particularly in the presence of liquid water. In short, aircraft meteorological instrumentation was then and still is in the laboratory.

A more vigorous attack on these problems is recommended. Weather reconnaissance by aircraft is an expensive and important operation, yet relatively small sums have so far been spent on instrumentation for those aircraft. Though many important meteorological quantities are best observed visually, others require instruments, preferably recording instruments. There is need here for inventive genius, good engineering, and funds for development work.

THE PROBLEM

For any observation to be useful it must be located in time and space. Let us assume that location in time is no problem and that ordinary navigational aids will locate the measurements in a horizontal plane with sufficient accuracy. We may also assume that some form of radio altimeter will measure true altitude with sufficient accuracy to give significance to local barometric pressure readings. Then the measurable quantities which are most important to the meteorologist are temperature, humidity, pressure, wind velocity, and liquid (or solid) water content. Also of considerable importance are droplet or snowflake size, turbulence and drafts, and electric field strength. Most of these quantities can be either measured directly or calculated from several related quantities, but are specified above in something approaching fundamental parameters. More precisely, the basic quantities referred to are:

1. *Air temperature* T, in degrees centigrade.
2. *Humidity* q, in grams of water vapor per kilogram of moist air.
3. *True altitude* h, in meters above mean sea level.
4. *Air pressure* p, in millibars.
5. *Wind velocity* V, referring to both the direction in degrees and the speed in knots.
6. *Liquid (or solid) water content* M, in grams per cubic meter.

All of the above quantities can be measured with relative ease at the ground. Most of the difficulties aloft stem directly or indirectly from the high velocity of the measuring "platform." Problems of instrumental lag, accurate location of the point of measurement, and automatic recording are far more acute, and new problems involving kinetic energy arise. Aircraft velocities are about ten times greater than the wind velocities and raindrop fall velocities encountered at a ground station. Quantities involving energy transfer are then one hundred times greater. This means that adiabatic heating effects, and difficulties caused by the presence of liquid water, are so severe as to be unsolved for some conventional instruments. These problems become particularly acute in measuring temperature, and will be treated at some length in the next section, where several new and promising methods are also described.

MEASUREMENT OF TEMPERATURE

The measurement of temperature from aircraft at speeds over 100 knots is seriously complicated by dynamic heating of the thermometer element. The heating is partly due to adiabatic compression of the air and partly to friction. It differs, therefore, for each type of thermometer housing, or lack of housing, and for various mounting locations on the aircraft, but is generally proportional to the square of the true air speed.

This source of error has received careful study [21, 29]. Theoretical and empirical correction factors as functions of air speed are available for the most common thermometer types and are reasonably satisfactory in dry air [47]. Some engineers have even designed built-in compensators working from air-speed devices. A more reasonable approach has been made by others [44, 51] using expansional cooling in the housing to

compensate for the heating at the entrance to the housing and at the thermometer bulb. The most promising is that which uses a vortex chamber for the required cooling, placing the thermometer at the center of the vortex (see Fig. 1). By proper construction of the

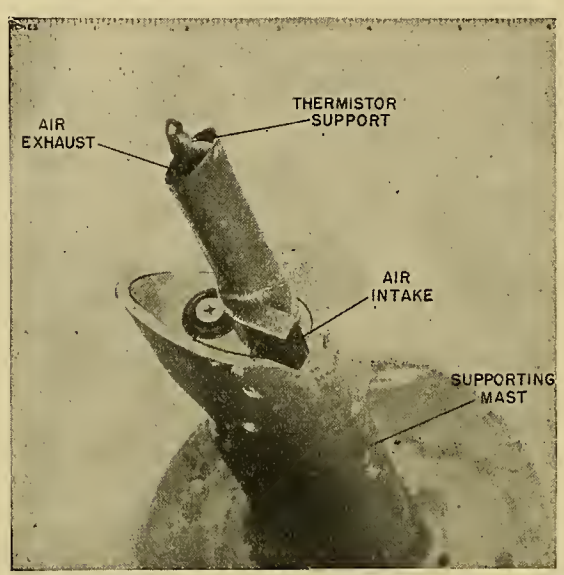

FIG. 1.—Photograph of a "vortex thermometer" as designed by P. J. Harney for measuring true air temperature from an airplane. (*Courtesy of Signal Corps Weather Radar Research at M.I.T.*)

housing and controlled throttling of the flow, the thermometer can be made to indicate free-air temperature correctly over a wide range of air speeds [51]. If another thermometer element is mounted on the same aircraft so as to receive the full adiabatic heating effect, the difference between the two will be a measure of true air speed. The vortex-type housing also provides good mechanical protection for the element. All factors considered, it appears to be the most promising recent development in aircraft thermometry.

Radiation effects, particularly radiation from the sun, may be another source of error. However, with a well designed radiation shield, and with the high ventilation speeds available on aircraft, radiation effects may be made negligible.

The most serious problem is accurate measurement in the presence of liquid water. The effects of liquid water are various. First, any housing so far devised which provides adequate ventilation will allow the thermometer element to become wet, and it will remain wet for a time after emergence into dry air. (First tests of the vortex thermometer in clouds indicate that either its element is wetted to some extent, or water present when the pressure is high causes evaporational cooling "upstream" from the element.) The thermometer will then read some sort of wet-bulb temperature. If it indicated the true wet-bulb temperature, it would be a useful quantity, but it might not be completely wetted and would undoubtedly be affected by the temperature of the water, as well as that of the air. One simple, but only partially adequate, solution is to use two elements, one coated with a hydrophobic substance, the other with a hydrophilic substance, and both exposed to the direct air flow [7]. In air of low liquid-water content, the hydrophobic bulb is then assumed to indicate the dry-bulb temperature (with appropriate corrections). In air of high water content, the hydrophilic element is assumed to measure the wet-bulb temperature (again with appropriate corrections). (See Fig. 3.) The difficulties are (1) obvious uncertainties in the case of intermediate water contents, (2) uncertainties in the appropriate corrections to use, particularly for the wet-bulb temperature, and (3) uncertainties regarding the effects of the temperature of the water striking the thermometer. This general method might be slightly improved by the use of a constantly wetted wick instead of a hydrophilic coating, but it would remain inadequate.

Second, we must consider the effects of water on the temperature of the air before it reaches the bulb, as well as the effects of water on the bulb itself. All heat-transfer-type thermometers must have adiabatic heating effects at the thermometer element or upstream from it. If there is liquid water present, there will be some evaporation which may or may not be at the moist-adiabatic rate. The vortex thermometer corrects for dry-adiabatic heating by subsequent cooling, but it is not yet clearly established that the cooling process will introduce the right correction in the presence of liquid water.

In spite of these heating and cooling uncertainties, it seems worth while to make a further study of means of keeping the thermometer element dry. This would not seem impossible, although the usual means of removing water from the air mechanically requires deflecting surfaces, upstream from the element, which themselves become wet and consequently lower the temperature by evaporation. Even when the air is originally saturated, the temperature rise at the deflecting surfaces due to dynamic effects will lower the relative humidity and permit evaporation. Possibly some modification of the vortex thermometer with porous capillary surfaces to remove the water would be worth trying.

This general problem of temperature measurement in the presence of liquid water has been dealt with at some length because it presents such a challenge. Even if one succeeds in conquering it at temperatures above freezing, then a whole new set of difficulties arises under icing conditions. (Dry snow appears to cause no trouble.) All these difficulties naturally make one turn away from thermometers operating on conductive heat transfer from the air. At least two entirely different principles have been used. In one the speed of sound [1, 49], which is a function of temperature and humidity, is measured. If one defines temperature in terms of molecular motion, the velocity of sound is a more direct measure of that temperature than observing the temperature of some secondary material, as one does with a conventional thermometer. Several very ingenious variations of this sonic-velocity idea have been devised, some of which are suitable for aircraft use. The presence of liquid water, even under icing condi-

tions, would introduce only secondary effects and should pose no insurmountable problem. High accuracy is possible with very short time lags, and there would be no radiation effects. The difficulties seem to be those of a relatively cumbersome installation, the usual but in this case not very difficult deicing problem, interference from sound produced by the aircraft, and an over-all instrument that is very complex compared to a common thermometer. At its present stage of development it stands as an interesting and valuable instrument for research purposes, but it is too complicated for routine use. However, its potentialities are very great.

A second very different principle would use radiant energy. Many radiant-energy thermometers have, of course, been developed, but the author knows of no published work on one for the measurement of free-air temperature from aircraft. However, an instrument has been devised for measuring the temperature difference between the air at flight level and any clouds within the line of sight of the instrument [54]. If the energy received by such a device could be confined to wave lengths strongly absorbed and radiated by the atmosphere (carbon dioxide and water-vapor bands), an accurate free-air temperature device might result. On paper such an instrument appears barely possible with some of the new infrared radiation devices developed over the past ten years [20, 55]. It would be less accurate at low temperatures where energy levels and humidities are also low. In dense cloud, rain, and snow, it would tend to indicate the temperature of the particles instead of the free-air temperatures.

It seems unnecessary to discuss here the relative advantages of thermocouples, resistance thermometers, bimetallic strips, and other types of temperature-measuring devices. The choice is primarily one of the simplicity of auxiliary equipment and time of response. The latter requirement is largely one of the mass and shape of the element. The lowest time lags are usually obtained by using small thermocouples or resistance elements and electronic amplifiers. With such devices, time lags can be reduced to a tenth of a second or less.

It becomes important then to consider what time lags are desirable. We will assume an aircraft travelling at 100 m sec^{-1}. Temperature discontinuities are of two types. Those produced by instability and turbulence will cover a wide scale range. The shorter the time lag the finer the observed temperature detail. For most purposes we are interested only in the larger convective motions with dimensions of several hundred meters, so that a time lag of one second is adequately short. Temperature discontinuities produced by horizontal stratification may amount to several degrees within a few meters but lie nearly parallel to the direction of motion of the aircraft. However, interesting wave phenomena are often observed in such surfaces and may be of importance. Such wave structure is sometimes made visible by clouds, and, if this be a criterion, is seldom less than 100 or 200 meters in wave length. In such cases, to obtain at least a rough measure of the sharpness of the inversion, the time lag should be of the order of a few tenths of a second. Most aircraft thermometers in use today have lags of several seconds, so there is much room for improvement here.

MEASUREMENT OF HUMIDITY

There is a great variety of methods of measuring humidity, both at the ground and aloft. Most aircraft humidity instruments are beset with the same problems as aircraft thermometers, and in addition must be accurate at very low values. Wet bulbs, electrolytic conductivity elements, hair hygrometer types, and all their counterparts become very sluggish and inaccurate at low temperatures and humidities. Some sluggishness is inherent in these types due to the necessity for moisture transfer between the measuring element and the air. This moisture transfer requires ventilation, and again, as in the case of temperature measurement, dynamic heating effects cause errors. The "standard" aircraft instrument at present in use in the United States is the military ML-313/AM, which is simply wet- and dry-bulb mercury thermometers in a special housing [29, 47]. Its use below 0C is awkward, slow, and of questionable accuracy. It has the high time lag characteristic of mercury-in-glass thermometers. In the presence of liquid water its dry-bulb reading has no significance.

Much development work has gone into improvement of electrolytic and hair hygrometers (using the term hair hygrometer in its broadest sense). It seems reasonable to expect that an electrically conducting material may some day be developed which, as an electric hygrometer, will have low lag and constant calibration. The use of carbon shows promise.[1] However, the liquid-water problem must be kept in mind. A drenching in liquid water changes the calibration of some elements, requires a long drying-out period for others, and certainly results in a false reading for most elements when flying through rain in unsaturated air.

As in the case of temperature measurement, the most accurate instruments under all flight conditions are the most complicated. One of these automatically measures and records the dew point [14, 45]. The dew point obviously is unaffected by transient changes in temperature and pressure, so that the sampling problem is relatively simple. When liquid water is present, it will be difficult but perhaps not impossible to obtain a representative sample. The problem is to avoid evaporation or condensation while separating the liquid water from the moist air. Separation of the larger drops is relatively easy, and fortunately more important. When many small cloud drops are present, nearly saturated air can be assumed. With this instrument there may be uncertainty between dew point and frost point due to supercooling. Except for this factor, which can perhaps be eliminated, it is accurate to about 1C and is useful down to dew points of −40C or below. Although this instrument also requires exchange of moisture between the air and the sensing element, it is only a surface phenomenon. Most of the lag occurs in the heating and

1. See "Instruments and Techniques for Meteorological Measurements" by M. Ference, Jr., pp. 1207–1222 in this Compendium.

cooling cycle. It is short, however, a matter of 1 or 2 seconds. This instrument is complex and requires some cooling agent, such as dry ice, for the dew-point surface, but these problems are not fundamental difficulties and have been overcome for certain special studies. Dew-point recorders of this type have been successfully flown in both airplanes [14] and sounding balloons [3].

Another interesting device is the spectral hygrometer [13, 19, 36] operating on absorption of radiation by water vapor. Several absorption bands occur between the visible spectrum and a wave length of 4 μ. Most of these bands are too far into the infrared for good sensitivity with ordinary photocells so that an instrument with satisfactory sensitivity has not yet been developed, but there are newly developed photoconductive cells [6, 20, 43] now available which might make such an instrument more useful. Stronger and very broad-band absorption occurs at and around 6.5 μ where thermal detectors must be used. Here again there are newly developed infrared detectors [20, 55] which might make the instrument practical. Possibly an optical instrument of this type could be arranged to measure attenuation of its light beam due to liquid and solid particles when present in the air, as well as absorption due to water vapor, thus serving a double function. This would require comparison of attenuation over three paths: one restricted to a water-vapor-absorption band, another where gaseous absorption was a minimum, and the third a standard reference path.

It was pointed out when mentioning the sonic thermometer that the speed of sound is a function of humidity as well as temperature, so that the instrument can be used as a hygrometer if the temperature is accurately known. At low humidities, however, its moisture dependence is very small. At present the dew-point hygrometer leads the field in accuracy at low humidities.

MEASUREMENT OF PRESSURE, ALTITUDE, AND WIND VELOCITY

These three measurements are grouped together because they are made with standard aircraft instruments available on any long-range aircraft [47]. Measurement of barometric pressure is the simplest of all instrumental problems. A standard precision aircraft altimeter, when attached to a properly designed static fitting, is accurate to ± 1.5 mb (50 ft) [29]. It is most important, however, that the static pressure fitting be carefully installed and calibrated on each individual aircraft.

Of course, for the pressure reading to have significance as such, the altitude must be known, and accurate measurement of altitude is relatively difficult. Fortunately, constant pressure surfaces have little slope in the atmosphere, so that it is sufficient to fly along such a surface by pressure altimeter, making periodic measurement of true altitude. Knowledge of the barometric pressure at the surface, and the density of the air at all levels from the surface to flight level, permits accurate calculation of true altitude. This information could be obtained by parachute radiosonde, but with poor accuracy.[1] However, altitude above terrain can be accurately measured (± 50 ft) by a radio altimeter [47]. Such an altimeter should be carried by any reconnaissance aircraft for navigational purposes as well as for meteorological purposes. Consequently, the measurement of altitude and pressure offers no problem over ocean surfaces or flat terrain of known altitude. Over mountainous terrain, certain established check points might extend the usefulness of the radio altimeter. On a regular route or airway, radio responders or beacons could be used.

Wind velocity and direction at flight level are determined by drift meters or other navigational aids. These methods are well established and are a routine part of aircraft navigation [47]. The accuracy is generally inferior to the best balloon-tracking techniques, but satisfactory for many purposes.

MEASUREMENT OF LIQUID-WATER CONTENT

Liquid-water content M is the equivalent aloft of precipitation rate at the ground, and just as important a parameter. Its most common values are below 1 g m^{-3}, but values in excess of 5 g m^{-3} have been observed. M should be measured to an accuracy which will match the accuracy of the humidity measurement q, so that the contribution of liquid water to the total water content will have significance. This requires about 10 per cent accuracy, which is not difficult to attain under good conditions. In practice, the observation of water contents below 0.1 g m^{-3} is most difficult, and in that range plus or minus 0.02 g m^{-3} is a common error. Even at -30C saturated air holds 0.34 g m^{-3} of water vapor, so that M measured to plus or minus 0.02 would be close to the required accuracy limits.

Most M-measuring instruments present a trapping surface or opening of some kind to air flowing past the aircraft and measure the water caught per unit time. From the true air speed and the area of the surface, one can calculate the volume swept per unit time and hence M, if one knows the efficiency of collection. No surface is 100 per cent efficient for all drop sizes. The smaller drops are deflected around the surface by the air stream. Because the problem of collection efficiency, in its various phases, is of first importance in studies of aircraft icing, it has received much attention [31]. The first curve in Fig. 2 gives the collection efficiency of a sphere 1 cm in diameter as a function of drop size. It shows that a collector must be at least that small to catch a representative sample of cloud drops. This results in a secondary problem because the low rates of collection are difficult to measure. Also a small collector which is efficient for cloud drops is inadequate for light rain because the wide spacing of the drops may cause a serious sampling error. A satisfactory solution may be a long narrow collecting surface. It is sometimes convenient to use two collectors of different sizes as a means of separating the M due to rain

as compared with the total M. The second curve in Fig. 2 gives the collection efficiency of a large area, in this case the nose of a B-17 airplane. A collector in the

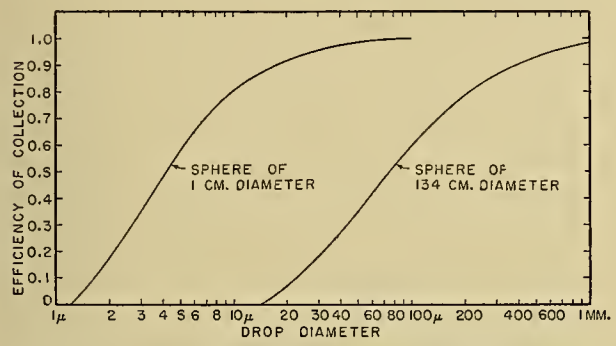

FIG. 2.—Collection efficiencies for cloud and raindrops at the stagnation points of two spheres. The calculations were made by R. M. Cunningham for a 1-cm sphere (showing the performance of a small capillary collector) and for a 134-cm sphere (indicating the collection efficiency for a collector centered at the nose of a B-17 airplane). Pressure was assumed to be 800 mb, temperature +5C, and air speed 200 mph.

center of the nose would be less than 60 per cent efficient for drops of less than 100 μ in diameter.

Having removed the water from the air, we must measure the rate of collection. The most obvious means is to pipe it to a flow meter, but unfilled tubes of any length cause lag. The most widely used M meter is called a "capillary collector" [50] because it employs a capillary porous surface as a collector so as to keep its plumbing full of water at all times. The lag of such a system is limited only by the method of measuring flow rate. Many such methods have been devised, none of them entirely satisfactory [12, 52].

Evaporation from the collecting surface is a serious limitation of the capillary collector and similar types of M meters. Evaporation losses are assumed to be negligible in dense cloud, but may be appreciable in rain; and evaporation makes it nearly impossible to use deicing heat for supercooled water particles. Because of evaporation in clear air, the plumbing system should permit reverse flow or correct for the loss of water in some way.

Another method is to collect both water and air by means of a scoop and determine the amount of water by measuring the amount of heat required to evaporate it, or by measuring the dew points of the air before and after all the water has been evaporated. The latter procedure is inaccurate because it determines a small quantity as a difference between two large quantities [27]. Other types using heat evaporate the water as it impinges on the collecting surface. One can either supply heating power at a constant rate and measure the temperature, or maintain a constant temperature and measure the heating power. Another variation is a heated surface whose electrical conductivity is a function of its wetness. For all of these, the major problems are constancy of calibration and dependence on factors other than M, for example, air temperature, waterdrop temperature, and humidity. The heated types, however, can be designed for use under icing conditions.

An icing-rate meter is a useful instrument for measuring M under icing conditions in supercooled clouds [32]. Such meters are not readily available, but several types have been built, the most successful being some variation of the rotating-disc type [52], in which ice accretion is continuously measured on the edge of a disc rotated at a uniform rate. This type, however, is usually built with a thin disc which has good collection efficiency for cloud drops but does not measure icing rate in rain due to splash and "run-back" effects. Another method is to expose a rotating cylinder or series of rotating cylinders of different diameters to the air stream and weigh the ice accumulation after a known time at a known air speed [39, 52]. This process also gives a measure of the drop-size distribution but is awkward and discontinuous.

For reconnaissance aircraft a simple recording instrument must be chosen. The N.A.C.A. reports success with one of the heated types just mentioned [32]. A small heated cylinder is exposed at right angles to the air stream with a thermocouple measuring and recording its surface temperature at the stagnation point. A sharp drop in recorded temperature indicates entry into a cloud, and subsequent variations give a rough measure of M. The instrument reacts less and somewhat differently to snow, so that snow can be differentiated from rain under some conditions. By using two such heated cylinders, one centered at the nose of the aircraft and one exposed so as to collect small drops efficiently, the records should give a rough idea of drop size as well as of M.

Electromagnetic-radiation devices may prove to be useful instruments for measuring liquid-water content if the drop-size distribution is known [22]. A light-transmission device working in the visible spectrum (a type of visibility meter) seems the simplest type. Assuming a uniform drop diameter d, M is proportional to $d \log_e I_0/I$, where I_0/I is the ratio of transmitted light intensity in clear air to that in the cloud. Flight models of such instruments have been successful [28, 35]. An instrument operating on back-scattered light may also be possible [33]. Microwave radar may be used as well as light, since the intensity of back-scattered radiation at those frequencies is proportional to Md^3 and since radar detection of clouds is possible over short ranges.[2] The strong dependence on drop size is unfortunate for this application.

Radar, of course, is a very complex instrument; but if it is to be carried on an aircraft for other purposes, it should be considered for M measurement. It would have the advantage of indicating the value of the quantity Md^3 over any selected neighboring region instead of only at the aircraft.

In summary, it is clear that rather complex and specialized instruments are necessary for accurate measurement of liquid-water content, but simple and useful instruments such as the N.A.C.A. "cloud indicator" [32] have been devised which can dependably record

2. See "Radar Storm Observation" by M. G. H. Ligda, pp. 1265–1282 in this Compendium.

some quantity related to M. Such instruments should be more widely used.

SPECIAL RESEARCH INSTRUMENTS

Obviously, there are meteorological quantities other than temperature, humidity, pressure, wind velocity, and liquid-water content which are important for particular studies, and in some cases for general meteorological use. Some research programs have required very extensive aircraft instrumentation, and many ingenious instruments have been devised [10]. Figure 3

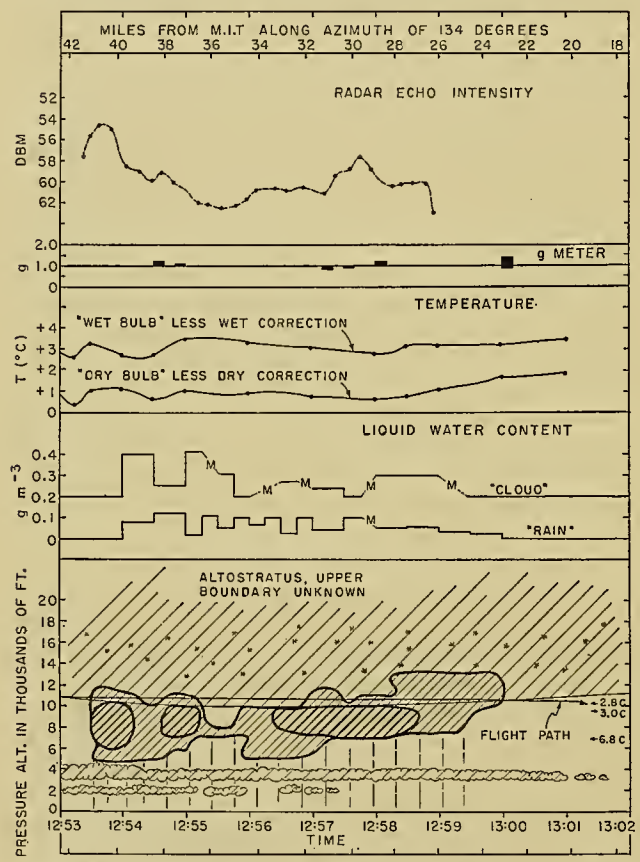

FIG. 3—An atmospheric cross section and plot of instrumental measurements and observations, most of which were obtained from a B-17. At the top is a plot of radar echo intensity (DBM = decibels below one milliwatt) from the storm; next are recorded vertical accelerations; then temperature records, liquid water contributed by cloud and by rain, and a vertical cross section along the flight path constructed from radar information as well as direct observations. The flight was at a level where snow was melting to rain, creating a stratified radar echo as shown by the heavy slant hatching. (*Courtesy of Signal Corps Weather Radar Research at M.I.T.*)

presents in chart form some of the measurements obtained with equipment designed for measurements associated with the uses of radar in meteorology [7]. Aircraft icing studies have also required many specialized instruments. Only a few can be mentioned here.

Cloud and Raindrop Size. A small cloud drop may be only 5 μ in diameter, a large raindrop 5000 μ. So wide a range of sizes requires quite different techniques of measurement. In both cloud and rain there always exists a range of sizes, so that a size distribution is what should be measured. To obtain a representative result, an instrument must sample or measure upwards of a thousand drops.

Cloud drops have been measured at mountain stations by catching samples in oil or on greased slides and measuring them with microscope techniques [23, 25]. Some success with these techniques in airplanes has been reported [8], but a simpler airborne method is to expose a sooted slide [40, 52] to the air stream for a brief known interval and measure afterwards the splash traces remaining. As in the case of liquid-water collectors, the sampling device must be kept small. The rotating cylinder method [39], which makes use of selective collection efficiencies, has been mentioned as a liquid-water measuring instrument. All these methods are seriously limited by being essentially discontinuous and far from automatic.

The measurement of associated optical phenomena [26, 56] shows much promise, as it provides a means of sampling a large number of drops simultaneously, and yields a size distribution instead of individual size measurements. The corona has been used extensively [30], and the rainbow [33] and forward-scattering [24] studied as size measuring methods. Transmission measurements [28, 35] and back-scattering for either light or radar energy[2] might also be used if the water content were known, but such measurements would determine only an effective drop size, not a drop-size distribution. In designing such equipment, it is important to remember that cloud density and general illumination may change rapidly, making it difficult, for example, to locate the angle of a corona or rainbow by means of angular scanning.

Direct photography of the droplets has been attempted [11], but so few drops are found in focus per photograph that a representative sample is not feasible within the short time available. Electrical methods are interesting. One, similar to measuring naturally charged particles [16], calls for inducing and measuring the maximum charge on individual drops as they pass through the instrument. Another measures the electrical effect of drops impinging on a charged probe [18].

Most of these instruments for airborne use have been developed in connection with research programs in cloud physics and aircraft icing, and have resulted in a general knowledge of drop-size distributions for different types of clouds. For more exacting studies, an accurate, short-time-constant instrument with automatic recording is needed.

No satisfactory instrument exists for measuring raindrop size from aircraft. Because the mass of raindrops is more than a thousand times greater than that of cloud drops, most methods which involve physically catching and measuring individual drops are impractical. Soot-coated screens have been tried in place of the sooted slides or solid surfaces used for cloud drops [2]. To obtain a satisfactory sample on one screen would require large unwieldy sizes. Some study has been made of techniques of measuring momentum transfer from individual drops to small collecting plates

[15], but a practical instrument has not resulted. Another approach is to allow the drops to enter a box of quiet air (carried with the airplane) and observe in some way the different rates of deceleration.

A raindrop-size meter which has received much attention to date operates on the attenuation of a small-area light beam by individual drops passing through the beam [34]. This method avoids some of the uncertainties of those which require catching the drops on any sort of collector. For example, the drops are unaffected by the instrument as they are measured, its "collection efficiency" can be 100 per cent for all sizes, and its calibration is only a second-order function of air speed. Attenuation of the light beam causes a phototube to emit an electrical pulse for each drop. The size of the pulse is a measure of the size of the drop, so that sorting and counting circuits can be used to give a nearly continuous measure of drop-size distribution. Calibration can be accomplished with accurately sized solid spheres such as glass beads. The method, however, has a poor signal-to-noise ratio, and is much too complex and expensive at present for more than research use.

Snowflake and Ice-Crystal Size. Observation of snowflake and ice-crystal size and type is obviously of parallel importance to the measurement of rain and cloud particles. It is also obvious that it is a more complex assignment, due to the intricate and varied shapes of snowflakes. An ingenious plastic replica technique has been developed [37] which can be used at the ground or in the air. For aircraft observations, a decelerating tube [38] is mounted forward from the nose of the aircraft to catch the samples with minimum damage by allowing them to decelerate with respect to the aircraft in a cushion of still air. Large crystals and agglomerations usually break apart. Plastic replicas are then made and can be examined at any later time. However, the method is discontinuous and requires the operator's full attention. A count of the number of particles caught in a given time is an indication of the number per cubic meter originally in the air. A better count might be made by one of the raindrop-counting devices, which, for snow, would give little idea of the size but might still count the number per cubic meter.

Other Research Instruments. Many other measurements now made for research purposes may soon become of more general importance. For example, a nuclei count, particularly of nuclei of crystallization, may become a significant observation [42]. Such an instrument would require a representative sample of air, which, in this case, should be easy to obtain on an aircraft since particles as small as nuclei follow the air stream closely.

The Thunderstorm Project [5] made extensive use of vertical gust and draft measurements. Accurate measure of these quantities is extremely difficult because of their very nature, and because the characteristics of the aircraft and the manner in which it is flown enter the measurements. Fortunately, for many purposes only a general indication of turbulence and vertical drafts is required. To obtain such information, the aircraft should be trimmed for level flight and flown with as little control as possible. Vertical accelerations and air-speed fluctuations are then a rough measure of turbulence, and altitude changes are a rough measure of vertical drafts. Standard, relatively simple instruments are available for recording accelerations, air speed, and altitude; but conversion of the measurements to meteorological parameters is difficult [9]. Changes of the angles of pitch and yaw, that is, relative direction of the air stream past the aircraft, may also indicate turbulence, and instrumentation for measuring these angles also exists [48].

A project investigating atmospheric electricity has developed electric field strength meters [17, 53] for airborne use, and instruments for measuring and recording the electric charges on individual precipitation particles. These instruments appear to be entirely satisfactory, and could be engineered for routine use.

Certain other research instruments have already been described. For example, instruments for measuring light transmission and hence visibility were discussed as means of determining liquid-water content. As visibility meters, they would naturally be restricted to low visibilities (less than 1500 m) due to short path lengths [28, 35]. Velocity-of-sound instruments were first mentioned as thermometers. They also have application as hygrometers, anemometers, and possibly other purposes [1].

A rather specialized but interesting instrument has been suggested [36] which would measure directly the refractive index of air at microwave radio frequencies. The index is a function of temperature and humidity.

Some meteorological quantities at a distance from the aircraft can be measured, others observed. Conditions below are measured by "dropsonde," a radiosonde released from the aircraft to parachute to the surface.[1] When precipitation, rain or snow, is present within a hundred miles, or perhaps more, its location can be accurately determined by airborne radar and its intensity estimated [46]. Active research proceeds in this field, so that the usefulness of radar may be expected to increase in the near future. It is already possible to detect clouds over short ranges, permitting the altitude and thickness of cloud layers above and below flight level to be observed. The freezing level can often be located by radar, turbulence within storms indicated, and, as mentioned earlier, some indication of liquid-water content given. The effectiveness of hurricane reconnaissance is tremendously increased by airborne radar. Because of the continuing development of weather radar, and because of its navigational use to aircraft flying in bad weather, the meteorological applications of airborne radar should receive serious study. Further space is not devoted to radar here because of detailed discussion elsewhere.[2]

SUMMARY

It is apparent from the foregoing discussion, first, that meteorological measurements from aircraft are of increasing importance; second, that techniques, however complex, have been devised for a wide variety of

measurements; and third, that simplified dependable instruments are seriously needed both for routine use and for specialized research programs. Improvement in this field of endeavor might be accelerated by a more integrated approach, closer coordination among those working in the field, and more unified objectives. It is time, for example, to consider a "one-piece" instrument which would record a number of the quantities we have discussed above. The military aerograph AN/AMQ-2 [29, 47] was a step in that direction, but it records only temperature and humidity (with serious lag), pressure altitude, and air speed. In a unified instrument many of the quantities could be reduced to the same type of measurement—a temperature or a pressure measurement, for example—and all quantities might be recorded coincidently on a single chart or magnetic tape. It is clear that advancement requires both sound engineering applied to known techniques, and able scientific attack where techniques are now inadequate.

In addition to much helpful advice from many coworkers in this general field, I wish especially to acknowledge the constructive criticism of Robert M. Cunningham who has been actively associated with the development of aircraft meteorological instruments since 1942, and to recognize the able assistance of Mrs. B. A. Wallace in the preparation of the manuscript.

EXPERIMENTAL ANALOGIES TO ATMOSPHERIC MOTIONS

By DAVE FULTZ

University of Chicago

Introduction

One of the very old dreams of meteorologists and other scientific observers who have concerned themselves with the phenomena of the atmosphere has been that of solving some problems (as many as possible, of course) by means of experimental work on a small scale. In view of the difficulties of purely theoretical approaches and of interpreting the uncontrollable variations of the actual atmosphere, many have had hopes of obtaining valuable results and insights from such experiments as a supplement to, and a source of, theoretical ideas. Typical statements of such views are those of Schmidt [56, p. 1135] and Richardson [89]. In recent times the increasingly far-reaching successes of model experimentation in aerodynamics, hydraulics, oceanography, and other fields have given renewed impetus to efforts at serious work on meteorological questions by this means.

There are many serious difficulties in the application of model techniques, as they have been developed in other fields, to the study of such a complex system as the atmosphere.[1] Particularly in the medium- and large-scale aspects of atmospheric motions, so many factors are involved that a straightforward dynamic-similarity analysis of the usual kind leads inevitably to the conclusion that, within practical limitations, the model must be identical with the prototype. The choice of real fluids available for experimentation, the serious inconveniences connected with the presence of gravity, and many other factors made this conclusion unavoidable. Basically, therefore, any model experimentation that aims at real resemblance to the atmosphere of a planet and thence to the discovery of principles governing phenomena in such atmospheres, will have to accept deliberate distortions of certain kinds and will have to intercompare many partial types of experiments and analyses in the effort to arrive at valid conclusions concerning the operation of these principles. In this respect the situation is similar to, though more complicated than, that which is encountered in sedimentation studies on river models.[1]

I hope in the succeeding parts of this paper to review briefly some of the rather considerable amount of experimental work of various types which has been done with the atmospheric problem more or less in mind, to mention some of the reasons for expecting a renewed and vigorous attack on this area to be more profitable in the future than it was in the past, and to suggest some immediate directions along which such an attack might develop. With some exceptions, the topics to be discussed will be restricted to problems concerned with relatively large-scale motions, such as cyclones or the general circulation. Experimental work on certain small-scale phenomena, such as convectional layers and flow in the friction layer, are discussed by D. Brunt[2] and H. Rouse.[1]

General Considerations

In the problem of the atmosphere as a hydrodynamic fluid we are concerned essentially with these factors:

1. Strong effects of rotation.
2. Thermodynamic activity or "convection" as an important ultimate driving mechanism and probably the only one of real significance.
3. Primary effects of "friction" in one sense or another.
4. Important alterations brought about in the operation of all the preceding factors by the great horizontal extent of the atmosphere relative to its vertical extent.

The last factor, perhaps more than any of the others except rotation, fixes the specific character of an atmospheric motion and must somehow be dealt with in the interpretation of experiments. Since these factors are inextricably combined with other dynamic factors which are more fully understood and more completely analyzed, the task of disentangling them and assigning each to its proper place is formidable.

In an experimental approach, which must of course be guided as closely as possible by theory and observation, a more than ordinary amount of groping will be inevitable. Similarity analyses need to be made but, for example, even the significance of Π-terms such as $g/a\Omega^2$, where g is the acceleration of gravity, a is the radius of the experimental sphere or a planet, and Ω is the angular velocity of the sphere, is not the same in the heating experiments in a thin spherical shell reported by Fultz [22] (and discussed below) as for the planet. In the planetary case, g is the intensity of a central force, and the solid surface is an equipotential surface for gravity plus the centrifugal force. In the experiments mentioned above, g refers to the intensity of a uniform field of force, and the spherical surface is not an equipotential surface. In spite of this and other differences, kinematic similarities at least did appear in these experiments; furthermore, there are qualitative theoretical reasons for expecting this to be so. Thus the fact that kinematic similarities were found is not likely to be mere coincidence.

It would be foolish to expect these similarities to extend to every aspect of the dynamics of these two systems. But it is not unreasonable to expect similarity in some predominant, basic mechanism. As suggested

1. Consult "Model Techniques in Meteorological Research" by H. Rouse, pp. 1249–1254 in this Compendium.

2. Consult "Experimental Cloud Formation" by D. Brunt, pp. 1255–1262 in this Compendium.

by the theory from which these experiments developed, this mechanism, if substantiated by further checks, would principally be "frictional" (turbulent) mixing processes that are similar in the two cases.

The obvious step beyond the purely kinematic check of average velocity fields is to proceed to more refined measurements of important dynamical quantities over a more extensive range of parameter values. Once an accurate picture is obtained of how far qualitative and quantitative similarity extends, many avenues of reasoning and experiment will be opened for attempts to interpret both the agreements and the disagreements in terms of unifying principles.

An important step in this process will be to attempt to produce experimental arrangements which have close resemblances in one or two selected Π-parameters at the expense, in general, of similarity in others. Perhaps the most important example of this possibility is the case of convection in thin fluid shells on a rotating paraboloid as compared with the spherical shell experiments mentioned above. If the angular velocity of the paraboloid is such that the resultant of the gravitational and centrifugal forces is exactly perpendicular to the surface at every point, the solid surface will have the planetary property of being an equipotential surface. More realistic thermodynamic actions should be possible in this arrangement than in the above-cited experiments with a rotating spherical shell. A free upper surface can be attained and the Coriolis parameter would still be variable, but all these advantages are obtained, of course, at the expense of abandoning any approach to geometrical similarity to planetary shapes and of tolerating rather considerable horizontal variations of the apparent gravity acceleration. Various other practical advantages, such as the ability to produce vigorous convectional mixing with practicable temperature differences within the fluid, may possibly also be lost. By appropriate modifications of this or other types it should be possible so to vary the contributions of the three major factors in these experiments that each one can be more or less isolated for study.

In developing an experimental program, a certain backlog of experience will have to be built up on the purely practical side. Since the requirements of importance to meteorological questions involve somewhat different emphases than, for example, in aerodynamic experimentation, trials of satisfactory techniques in themselves will occupy a considerable period. However, the present development of experimental technique, both in general and in specific types of model experimentation, appears very favorable. Many alternatives are available which will require only slight further development to become adaptable to such a program.

In matters both of interpretation and of technique, any experimental problems which can be analyzed theoretically with relative completeness will be of great value in bringing difficulties out into the open. For example, the work concerned with the stability of a polar vortex, which will be referred to later, has been particularly illuminating in this direction [23, 42]. In this work, a relatively complete theoretical analysis could be carried out for at least the basic motion and compared directly with the experimental results. By quantitative comparisons, it was found that surface tension forces were making an appreciable dynamical contribution in the phenomenon being studied. Such a contribution, having no counterpart in the major atmospheric problem in view, can be eliminated either experimentally or analytically before drawing conclusions concerning the prototype from the model. It is quite doubtful that this effect would have been noticed if a quantitative theory had not been available. On the other hand, with this experience in mind, it will be easier to make qualitative estimates of the magnitude of such effects in any subsequent experiments of a similar nature.

Experiments on Rotatory Phenomena—Cyclones and Tornadoes

Almost from the beginning of modern meteorological thought, and after the discovery of the existence of barometric storms, attempts have been made to construct experimental models of cyclones. In fact, many of the cyclone theories of the early nineteenth century seem to have drawn their ideas from such experiments and from comparison with tornadoes. These experiments have usually shown a more distinct resemblance to tornadoes than to present-day ideas of cyclones. An early piece of work of this kind, which is in fact very similar to many later experiments, is that of Wilcke [33, 71] in 1780 at Stockholm. In all probability there were many others of the same general nature during the eighteenth century.

In Wilcke's experiments (Fig. 1), a thick steel wire

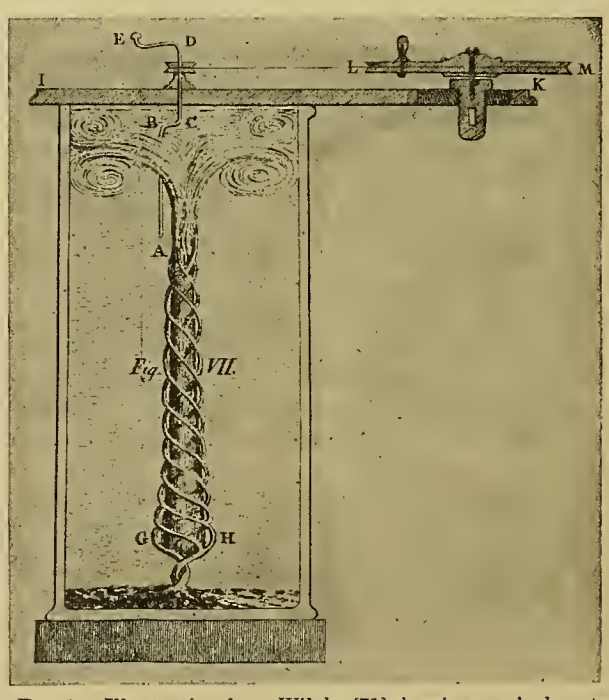

FIG. 1.—Illustration from Wilcke [71] showing a spiral vortex generated in water by mechanical rotation at the top of the cylinder. The cylinder is approximately 14 in. high and 7 in. in diameter. The rates of rotation are not specified but presumably are of the order of a hundred or so revolutions per minute. Wilcke also drove the vortex from the bottom, investigated an alcohol-oil system, and worked with vortices generated by outflow from a hole in the bottom of the cylinder.

a few inches in length was mounted eccentrically and rotated about the central axis of a large cylindrical container. A vortex was generated along the central axis with outflow at the wire end and inflow at the opposite end of the container. The motions were followed by means of burnt lime in the water.

All sorts of modifications of this experiment have since been made. Some investigators have used mechanical means, such as fans or other devices, for generating the vortex in both air and liquids. In this group were Andries [5], Hirn [82], Dechevrens [13], Weyher [45] (Fig. 2), and Dines [15], all in the last two decades of the 19th century, and Hale and Luckey [30], Exner [17], Lunelund [43], and Letzmann [41] (an extensive work on air vortices) since 1900. Others have investigated the vortices produced by mechanical removal of fluid in a field of gentle, initial rotation (the bath-tub drain experiment), for example, Aitken [3, 4] between 1900 and 1918, Letzmann [40] who worked with water in 1927, and also some others of the previous group. Among those who have investigated the vortex motions induced by the "secondary flows" associated with friction, especially where angular accelerations of the entire system are involved, are von Bezold [8] and Belopolsky [6, 7] in the latter part of the nineteenth century and Ahlborn [1] in 1924. The final group are those who have worked with thermally generated motions producing either isolated vortices or more complex fields of rotational motion. This group includes Vettin [67–69] (Fig. 5) and Czermak [12] (Fig. 3) before 1900, and Aitken [3], Exner [17], Sipinen [59], and Terada and Hattori [65], between 1915 and 1926. (Summaries of most of the above-mentioned investigations and other similar ones are given in [11] and [70].)

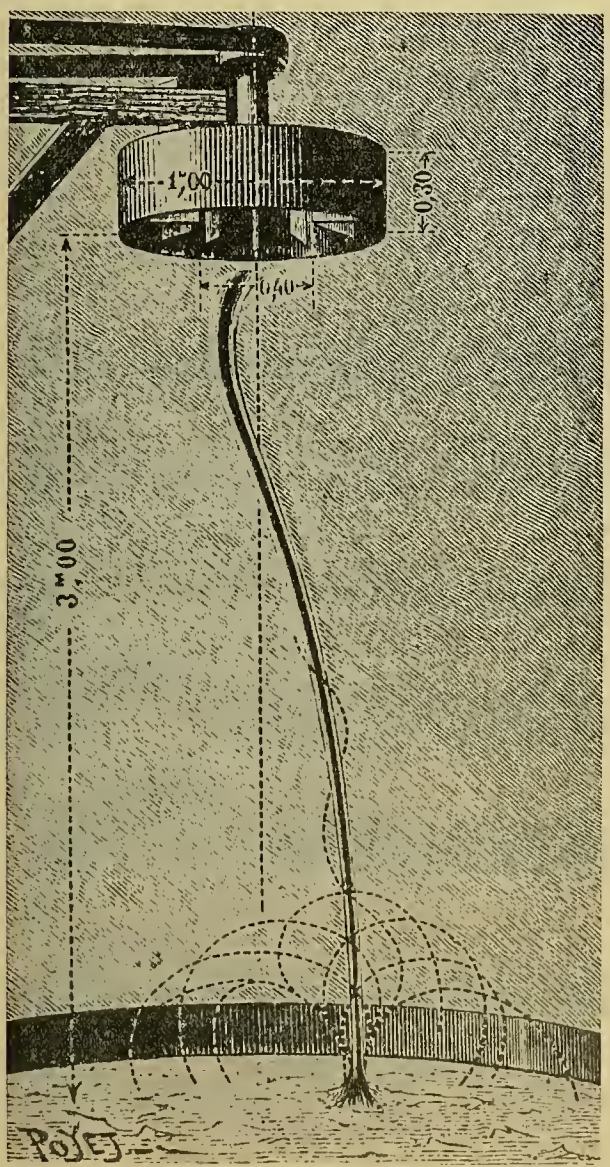

FIG. 2.—Engraving of a tornadolike vortex produced by Weyher in the open above a large basin of water. The fan at the top produces the motion. (*After Mascart* [45].)

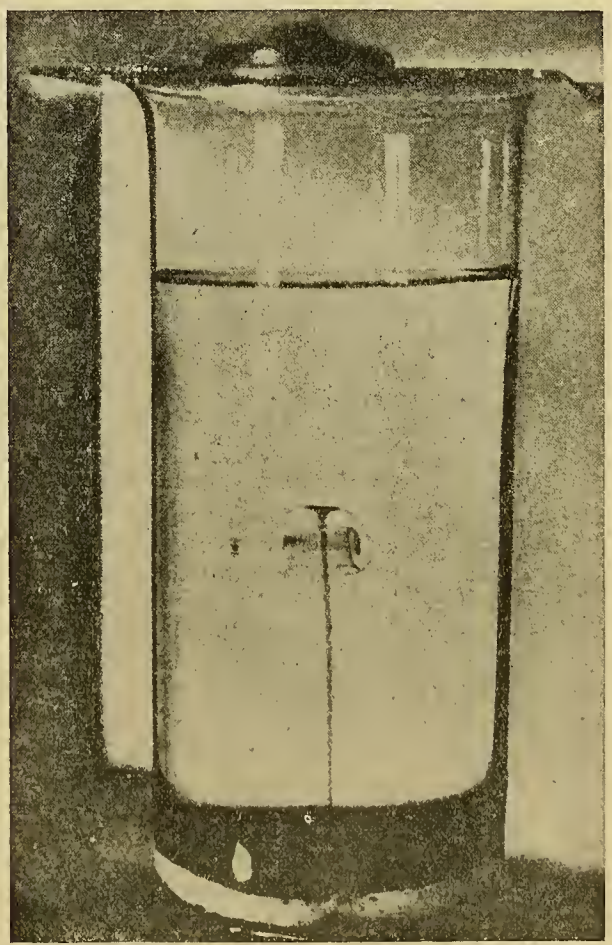

FIG. 3.—Photograph by Czermak of a convective column in a motion similar to those described by Oberbeck [47]. The water in the beaker is gassed-out and allowed to come to complete rest. Heating at the bottom of the beaker is produced electrically by a spiral of fine platinum wire 6 mm in diameter. Note the delicacy of the vortex motion at the cap. Czermak also investigated the effect of stratification on these motions. (*After Czermak* [12].)

It is difficult to sum up the net significance of all this work with respect to the problem of the cyclone or even the tornado. Many curious and beautifully well-defined phenomena are discussed in these studies, but their actual implications for the questions which, in most cases, they were specifically intended to illuminate

are still uncertain. The two atmospheric phenomena to which these studies show the most resemblance are tropical cyclones and tornadoes. Generally speaking, aside from qualitative details, the experiments lead only to conclusions that result also from elementary theory and go back to the seventeenth and eighteenth century beginnings of the discussion. An example of this is the conclusion that necessary conditions for vortices of these types are concentrated regions of ascent or descent (thermally produced or due to the initial field of mechanical motion) combined with initial absolute circulations in fluid circuits enclosing the regions. One fairly general result obtained by experiment, that as far as I know was not anticipated in theory, concerns a general tendency of concentrated vortices to arrange themselves so as to end at a boundary, for example at the earth's surface (Fujiwhara [21], Hale and Luckey [30]). Thus one might generate a horizontal vortex and have it break and arrange itself so as to meet the surface vertically. (See Wegener [70] for tornado developments of this kind, or Fujiwhara for possible synoptic applications.) This result is, of course, probably related to Helmholtz' proposition that a vortex filament cannot have a free end in the interior of a fluid in continuous motion.

However, one gets the impression that, at least with respect to the tornado problem, there is something worth studying in much more detail in some of these experiments. The phenomena in Letzmann's work, or in that of Dines and Weyher in air with water vapor as the tracing element, show almost complete qualitative similarity to actual tornadoes, even to the hollow sheath apparent along the tornado tube in many photographs, or to the swellings traveling along the tube as noted in a few descriptions of the natural phenomenon [70]. It is a curious fact in this connection that hardly anywhere in these investigations, or for that matter in most of those to be mentioned later, has any real attempt been made to make numerical measurements of even the simplest and most obvious field quantities. The principal exception among the investigations mentioned above is that of Lunelund [43], who generated vortices in a liquid with a free surface by rotating a simple shaft below the surface. He then measured the geometry of the free surface on photographs, mainly for comparison with the form to be expected for a Rankine combined vortex ("*vr*" vortex in the outer part and solid rotation in the inner part). Another exception is an investigation carried out by Stümke [62] at Göttingen in 1940 on the anticyclonic motions induced by a slow expansion motion from the center of a rotating pan. The measured quantity, the slope of the free surface, showed good agreement with Stümke's theory of the phenomenon.

Experiments Involving Discontinuities—Cold Fronts and Cyclone Systems

The study of discontinuous fluid motions begun by Helmholtz in the 1850's and illustrated in the demonstrations of Oberbeck [47] in 1877 has had a special importance in meteorology since it culminated in the work of Margules and the polar-front studies by the Norwegians. Here also the climate of opinion on the meteorological side was influenced, though probably not essentially suggested, by a number of experimental investigations. Those of special interest to us fall into two groups: an early one which stemmed from studies of squall lines (*Böen*) and later, explicitly, of the cold front; and the other one, much later (after the idea of cyclone families along the polar front had been constructed by V. and J. Bjerknes), which was concerned with systems of vortices developing along similar discontinuity surfaces.

In the first group we have the cold-front propagation studies with liquids by Schmidt [56, 57, 92] around 1910 and by Ghatage [27] in 1936, the interna' wave studies in 1923 by Defant [14] which included some internal hydraulic jumps, the more recent work on jets by Spilhaus [60], and the demonstration possibilities indicated by Haynes [32] and Dinkelacker [76]. These studies have had some historical significance in the development of ideas on cold-front and squall-line phenomena. For example, the nose of the front (*Böenkopf*) (Fig. 4) as discussed by, say, Koschmieder [38], seems

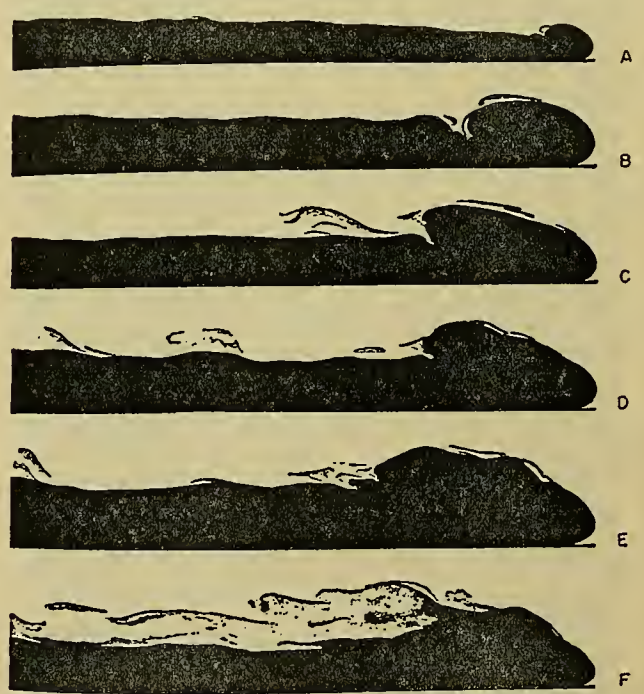

FIG. 4.—Cold-front forms produced by Schmidt in a glass-walled trough 181 cm long, 31 cm high, and 4 cm wide by allowing a salt solution to flow into clear water. The density differences increase toward the bottom of the figure. The pictures were obtained by exposing sensitized paper behind the tank to a magnesium flash. (*After Schmidt* [56].)

to have been suggested primarily by the experimental work. Not very much has actually been done, except by indirect reasoning, to verify observationally the occurrence of this characteristic. (See, however, Weickmann [94].) Similarly the velocity formulas for the front evaluated from the work of Schmidt, Ghatage, and the more recent work of Yih [72] have not been carefully

checked. These all are in qualitative agreement in giving a relatively constant velocity c for a fluid layer of density ρ_1, advancing under its own excess weight through another of density ρ_2. The velocity is given by

$$c = K\sqrt{gh\frac{\rho_1 - \rho_2}{\bar{\rho}}},$$

where h is approximately the height of the nose of the front, and where K has a numerical value from 0.6 to 0.9 for the total depths (two or more times h) used by these experimenters. The fact that the experimental case, during the steady part of the motion, represents a balance between a supply of gravitational energy and frictional dissipation alone, without any influence of tendencies toward Margules-type geostrophic equilibria, suggests that little is to be expected from the result on a large scale. It may, however, be significant in smaller occurrences such as the pseudo-fronts beneath thunderstorms or in very unsteady motions where Coriolis effects have little chance to develop.

The second group of investigations consists of work in air by Sipinen [59] in 1924 and Harwood [31] in 1945. Sipinen's work is particularly interesting because of the use he makes of the very thin, warm, smoky layers which can be put on a smooth surface by puffing cigarette smoke gently over it. Slight currents then induce vortices at the boundaries between clear (cool) and smoky (warm) air layers. Or they can easily be developed and seen via the smoke by slight warming (*e.g.*, by the hand) of a spot on the surface.

Harwood's work, however, is the more significant because it is capable of immediate quantitative extensions. He utilized a wind channel whose base was divided longitudinally into two equal parts. One half was cooled while the other was heated. Titanium tetrachloride smoke served as a tracer in either the cool or the warm layers. In certain ranges of air velocity, channel depths, and rates of heating and cooling, he was able to obtain either stable wave corrugations on the interface or families of vortices with members spaced at regular intervals along the deformed discontinuity surface. Some extensions which would be simple in principle, although perhaps difficult in detail, should make it possible to study wave propagation and instability rates for measured thermal and velocity conditions. Such studies, if sufficiently successful in yielding the required type of measurements, would have very obvious utility in checking and suggesting alterations in the many existing theoretical calculations for such wave properties.

The practical problems are such that the nonrotating case would obviously have to be tackled first. But there is no reason, provided the scale of the apparatus is sufficiently small (Harwood's working section was 1 yd. long by 16 in. wide), why the whole equipment could not be put on a rotating table of the moderate size being constructed at present at the University of Chicago, or certainly in a rotating room on the scale of that at Göttingen [49]. An arrangement, in fact, could be achieved here in which it certainly ought to be possible to investigate systems of light and heavy fluid arranged side by side, similar to those of Margules [44] and Starr [61] which arose from a discussion of the energy transformations in the atmosphere. The principal obstacles preventing a close approximation to Starr's system are the infinite extent, up- and downstream, of his east-west currents, and the assumption of passage through equilibrium states at every stage. The first could probably be obviated to a large extent by arranging the initially adjacent regions of heavy and light fluid along a narrow rectangular container sufficiently long to make the end effects rather small, and the second by using very small density differences (0.001 in specific gravity is quite feasible).

Thermal Convection Studies

In the field of thermal convection two groups of investigations of meteorological interest from our present viewpoint may be recognized. The first includes a number in which rotational effects were not considered in the experimental plan, and the second includes some in which they were incorporated. The latter group will be considered in connection with the general circulation.

The first class includes work by Aitken [2] between 1870 and 1880, by Terada and Hattori [65] in 1926, the investigation by Kobayasi and Sasaki [84] in 1932, and a long series of experiments described in papers by Sandström [53–55] between 1908 and 1919, V. Bjerknes [10] in 1916, Jeffreys [35] in 1925, and Godske [28] in 1936. The experiments considered in this latter series and in the convectional part of Terada's work consisted of various arrangements of heat and cold sources in rectangular containers of water. The important meteorological idea discussed in the Bjerknes-Sandström-Jeffreys controversy was that, on an atmospheric scale, a distribution of heat sources at levels higher than the corresponding cold sources would lead to a much less vigorous atmospheric circulation than the reverse case of, for example, cold sources on high plateaus versus heat sources at the ocean surface. This result was apparently verified by Sandström's experiments which showed much more vigorous and different types of circulations in the latter case than in the former. The theoretical arguments on this point depend on whether one adopts the assumptions of Bjerknes or those of Jeffreys or takes some intermediate position. Experimentally, Sandström obtained velocities which eventually became hardly perceptible when the heat source was above the cold source. However, unpublished work done by J. G. Phillips at the University of Chicago from 1942 to 1944 has shown definite back-and-forth currents in the zone between the hot and cold sources at quite low total temperature differences when the hot source is higher. The experimental conclusion depends on what is taken as the proper similarity criterion in this case (*e.g.*, on the relative importance of various types of horizontal and vertical heat transfer) and on whether Phillips' velocities correspond to small or great velocities in the atmosphere. Offhand one would expect that the relative vertical positions of the predominantly side-by-side thermodynamic sources affecting the atmosphere would not produce great effects, because of

the large horizontal extents involved and the importance of vertical turbulence. The experimental results here need to be extended so that some numerical similarity comparisons can be made.

Experiments on the General Circulation

Historically, the principal investigations which have proceeded with the general circulation problem in mind are those of Vettin [67–69] between 1857 and 1884, Exner [17] in 1923, and Ahlborn [1] in 1924 (see also the work of Rossby [90, 50] in 1926 and 1928). Vettin performed an extremely interesting series of experiments on convectional flows in rotating and nonrotating systems. The most important from our present standpoint utilized a rotating disc of air. In one case he placed ice at the center of the disc (Fig. 5) and obtained relative

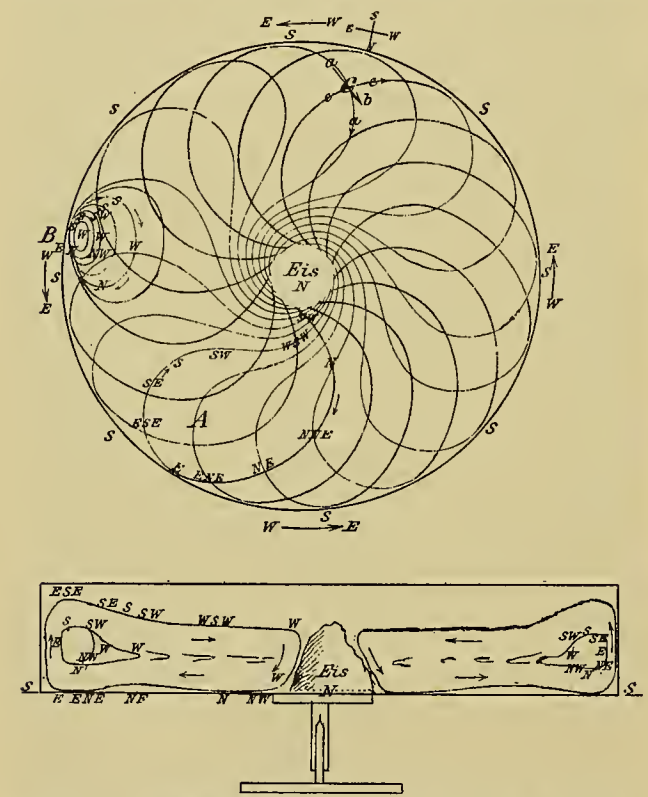

Fig. 5.—Idealized average relative circulation of air in a slowly rotating disc with a cold source at the center. Diameter 1 ft, height 2 in. approximately. The sharp disagreement with results in a disc of water of about the same height-diameter ratio (see Fig. 11) shows that extreme care is necessary in interpreting the mechanisms responsible for such motions. (*After Vettin* [69].)

circulations corresponding with what has become the traditional picture of the trade-wind cell. With the same apparatus, using air again as the medium, he provided a small gas flame arranged so as to heat the same point on the rotating base plate. This generated well-defined vortices within the air, accompanied by average relative circulations.

Vettin had the disadvantage in 1857 of writing before any clearly developed theory of dimensional or model analysis had been formulated. He attempted to draw sweeping meteorological conclusions from his work and was consequently criticised very severely by Dove [16], who was one of the prominent meteorologists of the time. Certain of the experimental phenomena which Vettin attempted to interpret meteorologically were trivially, if at all, related to the atmospheric case, but Dove's criticisms, on the other hand, were oversevere. In fact certain of the ideas which Vettin derived from his experiments, for example, those regarding the steering of storms, are more nearly in accord with the facts than the objections which Dove raised against them.[3]

Exner's experiments [17] nearly three-quarters of a century later were almost identical in one phase with Vettin's except that he used water. (However, Exner included the air vortex study mentioned earlier.) He placed a thin cylinder of ice, dyed with an ink, at the center of the rotating pan of water. The cooled portions of the water were consequently colored and could be seen spreading out along the bottom in tongues, as seen in Fig. 6. Systems of vortices, which Exner stated

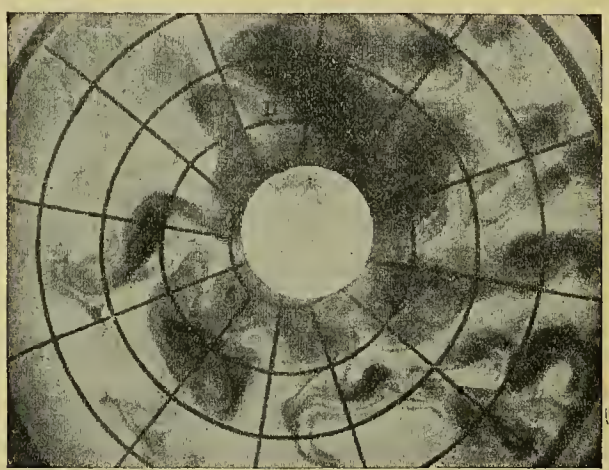

Fig. 6.—Photograph from above of Exner's experiment with tongues of ice water (colored) spreading along the bottom from a center cylinder of ice and developing vortices along their edges. Exner states the circulation in the cold water to be easterly on the average. (Rotation counterclockwise, periods 3–7 sec; diameter of pan 1 m, height of water 4–6 cm; gas flames at edge; camera rotating with pan.) (*After Exner* [17].)

to be not unlike a polar-front cyclone family in appearance, developed along their boundaries. The mean rela-

3. The whole affair ended in a rather curious and interesting way. Vettin did not publish anything further for 27 years—until persuaded to do so, apparently by friends. In a note to the article which Vettin finally wrote in 1884 [69], in the first volume of the *Meteorologische Zeitschrift*, W. Köppen says the following, after mentioning that Dove's "Law of Storms" also appeared in 1857: "Dove, der sich durch äusserst umfassende Literaturstudien und mit Hülfe einer lebhaften Phantasie, aber mit wenig eigenen Beobachtungen, ein scheinbar in sich abgeschlossenes Bild um den grossen Bewegungen der Atmosphäre entworfen hatte, wandte sich gegen den kühnen Eindringling in das von ihm beherrschte Gebiet . . . mit einer Abweisung von schwer verständlicher Heftigkeit . . . Wir dürfen hoffen das die Zeit . . . günstiger . . . ist, und das die Einführung des Experiments in die Meteorologie nicht mehr als Kinderspiel sondern als ein Gegenstand von höchster Bedeutung anerkannt werden wird . . . ."

tive motions were not observed, but should be the same as those of Fig. 5 if Vettin's observations were accurate on this point (see discussion of Fig. 11 below).

Ahlborn's experiment [1] in 1924 consisted principally of rotating a small sphere, 10 cm in diameter, in a cubic container of water. The container was 50 cm on a side. The angular velocity used was about 140 rpm, which is a relatively high speed. The motions observed in the water resembled two ring vortices centered in planes at about twenty degrees of latitude on either side of the equatorial plane. Again the relative motions in these vortices were presumed to resemble trade-wind cells. But since the action is simply that of a centrifugal pump with frictionally induced secondary flow and depends essentially on having fluid brought to rest at the outer boundary by the box, it is quite difficult to see the relevance of this particular physical mechanism in this special form to the atmospheric problem. It is, of course, conceivable that frictional effects might, for different reasons, add up in similar ways.

At this point some work of J. Thomson [66], which was outlined in his Bakerian Lecture to the Royal Society in 1892, may be mentioned. Thomson constructed a semitheoretical picture of the general circulation of the atmosphere in 1857, one of the earliest of the modern series of such attempts. This involved a meridional picture of a trade-wind type of cell extending from equator to pole aloft with a low-level cell in mid-latitudes to give the presumed average poleward drift in the westerlies at the surface. His interpretation of this cell as a secondary flow resulting from friction was somewhat similar to the ideas of Ahlborn but envisaged a more reasonable mechanism. The poleward drift in mid-latitudes he considered to be due to frictional reduction of the speed of the low-level westerlies below that corresponding to balance with the pressure field imposed from above by the very rapid westerlies of the antitrades. This effect he illustrated at the lecture by vigorously stirring the water in a round pan and then observing the inward (poleward) transport at the bottom during the decay of the motion by means of particles slightly heavier than the water. Evidently he was unaware of the work of Vettin, but he suggested a systematic series of experiments with a rotating cylindrical pan, a heat source at the bottom along the outer rim, and a cold source near the center as one means of demonstrating his theory. (This is the experiment illustrated in Fig. 11 except for the lack of a strong cold source at the center.) So far as I have been able to discover, no one acted on Thomson's suggestion until Exner began his work. Apparently Exner was unaware of Thomson's ideas on the subject.

In recent years, results have been obtained at the University of Chicago which tend to indicate that more intensive work of this type is worth carrying out. This work was begun in 1946 by the writer at the suggestion of Professors Rossby and Starr. Theoretical work [51] had suggested that the effects of lateral mixing in a *thin* spherical shell might be predominant in determining the gross character of the mean zonal circulations of a planetary atmosphere. Apparatus was constructed for rotating an inverted hemispherical shell of liquid of relatively small thickness (contained between two concentric glass bowls) and for causing convective interchange of the liquid between pole and equator by means of a heat source at the lower pole.

These experiments have shown conclusively that systematic relative zonal motions do occur in such a situation (Figs. 7 and 8). Moreover, for the particular sets

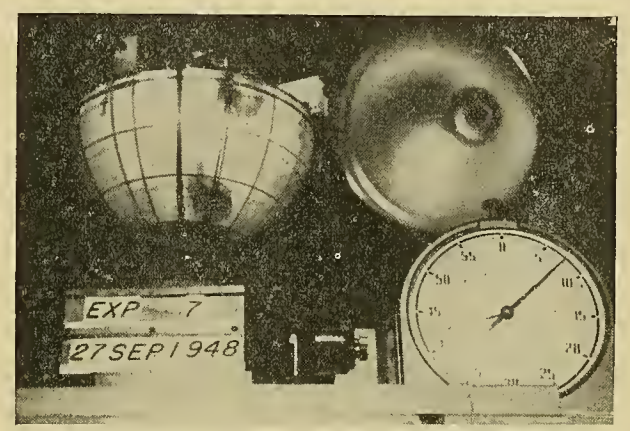

FIG. 7.—Photograph of water in the hemispherical shell apparatus taken shortly after injection of two ink clouds, at approximately latitudes 5° and 50°, from a long hypodermic needle and ink tank fixed to the glass shell. An electric heating element is located at the pole. (Rate of rotation is 8.18 rpm, heating at 20 v, mean radius of shell 10 cm, thickness of space containing water 1.6 cm, rotation is from right to left as seen.) (*After Fultz* [22].)

of conditions so far investigated, if these relative motions are represented nondimensionally as ratios of relative speed u to the absolute speed C_E of a point

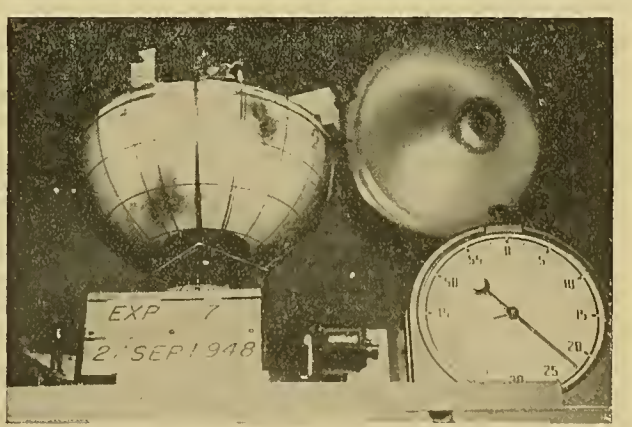

FIG. 8.—Photograph taken 14.6 sec after Fig. 7. For 10° latitude u/C_E is close to +0.016, while for 50° latitude it is close to −0.036 (*cf.* Fig. 7). (*After Fultz* [22].)

fixed on the equator of the bowls, they have values ranging up to 0.15.[4] This is just the order of magnitude of such ratios in the earth's atmosphere where C_E is about 1000 mph. Also, as shown in Fig. 9, even the

4. This ratio $u/C_E = u/r\Omega$ is apparently an even more important similarity parameter than is indicated by its kinematic significance as a velocity ratio. In the form $\Omega u/r\Omega^2$ it is a ratio of a characteristic Coriolis force to a characteristic centrifugal force (except for the unimportant numerical factor). In the form $(u^2/r)(1/\Omega u)$ it is a ratio of a characteristic rela-

latitudinal distribution of the zonal motion, under some heating conditions, shows considerable resemblance to atmospheric zonal wind profiles at moderately high levels. This and other resemblances mentioned in the original paper [22] suggest that a study of the mechanics of these systems in as great quantitative detail as possible will have real significance in suggesting working principles which would be applicable to the earth's atmosphere. The opportunity will then exist to establish areas in the conditions of the experiment that give the closest resemblances to planetary cases. More or less data for comparison exist at least for atmospheric layers on the earth, the sun, Mars, and Jupiter. With the controllability conferred by the experiment, one can then compare these areas with conditions which do not give similarity and have some hope of separating out the way in which the essential factors are operating. For example, it would be of the greatest interest, if it should turn out to be possible to generate such motions, to compare conditions required for producing motions divided sharply into zones, like those of Jupiter, with the conditions mentioned above that give motions resembling to some extent those of the earth's atmosphere.

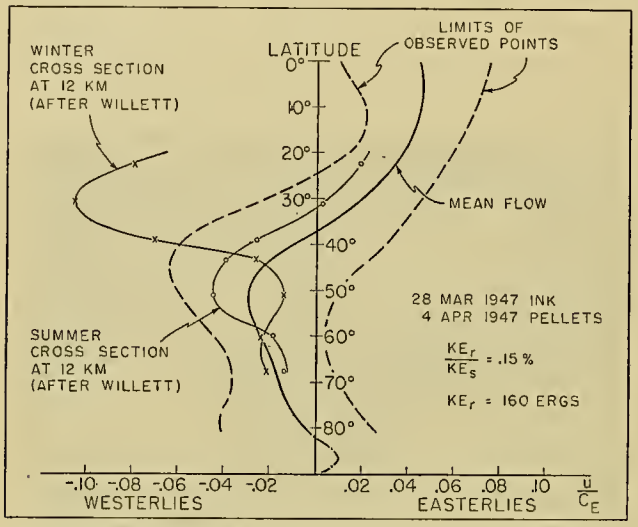

FIG. 9.—Mean estimated curve of u/C_E in the hemispherical shell of Figs. 7 and 8 for 16.27 rpm and 30 v indicated heating compared with the mean zonal winds for winter and summer at 12 km along a cross section (from Willett; see [22]) running from Havana to Aklavik, N. W. T. (*After Fultz* [22].)

In many respects the possibility of making measurements in an experiment is restricted by purely instrumental or observational difficulties. Any practicable experimental size is so small, for instance, that measurements of any velocity field to a density comparable with meteorological synoptic measurements is possible only by indirect means. In this case the utilization of the double refraction property of certain viscous fluids in deformation flow is one of the most promising possibilities [22]. Other devices which we have found to be of such great utility as to allow measurements to be made which would otherwise be almost impossible to secure include such an instrument as the "rotoscope" shown in Fig. 10. This instrument is modeled on one used by D. Thoma [19, 23] for observing the relative flow in centrifugal pumps. Provided observation is carried out on a line of sight coinciding with the axis of rotation of an object, the image of the object can be reduced to apparent rest by rotating the Dove reversing prism in the rotoscope at the proper rate. Effectively, therefore, observations can be carried out in a relative coordinate system rotating at any desired rate. The advantages of such a system are difficult to appreciate without one's having had experience with attempts to make reasonably precise measurements on a rotating object, but these advantages have been demonstrated again and again in some of our more recent investigations. These experiments have concerned a mechanically driven vortex in a two-fluid layer occupying the hemispherical shell in a slightly modified version of the original apparatus. A large amount of data on wave velocities and various types of instability points in this system has been collected very rapidly by this means. Such data could hardly have been obtained so well in any other way.[5]

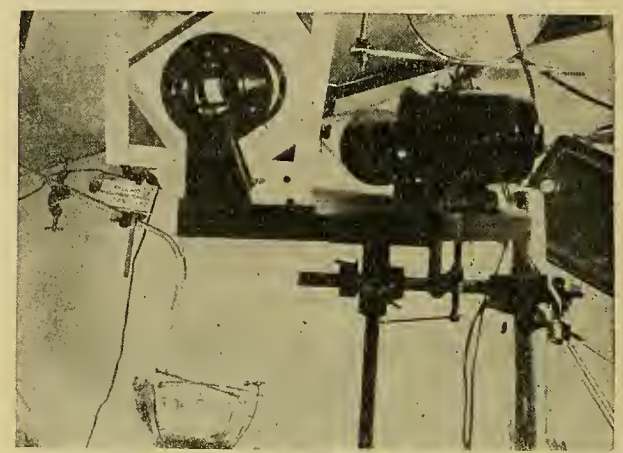

FIG. 10.—General view of rotoscope setup for observing the rotating hemispherical shell apparatus. The hemisphere is at the bottom and is viewed in a first-surface mirror (partly concealed by the rotoscope) so as to obtain a convenient direction for the line of sight. Part of the image of the hemisphere can be seen in the Dove reversing prism which is rotated in its barrel by the variable speed motor at right.

Suggestions for Future Research

The impression one receives in reviewing this long series of experimental work is that to make it really

tive inertia force to a characteristic Coriolis force. In addition, as pointed out to me by R. R. Long, it is a factor in a ratio of characteristic fluid velocity to the velocity of Rossby long waves relative to the basic current. The remaining factor in this ratio depends on geometrical quantities only. It would thus appear that this parameter measures the approach of a given system of currents to several properties peculiar to large-scale meteorological motions. For example, as $u^2/r(\Omega u)$, it indicates the degree of approximation to quasi-geostrophic motions.

5. The problem in this investigation was suggested by Rossby's pole-flight result for anticyclones [52]. At the present time it seems almost certain that an exactly analogous phenomenon has been demonstrated in the experiments. The results will be presented at length elsewhere [23, 42].

fruitful there must be a *systematic and sustained effort, guided by theory, to obtain numerical measurements of as great a variety as is practically possible.* The rather sterile, though often remarkably interesting, results of the large majority of these investigations can probably be traced to the qualitative character of the observations more than to any other factor. Another basic difficulty with applications of these experiments to the atmosphere has been the lack of simple, theoretical, guiding principles which take into account the thinness of the atmosphere. Experiments need to be designed around principles, even if only semi-quantitatively. In the experiments at the University of Chicago, for example, various applications of the vorticity theorem due to Rossby (*e.g.*, [51]) have provided the theoretical suggestions for much of the experimental work. It is not going to be easy, nor even possible in some cases, to measure adequately the field quantities which may appear to be most immediately required in comparing possible theoretical explanations. Nevertheless, certain types of measurements are quite possible. As experimental work progresses, techniques and altered concepts of the quantities to be measured should develop to a far higher point than is the case at present.

In connection with general circulation problems, the following experimental steps appear to me to be the next ones to take.

1. The simple types of techniques used in hydraulic or aerodynamic experiments (or in the studies cited above) to measure velocity and temperature should be extended to the cylindrical discs studied by Vettin, Thomson, and Exner. Several modifications would be necessary and height-diameter ratios should be investigated to as low values as are possible.[6] Besides the general possibility of investigating the motions near a pole for thin shells, there are indications that evidence could be obtained bearing on a comment by Jeffreys [36] that a reversed distribution of thermodynamic sources might reverse the sense of the average relative zonal motions of the atmosphere as functions of latitude (see also below). Preliminary observations on a rotating dishpan apparatus constructed by F. Hall for a similar type of study indicated that with a Bunsen burner under the center (instead of a cold source there) the more rapid outward radial currents show relative westerlies instead of easterlies as should be the case to correspond with Vettin's result. The particular equipment is subject to vibration so that some reservations must be entered, but very recent (March, 1950) rotoscope observations and photographs with the dishpan (radius 7 in.) filled with water to a depth of from $2\frac{1}{2}$ to 3 in. and heated at the outer rim show some extremely striking patterns. Figure 11 shows an aluminum-powder

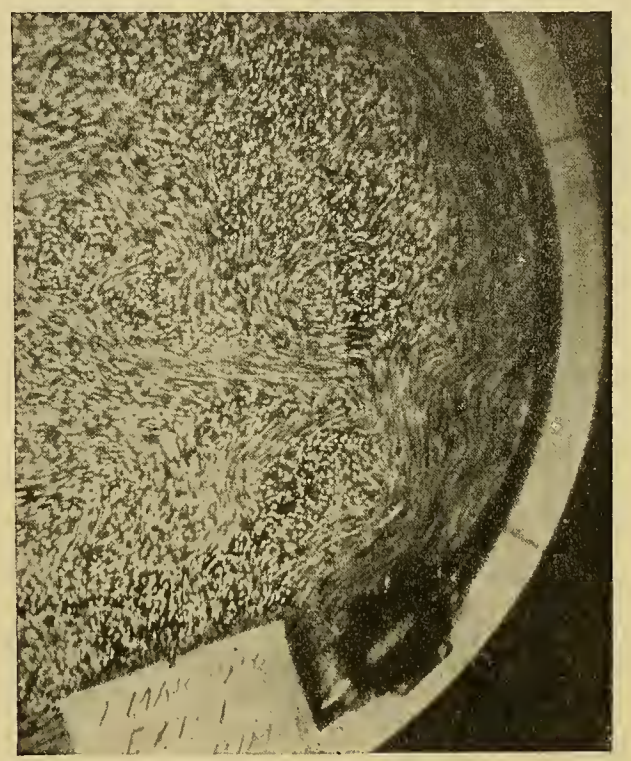

FIG. 11.—Aluminum-powder streak photograph of the relative circulation at the top surface of water in a pan rotating clockwise (12 rpm), which is being heated at the bottom near the rim. The narrow current near the rim is westerly (*i.e.*, moving more rapidly than the pan) while that near the middle is predominantly easterly. The second current radially in from the counter, for example, is almost certainly easterly, on the basis of visual observations. (Photograph 8 min after heating began, exposure $\frac{1}{2}$ sec, westerly current $u/C_E = -0.05$; at 12 min after heating began, temperature at top center was 30.7C, at bottom rim 31.9C taken with a mercury thermometer.)

streak photograph taken through the rotoscope with an exposure of $\frac{1}{2}$ sec so as to show the motions relative to the pan. The narrow band of motion near the rim (moving clockwise) is a *westerly* current with u/C_E values running to about -0.06 or more, when the angular velocity of the pan is 12 rpm. The rest of the top surface is occupied by a number of eddies of various sizes which, for example, give average values of $+0.02$ for u/C_E at a distance of $0.6r_0$ from the center (r_0 is the rim radius). In this condition the water temperature away from the pan surface is hotter at the rim than at the center by 1–2C. The burner was also moved in to $0.5r_0$. The average temperature gradient in the water is then reversed with the temperature at the pole perhaps $\frac{1}{2}$C warmer than at the rim because of the rapid heat conduction in the metal of the pan. The relative

6. It has recently come to my attention that in 1902 C. A. Bjerknes carried out experiments with a rotating cylinder of water (12 cm high, 36 cm wide, 7 rpm) to verify qualitatively Ekman's theory of the surface drift current in the ocean. A jet of air 10 cm broad was blown along a diameter relative to the rotating cylinder. Measurements of the currents with floating balls and a sensitive directional vane showed the proper deflection to the right (Northern Hemisphere rotation) at the surface and increasing rightward deflection in the top centimeter where the Ekman spiral would be expected. This suggests the possibility of studying wind-driven currents in oceanic basins of suitable shapes on an experimental basis, so long as variations of the Coriolis parameter are not important, and of utilizing paraboloidal shapes where such variation is important. (See Ekman, V. W., "On the Influence of the Earth's Rotation on Ocean Currents." *Ark. Mat. Astr. Fys.*, Vol. 2, No. 11, pp. 51–52 (1905) and also [85] and [86].)

velocity distribution, on the other hand, is not strongly altered. The westerly current at the rim is weaker and narrower and the easterly current, at say $0.7r_0$, is stronger and better defined with u/C_E as much as $+0.04$ or more. In this case, narrow, strong, easterly currents are set up *inward* toward the center as observed earlier by F. Hall. One of the important differences between this and Vettin's experiment is the high conductivity of the pan (his base plate was of glass). This leads to static instability over the entire bottom that is of course relatively stronger near the burner position. Thus, ink observations suggest that systematic vertical motions, if present at all, are very vaguely defined and that the rising motions are rather irregularly distributed over the pan from a Bénard-like hot layer at the very bottom. At any rate, considerable additional doubt (see also below) is thrown on any simple reasoning of the usual textbook variety concerning the effects of simple heat-source distributions and the conservation of angular momentum in the general circulation. Such reasoning certainly ought to apply to a simple disc if anywhere, but it is very hard to conceive of an axially symmetrical circulation which would account for both the westerlies and the easterlies at the top surface in this experiment without introducing various epicycles that have no obvious relation to the heat sources.

Figure 12 illustrates another striking effect which was accidentally observed in the rotating pan. This effect is a result of the rotational property stated by Taylor [63, 64] (see also a more recent discussion by Görtler [29]) that slow relative motions in a fluid initially rotating as a solid should tend to be two-dimensional in planes perpendicular to the axis of rotation. In Fig. 12, ink is seen a minute or so after being poured into the rotating pan in a quite arbitrary manner. The mass of ink, instead of spreading out in the usual eddying fashion, rapidly forms vertical walls and the cylindrical surfaces gradually wind around one another, retaining their parallelism to the axis.[7] They diffuse much more slowly than in a nonrotating pan. Such an effect of rotation would obviously be of the greatest importance in diffusion or convection problems in establishing preferred directions with radically different coefficients of transfer. In the apparatus the effect is still strongly present when the rotational instability parameter $g/a\Omega^2$ is as high as 140 (6 rpm) and is even evident to a lesser extent when heating is going on with a metal bottom (*e.g.*, whole vertical streamers of ink transfer laterally without tilting much). The rotational *stability* is obviously much higher and the hydrostatic stability probably much less in this case than for the earth. However, certain other preliminary experiments with the same dishpan apparatus show that this effect has some very important implications from a meteorological standpoint. The bottom of the rotating dishpan was insulated with a layer of plaster and heating carried out as before at the rim [25]. The top surface then shows a wide meandering band of strong westerlies (u/C_E of order 0.1) with rather larger vortices than before. Toward the small central area the average motion is uncertain but is at least very weak westerly or perhaps easterly. If the Taylor ink columns are produced before heating is started and then allowed to remain, they *retain* their cylindrical character while moving with the thermally induced currents. In other words, the motions appear to remain quasi-barotropic and are certainly in addition quasi-geostrophic. On the other hand, the temperature field shows strong static stability and is strongly baroclinic with a dome of cold water occupying the center bottom. The rim-center temperature differences run to the order of 5C. Tentatively then, one can conclude that it is quite possible to have a strongly baroclinic and reasonable pole-equator temperature distribution in this experiment and yet also have quasi-barotropic currents and disturbances.[8]

FIG. 12.—Ink initially of slightly greater density, a couple of minutes after being poured into a pan of water in solid rotation at 15 rpm. Note the vertical walls. As in Taylor [63] the walls remain vertical for many minutes and gradually draw out into surfaces which are sharply divided by clear areas when viewed end-on. The same effect is very marked to at least as low as 5 rpm and occurs under the heating conditions of Fig. 11 when the pan bottom is insulated by a layer of plaster.

7. One is reminded of the Margules-Helmholtz slope condition for a discontinuity surface of wind which reduces to parallelism to the earth's axis when the density difference is zero.

8. There are a number of observational difficulties concerning the representativeness of the top surface motions and other matters that make it necessary to regard any detailed

2. The work of Fultz [22] should be extended to spherical shells incorporating variable depth-radius ratios which Rossby's theory would imply to be important. The data from these experiments need to include much more complete temperature values and also more extensive velocity observations. By use of the rotoscope and appropriate mirror or lens systems it will be possible to obtain velocity values much more easily and accurately. With enough data to be statistically significant, it will be possible to calculate such properties of the motion as the horizontal Reynolds' stresses (momentum transfers). The data taken in 1947 have been found insufficient to give reliable estimates of such secondary quantities.

3. A most important companion set of experiments to these spherical shell studies needs to be carried out in paraboloidal shells rotated at rates such that the free surface figure coincides with that of the paraboloid.[9] All the previous types of work should be carried out here. An even better check on the Jeffreys comment above would be obtained by comparing a cold-pole–warm-rim setup with a warm-pole–cold-rim. With a moderately deep layer it should be possible to compare the efficacy of heat sources at high altitudes and cold sources at low altitudes with the opposite case in a way that would have relatively conclusive application to the controversy mentioned earlier.

There is one caution here that a rough calculation brings up. If we consider the thermal expansion of water (or most other practicable liquids) and ordinarily available temperature gradients, it appears that the thermally developed horizontal pressure-gradient forces are likely to be of a very small order relative to gravity. If these forces are not to be masked by inaccuracies of figure (which would give rise to components of the external action along the surface), the paraboloid may need to have a slope at each radius accurate to 10^{-3} parts or better. Corresponding requirements would subsist for the constancy of angular velocity of the basic rotation. Such accuracy will be very difficult to obtain practically. There may be means of handling the situation without proceeding to this degree of precision, but some experience and trial and error will be needed to work them out.

4. Shearing waves and instability at density discontinuity surfaces in general deserve extensive investigation, in both the rotating and nonrotating cases with various geometrical forms (see, for example, Keulegan [37]). Here the problem of obtaining velocity measurements of the required density and accuracy for meteorological application is very serious. But, at least in the case of liquids, modifications of the standard aerodynamic aluminum-powder techniques using sparser distributions (or possibly liquid bubble tracers) with rapid-sequence flash photography should be valuable.

In all of the cases mentioned above there are many obvious extensions such as (*a*) varying the contour and roughness of the underlying surfaces, for example. mountain barriers or other forced depth changes, (*b*) studying the motions of thermally induced currents around obstacles of various shapes or moving the obstacles themselves through the fluid with and without concomitant convective motions (see [26] and [24]), and (*c*) studying the effect of a varying horizontal conductivity of the underlying surface on convective motions, for example, ocean versus land differences of this kind.

Concerning smaller-scale problems it appears that important work could be done on vortices (tornadoes and hurricanes) by careful measurements of field quantities around one or the other of the experimental cases. Probably the simplest would be one of the steady mechanically driven air vortices such as Weyher's. Velocities could be obtained by a series of probes with a microsized Pitot tube or hot-wire anemometer. The vexing problem of just how much weight to attach to all the reasoning concerning "*vr*" vortices and momentum conservation in these circumstances should receive some elucidation. Projected experiments of other types have been referred to earlier.

There exist at least two fields in which the possibilities of significant experimentation seem very large and which, from the meteorological angle, are just opening up at the present time. One of these is the field of hydraulic and supersonic gas flow analogies, opened for meteorology by Freeman [20]. Current work by Rossby indicates that there may exist even larger-scale analogies to the hydraulic jump than those considered by Freeman and later workers. Quite aside from the desirability of modifying the extensive experiments which have been carried out in this field so as to lay special stress on the meteorologically important quantities, there is every prospect that significant amounts of rotation can be introduced experimentally. For example, a small version of the complete table described by Matthews [46] could rather easily be arranged so as to be rotatable. Similar open-channel work with subcritical flow has in fact already been done in the rotating room at Göttingen by Fette [18].

The second field is one in which hardly anything of meteorological significance has yet been done experimentally, but in which many possibilities must exist. This area is that of electromagnetic analogies. Such analogies have quite often been used in potential flow problems where a direct electrical analogy in conducting fluids is very easy to apply in practical problems for which the boundaries are complicated [39, p. 65].

An extensive discussion of another sort of identity between electromagnetic and hydrodynamic systems (with experimental illustrations) has been given by V. Bjerknes [9]. Another has been interestingly pointed out and used by Ising [34]. In this paper, advantage is taken of the fact that there is complete identity in form between the equations for an incompressible fluid in the usual meteorological relative coordinate system rotating at a constant angular velocity and those for a corresponding system of electric currents in a uniform

conclusions concerning these experiments as quite provisional. They will be discussed as comprehensively as possible in an early publication on this aspect of our work.

9. This was first brought to my attention in this connection by the group at the University of California at Los Angeles.

magnetic field. For example, there is a phenomenon of "hydraulic induction" exactly corresponding to electromagnetic induction, in which fluid currents develop in any closed circuit whose orientation changes in such a way as to change the flux of the earth's rotation vector through the circuit.[10] Ising was able to demonstrate this effect experimentally in an apparatus exactly corresponding to a single-turn electric generator.

One type of experiment suggested by the analogy would be to place a disc of fluid in a uniform magnetic field whose direction is perpendicular to the plane of the disc. The fluid would then be electrically charged and convection currents generated in it by appropriate heat sources or by other means. The Coriolis forces would be replaced by electromagnetic forces on the moving fluid, and the experiment would have the advantage over rotating disc experiments of not involving a centrifugal force. A numerical check on this experiment was carried out by S. L. Hess who found that the charges, electric potentials, and magnetic fields required to produce mechanically significant forces from such slow motions are so large as to make the experiment thoroughly impractical. Nevertheless, there are many other possibilities, and it is altogether likely that useful ones will eventually be developed.

MODEL TECHNIQUES IN METEOROLOGICAL RESEARCH

By HUNTER ROUSE

Iowa Institute of Hydraulic Research, State University of Iowa

Introduction

Scale-model investigations of fluid motion have long since proved their worth in such widely varied fields as aeronautics, ballistics, hydraulics, and naval architecture. New aircraft, projectiles, turbines, spillways, and ships are almost invariably tested at reduced scale before final acceptance of design, and prototype behavior is being predicted with ever-increasing accuracy. Particularly in the field of flood control and river regulation, economies of construction or improvements in design which model studies generally reveal have offset the costs of the studies many times over. It is therefore hardly surprising that meteorologists frequently wonder whether model techniques would not be useful in meteorological research as well.

Wind-tunnel studies of meteorological phenomena have, in fact, already been described in the literature on at least a dozen occasions, a card file of such papers being maintained by the U. S. Weather Bureau. During World War II, moreover, a considerable number of model investigations were made of particular atmospheric occurrences, although many of the results have not yet been published. Each project of this nature was undertaken for the specific reasons behind all laboratory research at small scale: on the one hand, the essential variables can be controlled at will; on the other hand, small-scale experimentation generally reduces to an extreme degree the time and expense involved. It is true, of course, that few large-scale occurrences can be reproduced to perfection in a laboratory model, while some—such as those of the atmosphere as a whole—are so complex that their duplication in miniature would be utterly impossible. Nevertheless, many flow phenomena become subject to analysis only when reduced to their bare essentials, and hence even a very rough approximation of actual conditions is often fully justified.

If model studies are to provide useful prototype indications, the following steps are generally necessary in addition to the actual tests. First of all, a preliminary analysis of the problem should be made, based upon dimensional considerations and such physical principles as are readily applicable, so that the subsequent experiments may be efficiently conducted. Secondly, the experiments should be planned to make optimum use of available equipment and instruments, or suitable apparatus must be devised. Finally, the results of the experiments should be reduced to their most general form for utilization at prototype scale. In the following pages each of these aspects of model technique is discussed in detail with particular application to meteorological research, and typical problems already investigated by such means are described.

Similitude Requirements

A very powerful tool of laboratory research is the procedure known as dimensional analysis [3]. Frequently maligned by some because of its limitations and frequently misused by others who do not recognize its limitations, the method is actually of great worth as a systematic guide and check in planning new experimental studies. Based upon the physical requirement of dimensional homogeneity in any functional relationship, such analysis permits the variables involved to be reduced in number, generalized in form, and brought into an arrangement suitable for experimental investigation.

The Π-theorem [4] of dimensional analysis states that if the n variables involved in a function require m dimensional categories for their expression, then the function can be rewritten in terms of $n - m$ dimensionless groups of these variables. Moreover, this theorem provides a systematic algebraic procedure whereby any series of variables involved in a phenomenon, regardless of their number or the number of the dimensional categories, may be reduced to a significant dimensionless form. Here it is sufficient to say that any problem of geometry alone will thus be expressible in terms of ratios of lengths, and that model and prototype boundaries and flow patterns will be geometrically similar if all corresponding length ratios have the same numerical value in both cases. Likewise, a problem of kinematics will be expressible in terms of ratios of lengths and times —or combinations thereof, such as velocities—and hence model and prototype occurrences will also be kinematically similar if all corresponding kinematic ratios are identical. Finally (at least so far as phenomena of mechanics are concerned), a problem of dynamics will be expressible in terms of ratios of quantities involving length, time, and either force or mass; accordingly, model and prototype occurrences will be dynamically similar as well if all corresponding dynamic ratios are the same in both.

The various quantities required to describe any phenomenon of fluid mechanics include a series of lengths a, b, c, . . . descriptive of the boundary geometry; a series of flow characteristics such as velocity V and differential pressure Δp; and a series of fluid properties —the density ρ, the differential specific weight $\Delta\gamma$, the dynamic viscosity μ, and the bulk modulus of elasticity e. Although many different dimensionless arrangements of these variables may be obtained by the Π-theorem, the following is most significant for conditions of similarity [14]:

$$\frac{V}{\sqrt{2\Delta p/\rho}} = \varphi\left(\frac{b}{a}, \frac{c}{a}, \cdots \frac{V}{\sqrt{a\Delta\gamma/\rho}}, \frac{Va}{\mu/\rho}, \frac{V}{\sqrt{e/\rho}}\right).$$

The first term is a dependent parameter sometimes known as the Euler number $\mathbf{E} = V/\sqrt{2\Delta p/\rho}$, consisting primarily of the flow characteristics. The next two (or more) are length ratios. The last three are groups involving the fluid properties, known respectively as the Froude number $\mathbf{F} = V/\sqrt{a\Delta\gamma/\rho}$ (gravity), the Reynolds number $\mathbf{R} = \rho Va/\mu$ (viscosity), and the Mach number $\mathbf{M} = V/\sqrt{e/\rho}$ (compressibility). Evidently, even though the actual form of the function is unknown, the dependent parameter will be the same at model and prototype scale if the corresponding independent parameters have the same numerical values—in other words, the model and the prototype flows will then (but only then) be mechanically similar.

Since all problems in mechanics are expressible in terms of three-dimensional categories, the Π-theorem will be seen to reduce by three the number of terms in the function, each of the dimensionless parameters differing from the others by one variable only. It is thus possible in such problems to distribute the various fluid properties singly (except for the density) among the three independent parameters **F**, **R**, and **M**. A problem which combines mechanics and thermodynamics, on the contrary, requires one more dimensional category—temperature—for its expression, as well as such additional flow-variables as temperature rise and heat flux, and such fluid variables as thermal capacity and conductivity [20]. The functional relationships—and hence the similitude requirements—obviously become far more complex under these conditions. Finally, if electrical phenomena are also involved—as is conceivable in certain meteorological problems—any possibility of complete similitude is removed from practical consideration.

In view of the great difficulty of reproducing large-scale phenomena in accurate detail at a convenient model scale, recourse must generally be had to various laboratory expedients. Some occurrences, of course, are relatively simple in their basic aspects, and hence may be simulated—and even investigated functionally—with relative ease. Typical of these is the matter of the velocity distribution in turbulent flow near very rough boundaries without regard to gravitational, viscous, or thermal effects. In many phenomena, however, the secondary effects can be ignored only as a first approximation, and then must be restored to consideration by analytical or experimental means. Conditions illustrative of this situation are encountered in ship testing, in which the model hull is towed at such a rate as to produce similarity of the gravity-wave pattern only, that portion of the resistance due to viscous action being evaluated from supplementary tests on thin plates [9]. Likewise, in some problems of heat transfer the temperature differences are too small to influence the flow pattern appreciably—or at the worst can be assumed to cause gravitational effects but not the more complex thermodynamic effects. However, many phases of fluid motion are completely impossible to simulate in even approximate detail, and efforts must be directed toward reproduction of the over-all occurrence regardless of the discrepancies in minor effects. River models with movable beds [6] are outstanding examples of willful distortion of slope, roughness, and vertical and horizontal proportions to achieve this end; the model channels are exaggerated in depth to maintain turbulent flow, and the proper time and discharge scales for over-all similarity are then determined in preliminary tests through reproduction of known past occurrences before the desired future occurrences are investigated.

Laboratory Methods of Prototype Simulation

Since air is the fluid medium involved in nearly all meteorological phenomena, the familiar wind tunnel of aeronautical research [19] is the type of pertinent equipment which first suggests itself. Such equipment has, in fact, already been used, without modification, for the study of flow over particular boundary configurations. The fact remains, however, that aeronautical wind-tunnels are designed for specific purposes which are generally quite different from those of research in meteorology. Whereas aeronautical studies require high speeds, test sections only long enough to accommodate model planes, and dynamometers capable of measuring complex force systems, meteorological needs usually involve high capacities rather than speeds, test sections which can be adapted to a wide variety of boundary forms, and means of measuring the characteristics of the flow pattern rather than the forces exerted. In fact, various meteorological studies have been made in an open hall without any tunnel whatever, the air flow being produced by means of a series of blowers directed as desired.

Although a technique such as that last cited is often satisfactory for qualitative studies, the fact remains that the air stream in quantitative investigations must generally be uniform and of moderately low turbulence, a condition which cannot be achieved by unconfined jets from blowers except in their immediate vicinity. It is therefore preferable to house the model in a uniform duct with a properly formed bell inlet, and to draw the air through this duct by means of an exhaust fan or fans at the downstream end. Because of the large capacities rather than speeds (and hence the small pressure changes) which are involved, such ducts may be erected quite cheaply for the particular project in question, and then readily modified for the next problem to be studied. The cost of a closed circuit on a large scale is generally prohibitive, and only smaller tunnels need be made recirculating. However, complete enclosure of the duct in a large hall is desirable in order to eliminate the effect of atmospheric disturbances upon the inflow, provided the hall is of sufficient size to permit stilling of the exhaust from the blowers before the air re-enters the inlet. On the other hand, tunnel systems utilizing smoke, gas, or heated air sometimes draw directly from and discharge into the out-of-doors; such tunnels require a relatively large stilling room just upstream from the test section to eliminate the variable effect of winds. While blowers may be obtained commercially for a wide variety of flow conditions, because of the small pressure changes involved in such studies the use of surplus airplane propellers driven at relatively

low speed often provides a cheap solution for temporary installations. Although the air speed should be controllable over as wide a range as possible, peak speeds greater than 100 ft sec^{-1} are seldom necessary—a matter of considerable practical importance, since power requirements vary with only the first power of the capacity but with the cube of the speed.

Just as problems of liquid flow are sometimes studied with gas as the fluid medium in order to utilize particular measuring equipment, some phases of gaseous movement may be investigated more conveniently with liquids. This is particularly true in the observation of low-velocity convection currents in which the variation of the specific gravity of the atmosphere due to thermal effects is simulated in water either thermally or through admixture of ordinary salt. The use of different dyes to indicate the various specific gravities is far simpler than the use of smoke in air, and the greater density of water makes the measurement of low velocities more feasible. Under such circumstances the glass-walled channel of the hydraulics laboratory can become a useful observational tool in meteorological research.

Aside from such specific apparatus, perhaps the most important requisite for the meteorological model laboratory is available space in which temporary equipment of any desired nature may be constructed. Head room as well as floor area is essential, together with the possibility of erecting light walls wherever desired to eliminate extraneous currents. The frequent requests for space in university field houses for such projects during the war are indicative of research needs; a small airplane hanger would be ideal for a laboratory of this nature.

As for the specific instruments involved in model studies of atmospheric movement [10, Vol. I; 11], probably the most essential is a series of anemometers of various types for the measurement of velocity. These range from indicators of spatial mean flow of the air stream itself, through point indicators of temporal mean flow varying spatially in both magnitude and direction, to point indicators of turbulent fluctuations. If the air speeds are above some 10 ft sec^{-1}, the ordinary Pitot tube in connection with a sensitive differential gage of the Wahlen type is useful in making either point indications of mean velocity or velocity traverses for integration to yield the spatial mean. Directional Pitot tubes are also available. Duct or tunnel systems producing a pronounced acceleration of the flow into the test section permit the mean air speed to be indicated in terms of the accompanying pressure change by means of boundary piezometers at suitable points. Vaned anemometers with either counter or direct electrical indication are also useful in large passages, and midget anemometers of this nature have been made for either small-scale or low-velocity conditions. The only satisfactory instrument yet devised for the measurement of velocity fluctuations as well as mean values is the hot-wire anemometer [17], which requires for its proper operation a mean air speed in excess of about 5 ft sec^{-1} and essentially constant temperature of the ambient fluid. The hot-wire technique has progressed to the point that not only the intensity but also the scale of the turbulence and the intensity of the resulting shear can be measured. The mixing characteristics of the turbulence may also be determined by the diffusion of heat or gas from a point or line source. Such other flow characteristics as the variation of pressure and temperature require the use of standard piezometers and thermocouples, respectively.

Quite as important as the actual measurement of the model flow characteristics is the visual or photographic observation of the flow pattern [10, Vol. I; 12]. Because of the normal transparency of either air or water, it is necessary to observe the alignment of short threads or the motion of opaque material suspended in the flow, such material being so finely divided or of a specific gravity so nearly equal to that of the fluid that its motion will be essentially the same. The use of dye filaments, aluminum powder, or oil droplets is common in water. Very fine powders are sometimes used in air, but either an oil fog or a chemical smoke such as that from titanium tetrachloride is more generally satisfactory. In all cases a dark background with top lighting slightly to the rear is desirable. In both media the change in refractive index with a local change in density is sometimes utilized, rear lighting from a point source such as a carbon arc being required.

In addition to permitting visual observation or photographic recording of flow patterns, the foregoing methods are also directly useful in the preparation of motion-picture sequences for instructional purposes. Since many phenomena of atmospheric motion which are not subject to quantitative study in the laboratory can still be simulated qualitatively with relative ease, graphic training films in which the essential characteristics of these phenomena are emphasized may readily be prepared. One such film, assembled during the war by the Iowa Institute of Hydraulic Research for the Chemical Warfare Service, showed at model scale in a low-velocity air tunnel the diffusion of smoke and gas by wind under various conditions of thermal stratification, boundary roughness, forestation, and urban development. Another, prepared by the Hydrodynamics Laboratory of the California Institute of Technology, simulated by gravity currents in water the characteristics of a gas attack on a valley stronghold.

Typical Laboratory Investigations

One of the earliest scale-model investigations of atmospheric phenomena is the study by Abe [1] of wind structure over Fujiyama. According to the general criteria for similitude discussed in an earlier section, it would appear that the Reynolds number should have the same magnitude for the model and prototype flows if viscous similarity is to prevail. Abe reasoned, however, that the analogy between molecular motion on a very small scale and eddy motion on a very large scale permitted similarity to be obtained by using the molecular viscosity (a fluid property) in the model Reynolds number and the estimated eddy viscosity (a flow characteristic) in the prototype Reynolds number. As a result, his model air speeds resulted in flows which were nearly, if not wholly, in the viscous range.

Modern boundary-layer theory indicates that even the qualitative indications which Abe obtained cannot be considered trustworthy, since the separation pattern for a particular boundary configuration varies markedly with the usual Reynolds number [10, Vol. II]. In other words, as the quantity VL/ν changes from a very small to a very large magnitude, at least four distinct types of flow may be recognized, as follows: (1) at extremely low values the viscous boundary layer extends a great distance from the boundary, and the low-velocity flow near the boundary is quite stable; (2) at somewhat higher values the zone of viscous action decreases in thickness and stable eddies develop behind the major irregularities; (3) at moderate values the boundary layer becomes thin but remains laminar, separation eddies forming more irregularly and passing off into the flow; (4) at high values the boundary layer becomes turbulent and the tendency toward eddy formation is restricted to the more angular portions of the boundary. The relative Reynolds-number ranges of these several types of flow depend to a considerable degree upon the form of the boundary configuration; no general values can therefore be given, but for rough indications reference may be made to standard diagrams of surface and form resistance for simple plates and bodies of revolution [15].

While the complete simulation of flow over gently undular terrain cannot be accomplished at model scale because of the extremely high velocities which would be required to maintain constancy of the Reynolds number, it so happens that flow past angular boundary configurations at all but very small scales and air speeds is essentially independent of viscous effects. In other words, at moderate to high Reynolds numbers the separation pattern for such "unstreamlined" forms is determined almost solely by their geometry. Therefore, with geometric similarity of the boundary the normal air speed of a wind tunnel is sufficiently high for similitude to be obtained. Typical of such an investigation is the study at model scale of air currents in the vicinity of the Rock of Gibraltar [8], the laboratory indications being in close agreement with observations made at the actual site.

If the terrain is not sufficiently irregular to ensure freedom from viscous effects, one is tempted to distort the vertical scale of the model until the necessary degree of angularity is secured. The success of such a procedure depends largely upon the degree of similitude to be obtained, since the theory of both the potential flow around a body and the viscous effects upon the basic pattern point to a gradual departure from similarity as the boundary geometry is distorted. It is altogether probable that the gain in freedom from viscous effects is wholly offset by the changes in pattern which this distortion produces. In other words, as the terrain in question becomes less irregular, true similitude can be approached in the model only by increasing the velocity of flow accordingly. The obvious limit of such increase is the onset of marked compressibility effects as the Mach number of the model approaches unity.

In addition to the mean flow pattern and the pattern of the major eddies, which formed the basis of the Gibraltar study, the accompanying pattern of turbulence is often of importance. As in all turbulence studies, at least three characteristics of the turbulence may be involved: (1) the intensity, or root-mean-square velocity of fluctuation; (2) the scale, or mean eddy size; (3) the diffusivity, or eddy viscosity, which is proportional to the product of the intensity and the scale. For flow over relatively smooth boundaries, the development of the turbulent boundary layer is primarily a function of the Reynolds number, and model similarity would hence require approximately the same magnitude of the Reynolds number as in the prototype. While this is practically out of the question, enough is now known about the mechanics of the boundary layer to permit evaluation of prototype conditions by analytical rather than experimental means [5]. With uneven boundaries, however, particularly those which involve large-scale irregularities rather than small-scale roughness, not only is the boundary-layer theory incomplete but specific problems are more readily subject to model investigation. Fortunately, although true atmospheric turbulence contains eddies varying over an extremely wide range of intensity and scale, it is usually the larger magnitudes of each which are of major interest and are at the same time most nearly reproducible by models.

Laboratory investigations of the turbulent diffusion of heat, gas, and water vapor in the neighborhood of smooth boundaries have frequently been made—but as general studies of the mechanics of such diffusion rather than as specific model studies of particular prototype conditions. In connection with the previously mentioned training film on chemical warfare, on the other hand, evaluation of diffusion characteristics for various rough-boundary configurations studied at the Iowa Institute required the detailed measurement either of the turbulence characteristics or of the actual diffusion of some material introduced into the flow. Typical of such evaluation, for example, was the experimental determination of the diffusion of gas or smoke from point

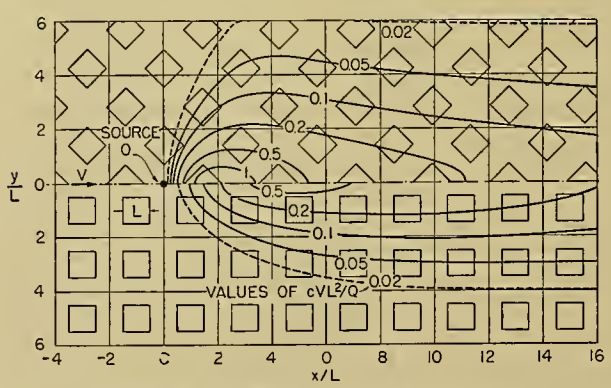

FIG. 1.—Generalized diffusion patterns at height L for two different block arrangements.

and line sources in typical urban districts. Owing to the pronounced angularity of the model buildings, the pattern of turbulence (or at least the large-scale portion

thereof) was essentially independent of the Reynolds number. Measurements of gas concentration c could therefore be reduced to generalized nondimensional contours of relative concentration cVL^2/Q, in which Q is the rate of gas release, V the mean air speed, and L a characteristic building dimension, as shown schematically in Fig. 1. Similar techniques are evidently applicable to studies of smoke abatement, the dispersion of radioactive by-products, or—at least qualitatively—the mixing of moisture-laden air in mountainous terrain.

Two somewhat allied phenomena of the atmosphere are impossible to reproduce quantitatively to scale in the laboratory, yet they involve complexities which are so great that even the qualitative laboratory simulation of their primary characteristics is often useful. One of these is the effect of the earth's rotation, and the other the effect of thermal stratification. Since the accelerative forces due to rotation of the flow system as a whole cannot well be included in a general model, it is usually necessary [13] to reproduce the effect in a rotating tank at very small scale, as is described elsewhere in this volume,[1] or—as is sometimes done—in a small rotating room. At such scale, of course, viscous action plays a role which is wholly out of proportion to that of any prototype condition, and the indications must be interpreted in the light of the mechanics of viscous flow. Although studies of this nature generally involve thermal (or density) stratification of the fluid [7], other stratification phenomena warrant detailed study in their own right. These, in fact, are of interest to a number of professions (oceanography, harbor hydraulics, and sedimentation), and have often been reproduced in the laboratory [2].

For purposes of convenience, studies of this nature are usually conducted in water, the density stratification being obtained by means of saline solutions of various concentrations. This technique has permitted the study of (1) wave motion at and mixing across a density interface, (2) the progress of sediment underflow (comparable to a dust cloud or even a cold front) through a reservoir, and even (3) the effect of a schematic mountain range upon successively higher thermal zones of the atmosphere. Under certain conditions, to be sure, viscosity plays a role which is quite out of keeping with prototype conditions, and thermal effects other than that of the density differential cannot be reproduced. However, so long as the interrelationship between gravitational action and mass reaction is the primary factor involved, model studies of this nature can be expected to yield useful indications if not reasonably accurate numerical results. Noteworthy is the fact that the relative motion of wind and water represents simply an extreme degree of stratified flow, moderately small-scale investigations of wind-driven waves having yielded useful indications of the forces involved [18].

Previous mention of turbulence has been restricted to that resulting from the surface resistance or form resistance of the flow boundary. The diffusion resulting from such turbulence is known as forced convection. Related in mechanism but distinct in origin is that type of turbulent mixing resulting from an unstable density-stratification of a fluid, the result being known as free convection. Typical of free convection is the pattern of mean flow and eddy motion produced by a boundary source of heat below an otherwise quiet fluid. The heated fluid becomes less dense than its surroundings and tends to rise, and at the same time inflow toward the rising column of eddies is induced through displacement and entrainment. Although other thermodynamic effects are involved in both the original heating and the subsequent mixing and cooling, except under extreme conditions these remain secondary to the effects of gravitational acceleration and turbulent diffusion. In other words, the essential aspects of the free convection could be reproduced in water by the introduction of heat or finely dispersed bubbles at a lower boundary or by the removal of heat or introduction of sediment at an upper boundary. In view of the complexities involved in giving proper consideration to an additional dimension and to the corresponding flow and fluid variables, it is therefore expedient as a first approximation to disregard the thermodynamic effects in such investigations and reduce the problem to one of mechanical (*i.e.*, dynamic) similarity alone.

Up to the present, laboratory studies of this nature have been restricted to the analysis of free convection under generalized conditions. There is no obvious reason, however, why similar techniques could not be applied to specific prototype conditions of boundary configuration and wind orientation; under any circumstances, existing data obtained at small scale should be applicable at least approximately to general prototype conditions. Results now at hand apply to convection from a point source and from a line source in stagnant fluid and from a line source in a uniform wind [16]. In each case the convection was attained in air by means of heat (either low gas flames or electric hotplates), the measurements of temperature differentials being reduced to specific-weight differentials by the simple ideal-gas equation. With reference to the defini-

tion sketch of Fig. 2 for the point source, measurements of temperature and velocity made by Yih at the Iowa Institute over a considerable range of distance and heat output could thus be generalized in the composite dimensionless plots shown in Fig. 3. Noteworthy is the

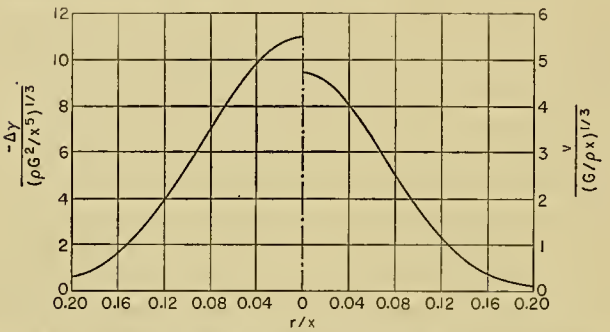

FIG. 3.—Dimensionless representation of experimental results for the conditions of Fig. 2.

fact that for any particular value of r/x a number of the Froude type—$F = v/\sqrt{x\Delta\gamma/\rho}$—is constant, indicating that the phenomenon is truly gravitational in its fundamental aspects.

Summary and Conclusions

Through the many professions dealing with fluid motion, there has been obtained a considerable amount of experience with scale-model investigations, which should be of use in developing comparable procedures for research in the field of meteorology. The general principles of dimensional analysis at once indicate the criteria for similarity of the various pertinent flow phenomena, and at the same time serve as a guide for effective research. Likewise, the closely related aspects of many problems in fluid motion make various techniques developed in other fields directly applicable to that in question. In other words, the scale model is now an established rather than an untried scientific tool, and the problem is one of adaptation to somewhat new requirements rather than of complete origination.

Nevertheless, too great emphasis cannot be given to the fact that each of the professions now utilizing model techniques has perfected them only through many years of painstaking labor. Dimensional analysis is an invaluable guide but in no sense an automatic control, and its proper use continues to depend upon sound experience both in selecting the essential variables and in reducing to a practicable form the complex relationship which usually results. Moreover, the extent to which special requirements of each particular field govern the experimental techniques can be thoroughly understood only through actual laboratory contact. The fact therefore remains that the foregoing presentation by one who is only indirectly familiar with the problems of this specific field can be but a rough indication of the situation which should exist after a number of years of direct accomplishment by future specialists.

At present writing it appears that meteorologists could profitably expand, according to their own requirements, many aspects of model investigations already proven useful in related fields. These include studies of both the mean flow pattern and the eddy structure produced by irregular boundary configurations; research in the diffusion of heat and vapor by both forced and free convection; experiments on stratified flows; and—at least in an exploratory manner—the simulation of conditions which combine two or more such effects. To what extent attainment of the Reynolds criterion of viscous similitude may become possible for other boundary conditions, and whether or not thermodynamic similarity may also become practicable, must be decided in the future. In any event, the profession can rest assured that the perfection of meteorological model techniques will open many an avenue of fruitful study hardly conceivable in advance.

EXPERIMENTAL CLOUD FORMATION

By SIR DAVID BRUNT

Imperial College of Science and Technology

Historical Note

The motions which occur in unstable layers of fluid in which there is no general motion of the fluid have been described independently by a number of writers. The "cellular" convection which occurs in unstable fluids has been associated with the name of Professor Henri Bénard, on account of the thorough study which he made of the phenomena which he described in detail [1]. The present writer gave the name of "Bénard cell" to the typical convection cell which occurs in unstable layers initially at rest [3]. Bénard's observations were anticipated about twenty years earlier by James Thomson [17] (the brother of Lord Kelvin), who observed a "tessellated structure" in cooling soapy water in a tub casually seen in the yard of an inn. Thomson later reproduced the phenomenon in the laboratory. Weber [18] also observed a structure, similar to that described by Thomson, in a layer of alcohol and water on the slide of a microscope, but Weber gave a wrong interpretation of his observations. A correct interpretation was given later by Lehmann in *Molekularphysik*, Vol. I, p. 279. Many other subsequent writings by various authors followed the accidental discovery of convection in a cellular form, but only the earliest discoverers need be mentioned at this stage. Further brief accounts of independent discoveries of the same phenomena in a variety of liquids will be found in *Nature* (April and May, 1914).

In Fig. 1 are shown the lines of flow in a central vertical section of the typical Bénard convection cell. When the fluid has a large shearing motion, the axis of convection is replaced by a vertical plane of convection, and the fluid is divided into a series of parallel rolls, rotating in opposite directions, and Fig. 1 now

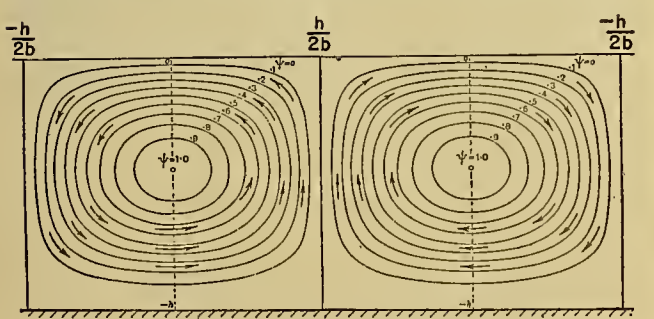

Fig. 1.—Circulation in the Bénard convection cell.

gives the general features of the circulation, transverse to the axis of shear, for a pair of adjacent rolls.

The first detailed investigation of the effects of shear was made by Terada [16], who carried out a series of investigations with a variety of liquids in which the rate of flow increased with height, but without change of direction. Terada's paper contains a number of striking photographs of these longitudinal (downwind) rolls, and the author draws attention to the opposite sense of rotation of adjacent rolls, stating that the rolls have a circular cross section.

Phillips and Walker [13] showed, by experiments in air, that rolls transverse to the direction of shear can be formed when the shear is small, and Graham [8], a pupil of Walker, later confirmed this result.

The Nature of the Simple Convection Cell

When instability in a fluid initially at rest breaks down, the fluid is seen to become divided into a number of polygonal cells. In a liquid, the motion normally consists of ascent in the centre of the cell, outward motion at the top, downward motion at the outer margin, and inward motion at the bottom of the cell.

The simplest illustration of such motion is obtained by pouring *cheap* gold paint into a small vessel to a depth of, say, a quarter of an inch. In cheap gold paint the liquid medium is usually benzene or some other highly volatile liquid, while the "gold" is in the form of thin flakes. The evaporation of the liquid leads to such rapid cooling at the top of the layer that marked instability is immediately produced. As the thin flakes tend to set themselves parallel to the motion, they are

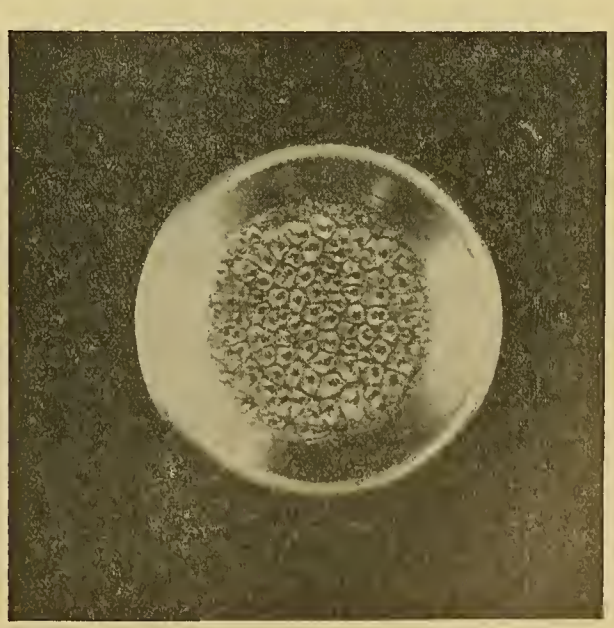

Fig. 2.—Convection cells formed in gold paint.

not visible at the centre or periphery of the cell, where they are seen edgewise from above. The cell will thus appear to have clear liquid at the centre and at the

outer boundary, as is shown in Fig. 2. Similar motions are produced in molten wax and in molten metals cooled from above, just as in any liquid cooled from above. Thus Bénard's discovery of convection cells was made, during experiments with liquid coherers containing metallic particles, in early experiments on wireless reception.

The clearly defined convection cells shown in Fig. 2 do not form immediately. When the volatile liquid is poured into a dish the liquid at first appears to be violently disturbed, showing no recognisable pattern. If the liquid is exposed to a light current of air, or if, even in still air, it is left uncovered, the violently disturbed state continues for a long time. When the vessel containing the volatile liquid is covered by a sheet of glass placed above the surface, but not in contact with the edges of the vessel, the free evaporation of the liquid is checked, and the cells as shown in Fig. 2 are quickly formed and retain their general form for an almost indefinite period.

Similarly, in the experiments on polygonal convection cells in air, described below, there is an initial stage in which the air is divided into polygonal cells of four, five, or six sides. These cells are unsteady, and eventually settle down to a fairly steady pattern with five or six sides.

The Theoretical Discussions of Lord Rayleigh and Others

Lord Rayleigh [14] was led to examine the physical conditions leading to the formation of the convection cell by seeing Bénard's description of his experiments, in some of which the cells were all truly hexagonal. Rayleigh started from the hypothesis that the velocities, and the departures of pressure and temperature from their initial values, were all of the form $e^{i\alpha x}\, e^{i\beta y}\, e^{i\gamma z}\, e^{ct}$, and that the motion with the highest increment would rapidly predominate over all others. He found a new criterion, showing that no motion will occur in a "statically" unstable liquid, unless

$$\frac{\rho_1 - \rho_0}{\bar{\rho}} > \frac{27\pi^4 \kappa \nu}{4gh^3},$$

where ρ_1, ρ_0, and $\bar{\rho}$ are the densities at the top and bottom of the layer and the mean density within the fluid, respectively; κ is the coefficient of thermometric conductivity; ν the kinematic coefficient of viscosity; and h the depth of the layer.

Thus for any given depth of layer there is a finite value of the difference of density at top and bottom of the layer which must be exceeded before motion can occur. Moreover, the shallower the layer, the greater is the difference of density required to produce motion, while for a given difference of density there is a lower limit to the depth in which motion can occur. This last feature is readily displayed in any suitable liquid. If, for example, a cheap gold paint is used as a medium, and the containing vessel is tilted so that at one side the depth decreases to zero, the diameter of the cells will be greatest at the deeper edge and will decrease with decreasing depth, but only to a finite size, beyond which there will be a shallow layer showing no cellular motion.

Bénard [2] showed that Rayleigh's theory gave, for a circular cell, the value of 3.285 for the ratio of diameter of cell to depth of fluid. Bénard's own experiments on spermaceti gave values of 3.27 to 3.34 for this ratio.

Rayleigh treated the case when the fluid is limited by two free surfaces. Two other cases require consideration, that of two rigid boundaries, and that of one free surface, the other surface being a rigid boundary. The constant A in the criterion

$$\frac{\rho_1 - \rho_0}{\bar{\rho}} > \frac{A\kappa\nu}{gh^3}$$

has been evaluated for different cases by Jeffreys [9] and more recently by Pellew and Southwell [12]. The latter writers give the following values of A:

	A
1. Two free surfaces	657.5
2. Two rigid boundaries	1708
3. One free, one rigid surface	1101

Rayleigh gave for case (1) the same value of A, equal to $\frac{27\pi^4}{4}$ or 657.5. Jeffreys [9] gave 1709.5 for case (2). The detailed methods of computation used by these authors differed somewhat, and so the values given above may be accepted as reasonably accurate.

The theoretical treatment by all the above-mentioned authors is based on the assumption that the components of velocity are sufficiently small to justify the neglect of their squares or products. This is a limitation which may lead to some uncertainties in the comparison of theory and experiment. Rayleigh further points out that in his treatment of the problem it is tacitly assumed that $(\rho_1 - \rho_0)/\bar{\rho}$ is small. If, then, the depth of the unstable fluid is small, the critical value of $(\rho_1 - \rho_0)/\bar{\rho}$ as defined by $\frac{A\kappa\nu}{gh^3}$ becomes large, and the interpretation of the criterion as stated by Rayleigh is open to doubt. When the fluid is a gas and the instability is produced by heating the gas from below, it becomes impossible to satisfy the criterion for small depths of the unstable layer, and polygonal cells of convection will not then occur.

We have therefore to embark upon the consideration of small-scale laboratory experiments bearing in mind that the theory of Rayleigh and of others is not likely to include all phenomena that may occur.

Motion in Unstable Layers of Air Having No General Motion

A convenient apparatus for studying the motions in unstable air can readily be constructed, having as base a smooth metal plate, fitting on top of a shallow box containing a series of parallel glass rods on which a thin wire is wound. The base plate is heated by the passage of an electric current through the wire. The top of the chamber consists of a plane sheet of glass which forms the base of a vessel that can be filled with water to a sufficient depth to act as a check

against any great rise of temperature at the top of the chamber. In a series of experiments carried out by Chandra [4] at the Imperial College of Science and Technology, South Kensington, London, a chamber so constructed was used, and the top of the chamber was supported on a series of brass cylinders, sets of such cylinders being made of lengths from 2 to 16 mm. The sides of the chamber were filled in by layers of felt, sufficient to prevent a rapid leakage of air into or out of the chamber.

In Chandra's experiments the temperature of the air was measured by means of platinum resistance thermometers, fixed as near as possible to the top and bottom plates respectively, while a third was fixed halfway between the plates. Observations of the temperature distribution within the chamber could thus be made at any time. The motion within the chamber was made visible by means of cigarette smoke, which was injected by means of a two-way pump. The motion could be watched and photographed through the top plate.

As might be inferred from Rayleigh's formula, no motion was observed until the excess of temperature at the base over that at the top exceeded a finite limit. Thus, with a chamber of depth 10 mm, the critical temperature difference was 11.4C. Observations were made with depths from 2 to 16 mm.

Figure 3 shows the structure found in a chamber of depth 8 mm, with a temperature difference of 28C

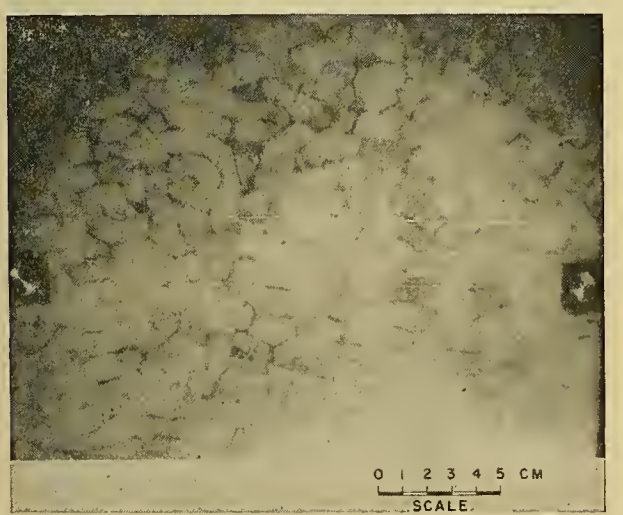

Fig. 3.—Convection pattern in a chamber of depth 8 mm; temperature difference between top and bottom of chamber, 28C.

between top and bottom of the chamber. This shows a series of polygonal cells, in each of which the motion was downward at the centre, upward at the outer margin, and inward at the top. In addition, there are some long rolls which fill the chamber when the smoke is first injected, and which gradually break up into separate polygonal cells. This feature was particularly noticeable in all chamber depths of 8 mm or more, but eventually the long rolls were replaced by polygonal cells.

Figure 4 shows the structure found in a chamber of depth 7 mm, the whole chamber being filled with polygonal cells almost instantaneously after the injection of the cigarette smoke. The rapidity with which the initial long rolls or strips of smoke would break up into the cellular pattern in a chamber of depth 7 mm was very striking. In Fig. 4 the diagonal of the hexagonal polygons was approximately three times the depth of the chamber, while in Fig. 3 the diagonals of the polygons were usually little greater than twice the depth, as the steady state had not been attained.

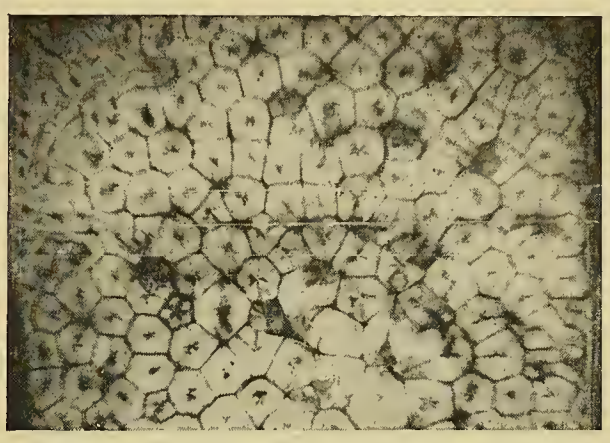

Fig. 4.—Convection pattern in a chamber of depth 7 mm.

With a chamber of depth 6 mm or less, polygons could not be formed with any vertical distribution of temperature. The change in the nature of the phenomena in going from 7 mm to 6 mm is best illustrated by Fig. 5, in which the base plate of the chamber was

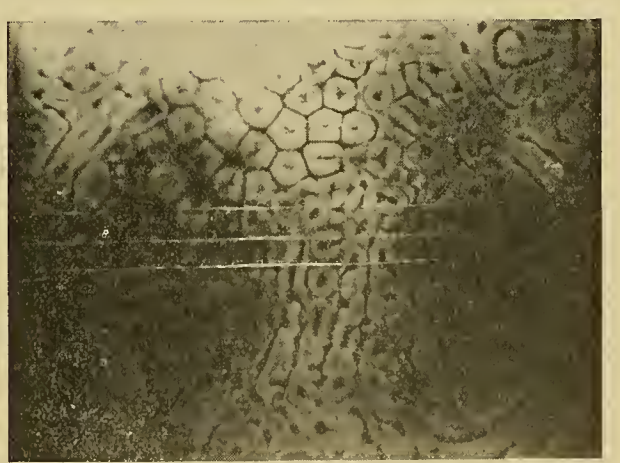

Fig. 5.—Convection pattern in a chamber of depth 6 mm. Where polygonal cells appear, a dent in the base plate yielded a depth of 7 mm.

dented downwards over the area covered by polygonal cells in the diagram. Over this area the depth of the chamber was about 7 mm, and above the remainder of the plate the depth was 6 mm, when the photograph was taken. When the smoke is first injected into the chamber it forms long rolls such as still appear in the photograph at one side. Each roll has a central white

line at first, but after a short time the pattern changes to a series of almost circular cells, each having a well-marked, clear centre. No motion is readily detected, but by the injection of small puffs of smoke through a capillary tube with its open end placed at the centre of the clear space, and in contact with the base plate, it was easily possible to detect ascent at the centre of these cells.

A structure similar to that found in layers of air of depth 6 mm was also obtained in deeper layers at very high temperatures. The reason for this is readily seen from a consideration of Rayleigh's criterion quoted above. If the difference of density, *i.e.*, of temperature, required to produce cellular motion is to be attained by heating the base of the chamber, it is clear that when there is a large difference of temperature between the top and bottom of the chamber, the mean temperature of the chamber will also be raised considerably. This leads to a rapid increase in the product $\kappa\nu$, and in shallow chambers it will be impossible to satisfy Rayleigh's criterion for motion.

The curious structure shown over the greater part of Fig. 5 can be formed with quite small differences of temperature in shallow chambers, differences which are much lower than are required by Rayleigh's criterion.

A simple expedient made it possible to test the view stated above. A chamber was constructed with a glass base and a metal top around which was fixed a narrow flange, so that liquid air could be poured into the vessel so formed. The evaporation of the liquid air cooled the top of the chamber, and gave polygonal cells readily in chambers of any depth. These could be easily seen from below, though the condensation produced inside the chamber quickly frosted the glass and shut off any view of the inside of the chamber.

A final experiment in the production of the simple convection cells merits mention. A depth of 12 mm was given to the chamber, and it was found possible to lay a dense but very shallow layer of smoke over the base plate. Almost immediately after the layer was formed a series of round holes were punched in the layer of smoke by the descent of colder air from above, giving a series of circular clear patches over the plate. Within a few seconds, convection patterns began to show within the chamber, placed centrally over the holes in the smoke carpet. This circulation carried small streamers of smoke upward and inward towards the centre, as shown in Fig. 6, and here and there it is possible to detect the streamers of smoke which have not yet reached the centre. After some minutes the whole chamber became filled with convection cells such as are normally obtained when smoke is injected into the chamber.

In the laboratory experiments described above, the convection cell has both centre and periphery clear of smoke. This is presumably to be explained by the formation of a "dust-free" space in immediate contact with the heated base plate. The air which fills the centre and periphery of the cells has been drawn from this dust-free space immediately above the base plate.

It should be emphasised that two types of motion are found in the course of these experiments. In the first type, the genuine Bénard convectional cell of polygonal form, the motion is downward in the centre.

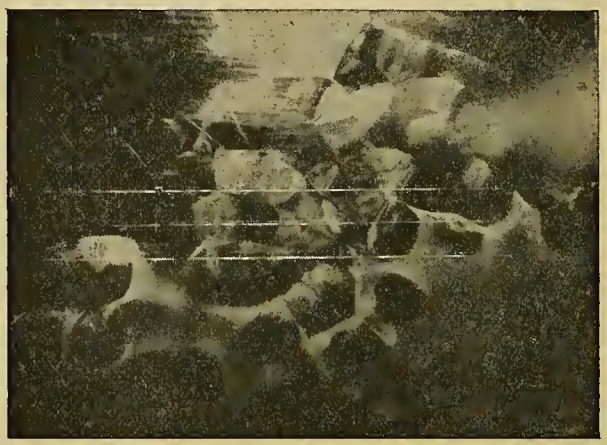

FIG. 6.—Dense layer of smoke over base plate in a chamber of depth 12 mm, showing clear holes formed in this smoke layer, and subsequent development of convection cells above the holes.

In the second type, shown in Fig. 5, alongside the typical polygonal cells over a restricted area, there is some difficulty in determining the nature of the motion by simply watching it with the naked eye, though it was found by injecting small quantities of smoke that there was ascent in the centre of the roughly circular structures. The motion in these cases will be referred to as "convection of the second type."

The results derived by Chandra are summarised in Fig. 7. The continuous line separating the two

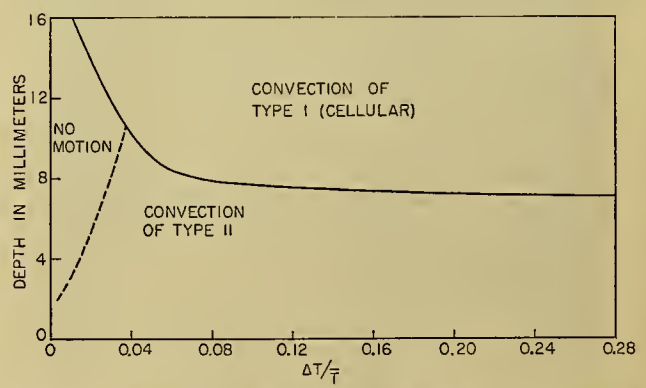

FIG. 7.—A summary of Chandra's observations of limiting conditions in air (*cf.* Fig. 12).

types of convection becomes asymptotic to a horizontal line a short distance below the 7-mm level, indicating that only the second type of convection can be obtained in chambers of depth appreciably less than 7 mm.

Motion in Unstable Layers Having a Shearing Motion.

Depth of Chamber 7 mm or Greater. A modification of the apparatus previously described was used to investigate the effect of shear on the form of the cir-

culations produced in unstable layers. In this modification the top of the chamber was a long glass plate, which could be moved across at any desired rate, being driven by a small electric motor. The top plate produces a shear, analogous to a wind varying with height.

It was found that unless the excess of temperature at the base over that at the top was above the limiting value found in the investigation with the top at rest, no structure was observable in the smoke, no matter what the rate of shear. In all the experiments with shear, care was therefore taken to ensure that the vertical gradient of temperature exceeded the limit appropriate to the depth of chamber.

In the first experiments made in these conditions, the shear was given a high value. Figure 8 represents

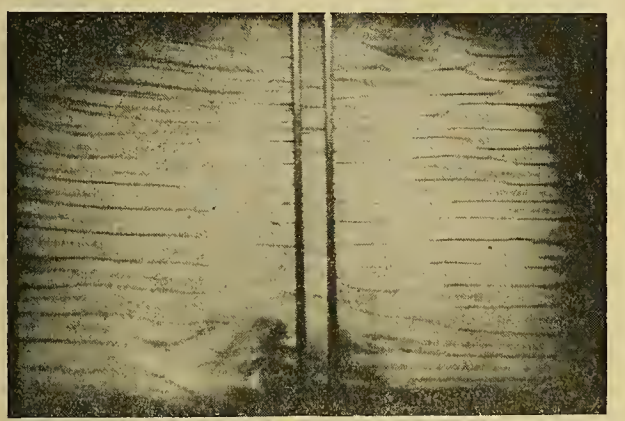

FIG. 8.—The effect of shear, by motion from left of right of the top plate, in a chamber of depth 8 mm, with temperature difference of 5°C.

the flow pattern in a layer 8 mm in depth, with a temperature difference of 5°C, and with the top plate moving at a rate of 10 cm sec^{-1}. The chamber is filled by a set of double rolls, with descent at the common boundary of the two rolls in a pair, and ascent at the

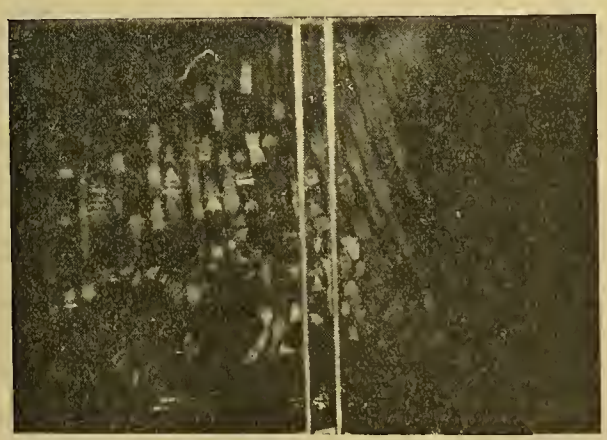

FIG. 9.—Transverse rolls formed by small shearing motion, with temperature difference of 9°C and rate of motion of top plate of 9 cm sec^{-1}.

other boundary. The central boundary of a pair, at which there is descent, is not so clearly defined as the boundary which separates adjacent pairs. This is clearly shown in Fig. 8. Rolls which are directed along the direction of shear are called "longitudinal" rolls.

When the rate of motion of the top plate is decreased to a considerably lower value, the longitudinal rolls are replaced by "transverse" rolls, or rolls perpendicular to the direction of shear. Careful observations were made to investigate whether these rolls had alternating sense of rotation, and it was established that adjacent transverse rolls do undoubtedly rotate in opposite directions. Figure 9 shows a system of transverse rolls.

With a still smaller rate of shear, and with the vertical gradient of temperature held constant, it was found that no rolls, either longitudinal or transverse, were formed, but that the original polygonal structure with no shear was distorted, as shown in Fig. 10. The

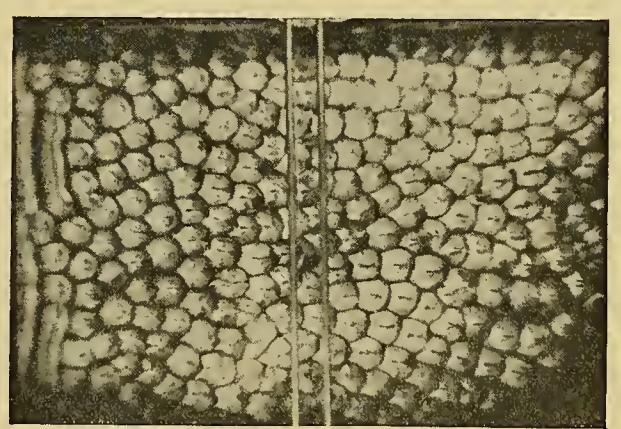

FIG. 10.—Distortion of the cell pattern by small shear.

observations made by Chandra [4] and by Dassanayake [5] indicate that the maximum rate of shear which will produce transverse rolls increases as the vertical gradient of temperature increases. Dassanayake made a special effort to maintain a constant vertical temperature difference of 4°C with a chamber 10 mm deep, and to approach as nearly as possible to the limiting shear above which the rolls are longitudinal, and below which the rolls are transverse. He succeeded in obtaining photographs showing both transverse and longitudinal rolls, occurring simultaneously, and superposed over a part of the chamber, when the top plate was moved at a rate of 0.5 cm sec^{-1}. The photographs were, however, not suitable for reproduction, being lacking in marked contrast.

With a difference of 4°C in temperatures at top and bottom of the 10-mm chamber, motion of the top plate will give transverse or longitudinal rolls, according as the rate of motion of the plate is less than, or greater than, 0.5 cm sec^{-1}. The mechanical arrangement used by Chandra for moving the top plate was insufficiently reliable to permit of accurate control of the shear, and his observations were limited to high values of the temperature difference and high rates of shear. We can therefore analyse the phenomena, in chambers of depths of 7 mm or more, as follows, for a given difference of temperature between top and bottom of the plate:

1. When there is no shearing motion, the chamber

is filled with polygonal convection cells, as described earlier.

2. When the top plate is moved at a rate not exceeding a certain low limiting value u_1, the original convection cells are distorted into a horseshoe pattern, as shown in Fig. 9.

3. When the top plate is moved at a rate exceeding u_1, but not exceeding another limiting value u_2, the chamber is filled with transverse rolls.

4. When the top plate is moved at a rate exceeding u_2, the chamber is filled with longitudinal rolls.

For a given depth of chamber, u_1 and u_2 will both increase as the difference of temperature between top and bottom of the chamber increases. It is not possible to state the values of u_1 and u_2 for different depths of chamber and for different temperature gradients. Only one value, u_2 for depth 10 mm and temperature difference 40C, is known, u_2 then being 0.5 cm sec^{-1}, approximately.

Depth of Chamber Less Than 7 mm. In the absence of shear the chamber is filled with structures such as are shown in Fig. 5. When a large shearing motion is imposed, the chamber is filled with spindlelike structures, and never shows the long continuous rolls which occur in deeper chambers. As the rate of shear is decreased the spindlelike structures become shorter and more irregular, but at no stage is the chamber filled with transverse rolls. Some idea of the completely different structures obtained in different depths of fluid may be gathered from Fig. 11, which was taken in a

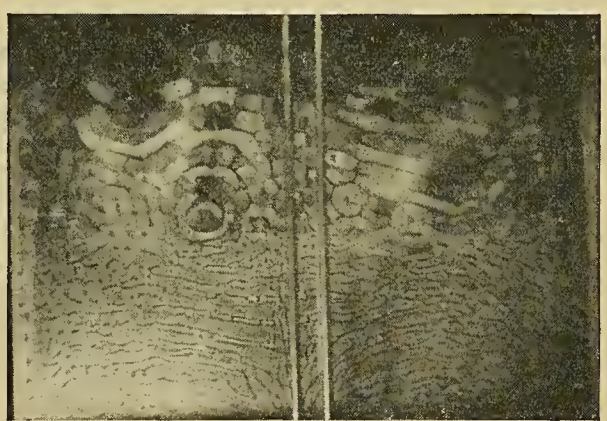

FIG. 11.—Change of cell pattern with depth. The picture represents a chamber of depth 8 mm at the top and 6 mm at the bottom of the picture. The temperature difference between top and bottom of the chamber was about 42C, and the rate of motion of top plate was 7 cm sec^{-1}.

chamber in which the depth varied from 6 mm at one side to 8 mm at the opposite side, with a temperature difference of 42C. The photograph in Fig. 11 was taken shortly after the top plate had been stopped.

A Comparison of the Phenomena in Air and in Carbon Dioxide

Dassanayake [5] carried out an investigation of the forms of convection in carbon dioxide, the gas being bubbled through hydrochloric acid and a solution of ammonium carbonate in Dreschel bottles, and finally through concentrated sulphuric acid to remove all water drops. The amount of fogging was kept as low as was consistent with ease of observation of the patterns of flow, in order to avoid seriously altering the character of the medium.

Carbon dioxide was chosen as a medium for this investigation because the values of κ and ν are considerably lower for carbon dioxide than for air. Thus at 15C $\kappa\nu$ is 0.030 for air, and 0.0076 for carbon dioxide. In Rayleigh's criterion quoted earlier, the critical difference of relative density is proportional to $\kappa\nu/h^3$. Thus for a given depth of chamber the critical condition established by the criterion is satisfied by a much lower gradient of relative density in carbon dioxide than in air. Thus it was found possible to form polygonal cells in carbon dioxide in a chamber of 4.5 mm depth, whereas in air no polygonal cells could be formed in a chamber of less than 7 mm depth. It should be noted that $(4.5/7)^3$ is equal to 0.265, which is in reasonable agreement with the theoretical value (0.25) of the ratio of $\kappa\nu$ for the two gases at 15C.

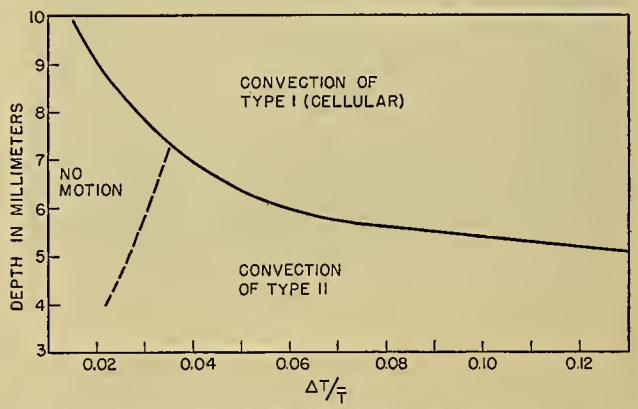

FIG. 12.—A summary of Dassanayake's observations of limiting conditions in carbon dioxide (*cf.* Fig. 7).

Figure 12 shows the limiting curves derived by Dassanayake for carbon dioxide. The results are similar in character to those of Chandra shown in Fig. 7.

Applications To the Atmosphere

In the atmosphere, motion in the convection cell is normally the reverse of that observed in the laboratory experiments, a central ascending current being surrounded by a descending current of much smaller speed. Clouds form within the ascending currents when these extend to a sufficient height to produce condensation. In considering the atmospheric analogues of the laboratory phenomena, we should therefore look for cloud formation within the regions corresponding to those in which descending motion is found in the laboratory experiments, bearing in mind that instability is an essential condition for the occurrence of these phenomena. The precise nature of the clouds will depend on the rate of shear, that is, on the rate of variation of wind with height. The main classes of convection cloud are classified in Table I. This table includes both cloud forms directly formed by condensation, and those

which are formed in the process of dissipation of clouds within which instability is set up, either by the joint effect of radiation and absorption, or by subsidence.

TABLE I. CLASSES OF CONVECTION CLOUD

Rate of variation of wind with height	Type of cloud	International Cloud Atlas
Zero	Isolated cumulus	N 10, 25, 55, 56
Very small	Cloudlets arranged in lines	N 16
Small	Short rolls, or long irregular wavy rolls, nearly across wind	N 11, 18, 29
Large	Long rolls roughly downwind	N 37, 51, 57 A 14, 16; C 23

The last column gives reference to pictures in the *International Cloud Atlas*.

Since the rate of change of wind with height is closely proportional to the horizontal gradient of temperature, we may say that the rate of change of wind is large or small according as the isotherms are closely clustered together or far apart. It follows that convectional cloud will be aligned along the isotherms when these are clustered closely together, but at right angles to the isotherms when these are widely separated.

Some attention was devoted by Deslandres [6] to the possibility of explaining the structure of the solar chromosphere as an aggregation of convection cells of the type we have called Bénard cells. This deserves passing mention as an early attempt to use the results of Bénard's small-scale experiments to explain phenomena on a much larger scale. There is, in addition to this, a considerable literature in French dealing with attempts to explain lunar craters by the same mechanism.

Some Further Notes On Convection

Durst, in Part III of a memoir by Giblett and others [7], has interpreted observed variations of wind in the horizontal as due to convective motions such as are shown in Fig. 10, in which the simple convection cell is distorted by a small shear of wind. Durst's results do not admit of brief summarising, and the reader is referred to the original memoir for details of the work.

The effect of entrainment of air by an ascending current, in diminishing the local variation of wind with height has been discussed by Malkus [10] in a paper of considerable interest, in which the slope of an ascending current to the vertical is derived theoretically, and in which it is shown that clouds may move with a speed different from that of their environment. The magnitude of this difference is shown to be a function of the vertical shear and the rate of entrainment of mass into the jet of rising air. If the entrainment of the ambient air is greatest on the upwind side, Dr. Malkus finds that the cloud will tend to grow on the upwind side, and to dissipate on the downwind side.

Malkus, Bunker, and McCasland, in a paper on observational studies of convection [11], have discussed clouds formed by forced convection due to the islands in the neighbourhood of Woods Hole, and have elaborated the discussion of the effects of wind shear previously given by Malkus.

The Theory of Bénard Cells by O. G. Sutton

In a recent paper Sutton [15] has shown that all the critical temperature differences (ΔT), as observed by Chandra and by Dassanayake, should satisfy a relationship:

$$\frac{\Delta T}{T_0} = f(\Delta T^{3/4}),$$

where T_0 is the temperature at the base of the chamber.

In the course of the development of his theory, Sutton shows that, when the curve and line whose equations are

$$y = 8.1 \times 10^{-3}(\Delta T)^{3/4} - 0.0117,$$
$$y = \Delta T/T_0$$

are plotted for any given T_0, their intersections will yield the critical temperature differences. The straight line intersects the curve in two points, is tangential to the curve, or has no intersections. The striking feature is the possible existence of two real roots, the higher root corresponding to the polygonal or Type I convection, and the lower root to the Type II convection, of the type shown in the greater part of Fig. 5.

While the values of ΔT varied from 3.5C to about 90C, the base absolute temperatures varied from 295K to 380K, and the depths of the chamber varied from 0.4 cm to 1.6 cm, Sutton's plot of $\Delta T/T_0$ against $(\Delta T)^{3/4}$ gives an amazingly accurate linear relationship between the plotted variables, the equation for which is

$$\frac{\Delta T}{T_0} = 8.1 \times 10^{-3}(\Delta T)^{3/4} - 0.0117.$$

Sutton's paper is by far the most important theoretical contribution to this subject since Rayleigh's original paper.

Desirable Extensions of the Investigations Mentioned Above

The most desirable investigations would be the collection of details of variation of temperature and wind with height within the types of cloud discussed above, the depth of the cloud layer being carefully measured at the same time.

The essential details of the laboratory phenomena have been collected, but the theoretical discussions referred to fail to lead to such results as are summarised in Figs. 7 and 12, for convection of Type II.

RADAR STORM OBSERVATION

By MYRON G. H. LIGDA

Massachusetts Institute of Technology

INTRODUCTION

Through the use of radar for precipitation detection the science of meteorology has acquired an entirely new and unique method of weather observation [14]. As a result of this use the meteorologist has been presented with graphic, dynamic, and up-to-the-second depictions of precipitation formations of all types, and these in several dimensions. Techniques for analysis of radar precipitation echo signals have not yet been completely developed, and for this reason radar is presently of minor (but rapidly increasing) meteorological importance. It appears to have vast potentialities both in the fields of physical meteorological research and weather observation and forecasting, as well as other closely allied activities.

Radar is of interest to the meteorologist in several different ways: (1) in the field of hydrometeor detection and the study of storm structure, (2) in the observation of winds aloft under adverse conditions [35], and (3) in certain regions of the world radars occasionally have their propagation radically modified by atmospheric conditions which meteorologists have been called upon to forecast [18, pp. 11–17]. Each of these subjects may be treated quite independently of the others, although one particular radar system may be involved in all three. For a discussion of the second and third of these subjects the reader is invited to refer to articles elsewhere in this Compendium.[1]

Radar operates on the principle that radio energy is scattered and reflected by the dielectric gradients which exist at the surface of various objects which, when they are detected by radar, are designated as *targets* [49, pp. 1–6]. A *pulse radar*, as distinguished from other types of radar systems, consists of a powerful radio transmitter which emits radio energy in short bursts or pulses, a highly sensitive radio receiver which detects the back-scattered energy, and indicators of various types (called *scopes*) which present the information visually for use by the operator. Radars discussed in this article are of the microwave pulsed type, *microwave* indicating that the operating wave length lies between 1 and 20 cm.

Radar indicates the relative position of a target in terms of polar coordinates: elevation angle, azimuth or bearing from a given direction, and range. Elevation and azimuth angle information is obtained from the orientation of the antenna at the instant of detection. Range determination is accomplished by timing the interval between the transmitted pulse and the received echo.

Subject to certain restrictions, the information presently available to the forecaster or physical meteorologist by means of radar observation is as follows:

1. "Instantaneous" location of all precipitation over several thousand square miles horizontally, and at all altitudes from a *single* observing station.
2. Direction and velocity of precipitation movement.
3. Qualitative information concerning intensity of precipitation.
4. Heights of cloud bases and tops.
5. Approximate height of the freezing level.
6. Information as to whether or not certain storms are thunderstorms.
7. Position, direction, and speed of hurricanes.
8. Upper-level wind data to high altitudes, with great accuracy and under adverse conditions of visibility and precipitation.
9. Wind shear when precipitation is falling through shear surfaces.
10. Turbulence within precipitation.
11. Distribution of fall-velocity for precipitation particles at any level above the radar.
12. Qualitative information regarding water-vapor and temperature distribution in the vertical.

Not all of the information contained in the list above is yet obtained to a useful degree of accuracy. For example, rainfall intensity can be measured only in the immediate vicinity of the radar and even then only approximately. Considerable effort is being made to improve the accuracy of such measurements and to remove as many restrictions and limitations from the above list as is physically possible.

THE BACKGROUND OF RADAR STORM DETECTION

About 1940 it became evident to those working on the development of radar that it was possible to construct radar systems with operating wave lengths of 20 cm (1500 mc sec^{-1}) and shorter. Before these systems were completely operational, Ryde [50] of the General Electric Laboratories Ltd. in England made a study to determine if the performance of such radar systems would be affected by precipitation. This information was necessary in order to determine whether aircraft could escape microwave radar detection by flying in clouds, rain, snow, or dust and sand storms. Ryde's calculations indicated that microwave radars *would* receive echoes from precipitation, and the results he obtained concerning the relative signal strengths of precipitation echoes and aircraft echoes were later

1. Consult "Instruments and Techniques for Meteorological Measurements" by Michael Ference, Jr., pp. 1207–1222; and "Meteorological Aspects of Propagation Problems" by H. G. Booker, pp. 1290–1296.

shown to be quite accurate. About three months after he had completed the essential parts of his calculations, the first radar-detected storm (a thunderstorm from which hail was observed to fall) was reported on February 20, 1941, in England. The operating wave length of the radar used was approximately 10 cm and the storm was followed out to sea to a distance of seven miles. At about the same time a like phenomenon was also observed at the Radiation Laboratories of the Massachusetts Institute of Technology in the United States.

Because of the secrecy enveloping the entire radar program, it was not until many months later that the potentialities of this discovery were realized by meteorologists; but even then, again because of security regulations, few were given detailed information. Consequently, exploitation of this new observational technique was greatly hindered. Also radars were generally inaccessible, those useful for storm-detection purposes were limited in number, and most of these were assigned to very high priority work for aircraft detection.

After World War II, several agencies in different countries initiated research programs in the field of radar storm detection. A large part of the information contained in this article is the result of this research. The rapid progress is due to the wealth of surplus radar and electronics equipment, aircraft, and the intense interest in the subject by persons skilled in the fields of meteorology, mathematics, physics, aviation, and electronics.

THEORY AND FACTORS OF RADAR STORM DETECTION

The theory of radar storm detection defines the process by which precipitation is detected by radar. A large number of factors must be taken into consideration, and determination of the value of some of them is an extremely difficult problem due to their nature or variability. A direct approach to the problem often employed is that of definition of the power received from a given or defined volume of the storm. It may be shown [8; 65, pp. 23–29] that the power received at the antenna due to the echo from precipitation is

$$P_r = \frac{\pi^2}{18(360)^2}\left(\frac{P_t A^2 \phi\theta h}{\lambda^6}\right)(\eta\lambda^4)\left(\frac{k}{R^2}\right), \qquad (1)$$

where P_r = power received (w),
P_t = power transmitted (w),
A = aperture of the parabola (m^2),
ϕ = beam width, vertical (degrees),
θ = beam width, horizontal (degrees),
h = pulse length (m),
λ = wave length (cm),
η = reflectivity of the storm region per unit volume (cm^{-1}),
k = attenuation factor,
R = distance of the storm (km).

The term $(P_t A^2 \phi\theta h/\lambda^6)$ is dependent upon the type of radar; the term $(\eta\lambda^4)$ concerns the nature of the precipitation; and the term (k/R^2) takes into account the effect of intervening space between the radar and the region of the storm for which the power of the echo is to be determined.

Equation (1) may be stated in slightly different form to facilitate computation:

$$P_r = 6.1 \times 10^{-16}\,\frac{P_t G^2 \lambda^2 \phi\theta h k \eta\psi}{R^2}, \qquad (2)$$

where G = gain of the antenna and parabola (pure number), and ψ = fraction of the beam filled by the storm.

Equation (2) states in convenient form all factors entering the problem, and these factors may be inserted in the equation in commonly used units. The new term G may be determined from A and λ. The term ψ is employed to remove the restriction that the beam must be entirely filled by the storm, thus making the equation general.

A clear understanding of the meaning and significance of these various terms is mandatory if correct interpretations are to be made of radar storm presentations. It is well beyond the scope of this article to give this subject the treatment it deserves, but brief discussions concerning each of the terms in equation (1) will be given, with references to enable more thorough study.

Factors Pertaining to the Radar System. *Transmitted and Received Power, P_t and P_r.* It should be readily apparent that the amount of power transmitted will affect the power of the echo signal; the stronger the former, the greater the latter. Maximum power output of a radar system is normally limited by the characteristics of its magnetron (a special type of vacuum tube used to convert direct-current power into radio energy of very high frequency). The great peak power of pulsed radar systems, which may be in terms of megawatts, is explained by the fact that the magnetron is operating only a few tenths of one per cent of the time [49, pp. 344–348]. This is determined by the ratio between the pulse repetition frequency and the duration of the radiated pulse of energy.

The lower limit of power which the receiver can detect is limited by the receiver's sensitivity. In microwave regions this sensitivity limit is not set by atmospheric static, but rather by the electron or thermal "noise" which originates in the various receiver components [49, pp. 28–41]. If the power for the signal which may just be distinguished from "noise" is used in equation (2), the equation may be solved for range, which will then become the *maximum* range at which a given storm may be detected.

Antenna Gain, G, and Aperture of the Parabola, A. The antenna aperture defines the projected area of the parabola (used to focus the radio energy) normal to the axis of the beam (see Fig. 1). Either A or the antenna gain G, whichever is more convenient, may be used in these formulas, since they are related by the semi-empirical formula

$$G = \frac{4\pi A f}{\lambda^2}, \qquad (3)$$

where f is a dimensionless factor which depends on the design and efficiency of the antenna and parabola (usually about 0.6 or 0.7).

FIG. 1.—Antenna parabolas of two of the radars used by the M.I.T. Weather Radar Research. The parabolic reflector to the left forms a conical beam of circular cross section. The one to the right (AN/TPS-10A) forms a "beaver-tail" beam of elliptical cross section 0.7° vertical and 2° horizontal. Both radars have an operating wave length of about 3 cm. (*M.I.T. Weather Radar Research.*)

The antenna gain is a term used to express the increase of power resulting from the focusing of the radiated energy into a narrow beam, in contrast to isotropic radiation [49, pp. 18–21]. Microwave radar operates at such high frequencies in the radio spectrum that the radio energy may be focused by parabolic reflectors in a manner analogous to visible radiation focused by a searchlight. Directivity is desirable from the standpoint of target direction determination; energy conservation is necessary for maximum range of detection. The gain factor is dimensionless and may be loosely regarded as the ratio between the power density in the beam, resulting from focusing, and the power density which would exist at the same range if the transmitter radiated isotropically.

Beam Width, ϕ and θ. The beam width is usually defined as the angle subtended at the antenna between points across the beam where the power density is one-half that along the axis. When using this term it must be understood that an appreciable amount of power is actually present beyond this angle. However, the power beyond the half-power point decreases rapidly with increasing angle, so for most purposes this definition is probably sufficient. If the beam is circular in cross section, it may be depicted as a cone with the apex at the radar antenna.

Cross-section figures of radar beams may be in a variety of shapes, depending upon the use for which the radar is designed [49, pp. 22–28]. Most common shapes are circular and elliptical, especially for radars useful for storm detection purposes. Elliptical sections are employed when high directional accuracy or resolution is desired in one dimension and good coverage in the other. For example, a radar used for height determination would require excellent elevation angle discrimination, but only fair azimuthal resolution. It is neither easy nor desirable to have a beam with no angular spread. It is not easy because the long wave lengths (compared to light) would require prohibitively large parabolas to bring them into exact focus. It is not desirable because the beam would have to be precisely pointed at a target in order for the radar to detect it, if the target were small in size. For storm detection this would be no particular drawback because of the extent of most storm cells. However, the difficulty and expense of construction and control of large-size parabolas rules out beam widths much less than about 1° for radars with wave length of operation of about 3 cm. For a 10-cm wave length radar this angle is at least doubled.

The subjects of beam width and pulse length (which follows) are worthy of careful study by radar meteorologists, for these two factors define the volume of space which is analyzed and strongly influence interpretation of the scope presentations of precipitation. There are distortions resulting from the finite beam width in the nature of azimuth and elevation angle errors, and from the pulse length in the nature of a range error [65, pp. 20–22].

Pulse Length, h. As beam width affects azimuthal and elevation angle resolution, so pulse length affects range resolution. Pulse length may be defined either in terms of time or length; a pulse one microsecond in duration has a wave-train of energy about 300 m long. Two targets in the beam of the radar will be resolved if—and only if—their range separation exceeds one-half the pulse length [65, pp. 17–20]. Extension of the analysis to storm detection results in the corollary that energy from the particles in only one-half the volume illuminated by the pulse can reach the receiver at the same time.

The volume illuminated by the pulse is determined by the pulse length and the linear distance across the beam. The greater the number of scattering particles lying within this volume the stronger will be the echo. By increasing this volume the signal power of the echo may be strengthened, provided this increase in volume does not result in a decrease in the transmitted power density per unit area normal to the beam. However, loss of resolution results both from widening the beam and from lengthening the pulse. Therefore, a designer of radar equipment for storm-detection purposes must balance these factors in order to achieve the best possible presentation of the storm.

Wave Length, λ. The evaluation of a radar as a storm detector depends to a major extent upon the operating wave length. Wave length and frequency are used interchangeably in radar discussion, one being related to the other by the simple formula:

$$f = \frac{c}{\lambda}, \tag{4}$$

where f = frequency (cycles sec^{-1}),
c = velocity of light (cm sec^{-1}),
λ = electromagnetic wave length (cm).

Roughly speaking, a wave length of 10 cm corre-

sponds to a frequency of 3000 mc sec^{-1}. During the war, radar wave length of operation was highly confidential information, since radar countermeasure development by the enemy was considerably facilitated if this was known to him. Accordingly, wave lengths on which radars operated were designated by letters: S-band for 10 cm; X-band for 3 cm; and K-band for about 1 cm. Thus, a radar with an operating wave length of 10 cm was called an "S-band" radar. These designations have persisted since the war, and are utilized in this article to familiarize the reader with terms widely encountered in the literature.

The radar energy back-scattered toward the receiver by a raindrop is inversely proportional to the fourth power of the wave length if Rayleigh scattering [48] applies. However, absorption and attenuation of the scattered energy may become great enough at very short wave lengths to restrict maximum range seriously, and a compromise value of wave length must be used. Speaking in general terms, we may say that for use in areas of very heavy rainfall a wave length of about 10 cm is best, while in regions where the average drop size is somewhat smaller, a wave length of about 3 cm is desirable [15,16]. From an analysis of this problem it seems that a storm-detection radar should be designed for the climate in which it is to be used [68]. Many authorities agree that the best "all-round" frequency for storm-detection radar equipment would probably be about 6000–7000 mc sec^{-1}, corresponding to a wave length near 5.5 cm.

Reflectivity Per Unit Volume of the Storm Region, η. This is a measure of the energy back-scattered by particles in the storm. It is a function of the number of particles per unit volume, their size distribution, the frequency of the energy scattered [65, pp. 30–34], the composition of the particles, and their shape and aspect. The process of electromagnetic scattering by hydrometeors is similar to that of the scattering of visible radiation by large molecules, by which the color of the sky is explained. Fundamental laws of scattering developed by Rayleigh [48] and Mie [45] were applied by Ryde [50] to the special case of electromagnetic scattering and diffraction by raindrops. It was found that a spherical particle which is small relative to the wave length of radiation falling upon it scatters the energy proportionally to the sixth power of its diameter [49, pp. 33–66]. This indicates that if the size of a drop is doubled, its scattering efficiency is increased by a factor of 64. Therefore it is evident that size is of much greater importance than number in the determination of reflectivity. Reflectivity per unit volume turns out to be a function of NR^6 where N is the number of drops and R is their radius. However, when the drops become large compared to the wave length ($2R > \lambda/10$), "Rayleigh scattering" no longer applies and the exact dependence of the scattering cross section upon λ is a complex function.

The composition of the particle affects its dielectric properties, and therefore its efficiency as a scatterer. For example, water has a greater dielectric constant than ice, hence for two spheres of equal diameter, one of water and the other of ice, the water sphere will scatter about five times as much electromagnetic radiation of 3- or 10-cm wave length. Shape and aspect are important for nonspherical particles, therefore the problem of evaluating the power of the echo from snow is difficult.

If the rainfall intensity is known and one assumes a drop-size distribution in accordance with Laws and Parsons' data [38], it is possible to compute the reflectivity per unit volume [6]. It is necessary, however, to assume that this reflectivity remains constant throughout the area covered by the radar beam (or fills a known fraction of it). The fact that reflectivity per unit volume is not a unique function of drop-size distribution greatly complicates the problem of determination of rainfall intensity by radar. At present, measurement of a given level of echo-signal power indicates only that the rainfall at that point lies within certain limits of intensity. This conclusion becomes evident when one realizes that a few large drops can give an echo signal equal to that from many small drops.

An additional factor which should be mentioned in connection with reflectivity is the variability of the back-scattered energy. This energy fluctuates rapidly with time because of interference between the electromagnetic waves scattered by a large number of moving drops. The received power P_r is the *average power* of a number of individual precipitation echo signals [49, pp. 81–85].

Attenuation Factor, k. During passage through the atmosphere between antenna and storm the electromagnetic energy radiated by the transmitting antenna and scattered by the precipitation particles suffers attenuation due to several causes: (1) water-vapor and oxygen absorption, (2) molecular scattering by atmospheric gases, and (3) hydrometeor scattering and absorption [51, 63, 65].

The problem of electromagnetic atmospheric attenuation, being a question not confined to the field of radar, has received the attention of a number of investigators [18]. Tables have been constructed giving attenuation in the free atmosphere and in rain in terms of decibels, as a function of path and wave length [49, pp. 58–62]. Precipitation attenuation is not a serious factor until drop sizes become appreciable in comparison to the wave length (about $\frac{1}{10}$ or larger). Because large drops are frequently present in thunderstorms and tropical rain, X-band (3-cm) radar may sometimes not be the best for observation of storms of these types [13]. Rain attenuation and atmospheric absorption are seldom observed with S-band (10-cm) radars.

Fraction of the Beam Filled by the Storm, ψ. Determination of the magnitude of this factor under certain conditions is difficult or impossible, but its significance cannot be minimized. The echo signal from a weak storm which fills the beam may equal that from a strong storm which only partially fills it, but at present it is not possible to tell from signal characteristics alone what the true condition is. The distances between half-power points at various ranges for beams of different angular widths are listed in Table I; it will be seen that

these distances are considerable even with respect to the heights of thunderstorms.

In the determination of rainfall intensity by radar, it must be assumed that the reflectivity per unit volume is constant in the volume of space contained by the limits of the beam and the pulse length. Because of the beam width of existing radar equipment, this condition can rarely be fulfilled except very close to the radar where the linear distance across the beam is small. Even then, reasonably uniform rainfall conditions must exist.

Table I. Beam Width Between Half-Power Points (in ft)

Range (miles)	Angular Width of Beam		
	0.7°	2°	4°
5	320	920	1,840
25	1,610	4,600	9,210
50	3,230	9,210	18,400
100	6,450	18,400	36,900

Distance of the Storm, R. This term is included in the equation to provide for range attenuation. If the storm completely fills the beam, range attenuation increases with the square of the distance. If the target consists of a point, such as an airplane, range attenuation increases with the fourth power of the range. Most investigators, in making rainfall intensity measurements by radar, endeavor to make their observations as close as possible to the radar for two basic reasons: (1) to insure complete beam filling by relatively uniform rain or snow, and (2) to reduce range attenuation, thus increasing the signal strength of the received echo [6].

OBSERVATIONAL VERIFICATION OF RADAR STORM-DETECTION THEORY

Exact verification of the theory (or of equation (1)) is very difficult because of several factors. The value of P_r must be measured by averaging the power of very weak signals (about 10^{-8} to 10^{-12} w) which are fluctuating rapidly. Moreover, the precipitation echo signal is not received continuously from a given point in the storm but at intervals equal to the transmitted pulse repetition frequency. Techniques have been developed to measure P_r, however, and they will be discussed in the section on signal analysis. A more fundamental difficulty lies in the problem of determining the number and size of the drops within the illuminated portion of the beam in order to calculate the reflectivity. This must necessarily be a sampling process which may be performed either on the surface or aloft [65, pp. 70–76]. Surface sampling, while easier to accomplish, may not be representative of conditions aloft in the atmosphere where the radar beam may be directed.

One greatly desired meteorological use of radar is the determination of rainfall intensity over a wide area, or at various points distant from the radar. It is evident from the theory that the only radar factors closely related to rainfall intensity are the reflectivity per unit volume of the storm and the attenuation [9]. Reflectivity is generally the more useful. Establishing the relationship, however, is a formidable undertaking, requiring assumed drop-size distribution, particle shapes and spatial distributions, as well as power measurements of weak, rapidly fluctuating signals. Several investigators [32, 34, 42] have reported empirical relationships between precipitation intensity and echo-signal power, but only at limited ranges and under certain specific conditions of precipitation.

OBSERVATION OF WEATHER PHENOMENA ON RADAR SCOPES

Types of Radar Scopes. Radar targets are usually presented visually by means of cathode ray tubes or *scopes*. There are about a dozen methods of presentation, depending upon the type and use of the radar, but only four or five of these are of more than casual interest to the meteorologist for storm-detection purposes [49, pp. 160–175]. A brief discussion of these will be given to assist the reader in understanding later descriptions of radar storm displays.

The A Scope. This scope is the simplest and most widely used display; its appearance is illustrated in Fig. 2. From it the operator learns several things about a target: its straight-line distance from the radar, the approximate intensity of its echo signal, and not infrequently its nature. Target echo signals are usually displayed as vertical deflections from a horizontal base line. The amount of vertical deflection is proportional to the power of the echo signal. The distance of the target from the radar is indicated by the relative position of the deflection from one end of the base line, usually the left. There are usually several strong echoes present at close range at all azimuths; these result from the presence of buildings or uneven terrain in the immediate vicinity of the radar. These echo signals are sometimes called "ground clutter."

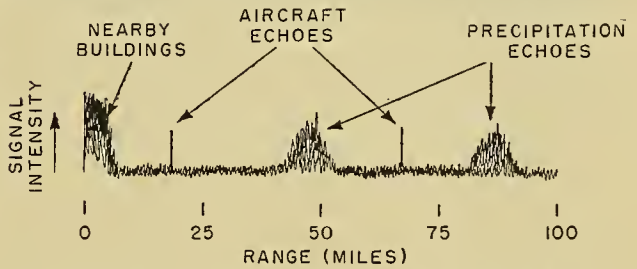

Fig. 2.—Diagram illustrating the appearance of A scope of SCR 615B (S-band) radar, showing characteristics of various types of echo signals. Range information is virtually useless without elevation and azimuth angle information, neither of which is shown on this type of presentation.

The A scope is also useful for target identification. An experienced operator can detect differences in echo-signal characteristics which are sufficient to inform him whether the target is an aircraft, ship, buildings or terrain, or precipitation. Precipitation gives a very distinctive echo signal because of its rapidly fluctuating character which is caused by the changing interference pattern established by the precipitation from pulse to pulse.

The R Scope. The R scope presents the same information as the A scope, but greatly expands the horizontal coordinate so that instead of some 100 miles being represented on the scope, only 5 or 10 miles of any desired portion of the A scope is displayed. Figure 3 illustrates the appearance of this presentation.

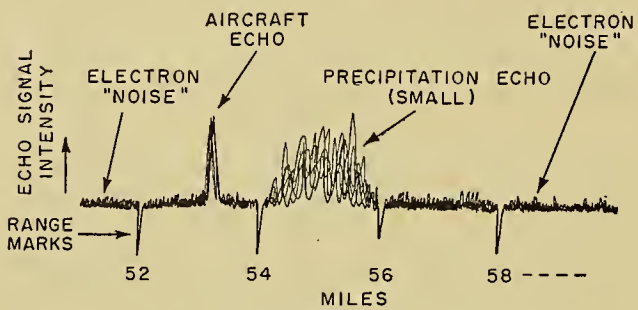

Fig. 3.—Diagram of R scope of SCR 615B radar (modified), illustrating difference in appearance of aircraft and precipitation echo signals.

The Plan Position Indicator or PPI Scope. The PPI scope, as it is popularly known, is one of the most favored scopes for storm detection purposes because of its graphic and easily interpreted display. The presentation is circular and therefore employs the entire area of the cathode ray tube face in contrast to the rather small portion utilized by the A and R scopes. When the radar beam is directed horizontally and rotated in azimuth, the PPI display takes the form of a circular map with the position of the radar represented at the center of the scope. Targets are displayed in position relative to the radar as if viewed from an infinite height directly above the radar. Range from the radar to any target may be determined from the relative distance from its echo signal to the center of the scope. To aid in range determination, an electronic circuit injects marks at proper intervals which correspond to range increments of 1, 10, or 20 miles or any other number and unit of length desired. As the sweep rotates, these marks draw concentric circles about the center of the scope. The appearance of the scope is illustrated in Fig. 4. The electron beam is so controlled that if the radar is not detecting a target at a given position, the face of the scope is not brightened at the corresponding point. When a target is detected, the electron beam is intensified so that it brightens the face of the scope at the proper position in azimuth and range from the radar. This process of target indication is called "intensity modulation" of the electron beam, as contrasted to the beam deflection method employed by A and R scopes, the beams of which are always on and are of constant intensity.

If the antenna is directed horizontally, the indicated range will correspond closely to the actual horizontal distance between target and radar, and its geographical position may be determined by reference to a map of the area. If the map is drawn on transparent material and is of proper scale, it may be laid directly over the face of the scope and geographical positions of targets can be determined directly.

Another version of the PPI scope may be controlled so that the indicated position of the radar may be displaced from the center in any direction to distances of

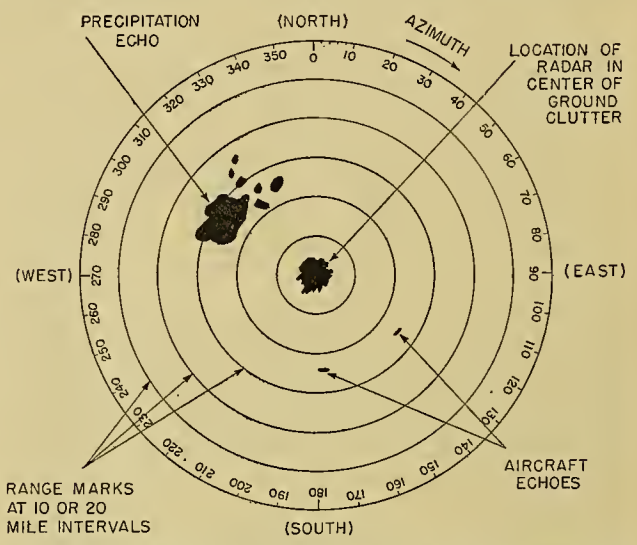

Fig. 4.—Diagram of features of a PPI scope. Some detail has been omitted to clarify the drawing. In all PPI-scope photographs which follow, north is at the top of the scope, east to the right, etc. Elevation angle in all cases is zero degrees.

about two diameters of the scope face. This scope is called an "off-center PPI" and enables close examination of selected areas by virtue of the great sweep expansion which can be employed.

The Range-Height Indicator or RHI Scope. This scope is particularly valuable for storm-detection purposes, but is found only on radars designed to scan a vertical plane. The electron beam is intensity-modulated like that of the PPI scope. The radar antenna scans cyclically from the horizon upwards to any angle, depending upon control settings or the design of the radar. In order for the display on the scope to be intelligible, the azimuth of the beam must remain nearly constant during the scanning process. Targets in the vertical cross section along a given azimuth are displayed on the face of the scope in coordinates of range versus altitude or elevation angle. Because practically all targets, whether storms or aircraft, will be found at altitudes less than 10 miles, and since the horizontal range of the radar is nearly always more than 50 miles, it is usually desirable to expand the vertical scale in order to utilize the maximum available area of the scope face. This results in more precise altitude determination due to the vertical scale increase. For this reason, RHI scopes are usually designed to have an altitude distortion of about 10:1. The appearance of the scope of a typical height-finding radar (AN/TPS-10A) is shown in Fig. 5.

It will be noted that the range and height of a target may be determined directly from this scope by means of properly calibrated scales. In order to fix the target in space, its bearing or azimuth must also be known. This information cannot be obtained from the RHI display alone; consequently it must be read from a dial

or other indicator operating in synchronism with the antenna azimuth control. This is also true for A- and R-scope azimuth readings.

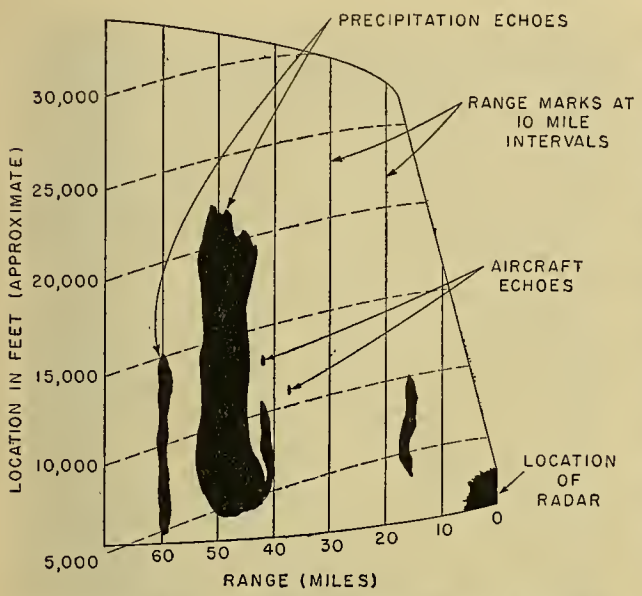

FIG. 5.—Diagram illustrating features of RHI scope of AN/TPS-10A radar (X-band). Photographic images (and this diagram) are reversed from normal presentation because of the design of camera used to obtain RHI-scope pictures which follow. Vertical distortion of scope about 10:1. Diagram illustrates appearance of mature thunderstorm at range of 40 to 55 miles.

Appearance of Scopes During Storms.[2] Precipitation may be divided into various types, using basic causes as the means of classification, as follows:

A. Frontal precipitation.
   1. Cold front.
   2. Warm front.
   3. Occluded front.
B. Orographic precipitation.
C. Hurricanes or typhoons.
D. Instability showers.
   1. Air mass.
   2. Thunderstorms.

This breakdown is convenient for the purposes of this discussion because the horizontal and vertical distribution of hydrometeors is indicative of the motivating cause. This distribution in space can easily be observed with radar.

A. *Frontal Precipitation.* 1. *Cold front.* Perhaps the most striking and easily understood of all radarscope displays is that of echo signals from the squalls associated with an active cold front. Photographs of PPI scopes similar to Fig. 6 have been widely published during the past few years and need little explanation, especially when accompanied by a synoptic map showing position and orientation of the surface front in the

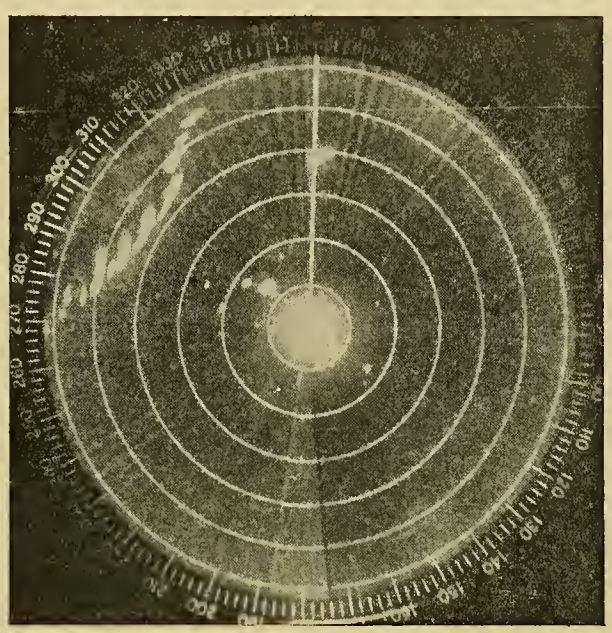

FIG. 6.—Photograph of PPI scope showing echo signals from showers accompanying cold front approaching Boston from the northwest. Isolated warm sector precipitation at azimuth 0°, range 79 miles, and at azimuth 310°, range 20–40 miles. (1730 EST, 3/27/48, S-band radar, range 120 miles, 20-mile markers.) (*M.I.T. Weather Radar Research.*)

conventional manner. Over fairly smooth terrain a well-sited radar with sufficient power will detect the precipitation accompanying an active cold front at distances in excess of 200 miles, depending upon the heights of the squalls.

Close examination of the precipitation pattern shown in Fig. 6 will reveal the distortion caused by finite beam width. This is a photograph of the PPI scope of an SCR 615B-type radar operating on a wave length of 10 cm and a beam width of 3° between half-power points. Notice that the individual cells have circumferential elongation [43]. This is not due to the meteorological situation, but is caused by the comparatively wide beam of this radar. Actually, the cells are usually almost as wide as they are long. This fact can be verified by observation with a radar which has a much narrower beam.

An important restriction on radar storm detection is the limited extent of the front which will pass within the range of this radar. As stated before, during favorable conditions the maximum range of detection may be more than 200 miles, but large portions of the average-sized cyclone will still escape detection by any single radar. This limitation is not due to the lack of power of radar systems, but rather to the curvature of the earth [49, pp. 53–55]. Under standard atmospheric conditions, the height h (in feet) of a horizontally directed beam above the surface of the earth at a range R (in miles) is approximately

$$h = \tfrac{1}{2}R^2, \qquad (6)$$

2. It should be noted that a single radar system cannot incorporate all the characteristics necessary for all types of radar weather observations. For example, the cloud-detection radar cannot be used for rain and snow observation because of severe attenuation of its energy when the size of the hydrometeors becomes appreciable with respect to its wave length of operation. In fact, this radar cannot even be used for cloud detection when the precipitation becomes moderate or heavy.

from which it may be seen that at a range of 200 miles the lowest portion of a horizontally directed beam of a radar located at sea level is about 20,000 ft above sea level [2].

One of the finest practical applications of radar storm detection is made when radar-equipped aircraft use it to avoid violent convective activity while flying through an active cold front [11, 46]. As Fig. 6 shows, the front is far from being a solid mass of storms of moderate altitudes. This application is especially useful at night or when the pilot's vision is restricted by clouds. A recent development has been shown to have value in selection of the least turbulent portions of storms when it is impossible to avoid them completely. This will be discussed in the section concerning echo-signal analysis.

Radar observations of the approach of a cold front show the following sequence of events [67]: Scattered storm-echo signals are first detected at maximum ranges (100–300 miles) depending upon the activity of the front. These echoes are caused by hydrometeors in the upper portions of the tallest cumulonimbus along the front, and generally lie in an arc which may be closely identified with the position of the front as reported by surface observation stations. As the front approaches, the radar detects precipitation at successively lower levels and the original cells appear to increase in size and intensity. When the nearest portion of the front is about 50 miles away, a large part of it appears to be a solid line of precipitation if the antenna elevation angle is kept at or near zero degrees. The inexperienced observer will sometimes conclude that the front is actually intensifying, whereas the radar is simply detecting rain at lower levels which is almost invariably more widespread. This trend continues until the front passes over the radar, at which time echoes from the more distant storms along the front may disappear from the scope entirely because of rain attenuation. At this time the precipitation may appear to be almost evenly distributed around the radar for a distance of many miles.

After frontal passage, the above sequence of events is reversed until the front passes beyond the maximum range of detection or dissipates.

While the line of storms taken as a whole appears to approach the radar, close examination reveals that the individual cells have a component of motion in the direction of the warm air movement ahead of and over the front. Thus, if the front appears to approach from the northwest and the warm air movement is from the southwest, the cells will show a movement just about due eastward, depending on the relative velocities of the cold and warm air masses.

2. *Warm front.* Interpretation of radar displays resulting from warm-front precipitation is considerably more difficult than the interpretation of echoes from cold-front precipitation. This is a result of the larger area covered by the precipitation and the possible variation of conditions. The precipitation causing the echo signals exhibits varying degrees of convective activity depending upon stability and convective stability conditions in the air masses involved. When conditions are stable in both air masses, the return appears as shown in Fig. 7. During more unstable warm-frontal conditions the PPI scope will show stronger echoes from individual storm cells. Absence of uniform or systematic

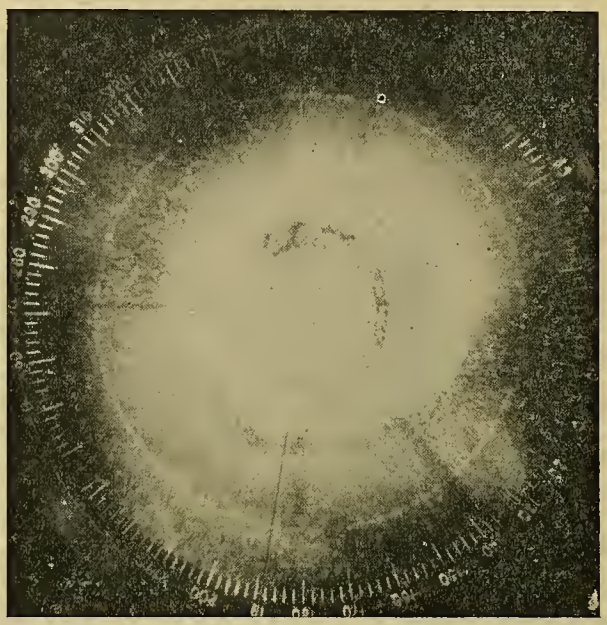

Fig. 7.—Stable warm-frontal precipitation echo signals on a PPI scope. Uniform snow echo signals are present at all azimuths. (1010 EST, 2/20/47, range 20 miles, 5-mile markers.) (*M.I.T. Weather Radar Research.*)

patterns is frequently observed. However, some sort of cellular structure is nearly always observed, and determination of the velocity and direction of cellular movement is usually straightforward. The movement of precipitation cells seems to be controlled by several factors, among which are the circulation within the system and the movement of the entire system itself. Attempts have been made to relate precipitation-cell movements to the winds aloft, but only rather general correlations have been found, and sometimes even these fail completely [29]. It is entirely probable that there is no simple relationship between the winds aloft and cell movement which can be applied to all storms. In order for a given precipitation cell to maintain itself it must have a continuous supply of moisture. This implies that air moves through the system at some speed different from that of the system itself.

At times it has been noted that the precipitation nearest to the radar is rain, while that detected at greater distances must be in the form of snow because of the increase in height of the beam with range (see equation (6)). As yet, no technique has been developed for positive determination of the nature of the precipitation, except in special cases, for example, when the height of the freezing level is known. The appearance of rain and snow echo signals on the PPI scope may be identical when both are present. However, differentiation is sometimes possible by R-scope inspection, as shown in Fig. 11.

The approximate height of the frontal surface may sometimes be determined by the presence of shear con-

ditions as shown by an RHI scope. This spectacular phenomenon is best detected when the precipitation is due to convective causes as was the case when the photograph shown in Fig. 8 was obtained. Where the

FIG. 8.—Photograph of RHI scope showing tall (snow) shower with abrupt shear below the altitude of 9000 ft. Lack of shear in showers more distant from the radar can best be explained by nonuniformity of the wind field. Storms are approaching the radar; shear therefore indicates decreasing wind velocity with altitude (in the plane of the picture) up to the point where echo signal edges become nearly vertical. Actual slope of shower in shear zone about 80° from the vertical (X-band radar). (*M.I.T. Weather Radar Research.*)

precipitation echo signal is vertical, the cell is embedded in air moving with constant velocity and direction. Where the echo signal slopes, the precipitation particles are descending into air moving at a different velocity along the direction of the radar beam. This difference may be due to a velocity differential with height, a direction differential, or a combination of both. The slope of the precipitation is a function of the fall velocities of the particles giving the echo and the wind velocities and directions involved. Unless the fall velocity is known, only relative wind velocities and directions may be calculated from observations of this type [21, 41]. In Fig. 8 it will be noted that in the actual storm the trajectory of the particles was almost horizontal in the shear zone; the 10:1 vertical expansion increases the slope on the scope by this factor.

With increasing use of narrow-beam radars for weather observation, hitherto unsuspected phenomena have been observed in conjunction with warm-front precipitation. Precipitation is occasionally observed to form in narrow, closely spaced parallel bands as shown in Fig. 9. The formation is suggestive of billow clouds formed by shear waves, and is in all likelihood partially due to the same action as that which causes clouds of this type. The phenomena are rather transient, usually persisting for only ten or fifteen minutes in any particular area. Observation of this occurrence usually requires narrow beam width radars (less than 2°) and careful adjustment of antenna elevation angle and gain. Also, rather short pulse lengths must be employed for best presentation. It is interesting to note that perfectly

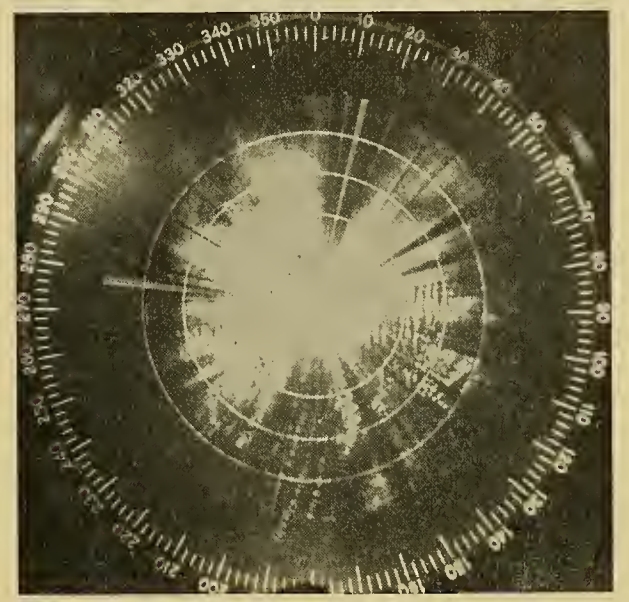

FIG. 9.—Photograph of PPI scope showing striking formation of precipitation echoes formed in parallel bands. Radial spokes are "shadows" cast by buildings and chimneys near the radar. Bands are suggestive of billow clouds, but are actually rain showers oriented north-south. Note the even, light rain echo signal which occupies the northern half of the scope. (1220 EST, 12/7/49, X-band radar, range 120 miles, 10-mile markers.) (*M.I.T. Weather Radar Research.*)

uniform precipitation conditions are seen, though rarely over any extended area. Finer and finer detail becomes evident as the resolving power of radars is increased by employment of narrower beam widths. It may be that reasonably uniform rain can extend only over an area of a few tens or hundreds of square meters.

Another phenomenon observed in conjunction with warm-front precipitation (and also under other conditions), is the descriptively designated "bright band." It receives this name from its appearance on RHI scopes; a typical example is illustrated in Fig. 10. Figure 11 shows its appearance on the R scope of a radar with a vertically directed antenna. It may be seen that the bright band is an approximately horizontal layer of exceptionally strong echo signal. The RHI scope has shown the following conditions to exist during bright-band detection:

1. The band may be the only precipitation return detected by the radar.

2. Precipitation may be seen below the band with no return above (and occasionally vice versa).

3. The bright band may be accompanied by precipitation echo signals both above and beneath it.

While certain detailed processes of bright-band formation are the cause of dispute, all investigators agree that it is in some way connected with the change of state which occurs at the freezing level. The band is invariably observed nearly at or slightly below this

level as determined by radiosonde and aircraft (and sometimes surface) observation [22, 25, 26]. The observed thickness of the band can never be less than the

FIG. 10.—Photograph of RHI scope showing horizontal layer of strong echo signal (bright band) at altitude of about 11,000 ft. Tall vertical showers are indicative of convective activity. (1930 EST, 9/25/47, X-band radar.) (*M.I.T. Weather Radar Research.*)

pulse resolution of the radar used to observe it, and since it has occasionally been determined to be no more than this amount for a given radar system, there is evidence that the thickness of the band may vary from as little as a few tens of meters to several hundred meters in thickness or more. It has been observed in connection with thunderstorms after convective activity has subsided [10, 19]. Two theories have been advanced to explain this phenomenon:

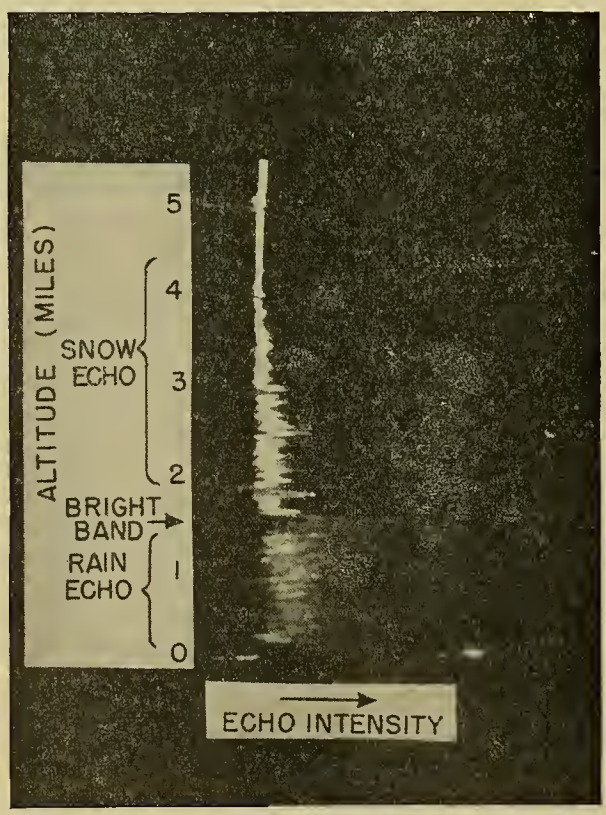

FIG. 11.—Photograph illustrating appearance of R scope when antenna is directed vertically and echoes are received from rain and snow. The weaker echo signal of the snow is due to its greater range and lower dielectric constant. The echo from rain shows much greater intensity variations because of the wider range of fall velocities of the water particles. (X-band radar, range 5 miles, 1-mile markers.) (*M.I.T. Weather Radar Research.*)

1. The region of strong echo is due to drop formation in the colloidally unstable layer of heterogeneous ice-water mixture. Any precipitation detected above that altitude would therefore probably be caused by convective transport [19].

2. Snow particles, too small to give more than a weak echo, fall to the zero degree isotherm, and melt at or just below this level. While melting, they have the low fall velocity of snowflakes, but the high reflectivity of water. Coalescence, often observed near melting temperatures, also serves to increase the reflectivity. After the snowflakes have completely melted, the fall velocity increases and the drops become widely spaced. The result is a region of weaker echo below the level of melting [10, 24, 52].

Most investigators are inclined to favor the latter theory, which the weight of observational evidence seems to support. There is little doubt that, in the absence of other observations, the bright band provides an excellent indication of the approximate height of the freezing level. To a lesser extent, it is also an indicator of the stability of the atmosphere; a thin band is indicative of relative stability, and a thick one (or the absence of a band) suggests convective activity near the freezing level [10]. At the present time, however, this is only a rough qualitative measure.

Under some conditions, the warm front provides the closest approximation to uniform precipitation rates which are so necessary at present for measurements made to study the relationship between rainfall intensity and the power of the echo signal. Efforts are being made to monitor the received power of storm echo signals continuously on two different frequencies [12, 42] (see Fig. 16). The radars are directed and ranged over a recording rain gage to establish relationships between rate of rainfall and echo-signal power. Best correlations between the two have been found during steady rainfall associated with warm-frontal conditions.

3. *Occluded front.* Little has been published concerning radar storm detection during occluded frontal conditions. Because of the complexity of the frontal system few generalizations can be made concerning precipitation types or patterns. Some situations show widespread stratified precipitation, others show just as widely spread convective cells. An excellent place to study fronts of this type would be in Norway or in British Columbia, where radars sited near the coast could be directed westward over the oceans, and observations could be made of fronts unmodified by topography.

B. *Orographic Precipitation.* This type of precipitation, being associated with uneven terrain, is somewhat difficult to observe on PPI scopes if the antenna is directed horizontally. Increase of the antenna elevation angle is necessary to eliminate echo signals from the terrain causing the precipitation. There are no unique

features in this type of precipitation except that, on occasion, it can be fairly uniform. Because of this factor, this type of precipitation might be useful for relating storm echo signals to precipitation intensity.

C. *Hurricanes and Typhoons.* Radar detection of hurricanes and typhoons is even more dramatic than radar detection of cold-front squall lines [66]. The rain-distribution pattern as seen on a PPI scope is illustrated in Fig. 12. It is startling in its similarity to the symbol ϕ

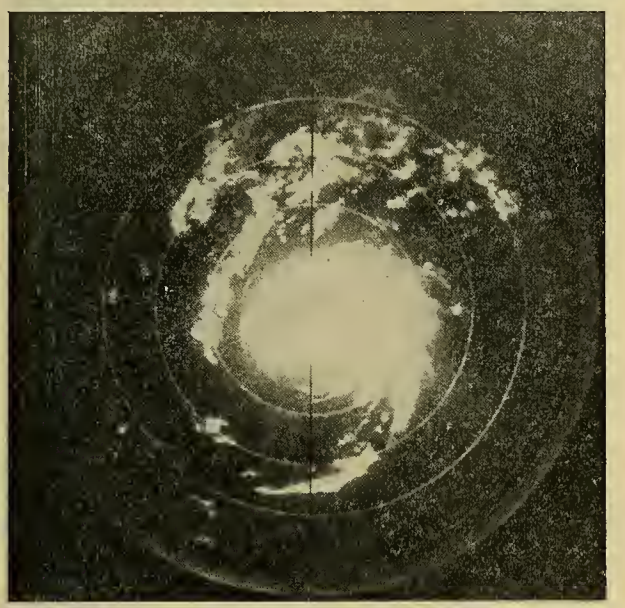

FIG. 12.—Hurricane of 18–21 Sept., 1948. PPI-scope photograph made just prior to passage of the eye over the radar at Key West, Florida. (0900 EST, 9/21/48, range about 125 miles.) (*Official U. S. Navy Photo.*)

which has been chosen to indicate the position of hurricane centers on weather maps.

The spiral rain bands visible in Fig. 12 have been observed in all hurricanes and typhoons detected by radar. These bands move slowly around the center; the cells in the bands move along the bands and into the center in a counterclockwise direction (in the Northern Hemisphere) [37]. As yet, no relationships between the band movement and winds aloft have been established, because of the difficulty of obtaining winds-aloft observations during storms of this type. It is possible that radar will also provide the solution to this problem.

From Fig. 12, it will be noted that a very definite position can be found for the center of rotation as far as the rain is concerned. There is evidence that this center detected by radar does not always coincide with the center of low pressure. Also, a clear "eye" may or may not be present, depending upon the intensity of precipitation at this point.

Radar hurricane detection is probably of greatest value in connection with aircraft hurricane reconnaissance. Early detection of the storm, while it is still far from land and out of range of land-based radars, is considerably facilitated by the use of air-borne radar equipment. It is not necessary for the aircraft to penetrate the storm in order to locate the position of the eye; this often eliminates the necessity of flying under extremely hazardous conditions [57].

By the time a hurricane is within range of land-based radars, its direction and speed are usually well known. However, these radars are useful for precise determination of the storm's position at any instant, and provide very valuable up-to-the-minute data on the storm [58]. It has been found by experience that the best wave length for use in hurricane detection is about 10 cm, at least from the standpoint of rain attenuation. Eventually it may be possible to measure wind speed in different portions of hurricanes by means of radar, and to obtain other clues concerning the structure of these severe storms. The great decrease in loss of life from hurricanes in the southeastern United States is due to highly accurate data concerning movement and velocity of the storms and the early warning of their existence. The importance of the part radar plays in the joint Air Force, Navy, and Weather Bureau hurricane program cannot be minimized.

The importance of radar as a research tool for studying the structure of hurricanes should not be overlooked. The possible use of this new presentation of the storm, in which the rain relative to the wind and pressure distribution may be known, should greatly enhance our understanding of hurricanes. Much work is yet to be done; for example, few, if any, RHI-scope photographs of hurricanes have yet been taken. These would give information concerning convective activity, and whether or not there are shearing forces present as indicated by sloping of the rain cells. It may well be that some of the spiral patterns shown in Fig. 12 are due to the shear and not entirely an indication of the shape of the convective cell.

D. *Instability Showers.* 1. *Air mass.* Air-mass precipitation, being largely convective in nature, generally shows somewhat finer detail in its echo signals on the PPI scope (Fig. 13) than does warm-frontal precipitation. There is an even greater lack of symmetrical arrangement of the convective cells; parallel bands (see Fig. 9) are rarely detected. Shear is rarely observed,

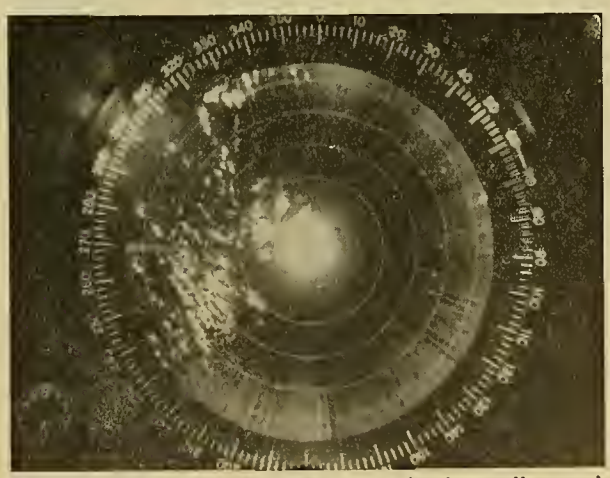

FIG. 13.—Group of air mass precipitation cells moving north-northeast. Note showery appearance in contrast with Fig. 7. Precipitation was in the form of rain showers. Some tendency for band formation is evident. Passage of sharp cold front from west occurred about six hours after this photograph was taken. (1830 EST, 3/8/50, X-band radar, range 60 miles, 10-mile markers.) (*M.I.T. Weather Radar Research.*)

because winds aloft are usually fairly uniform. Determination of the direction and speed of the cells is generally quite simple, especially if the cells are fairly well defined so that their positions may be determined at ten or fifteen minute intervals.

It has been observed in the northeastern United States that warm-sector precipitation, besides being broken into small convective cells, usually consists of rather large, isolated areas. That is, a precipitation area of roughly elliptical shape, perhaps 100 miles in extent, will be broken up into small-size cells of 1–5 miles diameter. The large areas follow each other through the region covered by the radar sweep, with almost no isolated showers occurring between them or on the fringes of the main groups.

2. *Thunderstorms.* The appearance of a thunderstorm echo signal on PPI and RHI scopes is similar to that shown in Fig. 6. These storms, because of their great height, are detectable at greater distances than any other type of precipitation. Well-developed storms have been detected at distances over 300 miles, although for a radar less than 100 ft above the surrounding country, the usual maximum range is nearer 200 miles. Radar played an important role in the extensive research program on thunderstorms in Florida and Ohio [60–62].

Using radar it is possible to determine when a given convective cell reaches the thunderstorm stage. Lightning gives a characteristic echo signal on A and R scopes as shown in Fig. 14 [39]. The echo signal from

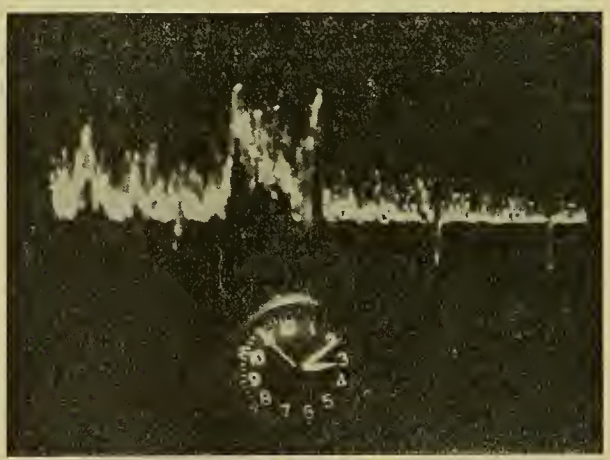

Fig. 14.—Photograph of R scope showing lightning echo signal. Low intensity echo signal from precipitation to right and left of lightning echo signal which persisted for about ¼ sec. (1510 EST, 7/20/49, S-band radar, azimuth 320°, range 50–58 miles, 2-mile markers.) (*M.I.T. Weather Radar Research.*)

lightning is transient, usually lasting less than ½ second, but is easy to detect visually on the scopes. Reflection or scattering evidently takes place from the dielectric gradient established by the stroke, but the mechanism is somewhat uncertain. It should be made clear that it is an actual radar echo signal which is detected, not a radio-static signal emitted by the stroke itself. This is proven by the fact that the lightning indication always occurs on the scope at the range and azimuth of the storm echo signal.

The best presentation of thunderstorm echo signals is found on the RHI scope, as shown in Fig. 15. Again, the reader is cautioned to keep in mind the 10:1 vertical

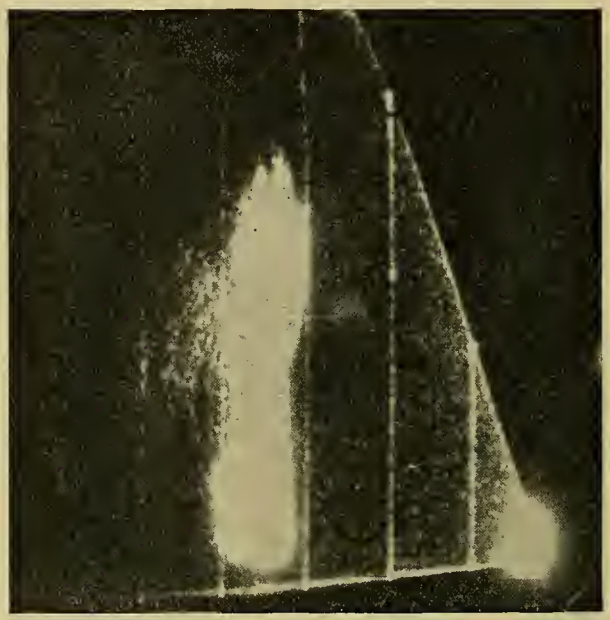

Fig. 15.—Cross section along an azimuth through a thunderstorm. Height of top about 20,000 ft. Note multiple towers at the top, and weak echo signal about 15,000 ft. (1645 EST, 7/31/47, X-band radar, azimuth 350°, range 60 miles, 10-mile markers.) (*M.I.T. Weather Radar Research.*)

expansion of this particular scope. Since this is a fairly representative example of the well-developed mid-latitude thunderstorm, it may be concluded that the precipitation core of such thunderstorms is approximately cylindrical in shape, and is about as wide as it is high. When analyzed by means of accelerated time-scale moving pictures, the RHI-scope echo signals of thunderstorms show discrete volumes of hydrometeors which may move upwards as well as downwards. These probably correspond to the heavy bursts of rain or hail which are occasionally experienced at the surface during intense thunderstorms. Precipitation strong enough to give intense echo signals at appreciable distances from the radar has occasionally been detected at heights exceeding 50,000 ft in mid-latitude thunderstorms. Somewhat rarely the precipitation echo signal will form in the typical anvil shape which the thundercloud itself assumes.

Aircraft have encountered hail in the regions giving intense echo signals, but as yet no reliable means exists for distinguishing the hail from rain or snow by means of radar. A recently developed technique of signal fluctuation analysis, which is discussed in detail under the section on analysis of the storm echo signal, has promise of being a powerful method of detecting the more turbulent regions in thunderstorms.

General Remarks. Because of the comparative recency of applications of radar as a meteorological observation instrument, questions concerning detection of some meteorological phenomena must remain unanswered for the present. Eventually it may be ex-

pected that descriptions of radar detection of such phenomena as tornadoes, waterspouts, dust storms, and other atmospheric anomalies will be available. Forest fires sometimes appear as areas similar to weak rain-echo signals on PPI scopes. The lack of vertical development, coupled with other meteorological information, is usually sufficient to provide correct identification. It is unknown at present whether the temperature gradients or the cinders and ash carried aloft by convective currents cause the echoes.

The small droplet size in fogs and drizzle make these hydrometeors poor targets for radar detection at 3- and 10-cm wave lengths. However, detection by radars operating on wave lengths near 1 cm (K-band) is common. Because of the scarcity of K-band radar, which has not been developed much beyond the laboratory stage, little information is available concerning radar fog and drizzle detection. This equipment may eventually prove valuable for reporting the rate of approach or development of coastal fogs.

The use of radar for determining meteorological conditions in the troposphere has been suggested by Friend [27]. An interesting application of K-band radar to meteorology has recently been developed by the Weather Radar Section of the United States Army Signal Corps Engineering Laboratories [7, 28]. This highly specialized radar system was designed with a vertically directed beam for the purpose of cloud base and top detection. The radar is equipped with an A scope, but in order to provide a permanent record the video signal is fed into a special slow-rate facsimile recorder in such a manner that a vertical time cross section of the clouds is plotted.[3]

Radar provides an ideal means of studying the results produced by seeding of clouds with CO_2, silver iodide, etc. If the seeding is done by aircraft, the position of the plane is known, and if particles of precipitable size form, such vital information as time of formation, height, and position are readily available from the radar scope indications [56].

Another type of echo which has been ascribed to atmospheric conditions [23] has been given the picturesque designation of "angel." "Angels" are most commonly seen with the cloud-detection radar described above and are strong echo signals with no *visible* cause. They occur most frequently in the lower levels of the atmosphere, preferring heights near inversions. They have been ascribed to insects too small to be seen, strong temperature and moisture gradients, and regions of high ionization. Their cause is not yet known.

ANALYSIS OF THE RADAR STORM-ECHO SIGNAL

Besides visual inspection of the scopes, there are other very powerful methods of studying the echo signals resulting from storms. Most of this work is still in the preliminary stages, but enough has been accomplished to warrant description of present techniques.

The Pulse Integrator. Echo-signal intensity may be measured at the radar in at least three different ways: (1) by the intensity of the spot on a PPI or RHI scope; (2) by the amount of vertical deflection on an A or R scope [32]; and (3) by the echo-signal voltage returned to the radar before it is presented on the scopes. The first method must be rejected at present because of fundamental difficulties as well as technical problems. The second method is commonly used, but some doubt exists as to the accuracy of this method and the possibility of observer bias. The third method employs a device designated as the "pulse integrator."

The pulse integrator [70] measures electronically the average strength of the pulsating, fluctuating storm echo signals over a short interval of time. This interval, which determines the number of pulses averaged, may be varied to suit conditions, but from two to four seconds has been found satisfactory. The output of the pulse integrator may be fed into any of several types of visual meters or recorders so that a permanent record is made. The precipitation-echo pulse integrator records are calibrated by feeding signals of known strength into the antenna and comparing the readings. This method of echo-signal intensity measurement is entirely free of observer bias and variability, but results obtained so far have not been satisfactorily correlated with rainfall intensity measurements in an absolute

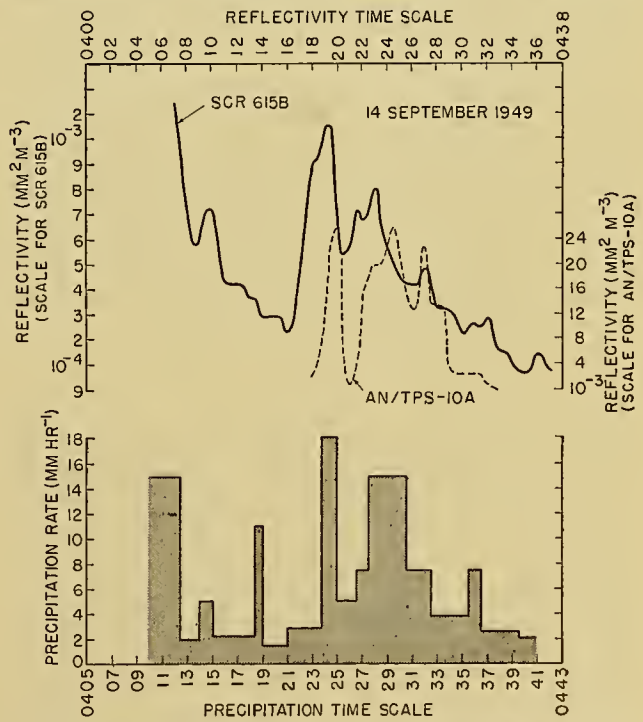

FIG. 16.—Pulse integrator records plotted against precipitation intensity. Echo-signal power records from X-band and S-band radars were converted to units of reflectivity and matched with the precipitation rate as measured with a modified Fergusson rain gage. Note the time-scale shift of about 5 min, used to improve the match between the records. This is explained by the time which elapses before a particularly heavy "burst" of rain, falling from a point well up in the beam, reaches the surface. (*M.I.T. Weather Radar Research.*)

3. For records showing typical results, see Figs. 8 and 9 in the article, "Instruments and Techniques for Meteorological Measurements" by M. Ference, Jr., pp. 1207–1222 in this Compendium.

sense. Fair-to-good *relative* correlations have been found. Figure 16 shows pulse-integrator records of two radars (with operating wave lengths of 3 and 10 cm) compared with a rainfall intensity record obtained from a modified Fergusson rain gage located 12 miles away. The two sets were directed and ranged over the gage. Fluctuations of the signal intensity of both radars show good agreement with variations of the rainfall intensity. The differences between the two radar pulse-integrator curves are due to differences between the radars (frequency, beam width, attenuation, and pulse length), and perhaps to slight errors in orientation and ranging.

Radar Signal Spectrograph. It has been shown both by mathematical analysis and by observation [30; 65, p. 35] that *relative* motions of scattering particles in *range* establish audio and sub-audio frequency fluctuations in the power return of radar storm echo signals. This is caused by the changing phase relationship, or interference patterns, of the return radiation from the separate particles as they move with respect to one another. This relative motion may take place in at least four different ways:

1. Random motion of the scattering particles.
2. Differences in fall velocity of the particles.
3. Small-scale turbulence.
4. Horizontal air streams moving in different directions or with different velocities, or both.

One type of radar signal spectrograph—designated by the abbreviation "rasaph"—is an electronic instrument designed to scan a range of frequencies from 3 to 300 cps and to record on a meter the average power of echo signals at any interval within this range. If the relative motion of the particles is random, the peak signal intensity will lie at zero cycles. As a great deal of random relative motion always exists, the spectrograph trace invariably shows a pronounced peak at the lowest frequencies observable. If large numbers of hydrometeors are moving at some definite velocity with respect to another large group (for example above and below a shear zone), a definite frequency is established in accordance with the following relation:

$$\nu = 2u/\lambda,$$

where ν = fluctuation frequency, u = difference in velocity (along a given azimuth from the radar) between the two groups, and λ = operating wave length of the radar. As is apparent from this relationship, high relative velocities between particles can cause high fluctuation frequencies. However, with pulsed radar there is a limit to the maximum frequency that can be observed; frequencies higher than half the pulse repetition frequency of a particular radar cannot be observed by that radar. (Pulse repetition frequencies usually lie between 200 and 1000 per second.)

Only relative, not absolute, velocities may be determined from the recordings of this instrument. Not enough observations have been made at this writing to enable accurate evaluation of its usefulness, but the following are a few potential uses which it may have:

1. Determination of turbulent conditions in storms.
2. Determination of the distribution of fall velocity for various kinds of hydrometeors. From this, the drop-size distribution may be obtained.
3. Determination of the behavior of freely falling particles as they descend through regions of wind shear.
4. Information concerning the horizontal velocity distribution of hydrometeors may be obtained if wind velocities are known from rawin observations.

Storm Echo Signal Contouring. Early investigators in the field of radar storm detection learned that while no simple relationship between rainfall intensity and echo-signal power existed, regions of more intense precipitation in a given storm could be located with fair accuracy by reduction of receiver "gain" to a point where only the strongest echo signals showed on the PPI scope [36]. By plotting the outline of the storm between successive equal gain reductions, the storm echo signal was reduced to a number of contours; each contour represented a level of equal echo-signal power. In general, it was found that the strongest echo signals, which were loosely associated with more intense rainfall, were near the center of storm-cell echo signals. It was then suggested [5] that the radar be made to do the work of contouring, and to accomplish this in a coarse fashion it was necessary only to block the echo signals of greater than certain power so that they would not appear on the PPI or RHI scopes. Then the area of strongest echo-signal power remained dark in the center of the storm cell presentation. To verify the presence of precipitation in this area, the blocking circuit could be shut off and the scope then regained its normal appearance. Only two levels of signal power could be discriminated by this technique, but this was sufficient for initial tests.

The American Airlines System tested the usefulness of this technique for aircraft storm avoidance, with interesting results [11]. An experimental test aircraft was equipped with an X-band radar modified to produce storm contouring when desired. This plane was deliberately flown into thunderstorms to test the reliability of this equipment for detection of areas of heavy turbulence and precipitation. It was found, at least for the storms penetrated, that areas of heavy turbulence did not necessarily coincide with regions of intense echo signal, as indicated by the contouring. Turbulent regions tended rather to lie where the radar indicated that *steep gradients of rainfall intensity* existed, as shown by narrow, closely packed contours. The contouring proved quite reliable for determining areas of heavy precipitation.

One difficulty with this system is contour distortion by precipitation attenuation, although this is not considered very serious. When X-band (3-cm) radars are used, this is a factor to be considered, because of the heavy rainfall that occurs in most thunderstorms. Additional distortion occurs as the aircraft approaches the storm, because the echo-signal power from the nearest particles increases more rapidly than from those on the far side of the storm, as a result of the range attenuation effect. Studies of these distortions are in progress in

order that the true characteristics of the storm may also be determined from the analysis of the echo signal presentation.

Radarscope Photography. Photography plays an important part in analysis of the storm echo signal because it is the only fully developed, practical method of obtaining accurate and permanent records of the scope displays [40]. Radarscope photography is not difficult; standard films, lenses, apertures, and shutter settings are quite sufficient to produce excellent results. In some respects, photographs of PPI and RHI scopes are more satisfactory for analysis than direct inspection of the scopes, because storm echo signals on all parts of the scope photograph may be studied in relation to each other. On the actual scope only a comparatively small portion is available for study at any instant, unless the antenna is scanning quite rapidly.

Only the sweep trace registers on the negative; the afterglow or persistence of the screen, while visible to the eye for many seconds, does not appreciably affect the film. For a complete PPI photograph the sweep must revolve through 360° during the time the shutter is open in order to enable the entire display to be photographed. With high-speed films (either panchromatic or orthochromatic), aperture openings of the order of f/6.3 are required to obtain photographs with scope-intensity settings comfortable to the unprotected eye.

The most dramatic application of photography to radar storm detection is obtained through cinematographic techniques. Using standard or special motion-picture cameras, one frame of the film is exposed for each successive and complete 360° scan of the antenna. This scanning process may take from 5 to 30 seconds to complete, depending upon the design of the radar. When the film is projected at the normal rate of about 16 frames per second a time-scale contraction of several hundred results. Consequently twenty-four hours of radar storm presentations may be viewed in five or ten minutes.

With this technique the movement and development of precipitation echo signals are beautifully demonstrated. It becomes possible to evaluate accurately such factors as cell life and growth, which may otherwise be studied only by means of laborious and time-consuming plots. This photographic technique has been applied to RHI as well as PPI scopes, with equally interesting results. By this method it has been observed that large numbers of hydrometeors are carried upwards, sometimes with high velocities. This is especially common in the early stages of development of active convective cells.

Another photographic technique which seems to be especially applicable to radar storm observation is photography of PPI and RHI scopes with Polaroid Land Camera film. Using this film, it is possible, without the use of complicated equipment, to have a finished print about one minute after exposure. Tests have shown that these prints are of sufficient contrast to permit accurate measurement of the movement and development of the precipitation-area echo signals. This technique should prove of great assistance to forecasters employing radar for storm observation, since it provides an accurate permanent record of the changes taking place.

Control of Polarization. The energy radiated by the radar is normally linearly polarized either in the horizontal or vertical plane. Only that portion of the received echo energy which is polarized in the same plane is accepted by the receiving antenna. Small raindrops have a unique property which distinguishes them from all other targets, that of perfect rotational symmetry with the line of sight [49, pp. 84–85]. As a result of this symmetry, the intensity and phase of the scattered radiation are not functions of the plane of polarization of the incident radiation.

To make use of this property, the linear polarized energy is altered to circular polarization by reorientation of dielectric slugs inserted in the antenna wave guide, or by "quarter-wave plates" placed in front of the parabolas. The circularly polarized energy back-scattered by spherical raindrops will be reconverted to linear polarization by the plate or slug, but in a direction perpendicular to the original plane of polarization. Therefore it will not be accepted by the radar, and is not presented on the scopes. That portion of the circularly polarized radiation which is scattered by asymmetrical targets will undergo a change of the *sense* of rotation of the vector representing the field of radiation. This back-scattered energy has no special preferred plane of polarization upon reconversion from circular to linear polarization; hence some of the energy will be polarized in the proper plane and will be accepted at the antenna.

Experimental tests have verified the usefulness of the theory outlined above for the detection of ground targets in the presence of rain [1]. As yet, it is not known conclusively whether the technique can be used to differentiate rain from snow particles. It should be pointed out that while the determination of the absolute power of an echo signal is at present quite difficult, measurement of the relative difference in signal strength of two echoes may be accomplished with relative ease and accuracy by means of the pulse integrator. If the back-scattered energy from a region containing both rain and snow is passed through a quarter-wave plate or dielectric slug and the percentage decrease in echo-signal strength of the two regions is unequal, a positive method of identifying the type of hydrometeors by radar is possible.

THE FUTURE OF RADAR STORM DETECTION

A discussion of the future of radar storm detection may logically be divided into three topics: possible future uses for forecasting, possible future equipment development, and possible use for research in physical meteorology. The three are somewhat interdependent, of course.

Use in Forecasting. The value of radar for weather observation can be greatly enhanced by increasing the range through suitable location of the systems. This can be done in two ways: (1) by placing radar sets on

high mountains, and (2) by flying them in aircraft. In either case, the scope presentations would have to be transmitted to weather forecasters; methods for accomplishing this are discussed later. Considering the capabilities of present systems, the entire United States could be covered by about thirty carefully sited ground radars.

With such extended coverage, a weather forecaster would have information concerning the distribution of precipitation in at least the major portions of cyclones. With this information he should be able to observe intensity changes and the speed of the entire system with considerable ease and precision. He should be able to keep a continuous watch on precipitation over a large area and perhaps forecast rainfall totals with accuracy at specified locations. From information gained from previous observations, he should know approximate visibility conditions relative to the precipitation areas. He should be able to determine wind distribution in the lower levels of the troposphere from the movement of the precipitation cells, almost from minute to minute. By means of signal analysis he should be able to differentiate between rain and snow in many regions, and be able to determine zones, kinds, and amounts of icing.

Radar should prove useful as a method of verifying forecasts; it should also be of assistance in the preparation of long-range precipitation forecasts for specific points by providing more information on the effect of topography on precipitation patterns. In addition, from the standpoint of icing and turbulence, it should be of great help in the selection of best flight paths through unavoidable storm areas.

Activities other than aviation should have a more than casual interest in the information which radar can yield. For example, electric power companies, by observing the progress of thunderstorms, should be able to anticipate power-demand peaks in various communities in the path of storms and adjust line loads accordingly. Also, accurate short-range forecasts for various sports and outdoor activities which may be affected by showers are already available in certain areas, and it may be expected that demands for this service will increase in the future.

Because of the ease of radarscope interpretation in location of the position of precipitation areas, television may be an excellent medium by which to convey the image of the PPI scope to the citizen for his own interpretation. Radarscope movies have already been shown several times on television programs in the Boston area.

A possibly valuable application of radar storm detection exists in the field of water conservation, flood control, and irrigation [20, 54, 56]. If rainfall intensity can be even approximately correlated with the intensity of the PPI storm echo image, it should be possible to measure with useful accuracy the total rainfall caused by a storm in a given area within range of the radar. Critical catch basins could be studied by masking all other portions of the PPI scope and integrating the light emitted with a photoelectric cell. If developed, this technique might also be applied to measure the amount of snowfall in mountainous regions, thereby eliminating the need for snow-survey teams in many areas.

Equipment Development. The usefulness of radar for storm detection can be greatly amplified by improving equipment as well as observational techniques. Many instruments and accessories developed for special applications have not yet been tested for their utility in radar storm detection work. It behooves the radar meteorologist to be alert for new developments in such fields as instrumentation, radar, television, communications, and photography, as well as meteorology. Also, he should be ready to suggest improvements or modifications which will increase the utility of radar for meteorological purposes. For example, following are two suggested modifications which would probably facilitate the observation of precipitation echo signals:

Horizon-to-Horizon RHI Scope. This scope, used in conjunction with an antenna which scans from horizon to horizon through the zenith, would greatly improve the cross-section display presently available to the observer. This type of scan, as well as increasing the scanned volume by 100 per cent, would appreciably decrease the time needed for observations in all directions.

Gated Range-Height Indicator. This scope would remove the necessity for vertical expansion of the RHI sweep by limiting the range presented on the scope to 15 or 20 miles. The maximum indicated altitude could be adjustable from 15,000 to 50,000 ft. The scope could be controlled in range to present any 15- to 20-mile range increment from 0 to 100 miles. In this manner the true proportion of range to height would be preserved while the same accuracy would be available for altitude measurements. There is no serious objection to limiting the range in this manner, for experience has shown that only rather limited portions of the RHI scope are of interest at any one instant.

A certain type of radar receiver which was designed for nonmeteorological purposes might be invaluable for radar storm detection [49, pp. 553–554]. This receiver, instead of giving linear amplification of the echo signal, amplifies logarithmically, the echo signals receiving less and less amplification as they increase in power. By use of these "linlog" receivers, or others of similar characteristics, a far greater range of echo-signal power lies within the limits of scope presentation for one particular gain setting. This type of amplification might be useful in the presentation of storm echo signals which may have a vast range of power at any given time. Over a short distance or period of time storm echo signals may cover a range in excess of 60 decibels, from minimum detectable signal to signals which "saturate" the receiver.

At present, one of the main restrictions on the use of radar for storm-detection information by weather forecasters is the lack of suitable means of disseminating the scope information to all persons interested in it. There are several ways in which this could be accomplished [49, pp. 726–735].

1. Verbal description, or code.
2. Television of the PPI scope.

3. Facsimile transmission of the PPI-scope display.

4. Remote scopes, distant from the radar, which get the video information either by wire or radio signals.

The first method is used at present and will continue to be the most practical for a while [59]. The fourth method has been used for remote presentation of scope information for military purposes; but it is expensive and somewhat limited in range [71]. Television is out of the question for the present and the immediate future because of lack of facilities.

Facsimile transmission of PPI photographs presents intriguing possibilities: first, facilities for facsimile transmission are presently available at many military and civilian weather stations; second, the facsimile record presents the recipient with a permanent picture of the scope (which television and remote scopes do not); and third, facilities for facsimile transmission between ground and aircraft have been nearly perfected. The main difficulty at present is getting a PPI picture to transmit, although this problem is practically solved in several ways. One way is by use of the fast development techniques (Polaroid Land Camera). A second way is by use of PPI tubes with very slow decay time phosphors. A third way is through the use of fast special papers such as Alphax.[4] Other more elegant and elaborate methods have also been suggested.

Research in Physical Meteorology. It is anticipated that radar will provide useful information concerning the structure and behavior of that portion of the atmosphere which is not covered by either micro- or synoptic-meteorological studies. We have already observed with radar that precipitation formations which are undoubtedly of significance occur on a scale too gross to be observed from a single station, yet too small to appear even on sectional synoptic charts. Phenomena of this size might well be designated as *mesometeorological.*

In addition to supplying observations in this mesometeorological region, radar is also expected to be of assistance to the physical meteorologist in his studies of the mechanism of precipitation; of the size and number distribution of hydrometeors; and of the behavior of hydrometeors under various conditions of turbulence. It may also provide him with clues concerning the processes of waterdrop and snowflake growth, coalescence, and evaporation.

Sincere and deep-felt appreciation is expressed to members of the M. I. T. Weather Radar Research Project; their helpful comments, corrections, and suggestions were of invaluable assistance in the preparation of this article. For permission to use photographs, the author is indebted to the U. S. Navy Department and to the M. I. T. Weather Radar Research Project operating under Signal Corps Contract W36-039-sc-32038.

THEORY AND OBSERVATION OF RADAR STORM DETECTION

By RAYMOND WEXLER

Imperial College of Science and Technology

Theory of Storm Detection

The basic problem in radar storm detection is the absorption and scattering of a plane electromagnetic wave by a sphere. This problem was first studied by Mie [8] who analyzed the absorption and scattering of light from gold particles suspended in a liquid. Application to the theory of the detection of precipitation was first made by Ryde [11]. The Canadian Army Operational Research Group showed that the theory was valid, at least in respect to order of magnitude, by measurement at the ground of the drop size in rainstorms observed by radar. More exact laboratory verification is presently being undertaken at Harvard University.

The equation for detection of a particle of scattering cross section σ at distance R by electromagnetic energy propagated isotropically from its source is given by

$$\frac{P_r}{A} = \left(\frac{P}{4\pi R^2}\right)\left(\frac{\sigma}{4\pi R^2}\right), \tag{1}$$

where P_r is the power received by the radar and P is the peak power emitted by the radar antenna of effective area A. If the radiation is directional, a gain factor must be included in the numerator of the right-hand side of the equation. This gain is derived from the fact that the radiation is propagated as a beam from the antenna and is G times the radiation from an isotropic source. Because of the fact that the beam is normally completely intercepted by the cloud at ranges under 75 miles, the directional aspect need not be considered.[1] The term $P/4\pi R^2$ will be recognized as the power density of the propagated radiation, and P_r/A the power density of radiation received at the antenna. The radar cross section σ is defined by the equation. It is the area normal to the radiation such that if all the power incident on it were scattered isotropically it would give, at the receiver, the same power as the observed echo.

For complete interception of the beam by the cloud, the equation must summate the total number of scatterers in the volume of air illuminated by the pulse. This volume V may be considered to be a spherical shell at radius R of half a pulse-length thickness:

$$V = 4\pi R^2 h/2, \tag{2}$$

where h is the pulse length of the radar. The reason for the factor 1/2 is that energy is emitted from a time $t = 0$ to $t = h/c$, the pulse duration, where c is the velocity of light. In that time the energy must make a round-trip distance $2R$. The maximum minus the minimum distance illuminated by one pulse is then

$$2(R + \Delta R) - 2R = (t + h/c)c - tc,$$

whence the distance illuminated by the pulse is $\Delta R = h/2$.

If within a unit volume there are n_i scatterers of cross section σ_i all located at random within the beam, then the equation becomes, by combining (1) and (2),

$$P_r = \frac{PAh}{8\pi R^2} \sum_i n_i \sigma_i. \tag{3}$$

If the beam is not completely intercepted by the cloud, the percentage of the beam so intercepted must be inserted on the right-hand side of equation (3).

The equation holds for scatterers randomly located within the beam on the assumption that the distances between drops are large compared to the diameter of the drops and the wave length of radiation. If there were forces causing the drops to fall coherently in pairs, the power received would be twice that indicated by equation (3). However, the assumption of random positions of the drops in a rain cloud appears to be justified.

The equation for storm detection including the effect of attenuation is

$$P_r = \frac{PAh}{8\pi R^2} \sum_i n_i \sigma_i 10^{-0.2KR}, \tag{4}$$

where K is the attenuation in decibels per unit distance. If P_r is the minimum detectable signal of the radar, a figure known for most sets, the distance R in (4) represents the maximum range of detection for the target $\sum_i n_i \sigma_i$.

From Mie's study of the diffraction of electromagnetic waves by a sphere, it is possible to determine the radar cross section in the form of an infinite series of spherical Bessel functions of parameter $\pi m D/\lambda$, where m is the complex index of refraction for the precipitation at a given wave length λ, and D is the diameter of the drop. For values of $D/\lambda \leq 0.05$, the Rayleigh law of scattering is approximately valid:

$$\sigma_i = \pi^5 \left(\frac{\epsilon - 1}{\epsilon + 2}\right)^2 \frac{D_i^6}{\lambda^4}, \tag{5}$$

where ϵ, the dielectric constant, is equal to the square of the index of refraction. At $D/\lambda = 0.08$, the value of σ is about 0.8 that of Rayleigh; it then rises to a value twice that of Rayleigh at $D/\lambda = 0.2$, beyond which it undergoes rapid and large fluctuations about a constant value near $\pi D^2/4$, the radar cross section of a large conducting sphere. This behavior varies somewhat according to the wave length, but qualitatively it char-

1. For a derivation using the directional aspect see, for example, Wexler and Swingle [16].

acterizes the scattering function in the microwave region. Figure 1 shows the ratio of true scattering to Rayleigh scattering for 1.25 cm and 3 cm as computed

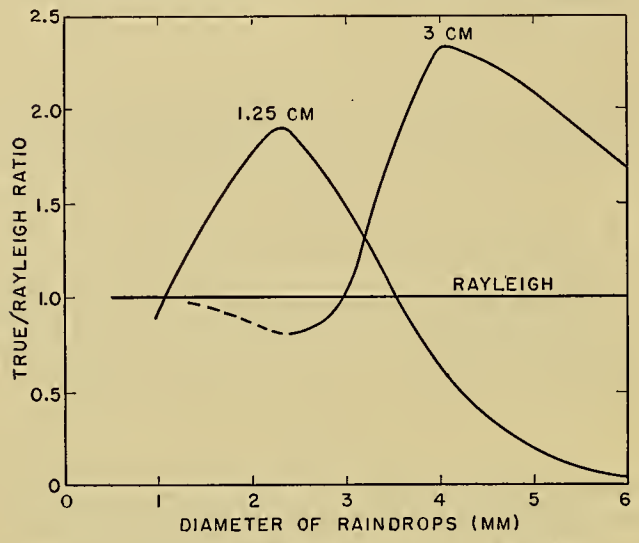

Fig. 1.—Ratio of true scattering to Rayleigh scattering.

by Haddock (unpublished) from calculations made by the National Bureau of Standards. For a wave length of 10 cm, Rayleigh scattering holds almost exactly.

Table I. Radar Cross Section (σ) for Various Rain Intensities
(in 10^{-8} cm^2 per cubic centimeter)

Rainfall intensity (mm hr^{-1})	λ = 1.25 cm		λ = 3 cm	
	Ryde	Haddock	Ryde	Haddock
0.25	0.534	0.570	0.0115	0.0143
1.25	6.58	6.50	0.116	0.156
2.5	18.2	19.5	0.337	0.459
12.5	162	176	4.57	5.59
25	390	415	14.5	16.8
50	901	968	46.2	49.1
100	2000	1920	148	139
150	3130	2890	289	238

Table I gives the radar cross section for different rain intensities based on the mean drop-size distribution of Laws and Parsons [6], as computed separately by Ryde and Haddock. In view of the complexity of the computations, the disagreement is not surprising.

Refraction

In passing through the atmosphere the radio waves are subject to refraction and thereby travel a curved path. The curvature of the ray is stronger the greater the gradient of the refractive index perpendicular to its path (the ray tends to curve towards higher refractive index). In a standard atmosphere of 60 per cent relative humidity the curvature of the ray in the lowest few kilometers of the atmosphere is about one-quarter the curvature of the earth. In tropical regions the curvature is greater; in Florida during summer it averages about 40 per cent of the earth's curvature.

In regions where the vapor pressure decreases rapidly with elevation through a temperature inversion, such as over the trade wind regions of the subtropical high, the curvature of the ray is greater than that of the earth. In such cases the rays, initially nearly horizontal with the earth's surface, may be said to be "trapped" within a narrow layer along the earth and the radar detection of objects near the surface may extend to abnormally long ranges. Generally, however, there is no precipitation on such occasions and, as a result, this "anomalous propagation" is of little importance for storm detection. Occasionally during such conditions, echoes from objects on the surface are detected by the radar and may be mistaken for a rain shower. By careful examination of the A scope,[2] the experienced observer can easily recognize the characteristic fluctuating signal of a rainstorm.

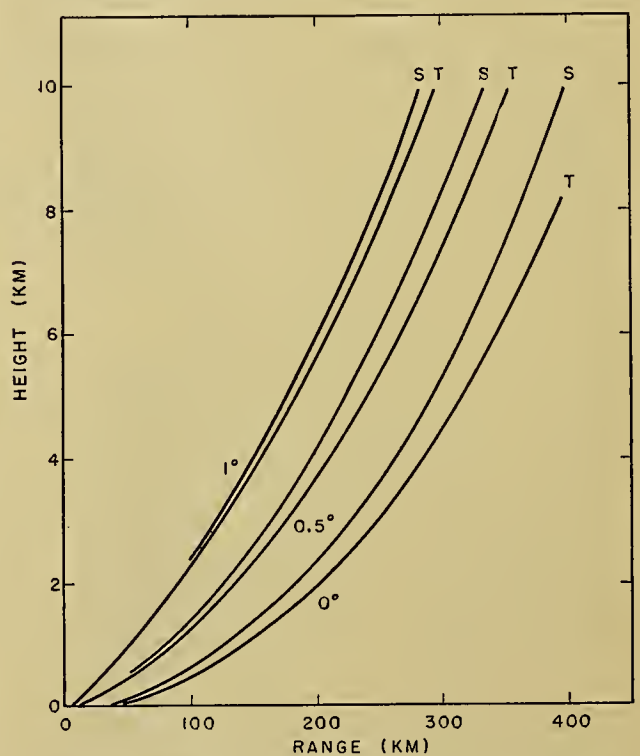

Fig. 2.—Range-height chart for refraction in a standard (S) and tropical (T) atmosphere for elevation angles of 0°, 0.5°, and 1°.

In Fig. 2 a range-height diagram is given for a standard and a tropical atmosphere for rays initially at angles of elevation of 0°, 0.5°, and 1° above the horizontal. As an example of the use of the diagram, it may be seen that a radar with a 1° beam can detect precipitation only between elevations of about 2 to 6 km at a distance of 200 km. If the top of the storm were at 4 km only one-half of the beam would be intercepted at that range.

It is evident that a serious deterrent to the detection of precipitation over long ranges is the fact that beyond a distance of about 200 km (varying from summer to winter) the upper portion of the beam is above most storms, and even at shorter ranges much of the beam

2. On the A scope the abscissa is distance and the ordinate is the relative signal strength at the receiver.

is detecting those portions of the storm which give relatively weak echoes.

Attenuation

Attenuation of microwaves is caused by absorption of oxygen and water vapor in the atmosphere and by absorption and scattering from cloud and precipitation. The water vapor molecule has an electric dipole moment which interacts with the electric field of the radiation and has resonance at 1.33 cm. A stronger absorption band at a wave length of less than 0.2 cm also contributes to the attenuation. The oxygen molecule has a magnetic dipole moment which interacts with the magnetic field of the radiation with resonance at 0.5 cm. Because of the uncertainty of the line breadths of the absorption bands, actual values of the oxygen attenuation are known only for certain regions. Table II gives Van Vleck's [12, 13] values of the attenuation

Table II. Attenuation* Due to Oxygen

Wave length (cm)	Oxygen	Water vapor
1	0.014 -0.036	0.071
1.25	0.010 -0.026	0.21
3	0.0072-0.018	0.0046
10	0.0066-0.014	0.0031

* In decibels per kilometer at 760 mm pressure and 10 g kg^{-1} water vapor, and at a temperature of 293K.

due to oxygen and water vapor. The attenuation due to oxygen is directly proportional to the atmospheric pressure. Van Vleck favors the lower values of oxygen attenuation. At a wave length of 3 to 10 cm the total atmospheric attenuation is therefore 0.01 to 0.02 db km^{-1}.

More serious is the attenuation due to rain. For moderate to heavy rains, computed on the basis of the mean drop-size distribution of Laws and Parsons, Ryde's values for wave lengths of 1.25, 3, and 10 cm are 0.14, 0.023, and 0.003 db km^{-1} mm^{-1} hr^{-1}, respectively. Values of theoretical attenuation given by Haddock in an unpublished paper differ somewhat from Ryde's values.

Considerable error is involved in experimental measurements of rain attenuation since intensity and drop-size distribution vary over the path. In experimental determination of the attenuation at 0.62 cm by Mueller [9] there was excellent agreement with Ryde's theoretical values. Measurements by Robertson and King [10] indicate a scatter of values and give a mean of 0.03 db km^{-1} mm^{-1} hr^{-1} at 3.2 cm. This is much higher than the average theoretical values but within the theoretical limits. For 1.25 cm, Anderson and collaborators [1] found an average attenuation of 0.18 db km^{-1} mm^{-1} hr^{-1} for Hawaiian rainfall. This exceeds Ryde's theoretical maximum values. Reasons for this discrepancy are difficult to see especially since Anderson's experiments appear to be the most careful.

Vertical Structure of Precipitation

Precipitation as observed by radar may be generalized into two categories: showers and continuous precipitation. Continuous precipitation is associated with small vertical velocities of the order of 10 to 30 cm sec^{-1}, while the vertical velocities of showery precipitation may exceed 1 m sec^{-1}. There is, of course, a continuous transition between the two. On an RHI scope,[3] continuous precipitation is characterized by a horizontal layer whereas showers appear as elongated vertical bands. The two types may occur within a few miles of each other and may be found mixed in almost any proportion.

A detailed study of the vertical structure of precipitation has been made by Langille, Gunn, and Palmer [5]. By calibrating the gain of the radar and by assuming that the summation of the sixth powers of the diameters of the drops is proportional to the square of the mass of water illuminated by the beam, they were able to determine lines of equal water content. Some conclusions from these and other observations of the two extremes of precipitation are:

1. Showers

a. Within the space of a mile the liquid water content may change by a factor of more than 100.

b. The liquid water content may be greater aloft than near the ground.

c. Heavier precipitation is generally associated with greater vertical extent of the storm.

d. The motion of the dense portion of a storm (high liquid-water content) is always towards the ground.

2. Continuous Precipitation

a. A bright band, a horizontal layer of high echo intensity 100 m to about 300 m below the freezing level, is an identifying feature of continuous rain. (A separate section below is devoted to the theory and description of this phenomenon in relation to the vertical structure of continuous precipitation.)

b. Radar echoes along the horizontal change less rapidly than echoes from showers.

c. The maximum height of precipitation echoes often remains constant while the rain intensity varies. Such behavior has been observed on both K- and X-band radar with the antenna directed towards the vertical.

The maximum height of the radar echo indicates the level at which particles first approach precipitation size (greater than 0.1 mm) and may vary with the radar. If the radar echo dies off gradually until it is indistinguishable from the noise level, there is no indication as to where the actual top of the cloud may be; but if the echo falls off suddenly (except near the bright band), then it is reasonable to expect that the visual top of the cloud is not far above. The latter type of echo is associated with precipitation from well-developed cumulonimbus clouds, while the former is associated with stratiform clouds and represents a very gradual growth of the precipitation elements.

The maximum height of radar echoes observed in temperate latitudes is found to be 15,000 to 20,000 ft for most widespread winter rains and near 30,000 ft for precipitation from cumulonimbus clouds in summer. The maximum height observed in a thunderstorm at

3. RHI = Range Height Indicator. The abscissa is horizontal range, the ordinate is usually angle of elevation.

Belmar, New Jersey, was 50,000 ft and in Florida it was observed by Byers to be 55,000 to 60,000 ft. Precipitation that reaches the ground as snow generally gives a lower maximum echo height than rain, and snow showers have been observed with maximum heights lower than 5000 ft.

The temperature at the top echo of most mature thunderstorms is generally below −30C. It is at about this temperature, according to W. and E. Findeisen [3], that the number of freezing nuclei become numerous, with large vertical velocities and rapid growth in the high liquid-water content of the thundercloud. However, small thunderstorms have been observed with the temperature at the top echo and the visual top at about −18C [7].

It has been observed that rainfall with maximum echo heights corresponding to temperatures above −9C rarely reaches the ground. The smaller number of ice particles produced at such high temperatures would grow rapidly to precipitation size, drop out of the cloud, and evaporate in the unsaturated air beneath. With greater vertical extent of the cloud above 0C, more numerous ice nuclei are produced which grow to precipitation size over a larger height interval and are numerous enough below the cloud to maintain near-saturated conditions.

Observations of twelve thunderstorms in New Mexico indicate that the first echo from a growing thunderstorm appears at about the −10C isotherm with the top of the cloud at about −30C. The echo then rises rapidly to a height where the average temperature is −30C with the visual top of the cloud at about −32C. Although visual observation of the top is difficult in a degenerating thunderstorm it appears that both the top of the echo and of the cloud descend thereafter.

The Bright Band and Precipitation Growth

A characteristic A-scope presentation of the bright band is shown in Fig. 3. The first intense signal is the transmitted pulse; above that, the weaker echoes from the precipitation are fairly constant in intensity up to the bright band, the intense saturated signal at about 7500 ft. The width of the bright band appears to be less than a thousand feet. Above the bright band the signal falls off gradually and disappears at about 15,000 ft.

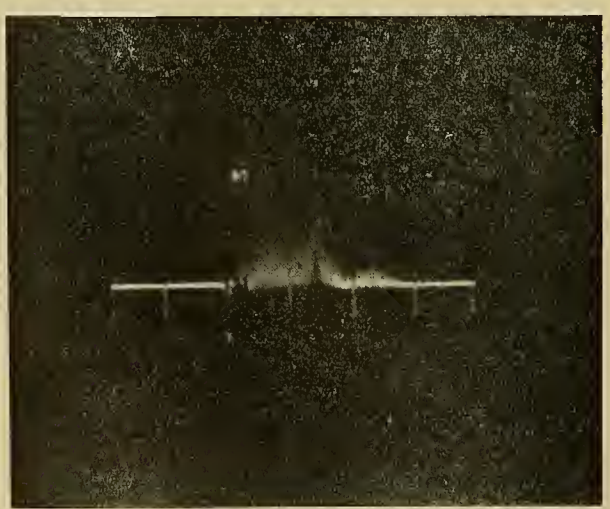

Fig. 3—Bright band observed at Belmar, N.J., January 26, 1949 by Weinstein [14]. The markers are at 1-mile intervals. The ordinate represents signal intensity.

Observation of the bright band was first reported by the Canadian Army Operational Research Group in 1945. From twelve days of observation it was concluded that the echoes from the bright band were from just below the 0C isotherm. It was observed only in stratified clouds although some vestiges of the bright band, considerably weaker in contrast, have been detected in the final stages of a thunderstorm. In some cases the bright band was observed in some sectors but not in others.

Subsequently, aircraft investigations revealed that immediately above the bright band the precipitation was in the form of snow, in the bright band it was melting snow, and below the bright band it was rain. As an explanation it was surmised that "a melting snowflake is covered by a film of water which causes it to act as a raindrop effectively larger than the size of the raindrop resulting from the complete melting of the snowflake."

Ryde [11] rejected this explanation and offered an alternative theory. At temperatures between −4C and 0C a cloud of individual ice crystals aggregate to form snowflakes, thereby giving increased reflectivity. As a result of this aggregation, the relative intensity was estimated to increase from 1 to 40. As the snowflake melts, the reflectivity is further increased owing to the higher dielectric constant of water as compared to ice. Because of this effect, a raindrop resulting from the melting of a snowflake has about five times the reflectivity of the original flake. The decrease in signal strength below the bright band was explained as due to the increased fall velocity of raindrops as compared to snow; hence the number of raindrops per unit volume of air is smaller than that of snowflakes above. Since the fall velocity of raindrops is about five times that of snowflakes, the signal strength would be one-fifth that of the melting snow.

From the theory of storm detection it may be seen that the reflectivity of a melting snowflake is proportional to $K^2/\rho V$ where $K = (\epsilon - 1)/(\epsilon + 2)$; ρ is the density of the mixture, and V is the fall velocity. Ryde assumed that

$$\frac{K}{\rho} = m_i \frac{K_i}{\rho_i} + m_w \frac{K_w}{\rho_w}, \tag{6}$$

where subscripts i and w refer to ice and water, respectively, and m_i and m_w are the respective percentages of the total mass of the snowflake ($m_i + m_w = 1$). This equation is true for a heterogeneous mixture of ice and water but it is not true where the water is on the outside of the snowflake. A particle with an inner core of ice and an outer shell of water has a dielectric constant more nearly that of the water than equation (6) would indicate because of the attenuation of the radio wave towards the interior of the particle (as in the "skin effect"). The increase in signal strength at the top portion of the

bright band is then due to this discontinuous increase of the dielectric constant as a film of water develops on the exterior of the snowflake. The decrease of signal on the bottom portion of the bright band is due to the rapid increase of fall velocity as the snowflake approaches complete melting. It is not necessary, however, to assume (as Ryde did) a nearly constant fall velocity of the snowflake until complete melting, but rather an increase, rapid with respect to one-half the pulse length; this is no serious limitation since the observed width of the bright band is of the same order as one-half the pulse length.

Bowen[4] has recently reported the presence of an upper band observed in Australia on about half the occasions on which the bright band was noted. This upper band, first located at temperatures between −12 and −17C, was observed to fall slowly towards the bright band, merge and intensify, after which the bright band and the precipitation below became more intense. There was a tendency for the process to repeat itself. Bowen ascribed this phenomenon to the freezing of large water droplets of about 400-μ diameter at about −16C and their subsequent rapid growth and fall toward the surface. If this were true the signal strength should first decrease by a factor of 5 and then slowly increase as the ice grew by diffusion.

It is more probable that the upper band is a layer of graupel developed in a region of high liquid-water content in the upper portion of the cloud. It may be shown that there is a critical water content below which crystals maintain their tabular shape and above which crystals convert into graupel of approximately spherical shape. Because of their increased fall velocity and efficiency of catch, graupel, once formed, will grow rapidly, by coagulation with the water droplets. A layer of graupel will deplete the water in its path rather rapidly and a succeeding layer will fall through air of smaller water content and will not acquire as great a mass in the same distance of fall. As an example, a layer of graupel initially of mass 0.001 mg and 150 m in depth (and of reasonable concentration) will grow in a cloud of 0.5 g m^{-3} liquid-water content to a mass of 0.20 mg in a 600-m fall distance. In so doing it will have depleted the water in its path to an average value of about 0.3 g m^{-3}. The next 150-m layer of graupel will grow to a mean mass of about 0.1 mg in the same 600-m fall distance. Since the resolving power of a radar with a 1μ sec pulse is only 150 m, the first layer will be observed to descend as a band of about four times the intensity of the second. Subsequently, the formation of graupel will cease due to depletion of the water below the critical value and will begin again only when the liquid water, replenished by the updraft, rises above that value.

Of meteorological interest is the increase in signal strength from above, as the bright band is approached, as shown in Fig. 3. The ultimate effect of the increase in dielectric constant and fall velocity is an approximate equalization of signal. However, A-scope photographs generally show a rapid increase of signal strength through the bright band, sometimes apparently beginning at the upper edge as in Fig. 3, but often starting from slightly below the 0C level. There is generally a gradual increase from several thousand feet above, where the signal is indistinguishable from the noise level of the radar, to almost the 0C level. Observations made by Austin and Bemis [2] show that the ratios of the signal strength from below the bright band to that above it vary from 1 to 17, with a median near 5. In some cases the signal from above the bright band is vanishingly small. Ryde ascribed the increase in signal strength from above the bright band as due to the aggregation of numerous snow crystals at temperatures of about −4C to 0C, and Austin and Bemis explain the increase in signal strength through the bright band (from above) as due to continued aggregation of snowflakes.

Radar observations of three warm-front rains by Browne in Cambridge, England, give the rate of decrease of signal strength with altitude from the 0C level. In comparing these observations with the rate of growth of ice crystals by diffusion in a supercooled water cloud, calculated according to the methods of Houghton [4], it was found that the calculated growth rates above about the −6C level are not compatible with the observations. The observations were found to be compatible with a growth in an ice cloud such that the crystals consume within a layer the water produced by the updraft and make use of little or no "stored" water from below. This result holds for a rate of mass transfer of air by the updraft that is constant with height. From −6C to −3C the observations are compatible with growth in a water cloud. Between −3C and 0C the observed increase in signal strength is greater than could be obtained by growth of ice crystals at water saturation at those temperatures. This discrepancy is explained by coalescence of some of the ice crystals as they approach the 0C level.

If x crystals of equal mass coalesce, the resultant signal strength is x times the original value. To arrive at an exponential law of drop-size distribution [6], a similar law for coalescence is required. Let the number of coalescences of x crystals of equal mass be given by $n = n_0 e^{-ax}$, then the number of crystals before coalescence is $\sum_x xe^{-ax}$ and the ratio of the radar echo from the coagulated crystals to that from the individual crystals is $\Sigma x^2 e^{-ax}/\Sigma x e^{-ax}$. For any ratio of signal strength from two levels between which coalescence is taking place, the constant a can be computed and the resultant size distribution calculated.

The observations and calculations indicate that coalescence of the particles begins at about the −3C level, possibly because of the cohesive effect of the thin film of water forming on the crystal at these higher temperatures. Below the 0C level, coalescence must continue in order to account for the increased signal below the bright band and the observed drop-size distribution at the ground. These conclusions also agree with snow observations which indicate individual crys-

tals arriving at the ground at low temperatures and large snowflakes near the freezing point. The ideas of Ryde, and of Austin and Bemis, on the coalescence of crystals from the −4C level to below the bright band are corroborated; Ryde's ratio of 40 to 1 between −4 and 0C is not indicated by Browne's observations. More observations similar to those by Browne for various cloud depths and precipitation intensities are desirable for a more detailed study of precipitation growth by diffusion and coalescence.

Horizontal Structure of Precipitation

On the PPI scope[5] of the radar, continuous precipitation appears as an extensive brightened area. Generally there are indications of definite edges to the storm, although in winter the precipitation may extend in all directions from the station out to the limit of the range of observation of the radar. An extensive area of warm-front precipitation is often seen to have an abrupt line of cessation.

In showery activity the precipitation may appear as scattered cells, 3–6 miles in diameter, located at random in some sectors of the scope. Occasionally these cells develop to form an area of continuous precipitation and curious patterns often occur. Such a development characterizes the rain areas observed from Belmar, New Jersey, during the afternoon of March 10, 1949 (Fig. 4). A cyclonic storm was located just west of Cape Hatteras at 1230 EST and was moving eastward at about 30 mph. At the 700-mb level a closed cyclonic center was located over southern Ohio, and south-southwest winds of about 20 mph prevailed over the New Jersey area. At 1350 EST showers appeared to be scattered almost at random out to a radius of 125 miles from the station. The remainder of the afternoon saw the virtual decay of the storms in the northern sector and a build-up of the storms to the south. At 1515 EST, what had previously been a loose coalescence of cells was a continuous pattern about 30–50 miles wide but narrowing in its central portion to about 10 miles and trailing off to a thin line at its most distant point, 180 miles distant at 160° azimuth. Farther south a strange pattern in the form of a wavy line of individual cells of precipitation 200 miles or more in length became visible at 1615 EST.

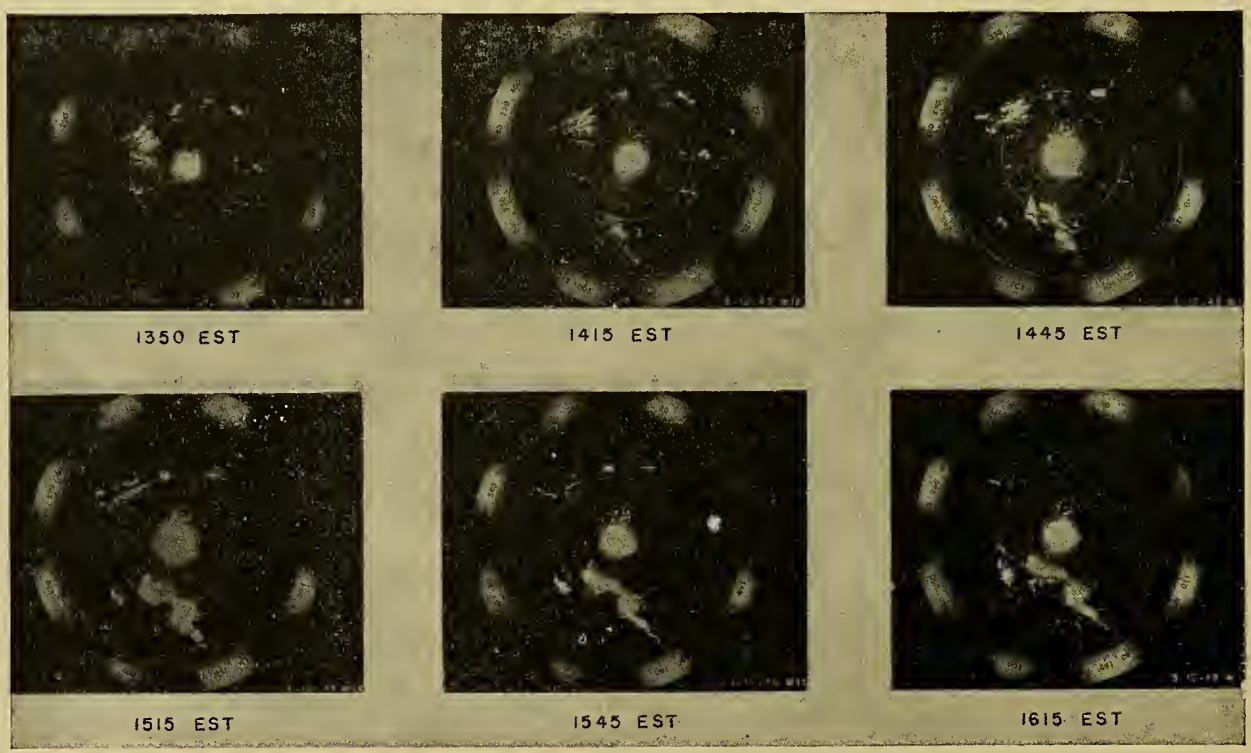

Fig. 4.—Precipitation patterns observed from Belmar, N. J., March 10, 1949. Circular range markers are at 25-mile intervals. (*Courtesy Signal Corps Engineering Laboratories.*)

A line squall that is observed to extend straight across the PPI scope is rare. A more usual situation is a series of line squalls, each perhaps a hundred miles in length, in parallel bands. The edge of the squall in the direction of the high pressure often trails off into a group of cells. The parallel bands of precipitation are generally associated with distinct wind shifts and pressure-gradient discontinuities.

As a front passes over the radar, the range of detection of precipitation along the front diminishes considerably at 3-cm or shorter wave lengths, because of rain attenuation. By comparing the maximum range at a given gain setting before the front has reached the station with the maximum range when the front is directly over the station, it is possible with the aid of equation (4) to

5. PPI = Plan Position Indicator, a polar coordinate plot of azimuth versus range.

determine roughly the average rain intensity over the path [15].

Conclusion

Although the theory of storm detection is fairly straightforward, the complexities of computation from the Mie theory still leave some discrepancies in the amount of reflection to be expected from various precipitation elements and in the values of attenuation. For the purpose of determining quantitatively the target characteristics of a storm, a greater source of error lies in the inaccuracies in measuring the power received at the radar. More exact measurements may open up a new field of estimating the rain intensities of distant storms and of making quantitative studies of the growth processes of precipitation along the vertical.

It would be particularly desirable to measure the rate of decrease with altitude of the signal strength from different clouds of varying depths, precipitation intensities, and atmospheric conditions. Such measurements would give information on the growth of precipitation particles by diffusion and the magnitude of the coalescence effects. Observations of the type, mass, and fall velocity of snow that reaches the ground would give considerable supplementary information for an understanding of the physics of precipitation.

Simultaneous radar and visual (theodolite) observations of cumuliform clouds, similar to those carried out by Workman in New Mexico, should also lead to a better understanding of thunderstorms. Fruitful research problems are (1) the rate of rise of the visual top as related to the echo top in growing thunderstorms, (2) coagulation and chain reaction effects in the heavy rain, again as revealed by the rate of decrease with altitude of signal strength, and (3) the characteristics of precipitation echoes during the formation of the bright band in the degenerate stages of the thunderstorm, as revealed by radarscope photographs taken with reduced gain. Although many complexities in the individual storms present themselves in the study of such problems, the complexities themselves offer fruitful paths of research. The ever-changing panorama of weather is nowhere better revealed than on the radar screen.

METEOROLOGICAL ASPECTS OF PROPAGATION PROBLEMS

By H. G. BOOKER

Cornell University

Introduction

We shall be concerned with the branch of radio-meteorology that deals with refraction of radio waves in the atmosphere. Refraction phenomena depend mainly on the profiles of temperature and humidity near, or comparatively near, the earth's surface. The first section is a description of the phenomenon of extra downward refraction, or *superrefraction*, as experienced at radar stations. The second section explains in broad outline how superrefraction comes about, while the third section focuses attention on the meteorological phenomena mainly responsible for it. In the last section some meteorological investigations that have been made especially in connection with radio propagation are discussed.

Description of Supperrefraction

The expression superrefraction is used because, even under conditions of orthodox propagation, there is some downward bending of radio waves in the atmosphere due to the normal decrease of air density with height. Radio people have a simple way of allowing for this normal downward refraction, so that it is with departures from orthodox atmospheric refraction that we have to deal. The most striking phenomena are associated with increases in downward refraction, and particularly with situations in which the downward refraction of radio rays exceeds the curvature of the earth, although reductions in downward refraction—subrefraction—also occur.

The phenomenon of superrefraction, although known before 1940 [8, 9], was brought vividly to attention during World War II by the development of radar. Under orthodox propagation conditions the region within which a radar may detect aircraft, ships, coast lines, etc., does not normally extend quite as far as the geometrical horizon, and radar vision of targets below the geometrical horizon is usually impossible. When radars came into operation, at first on a wave length of 13 m, the expectation that they would not see beyond the geometrical horizon was broadly fulfilled, although there was some evidence that echoes from objects on the ground were dependent upon atmospheric conditions. It was especially noticed that, during an intense anticyclone in January 1940 (with snow on the ground), echoes were obtained from tall towers some distance beyond the geometrical horizon, and at the same time the normal ability of the station to detect aircraft was somewhat modified. As time went on, radars were developed on progressively shorter wave lengths—7 m, 1.5 m, 50 cm, 10 cm, 3 cm—and it was found that the shorter the wave length in use the more frequently were conditions of unorthodox propagation encountered and the more intense was the degree of superrefraction experienced. Thus, when 10-cm radars were installed along the south coast of England, it was found that they were often able to see the coast of France even where the width of the English Channel was too great for ordinary visual observation of the opposite shore. The phenomenon, when it occurred, was usually most pronounced in the evening, though it sometimes started in the afternoon and extended far into the night. After a while it became clear that these conditions of unusual refraction were associated with fine weather and that they were a good deal more pronounced in summer than in winter. In addition it was realized that radars looking over land instead of over sea also experienced unorthodox propagation conditions in fine weather, but not usually in the afternoon.

Understanding of superrefraction was greatly assisted by the progressive deployment of radars in the various theatres of war. When 7-m and 1.5-m radars were established on coastal sites in the Mediterranean, it soon became clear that superrefraction in this area was much more intense than on the same wave lengths around Britain. The entire south coast of Sicily could frequently be seen with 1.5-m radars on Malta, and from time to time echoes from Greece and Sardinia at ranges of the order of 400 miles were obtained. Ships were sometimes plotted to a range of 200 miles, the range of the geometrical horizon being less than 20 miles. In contrast, ranges on aircraft were occasionally said to be subnormal, though these reports were confused by the possibility that the performance of the equipment may not have been up to standard. It soon became clear that unorthodox propagation was intense, frequent, and widespread over the Mediterranean in summer, though conditions largely returned to normal in winter.

During the course of the war many other areas of the world were found to be subject to superrefraction. These included:

1. Coast of French West Africa in the neighbourhood of the Canary and Cape Verde Islands.
2. Gulf of Aden in summer.
3. Persian Gulf in summer.
4. Northern part of the Arabian Sea during the Indian hot season.
5. West coast of India except during the southwest monsoon.
6. Bay of Bengal.
7. North coast of Australia except during the northwest monsoon.
8. North west coast of Australia all the year round, but particularly in summer.
9. West and south coasts of Australia and coast of

New South Wales in summer (but obliterated by passage of a meridional front).

10. Southeast coast of South Island, New Zealand, during a nor'wester (foehn wind from the Southern Alps).

11. Around North Island, New Zealand, in summer.

Inland it was found almost everywhere that conditions of unorthodox propagation, when they occurred, were largely associated with radiation nights. On such a night moderate superrefraction usually develops fairly quickly after sunset. If there is no tendency for formation of fog, superrefraction usually continues all night, disappearing after sunrise. But if fog forms, superrefraction may disappear during the night and may even be replaced by subrefraction before sunrise, after which conditions begin to return to normal. Fog, even over the sea, is often associated with unorthodox propagation, but this may vary all the way from subrefraction to quite intense superrefraction.

Most of the phenomena of unorthodox propagation outlined above were initially encountered in the course of operational use of ordinary radar equipment. Some examples of the observational material from which it was necessary to work have been given in *Weather* [2]. The qualitative results obtained in this way, however, were followed by quantitative observations made by specially designed equipment using one-way propagation mainly on wave lengths of 9 and 3 cm [10, 12, 16, 17, 20].

It is clear therefore that the simple idea that radars (which operate on metre, decimetre, and centimetre wave lengths) cannot see targets beyond the geometrical horizon may, under suitable conditions of weather and climate, be violated on a stupendous scale.

Explanation of Superrefraction

From the outset there was, of course, no doubt that the phenomena described in the previous section were due to refraction or reflection in the troposphere. In the early days, some confusion was caused by repeated suggestions that reflection from the interfaces constituting ordinary meteorological fronts was the cause. In fact, however, reflections from ordinary frontal surfaces, although sometimes observable at grazing incidence, are not the primary cause of superrefraction. But there is another way in which striking gradients of temperature and humidity can occur in the troposphere. Owing to advection, radiation, subsidence, or some combination of these phenomena, it can easily happen that the surface of the earth has a temperature substantially different from that representative of the superincumbent air mass. An important gradient of temperature then occurs near the surface of the earth. In the same way, the humidity representative of the superincumbent air mass may differ appreciably from that existing close to the earth's surface, and then there is an important gradient of humidity near the bottom of the air mass. Gradients of temperature and humidity that occur in this way are the main cause of unorthodox radio propagation.

Two extremely important parameters in radiometeorology are: (1) the temperature excess of the appropriate air mass in relation to the earth's surface, and (2) the humidity deficit of the appropriate air mass in relation to the earth's surface. The first is the excess of the potential temperature of the air mass over the value corresponding to the earth's surface, and the second is the deficit of the specific humidity of the air mass below that corresponding to the earth's surface (see Fig. 1). Quite a good qualitative idea of the degree of superrefraction can often be derived purely from knowledge of the values of these two parameters, large positive values indicating marked superrefraction. For a more detailed understanding of superrefraction, however, it is necessary to know not merely the temperature excess and humidity deficit but also the associated profiles of potential temperature and specific humidity. From these it is possible, by means of a formula due to Englund, Crawford, and Mumford [8], to deduce the profile of the radio refractive index and hence the propagational properties of the atmosphere.

The formula giving the radio refractive index n as a function of atmospheric pressure p in millibars, tem-

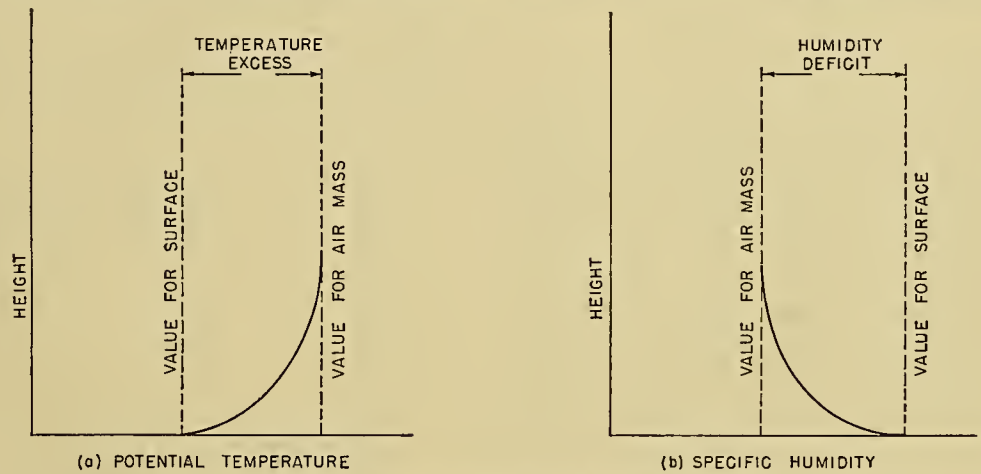

FIG. 1.—Modification of an air mass by surface conditions.

perature T in degrees absolute, and partial pressure e of water vapour in millibars is

$$(n-1)\times 10^6 = \frac{79}{T}\left(p - \frac{e}{7} + \frac{4800e}{T}\right). \qquad (1)$$

We need to know how large the vertical gradients of temperature and humidity must be in order to be of importance in radiometeorology. Consider first a situation in which the potential temperature is uniform with height; how large must the lapse rate of specific humidity be to make the downward curvature of a radio ray equal to the curvature of the earth? Let α be this critical lapse rate of specific humidity. Consider secondly a situation in which the specific humidity is uniform with height; how large must the negative lapse rate of potential temperature be to make the downward curvature of a radio ray equal to the curvature of the earth? Let β be this critical lapse rate of potential temperature, its numerical value being in fact negative. The values of α and β may be derived from (1) and depend somewhat on pressure, temperature, and humidity. They are of the order of

$$\alpha = 0.5 \text{ g kg}^{-1} \text{ per } 100 \text{ ft}, \qquad (2)$$
$$\beta = -5\text{F per } 100 \text{ ft}. \qquad (3)$$

Thus lapse rates of humidity in excess of about ½ g kg^{-1} per 100 ft and inversions of temperature in excess of about 5F per 100 ft are of great importance in radiometeorology as they cause downward bending of radio rays as great as or greater than the curvature of the earth, thereby making possible radio vision round the curved surface of the earth.

On the other hand, even in a well-mixed atmosphere, with specific humidity and potential temperature uniform with height, there is some downward bending of radio rays. This is the normal atmospheric refraction which is involved in orthodox propagation and to which reference has been made earlier in this article. Let κ_0 be the downward curvature of radio rays when there is no lapse rate of specific humidity or potential temperature. It is possible to deduce κ_0 from (1), and, like α and β, it depends somewhat on pressure, temperature, and humidity. It is convenient to compare κ_0 with the curvature κ_e of the earth (5×10^{-6} radians per 100 ft), and expressed in this way the value of κ_0 is of the order of

$$\kappa_0 = \tfrac{1}{6}\,\kappa_e. \qquad (4)$$

Thus, even in a well-mixed atmosphere, there is downward bending of radio rays amounting to about one-sixth of the earth's curvature.

In terms of the parameters κ_0, α, and β we may express the downward curvature κ appropriate to a lapse rate q' of specific humidity and a lapse rate θ' of potential temperature in the form

$$\frac{\kappa - \kappa_0}{\kappa_e - \kappa_0} = \frac{q'}{\alpha} + \frac{\theta'}{\beta}. \qquad (5)$$

This makes

1. $\kappa = \kappa_0$ when $q' = \theta' = 0$,
2. $\kappa = \kappa_e$ when $q' = \alpha$, $\theta' = 0$,
3. $\kappa = \kappa_e$ when $q' = 0$, $\theta' = \beta$.

From Snell's laws of refraction it is easily shown that the downward curvature κ of a ray is also equal, to a high degree of approximation, to the lapse rate of refractive index. Thus (5) also expresses the lapse rate κ of radio refractive index in terms of the lapse rates q' and θ' of specific humidity and potential temperature. In addition to these lapse rates, the actual values of humidity and temperature, as well as the value of the pressure, enter into (5) because κ_0, α, and β depend on these quantities to some extent, as implied by equation (1). But for quite a wide range of meteorological conditions it is often possible to regard κ_0, α, and β as constants, and (5) then expresses κ purely as a function of q' and θ'.

Now under conditions when the temperature and humidity of an air mass have been modified by surface conditions, simple though not unusual profiles of potential temperature and specific humidity are as indicated in Fig. 1. It is here supposed that the air mass is warm and dry in comparison with surface conditions. It is not uncommon for the steepest gradients of temperature and humidity to occur near the surface of the earth, and for them to be such as to make the downward curvature of radio rays near the earth's surface exceed the curvature of the earth. This leads to the state of affairs depicted in Fig. 2. Well up in the air mass the

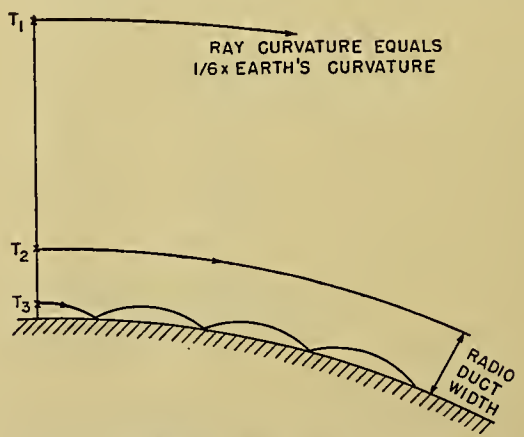

Fig. 2.—Effect of radio duct on radio rays.

lapse rates of potential temperature and specific humidity are zero, and so, in accordance with (5), the downward curvature of radio rays is κ_0, about one-sixth of the earth's curvature. A ray emanating horizontally from a radio transmitter T_1 at such a height would show only a slight tendency to follow the earth's curvature, as indicated in Fig. 2. Now let us bring the transmitter down to a level where modification of the air mass by surface conditions begins to be appreciable. In accordance with (5), the positive lapse rate of specific humidity and the negative lapse rate of potential temperature indicated in Fig. 1 increase the downward curvature of rays above the standard value κ_0. When the transmitter has been brought nearly down to the earth's surface, it reaches a certain level, T_2 in Fig. 2, where the downward curvature of the ray becomes equal to the curvature of the earth. With the transmitter at this

critical level, a ray emanating horizontally remains at the same height above the earth's surface and does not fly off at a tangent. This vital level, where the downward curvature of a ray is equal to the curvature of the earth, forms the top of what is known as the radio duct. As we bring our transmitter down below the top of the duct, a ray emanating horizontally, say from T_3 in Fig. 2, is bent downward to such an extent that it hits the earth and suffers successive reflections from it. The ray, in fact, is trapped within the duct. It is trapping of this sort that causes low-level radars to see low-level targets far beyond the geometrical horizon.

Trapping of rays in a radio duct as illustrated in Fig. 2, although it provides a clear insight into the phenomenon of superrefraction, gives a substantially oversimplified picture [4]. The oversimplification does not reside in the meteorological aspects of the problem, however, and therefore we need not go into the matter in great detail. The principal trouble with Fig. 2 is that it suggests that, under the appropriate atmospheric conditions, superrefraction would be experienced at all radio wave lengths. Now it is well known that, apart from ionospheric refraction, with which we are not concerned, there is no phenomenon of superrefraction at ordinary broadcasting wave lengths. Propagation in the lower atmosphere at ordinary broadcasting wave lengths is almost completely independent of weather. Even under meteorological conditions involving a pronounced radio duct and producing marked superrefraction at radar wave lengths, propagation in the lower atmosphere at broadcasting wave lengths is almost completely orthodox. The reason for this dependence of superrefraction upon wave length is that sufficiently long wave lengths respond only to a crude average of the atmospheric gradient, but sufficiently short ones fully appreciate all the fine structure. Thus, to produce marked superrefraction on a wave length of 1 km would require a radio duct extending from the earth's surface up to a height of the order of 30,000 ft. No approximation to such enormous ducts ever occurs in the atmosphere, and so serious superrefraction at ordinary broadcasting wave lengths is out of the question. On the other hand metre wave lengths can respond quite effectively to unusual gradients of temperature and humidity within the first few thousand feet of the atmosphere, while centimetre wave lengths can be seriously affected by unusual gradients within the first few hundred feet. It thus comes about that superrefraction is a phenomenon that is quite widespread at centimetre wave lengths, fairly widespread at decimetre wave lengths, only moderately widespread at metre wave lengths, quite exceptional at dekametre wave lengths, and virtually unknown at longer wave lengths. It therefore has to be realized that, in addition to meteorological parameters such as temperature excess, humidity deficit, wind speed, which control the distribution of radio refractive index in the lower atmosphere, there are nonmeteorological parameters such as wave length, height of transmitter, height of receiver, which also have a big influence upon radio propagation.

In Fig. 2 we have illustrated a situation in which the steepest gradients of temperature and humidity occur at the surface of the earth. This is by no means always the case however. For example, when superrefraction is produced by a subsidence inversion, the distributions of potential temperature and specific humidity with height are frequently of the type shown in Fig. 3 and

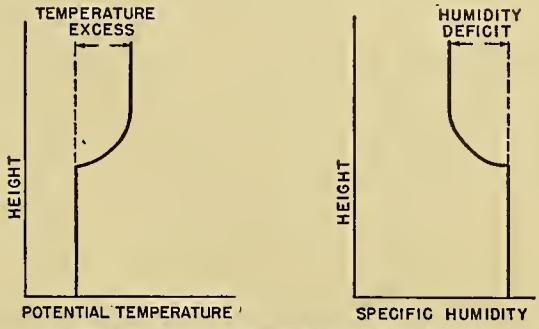

Fig. 3.—Profiles of potential temperature and specific humidity associated with an elevated refracting layer.

this leads to an elevated refracting layer instead of one resting on the surface of the earth. In such a case, the degree of superrefraction experienced in communicating between points on the earth's surface depends on (1) the temperature excess and humidity deficit of the air mass above the layer in comparison with that below the layer, (2) the precise profile of refractive index in the layer, and (3) certain radio parameters (particularly wave length), but it also depends quite vitally upon the height of the layer above the surface of the earth. The lower the height at which a layer exists, the more effective it usually is in causing superrefraction. The reason for this may be illustrated by supposing that the refractive index of the atmosphere suffers a small discontinuous decrease as we ascend through a level S, the refractive index above and below this level being uniform. Such a discontinuous drop in refractive index causes total internal reflection of a ray incident from below at a sufficiently glancing angle. But, on account of the curvature of the earth, even a ray leaving the surface of the earth horizontally attacks the level S at a nonzero angle to the horizontal, and this angle is larger the greater the height of the layer. As a result total internal reflection of a ray leaving the surface of the earth horizontally is impossible if the layer is too high. This picture, although grossly oversimplified, makes it clear why reflecting layers must be quite low in the atmosphere to produce marked superrefraction for communication between points on the earth's surface. Thus a striking subsidence inversion nearly always causes outstanding superrefraction if its base is as low as one thousand feet above the earth's surface, but if its base is at ten thousand feet the inversion is unlikely to be of much practical importance except for communication between airplanes.

To summarize, we may say that superrefraction is usually associated with an inversion of temperature exceeding about 5F per 100 ft and/or a lapse rate of humidity exceeding about $\frac{1}{2}$ gm kg^{-1} per 100 ft maintained over an interval of height of the order of 100 ft

or so at a level in the atmosphere not more than a few thousand feet above the earth's surface and often much less. If the lapse rate of specific humidity becomes sufficiently negative, superrefraction is replaced by subrefraction. The degree of superrefraction is vitally affected by the interval of height over which steep gradients are maintained and by the closeness to the earth's surface at which they occur.

The Meteorological Problem

From what has been said it is clear that we need to be able

1. To recognize those situations which involve a temperature inversion exceeding about 5F per 100 ft within a few thousand feet of the earth's surface.
2. To recognize those situations which involve a lapse rate of humidity exceeding about ½ g kg^{-1} per 100 ft within a few thousand feet of the earth's surface.
3. To state, within say 10 ft, over what interval of height the gradients exceed the values mentioned.
4. To state to an accuracy of say 10 per cent or 10 ft, whichever is the cruder, the height above the earth's surface at which the steep gradients occur.

The above requirements are the least that would make a definite contribution to quantitative radiometeorology, and are insufficient to provide all the information desirable. The complete profiles of temperature and humidity, with an accuracy indicated by the requirements listed above, are highly desirable, together with their statistical variations.

There is, of course, no particular difficulty in measuring the profiles of temperature and humidity as required above at a particular location by means of meteorological instruments attached to towers, balloons, kites, aircraft, etc. Important as such experiments are, however, they do not by themselves constitute an adequate understanding of the problem for radiometeorological purposes. The real problem is to be able to specify the profiles of temperature and humidity with sufficient accuracy purely from the weather data ordinarily available in synoptic meteorology. From this source, it would usually be possible to decide with reasonable accuracy what are the values of parameters such as temperature excess and humidity deficit, illustrated in Figs. 1 and 3. In addition wind speed and direction near the surface and at an appreciable height would normally be available, as well as information about the type of terrain. A good deal of additional information of a general character would also be available, and it is reasonable to suppose that contained in all these data are the values of the parameters which control those features of the profiles of temperature and humidity near the earth's surface that are vital in radiometeorology. The problem is therefore to obtain such a fundamental understanding of how the profiles of temperature and humidity near the base of the troposphere are controlled by such parameters as temperature excess, humidity deficit, wind speed, etc., that knowledge of the values of these parameters is adequate to provide answers to at least the four requirements stated at the beginning of this section.

This can be achieved, if at all, by developing a theory of the profiles of temperature and humidity near the earth's surface capable of standing the test of experimental verification. Such a theory should, ideally, specify the required profiles as a function of certain parameters; if these parameters could be deduced from ordinary synoptic weather data, and if the theory were to give the profiles with sufficient accuracy, the problem would be solved.

There are, of course, certain aspects of the problem which, even at the outset, are not in doubt. The most important physical process directly involved in controlling profiles of temperature and humidity is eddy diffusion. High eddy diffusion means almost uniform potential temperature and specific humidity, and consequently orthodox propagation. Low eddy diffusion permits the existence of substantial atmospheric gradients and so makes superrefraction possible. Eddy diffusion is low in a temperature inversion. Thus a temperature inversion is important in connection with superrefraction for two reasons. First, the gradient of temperature itself causes some downward refraction. But, more important, the associated stability of the atmosphere permits the existence of a steep gradient of humidity, and it is this that is frequently the immediate cause of unorthodox propagation.

The important ways in which marked inversions of temperature and associated hydrolapses can occur near, or relatively near, the surface of the earth arise from the processes of subsidence, advection, and nocturnal radiation. Over land, nocturnal radiation inversions are the principal feature associated with unorthodox propagation. Over sea, particularly in coastal waters, advection of warm dry air from land to sea is of great importance, often complicated by a coastal circulation arising from the land-sea difference of temperature. Subsidence in many cases is a prerequisite for surface inversions for which radiation or advection is the more immediate cause. Subsidence keeps the sky clear and permits the land to heat up to a high temperature during the afternoon and cool rapidly at night. This leads to a marked radiation inversion inland at night and often makes available, during the afternoon, a large excess of land temperature over sea temperature for production of advection inversions over the sea. Moreover subsidence brings warm dry air down relatively close to the earth's surface, frequently forming a subsidence inversion. A well-developed subsidence inversion is itself a potent cause of superrefraction propagation between points on the earth's surface provided it exists at a level less than say 5000 ft above the surface, but many subsidence inversions are too high to be of much direct practical importance in ordinary radio communication.

The problem therefore reduces to this: we need to understand the phenomena of subsidence, advection, and nocturnal radiation sufficiently well to form a workable theory of the associated profiles of temperature and humidity.

Some Special Meteorological Investigations

For the phenomenon of advection of air from land to sea, a special attempt has been made to carry out a program of research such as that outlined above, bearing in mind the particular needs of radio propagation. The most satisfactory results at present available are contained in two papers by Craig [6, 7], although reference may also be made to papers by Sheppard [15] and Booker [3]. The first of Craig's papers describes measurements of temperature and humidity made at various heights and at various distances off the coast of Massachusetts in air that had drifted from the land over the sea, the measurements being carried out in such a way as to reveal the modification in the air mass due to advection over the sea. The second of Craig's papers describes how these measurements were analyzed and fitted to a theory of the modification of the air mass by eddy diffusion. The center of interest in such a theory is the assumption to be made about the distribution of eddy diffusivity with height. Taylor [19] had originally assumed a uniform distribution of eddy diffusivity, but this does not reproduce the logarithmic profiles of temperature, humidity, and wind speed usually observed within the first few feet of the atmosphere [13]. Craig therefore used a model in which eddy diffusivity is proportional to height in the first few feet, but has a uniform value at greater heights. This is probably the most successful representation of the process of eddy diffusion near the earth's surface for stable atmospheric conditions that has so far been achieved.

Other distributions of eddy diffusivity with height have however been employed. Following Sutton [18], Booker [3] has assumed that eddy diffusivity is proportional to a power of height above the earth's surface. He shows that, for advection of a well-mixed air mass from land over a uniform sea, the heights at which the lapse rates of specific humidity and potential temperature have the important values (2) and (3) reach maximum values offshore which are proportional to humidity deficit and temperature excess, respectively, but which are independent of the absolute value of the eddy diffusivity. These maximum heights, which can be used in practice as radio duct-widths (see Fig. 2) over a wide range of distances offshore, do depend on the distribution of eddy diffusivity with height, even though they are independent of the absolute value at any particular level. The distances offshore at which the maximum heights occur, unlike the values of the maximum heights themselves, are dependent on the value of the eddy diffusivity, but this is not too important for some practical applications to radiometeorology. Booker thus concludes that, when a radio duct is produced over the sea by advection of air from the land, the radio duct-width is less dependent on the absolute value of the eddy diffusivity than might appear at first sight, and this result would probably also apply to the profile of eddy diffusivity used by Craig. The radiometeorological effect of changing the profile of eddy diffusivity is, however, quite important.

Conclusion

If all the meteorological phenomena involved in radiometeorology were subjected to as careful a treatment as that applied by Craig [6, 7] to the problem of advection of air from land to sea, it would be possible to feel that the basic meteorological factors underlying radiometeorology were understood as well as could be expected for some time to come.

Reference may be made to the discussions of radiational cooling, fog, subsidence, advection, evaporation, sea breeze, etc., given elsewhere in this Compendium. Additional general references in connection with radiometeorology are listed as [5],]11], and [14] in the references.

SFERICS

By R. C. WANTA

U. S. Weather Bureau, Upton, N. Y.

Sferics (less commonly spherics) is a contraction of the word atmospherics meaning natural electrical phenomena detected by radio methods. Sferics have variously been known as clicks, grinders, sizzles, X's, strays, *parasites*, and sturbs, and other names. They comprise natural static which interferes especially with amplitude-modulated radio wave reception. Electromagnetic waves at radio frequencies reaching the earth from outside the atmosphere, of solar or other origin, are sometimes included within the meaning of the term, but will not be discussed here. Sudden electrical discharges resulting in redistribution of charge within and between clouds, between clouds and the air space above or below, and between clouds and earth, give rise to electrostatic, induction, and radiation fields. It is the last which principally form sferics at a distance, and with which we are especially concerned here. The significance of sferics in meteorology is due to their origin in relatively intense convection intimately involving water vapor.

The reception of sferics preceded even the artificial generation of radio waves for transmission over long distances. A. S. Popov, using an elevated wire, noticed the association of lightning flashes with the indications of a coherer at Cronstadt in 1895 [9]. The history of sferics during the remaining years of the last century and the first two and a half decades of this century is sketched in two papers, by Cave and Watson-Watt [9] and by Watson-Watt [40]. Sferics were positively correlated with cyclones, polar fronts, thunderstorms, and cumuliform clouds, and less definitely, with showery precipitation. Rudiments of later methods of sferics study appeared—not only observation of frequency and intensity of sferics, but also coordinated observation of bearings of sources of sferics by means of direction finders. Sferics provided a key which opened the door to an understanding of radio wave propagation. Investigators in more than a dozen countries explored the nature and sources of atmospherics, and official international recognition soon was given to this new field of meteorology. Lugeon has recently written an historical account, which includes a summary of the more important international resolutions concerning sferics [17].

Is the source of sferics necessarily lightning? In Popov's case the answer seemed clear, but a complete answer has not yet been given. Nevertheless, Watson-Watt's dictum that no valid evidence contradicts the hypothesis that all sferics originate in lightning still stands [4, 41], at least as regards sferics received at a distance [24]. Besides the positive correlations already mentioned, supporting evidence was found early in the diurnal and annual variation of sferics; sferics originating over land exhibited afternoon and summer maxima, whereas those originating over water exhibited an early morning maximum. Good correspondence was obtained between prevailing areas of sferics origin and the distribution of thunderstorms given by Brooks [6]. Furthermore, the general features of the wave forms of sferics, as determined, for example, by Appleton and Chapman [2], Lutkin [19], and Schonland and Laby and their collaborators [15, 31, 33], corresponded with the details of the lightning discharge. In this connection, see Hagenguth's article[1] elsewhere in this Compendium. The meteorologist may feel safe in treating all sferics arising more than some one hundred miles from a sferics receiver tuned to very low radio frequencies as evidence of violent convection such as occurs in thunderstorms.

The observation of sferics has taken several forms: determination of direction of arrival, measurement of intensity and rate of occurrence, and display of the wave form of individual sferics. From Brooks' estimate that approximately 40,000 thunderstorms occur over the globe per average day and from the fact that day and night ranges of sferics at radio frequencies of the order of 10 kc sec^{-1} exceed, respectively, 1000 and 3000 miles, some idea is gained of the average frequency of occurrence of sferics.

In English-speaking countries the most commonly used device for determining the direction of arrival is a direction-finding system, justly associated with the name Watson-Watt, which uses two stationary loop antennas at right angles to one another. Each loop characteristically receives the maximum signal in a direction along its own plane, the signal intensity at angles of arrival other than zero varying as the cosine. The input circuits are tuned in the neighborhood of 10 kc sec^{-1}, corresponding to the quasi-frequencies of the lightning stroke. The signal in each loop is separately amplified and then added vectorially on an oscilloscope screen to produce a straight line representing the direction of arrival with 180° ambiguity. More recently, ambiguity of azimuth has been eliminated electronically. The signals are most often observed visually, less often recorded on stationary or continuously moving film. This form of sferics receiver has been used by numerous investigators in many countries [4, 11–13, 17, 32, 41]. (For an early analysis of such observations, see [39].) The Watson-Watt system was employed in networks of stations during World War II in England, the United States, the Caribbean, the western Pacific, China, Japan, and elsewhere. Radio or telephone intercommunication of stations comprising a network permits synchronized observation of the same instantaneous source. One station generally desig-

1. See "The Lightning Discharge" by J. H. Hagenguth, pp. 136–143.

nates the particular signal to be located, choosing those relatively distinct from others in the typically rapid sequence; indication of simultaneity and reliability is obtained in the plotting on gnomonic maps. Observations are generally made at two- or three-hourly intervals for periods of about half an hour. Base lines connecting stations may range in length from a few hundred miles to over a thousand.

A second direction-finding system, developed by Lutkin [20], also employs a pair of loops at right angles to one another, so arranged that a record of the incoming sferics signal is made only when the plane of one of the loops is directed toward the source. The pair of loops rotates at perhaps one revolution per minute, and the system provides a record on a drum turning with the loops. The receptive sector may be reduced to one degree of azimuth. Records obtained in this manner show direction of signal arrival as a function of time; a rough indication of the proximity of the source can be gained from the relative size and density of the marks made by the recording pen. The narrow sector system has been employed by Lugeon [16] and Bureau [8], among others. It provides very simply a record upon which statistics might be based, and rough conclusions may be drawn regarding the location of sources of sferics from observations made at several stations, or from the appearance and density of the record at one station. This system has found use in Switzerland, France, Australia, and other countries.

Other systems measure and record, as functions of time, the frequency of occurrence of sferics having an intensity greater than a present level (Bureau's radiocinemograph and Lugeon's atmoradiograph) [8], and the field strength of sferics (Lugeon and Nobile's radiomaximograph) [18]. Similar systems provide power companies with information on the proximity and course of intense local storms [29]. Rough determination of distance of sferics sources from single stations employing these and the narrow sector systems is made possible by astronomical methods involving the ozonosphere or ionosphere [14, 18]. Observation at a single station of the wave form of sferics indicating multiple reflections from the ionosphere also permits rough determination of distance [15, 23, 33]. Approximations of distance have also been based upon the assumption that the most intense discharges in all but the weakest storms have about the same average power [18].

Accuracy of determination of bearings of sferics varies diurnally because of changing polarization of the arriving radio wave. These errors are largest at night, and especially at sunrise and sunset [22, 23]; nevertheless, useful data may be obtained even then, although the efficiency of observation is reduced. Polarization errors are greatest in an intermediate range between a few tens of miles and some 1500 miles from the receiver, and are smaller at the very low than at the medium and high radio frequencies. Most other sources of error, due to nonhomogeneity of the site with respect to azimuth, and to instrumental and operational errors, can be made negligible. Use of antennas other than loops to decrease polarization errors is being investigated [1]. Regarding propagation, range, and attenuation of low-frequency radio waves, see, for example, [4, 5, 7, 10, 21]. In triangulation procedures with data obtained from direction finders, the errors of closure of polygons formed by laying out the several reported azimuths, together with observers' estimates of confidence in the value and synchronization of each azimuth, have been utilized empirically to assign estimates of accuracy to sferics fixes. Error charts based upon the geometry of a network with respect to any source of sferics have been constructed. These show which pairs of azimuths yield the smallest maximum error, under the assumption that there is a constant error (generally taken as $\pm$ 2°) in azimuth determination at each station. In network operation, the task of designating which sferics shall be observed is often rotated among the stations in the network, in order to avoid favoring a circle of detection about only one station, and to reduce the blanking effects of local storms. Probable errors are assigned for each fix based upon location with respect to the observing network, estimates of instrumental error, size and shape of triangle or polygon of intersection of bearings, and consistency. Significant contributions regarding selection of an optimum point for a fix, given several radio direction-finder bearings, have been made by Ross [28], Stansfield [34], and Barfield [3].

Of what value are sferics to meteorologists? Like radar, sferics instruments provide the equivalent of an extremely dense network of observing stations within the working range; the practical need for such high-density coverage depends upon the significance of the weather element(s) detected, the size of the area covered, and the density of the regular weather observational network over the area. Patterns of activity are more readily perceived than by use of point observations. In the present case, the forecaster insures that his map analysis, especially when based upon widely scattered observations, agrees with the fact of occurrence of vigorous convection at certain places in the pattern. Synoptic maps were revised on this basis as early as 1924 [4]. Petterssen and Berson [26] in a recent study of European and North Atlantic sferics reports and winter synoptic maps found concentrations of sferics sources at the apex of warm sectors of both nascent and occluding cyclones, in the former case even before the appearance of closed isobars at the surface. Maxima were also found on the cold front 400–500 miles from the apex, and secondary maxima 300–500 miles behind the cold front.

Study of the results of observations of a network of direction finders in South Africa led Schonland and his collaborators [32] to conclude that 70 per cent of sferics fixes could be verified by local observations of thunderstorms and precipitation, though perhaps more were real, but that the utility of sferics reports in forecasting tends to be marginal.

The performance of a United States direction-finding network consisting of stations in New Jersey, Florida, Newfoundland, and Bermuda has been studied [38] by comparison of sferics fixes with reports of thunder-

storms, lightning, and cumulonimbus from the relatively dense United States weather-reporting network east of the 95th meridian. For the six-month period, May to October, 1945, 87 per cent of 135 four-station fixes were within 100 miles of a thunderstorm, lightning, or cumulonimbus report within one hour of the sferics observation, and 68 per cent of 19,130 three-station fixes were similarly verified. On the other hand, of 11,006 reports of thunderstorms or lightning, 57 per cent were attended by fixes within 100 miles, and 80 per cent, within 200 miles. The diurnal variation averaged between ten and fifteen per cent on either side of the figures given, with poorest performance at 0600 and 0900 GMT, best at 2100 and 0000 GMT. A survey made in 1945 [38] of 98 U. S. Air Force weather stations located within the area of coverage of this network, selected only for having forecasting problems in the Gulf of Mexico, Caribbean, or western Atlantic, revealed that 42 per cent considered sferics reports over the oceans in middle latitudes to be "extremely useful," and 98 per cent considered them either "extremely useful" or "useful." Almost identical percentages resulted as regards sferics reports over oceans in the tropics. The average length of experience with sferics was nine months. In a series of airplane flights over the ocean bordering on the network, 81 per cent of the sferics reports near the flight path were attended by significant weather within 100 miles.

Interesting remarks on the use of sferics in weather forecasting in Switzerland, including a discussion of the implications of both active and quiet regions, may be found in [16]. The relation of sferics to the Indian monsoon may be found in [35, 36]. For examples of recent North Atlantic weather and corresponding sferics fixes, see [25]. Studies relating to the utility of sferics as regards hurricanes have thus far tended to be inconclusive or negative [30], although further work appears justified in view of reports from the western Pacific during World War II of their use in following the progress of easterly waves. Recently sferics have been studied in tornado investigations, with emphasis on analysis of wave forms.

More studies are needed relating broad meteorological patterns to the distribution of thunderstorms and other intense electrical activity occurring in regions of rapid charge separation. The physical nature of the lightning flash, its visible and photographic forms, the resulting field changes, the propagation of attending electromagnetic waves—these researches have been and are still emphasized. Consequently, sferics research has tended to appear in nonmeteorological publications. Doubtless room for further application of modern direction-finding techniques to sferics exists, if only because present systems are essentially those first employed two or three decades ago. However, if the field of sferics is to find important use in meteorology, studies of regional application of sferics observations to characteristic weather patterns must be undertaken; reference is made to the areal distribution of thunderstorms attending the large-scale flow patterns. Such patterns may include cyclogenesis, especially in regions off the east coasts of the continents. Presumably, departures from the normal in the disposition of sferics may yet be found in the neighborhood of developing tropical storms. As to the utility of sferics over land areas occupied by a dense meteorological observational network, the burden of proof rests with sferics, although the inexpensiveness of simple sferics receivers compared with radar sometimes recommends them for warning of the approach of local storms, especially during daylight hours when the detection of thunder is limited to a distance of the order of ten miles. Because of an essential requirement for a thunderstorm, that is, sufficient available moisture, sferics methods find negligible application in some areas, and only seasonal use in some others. The development of a synoptic climatology of sferics distribution over the oceans would contribute toward maximum utility of sferics methods. Great benefit should also be derived from the analysis of wave forms that indicates the relative frequency of cloud-to-cloud, cloud-to-air, and cloud-to-ground discharges.

Sferics study promises to refine our knowledge of the distribution of thunderstorms over the oceans. Brooks' classical work [6] was necessarily based largely upon ships' reports for the ocean, and it is expected that conclusions based upon this essentially small sample may be improved. A minor disadvantage in the use of sferics for this purpose lies in the loss in accuracy as one proceeds away from a central area or point, but this objection is not final as regards the refinement of our climatological knowledge over the oceans. The development of a climatology of radio static appears desirable [37]. It should become possible to estimate reasonably well for any given place on the globe the monthly, seasonal, and annual noise level, and its diurnal variation. Meteorologists may well assist in the interpretation of noise-level records made over the world. Specific results will depend upon increased acquaintance with the synoptic climatology of thunderstorm occurrence over the oceans.

Present sferics methods are time-consuming when it is desired to locate fixes accurately and to obtain a large sample. Photography has mostly found application for research purposes. Rapid techniques for handling the considerable volume of information obtained even with a simple direction finder will increase the utility of sferics in applications to forecasting. With small sample methods, the reliability of a sferics observation as an indication of electrical activity is greater than that of a negative observation as an indication of quiet conditions. Electronic methods are apparently available for the presentation of the areal distribution of electrical discharges continuously on oscilloscope screens [27]. The electronic determination of frequency distribution of azimuths of discharges above predetermined levels of intensity also seems feasible. It should be possible to present the results of a complete sferics observation made at map time well before the map is plotted and analyzed. Finally, it would be helpful to investigate the proper length of observational sample necessary in order to obtain a reasonably complete picture of the sferics activity occurring at a given time.

The expectation that sferics will become a more familiar tool for the meteorologist appears justified.

Practical Application of Microseisms to Forecasting *by James B. Macelwane, S. J.* 1312

OBSERVATIONS AND THEORY OF MICROSEISMS

By B. GUTENBERG

California Institute of Technology

Observations and Causes of Microseisms

As soon as fairly sensitive seismographs were available, it was found that the ground is never at rest. Various terms such as *pulsations*, *pulsatory oscillations*, *microseismic movements*, and *microseisms* were used to describe these continuous small movements which are not caused by earthquakes. Hecker, in 1906, divided the microseisms, as they are now usually called, into four groups: (1) those with periods of less than 4 sec, (2) those with periods of about 7 sec, (3) those with periods of about 30 sec, and (4) those with periods of about one minute and more. Later, additional types of microseisms were described. For a bibliography, see [4].

There is little agreement about the causes of microseisms. This is partly due to the fact that at one station certain types of microseisms prevail and are described; at another station, different types. In addition, the seismographs in use have widely different characteristics so that some emphasize waves with periods of a fraction of a second, others waves with periods of 10 sec or even more. (Compare Figs. 1*c* and 1*f*.) The fact that there are several types of microseisms which differ rather little in their appearance has added to the confusion. Many authors have claimed that hypotheses concerning causes of microseisms given by other seismologists are incorrect while, actually, completely different types of microseisms were involved in the discussions. In Table I a summary of some of the more common types of microseisms is presented, and Fig. 1 shows some typical records.

No movements of the ground due to traffic and industry (which are usually also called microseisms) are included here. In addition, "microseisms" of Type 10 (Table I) are frequently caused by the direct effect of air currents in the vault on the instruments, and Type 11 probably contains instances where subfreezing temperatures caused freezing of moisture on the instrument and spurious "microseisms." Movements with periods of more than 1 minute (for example from changing loads at coasts during high seas or high tides) are now usually classified as "tilt." In general, irregular and short-period microseisms are connected with rather local causes. On the other hand, Types 6 and 7 have been recorded thousands of miles from the source, for example in Irkutsk, Central Asia, during storms near the Norwegian coast.

Very little is known about Type 1 (Table I). These microseisms are under investigation by Father Macelwane and his collaborators [25]. Microseisms of Type 2 are observed at stations near coasts and are caused by local surf [15, p. 269].

Types 3 and 4 are probably of local origin. They have been attributed to effects of windstorms and cold fronts near the station, but no detailed theory has been published on the mechanism by which they are produced. They are being investigated at Fordham [24] and at Pasadena. Caloi [5] has found that microseisms with periods of 2–3 sec at Trieste are correlated with seiches in the Gulf of Trieste which in turn are caused by low pressure centers.

Types 5 to 8 usually originate at greater distance

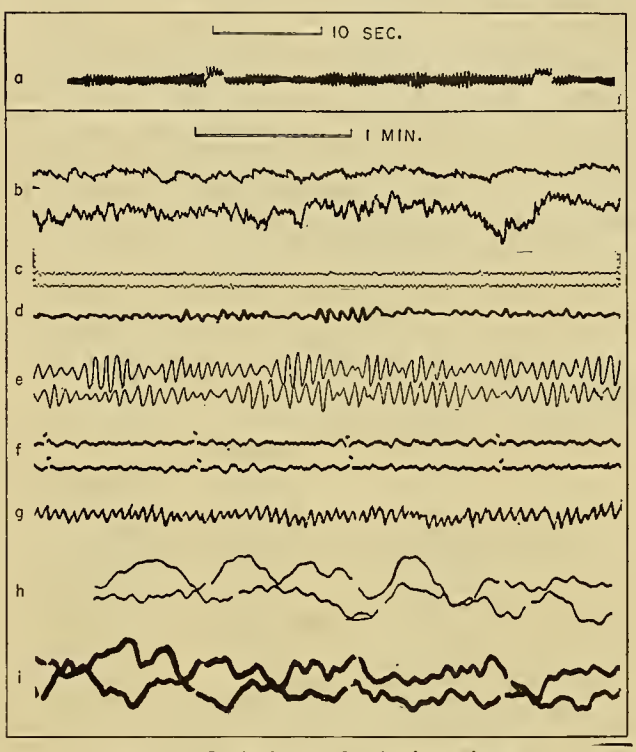

FIG. 1.—Typical records of microseisms.

a. Short-period microseisms (Type 1, Table I), Wood-Anderson torsion seismograph, Florissant, Missouri. (*After Macelwane.*)

b. Microseisms from local surf at Helgoland, January 18, 1918; Wiechert 200-kg horizontal seismograph; successive lines are about 1 hr apart. (*After Gutenberg.*)

c. Microseisms of Type 3 (Table I), recorded at Pasadena on December 26, 1948; short-period Benioff vertical seismograph.

d. Microseisms during windstorm at Göttingen, November 13, 1909; 1200-kg vertical Wiechert seismograph. (*After Gutenberg.*)

e. Microseisms recorded at Zi-ka-wei near Shaughai from typhoon over the ocean, October 3, 1923; Galitzin seismograph; lines are about ½ hr apart. (*After Gherzi.*) Records of Type 6 or 7 are frequently similar to this record.

f. Microseisms of Type 6 or 7 (Table I), recorded simultaneously with Fig. 1*c* at Pasadena by long-period Benioff vertical seismograph.

g. Microseisms during monsoon recorded at Zi-ka-wei on November 22, 1922; Galitzin seismograph. (*After Gherzi.*)

h. Microseisms of Type 10 (Table I). (*After Whipple.*)

i. Microseisms of Type 11 (Table I), recorded at Zi-ka-wei on January 4, 1917; Galitzin seismograph. (*After Gherzi.*)

from the stations. Microseisms of Type 5 have been studied recently in more detail because of their economic importance. They are probably caused by high ocean waves in hurricanes and typhoons. Most of the available theory is applicable to these microseisms.

At most stations more or less regular sinusoidal waves are recorded with periods between 4 and 10 sec, and such microseisms have been described in several hundred papers [4]. Nearly everywhere they have well-expressed maxima during winter and frequently are scarcely noticeable on typical records during summer. At some stations a slight increase during the night has been reported. Except for Type 9, it is generally pointed out that these microseisms are connected with windstorms over the ocean (Fig. 2), but there is no agreement concerning the mechanism by which the energy is transmitted from the storm to the ocean bottom and frequently it is not clear whether Type 6, 7, 8, or still another type (*e.g.*, those attributed to strong winds blowing against coastal mountains) is involved. According to the hypothesis stated in 1903 by E. Wiechert and developed by Gutenberg [15], ocean waves driven by storms toward steep coasts are the source of Type 7. On the other hand, Gherzi [11] believes that fast changes in air pressure (pumping) are a major cause of such microseisms. However, there is some doubt whether Type 8 actually exists, since air-pressure changes amount to only a small fraction of one atmosphere while the pressure changes produced by storm waves in the ocean are of the order of magnitude of one atmosphere.

It is very likely that a mechanism similar to that which produces microseisms during hurricanes also operates in extratropical disturbances. In this case the energy of the storms available in a given area is smaller, but the region affected by it is much more extended. The resulting microseisms are Type 6. On the other hand, Banerji [1] believes that the motion of gravity waves in water is large enough to reach the ocean bottom and cause microseisms of Type 6. Finally, similar microseisms are caused by monsoon winds [1] (Type 9).

In one of the most comprehensive of all studies of microseismic records and their relationship to meteorological phenomena, Båth [2] has shown that the microseisms with periods of 4 to 10 sec recorded at Uppsala, Sweden, belong to at least two types: one due to surf driven against the steep Norwegian coast; the other to cyclones in the North Atlantic which transmit a small fraction of their energy into the water and the ocean bottom. In instances like this, when microseisms from different sources arrive simultaneously at a station, waves with slightly different periods produce interference patterns; as a consequence, wave groups with gradually increasing and decreasing amplitudes are frequently found at certain stations, but rarely at others.

Great progress has been made in the study of Types 5, 6, and 7 by the use of tripartite stations which are described in the article in the Compendium by Father Macelwane.[1] For papers giving summaries of the literature concerning Types 6 to 9 see, for example, [12, 15, 18, 19, 32, 36].

It is possible that microseisms with longer periods include movements produced by strong winds (Type 10). These differ from Type 4 by their much greater periods. Possibly related to them are the compressional movements of more irregular appearance which are recorded by the strain seismographs at Pasadena during windstorms as well as during the presence of convection currents. These movements seem to be the result of compression and dilation of the hill on which the Seismological Laboratory is built.[2] Type 11 includes irregular movements, with periods of the order of one minute, which seem to be connected with freezing of the ground [15, pp. 294–298].

Table I. Types of Microseisms

Type no.	Period (sec)	Kind of movement	Hypothetical causes	Relative distance of causes	Figure
1	0.2–0.5	Regular	?	Local?	1*a*
2	0.2–2	Irregular	Surf	Local	1*b*
3	1–4	Regular	Fronts? Rain? Wind?	Local	1*c*
4	1–4	Irregular	Wind	Local	1*d*
5	2–6	Regular	Ocean waves in hurricanes, typhoons	Distant	1*e*
6	4–10	Regular	Ocean waves in extratropical disturbances	Distant	1*f*?
7	4–10	Regular	Surf driven by wind against steep coasts	Distant	1*f*?

Transmission of Energy from Meteorological Disturbances into the Ground

There is no type of microseism for which a complete theory has been worked out. The few theories which have been formulated mathematically cover only certain phases of the process. These theories may be divided into two groups. The first group deals with the transmission of energy from the meteorological disturbance into the ground, the second with the propa-

1. "Practical Application of Microseisms to Forecasting" by J. B. Macelwane, S.J., pp. 1312-1315.

2. See *Bull. Amer. meteor. Soc.*, 20:424, Fig. 3 (1939).

gation of the microseismic waves in the ground to the point of observation.

Energy Transmitted from Surf. The energy transmitted from surf to the coast [14] depends on the energy of these waves is transferred to the coast; f depends on the steepness of the coast, the loss of energy due to friction in the water approaching the coast, and the wind. The kinetic energy E^* (per second) of ocean

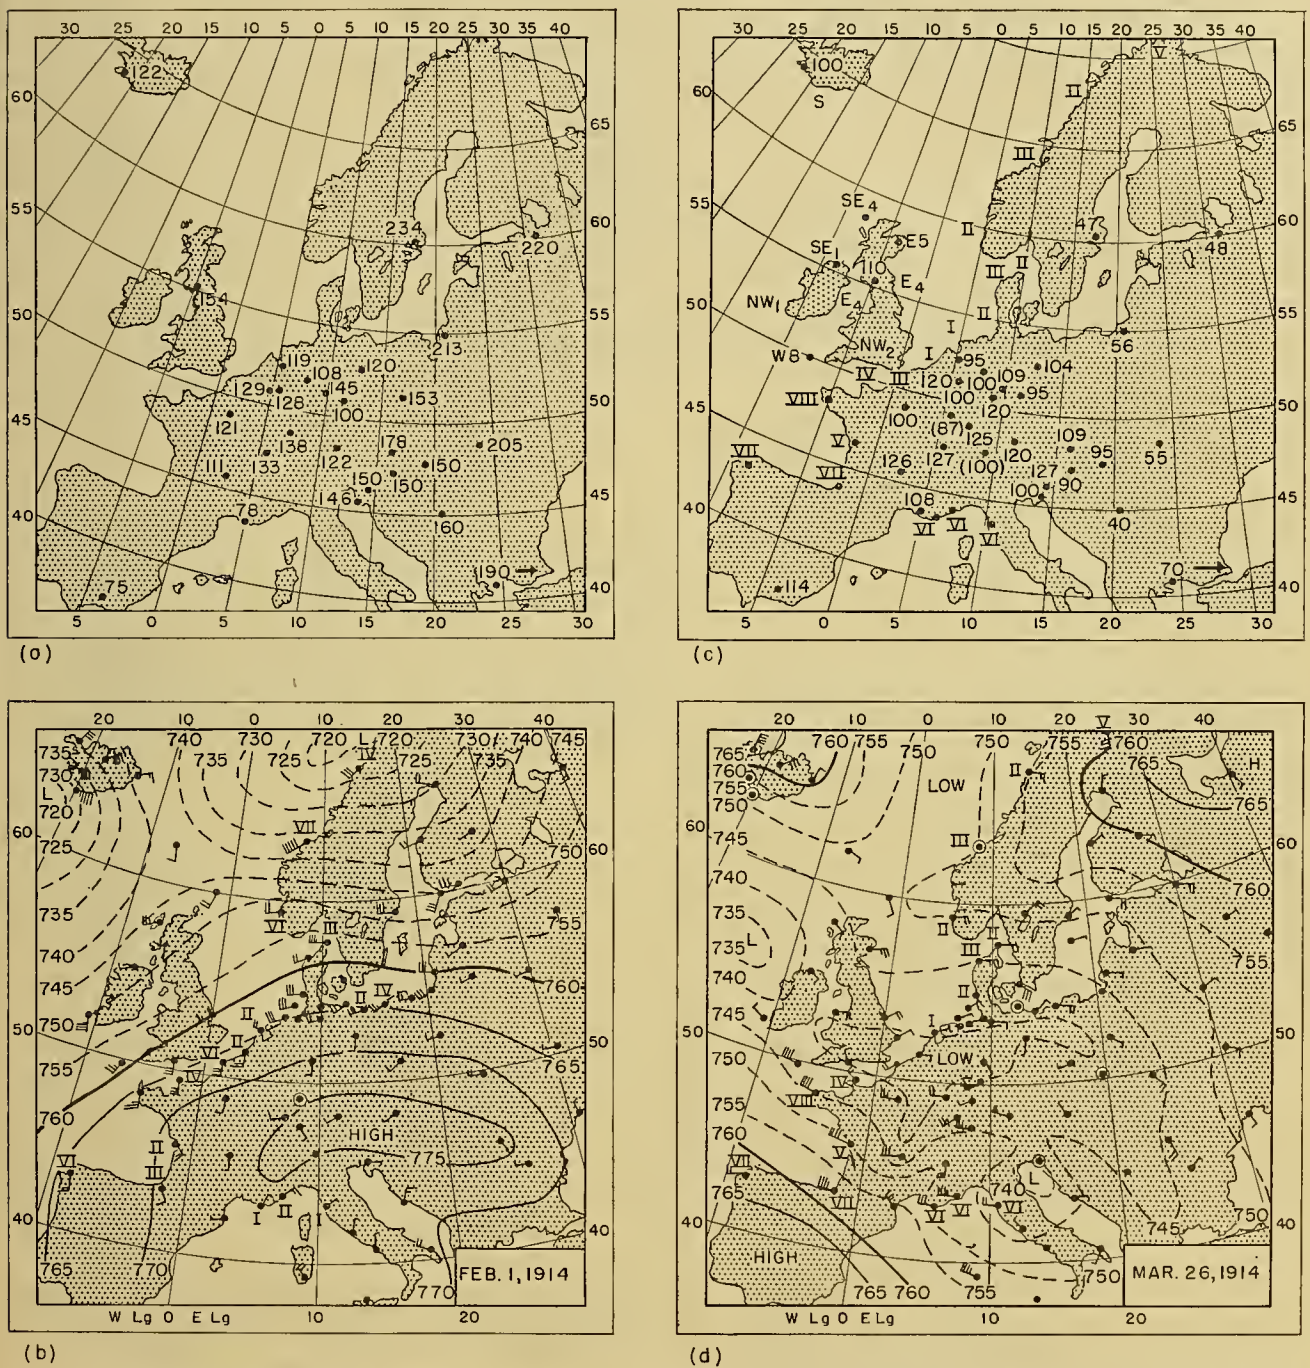

FIG. 2.—Relative amplitudes of microseisms (in per cent of the individual average amplitudes for each station for the same days with winter microseisms) and corresponding weather maps: (*a*) and (*b*) on Feb. 1, 1914; (*c*) and (*d*) on March 26, 1914. State of swell indicated by Roman numerals (on a scale from 0 to IX). (*After Gutenberg.*)

kinetic energy of the waves, the type and slope of the coast, the force of the wind, and its direction relative to the shore. The greatest energy will be transferred to the coast when a strong wind drives high ocean waves against a steep, rocky shore. Only a fraction f of the waves (period T, length L, velocity V, and height H is given approximately by

$$E^* = \frac{gLH^2}{16T} = \frac{gVH^2}{16}. \qquad (1)$$

The energy which is transferred to a coast of length l is given by

$$E = \frac{fgVH^2l}{16}. \quad (2)$$

During storms this may reach the order of $10^{18}f$ ergs sec^{-1}. The amplitude a of the corresponding microseisms with a period T and a wave velocity C at a distance D from the source is then given approximately [14] by

$$a^2 = \frac{TE}{5 \times 10^{11}C^2 \sin D}. \quad (3)$$

If $T = 7$ sec, $C = 3$ km sec^{-1}, $D = 10°$, $E = 10^{18}f$ ergs (as found above), and $a = 1$ micron $= 10^{-3}$ mm, f must be of the order of 10^{-3}, that is, one-tenth of one per cent of the wave energy must be transferred to the coast in order to explain the microseisms by the surf action. This value is not unreasonable. No arguments against this theory have been published and the theory explains the microseisms of Type 7.

Theory of Propagation of Waves from the Surface of the Ocean to the Bottom. In an attempt to calculate the energy transmitted from ocean waves at the surface to the ocean bottom, Scholte [35] supposed that waves of period T exist at the surface of the ocean. He started with the following equation given by Sezawa [37]:

$$\frac{\partial^2 \mathbf{r}}{\partial t^2} = c^2\nabla(\nabla \cdot \mathbf{r}) + g\nabla w, \quad (4)$$

which connects a displacement $\mathbf{r}$ (components u, v, w) in the water with the velocity c of its propagation and includes gravity waves as well as compressional waves. Scholte found under reasonable assumptions that near the surface of the ocean the ratio of the amplitudes of the gravitational and the elastic waves is of the order of 10^4 to 1. If the gravity waves at the surface have a height of 10 m, the elastic waves in the water would have an amplitude of the order of 1 mm. However, the gravity waves decrease exponentially with depth; the elastic waves change relatively little. Consequently, gravity waves should not be noticeable at great depths in the ocean (this result confirmed theoretical conclusions of earlier investigators), but elastic waves should remain perceptible with sensitive instruments down to the bottom of the ocean where they start the usual seismic waves in the surface layers. However, Scholte did not describe this latter process in detail. His paper is the only one giving quantitative results for the elastic microseismic waves at the ocean bottom.

Theory of Propagation of Elastic Waves in a Medium Consisting of an Upper Layer of Water Overlying a Homogeneous Layer of Solid Rock. Press and Ewing [31] have studied the propagation of elastic surface waves originating at the surface of an ocean with a homogeneous bottom layer. They have used an equation developed by Stoneley [38] which may be written in the following form:

$$\tan\left(\frac{2\pi AH}{L}\right) = \frac{\rho A[4(1-B)^{\frac{1}{2}}(1-C)^{\frac{1}{2}} - (2-B)^2]}{B^2(1-C)^{\frac{1}{2}}}, \quad (5)$$

where

$$A = \left[\left(\frac{c}{w}\right)^2 - 1\right]^{\frac{1}{2}}, \quad B = \left(\frac{c}{v}\right)^2, \quad C = \left(\frac{c}{V}\right)^2, \quad (6)$$

H = depth of ocean; L = wave length (measured in a horizontal direction) of waves formed by constructive interference between elementary waves of length l which undergo multiple reflections at the boundary of the liquid layer at an angle of incidence i; c = velocity of microseismic waves; w = velocity of sound in water (density 1.0); V and v are the velocities of longitudinal and transverse body-waves, respectively, in the material below the ocean which has the density ρ and is assumed to extend down to infinite depth. Scholte, too, has found and used this equation [35, equation bottom p. 674] apparently without recognizing the equation as Stoneley's. If the velocity c is assumed, then H/L can be calculated from equation (5). If the depth H of the ocean is very small as compared with the wave length L, equation (5) becomes the well-known equation for Rayleigh waves in the surface of the solid bottom. For a more detailed theory, see Pekeris [30].

Press and Ewing assumed, for example, $w = 1\frac{1}{2}$ km sec^{-1} (velocity of elastic waves in water), $V = 5.3$ km sec^{-1} and $v = 2w = 3.0$ km sec^{-1} in the ocean bottom where the density $\rho = 2.5$, and Poisson's ratio equals $\frac{1}{4}$. In order to get an exponential decrease of amplitudes with depth, that is, surface waves, A in equation (6) must be real ($c \geqq w$). Under their assumptions (which include $l = 1.5T$) the curve giving the wave velocity as a function of H/l consists of two branches (Fig. 3).

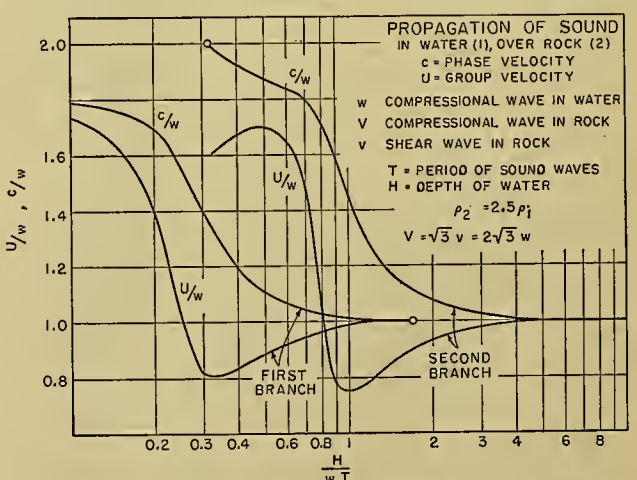

FIG. 3.—Theoretical phase and group velocity in a system consisting of a liquid layer overlying an infinitely thick homogeneous solid (under the specified assumptions). (*After Press and Ewing* [31].)

For the first branch, c' approaches the velocity of Rayleigh waves in the ground if H/l is small. Under the assumptions made in the figure, this requires an ocean depth of not over a few hundred meters for waves with periods of 3 sec. If the ocean depth H increases beyond the wave length ($l = 1.5T$) of the elastic waves in water, the velocity of the microseisms approaches the velocity of sound in water.

The second branch in Fig. 3 begins if the ocean depth exceeds a value of approximately $l/3$ (or about $\frac{1}{2}$ T), which is normally more than 1 km. The corresponding wave velocity of the microseisms is about twice the sound velocity in water or about 3 km sec^{-1}. If the ocean depth is smaller than the critical depth, the value of A in equation (6) becomes imaginary; the waves which correspond to this part of the branch are no longer surface waves. For $H = 0$, this corresponds to the second (physically nonexistent) branch of the solution for Rayleigh waves in a homogeneous layer. If the ocean depth exceeds a value of about four times the wave length, the velocity of the microseisms again becomes nearly equal to the velocity of longitudinal waves in water.

Press and Ewing have pointed out that (as in other seismic surface waves) the group velocity and not the wave velocity should be investigated in a study of the amplitudes of continuous waves. The group velocity U is given by the equation,

$$U = c - L \frac{\partial c}{\partial L}. \tag{7}$$

Under the assumptions of Fig. 3, there is a minimum group velocity in the first branch and a maximum as well as a minimum group velocity in the second branch. All three values can be expected to be associated with an increase in amplitude in the course of time; under the assumptions used in Fig. 3, Press and Ewing find the values given in Table II. All three values for T are

Table II. Periods for Group Velocity Maxima and Minima
(*After Press and Ewing* [31])

Branch	Group velocity U	U/w	H/L	T for $H = 4\frac{1}{2}$ km (sec)
First	Minimum	0.8	0.33	9.1
Second	Maximum	1.7	0.49	6.1
Second	Minimum	0.75	0.98	3.1

within the range which is observed in microseisms. However, although the assumed ocean depth $H = 4\frac{1}{2}$ km is a fair average in many instances, it must be considered that in many oceanic areas the depth is much less and consequently the periods of the microseisms should vary greatly depending on H. Such a great variation is not observed. However, the theory by Press and Ewing is a first approximation only; among other factors, the rather rapid increase in velocity with depth in the ocean bottom must be expected to affect the numerical results considerably. The effect of friction of the water on the sea bottom has no appreciable effect according to Menzel [26].

Scholte has not considered the effects of group velocity. However, since he discusses the vibrations of the ocean bottom relatively close to the source, the effect of the group velocity is probably negligible; it takes many wave lengths before the accumulation of energy becomes appreciable in waves with periods near those of the maximum or minimum group velocity. However, effects of energy accumulation near extreme values of the group velocity have to be considered in the propagation of surface waves in the crustal layers. This has not been discussed by Scholte.

Theoretical Periods of Pressure Waves in the Ocean. Comparison between the observed periods of microseisms and the simultaneous periods of ocean waves by Bernard [3] indicate that the periods of the microseismic waves frequently are about one-half of the periods of the corresponding ocean waves. Darbyshire [6, 7] confirmed the observations of Bernard by using examples where a depression had a distance of the order of 1000 miles from the west coast of the British Isles and comparing the ocean waves which arrived at the coast of Cornwall with the microseisms recorded at Kew. On the other hand, S. M. Mukherjee (unpublished manuscript) found that the periods of sea waves during the southwest monsoon in India are definitely not double the periods of microseisms.

In detailed theoretical investigations Miche [27] has shown that in a stationary wave motion there are second-order pressure variations of twice the wave frequency. These variations are not attenuated to zero with depth. On the other hand Longuet-Higgins [23] (assuming incompressibility) found that beneath two wave trains with the same frequency travelling on the ocean in opposite directions, pressure fluctuations result with a frequency double that of either wave and with amplitudes proportional to the product of the wave amplitudes. Such mechanisms could produce the pressure changes near the surface which are assumed by Scholte in his theory [35].

All the mathematical theories mentioned thus far probably give a rough approximation, each from a different angle, to a part of the causative mechanism which operates in microseisms. The theories of Miche, Longuet-Higgins, and Bernard could be combined with that of Scholte or that of Press and Ewing. In the latter theory, the effect of the maximum and minimum group velocities on the amplitudes would be smaller if the source of the microseisms had strongly prominent periods. Such periods (possibly somewhat modified) should also appear in the microseisms.

Theory of Propagation of Elastic Waves in the Ground

Since microseisms are observed at stations on land, some theoretical results on the propagation of elastic waves in the earth's crustal layers are needed for a discussion of microseisms.

Wave Types Observed in Microseisms. There are two major groups of seismic waves: (1) body waves (travelling through the interior of the material), and (2) surface waves. Group (1) contains longitudinal and transverse waves which have no noticeable dispersion, so that group velocity and wave velocity are practically the same. Group (2) includes Love waves (surface-shear waves) in which the particles move in the surface of the earth perpendicular to the direction of propagation, and Rayleigh waves in which, theoretically at least, the particles describe ellipses with their longer axis in the vertical direction and their shorter axis in the direction of propagation. In seismograms produced by disturb-

ances near the surface (but not from explosions) the surface waves are usually more prominent than the body waves.

The first attempt to find the type of movement which prevails in microseismic waves was made by Geussenhainer [10]. He found that in Göttingen the period of the vertical component of the microseisms normally changed gradually with time while in the horizontal component periods of 6, 7½, and 9 sec occurred more often than periods with intermediate values. If waves with one of these preferred periods existed in the vertical component, the corresponding waves had especially large amplitudes in the horizontal components; if the period of the microseisms in the vertical component was between two fundamental periods of the horizontal, both fundamental periods, sometimes changing repeatedly from one to the other, were recorded in the horizontal components. Geussenhainer believed that the vertical pendulums record mainly free vibrations of the earth's crust. Such free vibrations would require additional theoretical considerations since the resulting movements may be very different from those calculated for forced vibrations, especially if resonance phenomena are involved.

The observed velocities of microseisms are usually between about 2 and 4 km sec^{-1}; that is, in the range of velocities of surface waves with such periods. It is generally believed that the microseisms consist of surface waves. Unfortunately, measurements of the amplitude of microseisms as a function of depth in order to find the expected decrease are inconclusive [15, 19, 20]. The few authors who have studied the question of the wave type in microseisms agree that Rayleigh waves prevail [16, 22, 32]. On the other hand, waves of the Love type are also involved, although their amplitudes are relatively smaller.

Increase in Period with Distance. It has been found that the period of elastic waves usually increases as they are propagated. For example, in Eurasia the periods of microseisms frequently lengthen by several seconds as the waves are propagated from the Atlantic Coast into Asia. This increase is not due necessarily to a stronger absorption of the shorter periods but may be due to an actual increasing of the wave lengths with distance. Among attempts at a theoretical explanation are the wavelet theory by Ricker [33, 34], a theory developed by Munk [28], and a theory by Sezawa [37] (based on the assumption that the increase in period is due to internal friction) which has been extended by Gutenberg [13] and by Gutenberg and Schlechtweg [17]. This theory leads to the following equation for the period T at a distance D from the source:

$$T^2 = T_0^2 + \frac{5\eta D}{\rho V^3}, \tag{8}$$

where η = coefficient of internal friction (about 10^9 poises), ρ = density, V = wave velocity, and T_0 = period near the source. Values of T calculated from equation (8) agree well with the observed increase in period. For microseisms Gutenberg [14] found approximately

$$T^2 = T_0^2 + 0.01D, \tag{9}$$

where D is expressed in kilometers. The increase in period with distance makes it difficult to use microseisms recorded at a distance D from the source to find the period T_0 which prevails near the source.

Effect of Differences in the Structure of the Earth's Crust and of Faults on Microseisms. Microseisms in general have wave lengths of less than about 25 km; since their energy decreases exponentially with depth, they should be propagated mainly within the uppermost 25 km of the earth's crust, and short-period microseisms should be propagated in even a thinner layer. (This is the main reason for the observed dispersion of surface waves.) In geologically disturbed areas the loss of energy due to absorption is greater. This was recognized first for Europe (Fig. 4), where the regions in which the microseisms are relatively large for a given location of the source agree relatively closely with the geological units [15]. For example, microseisms originating in Scandinavia are propagated far into Asia without much loss of energy, but their amplitudes decrease considerably in southerly directions where surface layers of different geological ages and different physical constants are passed by the waves.

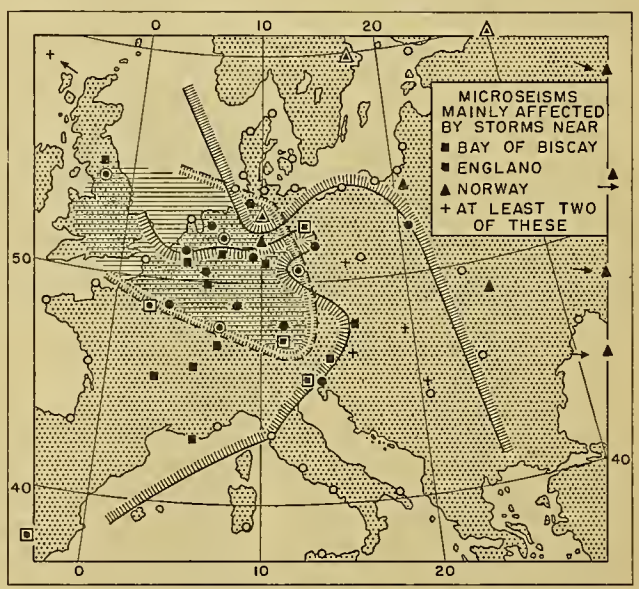

Fig. 4.—Areas with relatively large microseisms in Europe for three different locations of storm centers. (*After Gutenberg.*)

In the Pacific, microseisms with relatively large amplitudes are recorded if the station and the source of the microseisms are on the same side of the andesite line. This line (sometimes called the Marshall line) is the surface trace of a discontinuity (considered to extend to a depth of at least 30 km) which separates the less andesitic material of the upper layers in the bottom of the "Pacific Basin" from the more andesitic material with different physical properties on the continental side. In the western Pacific, the andesite line follows

the ocean deeps off Kamchatka and Japan, then runs to the east of the Marianas and of the Palau Islands and then southeastward off New Guinea and the Solomon Islands. Japanese scientists have pointed out that typhoons to the east of Japan are accompanied by large microseisms at the stations along the east coast of Japan, but only by insignificant microseisms on the west coast of Japan. The station operated at Guam under the project of the United States Navy Department is close to the andesite line. It records microseisms from typhoons which are centered far away in the ocean

Much smaller effects are to be expected from displacements along faults inside the major crustal blocks. Such faults cover greater parts of the earth's surface than is generally believed by nongeologists. Amplitudes of microseisms passing them (*e.g.*, along the Pacific coast of the United States) are not much reduced, especially in instances where the velocities on both sides of the fault zone do not differ much, thus contrasting with the deep structural discontinuities of the type represented by the andesite line surrounding the Pacific Basin. Microseisms are propagated across large parts

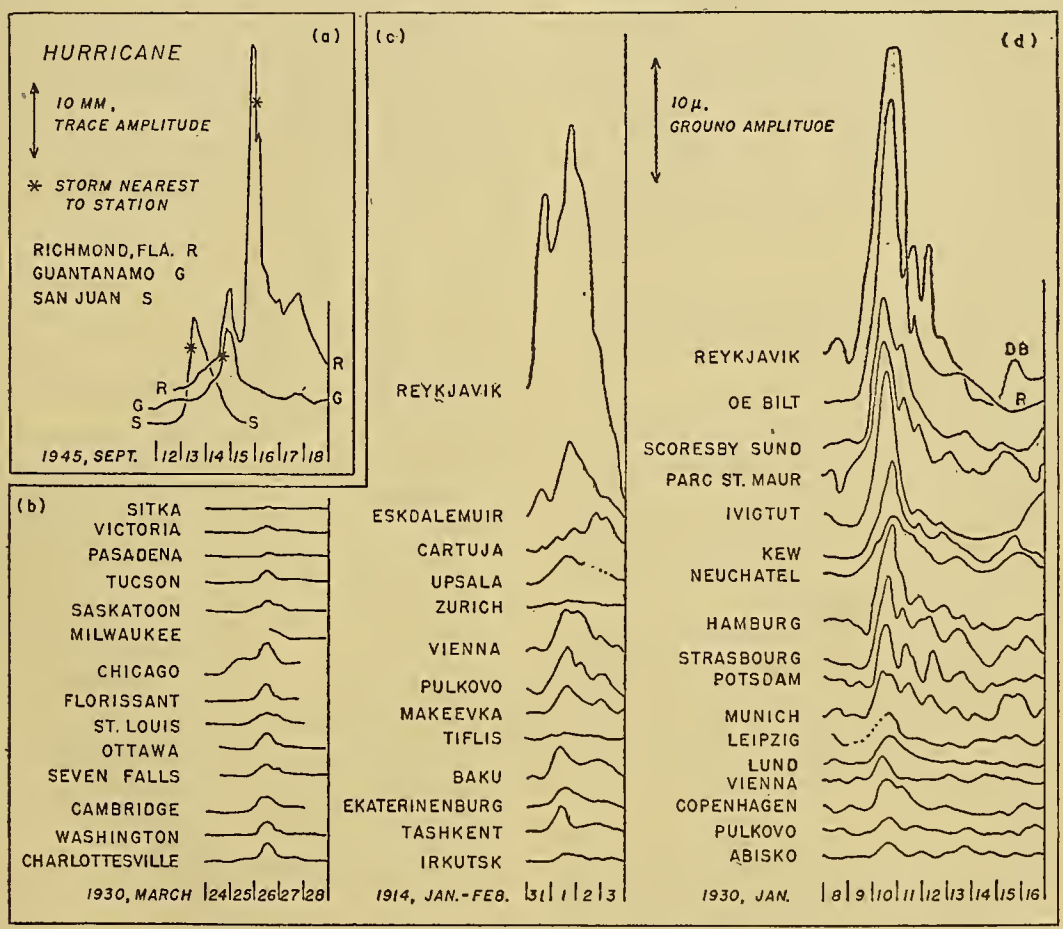

FIG. 5.—Amplitudes of microseisms: (*a*) in the Caribbean during a hurricane (*after Gilmore*), (*b*) in North America during a storm in eastern Canada (*after Gutenberg*), (*c*) in Europe and Asia during a storm approaching northern Norway (*after Gutenberg*), (*d*) in Europe and Greenland during a storm north of Scotland (*after Lee*). (*Taken from Gutenberg* [16].)

southeast of Japan; there is some indication that typhoons moving westward south of Guam produce relatively irregular and small microseisms at Guam until they cross the andesite line in the Caroline Islands.

The Caribbean loop is usually considered to be the boundary of a block with "Pacific" (less andesitic) material in the interior of the Caribbean. This explains why records of microseisms produced by hurricanes in the Caribbean area and recorded there at stations of the United States Navy Department show that the amplitudes of the microseisms decrease rapidly from one island to the other (Fig. 5). For other regions, see [5, 20, 21, 29].

of the United States without much loss of energy beyond regular absorption (Fig. 5b).

Effect of the Ground on Microseisms. Amplitudes of elastic waves at the surface of the earth depend appreciably upon the ground on which the instrument is located [15, p. 272; 20; 21]. For example, ground saturated with water is more likely to vibrate with large amplitudes than is solid rock, thus providing "increased sensitivity." However, the greater complexity of the records from such stations is a disadvantage and frequently more than offsets the advantage of the greater amplitude. For example, the station installed at Corpus Christi, Texas, in 1946 on loose sand recorded such

large microseisms of irregular types that it had to be discontinued. Solid rock is most suitable for the installation of seismographs for practically all purposes.

Desirable Lines for Future Research

The empirical and theoretical results concerning microseisms can be considered to be first approximations at best. While some progress can be expected from various extensive projects now under way, many important studies remain to be undertaken. Among those in which progress would be most helpful are the following, many of which offer no practical difficulties but have not been investigated because of the high cost:

1. Empirical

a. More detailed studies (similar to those described in [2]) on types of microseisms and their causes (leading to improvement of Table I).

b. Study of wave types and characteristics of observed microseismic waves (for all types in Table I), and determination of the "spectrum" of microseisms at a variety of locations.

c. Determination of the direction of approach of microseismic waves of various types at different stations by use of tripartite stations and of different types of instruments at a given station.

d. Additional determinations of velocities of microseismic waves and their correlation with velocities of seismic waves found from earthquakes and from blasts in the same region.

e. More data on the relationship between the periods of the cause of the microseisms in specific instances and the periods of the recorded microseismic waves in various parts of their "spectrum."

f. Study of the relationship between microbarometric waves and microseisms (only a few data exist).

g. Measurements of pressure variations at greater depths in the ocean and their correlation with ocean waves at the surface (amplitudes and periods) as well as with microseisms recorded nearby on land.

2. Theoretical

a. Study of the effect of free vibrations of the ground on microseismic waves, especially resonance effects. (This is a minor problem for earthquake waves where there are rarely "continuous" waves within the range of periods prevailing in microseisms.)

b. Quantitative data on effects of maximum or minimum group velocity on amplitudes (Press and Ewing's theory [31]).

c. Extension of the theory of Press and Ewing to other models, especially under assumption of a gradual or sudden increase of velocity with depth in the materials which form the ocean bottom.

d. Study of the transition of elastic waves from one structure to another, for example, gradually or suddenly from a model of the type considered by Press and Ewing to a typical continental structure.

e. Study of the transition of surface waves from one structure to another with different elastic constants down to a depth of (1) a fraction of the wave length, (2) a multiple of the wave length.

PRACTICAL APPLICATION OF MICROSEISMS TO FORECASTING

By JAMES B. MACELWANE, S. J.

Saint Louis University

The term *microseisms* applies to all elastic wave systems which are propagated along the surface of the earth and which, on the one hand, are not caused by earthquakes and, on the other hand, are not purely local man-made disturbances due to traffic or industrial activity. We may also exclude from present consideration the more or less irregular local vibrations produced by natural causes, such as varying pressure of the wind on a particular structure, wind friction on a landscape, freezing and thawing of the ground, jerky movements due to cooling of structures or of hills or other topographic features, although these are often referred to in the literature as a class of microseisms. We are thus restricting our attention to elastic surface waves which are propagated in the earth's crust over appreciable distances. These microseisms seem to be of different types and to appear in discontinuous frequency bands rather than in a continuous spectrum.

The type of microseisms to which most study has been devoted since the time of Bertelli is characterized by wave periods which, in the majority of cases, lie somewhere between four seconds and seven seconds, that is, by frequencies between 140 and 250 milliherz (1 herz equals 1 cycle per second). The reason for this emphasis is not far to seek. These frequencies fall within the optimum response range of most of the earthquake seismographs in common use and hence the microseisms of this type appear as a more or less disturbing background on most of the earthquake records.

Some connection between this type of microseisms and meteorological conditions in general had been noted by many workers beginning with Bertelli. These microseisms are regular in wave form and appear in a succession of groups of a few large waves each with short intervals of slight motion between the groups. They do not appear at all times but in discrete sequences which may last for a period of hours or days, building up to a maximum and dying down again. Such a sequence has come to be known as a *microseismic storm* (Fig. 1).

Four principal theories have arisen concerning the nature and origin of this type of microseisms. The first group of theories related them to the meteorological and geological conditions surrounding the recording station. The rise and fall of amplitude was attributed by some to the simultaneous arrival of vibrations of slightly different frequencies so as to produce an effect of beats. The second theory related the microseisms to steep barometric gradients on land or sea. A third theory, championed principally by Wiechert and other scientists of the Göttingen school, and particularly by Gutenberg through a period of three decades, ascribed

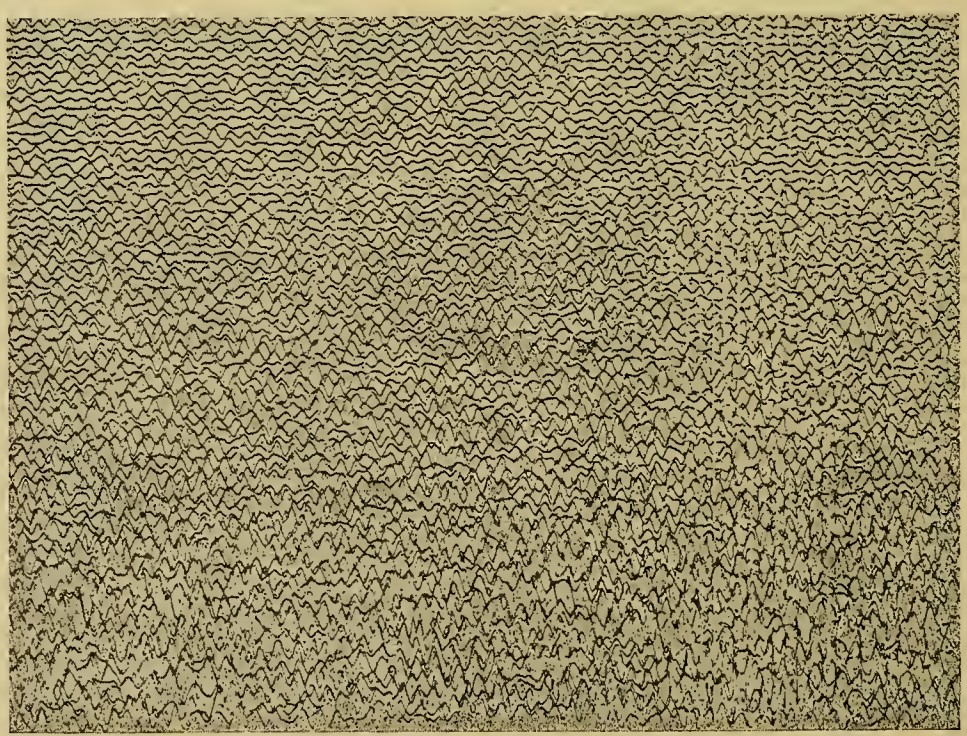

FIG. 1.—Storm microseisms recorded by a Wood-Anderson seismograph. Interval between time marks, 1 min.

this type of microseisms to vibrations caused by the beating of surf on a rocky coast. The fourth theory held that group microseisms are produced in some manner by storm centers at sea and are propagated through the earth's crust to the continents. This theory was espoused by Klotz, Shaw, Lee, Banerji, and especially by Gherzi who suggested as the mechanism a "pumping" or vertical oscillation of the air vortex in a typhoon, hurricane, or other closed circulation over deep water, thus explaining why microseisms cease to be produced when the storm center reaches land.

Many investigators have attempted to decide between these various theories by correlating large amplitudes chronologically with other phenomena, but without any decisive results. Several, for example, Linke, Lee, Archer, Neumann, and Leet, have attempted to determine the direction of arrival of the waves, on the assumption that they are true Rayleigh waves, by determining the relative amplitudes of the three components on the records of a single station. This method also proved inadequate.

A direct attack on the problem of direction of the propagation of the microseisms without any assumption was made independently by Ramirez at Saint Louis and by Trommsdorf at Göttingen in 1938 by means of the observations of the time intervals between the successive arrivals of the same wave at the three corners of a tripartite station, using these time intervals between successive arrivals to calculate both the direction of propagation and the speed of travel. Suitable equations for this purpose were developed by Krug, Gilmore, Macelwane, and Schuyler who also devised a nomogram.

The following equations are valid for any tripartite station. Let A, B, and C (Fig. 2) be the known angles of the triangle named counterclockwise; and let a, b, and c represent the respective opposite sides of known length. Assume that a given microseismic wave front has passed over vertices B and C and is now at A. Drop perpendicular BP from vertex B to the wave front and another perpendicular CQ from vertex C to the wave front. Let X be the angle QAC between the wave front and the side b, and let Y be the angle PAB between the wave front and side c. Let ctn $A = k$ and let the constants (b/c) sec $A = m$ and (c/b) csc $A = n$.

Now let the interval of time (Fig. 3) between the instants at which the chosen wave crest passed over B and A be t_{BA}, and that between the times of its passage over C and A be t_{CA}. Then,

$$\text{ctn } Y = n\frac{t_{CA}}{t_{BA}} - k,$$

and

$$\text{ctn } X = m\frac{t_{BA}}{t_{CA}} - k.$$

Ramirez found that the direction from which the group microseisms arrived at Saint Louis always pointed toward a storm at sea. The U. S. Navy adopted the Ramirez method in 1943. While the method as applied by Ramirez at a single tripartite station gave only the direction, it showed as a matter of fact, in the case of a hurricane off the Atlantic Coast, that this direction continuously pointed toward the center of the storm as it moved up the coast and did not point

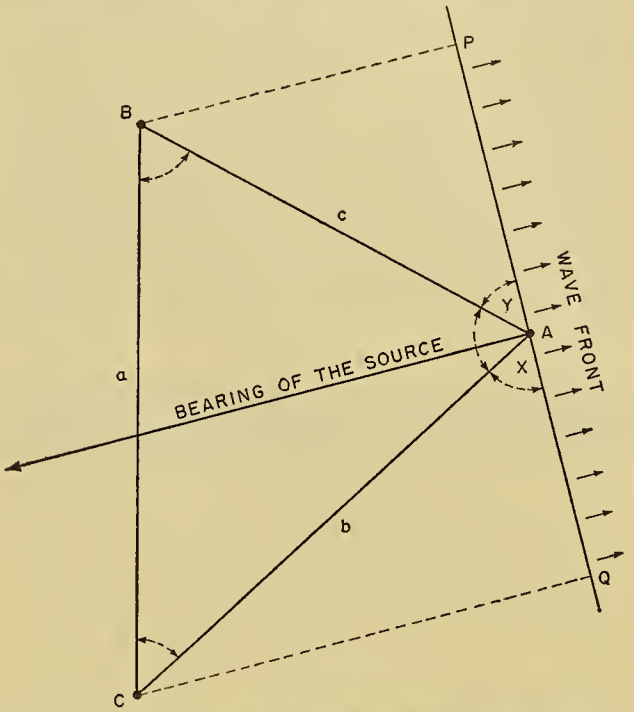

FIG. 2.—A wave front of microseisms passing any tripartite station with a seismograph at A, B, and C, respectively.

toward the area where heavy surf existed. The location of the storm center in latitude and longitude could only be found by cross bearings from more than one tripartite station. By 1945 the U. S. Navy installations in the Caribbean area under Orville and Gilmore had

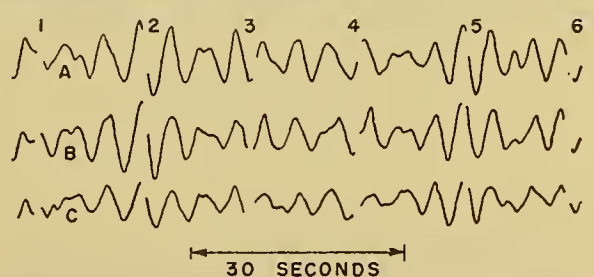

FIG. 3.—Simultaneous time marks showing succession of arrivals at stations A, B, and C. (*Courtesy M. H. Gilmore.*)

obtained satisfactory evidence that these microseisms actually do originate in the storm area at sea. Accordingly the method has been carried to the Pacific Ocean with equal or even greater success. There is no longer any doubt of the origin of this type of microseisms and of its direct applicability to the tracking of hurricanes, typhoons, and other similar storms from the time of their formation until they reach the land.

The seismographs in use by the U. S. Navy are of the horizontal component, electromagnetic, Sprengnether type. Their periods and those of the Leeds and Northrup galvanometers are set at about six seconds

so that their optimum response range will be in resonance with the microseisms. Horizontal component instruments were chosen in preference to vertical component seismographs because they are simpler to operate and are much less sensitive to fluctuations in temperature and hence require much less elaborate vault insulation.

The seismographs at the outlying corners are connected by shielded cable to the respective galvanometers in the main vault of the tripartite station where they record on a triple drum whose speeds of rotation and endwise translation are variable. Moderate speeds are used as long as there is no evidence of a storm. When the amplitudes of the microseisms are seen to increase, the drum rates are greatly accelerated (Fig. 4).

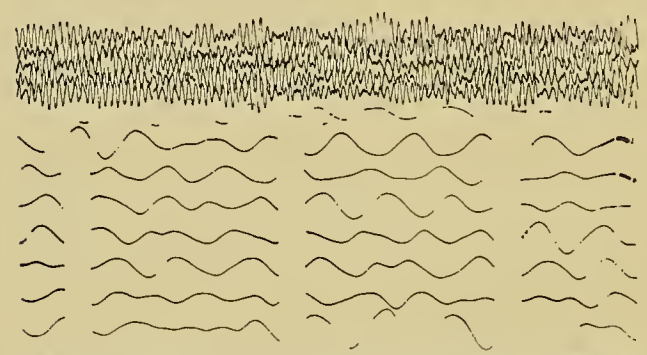

FIG. 4.—Part of a record made at the Miami, Florida, tripartite station of the U. S. Navy, August 23, 1949, showing large microseisms recorded at the stand-by rate (top) and at the hurricane rate (bottom). Time interval between interruptions in both cases, 15 sec.

However, the problem still remains as to the mechanism by which a storm center produces the elastic waves on the ocean bottom and why they are so conspicuously characterized by groups resembling interference patterns (Fig. 5). An argument in favor of swell and decay of activity at the source rather than interference from independent sources within the storm area is the similar appearance of the records in many different directions. A thorough study of the "groups" from this point of view remains to be made.

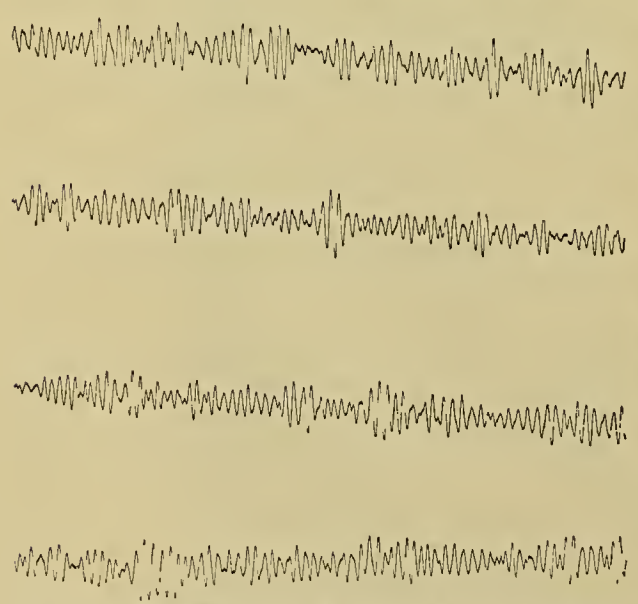

FIG. 5.—Samples from a record made at the Bermuda tripartite station of the U. S. Navy, September 6, 1949, showing the swell and decay "group" effect. Time intervals, 15 sec.

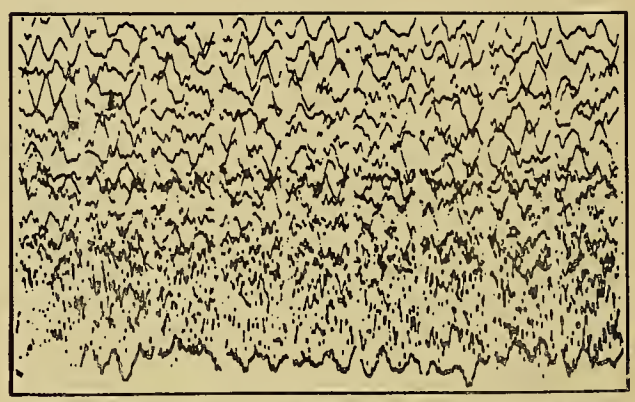

FIG. 6.—Record at Corpus Christi for July 9, 1947, showing increase in amplitude of 1.3-sec microseisms on lower portion of record at the time of a local thunderstorm. Time breaks are at 15-sec intervals.

Suggestions as to the mechanism by which these microseisms are produced have been offered by Banerji, Gherzi, Macelwane, Longuet-Higgins, and others. But the observations necessary to test the validity of any one of them are lacking. In most cases the accumulation of the necessary critical data would be both difficult and costly. For example, observations would be required of the existence or nonexistence of standing ocean waves in a disturbed area of a hurricane or typhoon. The observation of regular "pumping" in the air vortex or of vertical oscillation in a water vortex

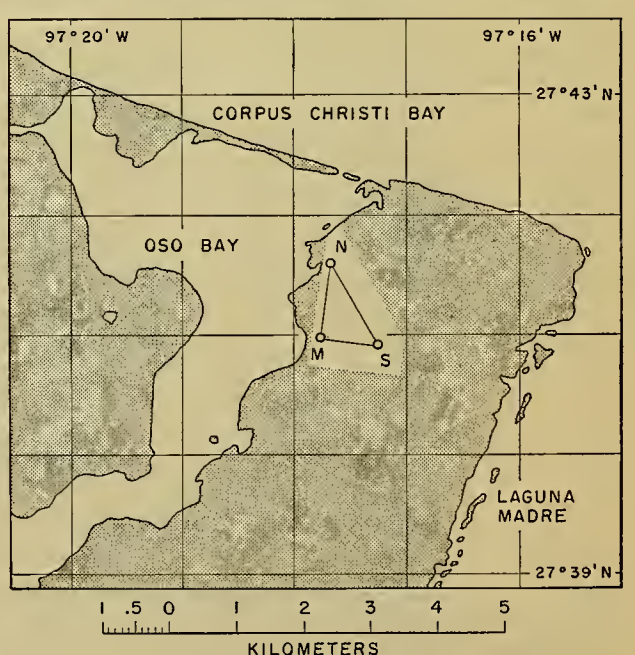

FIG. 7.—Position of the U. S. Navy tripartite station MNS at Corpus Christi, Texas.

underneath the wind system would challenge the resources of any but a governmental organization.

Another type of microseisms is found in a band whose dominant period lies in the neighborhood of two seconds (Fig. 6). Much less is known about these microseisms than about those of longer period. For some time the U. S. Navy maintained a tripartite station near Corpus Christi, Texas (Fig. 7). A preliminary study of the records was made by Jennemann. There were times when this type of microseisms dominated the records sufficiently to permit a determination of the direction of arrival at the station. They appeared to come from west of north. This means that these microseisms were coming not from the Gulf of Mexico

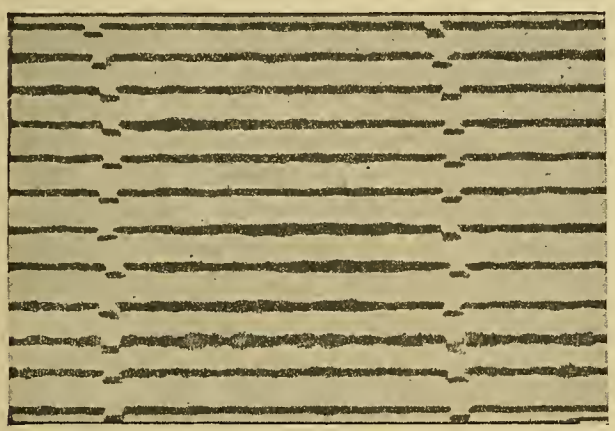

FIG. 8.—Short-period microseisms. Wood-Anderson record, Florissaut station. Time marks every half-minute.

but from the continent. It was possible to correlate these microseisms tentatively with disturbed weather conditions existing to the northward of the station. At Fordham University a tripartite station has been set

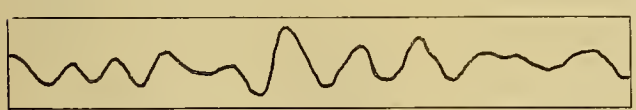

FIG. 9.—Three-tenth-second microseisms as recorded by a Sprengnether-Volk seismograph.

up for the express purpose of studying these two-second microseisms on contract with the Office of Naval Research. Other preliminary studies have been made by Leet and Gutenberg. While it is too early to form a positive judgment, the results so far seem to hold promise for forecasting of conditions related to frontal disturbances.

Preliminary studies are in progress on quite another type of microseisms of frequency of two to three cycles per second on a contract between Saint Louis University and the Office of Naval Research (Fig. 8). They are being studied with a tripartite station equipped with three components at each corner of the triangle and separated by distances considerably less than a wave length with a view to determining how, if at all, they are related to weather conditions and whether they have forecasting value (Fig. 9).

There are other bands of frequencies in the spectrum of microseisms but their possibilities for weather forecasting have not been tested.

Conclusions. There is a limit to what can be done with statistical studies of microseisms. The record of more than three quarters of a century of such studies shows what great care must be taken in their planning and in the interpretation of results. Quite contradictory conclusions have been drawn from parallel correlations. Much the same may be said of vectorial analysis of microseismic records. A very fruitful line of research has been opened up by the use of tripartite stations whose dimensions are less than one wave length. This method is independent of all assumptions except the successive arrival of an identical wave front at the three corners of the tripartite station. It gives a completely independent determination of the direction and speed of wave travel. Cross bearings between two or more tripartite stations locate the source of the microseisms and thus furnish a clue for the investigation of the point of origin within the storm provided there are a sufficient number of tripartite stations available for the observation of one storm. Research on the origin of the microseisms or the mechanism by which they are produced is difficult but very necessary. The possibility of air oscillations acting as a hammer may be investigated by means of microbarographs disposed on small islands in the path of typhoons and hurricanes. A similar system for the investigation of standing waves, or of the oscillations of a water vortex, would be much more difficult and costly. One might think of pressure gauges on a submarine cable laid in a path frequently followed by tropical storms and terminating at a recording station somewhere on land.
