A wealth of information is available concerning details in the spot periods of Jupiter. Occasionally, spots near the boundaries of the currents are found, with periods differing from those of the main currents by as much as 5 min (100 m sec^{-1}). These spots are indicated by light circles in Fig. 3. Again, one might expect them to be located at levels different from those used in the determination of the periods of the principal currents, yet these unusual spots often move around the normal spots. An analysis of these unusual spots was made under the assumption that they were situated at approximately the same level as the normal markings. This analysis indicated systematically that the bright zones are regions of anticyclonic shear, and the dark belts are regions of cyclonic shear (see the line in Fig. 3). This idea is substantiated by the behavior of the

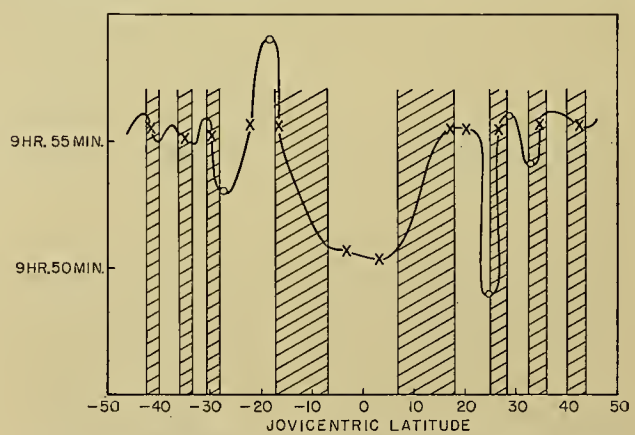

Fig. 3.—Distribution of spot periods on Jupiter with latitude. Heavy crosses indicate average periods for the latitude band; light circles indicate occasional periods. The hypothetical current distribution is represented by a line. Hatched areas are dark belts; clear areas are light zones.

"reversing spots." These spots are some of the few markings on Jupiter which show meridional movement in addition to zonal motion; they actually describe an anticyclonic orbit relative to the bright tropical zone in the Southern Hemisphere. First they move more slowly than the main current, at its northern edge, then they traverse the main current, and finally they move faster than the main current at its southern edge.

If the cyclonic shear in the dark belts and the anticyclonic shear in the light zones are permanent features, it is possible to speculate further. In that case, the bright zones would be high-pressure regions; furthermore, due to lateral friction, they would be regions of horizontal divergence. Since we are looking at a high level in the atmosphere, regions of divergence would be regions of upward vertical motion. It is then possible to explain the light color of these zones by the ammonia crystals formed in rising currents.

Jupiter is observable for about eight out of every thirteen months. In the remaining five months it is too near the sun. For each of these eight-month periods, average speeds of the different currents are available. Usually, the periods in these different observing "seasons" are based on different markings, and represent averages over a number of spots; variations from year to year may not be due to real variations of the currents but to more or less random variation between spots, since the difference of the periods of individual spots in given currents is usually much larger than the change of the average speed from "season" to "season." Occasionally variations in speed of as much as 10 m sec^{-1} occur from one season to the next, especially in the south equatorial current. These jumps affect all visible spots and are certainly not statistical accidents. Also, gradual changes which are real occur over periods of the order of 40 years.

Whatever the physical nature of the Red Spot, the variations of its speed of rotation from year to year are certainly real. The period of rotation has varied from 9 hr 55 min 33 sec to 9 hr 55 min 42 sec, with changes from year to year never exceeding 3 sec (1 m sec^{-1}). Two different, but not independent, methods showed correlations of 0.61 and 0.62, respectively, between the speed of the Red Spot and the speed of the surface westerlies on Earth at moderate north latitudes, based on 37 pairs of observations [6]. Little is known concerning the significance of correlation coefficients between time series. Perhaps a correlation of this type might be accounted for if variations in the radiation from the sun would affect the intensities of circulation both on Jupiter and on Earth. Several objections may be raised against such a hypothesis. The distance of Jupiter from the sun varies by 10 per cent during its orbital period of 12 years. Yet there is no correlation between the period of the Red Spot and the distance of Jupiter from the sun. This means that changes of total radiation of 20 per cent have no effect on the general circulation of Jupiter. The possibility remains that the ultraviolet radiation of the sun may vary by 100 per cent or more, and this large change may produce variations of the speed of air currents both on Jupiter and on Earth.

Another objection against the reality of the correlation is the fact that there is a negligible correlation between Red-Spot period and easterly index on Earth. It is hard to see why the Red Spot, which is located in the south tropical regions of Jupiter, should exhibit variations in motion similar to those in moderate terrestrial latitudes in the Northern Hemisphere.

Little information is available concerning the general circulation of the other major planets. The few spots observed on Saturn indicate the shortest periods near the equator with a *gradual* increase toward higher latitudes. The distribution of rotational velocities determined spectroscopically agrees with this picture [5].

Suggestions for Future Work

For Venus the outstanding meteorological problems are (1) determination of the nature of the variable light and dark bands observed in the ultraviolet, and (2) determination of the cause of the variability of the emission from the planet's CO_2 at 10 μ. These two phenomena may well be related, and a concerted attack should be planned, involving simultaneous observations with the spectrograph, the ultraviolet camera, and the radiometer. Once such basic data have been gathered, further interpretation may prove possible.

For Mars one would most like to see a verification and extension of the work on the temperature field and general circulation. This could best be done at the good oppositions coming in 1954, 1956, and 1958. It would require a coordinated program of radiometric observations of the temperature distribution combined with careful visual and photographic determination of the drift of clouds. This is an observing program of considerable magnitude, but is worth while in view of the basic nature of the result to be derived. We also need further observations of such fundamental quantities as the atmospheric pressure, the amount of water vapor, the height and composition of the blue haze layer, and the value of the nocturnal temperatures.

Additional information concerning Jupiter can be obtained from a study of the latitudinal variation of ammonia and methane absorption. If ammonia is saturated near the cloud surfaces, such a study should indicate the latitudinal variation of temperature and of cloud level. Studies of limb darkening in the zones and belts have so far been carried out without consideration of the extremely important selective absorption of methane and ammonia. Careful investigations of this type are necessary to determine the relative optical depths of light and dark areas. Finally, the correlation between the motion of the Red Spot and the zonal index on the Earth should be verified on observations since 1939, since standard tests of significance of correlation coefficients do not apply here.

For Saturn, similar investigations might be suggested, especially as far as the evaluation of the limb darkening is concerned.

THE PERTURBATION EQUATIONS IN METEOROLOGY

By B. HAURWITZ

New York University

INTRODUCTION

Before entering into a discussion of the systems of hydrodynamic equations suitable for the investigation of atmospheric dynamics, it is appropriate to make some general remarks on the typical difficulties of investigations in theoretical meteorology and on the general principles on which the formulation of the perturbation equations is based. Such a discussion naturally includes an enumeration of the types of problems where the application of perturbation methods is particularly suitable.

The Problem of Dynamic Meteorology. Meteorology concerns itself with the exploration and the study of the gaseous envelope of the earth. Dynamic meteorology in particular aims at a quantitative explanation of the observed variations and motions of the atmosphere on the basis of physical "laws." If a complete quantitative explanation has been accomplished, a quantitative weather forecast will be a by-product. Conversely, quantitative forecasts of the future state of the atmosphere from a given set of initial conditions may be regarded as the ultimate goal of dynamic meteorology because such forecasts require a thorough understanding of the laws governing the atmosphere.

The peculiar difficulties in meteorology, as in the other earth sciences, in comparison to physics, are that very many different factors act simultaneously on each phenomenon and that it is impossible to perform controlled experiments. In order to study the atmosphere the meteorologist has to consider a fluid shell surrounding a sphere. This fluid is neither homogeneous nor incompressible, a circumstance which complicates the purely hydrodynamical problem. Moreover, one of the constituents which make up the fluid may change from the gaseous to the liquid or solid state at temperatures and pressures regularly occurring in the atmosphere. This versatility of water vapor would be bad enough by itself, but the complications increase further because the fluid shell receives radiant energy in amounts which vary with time and location on the sphere and with the state of the water in the atmosphere. Also, the properties of the lower boundary of the fluid shell are by no means uniform, the greatest differences being those between water and land which react differently to the incoming solar radiation and which have a different frictional effect on the motions of the gaseous layer. Further, the properties of the earth's surface are by no means independent of the atmosphere, but depend rather strongly on its state; the ocean surface, for instance, may be made rougher by wind-generated waves, and the radiative properties of the land surface may be modified drastically by a snow cover. Nor is the land surface itself of uniform elevation, but rather it presents formidable obstacles to the air motion. It would be easy to continue this account of the complications which the atmosphere presents to the meteorologists, and to dwell on such matters as the fact that one of the gases (oxygen) appears in one layer in the triatomic state, in another in the monatomic state, with importantly different absorptive properties, or to discuss the electromagnetic effects in the high atmosphere. However, it may suffice here to state that finally this complex fluid system, bounded by an inhomogeneous surface and subjected to unequal influx of energy, is surrounding a rotating globe.

At that it must be admitted that the problems of astrophysics are presumably more complicated. Such phenomena as sunspots or chromospheric eruptions are subject to additional influences, for instance, to a strong electromagnetic field, or to radiation pressure, influences which the meteorologist can mercifully neglect, at least in the lower atmosphere. However, the solar physicist has the advantage of a really detached viewpoint. He is not concerned with the detailed behavior of the individual sunspot or the individual chromospheric eruption and their detailed structures. The meteorologist, on the other hand, attempts to explain the detailed structure of a cyclone or the motion of an individual hurricane. It is likely that meteorology would appear to be in a much more satisfactory state if we could apply our knowledge to observations of the earth's atmosphere as viewed from Mars.

As stated before, for the solution of its rather formidable problem, dynamic meteorology uses the laws of physics which in the case of the lower atmosphere means mainly the theorems of thermodynamics and hydrodynamics. Because of the complexity of the problems it is always necessary to make restrictive simplifying assumptions, in other words to consider models which include only some of the features of the real atmosphere. Even with these assumptions the necessary mathematical analysis offers as a rule considerable difficulties. One of the most frequently recurring difficulties arises out of the fact that the hydrodynamic equations which describe the motion of any fluid are nonlinear. Very little is known about the solution of nonlinear differential equations. Progress in this direction may presumably be expected eventually from work with high-speed computers because the study of individual nonlinear problems will point the direction in which a theory of nonlinear differential equations should be developed. In the absence of such a general theory it has long been the practice in hydrodynamics to linearize the basically nonlinear equations of fluid motion. In some types of problems of classical hydro-

dynamics the linearization is achieved directly as a result of the far-reaching simplifying assumptions. For instance, the two-dimensional irrotational motion of a homogeneous and incompressible fluid can be dealt with by the methods of the theory of complex functions. In other cases it is necessary to adopt different procedures. In tidal theory, for instance, it is customary to assume that the motion is sufficiently small so that terms which consist of products of the velocities and their derivatives can be neglected in comparison with terms which are of the first order with regard to the derivatives of the velocity components. In consequence of this assumption the convective terms in the equations of motion can be neglected, and the system of hydrodynamic equations becomes linear, at least as long as an incompressible fluid is considered. The characteristic feature of this approach is that the tidal motion is considered as a small perturbation of an original undisturbed state. This method has been used frequently in hydrodynamics, but V. Bjerknes was the first to systematize this procedure and to apply it to atmospheric problems when the earth's rotation and the compressibility and the inhomogeneity of the fluid system have to be taken into account. The system of hydrodynamic equations obtained by him is referred to as the atmospheric perturbation equations. The present article deals with their derivation and shows how they can be applied to various geophysical problems. It is not the purpose of this article to deal with the mathematical methods of solving the resulting systems of differential equations; that is a problem in mathematical physics and is treated in the appropriate textbooks. Neither is it the aim of this article to discuss some special meteorological problems. It is solely the method of approach which is being stressed here; for the solution of specific problems the reader is referred to the literature. Only some very simple examples are given as illustrations in later sections.

Basic Assumptions of the Atmospheric Perturbation Theory. As stated in the preceding section the perturbation equations are derived under the assumption that the state of the fluid motion can be regarded as made up of two parts, namely an undisturbed motion on which is superimposed a perturbation, the sum of the two representing the total motion. Such a division of an actual state of motion is often directly suggested by observations. The capillary ripples on the free surface of a pond can be regarded as a perturbation produced by a slight gust on a fluid otherwise at rest. On a much larger scale the nascent cyclones have been regarded in the wave theory of cyclones as disturbances in an undisturbed flow which consists of two currents of different densities, flowing side by side. It was, in fact, the wave theory of cyclones which led V. Bjerknes [2, 3] to the formulation of the perturbation equations as the tools by means of which the stability of such a system could be investigated.

Since the total motion thus consists of an undisturbed motion on which a perturbation is superimposed, it follows that not only the total motion, but also the undisturbed motion alone must satisfy the system of hydrodynamic equations, that is, the three equations of motion, the equation of continuity, physical equations, and such initial and boundary conditions as are appropriate for the specific problem under consideration. That the undisturbed motion by itself must satisfy the hydrodynamic equations is evident from the fact that it can exist without a superimposed perturbation. It is possible to select for any specific problem a sufficiently simple fluid state as the undisturbed motion so that little or no difficulty is encountered in satisfying the hydrodynamic equations. For instance, in the two cases mentioned above, the undisturbed state would appropriately be one of rest or geostrophic wind motion, respectively.

For the subsequent discussion, the variables expressing the actual disturbed plus undisturbed state will be denoted by letters with an asterisk, the undisturbed state will be denoted by capital letters, and the effect of the perturbation by the corresponding lower-case letters. Thus we have the following relations:

$$\text{for the position vector} \quad \mathbf{r}^* = \mathbf{R} + \mathbf{r}, \tag{1}$$

$$\text{for the velocity} \quad \mathbf{v}^* = \mathbf{V} + \mathbf{v}, \tag{2}$$

$$\text{for the pressure} \quad p^* = P + p, \tag{3}$$

$$\text{for the density} \quad q^* = Q + q. \tag{4}$$

It is now assumed that the deviation from the undisturbed state produced by the perturbation is so small that those terms in the equations which contain products of the perturbation quantities and their derivatives can be neglected as being small of higher order compared to those terms which are of the first order in the perturbation quantities. It is immediately apparent that with this assumption the hydrodynamic equations become linear with regard to the variables expressing the effects of the perturbation.

This basic assumption about the smallness of the perturbation does not, of course, represent an equally satisfactory approximation to the actual state of affairs in every case. It is particularly appropriate in cases where the stability of a certain state is to be investigated. This state will then be regarded as the undisturbed state and the stability investigation becomes the problem of determining whether or not a superimposed small perturbation will grow with time. In such a case the initial perturbation of the undisturbed motion may be regarded as infinitely small since a deviation from this motion must start gradually. If the perturbation increases with time the motion is unstable, otherwise it is stable. The limitations of this statement will be discussed later. The wave theory of cyclones and many other types of atmospheric and oceanic motions pose such stability problems. In other instances where the perturbation equations are applied it will depend on the particular circumstances how well the resulting solution represents reality, and it is impossible to make general statements about the success or failure of the method. However, it can at least be said that in many cases the linearized perturbation equations give a satisfactory approximation to the observed fluid motions.

The results of hydrodynamic wave theory give numerous examples to support this statement.

It may be remarked here in passing that there are certain problems in fluid motion which reduce to linear equations without the introduction of the assumptions of the perturbation theory. Consider, for instance, the frictionless horizontal motion of an incompressible and homogeneous fluid. Then the continuity equation can be satisfied by assuming a stream function $\psi(x, y, t)$, and the pressure can be eliminated from the two equations of motion by cross differentiation resulting in the so-called vorticity equation which is in this case a nonlinear differential equation for ψ. However, if

$$\nabla^2\psi = \text{const}\,\psi,$$

the two quadratic terms cancel each other (more generally if $\nabla^2\psi = f(\psi)$, but this relation is no longer generally linear). The foregoing equation for ψ comprises a great number of equations arising in mathematical physics. In the meteorological literature, examples for this type of motion will be found, among others, in papers by Craig [7], Neamtan [15], and Rombakis [17].

SYSTEMS OF HYDRODYNAMIC EQUATIONS

Only a very short review of the equations of motion and of continuity in the Eulerian and the Lagrangian systems will be given here since these equations can be found in all treatises on hydrodynamics. But since in classical hydrodynamics the fluid is as a rule regarded as incompressible and homogeneous, some more detailed remarks are in order concerning the modifications which are necessary when such inhomogeneous and compressible fluids as the atmosphere are considered.

Barotropic and Baroclinic Fluids. In fluids which are inhomogeneous and compressible the surfaces of equal density and of equal pressure do not as a rule coincide; the stratification of the fluid is baroclinic. In special cases, however, the density distribution may be given completely by the pressure distribution; then the stratification of the fluid is called barotropic. A barotropic stratification exists, for instance, in an ideal gas whose temperature is the same everywhere or in a fluid where pressure and density are functions only of the elevation. An incompressible and homogeneous fluid is evidently barotropic and will always remain barotropic. A fluid whose stratification always remains barotropic is called autobarotropic. In general, a barotropic state will be destroyed by the motion of the fluid; the fluid will become baroclinic.

The significance of the distinction between barotropy and baroclinity for the variation of the circulation of a fluid need not be discussed here since it is explained in the texts on dynamic meteorology.

It is often convenient to introduce a "coefficient of barotropy" when the stratification is barotropic,

$$q^* = q^*(p^*). \tag{5}$$

The coefficient of barotropy Γ is then defined as follows,

$$\Gamma = \frac{dq^*}{dp^*}. \tag{6}$$

In an atmosphere obeying the ideal-gas law with a constant vertical temperature gradient ϵ, for instance,

$$\Gamma = \left(1 - \frac{R}{g}\epsilon\right)\frac{1}{RT}, \tag{7}$$

where R is the gas constant for this atmosphere, g the acceleration of gravity, assumed to be constant, and T the temperature.

It is possible to generalize this terminology of baroclinity and barotropy to apply to the distribution of other variables besides pressure and specific volume [4, p. 3].

The Physical Equation. Since in meteorological and oceanographic investigations the fluid medium can rarely be considered as homogeneous and incompressible, the density has to be regarded as one of the unknown variables. In this case the four equations used mainly in classical hydrodynamics, namely, the three equations of motion and the equation of continuity, are not sufficient to describe the fluid motion because the density has been added as a fifth variable to the three velocity components and the pressure. It is therefore necessary to have an additional equation describing the behavior of the fluid. Such an equation, in the case of the atmosphere, can be derived from thermodynamic considerations. In the first place for the variables of state, pressure p^*, density q^*, and temperature T^*, an equation of state holds of the form

$$F(p^*, q^*, T^*, A, B, C, \cdots) = 0, \tag{8}$$

where $A, B, C, \cdots$ indicate additional parameters characterizing the state of the fluid. In the case of the atmosphere the parameters A, B, etc., refer to the differences in the composition of the atmosphere. For many problems it is sufficient to use the equation of state for ideal gases:

$$p^* - Rq^*T^* = 0, \tag{9}$$

where R is the gas constant for air, which depends on the composition of the atmosphere. In the lower atmosphere, R is mainly affected by the variable amount of water vapor; at higher levels it depends on the separation of the various atmospheric constituents and dissociation of some of the molecules. Consequently R may vary from parcel to parcel in the atmosphere. While equation (8) or (9) adds an additional equation to the system of hydrodynamic equations it is not sufficient to complete the system since it involves also an additional variable, namely, the temperature T^*.

In order to obtain a more complete system of equations the first law of thermodynamics may be added:

$$dh = de + p^*d(1/q^*), \tag{10}$$

where dh denotes the amount of heat added to the unit mass during an infinitely small change of state, de the change of internal energy per unit mass, and where $p^*d(1/q^*)$ represents the amount of work done because of the expansion of the unit mass. The amount of heat

is not a variable of state. If this quantity is also to be considered as unknown, further additional equations have to be introduced for the transfer of heat by conduction and radiation. In many instances in meteorological problems it may be assumed that the changes of state are adiabatic, so that $dh = 0$. A slight generalization of this procedure is to assume polytropic changes where

$$dh = c\, dT^*. \tag{11}$$

Here c is a constant of the character of a specific heat. In most meteorological problems it can further be assumed that

$$de = c_v\, dT^*,$$

where c_v is the specific heat at constant density, an assumption which holds for an ideal gas and is consequently as a rule a satisfactory assumption for the atmosphere. Then with the aid of (9),

$$c\, dT^* = c_p dT^* - \frac{RT^*}{p^*}\, dp^*,$$

since the specific heat at constant pressure for ideal gases

$$c_p = c_v + R.$$

By integration of the preceding differential relation under the assumption that the specific heats are constant, which applies to ideal gases,

$$\frac{T^*}{T_0^*} = \left(\frac{p^*}{p_0^*}\right)^{\bar{K}}, \tag{12}$$

where $\bar{K} = (c_p - c_v)/(c_p - c)$. The relation between pressure and specific volume consequently becomes

$$p^* q^{*-\bar{\lambda}} = p_0^* q_0^{*-\bar{\lambda}}, \tag{13}$$

where $\bar{\lambda} = (c_p - c)/(c_v - c)$, the modulus of the polytropic curve. We shall confine ourselves in the following discussions to the special case of adiabatic changes when

$$\bar{\lambda} = \lambda = \frac{c_p}{c_v}$$

and

$$p^* q^{*-\lambda} = p_0^* q_0^{*-\lambda}. \tag{13a}$$

Equation (13) or (13a) gives the variation of the specific volume of a fluid particle as a function of the pressure variation. The original pressure and density, p_0^* and q_0^* will, of course, in general vary from one particle to another. Compared to the more general equation (8), equations (13) and (13a) have one variable less since the temperature is eliminated by the additional assumptions about the physical process by which the particle changes its density. Thus, the number of dependent variables is reduced by one. Such an equation for the change of state of a particle which, in addition to the pressure, contains only one more variable of state has been called by V. Bjerknes an equation of piezotropy, and a fluid whose every particle is following an equation of this type is called piezotropic. More generally, a piezotropic fluid satisfies an equation of the form

$$f(p^*, q^*, A, B, \cdots) = 0, \tag{14}$$

where the parameters $A, B, \cdots$ will in general not be the same as in (8). Equation (14) may also be written in the form

$$q^* = g(p^*, A, B, \cdots). \tag{14a}$$

It is often convenient to introduce the coefficient of piezotropy,

$$\gamma = \frac{dq^*}{dp^*}. \tag{15}$$

In the case of adiabatic changes, for instance,

$$\gamma = \frac{1}{\lambda RT^*}. \tag{15a}$$

It should be clearly understood that this coefficient of piezotropy describes the physical changes which a particle undergoes, while the coefficient of barotropy depends on the distribution of the fields of pressure and specific volume.

When an equation of piezotropy exists for the fluid, the system of hydrodynamic equations is complete because it consists now of five equations with five dependent variables.

The properties of barotropy and piezotropy are entirely unconnected. The former refers to the stratification of a fluid, the latter to its changes of state. A fluid whose stratification is barotropic at a given instant will in general not remain so if in motion. However, if the appropriate state of piezotropy prevails, barotropy may be maintained. Such a fluid is called autobarotropic, as mentioned before. The condition for autobarotropy is that the coefficients of barotropy and of piezotropy are identical, provided, of course, that the fluid was barotropic at a fixed instant. Examples of autobarotropic fluids are a homogeneous and incompressible fluid, or an atmosphere with adiabatic changes of temperature and an adiabatic lapse rate of temperature. In such a fluid a displaced particle has always the same density as its environment so that indifferent equilibrium is maintained. Consequently, autobarotropic fluids are only a minor generalization of the homogeneous and incompressible fluids considered in classical hydrodynamics.

The Hydrodynamic Equations. Any fluid, whether compressible or not, is subject to the laws of dynamics. For continua, the equations expressing these laws are more complicated than for the mass points of particle dynamics, because the direct effects of neighboring fluid particles on each other have to be taken into account. This interrelationship leads to the appearance of the terms for the viscous stresses and for the pressure-gradient forces in the hydrodynamic equations of motion. In many instances in classical hydrodynamics and in geophysical applications, however, the effects

of viscosity and friction are disregarded, and an "ideal," nonviscous fluid is considered. In particular, the atmospheric perturbation equations have so far almost exclusively been developed for and applied to such ideal fluids. Very often, far-reaching agreement has been obtained between theoretical models dealing with ideal fluids and observed atmospheric motions, so that there is considerable justification for making use of the substantial simplifications which arise when the effects of viscosity on fluid motion are neglected.

In the case of the atmosphere it is customary to describe the motions relative to the rotating earth since the observing meteorologist participates in the earth's rotation. According to the laws of Newtonian mechanics we may then write that

$$\frac{d^2\mathbf{r}^*}{dt^2} + 2\boldsymbol{\Omega} \times \frac{d\mathbf{r}^*}{dt} = -\left(\frac{1}{q^*}\right)\nabla p^* - \nabla\Phi. \qquad (16)$$

Here $\mathbf{r}^*$ is the radius vector of a fluid particle, $\boldsymbol{\Omega}$ the vector of the earth's rotation, q^* the density, p^* the fluid pressure. It is assumed that the external forces acting on the fluid have a potential Φ, because in the case of the atmosphere this external force is, as a rule, only gravity—composed of the gravitational attraction of the earth and the centrifugal acceleration due to the earth's rotation—which has a potential. In some cases, of course, this gravity potential may have to be replaced or augmented by additional forces, for instance, in the study of tides.

In order to apply equation (16) to problems of fluid dynamics one can either focus one's attention on each individual particle and describe its future position, pressure, density, etc., or describe the distribution of velocity, pressure, density, etc., throughout the space occupied by the fluid, as functions of the time. The first method leads to the so-called Lagrangian equations, the latter to the Eulerian equations, although both systems of equations were originally derived by Euler. The Eulerian system is used much more widely in hydrodynamics and will be described first. We introduce in (16) the velocity

$$\mathbf{v}^* = \frac{d\mathbf{r}^*}{dt}.$$

The operator d/dt represents the time differentiation of an individual particle. In order to have only quantities referring to a fixed point in the coordinate system in the equation, this operator may be written

$$\frac{d}{dt} = \frac{\partial}{\partial t} + \mathbf{v}^*\cdot\nabla. \qquad (17)$$

Thus the Eulerian equation of motion becomes

$$\frac{\partial \mathbf{v}^*}{\partial t} + \mathbf{v}^*\cdot\nabla\mathbf{v}^* + 2\boldsymbol{\Omega} \times \mathbf{v}^* = -\left(\frac{1}{q^*}\right)\nabla p^* - \nabla\Phi. \qquad (18)$$

In addition the fluid must satisfy the equation of continuity,

$$\frac{\partial q^*}{\partial t} + \operatorname{div}\,(q^*\,\mathbf{v}^*) = 0, \qquad (19)$$

according to which the density change anywhere in the fluid must equal the mass convergence there. In order to complete the system the physical equation has to be added as explained in the preceding section. We shall assume that the fluid is piezotropic so that an equation of the form (14) holds. Most investigations so far have been dealing with piezotropic fluids, although in some cases it has been assumed that a certain amount of heat energy, given as a function of space and time, is added to the system (for instance, [14]) or that heat is conducted from the earth's surface into the atmosphere (for instance, [12]). In the latter case the effects of eddy viscosity are taken into account in order to have a consistent fluid model.

Equation (14) does not fit into the Eulerian system because it refers to an individual particle, but upon individual differentiation with respect to time and with (15) and (17) it follows that

$$\frac{\partial q^*}{\partial t} + \mathbf{v}^*\cdot\nabla q^* = \gamma\left(\frac{\partial p^*}{\partial t} + \mathbf{v}^*\cdot\nabla p^*\right). \qquad (20)$$

It should be noted that in general γ will vary in space. Equations (18), (19), and (20) represent a complete system of equations which together with the boundary conditions (to be discussed in the next section) and initial conditions, determine the motion of the fluid.

In order to apply the Lagrangian method to the study of the fluid motion it is necessary to identify each particle individually. This can be done by the use of three suitable parameters, a, b, and c, so that the state of the fluid and each of its individual particles is described by expressing $\mathbf{r}^*$, p^*, and q^* as functions of t, a, b, and c. The choice of these parameters is free provided that they permit one to characterize and identify each particle uniquely. It has, for instance, been suggested that under certain conditions potential temperature, specific humidity, and potential vorticity would be suitable parameters [21]. As a rule the coordinates at a given time t_0 are chosen as the three identification parameters, and this practice will be used here.

In order to write the Lagrangian equations in vector form we shall make use of the operation $\nabla\mathbf{B}\cdot\mathbf{A}$. The meaning of this expression is that after the scalar product $\mathbf{B}\cdot\mathbf{A}$ has been formed the vector operator ∇ operates only on the first vector. Thus

$$(\nabla\mathbf{B}\cdot\mathbf{A})_x = A_x\left(\frac{\partial B_x}{\partial x}\right) + A_y\left(\frac{\partial B_y}{\partial x}\right) + A_z\left(\frac{\partial B_z}{\partial x}\right).$$

It may be noted that

$$\nabla\mathbf{r}\cdot\mathbf{A} = \mathbf{A}. \qquad (21)$$

In the case of the Lagrangian equations the operator ∇ has the components $\partial/\partial a$, $\partial/\partial b$, and $\partial/\partial c$. When the operator with the components $\partial/\partial x$, $\partial/\partial y$, and $\partial/\partial z$ is used in the remainder of this section it will be denoted by $\nabla_{\mathbf{r}}$. It should be noted that instead of the total derivatives with respect to time in (16) we may now write the partial derivatives since a, b, and c are independent of time. Furthermore, according to (21),

$$\nabla\mathbf{r}^*\cdot\nabla_{\mathbf{r}} p = \nabla p,$$

and an analogous relation holds for Φ. Hence, the operation $\nabla \mathbf{r}^* \cdot$ applied to (16) results in the Lagrangian equation of motion

$$\nabla \mathbf{r}^* \cdot \left[\frac{\partial^2 \mathbf{r}^*}{\partial t^2} + 2\boldsymbol{\Omega} \times \left(\frac{\partial \mathbf{r}^*}{\partial t} \right) \right] = -\left(\frac{1}{q^*} \right) \nabla p^* - \nabla \Phi. \quad (22)$$

The equation of continuity may be written in the following form:

$$q^* \left(\frac{\partial \mathbf{r}^*}{\partial a} \right) \times \left(\frac{\partial \mathbf{r}^*}{\partial b} \right) \cdot \left(\frac{\partial \mathbf{r}^*}{\partial c} \right) = q_0^*, \quad (23)$$

where q_0^* represents the density of the fluid particle at the time t_0 when a, b, and c were the coordinates of the particle. It is easily verified that in a rectangular Cartesian coordinate system (23) is identical with

$$q^* \frac{D(x^*, y^*, z^*)}{D(a, b, c)} = q_0^*, \quad (24)$$

where the Jacobian is used to express the volume change of the fluid particle.

To complete the Lagrangian system of equations the physical equation has to be added. While for the Eulerian method this equation had to be differentiated in order to obtain quantities referring to fixed points no such differentiation is required in the present case since both the physical equation and the equations of motion refer to individual fluid particles. Of course, the parameters $A, B, \cdots$ in (14) may differ from particle to particle so that they may have to be considered as functions of a, b, and c, but they will not change with time.

The Boundary Conditions. At rigid or internal boundaries and at free surfaces the fluid has to obey certain conditions which exert considerable influence on the possible motions. We shall again first consider the form of these boundary conditions in the Eulerian system. The boundary of the fluid is given by an equation of the form,

$$f^*(\mathrm{r}, t) = 0. \quad (25)$$

The kinematic boundary condition expresses the fact that a fluid particle which forms part of the boundary must remain on this surface and that a particle which is not at a given time part of the boundary can never become part of it. This condition is expressed by the following relation,

$$\frac{\partial f^*}{\partial t} + \mathbf{v}^* \cdot \nabla f^* = 0. \quad (26)$$

As is known from hydrodynamics this relation can also be interpreted as the condition that a fluid particle at the boundary has a velocity component normal to the boundary which must equal the velocity of the surface itself.

If the boundary is a rigid surface, as for instance the surface of the earth, f^* is independent of the time (neglecting such unpleasant geophysical phenomena as earthquakes) and (26) becomes

$$\mathbf{v}^* \cdot \nabla f^* = 0, \quad (26a)$$

which states that the fluid velocity at the boundary must be parallel to the boundary.

In the case of an internal boundary between two different fluid layers a condition similar to (26) must hold on the other side of the boundary, in the second fluid layer, where the velocity is $\mathbf{v}^{*\prime}$,

$$\frac{\partial f^*}{\partial t} + \mathbf{v}^{*\prime} \cdot \nabla f^* = 0. \quad (27)$$

In addition to the kinematic boundary conditions the dynamic boundary condition has to be satisfied, that is, the pressure across the boundary must be continuous,

$$p^*(\mathrm{r}, t) - p^{*\prime}(\mathrm{r}, t) = 0, \quad (28)$$

where the prime refers again to the second fluid. At a free surface

$$p^*(\mathrm{r}, t) = \text{const.} \quad (28a)$$

This constant may be zero, for instance if the fluid is bounded by empty space. In some cases the constant may have to be replaced by a function of space and time, for instance when the effect of variations in atmospheric pressure on the ocean surface is to be studied. Equation (28) or, in the case of a free surface, (28a) represents the boundary given by (25). In many problems the function appearing in (25) will, in fact, have to be determined by (28) or (28a). Therefore, the pressure difference at the boundary, or in the case of a free surface the pressure there, may be introduced into equations (26) and (27). Thus, the following boundary conditions, which represent a mixture of kinematic and dynamic conditions [19], are obtained:

$$\begin{aligned} \frac{\partial}{\partial t}(p^* - p^{*\prime}) + \mathbf{v}^* \cdot \nabla(p^* - p^{*\prime}) &= 0, \\ \frac{\partial}{\partial t}(p^* - p^{*\prime}) + \mathbf{v}^{*\prime} \cdot \nabla(p^* - p^{*\prime}) &= 0. \end{aligned} \quad (29)$$

It is only at a rigid boundary that the dynamic condition need not be satisfied, and the geometric form of the boundary must here be known from other sources. Then equations (26) and (27) have to be used.

In the Lagrangian system the form of the boundary conditions corresponding to those just given for the Eulerian system is considerably more complicated because attention is now focused no longer on points in space but on individual particles on both sides at the boundary which may have been neighboring at the time $t = 0$, but will in general be at a finite distance from each other at a later time. A complete discussion of these conditions is given by V. Bjerknes and collaborators [4, pp. 63–64, 103–104]. We shall here discuss only some simpler forms, also given by V. Bjerknes [3], which are adequate for many problems of fluid motion.

At the time $t = 0$ fluid particles which are at the boundary must satisfy one of the following two equations,

$$f_0^*(a, b, c) = 0, \qquad f_0^*(a', b', c') = 0, \quad (30)$$

where the primes refer to one fluid layer, the coordinates without primes to the other layer and where, as indicated, the same function applies on both sides of the boundary. When the components of the radius vector $\mathbf{r}^*$, or $\mathbf{r}^{*\prime}$ in the other fluid layer have been determined, a, b, c or a', b', c' have to be expressed by these components and t. The results are two equations,

$$f^*(\mathbf{r}^*, t) = 0, \qquad f^{*\prime}(\mathbf{r}^{*\prime}, t) = 0, \tag{31}$$

where the functions will now be different for the different fluid layers. The kinematic boundary conditions require that both equations (31) represent the same surface at all times t, a requirement which V. Bjerknes writes symbolically

$$[f^*(\mathbf{r}^*, t) = 0] \equiv [f^{*\prime}(\mathbf{r}^{*\prime}, t) = 0]. \tag{32}$$

The functions $\mathbf{r}^*$ and $\mathbf{r}^{*\prime}$ of a, b, c, t and a', b', c', t, respectively, will contain certain arbitrary integration constants which have to be chosen so that (32) holds. At a free surface or a rigid lower boundary only one of the two equations in (30) and (31) exists, and this equation has then to be adjusted in such a manner that any prescribed condition concerning the motion at this boundary is satisfied. For instance at a rigid boundary, $\mathbf{r}^*$ must be such that displacements are parallel to it.

In addition the dynamic boundary condition has to be satisfied, namely, that the pressure at an internal boundary is continuous. The pressure in both layers is given by $p^*(a, b, c, t)$ and $p^{*\prime}(a', b', c', t)$. Then, after $\mathbf{r}^*$ and $\mathbf{r}^{*\prime}$ have been determined as functions of a, b, c, t and a', b', c', t, respectively, p^* can be expressed as a function of t and $\mathbf{r}^*$, or rather of the components of the radius vector, and after obtaining the analogous expression for $p^{*\prime}$ one has to satisfy the condition that

$$p^*(\mathbf{r}^*, t) = p^{*\prime}(\mathbf{r}^{*\prime}, t) \quad \text{for} \quad \mathbf{r}^* = \mathbf{r}^{*\prime}. \tag{33}$$

At a free surface the right-hand side of this equation has to be put equal to zero or to the given external pressure.

THE PERTURBATION EQUATIONS

The two systems of hydrodynamic equations derived in the preceding sections can be linearized by the assumptions set forth on page 402. This linearization will now be performed, first on the Eulerian system, then on the Lagrangian system. From the perturbation equations in vector form it is more or less easy to obtain the equations in the coordinate form which is most suitable for any particular problem. As an example which is important for the study of large-scale motions on the earth, the perturbation equations for spherical polar coordinates in the Eulerian system are derived rather explicitly in a later section.

The Eulerian System of Perturbation Equations. The undisturbed motion will be denoted by capital letters as stated earlier. In order to write the complete system of equations for the undisturbed motion it is therefore merely necessary to replace in the relevant preceding equations the quantities with asterisks by the corresponding capital letters. Thus the equation of motion is obtained from (18), the equation of continuity from (19), the physical equation from (20) (with the previously stated restriction that only piezotropic fluids are considered), the boundary equation from (25), the kinematic boundary condition from (26) (from (27) if an internal boundary exists), the dynamic boundary condition from (28), and the mixed boundary condition from (29) which may be used instead of the kinematic boundary conditions. Thus the equations of the undisturbed state are

$$\frac{\partial \mathbf{V}}{\partial t} + \mathbf{V}\cdot\nabla\mathbf{V} + 2\boldsymbol{\Omega} \times \mathbf{V} = -\left(\frac{1}{Q}\right)\nabla P - \nabla\Phi, \tag{34}$$

$$\frac{\partial Q}{\partial t} + \operatorname{div}(Q\mathbf{V}) = 0, \tag{35}$$

$$\frac{\partial Q}{\partial t} + \mathbf{V}\cdot\nabla Q - \gamma\left(\frac{\partial P}{\partial t} + \mathbf{V}\cdot\nabla P\right) = 0, \tag{36}$$

$$F(\mathbf{r}, t) = 0, \tag{37}$$

$$\frac{\partial F}{\partial t} + \mathbf{V}\cdot\nabla F = 0, \qquad \frac{\partial F}{\partial t} + \mathbf{V}'\cdot\nabla F = 0, \tag{38}$$

$$P(\mathbf{r}, t) - P'(\mathbf{r}, t) = 0, \tag{39}$$

$$\begin{aligned} &\frac{\partial}{\partial t}(P - P') + \mathbf{V}\cdot\nabla(P - P') = 0, \\ &\frac{\partial}{\partial t}(P - P') + \mathbf{V}'\cdot\nabla(P - P') = 0. \end{aligned} \tag{40}$$

It is understood that in the boundary conditions the coordinates have to satisfy (37). If any particular motion whose perturbations are to be investigated is selected, one has to make sure first that this undisturbed motion satisfies equations (34)–(40).

In order to derive the perturbation equations one has now to substitute in the equations previously mentioned, namely, (18)–(20) and (25)–(29), for the quantities with asterisks the sums (2)–(4). Furthermore f^* has to be replaced by $F + f$, where F refers to the boundary in the undisturbed position while f denotes the variation of the boundary due to disturbance. The resulting equations can be simplified, as explained on page 402, because

1. The undisturbed quantities must satisfy (34)–(40), and
2. Terms of second or higher order in the perturbation quantities can be neglected.

Consider, for instance, equation (18) which may now be written

$$\frac{\partial \mathbf{V}}{\partial t} + \frac{\partial \mathbf{v}}{\partial t} + \underline{\mathbf{V}\cdot\nabla\mathbf{V}} + \mathbf{V}\cdot\nabla\mathbf{v} + \mathbf{v}\cdot\nabla\mathbf{V} + \underline{\underline{\mathbf{v}\cdot\nabla\mathbf{v}}} + \underline{2\boldsymbol{\Omega} \times \mathbf{V}}$$

$$+ 2\boldsymbol{\Omega} \times \mathbf{v} = -\left(\frac{1}{Q + q}\right)\nabla(P + p) - \underline{\nabla\Phi}.$$

The first term on the right-hand side may be expanded as follows,

$$\left(\frac{1}{Q+q}\right)\nabla(P+p)$$
$$= \frac{1}{Q}\left(1 - \frac{q}{Q} + \frac{q^2}{Q^2} - \cdots\right)\nabla(P+p)$$
$$= \underline{\frac{1}{Q}\nabla P} - \frac{q}{Q^2}\nabla P + \underline{\underline{\frac{q^2}{Q^3}\nabla P}} - \cdots + \frac{1}{Q}\nabla p - \underline{\underline{\frac{q}{Q^2}\nabla p}} + \cdots.$$

Here the singly underlined terms vanish because they form together the undisturbed equation. The doubly underlined terms can be omitted because they are small of higher order. In a similar manner the other perturbation equations can be obtained so that the complete system becomes

$$\frac{\partial \mathbf{v}}{\partial t} + \mathbf{V}\cdot\nabla\mathbf{v} + \mathbf{v}\cdot\nabla\mathbf{V} + 2\boldsymbol{\Omega}\times\mathbf{v} = -\frac{\nabla p}{Q} + \frac{q\nabla P}{Q^2}, \tag{41}$$

$$\frac{\partial q}{\partial t} + \operatorname{div}(q\mathbf{V}) + \operatorname{div}(Q\mathbf{v}) = 0, \tag{42}$$

$$\frac{\partial q}{\partial t} + \mathbf{V}\cdot\nabla q + \mathbf{v}\cdot\nabla Q - \gamma\left(\frac{\partial p}{\partial t} + \mathbf{V}\cdot\nabla p + \mathbf{v}\cdot\nabla P\right) = 0, \tag{43}$$

$$F(\mathrm{r}, t) + f(\mathrm{r}, t) = 0, \tag{44}$$

$$\frac{\partial f}{\partial t} + \mathbf{V}\cdot\nabla f + \mathbf{v}\cdot\nabla F = 0, \qquad \frac{\partial f}{\partial t} + \mathbf{V}'\cdot\nabla f + \mathbf{v}'\cdot\nabla F = 0, \tag{45}$$

$$P(\mathrm{r}, t) - P'(\mathbf{r}, t) + p(\mathrm{r}, t) - p'(\mathrm{r}, t) = 0, \tag{46}$$

$$\frac{\partial}{\partial t}(p - p') + \mathbf{V}\cdot\nabla(p - p') + \mathbf{v}\cdot\nabla(P - P') = 0, \qquad \frac{\partial}{\partial t}(p - p') + \mathbf{V}'\cdot\nabla(p - p') + \mathbf{v}'\cdot\nabla(P - P') = 0. \tag{47}$$

In equations (44) and (46) the undisturbed terms alone are no longer zero in spite of (37) and (39), because these equations hold only if the values at the undisturbed boundary are substituted for r, while in (44) and (46) the values at the disturbed boundary have to be inserted into F, P, and P'. On the other hand, it is permissible to replace in the perturbation quantities contained in the equations (44)–(47) the values at the disturbed position of the boundary by the values at the undisturbed position because this substitution produces only an error of higher order. Consider, for instance, the perturbation pressure p. For the moment let r be the undisturbed position of the boundary, $\mathrm{r} + \Delta\mathrm{r}$ the disturbed position where $\Delta\mathrm{r}$ must be small of the same order as the other perturbation quantities. Then

$$p(\mathrm{r} + \Delta\mathrm{r}, t) = p(\mathrm{r}, t) + (\Delta\mathrm{r})\cdot\nabla p(\mathrm{r}, t),$$

where the second term on the right-hand side is smaller than the preceding by one order of magnitude.

V. Bjerknes has pointed out that the perturbation equations (41)–(47) can be obtained from the equations of the undisturbed motion (34)–(40) by forming the variation of these equations and substituting the perturbation quantities wherever variations of the undisturbed quantities appear.

The Lagrangian System of Perturbation Equations. In the formulation of the perturbation equations in the Lagrangian form it will be assumed that at the time $t = t_0$ the position and the parameters of state for the undisturbed particle are the same as in the undisturbed case. This assumption implies that the perturbation is induced suddenly at the time t_0. It has the advantage that the three parameters a, b, and c, which identify each particle, are not only the components of the radius vector $\mathbf{R}_0$ for the undisturbed motion at the time t_0, but also for the disturbed motion since r_0, the deviation of the disturbed from the undisturbed position at t_0, vanishes. The equations for the undisturbed motion in the Lagrangian system are now obtained by substituting for the appropriate quantities with asterisks in (22), (23), (14), (30), (32), and (33) the corresponding quantities characterizing the undisturbed motion which are denoted by capital letters. Thus,

$$\nabla\mathrm{R}\cdot\left[\frac{\partial^2\mathrm{R}}{\partial t^2} + 2\boldsymbol{\Omega}\times\left(\frac{\partial\mathrm{R}}{\partial t}\right)\right] = -\frac{\nabla P}{Q} - \nabla\Phi, \tag{48}$$

$$Q\left(\frac{\partial\mathrm{R}}{\partial a}\right)\times\left(\frac{\partial\mathrm{R}}{\partial b}\right)\cdot\left(\frac{\partial\mathrm{R}}{\partial c}\right) = Q_0, \tag{49}$$

$$Q = Q(a, b, c, P), \tag{50}$$

$$F_0(a, b, c) = 0, \qquad F_0(a', b', c') = 0, \tag{51}$$

$$[F(\mathrm{R}, t) = 0] \equiv [F'(\mathrm{R}', t) = 0], \tag{52}$$

$$P(\mathrm{R}, t) = P'(\mathrm{R}, t) \quad \text{for} \quad \mathrm{R} = \mathrm{R}'. \tag{53}$$

The physical equation (50) has here been written somewhat differently from (14) by making use of the fact that the parameters A, B, and C, $\cdots$ may vary from particle to particle and are therefore functions of a, b, and c.

The perturbation equations are now obtained by making in these same six previously mentioned equations the substitutions indicated by (1), (3), and (4) and taking into account also that the surface of discontinuity will in general change its position because of the perturbation motion. The resulting equations can be simplified by the same two considerations as stated on page 407 for the Eulerian equations. It is to be noted that the force potential Φ depends on the position in space. Hence, while in the undisturbed motion it is given by $\Phi(\mathrm{R})$, it will be given by $\Phi(\mathrm{R} + \mathrm{r})$ for the same particle after the beginning of the perturba-

tion. According to Taylor's theorem,

$$\Phi(\mathbf{R} + \mathbf{r}) = \Phi(\mathbf{R}) + \mathbf{r}\cdot\nabla_R\Phi + \text{higher-order terms.}$$

Here, the operator ∇_R denotes space differentiation with respect to the undisturbed position vector R. Similarly, for the vector of the earth's rotation,

$$\Omega(\mathbf{R} + \mathbf{r}) = \Omega(\mathbf{R}) + (\mathbf{r}\cdot\nabla_R)\Omega.$$

The boundary condition (51) given above for the undisturbed state remains the same for the disturbed state since the condition refers to the time t_0 when the particles were in their undisturbed position. The functions $F(\mathbf{R}, t)$ and $F'(\mathbf{R}', t)$ in (52) are modified in the perturbed motion because the particles at the boundary whose position vectors in the undisturbed motion were R and R′ are now R + r and R′ + r′, respectively. According to Taylor's theorem,

$$F(\mathbf{R}+\mathbf{r}, t) = F(\mathbf{R}, t) + \mathbf{r}\cdot\nabla_R F + \text{higher-order terms,}$$

and an analogous relation holds for $F'(\mathbf{R}' + \mathbf{r}', t)$. Thus, because of (52) the kinematic boundary condition for the disturbed motion becomes as written below in (58). In deriving the dynamic boundary condition (59), use is made of the facts that the same particles are considered in the undisturbed and the disturbed case and that in the perturbation quantities the disturbed position may be replaced by the undisturbed position. Thus the system of perturbation equations in Lagrangian form becomes

$$\begin{aligned}\nabla\mathbf{R}\cdot\left\{\frac{\partial^2\mathbf{r}}{\partial t^2} + 2\Omega\times\left(\frac{\partial\mathbf{r}}{\partial t}\right) + \left[(\mathbf{r}\cdot\nabla_R)\Omega\right]\times\left(\frac{\partial\mathbf{R}}{\partial t}\right)\right\} \\ + \nabla\mathbf{r}\cdot\left[\frac{\partial^2\mathbf{R}}{\partial t^2} + 2\Omega\times\left(\frac{\partial\mathbf{R}}{\partial t}\right)\right] = -\frac{\nabla p}{Q} \\ + \frac{q(\nabla P)}{Q^2} - \nabla(\mathbf{r}\cdot\nabla_R\Phi),\end{aligned} \tag{54}$$

$$\begin{aligned}&\frac{q}{Q}\left(\frac{\partial\mathbf{R}}{\partial a}\right)\times\left(\frac{\partial\mathbf{R}}{\partial b}\right)\cdot\left(\frac{\partial\mathbf{R}}{\partial c}\right) \\ &\quad + \left(\frac{\partial\mathbf{r}}{\partial a}\right)\times\left(\frac{\partial\mathbf{R}}{\partial b}\right)\cdot\left(\frac{\partial\mathbf{R}}{\partial c}\right) \\ &\quad + \left(\frac{\partial\mathbf{R}}{\partial a}\right)\times\left(\frac{\partial\mathbf{r}}{\partial b}\right)\cdot\left(\frac{\partial\mathbf{R}}{\partial c}\right) \\ &\quad + \left(\frac{\partial\mathbf{R}}{\partial a}\right)\times\left(\frac{\partial\mathbf{R}}{\partial b}\right)\cdot\left(\frac{\partial\mathbf{r}}{\partial c}\right) = 0,\end{aligned} \tag{55}$$

$$q = \gamma p, \tag{56}$$

$$F_0(a, b, c) = 0, \qquad F_0'(a', b', c') = 0, \tag{57}$$

$$\mathbf{r}\cdot\nabla_R F = \mathbf{r}'\cdot\nabla_R F', \qquad \mathbf{R} = \mathbf{R}', \tag{58}$$

$$p(\mathbf{R}, t) = p'(\mathbf{R}', t), \qquad \mathbf{R} = \mathbf{R}'. \tag{59}$$

As in the case of the Eulerian system the perturbation equations (54) to (59) can be obtained from the equations (48) to (53) by forming the variation of these equations.

A comparison of the three basic equations, namely, of motion, of continuity, and physical changes in the Eulerian system and in the Lagrangian system, shows that the equation of motion is of the first order in the Eulerian form (41) while it is of the second order in the Lagrangian form (54). The equation of continuity in the Eulerian form (42) as well as in the Lagrangian form (55) is of the first order. But the physical equation is a first-order differential equation in the Eulerian system (43) while in the Lagrangian system it has the simple form (56) so that the perturbation density q can, with the aid of these equations, be eliminated directly from the equations of motion and continuity. In the Eulerian system, on the other hand, additional differentiations will in general be necessary in order to eliminate the perturbation density, so that for a compressible fluid the Eulerian equations are not simpler than the Lagrangian equations. The Eulerian system is simpler than the Lagrangian system only for an incompressible and homogeneous fluid, the case mostly considered in classical hydrodynamics.

From a physical viewpoint it may be remarked that meteorological observations are made at a given locality and not following individual air particles so that the Eulerian rather than the Lagrangian method is used in this case. However, when trajectories or the motion of air masses are studied the Lagrangian method offers a more direct approach than the Eulerian method. It is, of course, always possible to make the transition from the results in the one system to those in the other. When the Lagrangian system has been used the positions of the particles and their pressures and densities are given. By a differentiation the particle velocities can be obtained, and the distribution in space of the velocity, pressure, and density can then be found because the position of the particles in space is known. When the Eulerian system is used the particle trajectories can be found from the known velocity distribution.

In some instances a certain simplification may be achieved in the work leading to the mathematical solution depending on whether the problem is formulated in the Eulerian or Lagrangian system. But no general statements about the relative difficulty of the one or the other approach can be made, and it has to be seen by direct comparison whether the Lagrangian or the Eulerian method is more advantageous.

Perturbation Equations for Special Coordinate Systems. From the general equations given in the two preceding sections the special forms suitable for a specific problem can be derived. It will depend on the particular fluid model to be considered, in particular on the boundary conditions, what simplifications can be made in the system of perturbation equations, and which type of coordinates is most suitable. As long as the earth can be considered as flat, a rectangular Cartesian coordinate system is the best choice, unless the motion has a circular symmetry. In the latter case, cylindrical polar coordinates are most appropriate. For large-scale disturbances on the earth its curvature has to be taken into account, and in this case spherical polar coordinates represent the most suitable frame of reference.

Some simple typical examples of problems to be treated by the perturbation method will be considered later. Here we shall discuss the transition from the vector form of the equations to the coordinate form. This transition presents little or no difficulty in the case of straight-line coordinates, such as the Cartesian rectangular coordinate system, but it is somewhat more awkward if curvilinear coordinates, such as spherical or cylindrical polar coordinates, are to be used. The reason for this difficulty is that in the case of curvilinear coordinates the change in direction along the coordinate curves has to be taken into consideration.

The problem of writing the perturbation equations in arbitrary curvilinear coordinates has been solved by V. Bjerknes [3, 4], with the use of Lagrange's equations of the second kind, but the resulting equations will not be reproduced here since the vector equations given previously permit also the derivation of the equations in any particular coordinate system. In order to show by an example how the equations for the undisturbed and the disturbed motion can be derived for a curvilinear coordinate system from the vector equations given above, spherical polar coordinates will be chosen, and the equations will be written in the Eulerian system.

Depending on the amount of vector and tensor analysis assumed to be known this derivation naturally becomes shorter or longer. Here only the more elementary theorems of vector analysis will be used. Consider a right-hand rectangular Cartesian coordinate system whose z-axis, for convenience, is parallel to the earth's axis. Let ϑ, λ, and r be the colatitude, longitude, and distance, respectively, from the earth's center.[1] Further, let $\mathbf{i}$, $\mathbf{j}$, and $\mathbf{k}$ be the unit vectors in the x, y, and z directions, respectively. Then the radius vector

$$\begin{aligned}\mathbf{r} &= \mathbf{i}x + \mathbf{j}y + \mathbf{k}z \\ &= \mathbf{i}r\sin\vartheta\cos\lambda + \mathbf{j}r\sin\vartheta\sin\lambda + \mathbf{k}r\cos\vartheta.\end{aligned} \tag{60}$$

Further, since the radius vector $\mathbf{r}$ is also a function of λ, ϑ, and r

$$d\mathbf{r} = \left(\frac{\partial\mathbf{r}}{\partial\vartheta}\right)d\vartheta + \left(\frac{\partial\mathbf{r}}{\partial\lambda}\right)d\lambda + \left(\frac{\partial\mathbf{r}}{\partial r}\right)dr. \tag{61}$$

Here $\partial\mathbf{r}/\partial\vartheta$ is evidently a vector tangential to the curve of intersection between the coordinate surfaces

$$\lambda = \text{const} \quad \text{and} \quad r = \text{const},$$

or as it may be called briefly a "direction vector" in the direction ϑ. Similarly $\partial\mathbf{r}/\partial\lambda$ and $\partial\mathbf{r}/\partial r$ are direction vectors in the directions λ and r, respectively. These three direction vectors play in the polar coordinate system a role similar to that of $\mathbf{i}$, $\mathbf{j}$, $\mathbf{k}$ in the Cartesian system except that they are not unit vectors, a shortcoming which is immaterial here. By appropriate differentiations of (60) the following relations are obtained:

$$\begin{aligned}\frac{\partial\mathbf{r}}{\partial\vartheta} &= \mathbf{i}r\cos\vartheta\cos\lambda + \mathbf{j}r\cos\vartheta\sin\lambda - \mathbf{k}r\sin\vartheta, \\ \frac{\partial\mathbf{r}}{\partial\lambda} &= -\mathbf{i}r\sin\vartheta\sin\lambda + \mathbf{j}r\sin\vartheta\cos\lambda, \\ \frac{\partial\mathbf{r}}{\partial r} &= \mathbf{i}\sin\vartheta\cos\lambda + \mathbf{j}\sin\vartheta\sin\lambda + \mathbf{k}\cos\vartheta.\end{aligned} \tag{62}$$

From these three equations it is found that

$$\begin{aligned}\mathbf{i}r\sin\vartheta &= \left(\frac{\partial\mathbf{r}}{\partial\vartheta}\cos\vartheta + \frac{\partial\mathbf{r}}{\partial r}r\sin\vartheta\right)\sin\vartheta\cos\lambda \\ &\qquad - \frac{\partial\mathbf{r}}{\partial\lambda}\sin\lambda, \\ \mathbf{j}r\sin\vartheta &= \left(\frac{\partial\mathbf{r}}{\partial\vartheta}\cos\vartheta + \frac{\partial\mathbf{r}}{\partial r}r\sin\vartheta\right)\sin\vartheta\sin\lambda \\ &\qquad + \frac{\partial\mathbf{r}}{\partial\lambda}\cos\lambda, \\ \mathbf{k}r &= -\frac{\partial\mathbf{r}}{\partial\vartheta}\sin\vartheta + \frac{\partial\mathbf{r}}{\partial r}r\cos\vartheta.\end{aligned} \tag{63}$$

In the following we shall for the moment consider only the undisturbed motion. The extension to the disturbed motion will be recognized easily. From (61) it follows by individual differentiation with respect to time that

$$\mathbf{V} = \frac{d\mathbf{R}}{dt} = \left(\frac{\partial\mathbf{R}}{\partial\vartheta}\right)\dot{\Theta} + \left(\frac{\partial\mathbf{R}}{\partial\lambda}\right)\dot{\Lambda} + \left(\frac{\partial\mathbf{R}}{\partial r}\right)\dot{R}. \tag{64}$$

Here the dots indicate individual differentiation with respect to time. The following relations exist between the linear and angular velocity components,

$$r\dot{\Theta} = V_\vartheta, \qquad r\sin\vartheta\dot{\Lambda} = V_\lambda, \qquad \dot{R} = V_r. \tag{65}$$

For the present the notation in (64) will be retained. With the foregoing relations the Coriolis term $\boldsymbol{\Omega}\times\mathbf{V}$ can be evaluated. Since $\boldsymbol{\Omega}$ is in the direction of z, $\boldsymbol{\Omega} = \Omega\mathbf{k}$. Further, $\mathbf{V}$ may be expressed by its components in the directions of x, y, and z with the aid of (64) and (63) and the vector product of $\boldsymbol{\Omega}$ and $\mathbf{V}$ may be evaluated. In the resulting expression the unit vectors $\mathbf{i}$, $\mathbf{j}$, and $\mathbf{k}$ can be replaced again by the direction vectors $\partial\mathbf{R}/\partial\vartheta$, $\partial\mathbf{R}/\partial\lambda$, and $\partial\mathbf{R}/\partial r$ so that

$$\begin{aligned}2\boldsymbol{\Omega}\times\mathbf{V} = &-2\Omega\left\{\sin\vartheta\left[\left(\frac{\partial\mathbf{R}}{\partial\vartheta}\right)\cos\vartheta + \left(\frac{\partial\mathbf{R}}{\partial r}\right)r\sin\vartheta\right]\dot{\Lambda}\right. \\ &\left. + \left[\dot{\Theta}\cot\vartheta + \frac{\dot{R}}{r}\right]\left[\frac{\partial\mathbf{R}}{\partial\lambda}\right]\right\}.\end{aligned} \tag{66}$$

1. It is also possible to use elliptic coordinates if the flattening of the earth is to be taken into account [20]. For most meteorological considerations, however, this factor can be neglected, and the sum of gravity and centrifugal force due to the earth's rotation can be assumed in the direction to the center of the earth.

The operator

$$\nabla = \frac{1}{r^2}\left(\frac{\partial \mathrm{R}}{\partial \vartheta}\right)\left(\frac{\partial}{\partial \vartheta}\right) + \frac{1}{r^2 \sin^2 \vartheta}\left(\frac{\partial \mathrm{R}}{\partial \lambda}\right)\left(\frac{\partial}{\partial \lambda}\right) + \left(\frac{\partial \mathrm{R}}{\partial r}\right)\left(\frac{\partial}{\partial r}\right). \tag{67}$$

This relation can for instance be verified directly from the form of ∇ in Cartesian rectangular coordinates with the aid of (63). Further,

$$\mathbf{V}\cdot\nabla = \dot{\Theta}\left(\frac{\partial}{\partial \vartheta}\right) + \dot{\Lambda}\left(\frac{\partial}{\partial \lambda}\right) + \dot{R}\left(\frac{\partial}{\partial r}\right). \tag{68}$$

In order to obtain the expression $\mathbf{V}\cdot\nabla\mathbf{V}$ which appears in the equations of motion the direction vectors have also to be differentiated with respect to ϑ, λ, and r. This differentiation can be carried out with the aid of (62), and the resulting expressions can again be written as direction vectors according to (63). It will be found that

$$\begin{aligned}\mathbf{V}\cdot\nabla\mathbf{V} = {} & \left(\frac{\partial \mathrm{R}}{\partial \vartheta}\right)\left[(\mathbf{V}\cdot\nabla)\dot{\Theta} + 2\dot{\Theta}\frac{\dot{R}}{r} - \dot{\Lambda}^2 \sin\vartheta\cos\vartheta\right] \\ & + \left(\frac{\partial \mathrm{R}}{\partial \lambda}\right)\left[(\mathbf{V}\cdot\nabla)\dot{\Lambda} + 2\dot{\Theta}\dot{\Lambda}\cot\vartheta + 2\dot{\Lambda}\frac{\dot{R}}{r}\right] \\ & + \left(\frac{\partial \mathrm{R}}{\partial r}\right)\left[(\mathbf{V}\cdot\nabla)\dot{R} - \dot{\Theta}^2 r - r\dot{\Lambda}^2 \sin^2\vartheta\right].\end{aligned} \tag{69}$$

The expression for the divergence in polar coordinates is sufficiently well known so that it need only be quoted here:

$$\operatorname{div}\mathbf{V} = \frac{\partial \dot{\Theta}}{\partial \vartheta} + \frac{\partial \dot{\Lambda}}{\partial \lambda} + \frac{\partial \dot{R}}{\partial r} + (\cot\vartheta)\dot{\Theta} + \frac{2\dot{R}}{r}. \tag{70}$$

With these foregoing transformations the equations (34) to (40) can now be written in polar coordinates. The three component equations of (34) can be obtained if, after the necessary substitutions are made from (64) and (66)–(69), the factors of each of the direction vectors are equated separately. In writing down these equations the linear velocities have been substituted according to (65). Then

$$\mathbf{V}\cdot\nabla = V_\vartheta\left(\frac{\partial}{r\partial\vartheta}\right) + V_\lambda\left(\frac{\partial}{r\sin\vartheta\,\partial\lambda}\right) + V_r\left(\frac{\partial}{\partial r}\right), \tag{71}$$

and the equations of motion assume the following form:

$$\frac{\partial V_\vartheta}{\partial t} + \mathbf{V}\cdot\nabla V_\vartheta + \frac{V_r V_\vartheta}{r} - V_\lambda^2\left(\frac{\cot\vartheta}{r}\right) - 2\Omega\cos\vartheta\, V_\lambda = -\frac{1}{Q}\left(\frac{\partial P}{r\partial\vartheta}\right), \tag{72}$$

$$\frac{\partial V_\lambda}{\partial t} + \mathbf{V}\cdot\nabla V_\lambda + \frac{V_r V_\lambda}{r} + V_\vartheta V_\lambda\left(\frac{\cot\vartheta}{r}\right) + 2\Omega(V_\vartheta\cos\vartheta + V_r\sin\vartheta) = -\frac{1}{Q}\left(\frac{\partial P}{r\sin\vartheta\,\partial\lambda}\right), \tag{73}$$

$$\frac{\partial V_r}{\partial t} + \mathbf{V}\cdot\nabla V_r - \frac{V_\vartheta^2}{r} - \frac{V_\lambda^2}{r} - 2\Omega\sin\vartheta\, V_\lambda = -\frac{1}{Q}\left(\frac{\partial P}{\partial r}\right) - \frac{\partial \Phi}{\partial r}. \tag{74}$$

The equation of continuity is

$$\frac{\partial Q}{\partial t} + \mathbf{V}\cdot\nabla Q + Q\operatorname{div}\mathbf{V} = 0, \tag{75}$$

where

$$\operatorname{div}\mathbf{V} = \frac{\partial(\sin\vartheta\, V_\vartheta)}{r\sin\vartheta\,\partial\vartheta} + \frac{\partial V_\lambda}{r\sin\vartheta\,\partial\lambda} + \frac{1}{r^2}\frac{\partial(r^2 V_r)}{\partial r} \tag{76}$$

and the physical equation as well as the boundary conditions have the same form as that given for the Eulerian system of perturbation equations on page 407 except that the operator $\mathbf{V}\cdot\nabla$ is now of the form given by (71).

As explained before, the perturbation equations can be written down directly by forming the variation δ of the equations of the undisturbed motion and replacing the quantities δV_ϑ, δV_λ, δV_r, δP, and δQ by the corresponding perturbation quantities. This procedure which is more rapid than the one used in the two preceding sections leads to the following equations:

$$\frac{\partial v_\vartheta}{\partial t} + \mathbf{V}\cdot\nabla v_\vartheta + \mathbf{v}\cdot\nabla V_\vartheta + \frac{v_r V_\vartheta}{r} + \frac{V_r v_\vartheta}{r} - \frac{2V_\lambda v_\lambda\cot\vartheta}{r} - 2\Omega\cos\vartheta\, v_\lambda = -\frac{1}{Q}\left(\frac{\partial p}{r\partial\vartheta}\right) + \frac{q}{Q^2}\left(\frac{\partial P}{r\partial\vartheta}\right), \tag{77}$$

$$\frac{\partial v_\lambda}{\partial t} + \mathbf{V}\cdot\nabla v_\lambda + \mathbf{v}\cdot\nabla V_\lambda + \frac{v_r V_\lambda}{r} + \frac{V_r v_\lambda}{r} + \frac{v_\vartheta V_\lambda\cot\vartheta}{r} + \frac{V_\vartheta v_\lambda\cot\vartheta}{r} + 2\Omega(v_\vartheta\cos\vartheta + v_r\sin\vartheta) = -\frac{1}{Q}\left(\frac{\partial p}{r\sin\vartheta\,\partial\lambda}\right) + \frac{q}{Q^2}\left(\frac{\partial P}{r\sin\vartheta\,\partial\lambda}\right), \tag{78}$$

$$\frac{\partial v_r}{\partial t} + \mathbf{V}\cdot\nabla v_r + \mathbf{v}\cdot\nabla V_r - \frac{2V_\vartheta v_\vartheta}{r} - \frac{2V_\lambda v_\lambda}{r} - 2\Omega\sin\vartheta\, v_\lambda = -\frac{1}{Q}\left(\frac{\partial p}{\partial r}\right) + \frac{q}{Q^2}\left(\frac{\partial P}{\partial r}\right), \tag{79}$$

$$\frac{\partial q}{\partial t} + \mathbf{V}\cdot\nabla q + \mathbf{v}\cdot\nabla Q + Q\operatorname{div}\mathbf{v} + q\operatorname{div}\mathbf{V} = 0. \tag{80}$$

The expressions $\mathbf{v}\cdot\nabla$ and $\operatorname{div}\mathbf{v}$ are analogous to (71) and (76), respectively. The physical equation and the boundary conditions have again the same form as the analogous equations in the Eulerian system of perturbation equations.

EXAMPLES OF THE USE OF THE PERTURBATION METHOD

The present article deals with a method of handling theoretical problems rather than with a theory and interpretation of atmospheric phenomena. Therefore, the discussion of the following examples stresses this method rather than the application of the results to

specific meteorological problems. Even the method is discussed only to the extent to which it illustrates the application of the perturbation equations. The additional procedures of mathematical physics which lead to a solution of the problem are mentioned only very briefly.

Only a few fairly simple examples of the use of the perturbation method are given here which illustrate the various types of problems that can be handled in this manner.

Perturbations in Two Incompressible Fluid Currents, in the Lagrangian System. As a first example of the application of perturbation equations to fluid motions, a very simple case will be considered. This case has been discussed in the textbooks on hydrodynamics, although as a rule only with the aid of the Eulerian system. Here the Lagrangian equations will be used. Assume that we have two incompressible homogeneous fluid layers, both in constant horizontal motion. Let the density of the lower fluid be Q, its velocity U, while the density and velocity for the upper fluid are Q' and U', respectively. The earth's rotation will be neglected. The effects of capillary forces which are important for short water waves will also be disregarded. Further, let the lower boundary be horizontal and rigid at $Z = c = 0$, let the internal discontinuity be at the level h, and the free surface be at H, while the thickness of the upper layer may be denoted by h'. The last two statements imply that both the internal and the free surface are horizontal in the undisturbed case. This is physically obvious and will be corroborated by the equations for the undisturbed motion.

It is sufficient to consider the motion in a vertical XZ plane only. It is

$$X = a + Ut, \qquad Z = c. \tag{81}$$

The equations of motion and of continuity reduce, according to (47) and (49) to

$$0 = \frac{\partial P}{\partial a}, \tag{82}$$

$$0 = -\frac{1}{Q}\frac{\partial P}{\partial c} - g, \tag{83}$$

$$Q = Q_0 = \text{const.} \tag{84}$$

The subscript zero for the density can, of course, be omitted. Equations analogous to (81)–(84) hold for the upper layer. Since, according to (82) and (83), the pressure is a function of the vertical coordinate c only, it follows from the boundary condition (53) that the internal and free surfaces must both be horizontal. If (83) is integrated and if the outside pressure at the free surface vanishes,

$$P' = gQ'(H - c), \tag{85}$$

$$P = gQ'h' + gQ(h - c). \tag{86}$$

The integration constants have been chosen so that the two equations satisfy also the condition that the pressure be continuous at the internal surface. Since according to (53) at the free surface $P' = 0$, and at the internal surface $P - P' = 0$, it follows that both these surfaces must be horizontal in the undisturbed case.

The perturbation equations of motion and of continuity follow from (54) and (55), namely,

$$\frac{\partial^2 x}{\partial t^2} = -\frac{1}{Q}\frac{\partial p}{\partial a} - \frac{\partial}{\partial a}(gz), \tag{87}$$

$$\frac{\partial^2 z}{\partial t^2} = -\frac{1}{Q}\frac{\partial p}{\partial c} - \frac{\partial}{\partial c}(gz), \tag{88}$$

$$\frac{\partial x}{\partial a} + \frac{\partial z}{\partial c} = 0, \tag{89}$$

and analogous equations follow for the upper layer. From this system of three equations the three unknown variables x, z, and p can be determined as functions of the coordinates at the time $t = t_0$, namely a and c, and of the time t. Since the system is not only linear, but also has constant coefficients, exponential or trigonometric functions will represent solutions. It may be assumed that the functional dependence on a, c, and t can be expressed in the form

$$\begin{aligned} x, z, p &= A, C, D \exp\{i\alpha(X - \sigma t) + \beta Z\} \\ &= A, C, D \exp\{i\alpha[a - (\sigma - U)t] + \beta c\}, \end{aligned} \tag{90}$$

where A, C, and D are constants. The complex form for the periodicity term is more convenient than the trigonometric form and is therefore used here. For the subsequent physical interpretation either the real or the imaginary part of the solution or a linear combination of both can be used. The form of the solution given above represents a wave in the a direction of the length $2\pi/\alpha$ and moving with the speed σ. Special attention should be called to the appearance of U (and U' for the upper layer) in the exponent since the perturbation quantities remain small only with regard to the *undisturbed* position of the particle, but not with respect to its *initial* position.

The expressions (90) do not satisfy the condition that the perturbation quantities vanish at the time $t = t_0$ but it can be shown by transition to the corresponding Eulerian equations that the expressions developed here represent solutions of the problem.

Substitution of (90) into equations (87)–(89) leads to a system of linear homogeneous equations for A, C, and D. The system has nontrivial solutions only if its determinant vanishes. It follows that $\beta = \pm\alpha$. Two of the three constants A, C, and D may now be expressed by the third, and in view of the condition to be satisfied at the horizontal lower boundary, A and D may be expressed by C. Thus

$$A = i\frac{\beta}{a}C, \qquad D = -Q\frac{g\beta - \alpha^2(\sigma - U)^2}{\beta}C, \tag{91}$$

and analogous expressions hold for the upper layer. Because of the two values for β there are two different solutions, and a linear combination of the two solutions represents also a solution of the system of differential equations. When the two arbitrary constants

are denoted by C and C^* it follows that

$$z = [Ce^{\alpha c} + C^*e^{-\alpha c}] \exp \{i\alpha[a - (\sigma - U)t]\}.$$

Since, according to (58), z must vanish at the rigid lower boundary ($c = 0$), it follows that

$$C = -C^* = \frac{K}{2}, \text{ say.}$$

Consequently,

$$\begin{aligned} x &= [iK \cosh \alpha c] \exp \{i\alpha[a - (\sigma - U)t]\}, \\ z &= [K \sinh \alpha c] \exp \{i\alpha[a - (\sigma - U)t]\}, \\ p &= -QK[g \sinh \alpha z - \alpha(\sigma - U)^2 \cosh \alpha z] \\ &\quad \times \exp \{i\alpha[a - (\sigma - U)t]\}. \end{aligned} \tag{92}$$

In the upper layer the pressure is given by

$$\begin{aligned} p' = -Q'\{&g(C'e^{\alpha c} + C^{*\prime}e^{-\alpha c}) \\ &- \alpha(\sigma - U')^2(C'e^{\alpha c} - C^{*\prime}e^{-\alpha c})\} \\ &\times \exp \{i\alpha[a - (\sigma - U')t]\}. \end{aligned}$$

This expression must vanish at the free upper surface ($c = H$) according to (59), so that

$$\begin{aligned} &[g - \alpha(\sigma - U')^2]C'e^{\alpha H} \\ &= -[g + \alpha(\sigma - U')^2]C^{*\prime}e^{-\alpha H} = \frac{K'}{2}[g^2 - \alpha^2(\sigma - U')^4], \end{aligned}$$

where K' is a new constant introduced for convenience. Consequently,

$$\begin{aligned} x' &= iK'[g \cosh \alpha(c - H) \\ &\quad + \alpha(\sigma - U')^2 \sinh \alpha(c - H)] \\ &\quad \times \exp \{i\alpha[a - (\sigma - U')t]\}, \\ z' &= K'[g \sinh \alpha(c - H) \\ &\quad - \alpha(\sigma - U')^2 \cosh \alpha(c - H)] \\ &\quad \times \exp \{i\alpha[a - (\sigma - U')t]\}, \\ p' &= -Q'K'[g^2 - \alpha^2(\sigma - U')^4] \sinh \alpha(c - H) \\ &\quad \times \exp \{i\alpha[a - (\sigma - U')t]\}. \end{aligned} \tag{93}$$

At the internal boundary the two conditions (58) and (59) become

$$\left.\begin{aligned} z &= z' \\ p &= p' \end{aligned}\right\} \quad \text{for} \quad X = X' \quad \text{and} \quad Z = Z' = h.$$

Strictly speaking, these two conditions as well as the condition at the free upper surface are to be satisfied at the disturbed position of the boundary, but only an error of higher order is incurred as explained previously (p. 408) if the condition is made to hold at the undisturbed position. The two conditions at the internal boundary give two homogeneous linear equations for K and K', and again the determinant must vanish if nontrivial solutions are to exist. Thus the following equation is obtained:

$$\begin{aligned} &Q[g - \alpha(\sigma - U)^2 \coth \alpha h][g - \alpha(\sigma - U')^2 \coth \alpha h'] \\ &\quad = Q'[g^2 - \alpha^2(\sigma - U')^4]. \end{aligned} \tag{94}$$

An equation of this type is referred to as a secular or frequency equation. It permits the determination of the wave velocity, and thus the frequency, as a function of the wave length $2\pi/\alpha$ and of the physical parameters of the system. It is hardly necessary to discuss this equation in any detail because the wave motion in a fluid system such as is being considered here is too well known. In order to illustrate stability investigations one special example may be considered, however, namely that both layers are so deep compared to the wave length that

$$\coth \alpha h' = \coth \alpha h = 1.$$

In this case we may write

$$\begin{aligned} &Q[g - \alpha(\sigma - U)^2][g - \alpha(\sigma - U')^2] \\ &\quad = Q'[g + \alpha(\sigma - U')^2][g - \alpha(\sigma - U')^2]. \end{aligned} \tag{95}$$

A first solution of this equation is given by the following expression,

$$\sigma = U' + \left(\frac{g}{\alpha}\right)^{1/2}. \tag{96}$$

This value of σ gives the wave velocity of surface waves in deep water. It is physically plausible that such waves can exist in an infinitely deep layer with a free upper surface, even if the lower boundary is an internal discontinuity rather than a rigid plane, because the amplitude of the surface waves decreases to zero at the boundary. If this type of wave is disregarded, we obtain from (95) a quadratic equation for σ whose roots are

$$\begin{aligned} \sigma = &\frac{UQ + U'Q'}{Q + Q'} \\ &\pm \left(\frac{g}{\alpha}\frac{Q - Q'}{Q + Q'} - \frac{QQ'(U - U')^2}{(Q + Q')^2}\right)^{1/2}. \end{aligned} \tag{97}$$

This familiar expression shows that the wave velocity consists of two terms, the "convective" term which represents a weighted mean of the velocities in both layers and the "dynamic" term which depends on the density and the wind discontinuity. The latter term can evidently become imaginary for sufficiently small density differences and wave lengths or for sufficiently large wind discontinuities. Then we may write

$$\sigma = \sigma_1 \pm i\sigma_2,$$

and the periodicity terms of the perturbation equations become

$$\exp \{i\alpha[a - (\sigma_1 - U)t] \mp \alpha\sigma_2 t\}.$$

Thus the perturbation quantities depend exponentially on the time and, since one of the two exponentials has a positive exponent, a solution exists which increases exponentially with time, indicating that the motion is unstable. The particular type of instability arising here is referred to as shearing instability since it is due to the wind shear.

Once the solutions (90) with the various relations

between the different constants have been found it is, of course, possible to satisfy any required initial conditions by suitable linear combinations of expressions of the form (90).

Wave Motions in a Compressible Atmosphere. As an example of motion in a compressible medium, the case of an atmosphere may be considered where the temperature decreases linearly with the elevation at the rate ϵ. In the undisturbed state the atmosphere may be at rest. The lower boundary of this atmosphere may be at $c = -h^I$; there may be an internal discontinuity at $c = 0$ where the temperature, and consequently the density, changes abruptly. The upper surface is free. Its height is determined by the fact that temperature, pressure, and density all vanish here if the temperature decreases linearly with altitude. The earth's rotation will again be neglected; this is permissible for small-scale phenomena such as microbarometric oscillations or billow clouds.

It follows from these assumptions that in the undisturbed state the hydrostatic equation must be satisfied:

$$g = -\frac{1}{Q}\frac{\partial P}{\partial c},$$

and that pressure, temperature, and density are functions of c only, specifically,

$$\frac{P}{P_0} = \left(\frac{T}{T_0}\right)^{g/R\epsilon},$$

$$\frac{Q}{Q_0} = \left(\frac{T}{T_0}\right)^{(g/R\epsilon)-1}.$$

Further, we shall assume that changes of state are adiabatic. Then, according to (15a), the coefficient of piezotropy

$$\gamma = \frac{1}{\lambda RT}$$

and, according to (10), the coefficient of barotropy

$$\Gamma = \frac{1 - R\epsilon/g}{RT}.$$

Both coefficients become equal if

$$\epsilon = \bar{\epsilon} = \left(\frac{g}{R}\right)\frac{\lambda - 1}{\lambda}, \tag{98}$$

the adiabatic lapse rate.

Since the motion may again be assumed as two-dimensional the perturbation equations are given according to (54) and (55), if the perturbation density is replaced by the perturbation pressure according to (56),

$$\frac{\partial^2 x}{\partial t^2} + \frac{1}{Q}\left(\frac{\partial p}{\partial a}\right) + \frac{\partial}{\partial a}(gz) = 0,$$

$$\frac{\partial^2 z}{\partial t^2} + \frac{1}{Q}\left(\frac{\partial p}{\partial c}\right) + \frac{\partial}{\partial c}(gz) + g\gamma\left(\frac{p}{Q}\right) = 0, \tag{99}$$

$$\frac{p}{Q} = -\frac{1}{\gamma}\left(\frac{\partial x}{\partial a} + \frac{\partial z}{\partial c}\right).$$

The second of these equations may also be written in the form

$$\frac{\partial^2 z}{\partial t^2} + \frac{\partial}{\partial c}\left(\frac{p}{Q}\right) + \frac{\partial}{\partial c}(gz) - g(\Gamma - \gamma)\left(\frac{p}{Q}\right) = 0.$$

In general the system (99) has coefficients which depend on the elevation c. Only if the atmosphere is isothermal, $\epsilon = 0$, γ and Γ are constants, and in this case the coefficients are constant if p/Q rather than p is considered as an unknown variable. The case of an isothermal atmosphere is therefore particularly easy to deal with.

In the more general case of a nonisothermal atmosphere the functional dependence of the unknown variables x, z, and p on the height must be left open, and it may be assumed that

$$x,\ z,\ p = A(c),\ C(z),\ D(c)\exp[i\alpha(a - \sigma t)]. \tag{100}$$

If these expressions are substituted in (99), the system may be transformed into a second-order ordinary differential equation for one of the three functions A, C, and D of c. For instance, the differential equation for the pressure amplitude D becomes

$$\frac{d^2D}{dz^2} + \left(\frac{g}{R} - \epsilon\right)\left(\frac{1}{T}\right)\frac{dD}{dz} + \left\{-\alpha^2 + \frac{1}{RT}\left[\frac{\alpha^2\sigma^2}{\lambda} + (\bar{\epsilon} - \epsilon)\frac{Rg}{\sigma^2}\right]\right\} = 0. \tag{101}$$

When D is known, the vertical amplitude C can be obtained from the following expression,

$$QC = \frac{\sigma^2\frac{dD}{dz} + gD}{\alpha^2\sigma^4 - g^2}. \tag{102}$$

Similarly, the horizontal amplitude A can be expressed by D but this function need not be known to satisfy the boundary conditions.

The differential equation (101) can with the aid of the substitutions $D = e^{\alpha c}X(c)$ and $y = -2\alpha T/\epsilon$ be transformed into the confluent hypergeometric equation,

$$y\frac{d^2X}{dy^2} + \left[y - \frac{g}{R\epsilon} + 1\right]\frac{dX}{dy} - \left[\frac{\alpha\sigma^2}{2\epsilon R} + \frac{(\bar{\epsilon} - \epsilon)g}{2\alpha\epsilon\sigma^2}\right]X = 0. \tag{103}$$

The case of one atmospheric layer has been discussed by Lamb [13] and V. Bjerknes and collaborators [4].

In the case of an internal discontinuity surface where such phenonema as billow clouds arise it may be assumed that the wave motion does not extend far upward or downward from the interface. An approximate solution may then be obtained in the following manner. Since

$$T = T_0\left(1 - \frac{\epsilon c}{T_0}\right),$$

multiplication of (101) by $1 - \epsilon c/T_0$ permits one to

write (101) in the form

$$L(D) = \frac{\epsilon c}{T_0}\left(\frac{d^2D}{dc^2} - \alpha^2 D\right),$$

where L stands for the operator acting on D on the left-hand side of (101) when T is replaced by T_0. If we put

$$D = D_0 + \left(\frac{\epsilon}{T_0}\right) D_1 + \left(\frac{\epsilon}{T_0}\right)^2 D_2 + \cdots,$$

comparison of the coefficients of ϵ/T_0 shows that

$$L(D_0) = 0, \tag{104}$$

$$L(D_1) = c\left(\frac{d^2D_0}{dc^2} - \alpha^2 D_0\right), \text{ etc.} \tag{105}$$

The differential equation (104) for the zero approximation can readily be solved since it is homogeneous and has constant coefficients. It is, of course, the equation obtained from (101) if for the variable coefficient T in this equation its constant value T_0 at the interface is blithely substituted. The correction terms D_1, etc., can also be computed by elementary means since they involve the solution of a second-order linear and inhomogeneous equation with constant coefficients. It can be shown that the series for D converges, and for practical purposes when relatively short waves such as billow clouds are studied the zero approximation is sufficiently accurate. According to (104),

$$D_0 = e^{-\mu c/2}(K_1 e^{Nc} + K_2 e^{-Nc}), \tag{106}$$

where K_1 and K_2 are integration constants and

$$\mu = \frac{g/R - \epsilon}{T_0}, \tag{107}$$

$$N^2 = \left(\frac{\mu}{2}\right)^2 + \alpha^2 - \frac{\alpha^2\sigma^2/\lambda + (\tilde{\epsilon} - \epsilon)Rg/\sigma^2}{RT_0}. \tag{108}$$

In order to distinguish the upper and lower layer, primes will be added to the appropriate letters to indicate that these quantities refer to the upper layer. After D_0 has been determined for the lower layer, C_0 is found from (102). Since the vertical displacement must vanish at the lower rigid boundary where $c = -h$, it follows that a relation must exist between the two constants K_1 and K_2. With the introduction of a suitable new constant

$$C_0 = Ke^{-\mu c/2}\frac{\sinh N(c + h)}{Q\alpha^2(\sigma^4\alpha^2 - g^2)} \tag{109}$$

and

$$D_0 = Ke^{-\mu c/2}\left[\frac{\sigma^2 N \cosh N(c + h)}{\alpha^2(\varkappa_1 + g)(\varkappa_2 - g)} + \frac{(\sigma^2\mu/2 - g)\sinh N(c + h)}{\sigma^2(\varkappa_1 + g)(\varkappa_2 - g)}\right], \tag{110}$$

where $\varkappa_1 = \sigma^2(N - \mu/2)$ and $\varkappa_2 = \sigma^2(N + \mu/2)$. At the top of the upper layer ($h' = T_0'/\epsilon'$) the perturbation pressure must vanish ($D_0'(h') = 0$), so that with the introduction of a new integration constant K',

$$D_0' = K'e^{-\mu' c/2}\sinh N'(c - h'), \tag{111}$$

and consequently,

$$C_0' = K'e^{-\mu' c/2}\left[\frac{-(\sigma^2\mu'/2 - g)\sinh N'(c - h')}{Q'(\sigma^4\alpha^2 - g^2)} + \frac{\sigma^2 N' \cosh N'(c - h')}{Q'(\sigma^4\alpha^2 - g^2)}\right]. \tag{112}$$

At the interface ($c = 0$) the perturbation pressures and the vertical displacements must be continuous. Thus

$$D_0(0) = D_0'(0) \text{ and } C_0(0) = C_0'(0).$$

These conditions represent two linear and homogeneous equations for K and K', and a nontrivial solution exists only if the determinant of the foregoing system vanishes. This condition leads to the equation of frequency

$$Q_0\frac{\sigma^2 N \coth Nh + \sigma^2\mu/2 - g}{[\sigma^2(N - \mu/2) + g][\sigma^2(N + \mu/2) - g]} = -\frac{Q_0'}{\sigma^2\mu'/2 - g + \sigma^2 N' \coth N'h'}, \tag{113}$$

which gives the relation between wave velocity, wave length, and the parameters of the fluid system. Since σ is contained in the abbreviations N and N', the equation is transcendental. An approximation which is satisfactory for small-scale oscillations can be obtained by putting the hyperbolic cotangents equal to one which is strictly correct only for infinitely deep fluid layers. Then (113) changes into an algebraic equation which can be evaluated [9]. After an approximation has been obtained it can be used to substitute more accurate values for the hyperbolic cotangents and a new value for σ can be computed if necessary. Furthermore, the correction terms D_1, etc., can be computed, although it is found that the zero approximation gives a sufficiently good quantitative result, for instance in the theory of billow clouds.

Long Waves on a Rotating Plane. As an example of the application of perturbation equations when the earth's rotation is taken into account, the so-called trough formula given by Rossby [18] may be derived. The earth will be regarded as a flat, horizontal plane and the atmosphere as incompressible and homogeneous. The motion, disturbed as well as undisturbed, will be assumed as horizontal. If the atmosphere has a horizontal velocity U in the x-direction,

$$X = a + Ut, \qquad Y = b, \qquad Z = c.$$

It follows from (48) that for the undisturbed motion,

$$0 = -\frac{1}{Q}\frac{\partial P}{\partial a},$$

$$2\Omega_z U = -\frac{1}{Q}\frac{\partial P}{\partial b},$$

$$-g = -\frac{1}{Q}\frac{\partial P}{\partial c}.$$

The equation of continuity is satisfied for this type of motion since the density Q is constant. In the third equation above, the term with Ω_y has been omitted since it is small compared to g. In the following perturbation equations Ω_x and Ω_y will be set equal to zero as is customary when motion on a rotating plane is considered. Further, only the variation of Ω_z in the y-direction will be taken into account, a restriction which is justified if the undisturbed motion is predominantly zonal. Then, according to (54) and (55), the perturbation equations become

$$\frac{\partial^2 x}{\partial t^2} - 2\Omega_z \frac{\partial y}{\partial t} + 2\Omega_z U \frac{\partial y}{\partial a} + \frac{1}{Q}\frac{\partial p}{\partial a} = 0, \tag{114}$$

$$\frac{\partial^2 x}{\partial t^2} + 2\Omega_z \frac{\partial x}{\partial t} + 2\Omega_z U \frac{\partial y}{\partial b} + y \frac{\partial (2\Omega_z)}{\partial b} + \frac{1}{Q}\frac{\partial p}{\partial b} = 0, \tag{115}$$

$$\frac{\partial x}{\partial a} + \frac{\partial y}{\partial b} = 0. \tag{116}$$

In the last equation the variation of the height of the undisturbed fluid in the y-direction has not been taken into account. This height variation provides the meridional pressure gradient required by the undisturbed zonal current. It is equal to the small inclination of the isobaric surfaces and therefore presumably of little effect on the perturbation motion.

It may be assumed that

$$\eta = \frac{\partial (2\Omega_z)}{\partial b} = \text{const.}$$

The foregoing system of equations has coefficients which depend on b. It can therefore be satisfied if the unknown variables x, y, and p are assumed to be unknown functions of b and have the periodicity factor

$$\exp\{i\alpha[a - (\sigma - U)t]\}.$$

Instead of adopting this procedure we may directly eliminate all unknown variables but one by differentiations, a method which could also have been used in the preceding examples. The continuity equation (116) can be satisfied by a function $\psi(a, b, t)$ analogous to the stream function such that

$$x = \frac{\partial \psi}{\partial b}, \qquad y = -\frac{\partial \psi}{\partial a}.$$

By cross differentiation of (114) and (115) the vorticity equation is obtained,

$$\frac{\partial^2}{\partial t^2}(\nabla^2 \psi) + \eta \frac{\partial}{\partial t}\left(\frac{\partial \psi}{\partial a}\right) = 0, \tag{117}$$

where

$$\nabla^2 \equiv \frac{\partial^2}{\partial a^2} + \frac{\partial^2}{\partial b^2}.$$

Equation (117) is satisfied by the following expression

$$\psi = A \exp\{i\alpha[a - (\sigma - U)t] + i\delta b\}, \tag{118}$$

where A is an arbitrary constant, provided that

$$\sigma - U = -\frac{\eta}{\alpha^2 + \delta^2}. \tag{119}$$

The last relation is the trough formula which relates the speed of long waves in a zonal current to their wave length and width and to the parameters of the system. The formula has been discussed and applied widely in meteorological work.

Long Waves on a Rotating Globe. As an example of the application of the perturbation equations to motion on a sphere the same problem as in the previous section will be considered for a spherical fluid layer [11]. It will be assumed that the angular velocity of the undisturbed current, κ, is constant and that it is in the direction of the geographic longitude λ, so that the linear zonal velocity

$$V_\lambda = \kappa E \sin\vartheta, \tag{120}$$

where E is the earth's radius, and ϑ is the colatitude. Since vertical motion is neglected, we may substitute in the equations for polar coordinates on page 411 the earth's radius E instead of r because the vertical dimensions of the fluid layer are small compared to E. The following relations are thus obtained for the undisturbed motion. From (72)

$$-(\kappa + 2\Omega)\cos\vartheta\, V_\lambda = -\frac{1}{Q}\left(\frac{\partial P}{E\partial\vartheta}\right). \tag{121}$$

From (73) it follows that the undisturbed pressure field is independent of λ. The two terms on the left-hand side of (74) are so much smaller than the acceleration of gravity that hydrostatic equilibrium may be assumed, as in the preceding example. The equation of continuity is evidently satisfied by the assumed undisturbed motion.

As in the plane case the perturbation motion may be purely horizontal. Then the two equations for the horizontal motion are, according to (77) and (78), if (120) is noted,

$$\frac{\partial v_\vartheta}{\partial t} + \kappa \frac{\partial v_\vartheta}{\partial \lambda} - 2(\kappa + \Omega)\cos\vartheta\, v_\lambda = -\frac{1}{Q}\left(\frac{\partial P}{E\partial\vartheta}\right), \tag{122}$$

$$\frac{\partial v_\lambda}{\partial t} + \kappa \frac{\partial v_\lambda}{\partial \lambda} + 2(\kappa + \Omega)\cos\vartheta\, v_\vartheta = -\frac{1}{Q}\left(\frac{\partial p}{E\sin\vartheta\,\partial\lambda}\right). \tag{123}$$

Since static equilibrium is assumed, the third equation of motion need not be considered.

In analogy to (116) the small effects of the meridional variation of the height of the free surface may be disregarded so that the equation of continuity becomes, according to (80) and (76),

$$\left[\frac{1}{E\sin\vartheta}\right]\left[\frac{\partial(\sin\vartheta\, v_\vartheta)}{\partial\vartheta} + \frac{\partial v_\lambda}{\partial\lambda}\right] = 0. \tag{124}$$

Equation (124) may be satisfied by a stream function χ so that

$$v_\vartheta = -\frac{\partial \chi}{E\sin\vartheta\,\partial\lambda}, \qquad v_\lambda = \frac{\partial \chi}{E\partial\vartheta}. \tag{125}$$

By cross differentiation of equations (122) and (124) it follows that

$$\left(\frac{\partial}{\partial t}+\kappa\frac{\partial}{\partial\lambda}\right)\left[\frac{\partial}{\partial\vartheta}\left(\sin\vartheta\,\frac{\partial\chi}{\partial\vartheta}\right)+\frac{1}{\sin\vartheta}\,\frac{\partial^2\chi}{\partial\lambda^2}\right] + 2(\Omega+\kappa)\,\frac{\partial\chi}{\partial\lambda}=0\,. \tag{126}$$

If it is assumed that the perturbations are waves of the frequency β and the wave number m,

$$\chi = Cf(\vartheta)\exp\left[i(\beta t+m\lambda)\right], \tag{127}$$

where $f(\vartheta)$ must satisfy the equation,

$$\frac{1}{\sin\vartheta}\,\frac{d}{d\vartheta}\left(\sin\vartheta\,\frac{df}{d\vartheta}\right) + \left[2(\Omega+\kappa)(\beta+\kappa m)-\frac{m^2}{\sin^2\vartheta}\right]f=0\,. \tag{128}$$

It is known that this equation has solutions which are regular at the poles only if

$$2(\Omega+\kappa)(\beta+\kappa m)=n(n+1), \tag{129}$$

where n is an integer. The last relation represents the frequency equation, and $f(\vartheta)$ is then an associated Legendre function, $P_n^m(\cos\vartheta)$. From (129) the period of the oscillation can be obtained as a function of the earth's rotation, zonal wind velocity (expressed by the angular velocity κ), wave number m, and the integer n. This last number determines the meridional extent of the oscillation since

$$f(\vartheta)=C\sin^m\vartheta\,\frac{d^m(P_n\cos\vartheta)}{d(\cos\vartheta)^m}=P_n^m(\cos\vartheta).$$

Thus $f(\vartheta)$ vanishes at the poles and at $n-m$ circles of latitude which are symmetrical to the equator. The equator itself is a nodal parallel if $n-m$ is odd.

Quasi-static and Quasi-geostrophic Approximations. In a discussion of the simplifications made to obtain tractable models of atmospheric motions it is appropriate to consider the hypothesis of "quasi-static" motion. This hypothesis is based on the assumption that, in each vertical, equilibrium exists not only before the start of the motion, but also during motion, although the equilibrium may change with time and from one vertical to another. This assumption is, of course, the basis of all the evaluations of upper-air soundings and oceanographic soundings which are performed with the aid of integrals of the hydrostatic equation. The quasi-static hypothesis implies that the vertical accelerations of the motion can be neglected compared to the acceleration of gravity. Since the latter is in general much larger than the former, the quasi-static hypothesis appears quite plausible, but it is impossible to give an a priori justification for it as Solberg [20], especially, has emphasized. Its most satisfactory justification is to be found in the fact that it gives results which in many instances are in agreement with the observations.

Historically, the quasi-static assumption was first introduced in the theory of tides. It is also successfully used more generally in the theory of "long" waves, that is of waves whose length is large compared to the depth of the fluid layer. The notation "quasi-static," which characterizes the special dynamic nature of the fluid motion more clearly than the expressions "tidal" or "long" waves, was introduced by V. Bjerknes [1] when he generalized the quasi-static treatment from incompressible and homogeneous fluid layers to autobarotropic layers.

In order to illustrate the method, consider a fluid layer which is at rest in the undisturbed case. It will also be supposed that the coordinate system is nonrotating and that all motions take place in a vertical a, c plane. The undisturbed pressure and density depend then only on the c coordinate and satisfy the hydrostatic equation

$$gQ=-\frac{\partial P}{\partial c}\,. \tag{130}$$

The horizontal equation of motion may be written, according to (54),

$$\frac{\partial^2 x}{\partial t^2}+\frac{\partial}{\partial a}\left(gz+\frac{p}{Q}\right)=0. \tag{131}$$

Because the vertical acceleration of motion may be neglected and because of (56) and of (130), the equation for the vertical component becomes

$$\frac{\partial}{\partial c}\left(gz+\frac{p}{Q}\right)=\frac{g(\Gamma-\gamma)p}{Q}\,, \tag{132}$$

where Γ and γ are the coefficients of barotropy and piezotropy, respectively. In the last equation the undisturbed pressure P may be introduced for the height coordinate c with the aid of (130). Then

$$\frac{\partial}{\partial P}\left(gz+\frac{p}{Q}\right)=-\frac{(\Gamma-\gamma)p}{Q^2}\,. \tag{133}$$

The equation of continuity

$$\frac{q}{Q}+\frac{\partial x}{\partial a}+\frac{\partial z}{\partial c}=0$$

may be written with the aid of the physical equation and of the hydrostatic equation (130),

$$\frac{1}{Q}\,\frac{\partial x}{\partial a}-g\,\frac{\partial z}{\partial P}+\frac{\gamma p}{Q^2}=0\,. \tag{134}$$

By combination of (133) and (134) it follows that

$$\frac{\partial x}{\partial a}+\frac{\partial p}{\partial P}=0. \tag{135}$$

This equation relates the perturbation pressure to the horizontal divergence. It expresses the pressure as an effect of mass transport. If (131) is differentiated with respect to P and equation (134) is used, one obtains the relation:

$$\frac{\partial^2}{\partial t^2}\left(\frac{\partial x}{\partial P}\right)-\frac{(\Gamma-\gamma)}{Q^2}\,\frac{\partial p}{\partial a}=0. \tag{136}$$

The last equation becomes particularly simple if the fluid is autobarotropic. In this case the horizontal displacement is independent of the vertical coordinate. It is this property of the system of equations for quasi-static motion which permits the most important simplifications of which use is made, for instance, in the theory of ocean tides where as a rule only incompressible, homogeneous fluids are considered. For fluids which are not autobarotropic this simplification no longer holds, but it is in some instances possible to consider a fluid model which consists of a number of autobarotropic layers where the approach to more realistic baroclinic models is effected by assuming autobarotropic relations which differ from layer to layer. A rather comprehensive discussion of quasi-static motions has been given by Eliassen [8].

The limitations of the quasi-static hypothesis especially in its applications on the tidal theory have been discussed by Solberg [20]. The differential equation remains of the same type under the quasi-static assumption regardless of whether the oscillations are longer or shorter than half a sidereal day; but when the vertical acceleration is taken into account it changes from the elliptical through the parabolic to the hyperbolic type as the period increases to more than twelve sidereal hours. Under these conditions it appears possible that oscillations with periods longer than half a sidereal day are not reproduced very accurately by the quasi-static hypothesis, or that additional types of oscillations are possible which are not given by the quasi-static method.

Another way in which the hydrodynamic equations might successfully be simplified for investigations in theoretical meteorology and oceanography is indicated by the empirically known fact that the large-scale motions of the free atmosphere are nearly geostrophic. It thus appears possible when attention is to be focused on these large-scale motions to achieve substantial simplifications by assuming that the wind field is very nearly geostrophic. Such a "geostrophic" approximation has been developed by Charney [5] in systematic form from considerations of the orders of magnitude of the various meteorological variables. The most important step in this "quasi-geostrophic method" is the elimination of the horizontal divergence of motion from the system of hydrodynamic equations before the introduction of the geostrophic approximation. This elimination can be effected conveniently by means of the equation of continuity together with an equation expressing the conservativeness of a quantity such as the potential temperature. While for the vertical vorticity component, for instance, it is permissible to use the geostrophic approximation directly, the same is not true for the horizontal divergence. From a consideration of the orders of magnitude of $\partial u/\partial x$ and $\partial v/\partial y$ it follows that for the large-scale motions, these terms are one order of magnitude larger than their sum, the horizontal divergence. Since the geostrophic deviation, that is the difference between actual and geostrophic wind, is also one order of magnitude smaller than the wind itself it follows that a computation of the horizontal divergence by the geostrophic wind would not be a satisfactory approximation. By the elimination of the horizontal divergence in the manner indicated above, a consistent system of approximate equations for large-scale motions is obtained.

A linearization of this quasi-geostrophic system of equations has been used by Charney and Eliassen [6] as the basis for a numerical method to predict the future pressure distribution. This method and its extension to nonlinear mathematical models is discussed elsewhere in this Compendium.[2] But it is relevant to the topic of the present article to state that even the linear models based on the assumption of small perturbations have given satisfactory forecasts in a number of cases.

CONCLUSION

The atmospheric perturbation equations are a tool of theoretical meteorology which is to be used in the investigation of problems of atmospheric dynamics. In considering future work in this field we shall therefore concern ourselves with a general survey of types of problems and lines of attack in which the perturbation method may appropriately be used.

As was pointed out in the discussion of the basic assumptions of the perturbation theory, one of the important problems which is appropriately treated by the perturbation method is that of the stability or instability of a given atmospheric flow pattern. It was explained there that the method consists in superimposing a small perturbation on the basic flow pattern and investigating whether such a perturbation would increase with time or not. In the first case the basic flow pattern would be unstable, in the second case stable.

It is immediately apparent that such an instability investigation is not necessarily complete. When it has been found that an originally small perturbation increases with time it can be concluded that the perturbation equations do not describe satisfactorily the development of the perturbation beyond a certain state because sooner or later the perturbation will have grown to such a magnitude that the terms of higher than the first order in the equations can no longer be neglected. Thus, after the perturbation has grown to certain dimensions its future behavior can no longer be predicted by the original perturbation equations. It is possible that the growth of the perturbation ceases when this state is reached and, in fact, it is generally observed that atmospheric perturbations do not exceed certain limits. The foregoing remarks are not meant to imply that the study of stability and instability based on the perturbation method is unsatisfactory. The point is that, by means of the perturbation method, we can make statements about the development of the perturbation only for a limited time interval. It would evidently be highly desirable to extend these investigations in such a manner that they permit us

2. Consult "Dynamic Forecasting by Numerical Process" by J. G. Charney, pp. 470–482.

to follow the future life history of an unstable perturbation. In order to do so one has to find solutions of the complete hydrodynamic equations in their nonlinear forms, a mathematical problem which is much more complicated than the solution of linear problems because no general mathematical procedures exist for its solution. It is conceivably possible that solutions of the nonlinear problem of the later development of unstable perturbations can be obtained by successive approximations, starting out with the perturbation as described by the linear perturbation equations and obtaining the next approximation as a perturbation of the first approximation. However, it is doubtful if such a method would be simpler than a more direct approach which starts immediately with a consideration of the nonlinearized hydrodynamic equations. No matter which method of approach will be found feasible, a quantitative study of developing perturbations beyond their nascent linear stages appears indispensable for the future development of the perturbation theory.

Such a study may also be expected to shed additional light on another question connected with the perturbation theory, namely, the problem of how an unstable flow pattern can develop. If it is found that a given state of fluid motion is unstable, the implication is that any small disturbance will increase indefinitely in amplitude and lead to a breakdown of the original, undisturbed state. Since in a fluid system such as the atmosphere or the ocean such small disturbances are always present, it is difficult to see offhand how an unstable state could develop and exist for any appreciable length of time unless during a certain state of its development the factors which built up this state are more effective than those which contribute to its eventual breakdown due to its inherent instability. Perhaps the effect of friction is responsible for delaying the breakdown. In the stability investigations it is always assumed that the undisturbed state whose instability one wishes to investigate is given a priori. Supplementary investigations of the mechanism leading to its development are evidently in order. Again, as in the case of the nonlinear perturbations, it is doubtful whether the linear perturbation equations are the appropriate mathematical tool for such a study.

Even though the foregoing remarks indicate that for a future development of instability studies the investigation of nonlinear problems, either by approximation methods or by direct means, will be an important step forward, a continuation of studies along the lines conducted so far will deserve an important place in theoretical meteorology. For a first investigation whether a given state of motion is unstable, the linearized perturbation equations are evidently the appropriate system of equations. Since the model atmospheres whose stability conditions have been investigated so far are all only more or less close approximations to reality, it is evident that much work remains to be done in the study of progressively more realistic models. In view of the rapidly mounting difficulties of such analyses, as baroclinic wind fields, compressibility, and horizontally and vertically variable temperature distributions are taken into account, it is not likely that all fruitful problems which can be treated by the theory of linear perturbations will find an early solution.

It is necessary to make simplifying assumptions such as those discussed in the last section, namely, that the motion is quasi-static or quasi-geostrophic. These assumptions are physically plausible and permit the omission of certain terms in the equations. In view of the complexity of the equations such procedures are indispensable. In these simplifications, terms are neglected which are of smaller orders of magnitude than others. This may give rise to errors in the subsequent analysis because in the reduction of the system of differential equations to one equation it is necessary to carry out differentiations in order to eliminate all unknown variables but one. It is conceivable that while of two quantities one may be considerably larger than the other their derivatives may be of the same order of magnitude. Consequently, the omission of terms in the original system of equations may lead to erroneous equations when the necessary eliminations are carried out. This possibility has been discussed by Queney [16] who pointed to this as a possible explanation of some contradictory results which have been obtained by different authors. It is not proposed to discuss this question here but at any rate this controversy shows as stated before that a great number of problems remain to be settled with the aid of the perturbation equations.

The problems to be studied by means of the perturbation method should include questions not only of the stability and instability of given fluid states, but also of the fluid motions caused by these perturbations. The solution of the linearized equations of fluid motion has led to many satisfactory descriptions of fluid motions as, for instance, the theory of tidal and surface waves, of sound waves, and of atmospheric waves both where a smaller scale is involved, for instance, in the theory of mountain waves and of billow clouds, and where motions of a much larger scale are considered.

It may finally be repeated that very little work has been done so far to extend the perturbation theory to viscous fluids. Even though friction plays presumably only a minor role in the free atmosphere its effect is quite important near the ground and at very high levels, in the ionosphere, where the kinematic viscosity must reach large values. Along the same lines, presumably more attention will have to be given to the problem of heat conduction in perturbation motions. Such problems as the land and sea breeze, or the monsoon circulations, require that the conduction from the earth's surface into the atmosphere and the eddy conduction within the atmosphere be taken into account. Among other nonadiabatic processes which have received little attention in connection with the perturbation theory is radiation. Studies of perturbation motions when radiative transfer of heat occurs can presumably shed additional light on atmospheric circu-

lations. It would be easy to extend this list of new problems considerably. But it may suffice to say that the perturbation method almost invariably will have to be used to get a first insight into these problems because in all branches of mathematical physics linear differential equations are the only ones which can in general be dealt with successfully. Even in those deplorably rare instances when nonlinear problems can be handled, the linearized problem and its solution gives a valuable and helpful guidance in the solution of the nonlinear problem.

THE SOLUTION OF NONLINEAR METEOROLOGICAL PROBLEMS BY THE METHOD OF CHARACTERISTICS

By JOHN C. FREEMAN

The Institute for Advanced Study

INTRODUCTION

The Method of Characteristics. The method of characteristics is only one means of solving hyperbolic differential equations or systems of differential equations with real characteristics. Problems of this kind are also solved by related methods, such as simple wave theory, the Riemann method of integration, and the marching method. In addition, in a nonlinear system, shocks or jumps occur which cannot be studied by means of systems of equations with real characteristics, but must be studied by other methods. Loosely speaking, all methods mentioned above can be grouped under the single heading—the method of characteristics. If this definition is used, the method of characteristics is not new to meteorology. Richardson used the marching method correctly in the initial example in his monumental work on numerical weather prediction [15, pp. 6–10]. Rossby [16] used the Riemann method of integration to discuss the effect of a line source of planetary waves in a barotropic atmosphere. In all of its phases, however, the method of characteristics has been applied most often and most thoroughly to problems in gas dynamics and the flow of a shallow layer of fluid with a free surface. Riemann devised his method of integration to solve the problem of one-dimensional unsteady flow of a gas in a pipe, and most other methods have been developed with such problems in mind. Courant and Friedrichs [5] give a bibliography of this work.

Early Work on Hydraulic Jumps in the Atmosphere. Mathematically speaking, the theory of flow of a shallow fluid with a free surface is, to a certain degree of approximation, the same as the theory of flow of air under a shallow (1000–10,000 ft) inversion in the atmosphere [7]. A very striking phenomenon in the flow of shallow water with a free surface is the *bore* or *jump*. A model of the jump is the breaker on a gently sloping beach. A breaker moving over a surface, whose horizontal dimensions are about ten times the height of the breaker, may be viewed as a line along which the height and speed of water change abruptly. In fact, in some cases there is a very shallow outgoing flow near the shore, and the jump or breaker is a transition to a very deep incoming flow. When such a jump is stationary in a channel, it is called a hydraulic jump. If the force of gravity is modified by a buoyancy factor (which is unity in the case of flow in water, and depends on the ratio of the densities above and below an inversion in the atmosphere), the laws governing flow under an inversion are the same as those governing flow of shallow water. Thus, jumps can occur in the atmosphere.

A jump in the atmosphere was first recognized as such (to the writer's knowledge) and discussed by M. McGurrin [14] of the San Bruno Weather Bureau Forecast Center. He recognized that the jump might be the cause of several weather phenomena and gave a rather complete discussion of the equations for a steady-state jump in an inversion. His work has not been published. Mr. McGurrin has addressed local meetings of the American Meteorological Society in California, and probably because of his work the concept of a jump in an inversion is not new to many meteorologists. It should be emphasized here that McGurrin's paper [14] shows that he was completely aware that the steady-state jump could occur in the atmosphere on many scales and in many synoptic situations. He describes a stationary jump in the height of a fog bank. The winds blow through this jump as they blow into the San Bruno valley in California.

The method of characteristics is the application of methods related to those employed by Richardson [15] and Rossby [16] to problems related to those considered by McGurrin. Rossby [16] predicted that a study of the internal waves in the atmosphere would show that they develop sharp forward boundaries because of their dispersive character and the existence of a maximum value of energy propagation. The waves on an inversion are a limiting case of internal waves and have the properties which he predicted.

MATHEMATICAL FOUNDATIONS

Quasi-linear Differential Equations. We can use the method of characteristics, under certain conditions, on equations of the following type:

$$A_1 \frac{\partial u}{\partial t} + B_1 \frac{\partial u}{\partial x} + C_1 \frac{\partial w}{\partial t} + D_1 \frac{\partial w}{\partial x} = E_1, \qquad (1)$$

$$A_2 \frac{\partial u}{\partial t} + B_2 \frac{\partial u}{\partial x} + C_2 \frac{\partial w}{\partial t} + D_2 \frac{\partial w}{\partial x} = E_2. \qquad (2)$$

In these equations (for the moment) the independent variables x and t are Cartesian coordinates in the x, t plane. The dependent variables u and w are unknown functions of x and t. The coefficients A_1, B_1, etc., are known functions of x, t, u, and w. Any of them can be constant or zero. These equations are nonlinear if any of the coefficients, A_1, B_1, etc., are functions of u or w. They are called quasi-linear because they are linear in the derivatives of u and w and the method of solution does not depend strongly on their nonlinearity. This type of equation has been studied by many authors, and bibliographies concerning such studies appear in Courant and Friedrichs [5] and Isenberg [12]. The discussion here is very much like that of Isenberg.

Definition and Determination of Characteristics. The

characteristics of the system of equations (1) and (2) are defined as lines along which the partial derivatives $\partial u/\partial t$, $\partial u/\partial x$, $\partial w/\partial t$, and $\partial w/\partial x$ cannot be determined directly from the equations. These lines are very useful. It can be shown that these are lines along which discontinuities in the partial derivatives occur. For instance, in the rapid steady-state flow of water along a curb, a small notch in the curb causes small discontinuities in the derivative of the height of the water and a line of disturbed water slants out and downstream from the notch. Such lines and similar ones in steady-state gas flows are called *Mach lines*. Thus, in a steady-state flow, disturbances along the characteristics can actually be seen.

In order to find the characteristics of equations (1) and (2) a well-known equation from elementary calculus must be used. If u and w are functions of x and t, then

$$du = \frac{\partial u}{\partial t}\,dt + \frac{\partial u}{\partial x}\,dx, \tag{3}$$

and

$$dw = \frac{\partial w}{\partial t}\,dt + \frac{\partial w}{\partial x}\,dx. \tag{4}$$

Equations (1)–(4) are now looked upon as a system of linear algebraic equations for the unknown functions $\partial u/\partial t$, $\partial u/\partial x$, $\partial w/\partial t$, and $\partial w/\partial x$. They have the matrix

$$\begin{Vmatrix} A_1 & B_1 & C_1 & D_1 & E_1 \\ A_2 & B_2 & C_2 & D_2 & E_2 \\ dt & dx & 0 & 0 & du \\ 0 & 0 & dt & dx & dw \end{Vmatrix}. \tag{5}$$

From this it is seen that the value of $\partial u/\partial t$ at any point (x, t) is expressed in terms of u, w, x, and t by the equation

$$\frac{\partial u}{\partial t} = \begin{vmatrix} E_1 & B_1 & C_1 & D_1 \\ E_2 & B_2 & C_2 & D_2 \\ du & dx & 0 & 0 \\ dw & 0 & dt & dx \end{vmatrix} \div \begin{vmatrix} A_1 & B_1 & C_1 & D_1 \\ A_2 & B_2 & C_2 & D_2 \\ dt & dx & 0 & 0 \\ 0 & 0 & dt & dx \end{vmatrix}. \tag{6}$$

The condition that $\partial u/\partial t$ be indeterminate is that the denominator and numerator of the right-hand side of equation (6) be zero. This can be expressed for the denominator as follows:

$$\begin{aligned}(A_1C_2 - A_2C_1)\,dx^2 \\ - (A_1D_2 - A_2D_1 + B_1C_2 - B_2C_1)\,dx\,dt \\ + (B_1D_2 - B_2D_1)\,dt^2 = 0.\end{aligned} \tag{7}$$

This equation is solved (by using the quadratic formula) for dx/dt or dt/dx, whichever is desired. This is best done in specific cases where usually many of the coefficients, A_1, B_1, etc., are zero, but the symbolic solutions will be useful:

$$\begin{aligned} C_+\text{:}\quad & \frac{dx}{dt} = \alpha_+, \\ C_-\text{:}\quad & \frac{dx}{dt} = \alpha_-. \end{aligned} \tag{8}$$

These equations define the two characteristics (C_+, C_-) of equations (1) and (2). Note that the characteristics are functions of u, w, x, and t and not of their derivatives.

The Equations of Compatibility. The numerator of equation (6) must be zero where the denominator is zero. This condition is expressed by writing out the determinant in the numerator to obtain

$$\begin{aligned}\left(B_1\frac{du}{dt} - E_1\frac{dx}{dt}\right)\left(C_2\frac{dx}{dt} - D_2\right) \\ - \left(B_2\frac{du}{dt} - E_2\frac{dx}{dt}\right)\left(C_1\frac{dx}{dt} - D_1\right) \\ - \frac{dw}{dt}\frac{dx}{dt}(C_1D_2 - D_1C_2) = 0.\end{aligned}$$

Since this is to be true along the characteristics, the appropriate values of dx/dt are substituted in the equation. Then two equations of compatibility, one for each of the two roots dx/dt of equation (7), are obtained,

$$\begin{aligned}\left(B_1\frac{du}{dt} - E_1\alpha_+\right)(C_2\alpha_+ - D_2) \\ - \left(B_2\frac{du}{dt} - E_2\alpha_+\right)(C_1\alpha_+ - D_1) \\ - \frac{dw}{dt}\alpha_+(C_1D_1 - D_1C_2) = 0\end{aligned} \tag{9}$$

along $\dfrac{dx}{dt} = \alpha_+$, and

$$\begin{aligned}\left(B_1\frac{du}{dt} - E_1\alpha_-\right)(C_2\alpha_- - D_2) \\ - \left(B_2\frac{du}{dt} - E_2\alpha_-\right)(C_1\alpha_- - D_1) \\ - \frac{dw}{dt}\alpha_-(C_1D_1 - C_2D_1) = 0\end{aligned} \tag{10}$$

along $\dfrac{dx}{dt} = \alpha_-$.

Numerical Integration by the Method of Characteristics. The conditions (9) and (10) form the basis for the method of numerical integration which is called the method of characteristics. The approximation is made that if two points (t_i, x_i) and (t_j, x_j) are very close together on a curve, then the slope of the curve is

$$\frac{dx}{dt} = \frac{x_j - x_i}{t_j - t_i}.$$

Similar approximations are made concerning du/dt and dw/dt. The values of u and w are given at two points (t_1, x_1) and (t_2, x_2) not connected by a characteristic and it is required to find u and w at some other point (t_3, x_3) (not given) where it is unknown. We define t_3 and x_3 as the intersection of the characteristic line with slope α_+ through (t_1, x_1) and the characteristic line with slope α_- through (t_2, x_2). Therefore, t_3 and

x_3 can be found by solving the two simultaneous equations

$$\frac{x_3 - x_1}{t_3 - t_1} = \alpha_+; \qquad \frac{x_3 - x_2}{t_3 - t_2} = \alpha_-.$$

These values of t_3 can be substituted in the equations (9) and (10):

$$\left(B_1\frac{u_3 - u_1}{t_3 - t_1} - E_1\alpha_+\right)(C_2\alpha_+ - D_2) - \left(B_2\frac{u_3 - u_1}{t_3 - t_1} - E_2\alpha_+\right)(C_1\alpha_+ - D_1) - \frac{w_3 - w_1}{t_3 - t_1}\alpha_+(C_1D_2 - D_1C_2) = 0,$$

$$\left(B_1\frac{u_3 - u_2}{t_3 - t_2} - E_1\alpha_-\right)(C_2\alpha_- - D_2) - \left(B_2\frac{u_3 - u_2}{t_3 - t_2} - E_2\alpha_-\right)(C_1\alpha_- - D_1) - \frac{w_3 - w_2}{t_3 - t_2}\alpha_-(C_1D_2 - D_1C_2) = 0,$$

and these two equations can be solved for u_3 and w_3 because t_3 and x_3 are known. By proceeding in this manner from a line (such as the boundary of a flow, or an initial state) in the x, t plane, along which u and w are known, values of u and w over a portion of the (x, t) plane can be found. For instance, in Fig. 1 the

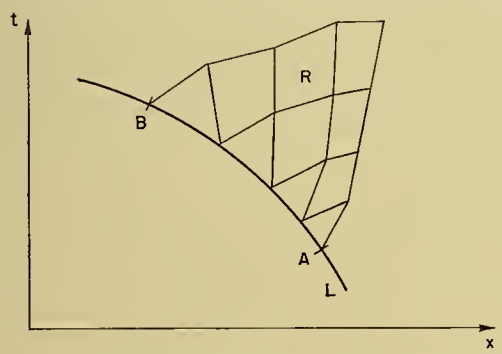

FIG. 1.—The region in which u and w can be computed from values given on L.

data between A and B on L allow a computation of the values of u and w in the hatched region R. For a full discussion of such "domains of dependence" and the related "regions of influence" the reader is referred to Courant and Friedrichs [5]. This method of integrating even the most complicated of such equations is easy to derive but is difficult to carry out in practice. Some simpler problems are easier to discuss.

Simple Waves. If, in equations (1) and (2), $E_1 = E_2 = 0$ and A_1, A_2, B_1, B_2, etc., are not functions of x or t but only functions of u and w, then the factor $1/dt$ can be removed from equations (9) and (10). These equations then define two functions of u and w (in implicit form, to be sure):

$$H(u,w) = K_+ \qquad \text{along } C_+,$$
$$L(u,w) = K_- \qquad \text{along } C_-,$$

where in general the constants K_+ are different for each C_+ characteristic and similarly for K_- and C_-. Courant and Friedrichs have shown that a region of constant u and w, say u_0 and w_0, is separated from a region of varying u and w by a characteristic. Assume that this is a C_+ characteristic. Since C_- characteristics intersect C_+ characteristics, some of the C_- characteristics are common to regions in which u and w are constant (u_0 and w_0) and to regions in which they vary. Along such C_- characteristics we can say

$$L(u, w) = L(u_0, w_0) \qquad \text{along } C_-.$$

This is true along every C_- characteristic extending into the region of constant u and w. Thus along such C_- characteristics u is a function of w only. Since these C_- characteristics cover all of a certain region, we need only have the assurance that we are considering motion inside that region to know that u is a function of w only. Inside such a region, if w remains constant along a line, u remains constant and vice versa.

We now focus our attention on the C_+ characteristics in this region where w is a function of u only. We can say $w = k(u)$; we then have

$$H(u, k(u)) = M(u) = K_+ \qquad \text{along } C_+.$$

This shows that u is constant along C_+. From equation (6) the slope of C_+ is given by

$$\frac{dx}{dt} = \alpha_+.$$

Now we have assumed (for simple waves) that α_+ is a function of u and w. Since u has been shown to be constant along C_+, and therefore w is constant along C_+, this means that α_+ is constant along C_+ or that C_+ has a constant slope and is then a straight line. When a flow has a family of straight characteristics it is called a *simple wave*. Much of Courant and Friedrichs's book *Supersonic Flow and Shock Waves* is concerned with simple waves and the reader is referred to it for a comprehensive discussion of them.

The two basic types of simple waves are the *expansion wave* and the *compression wave*. The names are derived from gas dynamics, but apply equally well to the expansion or compression of the distance between two straight characteristic lines in the general case presented above. If the given values of one of the dependent variables u and w, say u, along a line L are such that the straight characteristics in a simple wave diverge as they move away from L, then there is an expansion wave in that region (see Fig. 4). Note that, since u is constant along these lines, as we move away from L along a characteristic, the distance to the nearest point where u differs by a fixed amount is increasing. Thus gradients of u are decreasing. A more concrete example of such an expansion wave is given in the next section. If the given values of u are such that the straight characteristics converge, there is a compression wave in the region (see Fig. 2) and the gradients of u are increasing.

Envelope of the Characteristics. Figure 2 shows that a family of converging straight lines defines a double

envelope which encloses all points in the x, t plane covered by two or more characteristics. The meaning of such an envelope depends almost entirely on the physical nature of the problem and of the quantity u. The envelope has meaning if it is possible to have two values of u at a point. Usually the assumptions involved in deriving equations (1) and (2) are violated before the envelope is formed by the characteristics. If the region in which equations (1) and (2) cannot be used is very small and motion inside it is not important, it is assumed to be so thin that it can be drawn as a line in the x, t plane and it is called a *jump*. It is so called because there are jumps in values of u and w on going across such a line. Such an assumption can be made in gas dynamics where the jump is called a *shock*, in hydraulics where it is called a *hydraulic jump*, in flow under an inversion where it is called a *pressure jump*, and to a certain extent in flow in a planetary jet stream where the jump is called a *block*.

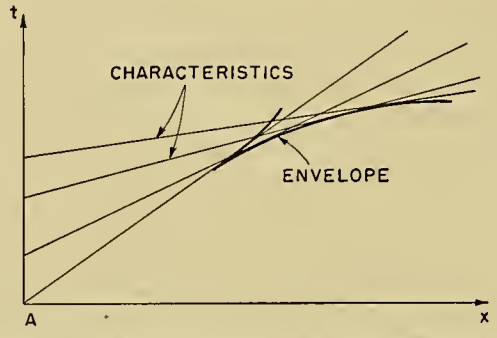

FIG. 2.—The characteristics of a compression wave.

FLOW UNDER AN INVERSION

Statement of the Problem. The changes in height of an inversion and the flow beneath an inversion are of great interest to synoptic meteorologists. The frontal contour charts of the Canadian Weather Service [6] bring home the fact that motions of the frontal surface are important even far behind its intersection with the ground. The behavior of low-level winds during and just after the passage of a surface cold front in the Western Plains is usually a topic of discussion among forecasters. Finally, the forecasters in tropical areas are interested in the variation of the winds below the trade wind inversion. It is the writer's opinion that a mathematical theory of flow under an inversion will help to describe these phenomena and perhaps will eventually lead to quantitative forecasting techniques. Several phenomena have been described by means of the simplest such theory (see Freeman [7], Abdullah [1], and Tepper [19]). Flow under a widespread inversion in the atmosphere can be approximated, at least somewhat better than qualitatively, by the flow of a shallow layer of liquid under a deep layer of almost the same density. The details of the validity of this approximation can be found elsewhere [7, 8, 18]. The pressure in a shallow layer of fluid flowing under a deep layer of fluid at rest is given by the formula

$$P = (h' - h)\rho' g + (h - z)\rho g,$$

where h is the height of the fluid with density ρ, and h' is the much greater height of the surface of the fluid with density ρ' ($\rho' < \rho$); z is the height of the point at which the pressure is measured, and g is the acceleration of gravity. If this is substituted in the two-dimensional equations of motion (neglecting the earth's rotation), we obtain the following results:

$$\frac{du}{dt} = -\frac{1}{\rho}\frac{\partial P}{\partial x} = -g\left(1 - \frac{\rho'}{\rho}\right)\frac{\partial h}{\partial x}, \tag{11}$$

$$\frac{dv}{dt} = -\frac{1}{\rho}\frac{\partial P}{\partial y} = -g\left(1 - \frac{\rho'}{\rho}\right)\frac{\partial h}{\partial y}. \tag{12}$$

If the flow under the interface at h does not depend on z, the equation of continuity is

$$\frac{\partial h}{\partial t} + \frac{\partial hu}{\partial x} + \frac{\partial hv}{\partial y} = 0. \tag{13}$$

Equations (11), (12), and (13) are the equations of motion and continuity for two-dimensional unsteady flow of a shallow layer of liquid under a deep liquid of smaller density. These equations are difficult to integrate as they stand, and very likely high-speed computing machines would be required to solve even the simplest problems involving all three variables x, y, and t. If the dimensions are restricted, however, results can be found numerically or graphically with comparative ease.

Time-Dependent Flow under an Inversion. If there is no variation in the y direction during the time a flow is studied, it can be investigated as a one-dimensional unsteady flow. If v is zero initially and remains zero, equation (12) need not be considered and equations (11) and (13) become

$$\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} + g\left(1 - \frac{\rho'}{\rho}\right)\frac{\partial h}{\partial x} = 0 \tag{14}$$

and

$$\frac{\partial h}{\partial t} + u\frac{\partial h}{\partial x} + h\frac{\partial u}{\partial x} = 0, \tag{15}$$

respectively. This is a system of quasi-linear partial differential equations of the type discussed in the previous section. If, in equations (1) and (2), the conditions

$$\begin{aligned} A_1 &= 1, & B_1 &= u, & C_1 &= 0, \\ A_2 &= 0, & B_2 &= h, & C_2 &= 1, \\ D_1 &= g\left(1 - \frac{\rho'}{\rho}\right), & D_2 &= u, \\ E_1 &= 0, & u &= u, \\ E_2 &= 0, & w &= h, \end{aligned} \tag{16}$$

are substituted, equations (14) and (15) result. If the values (16) are substituted in equation (7), the characteristics of (14) and (15) become

$$\begin{aligned} \frac{dx}{dt} &= u \pm \sqrt{gh\left(1 - \frac{\rho'}{\rho}\right)} \\ &= u \pm c. \end{aligned} \tag{17}$$

The values from equation (16), substituted in equations (9) and (10), give the results

$$u + 2c = \text{const} \qquad \text{along } \frac{dx}{dt} = u + c \qquad (18)$$

and

$$u - 2c = \text{const} \qquad \text{along } \frac{dx}{dt} = u - c. \qquad (19)$$

Thus the numerical or graphical computing scheme described for equations (1) and (2) can be performed using equations (18) and (19).

Simple Waves.[1] Since A_1, etc., are not explicit functions of x and t and $E_1 = E_2 = 0$, with proper initial conditions there can be simple waves in the model described by equations (14) and (15). This is a powerful method of investigating the results of certain initial conditions under an inversion. In addition, these equations are a suitable set to make the idea of a simple wave clear. A simple wave results when u and h are constant along the straight characteristic lines

$$\frac{dx}{dt} = u + c. \qquad (20)$$

Since these straight lines can be determined from the initial conditions, or conditions along any line in the x, t plane, u and h can be found throughout a region of the x, t plane by drawing the characteristic lines covering that region.

Expansion Waves. An expansion wave under an inversion is best demonstrated by the following example. The air under an inversion is at rest in a channel formed by two mountain ranges which restrict motion normal to them. It is held at rest by meteorological conditions at the termination of the mountain ranges. If these conditions change so that the air under the inversion begins to flow out from between the ranges, an expansion wave results. Figure 3 shows the height of the inversion and the wind speed along a cross section through the center of the channel under these conditions. The flow described qualitatively in Fig. 3 can be described quantitatively in the x, t plane (see Fig. 4). The observation of u at A and the initial height of the inversion at rest form the boundary conditions that determine the flow to the right of A. These values of u determine c and therefore $u + c$. Since u is constant along the lines $dx/dt = u + c$, we can compute it throughout the region between the mountains. This example emphasizes the ease with which the flow can be discussed if it is made up of simple waves. Note from formula (19), which applies in this case, that under these conditions the inversion height decreases as the speed of flow outward from between the mountains increases, that is, an increasing speed of east wind is a decreasing wind in this coordinate system. An example of an expansion wave that has synoptic importance will be given in the discussion of squall lines. It should be emphasized that the example of this paragraph is used for its definiteness and simplicity. Expansion waves in the atmosphere need not occur between mountain ranges and need not

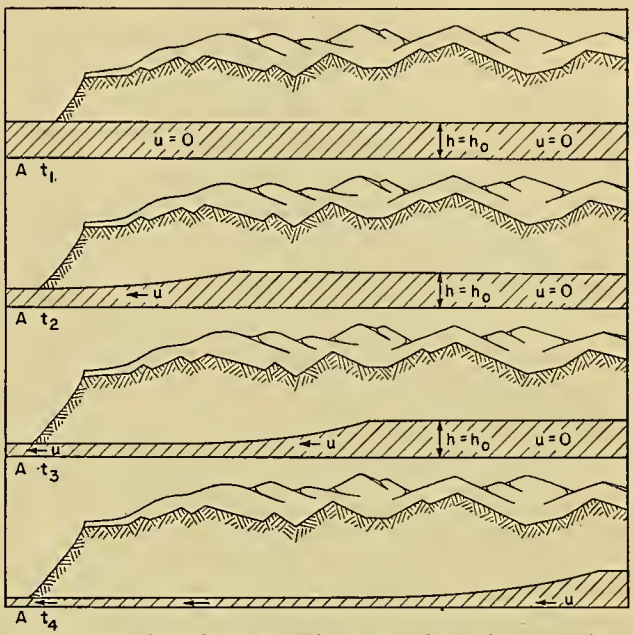

Fig. 3.—Motion of an expansion wave shown in successive cross sections.

be associated with air initially at rest. The whole system of flow (in particular, the zone of still air) can have a constant velocity of any direction superimposed on

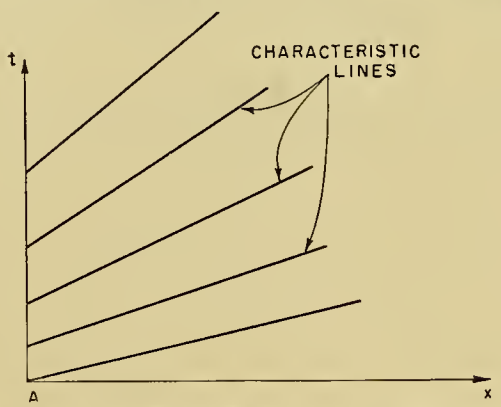

Fig. 4.—The characteristics of an expansion wave.

it. The rigid boundary is not necessary. Any flow which is essentially one-dimensional can be studied by the means presented here.

Compression Waves. If the flow at the mouth of the valley changes from zero velocity to a flow into the valley, a compression wave results. A cross section of such a compression wave for successive times is given in Fig. 5. The x, t diagram for such a flow is given in Fig. 6. Again the values of u and the inversion height at A are the boundary conditions that determine the flow. We have seen that a compression wave leads to an envelope of the characteristic lines. In this case the envelope cannot persist for any great length of time so that a pressure jump forms.

1. The word "wave" is used here in its general sense, familiar to meteorologists in "cold wave," "frontal wave," etc. No periodicity or sinusoidal properties are implied.

Pressure Jumps. The envelope of the characteristics illustrated in Fig. 2 has a definite physical meaning in the case of flow under an inversion. It means that the

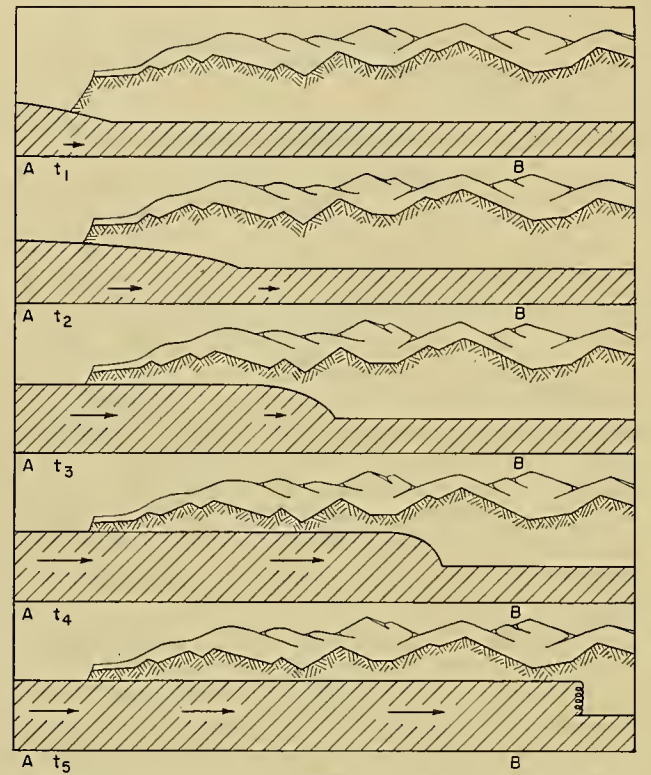

Fig. 5.—Motion of a compression wave shown in successive cross sections. The slope of the wave increases until it "breaks" and a pressure jump is formed.

higher values of inversion height have overtaken the lower and are covering the same values of x. This hypothetical situation is illustrated in Fig. 7. This is a

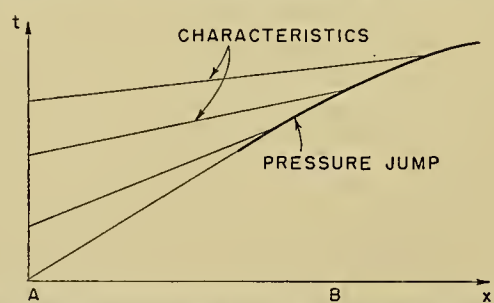

Fig. 6.—The characteristics of a compression wave in an inversion. The pressure jump is represented as a line in the x, t plane.

very unstable situation from a mechanical standpoint. The density ρ is greater than the density ρ' so that the overhanging air with density ρ will fall down into the rest of the fluid. This will usually occur before such an advanced unstable state as the one illustrated in Fig. 7 will occur. The zone in which this air is falling down is usually a rather narrow zone of the flow and is marked by chaotic motion of the air. Such a zone is illustrated in the cross section for t_5 in Fig. 5, and the x, t diagram is shown in Fig. 6. The heavy line in Fig. 6 is called a pressure jump. It is assumed to be a very narrow region in the x, t plane in which the transition from a low inversion height with still air (in this case) to a high inversion height and moving air is accomplished. The

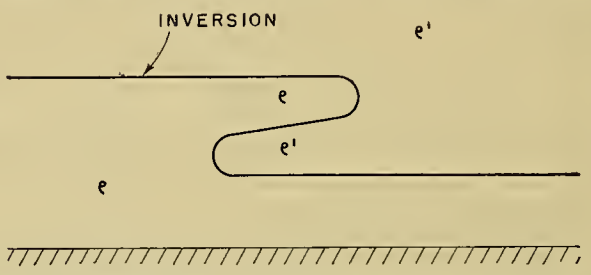

Fig. 7.—The shape an inversion would have after an envelope of the characteristics had formed if the pressure jump did not occur first.

best indication that this is a narrow region is given by synoptic data which will be discussed later. The fact that the hydraulic jump is confined to a narrow zone in the flow in a channel is an indication that this intimately related phenomenon will also be narrow. A barograph placed at station A (Fig. 5) will have a trace similar to trace A in Fig. 8, but an observer at station B will see a trace with a marked jump in the pressure (see trace B in Fig. 8). This effect of the jump in the inversion

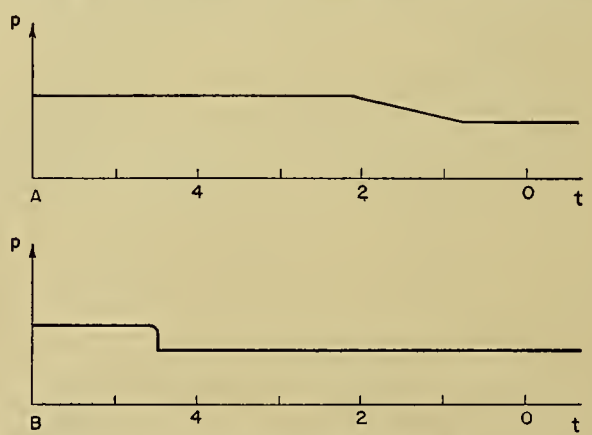

Fig. 8.—Barograph traces recorded during the history of a compression wave.

height on the pressure record at the station led Tepper [19] to adopt the name "pressure jump" for this phenomenon. The pressure surge (after it breaks) of Abdullah [1], the squall line (not the pressure pulse) of Brunk [4], and the jump of Freeman [7] are all pressure jumps. If a flow under an inversion is essentially one-dimensional and if for any reason there is acceleration of the air into a region covered by the inversion at a constant height, a pressure jump will form (if the Coriolis force is neglected). This is just a general description in words of the phenomenon illustrated in Fig. 5. The jump forms because if there is a region of constant inversion height, the flow is a simple wave. If the air is accelerating into this region, it is a compression wave and the straight characteristics converge to form the pressure jump.

Weather Associated with a Pressure Jump. Tepper [19] has described the surface weather phenomena that accompany the passage of a pressure jump. He refers to a larger-scale pressure jump than the one described between the mountains. The origin of the jump will be discussed in the next section, but the scale is one of a change from an inversion height of 2000–3000 ft to one of 5000–10,000 ft with temperature differences across the inversion of 1–5C. The jump in height is moving faster than the conditionally unstable air above. If this air were dry, the phenomena associated with precipitation would not occur. The data over a network of 55 stations in a rectangle 8 mi by 20 mi were averaged. Several outstanding phenomena accompanied the pressure jump of May 16–17, 1948: the wind shift, the temperature break, the rain gush, the wind-speed maximum, and the maximum pressure difference.[2] These terms are almost self-explanatory and a complete description may be obtained from Tepper's original paper. The magnitudes of some of these quantities are given below.

Average total rise in pressure	2.3 mb
Average maximum precipitation intensity	0.02 in. min^{-1}
Average maximum surface wind speed	27 mph
Average maximum rate of temperature fall	1C min^{-1}
Average total wind shift	75°

The foregoing tabulation gives the conditions averaged over all 55 stations, but the pressure jumps are better known and most respected for the more extreme weather phenomena. These are described in some detail by D. T. Williams [23] and are summarized here.

Pressure: The pressure would rise 2–6 mb during time intervals of the order of 5 min. Gradients were as steep as 1–2 mb mi^{-1}. Following the abrupt rise in pressure there was a leveling off or a slow fall.

Wind: Winds ahead of the line were usually southerly and an almost instantaneous shift to westerly or northwesterly accompanied its passage. The peak gust over the whole network was of the order of 50 mph. In many cases the winds blew at right angles to the isobars.

Precipitation: Rain in the first mile behind the pressure jump was usually light, becoming heavy farther back.

Temperature: Temperatures fell sharply upon the passage of a pressure jump. Maximum drops occurred while heavy rain was falling and usually the decrease was proportional to the rate of rainfall. With the ending of the period of heavy rain, temperatures rose slowly, frequently returning to near their original levels.

Such phenomena are naturally of interest to meteorologists who have expressed their interest throughout the years by marking such pressure jumps and their accompanying precipitation as prefrontal squall lines on weather maps. Harrison and Orendorff [11] describe the synoptic aspects of the squall line in great detail. They show that it is certainly not the result of an upper front. However, the importance of the barograph trace and the pressure pattern in locating squall lines has not been fully recognized. The careful and accurate analysis of the Daily Weather Map of the U. S. Weather Bureau since 1946 has made it increasingly evident that the squall line is a real phenomenon. In fact the squall lines and fronts on these maps move in a manner so similar to that of a shock wave and piston in theoretical discussions of gas flow in a tube that a connection only waited for someone who had sufficient knowledge of both motions. This connection was established by Tepper [19] in his detailed synoptic study of the squall line of May 16–17, 1949. He established that this particular squall line was a pressure jump and proposed that most persistent, well-developed, squall lines are pressure jumps.

The Prefrontal Squall Line. Tepper [19] has proposed that the prefrontal squall line is a line of showers and thunderstorms that is started by a pressure-jump line. A study of Fig. 5 shows that if the pressure jump represents a large jump in the height of the inversion, it will have the same effect as a rapidly moving cold front on the air above the inversion. In fact, since the slope of the advancing surface is usually much greater in a pressure jump, the release of whatever moisture is in the upper air should be more rapid and therefore more spectacular. It is believed that the lifting of the air above the inversion by the advancing surface of the inversion causes most of the precipitation in squall lines. (It is also possible that the sudden lifting of the air under the inversion will cause saturation and that the resultant change in the lapse rate will allow the air to break through the inversion and thus the origin of the storms will be in the lower air mass. This possibility is disregarded in this discussion because such a break-through would violate the theoretical model for which equations (14) and (15) are true. Of course, this does not mean that it cannot or does not occur.) Tepper [19] emphasizes that the storms that make up the squall line are caused by the mechanical lifting along a pressure jump and that the jump can occur with no resulting storms or precipitation of any type if the air above the inversion is dry enough. Tepper's study of prefrontal pressure jumps developed from an attempt to discover some theoretical explanation for the intense pressure gradients that occurred during the seven squall lines that were studied by Williams [23]. Williams' work was a synoptic study of the dense network of stations that the Cloud Physics Project maintained near Wilmington, Ohio. This study made it clear that there was a very narrow region in which the pressure changed very rapidly. This region also moved rapidly and was associated with the thunderstorms that made up the squall lines which he was studying. An idea of the width of the zone of rising pressure can be obtained from the accompanying map (Fig. 9). Tepper established that the surface phenomena discussed by Williams occurred in a sequence and moved in such a way that a jump in the height of an inversion (or a stable layer) was the most likely cause of the phenomena. He proposed a model of a squall line based on the work of Freeman

2. H. R. Byers maintains that these properties (the pressure trace in particular) are common in varying degrees to any line of thunderstorms. (Statement from the floor of the 108th meeting of the American Meteorological Society, at Tallahassee, Florida, December 1950.)

[7]. Naturally the line in the x, t plane along which data are known need not be a vertical line corresponding to a fixed value of x. As in the more general case of the previous section, it can be any line in the x, t plane

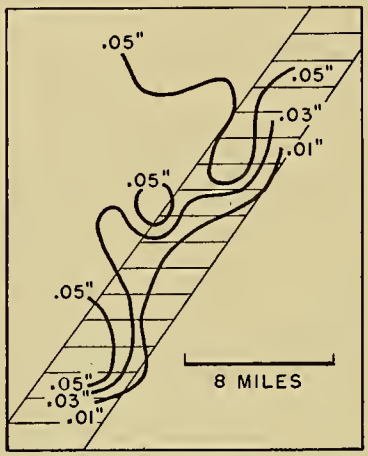

FIG. 9.—A "squall line" magnified in the same ratio as the scale of miles on a micromap showing the position of a pressure jump.

which is not a characteristic line. Accordingly, Tepper assumes that he knows the motion of a steep cold front on the weather map. This cold front is adjacent to a region in which there is an inversion and the air under the inversion is in some equilibrium state with equal inversion height and equal west-wind components throughout. (The north-south wind components and the Coriolis parameter are neglected entirely in this particular study.) The cold front then begins to accelerate and this pushes the inversion up in its vicinity. This compression wave ultimately develops into a pressure jump. In the meantime the front decelerates to its previous speed, or a lower speed, to the west and an expansion wave moves out behind the pressure jump. Some successive cross sections describing this phenomenon appear in Fig. 10.

Interaction of an Expansion Wave and a Pressure Jump. The whole area in which the characteristic lines in Fig. 4 are diverging is called an expansion wave. Such a wave has two speeds: it approaches from the left with a speed given by the slope of the first diverging characteristic and leaves to the right with a speed given by the slope of the last diverging characteristic. The approximate speed of a pressure jump can be computed by a method demonstrated to the writer by C.-G. Rossby. If the jump is assumed to have an unchanging shape and to be moving with constant speed V, the law that the difference in pressure force is equal to the loss in momentum can be expressed as

$$(u_1 - V)\rho u_1 h_1 - (u_2 - V)\rho u_2 h_2 = \int_0^{h_2} P_2\,dz - \int_0^{h_1} P_1\,dz. \tag{21}$$

Equation (21) reduces to

$$\rho(u_1 - V)u_1 h_1 - \rho(u_2 - V)u_2 h_2 = \frac{g}{2}(\rho - \rho')(h_2^2 - h_1^2). \tag{22}$$

The continuity of mass is expressed by the similar equation:

$$(u_1 - V)h_1 = (u_2 - V)h_2\,. \tag{23}$$

If the value of $(u_2 - V)$ from equation (23) is substituted in equation (22), the resulting equation can be solved for the following four possible values of V:

$$V_{1\pm} = u_1 \pm \left[g\left(1 - \frac{\rho'}{\rho}\right)\frac{h_2}{h_1}\frac{h_2 + h_1}{2}\right]^{1/2}, \tag{24}$$

$$V_{2\pm} = u_2 \pm \left[g\left(1 - \frac{\rho'}{\rho}\right)\frac{h_1}{h_2}\frac{h_2 + h_1}{2}\right]^{1/2}, \tag{25}$$

where $V_{1+} = V_{2+}$ and $V_{1-} = V_{2-}$.

If the jump is from a low value of h_1 to a higher value of h_2, it can be seen immediately that if we set

$$V = u + a \tag{26}$$

to correspond to the slope of the characteristics

$$\frac{dx}{dt} = u + c, \tag{27}$$

where

$$c = \left[gh\left(1 - \frac{\rho'}{\rho}\right)\right]^{1/2},$$

that

$$a_1 > c_1 \tag{28}$$

and

$$a_2 < c_2\,. \tag{29}$$

This is a quantitative statement of the following rule expressed for gas dynamics by Courant and Friedrichs [5]: Each member of a sequence made up of alternate expansion waves and jumps in the same family of characteristics will move to overtake the member preceding it. This is true because the expansion waves move at the speed $u + c$ and the jumps move at the

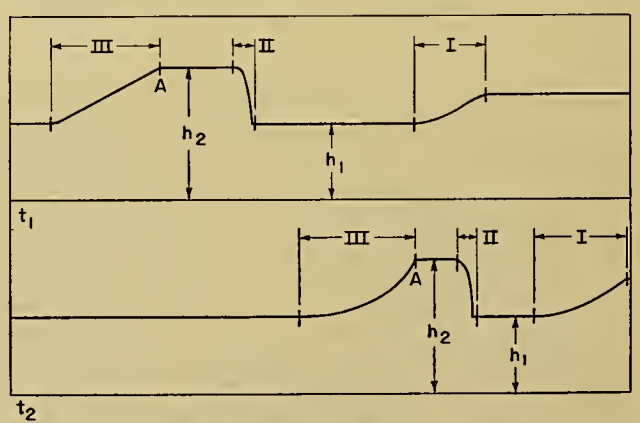

FIG. 10.—A series of simple waves and pressure jumps showing how they overtake and modify each other.

speed $u + a$. This rule is illustrated in Fig. 10 where it can be seen that the left-hand side of expansion wave I moving at $u_1 + c_1$ is being overtaken by jump II

moving at $u_1 + a_1$ because $a_1 > c_1$ and that jump II, in its turn moving at $u_2 + a_2$, is being overtaken by the right-hand side of expansion wave III moving at $u_2 + c_2$ because $a_2 < c_2$. This phenomenon was first demonstrated synoptically by Tepper [19], who showed that on May 16, 1948 the pressure maximum which coincides with point A in Fig. 10 had an average speed of 54 mph over the network stations at Wilmington, Ohio, while the jump had a speed of 45 mph. This phenomenon of overtaking leads to a modification of the expansion waves and jumps involved. The exact nature of this modification in all cases and the results of all "interactions" as they are called are not known. In some simple cases an approximation to the actual conditions can be made that has some validity. Fortunately, one of these simple cases is important in the study of squall lines. One manner of dissipation of a pressure jump is for it to be modified by a following expansion wave (Fig. 10).

Map Analysis with a Pressure Jump. The small amount of space and time occupied by a pressure jump has been discussed previously. The small dimensions in space of the pressure jump are emphasized in Fig. 9, where the line marking a squall line from the Daily Weather Map of the U. S. Weather Bureau is magnified in the same proportion as the scale of miles. These lines

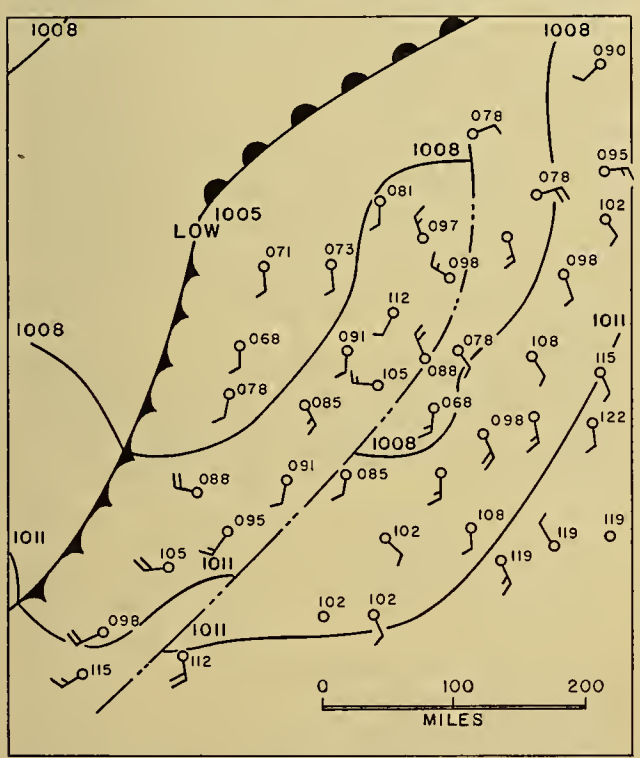

FIG. 11.—Proposed method of drawing isobars in the vicinity of a pressure jump. The map is for 2230 EST May 16, 1948 and the squall line is through northwestern Pennsylvania and southeastern Ohio.

are four miles wide and it can be seen that this one covers most of the zone of rising pressure. With this chart in mind it has been proposed [9] that the same approximation used in the mathematical analysis be made, and *that the pressure jump be analyzed as a discontinuity in the field of pressure.* This method of analysis would have the following advantages: (1) more of the winds would blow nearly parallel to the isobars, (2) the analysis would fit more of the pressures than is usually possible with conventional methods (as can be seen from Fig. 11), and (3) the analysis would correspond more closely to the proposed mathematical theory of pressure jumps. This type of analysis has the disadvantage that the isobaric field is not correct in the immediate vicinity of the pressure jump, but Fig. 9 shows that the area that is not accurately represented is almost covered by the line marking the pressure jump. Pressure jumps can be located rather accurately on a well-plotted synoptic map by this method. An example of such an analysis is given in Fig. 11. Pressure jumps could be located very accurately indeed if the suggestion were followed of sending a special report on the hourly network when a pressure jump passed the station.

Transmission of Energy by Means of Finite Disturbances in Inversion Height. Abdullah [1], working independently, established the existence of a pressure jump on the inversion behind a cold front. He advanced the hypothesis that the pressure jump in cool air was the medium that carried the energy of distant cold air to the vicinity of a cyclone and that this energy was then available to aid the formation or deepening of a cyclone on the front separating the cool air from the warm air. Abdullah also suggested that pressure jumps of finite lateral extent could be one of the "disturbances" needed to start the formation of a wave on a front in the frontal theory of cyclones. By means of an energy computation that can be found in his paper, he showed that for the usual dimensions of waves on a front a pressure jump of ordinary dimensions will supply more than ten times the amount of energy that is found in the frontal wave. Abdullah used the Riemann method of integration. The method is particularly well adapted for the study of a situation in which the boundary conditions appear in closed form. Assuming that the coldest air begins moving at $t = 0, x = 0$ with a constant acceleration α, he showed that a compression wave moving into air with a constant height h_0 of the inversion will break into a pressure jump (*i.e.*, the envelope of characteristics will form) at a point

$$T_0 = \frac{2}{3\alpha}\sqrt{gh_0\left(1 - \frac{\rho'}{\rho}\right)}, \tag{30}$$

$$x_0 = \frac{2}{3\alpha}gh_0\left(1 - \frac{\rho'}{\rho}\right). \tag{31}$$

Using these formulas, he constructed a table showing computed and observed distances (x) from the front at which breaking into a pressure jump occurred. The essential information from his table is presented in Table I in which T is the mean temperature of the cool air, and ΔT is the difference in temperature between the cool and the warm air. The best synoptic example of a pressure jump on a large scale to appear in the

literature is provided by Abdullah who showed how the energies of motion and the rise in inversion height are transmitted to the leading edge of the cool air.

TABLE I. DISTANCE OF PRESSURE JUMP FROM FRONT

Initial time of 12-hr period	h (m)	T (°K)	ΔT (°C)	x computed (mi)	x observed (mi)

Time-Dependent Flow as a Forecast Tool. The usefulness of the method of characteristics in making forecasts has been emphasized before [7, 21]. The success of Abdullah [1] in predicting the time of breaking and of Freeman [7] in predicting the height of the tropical inversion emphasizes this feature. Of course, the solution of any equation with time as an independent variable gives a method of prediction. In most sciences the problem is to predict the behavior of a system with a given set of initial conditions which will be applied repeatedly. In weather forecasting the prediction is usually made from a set of initial conditions that is never repeated. The method of characteristics is particularly suited for such a system because any set of initial conditions can be fitted to any accuracy desired, and regularity of the functions involved is not required.

In any region in which the flow under an inversion can be considered one-dimensional and the effects of the Coriolis force are not important there are two procedures for making forecasts that might be found useful. The most straightforward procedure is that of forecasting the weather along part of the x-axis from a given set of initial conditions on a larger part of that axis. The x-axis is a line in the x, t plane and the characteristics can be built up from it as in Fig. 12. Such a

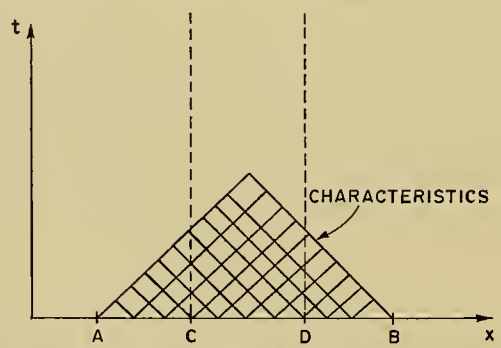

FIG. 12.—Area for which a prediction can be made from initial data on the x-axis.

method should be useful over large land areas in the tropics, such as Africa and South America, and probably in island-studded oceans like the northern part of the South Pacific Ocean. This method could also be developed into a method of making forecasts from data gathered from aircraft flights, particularly those which make periodic observations of the inversion height. The most useful method between stations (in the tropics particularly) is outlined in Fig. 13. The procedure above, or a good estimate of the conditions between A and B, is used initially and then new characteristics are found from information at A and B only. This pro-

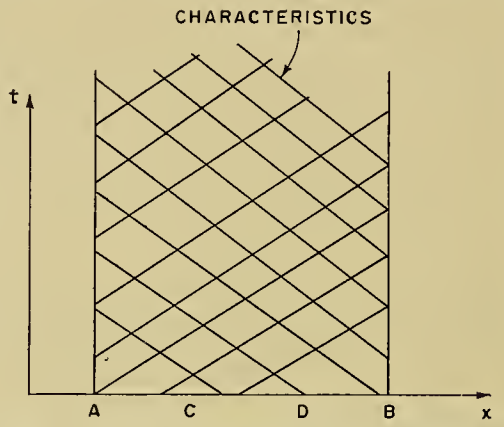

FIG. 13.—Area for which continuing predictions can be made from a series of weather observations (data along the t-axis) at two discrete points.

cedure could be used to great advantage to predict conditions between two islands in the easterlies. Of course, to be used to best advantage, A and B should be a reasonable distance to the east and west of the region for which forecasts are desired. Forecasts for C and D can be made for appreciable periods. The usefulness of this method as a forecast tool for anything other than the qualitative aspects of flow under an inversion in the middle latitudes awaits the incorporation of the effects of the Coriolis force into the method. High-speed computing machines will undoubtedly be needed to forecast two-dimensional time-dependent flow under an inversion. The extension to two dimensions will eliminate many of the restrictive assumptions involved in making a one-dimensional problem out of one that has such inherent two-dimensional aspects as the Coriolis force.

Equations for Steady-State Flow under an Inversion. If we assume that there is steady-state flow under an inversion, that is, that there are no changes in the flow with time, then equations (11)–(13) become

$$u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} = -g\left(1 - \frac{\rho'}{\rho}\right)\frac{\partial h}{\partial x}, \tag{32}$$

$$u\frac{\partial v}{\partial x} + v\frac{\partial v}{\partial y} = -g\left(1 - \frac{\rho'}{\rho}\right)\frac{\partial h}{\partial y}, \tag{33}$$

$$u\frac{\partial h}{\partial x} + v\frac{\partial h}{\partial y} + h\left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y}\right) = 0. \tag{34}$$

This is a system of equations similar to equations (1) and (2). It is complicated slightly by the presence of a third unknown h, but the same method of analysis is used on this set of equations. Three families of characteristics exist and the determinants used in equation (6) are of order six rather than four. In this case this third characteristic is a streamline and the vorticity $\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y}$ is constant along it. If we assume the flow is irrotational, this characteristic is not used. The flow

can then be studied in the x, y plane like equations (1) and (2). This equation is complicated by the fact that real characteristics exist only under certain conditions, that is, if

$$u^2 + v^2 > gh\left(1 - \frac{\rho'}{\rho}\right). \tag{35}$$

The study of steady-state flows has not been applied in synoptic meteorology to date. The only published discussions of a steady two-dimensional flow are the climatological example in the next paragraph and the conjecture of Tepper discussed below [19].

An Example of a Two-Dimensional Steady Flow. An example of the type of flow described in the previous section has been given by Freeman [9]. The chart from the *Climatic Charts of the Oceans* [22] showing mean resultant winds off the west coast of South America in October is reproduced in Fig. 14. This is to be compared

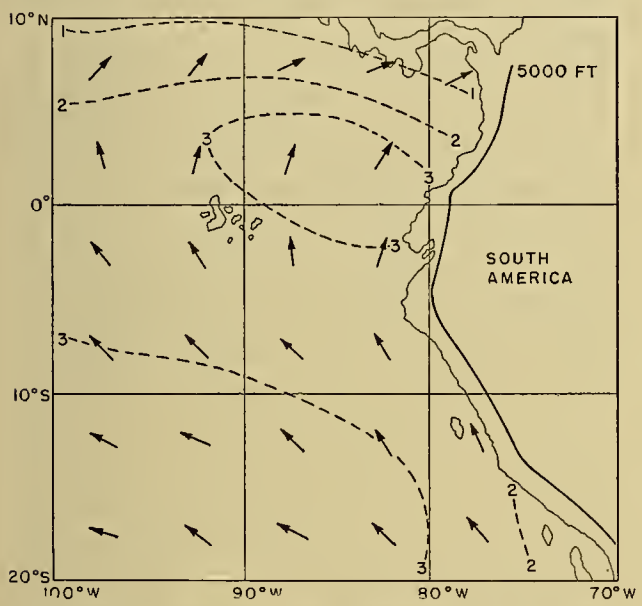

Fig. 14.—The resultant wind field east of South America in October from the *Climatic Charts of the Oceans*. The dashed lines are isopleths of Beaufort force.

to the Prandtl-Meyer type of expansion wave in Fig. 15. This expansion wave is computed from the following initial data: Winds of 5 m sec^{-1} (force 3) under an inversion of 1C at 0.65 km are blowing parallel to the coast of South America and pass the bend in the coast line. The wind speed is assumed to be somewhat higher than the observed surface wind to allow for slowing by surface friction. The height and strength of the inversion is that found by Alpert [2]. Points of similarity of these flows are that the change in wind direction occurs farther north as the longitude increases and that the winds increase their speed as they turn around the corner. The slowing down of the resultant winds north of 5°N is to be expected because the expansion wave does not always extend to that latitude and when it does it is more likely to be modified by the Northern Hemisphere wind systems. This may not be the only factor causing these winds, but it must certainly be an important one, since the data fit the theoretical model so well.

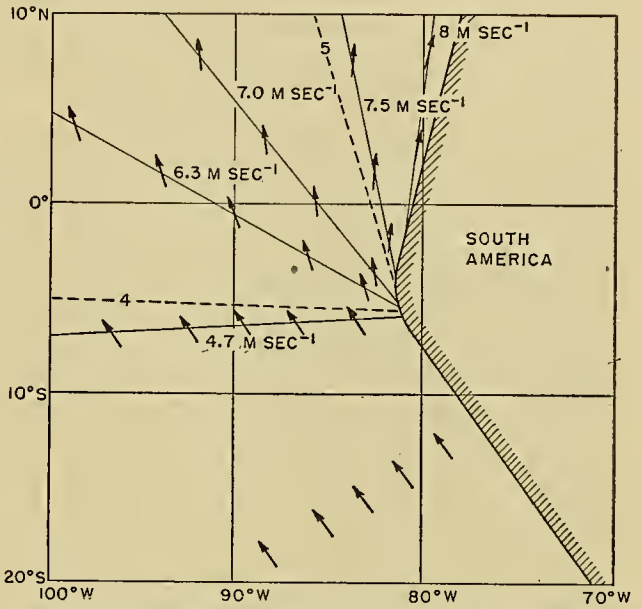

Fig. 15.—The computed wind field if the air under an inversion undergoes a Prandtl-Meyer expansion around the bend in the west coast of South America.

Interaction of Two Pressure-Jump Lines. It has been proposed by Tepper [20] that the intersection of two pressure-jump lines should be a region of preferred occurrence of tornadoes. He cited the discussion of interactions by Courant and Friedrichs [5] to lend support to this conjecture. When two shock waves intersect in the two-dimensional flow of a compressible fluid a vortex sheet is formed. This vortex sheet has been found experimentally in gas flows and in flow of water in a channel. Such a vertical vortex sheet should form behind the intersection of two pressure jumps. If the circular properties of a tornado are similar to those of the dust devils studied by N. R. Williams [24], then such a region of strong shear is a very likely zone for tornado formation.

Tepper [20] found that, in five out of the seven tornado situations he studied, the tornadoes formed within fifty miles of the intersection of two pressure jumps.

CURRENT PROBLEMS AND SUGGESTIONS FOR RESEARCH

The application of the method of characteristics to meteorological problems is an active field of research with many topics of interest. Most of the problems under consideration at the present time are concerned with flow under an inversion. The path to follow in the solution of many of these problems is clearly marked. Other problems are being attacked with success by Tepper. The success of Abdullah [1] in explaining the "secondary cold front" or "postfrontal squall line" and of Tepper in explaining the occurrence of the "squall line" indicates that many phenomena on the same and smaller scales can be studied with this theory in mind.

The usefulness of the method of characteristics is not confined to the study of flow under an inversion. Any problem in which certain elements are described by equations such as (1) and (2), with real characteristics, can be studied by these methods. It is hoped that this article will be useful to every meteorologist with such problems and that some may even be encouraged to study some of the problems mentioned below.

The Effect of the Coriolis Force on Flow under an Inversion. In all of the discussions of nonlinear flow under an inversion that have appeared in the literature the Coriolis parameter is neglected. The Coriolis force works to turn the winds parallel to the isobars, but it takes time for this force to act. If a parcel of air is under the influence of a pressure gradient for only a short time, it will follow the path dictated by the equations without Coriolis force so there is some justification in neglecting this parameter in the pioneering stages of such a study. If the value of the theory of flow under an inversion to middle-latitude forecasting is to increase, however, the Coriolis parameter must be included in the equations. Some of the physical effects of this force can be seen immediately. Suppose that a cold front is holding an inversion of constant height at rest at point x_0 and time t_0. At t_0 the front begins to recede, moving westward from the inversion. An expansion wave will be formed and the slope in the inversion height will be such that pressure will increase to the east. If the front continues to recede, the air parcels near it and beneath the inversion will be under the influence of such a pressure gradient for a long period of time and will therefore move northward, giving south winds in the now lower-pressure zone to the east of the front. If, on the other hand, the front pushes slowly into the inversion, the new pressure gradients will cause north winds. The equations that tell how much south or north wind is to be expected and how long it will blow are being studied at the present time.

The Characteristics of a Circular Vortex and the "Rings" of a Hurricane. The rings or spirals of violent convective activity in hurricanes have been observed by many authors [13, 25]. We have seen in earlier sections that the Mach lines and the envelopes of Mach lines are at least approximately the lines along which physical disturbances move in a flow. The Mach lines of a circular vortex in a fluid with a free surface are spirals almost tangent to the streamlines near the center of the vortex, making a larger angle with them as the distance from the center increases. If the presence of a stability retarding the vertical motion of air involved in a hurricane can be established, the theory of flow under an inversion can be applied and might lead to an explanation of these spirals. To the writer's knowledge no one is working on this problem at the present time.

Interactions and Frontogenesis. The discussion at the end of the previous section indicates that a vortex sheet (or wind shear line) is formed when two strong pressure jumps are involved in an interaction. If these vortex sheets can bring about frontogenesis, and this occurrence is frequent enough to be important to synoptic meteorologists, this should be a fruitful field of investigation. From synoptic experience we can say that if the vortex sheet persists it is very likely to bring about frontogenesis. A wind-shear line usually develops into a front because there usually are horizontal temperature gradients in an air mass. This problem is not being studied at the time of this writing.

The "Expansion-Wave Storm." Brunk [4] has made a complete and very interesting study of a wind storm in 1944. The winds over the northern part of the United States were from the east under a quasi-stationary front. A small wave moved from west to east along this front (rather rapidly) and, as it moved, the winds to the north of it became very strong from the east. This storm is now being studied as an expansion wave moving from the west followed by a compression wave and a subsequent pressure jump on the inversion north of the quasi-stationary front. The effect of the Coriolis force is being included in this investigation. The problems of flow under an inversion are very well suited for complementary work by theoreticians and synoptic meteorologists.

Blocking Waves in a Planetary Jet Stream. Rossby [17] has shown that an analogue to the stationary hydraulic jump can occur in a planetary jet stream. The jet stream he uses is defined as a symmetric stream of fast-flowing air moving through stationary surroundings. He showed that if the variation of the Coriolis parameter is considered and the momentum transport for a given volume transport is expressed as a function of velocity, the momentum transport has a minimum value. This means that for any other value of the momentum transport there are two possible flows with this volume transport. Thus, a necessary condition for the sudden change from one state of flow to another is satisfied. This is exactly what happens in a hydraulic jump. Rossby advances the theory that this analogue to the hydraulic jump appears on the weather map as a blocking wave of the type discussed by Berggren, Bolin, and Rossby [3]. Rossby's paper naturally suggested that a system of equations of a nonstationary flow of this type might be developed and that possibly they would be similar to equations (1) and (2). If the velocity profile of the jet stream is such that the vorticity in the jet is f_0 (*i.e.*, $u = u_0 + \beta y^2/2$), the jet stream has width a, the acceleration in the y direction can be neglected, and the geostrophic approximation can be made outside the jet stream, then the equations describing the flow of the stream are

$$\frac{\partial u_0}{\partial t} + \left(u_0 - \frac{\beta a^2}{2}\right)\frac{\partial u_0}{\partial x} = 0,$$

$$\frac{\partial a}{\partial t} + \left(u_0 + \frac{\beta a^2}{2}\right)\frac{\partial a}{\partial x} + a\frac{\partial u_0}{\partial x} = 0.$$

These are equations of the type (1) and (2). Simple waves are possible, and the compression waves lead to envelopes of the characteristics. Needless to say, this problem is being studied actively and in detail. The success of the method of characteristics in the study of this problem emphasizes the fact that the usefulness of this method to meteorologists is not confined to the

study of flow under an inversion. It is sincerely hoped that all meteorologists will keep this method in mind as a possible means of obtaining quantitative results in a problem.

HYDRODYNAMIC INSTABILITY*

By JACQUES M. VAN MIEGHEM

University of Brussels

Introduction

The concept of dynamic instability appeared along with the initial developments in the theory of atmospheric disturbances [2]. In the method of perturbations, which V. Bjerknes introduced into meteorology, a "small motion" is superimposed on a state of "simple motion" of the air. This "simple motion" is always a permanent motion characterized, at every point of the medium, by equilibrium of the forces perpendicular to the direction of the flow. These forces are gravity, the pressure gradient (hydrostatic equilibrium), the Coriolis force (state of geostrophic motion), and the centrifugal force (circular vortex). The "simple motion," therefore, is evidently a state of hydrodynamic equilibrium.

The "small motion" is simply a nascent perturbation, defined by quantities small enough that the values of the products and squares of the quantities as well as of their derivatives are negligible. Furthermore, it is assumed to begin with that the perturbation is restricted to a train of plane sinusoidal waves, propagated with constant velocity c in the same sense as the simple motion. This perturbation must satisfy linearized equations derived from Euler's dynamical equations and from the equations of continuity and of the adiabatic process; from these the amplitude relations are obtained. In addition it is necessary to satisfy restrictions imposed by external boundaries (surface of the globe, free surface) and, eventually, by internal boundaries (frontal surface, tropopause). There generally results a relation between the quantities describing the physical and dynamical state of the "simple motion," the wave length L, and the velocity of propagation c. When this "dispersion equation" admits only real roots for c, the perturbation is said to be stable regardless of the value of the wave length L; on the other hand, when the equation admits only imaginary roots for c, the motion is referred to as unstable. In general this equation admits real roots, for certain values of L and imaginary roots for others, that is, the stability or instability of a perturbation depends on its wave length. The condition for which the dispersion equation has only imaginary roots for c expresses the dynamic instability criterion in the sense of V. Bjerknes and H. Solberg [2]. This criterion, which depends not only on the state of simple motion, but also, and more significantly, on the wave length L, is thus a *selective* criterion that can be applied only to a flow pattern consisting of a perturbation of the type "plane sinusoidal waves" propagated uniformly in the direction of the simple motion.

This dynamic instability of selective character has been studied extensively since the first work of V. Bjerknes and H. Solberg, notably by B. Haurwitz, C. L. Godske, Z. Sekera, J. G. Charney, P. Queney, E. T. Eady, and others. On the other hand, the stability of the simple motion, upon which the nascent perturbation is superimposed, was not considered until very much later, although logically it should have been studied in the very beginning. It is evident, without further amplification, that the stability or instability constitutes an essential characteristic of the simple motion and must appear as such in the dispersion equation.

Kleinschmidt [17, 18] was the first to show that, along with the hydrostatic instability of masses at rest in the gravity field, there exists a hydrodynamic instability of air masses whose motion obeys the law of geostrophic flow. Although the hydrostatic equation amounts to an excellent approximation to the equation of atmospheric dynamics in a vertical direction, the classical criteria of stability and instability for the vertical distribution of the air are strictly applicable only in an atmosphere without wind, in which there are only vertical displacements and where only vertical forces, such as gravity and the vertical pressure gradient, come into play. In reality, on a synoptic scale, we must take account of the horizontal pressure gradient, the Coriolis force, and the centrifugal force, as well as of the vertical forces. In this case the criteria of stability and instability of hydrostatic equilibrium lose their validity, and it is expedient to substitute for them criteria of stability and instability of hydrodynamic equilibrium.

In general, the atmosphere is said to be stable (or unstable) at any point O at any instant t for any direction r when a particle displaced from this point, at this instant and in the direction r, acquires a relative motion with respect to the environment at O returning it toward (or carrying it away from) the equilibrium position O.

The Stability of Geostrophic Motion

Let us consider a mass of air in a state of geostrophic motion (hydrodynamic equilibrium in the sense of Kleinschmidt [17, 18]). In this case the isobaric surfaces P = const and the isentropic surfaces Θ = const of the air are cylindrical surfaces with horizontal generatrices parallel to the geostrophic current; the equipotential surfaces, Φ = const, of the gravity field are assumed to be planes parallel to the horizontal plane at any given point O in the interior of the air mass. We refer the motion of the air to a right-handed, rectangular, Cartesian coordinate system $Oxyz$, at rest with respect

* Translated from the original French.

to the earth and having the axis Ox directed parallel to the geostrophic current $\mathbf{u}$ and the axis Oz directed toward the zenith above point O. In this system we thus have $u_x \equiv u(y, x) > 0$, $u_y \equiv u_z \equiv 0$, $P \equiv P(y, z)$, $\Theta \equiv \Theta(y, z)$, $\Phi \equiv \Phi(z)$, and the components of the earth's rotation ω are given by $\omega_x \equiv \omega \cos\phi \sin\alpha$, $\omega_y \equiv \omega \cos\phi \cos\alpha$, and $\omega_z \equiv \omega \sin\phi$, where ϕ is the latitude of point O and α is the angle between the vector $\mathbf{u}$ and the west-to-east direction. Let us now introduce Exner's function $\Pi \equiv c_p(P/100)^{R/c_p}$ (in which P is expressed in centibars), where c_p stands for the specific heat at constant pressure and R for the specific ideal gas constant for air. Finally, to facilitate the presentation, any orientation parallel to the current $\mathbf{u}$ will be called *longitudinal* and any orientation perpendicular to this current will be called *transverse*.

The law of geostrophic motion expresses the equilibrium of the transverse forces $-\nabla\Phi, -\Theta\nabla\Pi$, and $-2\omega \times \mathbf{u}$, that is,

$$2\omega \times \mathbf{u} + \Theta\nabla\Pi + \nabla\Phi = 0. \tag{1}$$

By taking the curl of *equation* (1) *of hydrodynamic equilibrium*, we find the *equilibrium condition of Margules*,

$$2\omega\cdot\nabla u = [\nabla\Theta \times \nabla\Pi]_x \equiv N, \tag{2}$$

which expresses the integrability of equation (1) with respect to Π. In the equilibrium condition, therefore, the gradient of the air speed is proportional to the number N of isobaric-isosteric solenoids per unit of transverse area.

We shall now consider a certain particle, in the interior of the air mass which is in hydrodynamic equilibrium, carried along by the current $\mathbf{u}$ and occupying at any instant t_0 the position of an arbitrarily chosen point O; at the instant t_0 we apply to it a transverse impulse; then at the same instant we take away the impulse. Let $A(x, y, z)$ be the position occupied by the perturbed particle at instant $t > t_0$; let $\mathbf{v}(v_x, v_y, v_z)$ be the velocity of this particle relative to current $\mathbf{u}$ at A at the instant t, and let $\mathbf{V}(V_x, V_y, V_z)$ be the velocity of this same particle relative to the earth at the same instant; we then have

$$V_x \equiv \frac{dx}{dt} = u + v_x, \qquad V_y \equiv \frac{dy}{dt} = v_y, \qquad V_z \equiv \frac{dz}{dt} = v_z, \tag{3}$$

where the operator d/dt stands for the substantial derivative with respect to time t in the reference system $Oxyz$, at rest with respect to the earth.

We now propose to study the motion of the perturbed particle A around its equilibrium position O. This relative motion will be assumed to be a small motion; furthermore, we shall neglect the effects of friction, conduction, and radiation on the displaced particle, and we shall assume that its displacement involves no perturbation of the pressure field. Consequently the perturbed particle retains the potential temperature Θ_0 which it had at point O, and at any instant $t > t_0$ its pressure is equal to that at the point A which it is occupying at that instant. The motion of the perturbed particle $A(x, y, z)$ relative to the earth is then determined by the vector equation

$$\frac{d\mathbf{V}}{dt} + 2\omega \times \mathbf{V} + \Theta_0\nabla\Pi + \nabla\Phi = 0 \tag{4}$$

and by the initial conditions

$$x = y = z = 0, \quad t = t_0, \quad V_x = u_0 \equiv u(0, 0), \quad V_y = v_y^0, \quad V_z = v_z^0, \tag{5}$$

where v_y^0 and v_z^0 are the transverse components of the initial velocity communicated at O. By eliminating $\nabla\Phi$ between (4) and (1), we obtain

$$\frac{d\mathbf{V}}{dt} + 2\omega \times \mathbf{v} = (\Theta - \Theta_0)\nabla\Pi. \tag{6}$$

We observe that if, at the initial instant t_0, we apply the same impulse to all the particles which occupy the points of the Ox axis at this instant, all these particles will perform the same adiabatic, inertial motion (4) or (6). Consequently, the quantities which describe this motion will be independent of the longitudinal coordinate x, like all those which define geostrophic motion. It is thus natural to separate the motion (6) of point A into transverse and longitudinal parts.

In order to obtain the equation of longitudinal motion at A, it suffices to project equation (6) on the axis Ox; if we use (3), we obtain the equation of motion of the projection $A''(x, 0, 0)$ of A on the longitudinal axis through O:

$$dV_x + 2\omega_y\, dz - 2\omega_z\, dy = 0. \tag{7}$$

This equation gives the change dV_x, relative to the earth, which takes place in the longitudinal velocity of the perturbed particle when it undergoes transverse displacement (dy, dz). It is integrable at once; by virtue of (5) and of the relation $u = u_0 + (\partial u/\partial y)_0 y + (\partial u/\partial z)_0 z$, we obtain

$$v_x = \left(2\omega_z - \frac{\partial u}{\partial y}\right)_0 y - \left(2\omega_y + \frac{\partial u}{\partial z}\right)_0 z, \tag{8}$$

where the subscript zero serves as a reminder that the quantities in parentheses must be replaced by their values at point O. We see, therefore, that the longitudinal motion of point A is fixed, as soon as we know its transverse motion. The latter is governed by the equations obtained by projecting relation (6) on the transverse axes Oy and Oz; following (3), the equations of motion of the projection $A'(0, y, z)$ of A on the transverse plane through O are

$$\frac{dv_y}{dt} - 2\omega_x v_z = \psi_y, \quad \frac{dv_z}{dt} + 2\omega_x v_y = \psi_z, \tag{9}$$

where ψ_y and ψ_z are the components of the transverse force

$$\psi \equiv (\Theta - \Theta_0)\nabla\Pi - 2\omega \times \mathbf{v}_x \tag{10}$$

which the surrounding medium exerts on the unit mass of the displaced particle. This transverse force con-

sists of two parts: the first, perpendicular to the isobaric surfaces, reduces to the hydrostatic buoyant force of Archimedes, in the absence of the geostrophic current $\mathbf{u}$; the second, perpendicular to both the geostrophic current and the earth's axis, is an inertia force due to the earth's rotation. We observe that in an adiabatic atmosphere ($\Theta \equiv \Theta_0 \equiv$ const), where differences between the density of the displaced particle and that of its environment disappear, only the second of the two forces remains. If in (10) we replace $\Theta - \Theta_0$ by $(\partial\Theta/\partial y)_0 y + (\partial\Theta/\partial z)_0 z$ and v_x by its value in (8), we find, whatever the orientation of transverse axes y and z, provided always that the coordinate system xyz is rectangular and right-handed,

$$\psi_y \equiv -a^0_{yy}y - a^0_{yz}z, \quad \psi_z \equiv -a^0_{zy}y - a^0_{zz}z, \tag{11}$$

with

$$\left.\begin{aligned} a_{yy} &\equiv 2\omega_z\left(2\omega_z - \frac{\partial u}{\partial y}\right) - \frac{\partial \Pi}{\partial y}\frac{\partial \Theta}{\partial y}, \\ a_{yz} &\equiv -2\omega_z\left(2\omega_y + \frac{\partial u}{\partial z}\right) - \frac{\partial \Pi}{\partial y}\frac{\partial \Theta}{\partial z}, \\ a_{zy} &\equiv -2\omega_y\left(2\omega_z - \frac{\partial u}{\partial y}\right) - \frac{\partial \Pi}{\partial z}\frac{\partial \Theta}{\partial y}, \\ a_{zz} &\equiv 2\omega_y\left(2\omega_y + \frac{\partial u}{\partial z}\right) - \frac{\partial \Pi}{\partial z}\frac{\partial \Theta}{\partial z}, \end{aligned}\right\} \tag{12}$$

and the symmetry relation $a_{yz} \equiv a_{zy}$ resulting from the equilibrium condition (2).

Making use of equations (11) and (12), which give the components of the force Ψ that acts on perturbed particle A as functions of the physical and dynamical state of the atmosphere at the equilibrium position O of A, and of the transverse components of displacement $\overrightarrow{OA}$, it is easy to determine the nature of the hydrodynamic equilibrium at point O. Depending on whether the applied force (ψ_y, ψ_z) and the displacement (y, z) are of opposite or of the same sense, this force tends to return the displaced particle A toward its equilibrium position O or to carry it away from this position, that is, depending on whether $-\psi_y y - \psi_z z > 0$ or <0, the hydrodynamic equilibrium at O is stable or unstable.

We thus rederive E. Kleinschmidt's criterion: *the state of geostrophic motion at any point, for any transverse direction r_y, r_z at this point, is stable or unstable depending on whether* [17, 18, 33, 37]

$$Q(r_y, r_z) \equiv a_{yy}r_y^2 + 2a_{yz}r_y r_z + a_{zz}r_z^2 > \text{or} < 0, \tag{13}$$

or again,

$$Q(r_y, r_z) \equiv 2(\mathbf{r} \times \boldsymbol{\omega})_x(\mathbf{r} \times \operatorname{curl} \mathbf{U})_x - (\mathbf{r}\cdot\nabla\Theta)(\mathbf{r}\cdot\nabla\Pi) > \text{or} < 0, \tag{14}$$

where

$$\left.\begin{aligned} \operatorname{curl}_x \mathbf{U} &\equiv 2\omega_x, \\ \operatorname{curl}_y \mathbf{U} &\equiv 2\omega_y + \frac{\partial u}{\partial z}, \\ \operatorname{curl}_z \mathbf{U} &\equiv 2\omega_z - \frac{\partial u}{\partial y}, \end{aligned}\right\} \tag{15}$$

are the components of the curl of the absolute geostrophic velocity $\mathbf{U} = \mathbf{u} + \boldsymbol{\omega} \times \mathbf{R}$, in which $\mathbf{R}$ is the radius of rotation of the point relative to the earth's axis. As a special case, in an adiabatic atmosphere where no Archimedean buoyant force is possible, there is said to be *inertial stability* or *inertial instability* [32], depending on whether

$$2(\mathbf{r} \times \boldsymbol{\omega})_x(\mathbf{r} \times \operatorname{curl} \mathbf{U})_x > \text{or} < 0. \tag{16}$$

Next we multiply equations (9) respectively by dy/dt and dz/dt. By adding them we obtain, after integrating, the relation thus found and taking account of initial conditions (5),

$$\tfrac{1}{2}[(v_y)^2 + (v_z)^2] - \tfrac{1}{2}[(v_y^0)^2 + (v_z^0)^2] = -\tfrac{1}{2}[a^0_{yy}y^2 + 2a^0_{yz}yz + a^0_{zz}z^2]. \tag{17}$$

Consequently, depending upon whether the hydrodynamic equilibrium at O is stable or unstable for displacement (y, z), the kinetic energy per unit mass of the particle displaced transversely from (y, z) decreases or increases. The work E_0 which is performed in the course of a displacement (y, z) by the transverse force per unit mass, applied by the surroundings to the displaced particle, will be referred to as *energy of instability* per unit mass, latent at point O. It follows that

$$E_0 \equiv -\tfrac{1}{2}[a^0_{yy}y^2 + 2a^0_{yz}yz + a^0_{zz}z^2]. \tag{18}$$

In the case of stability this work is negative; the surrounding medium opposes displacement (y, z); in fact this displacement ceases as soon as the kinetic energy of the initial impulse is dissipated. Under conditions of instability, on the other hand, this work is positive: the surroundings further the displacement (y, z); to the kinetic energy of the initial impulse is added the energy of instability E_0 set free in the course of the displacement [35, 37]. This gives an interpretation on an energy basis of the quadratic form (13).

We return now to equation (4). By multiplying scalarly with $\mathbf{V}$, we obtain a differential expression which can be integrated directly. This furnishes the first integral of the equation of motion of the perturbed particle,

$$\tfrac{1}{2}[(V_x)^2 + (v_y)^2 + (v_z)^2] + \Theta_0\Pi + \Phi = \text{const}. \tag{19}$$

We set $S(y, z) \equiv \tfrac{1}{2}(V_x)^2 + \Theta_0\Pi + \Phi$, where V_x is given as a function of y and z by (3) and (8). After substituting initial conditions (5) and equation (17), equation (19) assumes the form [18]

$$S(y, z) - S(0, 0) = \tfrac{1}{2}[a^0_{yy}y^2 + 2a^0_{yz}yz + a^0_{zz}z^2]. \tag{20}$$

However, we have assumed that the perturbation of the particle considered is small, so that the right-hand side of (20) constitutes in reality only the first term of the expansion of the difference $S(y, z) - S(0, 0)$ in a Taylor series; therefore, $(\partial S/\partial y)_0 = (\partial S/\partial z)_0 = 0$ and $(\partial^2 S/\partial y^2)_0 \equiv a^0_{yy}$, $(\partial^2 S/\partial y \partial z)_0 \equiv a^0_{yz} \equiv a^0_{zy}$, $(\partial^2 S/\partial z^2)_0 \equiv a^0_{zz}$. *We conclude that a particle A, in the interior of an air mass in geostrophic motion, occupies an equilibrium position O when the sum of its longitudinal kinetic energy per unit mass $\tfrac{1}{2}(V_x)^2$, its specific enthalpy $\Theta_0\Pi$, and its*

potential energy per unit mass Φ is an extremum; depending upon whether this extremum is a minimum or a maximum, the equilibrium at O between gravity, the pressure gradient, and the Coriolis force is stable or unstable [38].

The Quadratic Form of E. Kleinschmidt

Let us now consider the case of vertical displacement ($r_y \equiv 0$, $r_z \neq 0$), the equilibrium being hydrostatic ($u \equiv 0$). In this case the earth's rotation can be neglected; by referring back to (12), we obtain $a_{yy} \equiv a_{yz} \equiv a_{zy} \equiv 0$ and $a_{zz} \equiv (g/\Theta)(\partial\Theta/\partial z)$, consideration having been taken of the hydrostatic equation in the vertical (z) direction. We thus rederive the classical criterion: the vertical distribution of air in the field of gravity g is stable or unstable depending upon whether $\partial\Theta/\partial z >$ or < 0. We observe that the energy of instability released per unit mass in the course of vertical displacement r_z of a particle in hydrostatic equilibrium is given by $-\frac{1}{2}(g/\Theta)(\partial\Theta/\partial z)r_z^2$.

In the case of a geostrophic current ($u \neq 0$), the vertical equilibrium is stable or unstable depending upon whether

$$a_{zz} \equiv 2\omega_y\left(2\omega_y + \frac{\partial u}{\partial z}\right) - \frac{\partial \Pi}{\partial z}\frac{\partial \Theta}{\partial z} > \text{or} < 0.$$

In the atmosphere, however, the second term is always at least one hundred times larger than the first and therefore determines the sign of a_{zz}.

We consider next the case of transverse isentropic displacement, which is defined at any point by $r_y^* \equiv \frac{r\partial\Theta/\partial z}{|\nabla\Theta|}$, $r_z^* \equiv -\frac{r\partial\Theta/\partial y}{|\nabla\Theta|}$. The value of the quadratic form (14) at this point for this displacement can be written independently of the chosen system of coordinates as follows [37]

$$Q(r_y^*, r_z^*) \equiv 2(\boldsymbol{\omega}\cdot\nabla\Theta)(\nabla\Theta\cdot\text{curl U})r^2/(\nabla\Theta)^2. \quad (21)$$

In order to give (21) a convenient analytical form, it is useful to adopt Kleinschmidt's rectangular, right-handed reference system XYZ [18], where axis X coincides with the longitudinal axis x and the transverse axis Y is perpendicular to the earth's axis and points toward the earth's interior. The direction cosines between the new axes X, Y, Z and the former axes x, y, z are as given in Table I. We can set $\kappa \sin\beta = \sin\phi$, $\kappa\cos\beta = \cos\phi\cos\alpha$, and $\kappa^2 = \sin^2\phi + \cos^2\phi\cos^2\alpha$.

Table I. Direction Cosines for Kleinschmidt's Coordinate System

	X	Y	Z
x	1	0	0
y	0	$\sin\beta$	$\cos\beta$
z	0	$-\cos\beta$	$\sin\beta$

In this coordinate system we have $\omega_X \equiv \omega\cos\phi\sin\alpha$, $\omega_Y \equiv 0$, $\omega_Z \equiv \kappa\omega$ and

$$\nabla\Theta\cdot\text{curl U} \equiv \frac{\partial\Theta}{\partial Z}\left(2\kappa\omega - \frac{\delta u}{\delta Y}\right), \quad (22)$$

where the operator

$$\frac{\delta}{\delta Y} \equiv \frac{\partial}{\partial Y} - \left(\frac{\partial\Theta/\partial Y}{\partial\Theta/\partial Z}\right)\frac{\partial}{\partial Z} \quad (23)$$

represents the isentropic derivative in the direction of the transverse axis Y. Following (21),

$$-\tfrac{1}{2}Q(r_y^*, r_z^*) \equiv \kappa\omega\left(\frac{\partial\Theta}{\partial Z}\right)^2\left(\frac{\delta u}{\delta Y} - 2\kappa\omega\right)\frac{r^2}{(\nabla\Theta)^2}. \quad (24)$$

It turns out that geostrophic motion at any point, for a transverse isentropic displacement from this point, is stable or unstable depending on whether

$$\frac{\delta u}{\delta Y} < \text{or} > 2\kappa\omega. \quad (25)$$

Furthermore we note that the right side of (24) gives the energy of instability released per unit mass during an isentropic displacement.

Finally, we come to the general case. Study of the sign of the quadratic form Q is accomplished with the help of its discriminant [18, 37]

$$a \equiv a_{yz}^2 - a_{yy}a_{zz} \equiv 2(\boldsymbol{\omega}\cdot\nabla\Pi)(\nabla\Theta\cdot\text{curl U}) \quad (26)$$

and of the coefficient of one of the squared terms. First we observe that, (1),

$$2\Theta(\boldsymbol{\omega}\cdot\nabla\Pi) = -2\boldsymbol{\omega}\cdot\nabla\Phi = -fg \quad (27)$$

where g represents gravity and f the Coriolis parameter $2\omega_z \equiv 2\omega\sin\phi$. After substituting (22) and (27) into (26), we obtain

$$a \equiv \frac{fg}{\Theta}\frac{\partial\Theta}{\partial Z}\left(\frac{\delta u}{\delta Y} - 2\kappa\omega\right). \quad (28)$$

We next find by reference to equations (12) that the coefficient of the term in $(r_Z)^2$ can be written

$$a_{ZZ} \equiv -\frac{\partial\Pi}{\partial Z}\frac{\partial\Theta}{\partial Z} = \frac{1}{\Theta}\frac{\partial\Theta}{\partial Z}\frac{\partial\Phi}{\partial Z} = \frac{g\sin\phi}{\kappa\Theta}\frac{\partial\Theta}{\partial Z}. \quad (29)$$

Since the sign of quadratic form Q depends upon the signs of a and a_{ZZ}, we see in the final analysis that this sign depends upon the sign of $\partial\Theta/\partial Z$ and the sign of $\delta u/\delta Y - 2\kappa\omega$; whence we can construct Table II [18, 37].

Table II. General Conditions for the Stability of Geostrophic Motion

Case	$\partial\Theta/\partial Z$	$\frac{\delta u/\delta Y}{-2\kappa\omega}$	a	Nature of the hydrodynamic equilibrium
I	+	−	−	Stable whatever the transverse displacement.
II	+	+	+	Unstable for transverse displacements close to the isentropic surface. Stable for transverse displacements close to the Z direction.
III	−	+	−	Unstable whatever the transverse displacement.
IV	−	−	+	Unstable for transverse displacements close to the Z direction. Stable for transverse displacements close to the isentropic surface.

When $a > 0$, that is, when the quadratic form Q at the point considered is positive for certain displacements and negative for others, it becomes zero for two transverse directions d' and d''. For these directions the hydrodynamic equilibrium at the point is neutral ($-Q \equiv \psi_y r_y + \psi_z r_z = 0$). It is simple to show that the angle between these two directions is given by

$$\tan (d'd'') = \frac{2\sqrt{2(\omega \cdot \nabla\Pi)(\nabla\Theta \cdot \text{curl } \mathbf{U})}}{2(\omega \cdot \text{curl } \mathbf{U}) - (\nabla\Pi \cdot \nabla\Theta)} = 10^{-2}. \quad (30)$$

Since the sign of Q at any point is that of $\partial\Theta/\partial Z$ for a displacement parallel to Z and is that of $2\kappa\omega - \delta u/\delta Y$ for a transverse isentropic displacement, and since these signs are different because of the inequality $a > 0$, the directions d' and d'' separate the transverse tangent to the isentropic surface at this point from the line parallel to the Z axis. The directions d' and d'' separate the transverse plane at this point into four regions, opposite to one another in pairs across the vertex. The two regions containing the displacements for which $Q > 0$ (<0) constitute the stable (unstable) sector of the transverse plane at the point considered. Moreover, the isentropic surface passing through this point lies in the unstable sector in Case II and in the stable sector in Case IV [8, 9, 14, 15, 17, 18].

When $a = 0$, the directions d' and d'' both coincide with direction

$$\frac{r_Z}{r_Y} = -\frac{a_{YZ}}{a_{ZZ}} = -\frac{a_{ZY}}{a_{ZZ}} = -\frac{\partial\Theta/\partial Y}{\partial\Theta/\partial Z},$$

that is, with the transverse tangent d to the isentropic surface at the point considered. When a becomes positive, in passing from Cases I and III to Cases II and IV, directions d' and d'' separate from this tangent and include between them an angle defined by (30). This angle is very small, averaging at the most on the order of a few tenths of a degree, and the isentropic surface at the point considered lies in the acute angle between directions d' and d'' from this point [37].

In the atmosphere we generally have $\partial\Theta/\partial Z > 0$, so that only Cases I and II are ordinarily possible, Case I being the most common. Therefore, in general, at any point in the atmosphere the state of geostrophic motion is stable whatever may be the transverse displacements from this point, with the exception of isentropic and quasi-isentropic displacements, when [37]

$$\frac{\delta u}{\delta Y} > 2\kappa\omega \quad \text{or} \quad \nabla\Theta \cdot \text{curl } \mathbf{U} < 0. \quad (31)$$

Hydrodynamic Instability as a Function of Latitude

Middle and High Latitudes. Let us return to the coordinate system $Oxyz$ introduced earlier. In the Northern Hemisphere, we have in this system $\partial\Pi/\partial y < 0$ and $\partial\Theta/\partial y < 0$. At the pole $\phi \equiv 90°$, so that $\omega_x \equiv \omega_y \equiv 0$. In the polar regions ϕ is close to 90° and the two horizontal components of ω are practically zero. Furthermore, we know that in middle latitudes we can neglect all the terms of the dynamic equations which contain $\omega \cos\phi$; when thus simplified the equations are exact, at least to the nearest hundredth. As a first approximation, we can thus eliminate the terms containing components ω_x and ω_y of the earth's rotation from all equations in the preceding sections. In particular we have, (12), [20, 37]

$$\begin{aligned}
a_{yy} &\equiv f\left[f - \dot{\Theta}\frac{\partial}{\partial y}\left(\frac{u}{\Theta}\right)\right] \cong f\left(f - \frac{\partial u}{\partial y}\right) \approx 10^{-8}\ \text{sec}^{-2},\\
a_{yz} &\equiv -f\Theta\frac{\partial}{\partial z}\left(\frac{u}{\Theta}\right) \cong -f\frac{\partial u}{\partial z} \approx 10^{-7}\ \text{to}\ 10^{-6}\ \text{sec}^{-2},\\
a_{zy} &\equiv \frac{g}{\Theta}\frac{\partial\Theta}{\partial y} \approx 10^{-7}\ \text{to}\ 10^{-6}\ \text{sec}^{-2},\\
a_{zz} &\equiv \frac{g}{\Theta}\frac{\partial\Theta}{\partial z} \approx 10^{-4}\ \text{sec}^{-2},
\end{aligned} \quad (32)$$

account having been taken of the simplified equation (1), and we have from (28),

$$a \equiv a_{yz}^2 - a_{yy}a_{zz} \equiv \frac{fg}{\Theta}\frac{\partial\Theta}{\partial z}\left(\frac{\delta u}{\delta y} - f\right), \quad (33)$$

as well as from (2),

$$\begin{aligned}
f\frac{\partial u}{\partial z} &= \frac{\partial\Theta}{\partial y}\frac{\partial\Pi}{\partial z} - \frac{\partial\Theta}{\partial z}\frac{\partial\Pi}{\partial y}\\
&\equiv N \cong -\frac{g}{\Theta}\frac{\partial\Theta}{\partial y} \approx 10^{-7}\ \text{to}\ 10^{-6}\ \text{sec}^{-2}.
\end{aligned} \quad (34)$$

The operator

$$\frac{\delta}{\delta y} \equiv \frac{\partial}{\partial y} - \left(\frac{\partial\Theta/\partial y}{\partial\Theta/\partial z}\right)\frac{\partial}{\partial z} \quad (35)$$

gives the transverse isentropic derivative in the direction of the horizontal y-axis. The sign of form Q for a transverse isentropic displacement (r_y^*, r_z^*) is that of the difference $f - \frac{\delta u}{\delta y}$, and for a vertical displacement r_z is that of a_{zz}, that is, that of $\partial\Theta/\partial z$. Thus we see that at any point the hydrodynamic equilibrium for a vertical displacement from this point is stable or unstable depending on whether the hydrostatic equilibrium in the field of gravity is stable or unstable. Therefore, to the approximation agreed upon here, the vertical gradient $\partial\Theta/\partial z$ of the potential temperature Θ reassumes its classical significance. We can also say that

$$\nu_s^2 \equiv \frac{g}{\Theta}\frac{\partial\Theta}{\partial z} \equiv g\,\frac{\gamma_a - \gamma}{T} \approx 10^{-4}\ \text{sec}^{-2} \quad (36)$$

defines the *static stability* in middle and high latitudes. In (36), T represents the absolute air temperature; γ, the vertical lapse rate of temperature; and γ_a, the adiabatic lapse rate. However, in the general case considered in the preceding section, $\partial\Theta/\partial z$ must be replaced by $\partial\Theta/\partial Z$ to be rigorous.

This having been established, we can adopt without change the reasoning of the previous section and substitute $\partial\Theta/\partial z$ and $\delta u/\delta y - f$ for $\partial\Theta/\partial Z$ and $\delta u/\delta Y - 2\kappa\omega$ in Table II. Since we generally have $\partial\Theta/\partial z > 0$ above the convective level, geostrophic motion in middle and high latitudes is stable for any transverse displacement, except in the neighborhood of the isentropic surfaces when $\delta u/\delta y > f$ [17, 18, 37]. In the extra-

tropical troposphere, $\partial u/\partial y$ is on the average negative and of the order of 10^{-5} sec^{-1}, $\partial u/\partial z$ is positive and of the order of 10^{-3} to 10^{-2} sec^{-1}, while the slope $-\dfrac{\partial\Theta/\partial y}{\partial\Theta/\partial z}$ of isentropic surfaces can attain the value 10^{-2}; consequently, under these conditions, $\delta u/\delta y$ is positive and of the order of 10^{-5} to 10^{-4} sec^{-1}. Then the vertical component $-\delta u/\delta y$ of the vorticity which the velocity field **u** produces in the isentropic surfaces is anticyclonic, and when it exceeds in absolute value the limit $f \approx 10^{-4}$ sec^{-1}, the geostrophic motion becomes unstable within the isentropic surfaces and in their neighborhood. In this case the transverse tangent d to the isentropic surface at any point is, to a first approximation, the bisector of the angle between directions d' and d'' which limit the sector of unstable displacements on either side of this surface at the point considered [37]. The energy of instability released per unit mass in the d direction is satisfactorily given by the approximation $(f/2)(\delta u/\delta y - f)r^2$ deduced from (24).

In the atmosphere we usually have $0 < \delta u/\delta y < f$ and $\partial\Theta/\partial z > 0$, and consequently the state of geostrophic motion is usually stable for any transverse displacement. In this case $a < 0$ and $a_{zz} > 0$. If we admit that the state of hydrodynamic equilibrium can be altered gradually, it may be asked which of the two quantities a and a_{zz} will be the first to change its sign. In reply it is enough to observe that if $a_{zz} = 0$, we have $a > 0$. Then a vanishes before a_{zz}, since for a and a_{zz} to vanish simultaneously it would be necessary that $a_{zz} \equiv a_{zy} \equiv 0$, that is, $\partial\Theta/\partial y \equiv \partial\Theta/\partial z \equiv 0$, a condition which does not occur in the atmosphere. From this follows the proposition [18]: *When the state of hydrodynamic equilibrium is altered, the threshold of hydrodynamic instability in an isentropic surface is reached before that of hydrostatic instability in the field of gravity.* In other words, in the atmosphere, hydrodynamic instability in an isentropic surface will develop before hydrostatic instability in the vertical direction.

In summary, in order for hydrodynamic instability to appear in a region—it will first appear in the isentropic surfaces—the vertical component of vorticity, produced by the geostrophic velocity field in the isentropic surfaces, must increase in absolute value and exceed the critical value f.

In the absence of Archimedean buoyant forces, form Q reduces to $f(f - \partial u/\partial y)r_y^2$. Then there is inertial stability or instability depending on whether $\partial u/\partial y <$ or $> f$. In the atmosphere we generally have $\partial u/\partial y < 0$ in the lower troposphere, as well as in the middle and high troposphere north of the "jet stream"; but south of the "jet stream" $0 < \partial u/\partial y < f$ [32]. The condition of inertial stability is thus generally attained in the atmosphere. We shall say that

$$\nu_i^2 \equiv f(f - \partial u/\partial y) \approx 10^{-8}\,\text{sec}^{-2} \tag{37}$$

defines the *inertial stability*.

Let us now examine more closely the criterion

$$\frac{\delta u}{\delta y} \equiv \frac{\partial u}{\partial y} - \left(\frac{\partial\Theta/\partial y}{\partial\Theta/\partial z}\right)\frac{\partial u}{\partial z} > f \tag{38}$$

for hydrodynamic instability. After $\partial\Theta/\partial y$ in (38) is replaced by its value taken from (34), this criterion assumes the form

$$\left[\frac{g}{\Theta}\frac{\partial\Theta}{\partial z}\right]\left[f\left(f - \frac{\partial u}{\partial y}\right)\right] \equiv \nu_s^2\nu_i^2 < N^2 = \left[f\frac{\partial u}{\partial z}\right]^2 \cong \left[\frac{g}{\Theta}\frac{\partial\Theta}{\partial y}\right]^2, \tag{39}$$

if we assume that static stability is in fact realized ($\nu_s^2 > 0$), which is usually the case. Inequality (39) shows that, whatever the magnitude of the inertial stability ν_i^2 and the static stability ν_s^2, the hydrodynamic instability can appear as soon as the baroclinity exceeds the critical value $N_* = \nu_s\nu_i$. *Instability of geostrophic motion is thus essentially dependent upon the baroclinic character of the atmosphere and can develop only in regions where this character is sufficiently pronounced*, that is, in frontal zones and in the tropical air immediately above and in the polar air immediately below these zones.

Inequality (39) suggests the introduction of the *hydrodynamic stability*

$$\nu_d^2 \equiv f\left(f - \frac{\delta u}{\delta y}\right) \cong \nu_i^2 - \frac{N^2}{\nu_s^2}, \tag{40}$$

which is always less than the inertial stability. We see at once that inertial instability ($\nu_i^2 < 0$ or $\partial u/\partial y > f$) implies *ipso facto* hydrodynamic instability ($\nu_d^2 < 0$); this is, what takes place in a region, generally of small extent, of the tropical troposphere south of the "jet stream" [22–24]. For a given static stability $(g/\Theta)\,\partial\Theta/\partial z$ and baroclinity $-(g/\Theta)\,\partial\Theta/\partial y$, the hydrodynamic stability is greater when the inertial stability is large, that is, when the vorticity $-\partial u/\partial y$, which current **u** produces in horizontal surfaces, is strongly cyclonic ($\partial u/\partial y << 0$); it is weaker when the inertial stability is small, that is, when the vorticity $-\partial u/\partial y$ is weakly cyclonic or anticyclonic ($\partial u/\partial y > 0$). This latter condition occurs in the tropical troposphere south of the "jet stream." In that case hydrodynamic instability can appear for a sufficiently large positive value of $\partial u/\partial y$.

The critical slope $\tan\alpha_\theta^*$ of the isentropic surfaces, defined by $\delta u/\delta y - f = 0$, can be expressed as

$$\tan\alpha_\theta^* = \nu_i^2/N \approx 10^{-2}. \tag{41}$$

The actual slope of these surfaces is given by

$$\tan\alpha_\theta = -\frac{\partial\Theta/\partial y}{\partial\Theta/\partial z} = N/\nu_s^2, \tag{42}$$

so that criterion (39) can also be written $\alpha_\theta > \alpha_\theta^*$. Thus hydrodynamic instability occurs whenever the slope of the isentropic surfaces exceeds its critical value (41).

Let us consider the isentropic surfaces Θ = const, drawn at constant intervals of, for example, $\Delta\Theta = 5°$. To a first approximation, the baroclinity at any point depends on the horizontal distance between two neighboring isentropic surfaces; the static stability depends

on their vertical separation. These two quantities increase or decrease depending on whether those distances decrease or increase. When the isentropic surfaces approach one another while maintaining constant slope, the baroclinity N and the static stability ν_s^2 both increase in such a way that N/ν_s^2 remains constant, so that by virtue of (40) or (41), packing of the isentropic surfaces can involve instability when a sufficient baroclinity is attained. On the other hand, when the slope of the isentropic surfaces increases while their horizontal separation remains constant, the static stability decreases while the baroclinity remains constant; this baroclinity can become critical for a sufficiently small value of the static stability. It follows that in a frontal zone where the static stability and the baroclinity are relatively large, instability can occur only if the baroclinity is particularly pronounced, that is, when the isentropic surfaces are not only very close to one another but also markedly inclined to the horizontal (case of active frontogenesis). On the other hand, in the tropical air immediately above the frontal surface and the polar air immediately below, where the static stability is much less pronounced, a much smaller baroclinity is enough for the threshold of hydrodynamic instability to be attained.

In the stratosphere, where the static stability is large (5×10^{-4} sec^{-2}), but where the baroclinity is relatively weak (quasi-horizontal isentropic surfaces), the state of geostrophic motion is stable [8, 9].

In summary, strong baroclinity and weak static stability favor hydrodynamic instability (see (40)).

The Lower Latitudes. At the equator, $\phi \equiv 0$, and therefore $\omega_x \equiv \omega \sin \alpha$, $\omega_y \equiv \omega \cos \alpha$, and $\omega_z \equiv 0$. By virtue of (1) $\partial \Pi/\partial y = \partial P/\partial y = 0$; furthermore we have (Table I) $\partial/\partial z = -\partial/\partial Y$ and $\partial/\partial y = \partial/\partial Z$. It follows that in (12), if (1) is taken into account, $a_{yy} \equiv a_{yz} \equiv a_{zy} \equiv a_{ZZ} \equiv a_{YZ} \equiv a_{ZY} \equiv 0$ and

$$a_{zz} \equiv a_{YY} \equiv 4\omega^2 \cos^2 \alpha + \Theta \frac{\partial}{\partial z}\left(\frac{u}{\Theta}\right) 2\omega \cos \alpha + \frac{g}{\Theta}\frac{\partial \Theta}{\partial z}. \tag{43}$$

All these formulas hold in the neighborhood of the equator, providing we assume that, as we approach the equator, $\partial P/\partial y$ approaches zero as does $\sin \phi$.

In equatorial latitudes the quadratic form Q reduces to the degenerate form $a_{zz} r_z^2$, which is thus independent of r_y; consequently, at the equator, out of all the possible transverse displacements only the vertical ones permit an energy exchange between the displaced particle and its environment. At lower latitudes the force acting on a displaced particle is vertical.

Finally, the hydrodynamic equilibrium in equatorial regions is stable or unstable depending on whether $a_{zz} >$ or < 0, that is, whether

$$\nu_s^2 \equiv \frac{g}{\Theta}\frac{\partial \Theta}{\partial z} > \text{or} < g\,\frac{2\omega \cos \alpha(2\omega \cos \alpha + \partial u/\partial z)}{2\omega u \cos \alpha - g} \cong -2\omega \frac{\partial u}{\partial z} \cos \alpha. \tag{44}$$

Since $|\, 2\omega(\partial u/\partial z) \cos \alpha \,| \leqq 10^{-6}$ sec^{-2}, we observe that *the threshold of hydrostatic instability in equatorial regions practically coincides with the threshold of hydrostatic instability in the vertical direction* [18].

Inertial Oscillations of the Geostrophic Current

The orbital motion of perturbed particle $A(x, y, z)$ is the motion of this particle relative to the geostrophic current $\mathbf{u}$. Referring to the coordinate system $Oxyz$ considered earlier, in which the origin O is the equilibrium position of A, the orbital velocity $\mathbf{V} - \mathbf{u}$ of A is defined by its coordinate components (3)

$$\left.\begin{aligned} \dot{x} = v_x = V_x - u = \frac{dx}{dt} - u, \\ \dot{y} = v_y = V_y = \frac{dy}{dt}, \\ \dot{z} = v_z = V_z = \frac{dz}{dt}. \end{aligned}\right\} \tag{45}$$

The dot indicates the substantial derivative with respect to time t in a reference system embedded in the geostrophic motion. Deriving (45) for time t in the reference system $Oxyz$, at rest with respect to the earth, we obtain

$$\left.\begin{aligned} \frac{dV_x}{dt} = \ddot{x} + \frac{\partial u}{\partial y}\dot{y} + \frac{\partial u}{\partial z}\dot{z}, \\ \frac{dV_y}{dt} = \frac{dv_y}{dt} = \ddot{y}, \\ \frac{dV_z}{dt} = \frac{dv_z}{dt} = \ddot{z}, \end{aligned}\right\} \tag{46}$$

account having been taken of the fact that v_x, v_y, and v_z are independent of the longitudinal coordinate x. By referring to equations (8) and (9) and to (11), (12), and (15), we obtain the equation of longitudinal orbital motion for the perturbed particle A,

$$\dot{x} = y \operatorname{curl}_Z^0 \mathbf{U} - z \operatorname{curl}_y^0 \mathbf{U}, \tag{47}$$

and the differential system of transverse orbital motion is

$$\left.\begin{aligned} \ddot{y} - 2\omega_x \dot{z} = -a_{yy}^0 y - a_{yz}^0 z, \\ \ddot{z} + 2\omega_x \dot{y} = -a_{zy}^0 y - a_{zz}^0 z. \end{aligned}\right\} \tag{48}$$

This system defines the motion of A', the projection of A on the transverse plane through O. We see at once that the transverse orbital motion is independent of the longitudinal motion and that the latter follows from the former. It is therefore sufficient to determine the motion defined by (48).

The problem of integrating a system with constant coefficients (48) is classical; we know that its general integral is a linear combination of circular and hyperbolic functions of time t. The form of this general integral depends on the nature of the roots of the characteristic equation of the system (48); this latter is

simply Solberg's equation of pulsations or orbital circular frequencies ν_0 of inertial oscillation [31], that is,

$$\nu_0^4 - b\nu_0^2 - a = 0, \tag{49}$$

where a is the discriminant (26) of Kleinschmidt's quadratic form Q (13) and $b \equiv a^0_{yy} + a^0_{zz} + 4\omega_x^2$.

We recall that to a positive root ν_0^2 of (49) there corresponds a periodic motion with an elliptical trajectory centered at O, and circular frequency ν_0, and to a negative root ν_0^2 there corresponds a motion with a hyperbolic trajectory about the same center, and of parameter $\sqrt{-\nu_0^2}$. In the first case ($\nu_0^2 > 0$), the inertial oscillation of A' around O is said to be stable, in the second case ($\nu_0^2 < 0$), unstable.

The sign of the roots ν_0^2 of (49) depends on the signs of a and b. But since the term a_{zz} in b is 10^4 times as large as either of the others, the sign of roots ν_0^2 of (49) depends in the final analysis on the signs of a and a_{zz}, that is, on the sign of the quadratic form Q. Consequently, *the inertial oscillations of A around O are stable or unstable depending on whether the hydrodynamic equilibrium at O is stable or unstable for transverse displacements* $\overrightarrow{OA'}$ *of the perturbed particle A.*

Let ν_S^2 and ν_D^2 be the roots of (49); we have

$$\nu_S^2 = \frac{b}{2}(1 + \sqrt{1 + 4a/b^2}),$$
$$\nu_D^2 = \frac{b}{2}(1 - \sqrt{1 + 4a/b^2}); \tag{50}$$

the first root is the larger when they are both real. Four cases can be distinguished, and they correspond to the four cases of Table II [31, 36, 37]:

Case I. When $\nu_S^2 > 0$ and $\nu_D^2 > 0$, the transverse orbital motion (48) is the resultant of two oscillations of circular frequencies ν_S and ν_D around elliptical trajectories with a common center O.

Case II. When $\nu_S^2 > 0$ and $\nu_D^2 < 0$, the motion is the resultant of a periodic motion on an elliptical trajectory of circular frequency ν_S and a motion on a hyperbolic trajectory of parameter $\sqrt{-\nu_D^2}$, with a common center O.

Case III. When $\nu_S^2 < 0$ and $\nu_D^2 < 0$, the motion is the resultant of two motions on hyperbolic trajectories with a common center O and parameters $\sqrt{-\nu_S^2}$ and $\sqrt{-\nu_D^2}$.

Case IV. When $\nu_S^2 < 0$ and $\nu_D^2 > 0$, the motion is the resultant of a periodic motion on an elliptical trajectory of circular frequency ν_D and a motion on a hyperbolic trajectory of parameter $\sqrt{-\nu_S^2}$, about the common center O.

As a special case when $\omega_x \equiv 0$, that is, when the current u is zonal ($\alpha \equiv 0$), these ellipses and hyperbolas degenerate into straight lines passing through O in the meridian plane from this point. The same situation holds under the approximation ($\omega_x = \omega_y = 0$) agreed to on page 438, but in this case the straight lines are transverse and no longer meridional. The straight lines which correspond to $\nu_S^2 \gtrless 0$ are quasi-vertical, while those related to $\nu_D^2 \gtrless 0$ lie in the neighborhood of the isentropic surface passing through O, which in general is very slightly inclined to the horizontal plane. In the latter case the straight line is a little more or a little less steeply inclined to the horizontal plane than the isentropic surface, depending on whether the inertial oscillation ν_D^2 is stable or unstable ($\nu_D^2 < 0$) [31].

When the current u deviates from the west-to-east direction, the longitudinal component ω_x of ω introduces an inertial influence which tends to substitute a transverse elliptical oscillation for the rectilinear meridional oscillation. The major axis of this very flattened ellipse is close to the vertical or to the isentropic surface depending on whether we are considering the oscillation of circular frequency ν_S or ν_D. In the case of instability these ellipses become hyperbolas elongated in the direction of the conjugate axis, which is quasi-vertical or quasi-isentropic depending on whether the motion is characterized by parameter $\sqrt{-\nu_S^2}$ or $\sqrt{-\nu_D^2}$.

Finally, the longitudinal motion (47) is superimposed on these transverse motions in such a way that the resultant orbital motion is on an elliptical or hyperbolic trajectory whose plane, to the approximation $\omega_x = \omega_y = 0$, is parallel to the current u and quasi-vertical or nearly tangent to the isentropic surface through O depending on whether one considers root ν_S^2 or ν_D^2 of equation (49) [31, 36, 37].

It is easy to see that $b \cong -\nabla\Theta\cdot\nabla\Pi \approx 10^{-4}$ sec^{-2} and $a \approx 10^{-12}$ sec^{-4}. The circular frequencies of the inertial oscillations are then approximated by the following values [31]:

$$\nu_S \cong \sqrt{b} \approx 10^{-2}\ \text{sec}^{-1} \text{ and } \nu_D \cong \sqrt{-a/b} \approx 10^{-4}\ \text{sec}^{-1},$$

and the corresponding periods approach the values $\tau_S \equiv 2\pi/\nu_S \approx 10$ min and $\tau_D \equiv 2\pi/\nu_D \approx 20$ hours ($\pi = 3.14\ldots$). From this there results the proposition [31]: *every geostrophic current allows two inertial oscillations, one of short, the other of long period.*

We shall now show that the inertial oscillation of short period is associated with the stability of hydrostatic equilibrium in the vertical direction z, and that the long-period oscillation is associated with the stability of hydrodynamic equilibrium in the isentropic surfaces [34, 37].

To the approximation $\omega_x = \omega_y = 0$, we have $\nu_S \cong \sqrt{b} \cong \sqrt{\frac{g}{\Theta}\frac{\partial\Theta}{\partial z}} \equiv \nu_s$, (critical circular frequency of Väisälä-Brunt). When hydrostatic stability prevails ($\partial\Theta/\partial z > 0$), ν_S is real, the corresponding displacement is a periodic function of time, and the short-period inertial oscillation is stable; on the other hand, when this equilibrium is unstable ($\partial\Theta/\partial z < 0$), ν_S is a pure imaginary, the corresponding displacement grows exponentially with time, and the oscillation is unstable.

Similarly we have

$$\nu_D \cong \sqrt{-\frac{a}{b}} \cong f\sqrt{1 - \frac{1}{f}\frac{\delta u}{\delta y}} \equiv \nu_d$$

(critical circular frequency of V. Bjerknes) and

$$\tau_D \cong \tau_0\left[1 - \frac{1}{f}\frac{\delta u}{\delta y}\right]^{-\frac{1}{2}},$$

where $\tau_0 \equiv 2\pi/f$ represents the Foucault pendulum half-day and the direction y is horizontal and perpendicular to current $\mathbf{u}$, pointing toward the left of this current (low-pressure region).

When the hydrodynamic equilibrium in the isentropic surfaces is stable ($\delta u/\delta y < f$), ν_D is real, the corresponding transverse displacement is a periodic function of time, and the inertial oscillation of long period is stable; on the other hand, when that equilibrium is unstable ($\delta u/\delta y > f$), ν_D is a pure imaginary, the corresponding displacement increases exponentially with time, and the oscillation is unstable. We also observe that the period τ_D is greater or less than the Foucault pendulum half-day depending on whether $\delta u/\delta y > 0$ or < 0. In the first case, which is the one usually encountered in the atmosphere, the period τ_D is of the same order of magnitude as the period of cyclonic waves. When, through an increase in the baroclinity, $\delta u/\delta y$ finally exceeds the threshold value f ($0 < f < \delta u/\delta y$) the quasi-isentropic inertial oscillations of period greater than the Foucault pendulum half-day and the hydrodynamic equilibrium for corresponding transverse displacements become unstable simultaneously. *It is worth noting that the inertial oscillation which may become unstable in the atmosphere is a quasi-isentropic oscillation whose period is precisely of the order of the period of atmospheric disturbances* [31], *and that this instability can appear only where these disturbances would normally occur* [34, 37].

In summary, there exists a unique and reciprocal correspondence between the stability and instability of inertial oscillations in the atmosphere on one hand, and the stability and instability of hydrostatic and hydrodynamic equilibrium on the other [34, 37].

Hydrodynamic Instability and Cyclogenesis in Extratropical Latitudes

Far from any perturbation, the vertical component of the velocity and the horizontal and vertical components of the acceleration of the air are practically zero. We can then reasonably assume that the state of geostrophic motion in these regions is that which precedes the initial stage of cyclogenesis. If we suppose that the geostrophic current $\mathbf{u}$ is zonal ($\alpha \equiv 0$, $\omega_x \equiv 0$), any particle displaced in the interior of this current from point (x, y, z) to point $(x + r_x, y + r_y, z + r_z)$ acquires an orbital motion according to equations (47) and (48)

$$\dot{r}_x = \left(f - \frac{\partial u}{\partial y}\right) r_y - \frac{\partial u}{\partial z} r_z, \qquad \ddot{r}_y = \psi_y, \qquad \ddot{r}_z = \psi_z. \tag{51}$$

Here ψ_y and ψ_z are the meridional and vertical components of the force ψ which acts on the displaced particle because of the nonuniformity of the field of flow $\mathbf{u}$ and of the field of potential temperature Θ associated with it [20]. These components are given by

$$\psi_y \cong -\nu_i^2 r_y + N r_z, \qquad \psi_z \cong N r_y - \nu_s^2 r_z, \tag{52}$$

where ν_s^2, ν_i^2, and N have been defined in (36), (37), and (34).

Let us first envisage a vertical displacement ($r_y \equiv 0$, $r_z \neq 0$). In this case the earth's rotation can be neglected ($f \cong 0$); therefore $\psi_y \cong 0$ and $\psi_z \cong -\nu_s^2 r_z$. Since the vertical distribution of mass is assumed to be stable, the vertical force ψ_z is a restoring force which tends to bring the displaced particle back to its point of departure, so that after several oscillations of short period (approximately 10 min) and of an amplitude which is smaller the greater the stability, the particle returns to its equilibrium position in the geostrophic current [39, 40]. Therefore, in an atmosphere possessing vertical hydrostatic equilibrium in which the air undergoes adiabatic transformations only, we can assume as a first approximation that on a synoptic scale the air particles are displaced along isentropic surfaces. The existence of these isentropic displacements, favored by vertical stability, led Rossby [29] to the concept of *lateral mixing* and Raethjen [27] to the similar idea of *Gleitaustausch* of the air.

To the approximation adopted above, the inertial oscillations of long period take place in the isentropic surfaces, and we are led to consider isentropic displacements. In this case we have $(\partial\Theta/\partial y)r_y + (\partial\Theta/\partial z)r_z \equiv 0$, and consequently the transverse force ψ which the surroundings apply to the displaced particle is horizontal to a first approximation; this gives $\psi_y \cong -\nu_d^2 r_y$ and $\psi_z \cong 0$. The horizontal orbital motion of the displaced particle is then defined by the differential system

$$\dot{r}_x - (\nu_d^2/f) r_y = 0, \qquad \ddot{r}_y + \nu_d^2 r_y = 0, \tag{53}$$

and the initial conditions $r_x = r_y = 0$ and $\dot{r}_x = 0$, $\dot{r}_y = v_0$, for $t = t_0 = 0$. Two cases can be distinguished depending on whether the meridional force is a restoring force ($\psi_y r_y < 0$, stability) or a force which carries the displaced particle always farther from its point of departure ($\psi_y r_y > 0$, instability) [39, 40].

First case: $\nu_d^2 \equiv f(f - \delta u/\delta y) > 0$. In this case the integral of (53) is an ellipse with parametric equations

$$r_x = \frac{v_0}{f}(1 - \cos \nu_d t), \qquad r_y = \frac{v_0}{\nu_d} \sin \nu_d t. \tag{54}$$

Having received at the initial instant a transverse impulse in the isentropic surface that contains it, the particle oscillates in this surface around an ellipse for which the longitudinal semiaxis is v_0/f and the horizontal projection of the transverse semiaxis is v_0/ν_d. The center of the ellipse lies on the longitudinal axis through the initial position, located with respect to that initial position in the same sense as current $\mathbf{u}$ or in the opposite sense depending on whether the particle rises ($v_0 > 0$) or descends ($v_0 < 0$) along the isentropic surface. The major axis of the ellipse is longitudinal or transverse depending on whether the vorticity, produced by the geostrophic current in the isentropic surface, is cyclonic ($\delta u/\delta y < 0$, great stability) or weakly anticyclonic ($0 < \delta u/\delta y < f$, slight stability). The ellipse reduces to an inertial circle when $\delta u/\delta y = 0$. The elliptical motion of the perturbed particle has a period $2\pi/\nu_d \geqq 20$ hours. Since $\dot{r}_x >$ or < 0 as $r_y >$ or < 0, the motion takes place in the anticyclonic sense. The surrounding medium, however, opposes this anticyclonic circulation, since in the stable case the dis-

placed particles do negative work at the expense of the energy of the neighboring air; displacement along the arc of the ellipse ceases as soon as the kinetic energy of the initial impulse is dissipated. Because of our original hypotheses, the displaced particles cannot describe their entire inertial trajectory, for they lose their individuality in a time less than $2\pi/\nu_d$. The particles descending the slope of an isentropic surface, following an elliptical arc, acquire a zonal velocity $u + \dot{r}_x$, less than that of the current u; those climbing the slope acquire a zonal velocity $u + \dot{r}_x$, greater than u. This transverse isentropic exchange, if it can be maintained, thus involves a weakening of the cyclonic vorticity ($-\delta u/\delta y > 0$) or an intensification of the anticyclonic vorticity ($0 > -\delta u/\delta y > -f$), that is, a decrease of the hydrodynamic stability in the isentropic surfaces or even the appearance of hydrodynamic instability.

Second case: $\nu_d^2 \equiv f(f - \delta u/\delta y) < 0$. In this case the integral of (53) is a hyperbola with the parametric equations

$$r_x = \frac{v_0}{f}(1 - \cosh|\nu_d|\, t), \qquad r_y = \frac{v_0}{|\nu_d|}\sinh|\nu_d|\, t. \quad (55)$$

Once the particle receives its velocity v_0, its distances r_x and r_y from initial position ($r_x = r_y = 0$) increase exponentially with time. Moving in the isentropic surface which passes through its point of departure, the particle traces a branch of a hyperbola, for which the longitudinal semiaxis is v_0/f and the horizontal projection of the transverse semiaxis is $v_0/|\nu_d|$. The center of the hyperbola lies on the longitudinal axis through the initial position, located with respect to that initial position in the same or in an opposite sense as the current u, depending on whether the particle rises ($v_0 > 0$) or descends ($v_0 < 0$) along the isentropic surface. The longitudinal axis is the transverse[1] axis of the hyperbola and is the major or minor axis depending on whether $\delta u/\delta y >$ or $< 2f$. The hyperbola is equilateral when $\delta u/\delta y = 2f$. We observe that the curvature of the branch of the hyperbola increases with the hydrodynamic instability. However, here $\dot{r}_x$ is $>$ or < 0 as $r_y <$ or > 0 and consequently the unstable isentropic inertial oscillation generates cyclonic circulation. Once set in motion, this circulation is maintained by the energy of instability released in the course of the isentropic displacement of the air particles. As before, it could be shown that the transverse isentropic exchange of air involves in this case a weakening of anticyclonic vorticity ($0 > -f > -\delta u/\delta y$), that is, a diminution of the hydrodynamic instability. *The cyclonic circulation which results from transverse isentropic displacement of the air in an unstable geostrophic flow tends to reestablish a state of stable dynamic equilibrium in the isentropic surfaces.* The result of this stabilizing action is that isentropic hydrodynamic instability is only a transitory state of short duration, which, according to what we have seen earlier, can develop only in regions of pronounced baroclinity.

1. As used here, the term "transverse" refers to the axis which passes through the vertices of the hyperbola.

This being established, it follows directly from the definition of the isentropic meridional gradient $\delta u/\delta y$ of a westerly geostrophic current u and from the criterion for hydrodynamic instability that this instability can appear only when the surfaces Θ = const and u = const are closely packed and intersect one another at a large angle. By referring to the vertical meridional cross sections of Palmén [22–24], we can verify that these conditions are established in only two regions [40]: (1) in the upper troposphere between 200 and 500 mb south of the belt of maximum westerlies, where $\delta u/\delta y - f$ is positive and of the order 10^{-5} sec^{-1}, and (2) in the lower troposphere between 600 and 900 mb in the zone of the polar front and immediately north of it. We observe that in the latter region the isopleths of Θ should be replaced by isopleths of the wet-bulb potential temperature, whose slopes are necessarily larger; actually therefore, the hydrodynamic instability in this portion of the lower troposphere is greater than Palmén's cross sections make it appear. In these two regions, hydrodynamic instability may occur.

On the other hand, (1) in the higher troposphere north of the belt of maximum westerlies the isopleths u = const and Θ = const are practically parallel, and (2) in the lower troposphere south of the belt of maximum westerlies the isopleths Θ = const are nearly horizontal. Hence these two regions are normally characterized by pronounced hydrodynamic stability [40]. In the higher troposphere, consequently, meridional isentropic displacements of air particles bring about the formation of cyclonic circulation at low latitudes in the temperate zone and anticyclonic circulation at higher latitudes [40]. The existence of these two circulations has been demonstrated by Rossby, Palmén, and their collaborators [32]. On the other hand, in the lower troposphere, meridional isentropic displacements of air particles bring about the formation of cyclonic circulation at high latitudes in the temperate zone and anticyclonic circulation at low latitudes in this zone. The existence of this latter circulation was shown by Wexler and Namias [45]. The cyclonic circulations at middle latitudes in the lower troposphere are simply those characterizing the normal activity of the polar front.

In summary, when the geostrophic motion becomes unstable for isentropic and quasi-isentropic transverse displacements in a baroclinic region of the atmosphere, the surrounding medium favors these displacements; the displaced particles set free energy of instability which augments the kinetic energy of the initial impulse [35–37]. Moreover, they acquire cyclonic circulation relative to the geostrophic current along branches of hyperbolas whose conjugate axes are perpendicular to the geostrophic flow [39].

Thus we perceive that an isentropic inertial oscillation of period greater than the Foucault pendulum half-day ($2\pi/f$), *which becomes unstable in a region of large baroclinity, may give rise to a cyclonic circulation.* A *nascent* cyclonic circulation hence seems to be no more than an unstable inertial oscillation of the atmosphere [31, 37]. But such a circulation inevitably involves major displacements of air and consequently a perturbation

of the pressure field. The motion then set up loses its inertial character. In short a theory of cyclogenesis cannot be established without consideration of a pressure perturbation [31, 42].

Hydrodynamic Instability and the Theory of Atmospheric Perturbations

In order to simplify the equations, we will designate by x^1 the horizontal meridional coordinate y and by x^2 the vertical coordinate z; hence the Eulerian variables x, y, z, and t will here be written x, x^1, x^2, and t. In this system of notation we have: $\omega_x \equiv 0$, $2\omega_y \equiv 2\omega \cos \phi = \partial W/\partial x^2$ and $2\omega_z \equiv f \equiv 2\omega \sin \phi = -\partial W/\partial x^1$, where $\mathbf{W} \equiv \boldsymbol{\omega} \times \mathbf{R}$ represents the linear velocity due to the earth's rotation. Equation (1) of zonal "simple motion" then assumes the form [42]

$$S\nabla P = \Theta\nabla\Pi = u\nabla W - \nabla\Phi, \tag{56}$$

while the equilibrium condition (2) can be written

$$\nabla u \times \nabla W = \nabla U \times \nabla W = \nabla\Theta \times \nabla\Pi = \nabla S \times \nabla P, \tag{57}$$

where $u \equiv u(x^1, x^2)$ represents the intensity of the westerly current, $U \equiv U(x^1, x^2) = W + u$ the absolute zonal current, and $S = S(x^1, x^2)$ the specific volume of air.

This being the case, the equations of adiabatic "small motions" [2] which can be superimposed on simple zonal motion (56) can be written [42]

$$Dv_x + \frac{\partial U}{\partial x^i} v^i + S\frac{\partial p}{\partial x} = 0, \tag{58}$$

$$Dv^i - \frac{\partial W}{\partial x^i} v_x + S\frac{\partial p}{\partial x^i} + s\frac{\partial P}{\partial x^i} = 0, \tag{59}$$

$$Ds + \frac{\partial S}{\partial x^i} v^i - S\frac{\partial v_x}{\partial x} - S\frac{\partial v^i}{\partial x^i} = 0, \tag{60}$$

$$Ds + \frac{S^2}{C^2} Dp + \frac{S}{\Theta}\frac{\partial\Theta}{\partial x^i} v^i = 0, \tag{61}$$

where $i = 1, 2$; p designates the perturbation pressure; s, the corresponding perturbation of specific volume; C, Laplace's speed of sound,

$$C^2 \equiv (c_p/c_v)PS \equiv (c_p/c_v)RT \approx 10^5 \text{ m}^2 \text{ sec}^{-2} \text{ [2]};$$

c_v, the specific heat at constant volume; T, the absolute air temperature; v_x, the zonal component; $v_y \equiv v^1$, the meridional component; and $v_z \equiv v^2$, the vertical component of the perturbation velocity v relative to the earth. We have also substituted $D \equiv \partial/\partial t + u\partial/\partial x$. The operator D represents the local derivative with respect to time t in a refereuce system embedded in the zonal current **u**. By eliminating v_x and s among the Eulerian equations (58), (59), and the equation of the adiabatic process (61), we obtain the equations of transverse perturbation motion (v^1, v^2) as a function of perturbation pressure p; these are

$$D^2 v^i + a_{ij} v^j = \frac{S^2}{C^2}\frac{\partial P}{\partial x^i} Dp - \frac{\partial W}{\partial x^i} S\frac{\partial p}{\partial x} - SD\frac{\partial p}{\partial x^i}, \tag{62}$$

where, (57),

$$a_{ij} \equiv \frac{\partial W}{\partial x^i}\frac{\partial U}{\partial x^j} - \frac{S}{\Theta}\frac{\partial P}{\partial x^i}\frac{\partial\Theta}{\partial x^j} \equiv \frac{\partial W}{\partial x^j}\frac{\partial U}{\partial x^i} - \frac{S}{\Theta}\frac{\partial P}{\partial x^j}\frac{\partial\Theta}{\partial x^i} \equiv a_{ji} \tag{63}$$

are simply the coefficients (12) of Kleinschmidt's quadratic form Q (13).

We next eliminate v_x and s between the equation (58) of zonal perturbation motion and the equations of continuity (60) and the adiabatic process (61),

$$D\frac{\partial v^i}{\partial x^i} + \frac{S}{C^2}\frac{\partial P}{\partial x^i} Dv^i - \frac{\partial U}{\partial x^i}\frac{\partial v^i}{\partial x} + S\left(\frac{D^2 p}{C^2} - \frac{\partial^2 p}{(\partial x)^2}\right) = 0. \tag{64}$$

System (62) and (64) of three equations containing partial derivatives of three unknown functions v^1, v^2, and p with respect to the independent variables x, x^1, x^2, and t, must be integrated under the following conditions at the external boundaries:

$$\left.\begin{aligned} &(a) \text{ at the surface of the globe:} \\ &\qquad x^2 \equiv z = 0; \qquad v^2 \equiv v_z = 0, \\ &(b) \text{ at the free surface:} \\ &\qquad P(x^1, x^2) + p(x, x^1, x^2, t) = \text{const}; \\ &\qquad Dp + (\partial P/\partial x^i)v^i = 0. \end{aligned}\right\} \tag{65}$$

We observe that setting $p \equiv 0$ in the differential system (62) reduces it to the differential system (48) for inertial oscillations of a zonal geostrophic current ($\omega_x \equiv 0$) and that the characteristic determinant

$$D^4 + (a_{11} + a_{22})D^2 + a_{11}a_{22} - (a_{12})^2$$

of (62) is formally identical with the left side (49) of Solberg's equation of circular frequencies. This circumstance demonstrates *the influence of the nature of the inertial oscillations or, what amounts to the same thing, the influence of the nature of the hydrodynamic equilibrium upon the solution of the differential system* (62) *and* (64) *for transverse perturbation motion.*

After having thus stated in all its generality the problem in mathematical analysis posed by the theory of perturbations, we make the customary restriction to a sinusoidal disturbance which is propagated by plane waves with constant velocity c parallel to the zonal axis x. In this case the quantities v_x, v^i, s, and p are proportional to $\exp[\sqrt{-1}\,\mu(x - ct)]$, with $\mu \equiv 2\pi/L$, where L is the wave length. We designate by ξ, ξ^i, σ, and ϖ the amplitudes of these quantities, which are functions of the transverse coordinates x^1 and x^2. The differential system (62) gives the amplitudes ξ^i directly as functions of ϖ; we find [42]

$$\xi^i = -\sqrt{-1}\,\mu(u - c)\,SA^{ij}\left(\frac{\partial\varpi}{\partial x^j} - K_j\varpi\right), \qquad (i, j = 1, 2) \tag{66}$$

where A^{ij} is the normalized algebraic minor of the element $A_{ij} \equiv -\mu^2(u - c)^2\gamma_{ij} + a_{ij}$ of the determinant $A \equiv \| A_{ij} \|$, with $\gamma_{ij} \equiv 1$ when $i \equiv j$ and $\equiv 0$ when

$i \neq j$. In (66) the K_j's are the components of the transverse vector

$$\mathbf{K} = \frac{S\nabla P}{C^2} - \frac{\nabla W}{u-c} = -\frac{\nabla W}{u-c}\left(1 - \frac{u(u-c)}{C^2}\right) - \frac{\nabla\Phi}{C^2}. \tag{67}$$

Equation (66) has meaning only if $A \neq 0$, that is, when the orbital circular frequency $\nu_0 \equiv \mu(c-u)$ of the perturbation is different from the circular frequencies ν_S and ν_D for inertial oscillations. When $\nu_0 \equiv \nu_S$ (or ν_D), and this may occur at certain points of the transverse plane, the amplitude relations deduced from (62) are compatible only if

$$\left(\frac{\partial\varpi}{\partial x^1} - K_1\varpi\right) \Big/ \left(\frac{\partial\varpi}{\partial x^2} - K_2\varpi\right) = A_{11}/A_{12} = A_{21}/A_{22}$$

at the above-mentioned points.

Continuing the analysis, we substitute (66) into (58) and (61) and obtain the amplitudes ξ and σ as functions of ϖ, that is,

$$\left.\begin{aligned} \xi &= SA^{ij}\frac{\partial U}{\partial x^i}\left(\frac{\partial\varpi}{\partial x^j} - K_j\varpi\right) - \frac{S\varpi}{u-c}, \\ \sigma &= \frac{S^2A^{ij}}{\Theta}\frac{\partial\Theta}{\partial x^i}\left(\frac{\partial\varpi}{\partial x^j} - K_j\varpi\right) - \frac{S^2\varpi}{C^2}. \end{aligned}\right\} \tag{68}$$

Finally we replace ξ^i, ξ, and σ in (60) by their values in (66) and (68); there results an equation in the partial derivatives of amplitude ϖ of the perturbation pressure p [31, 42],

$$\frac{1}{S}\frac{\partial}{\partial x^i}\left(SA^{ij}\frac{\partial\varpi}{\partial x^j}\right) - \left[\frac{1}{S}\frac{\partial}{\partial x^i}(SA^{ij}K_j) + A^{ij}K_iK_j - \frac{1}{(u-c)^2}\left(1 - \frac{(u-c)^2}{C^2}\right)\right]\varpi = 0. \tag{69}$$

We observe at once that equation (69) is of elliptic or hyperbolic type depending on whether $A >$ or < 0. The determinant $A \equiv \|A_{ij}\| \equiv \nu_0^4 - (a_{11} + a_{22})\nu_0^2 + a_{11}a_{22} - (a_{12})^2$ is identical with the first member of the equation for circular frequencies of inertial oscillation; therefore, we have $\|A_{ij}\| \equiv (\nu_0^2 - \nu_D^2)(\nu_0^2 - \nu_S^2)$. Since $|\nu_0| < |\nu_D| \ll |\nu_S|$ and $\nu_S^2 > 0$ in the atmosphere, $A >$ or < 0 as $\nu_D^2 >$ or < 0; there follows the proposition [42]: *the partial differential equation in the perturbation pressure is of elliptic or hyperbolic type depending on whether the geostrophic motion is stable or unstable.*

The amplitude ϖ which solves the present problem is that solution of the second order equation (69) which satisfies the boundary conditions [42]

$$\left.\begin{aligned} &A^{2i}\left(\frac{\partial\varpi}{\partial x^i} - K_i\varpi\right) = 0 \\ &\text{for } x^2 = 0 \text{ (or } z = 0), \text{ and} \\ &SA^{ij}\frac{\partial P}{\partial x^i}\left(\frac{\partial\varpi}{\partial x^j} - K_j\varpi\right) - \varpi = 0 \\ &\text{for } P(x_1, x_2) + \varpi(x^1, x^2)\exp\left[\sqrt{-1}\,\mu(x - ct)\right] \\ &= \text{const.} \end{aligned}\right\} \tag{70}$$

It is probable (1) that the existence of a solution ϖ of (69) satisfying (70) implies a dispersion equation among the quantities ν_s^2, ν_i^2, and N, characteristic of the simple motion, on one hand, and the wave length L and the speed of propagation c of the perturbation on the other hand; and (2) that the condition as to whether the dispersion equation has imaginary roots c depends on the sign of $\nu_i^2\nu_s^2 - N^2$, that is, the hydrodynamic stability. However, hydrodynamic instability is only a sufficient condition for dynamic instability of the perturbation, since selective instability of a perturbation is possible even in the case of a stable "simple motion."

Clearly the problem of these perturbations is so difficult that drastic assumptions are inevitable if one really wishes to undertake its solution. Generally the discussion is confined to homogeneous ($S \equiv$ constant), incompressible ($C = \infty$), or isothermal ($C \equiv$ constant) media; vertical accelerations are neglected (quasi-static hypothesis); the basic flow $\mathbf{u}$ is assumed to be constant or at most to be linearly dependent on altitude z [3], or it is assumed that the current $\mathbf{u}$ consists of two constant, parallel, adjacent flows; sometimes the meridional component of the perturbation velocity is even assumed to be geostrophic [3]. The effect of these simplifications is to make the partial differential equation (69) degenerate into an ordinary differential equation, integrable by means of simple functions.

Four fundamental factors are involved in the general equations (62) and (64): (1) *gravity* g (gravity waves), (2) *compressibility* C^{-2} (sound waves), (3) *the earth's rotation* (inertial waves) and the variation of the Coriolis parameter with latitude (planetary waves [28]) and (4) the *zonal current* u and its vertical and meridional gradients (shear waves). Examination, employing simple media, of each of these factors separately (the others being assumed to be zero) demonstrates that the atmospheric perturbations ($c \cong 10$ m sec^{-1}, $L \cong 10^6$ m) can be compared to inertial waves whose instability results from the gradient of u [2, 31].

On the whole, the qualitative results of the perturbation theory have been obtained under assumptions which are never even approximately realized in the atmosphere. To be convinced of this it is sufficient to refer to recently published vertical cross sections of the "jet stream" [22–24, 32]. The perturbations which interest us are those of a zonal baroclinic ($N \neq 0$) current whose intensity u depends not only on altitude z but also on latitude y. *The problem of atmospheric perturbations is thus one in partial differential equations* and not a problem of an ordinary differential equation. The synoptic weather charts show that the propagation velocity c and the wave length L are such that products and squares of the ratios u/C, c/C, and $(u-c)/C$, as well as the square of the ratio $[2\pi(u-c)/L]/f$, are negligible compared to unity [3, 4]. One is then justified in making these approximations, but they must be introduced *not* into the initial equations (58) to (61), which must retain all their generality, but *rather* into the final equation (69).

To this end we must calculate expressions for A^{ij} and K_i, substitute them into equations (69) and (70), carry out the derivations involving y and z, and finally estimate the order of magnitude of the terms in these equations, taking into account the above-mentioned approximations. By neglecting terms of order 10^{n-2} compared with those of order 10^n, we would obtain the approximate differential system of atmospheric perturbations, which would then have to be integrated. Unfortunately, it is impossible at present to make this choice of terms, for we have not drawn up tables giving the orders of magnitude of the meteorological elements and their first and second derivatives with respect to space and time as functions of altitude and latitude. It seems urgent to us to prepare such tables with the help of the sufficiently extensive aerological data which is already at our disposal.

Meanwhile, using Charney's theory of meteorological approximations [4], we can deduce from general equation (69) the approximate partial differential equation of the perturbation pressure associated with quasi-static, quasi-geostrophic long waves. There is obtained [43]

$$\frac{\nu_s^2}{f^2}\frac{\partial^2\varpi}{\partial y^2} + \frac{\partial^2\varpi}{\partial z^2} + \left[\frac{2}{S}\frac{\partial S}{\partial z} - \frac{g}{RT} - \frac{1}{T\nu_s^2}\frac{\partial(T\nu_s^2)}{\partial z}\right]\frac{\partial\varpi}{\partial z} - \left\{\frac{\nu_s^2\mu^2}{f^2}\left(1 - \frac{u_c}{u-c}\right) + \frac{1}{u-c}\left[\frac{\nu_s^2}{f^2}\frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2} - \left(\frac{g}{RT} + \frac{1}{T\nu_s^2}\frac{\partial(T\nu_s^2)}{\partial z}\right)\frac{\partial u}{\partial z}\right] + \frac{1}{S}\frac{\partial S}{\partial z}\frac{1}{T\nu_s^2}\frac{\partial(T\nu_s^2)}{\partial z}\right\}\varpi = 0, \tag{71}$$

where T designates the absolute air temperature and where $u_c \equiv (\partial f/\partial y)/\mu^2$ is the critical speed introduced by Bjerknes and Holmboe [1], that is, the intensity of zonal flow which corresponds to stationary, planetary waves of wave length $L \equiv 2\pi/\mu$ (Rossby [28]). Equations (66) and (68) reduce to

$$\xi^1 \equiv \eta = \sqrt{-1}\,\frac{\mu S}{f}\varpi,$$
$$\xi^2 \equiv \zeta = -\sqrt{-1}\,\frac{\mu(u-c)^2}{\nu_s^2}\frac{\partial}{\partial z}\left(\frac{S\varpi}{u-c}\right), \tag{72}$$

$$\xi \equiv -\frac{S}{f}\frac{\partial\varpi}{\partial y}, \qquad \sigma = \frac{S^2}{g}\frac{\partial\varpi}{\partial z}. \tag{73}$$

Equation (71) is identical with that of Charney [4] when T depends linearly on z (that is, $\partial(T\nu_s^2)/\partial z \equiv 0$, see eq. (36)) and u is a function of z only. Dividing the first term of (71) by ν_s^2, and letting ν_s^2 approach infinity, one obtains Kuo's equation [19].

Equation (71) is to be integrated with suitable boundary conditions. The boundary conditions other than those referring to the earth's surface ($\zeta = 0$ for $z = 0$) must be carefully chosen, for on them depend the form of the dispersion equation and the expression for the criterion of selective instability. The boundary conditions being linear in the unknown function and its first derivatives, the integration of equation (71) is a problem of the classic "mixed" type. This integration can be achieved only with computing machines.

It should be observed that in the case considered here the "simple motion" is a weakly baroclinic zonal current u ($N \approx 10^{-7}$) in which the isentropic surfaces have a slope of the order of 10^{-3}. Under these conditions equation (71) is always of elliptic type; for this reason any hydrodynamic instability is excluded and only the selective instability is possible. The constant c is then complex ($c = c_r + \sqrt{-1}c_i$), as is the function ϖ (that is, $\varpi \equiv \varpi' + \sqrt{-1}\,\varpi''$), so that the perturbation pressure assumes the form

$$p = e^{c_i\mu t}[\varpi'(y, z)\cos\mu(x - c_r t) - \varpi''(y, z)\sin\mu(x - c_r t)]. \tag{74}$$

Here the real functions ϖ' and ϖ'' satisfy a system of partial differential equations of elliptic type which is easy to deduce from (71). In this case the form of the perturbation pressure p demonstrates the phase lag, both in altitude and latitude, which the troughs and ridges of unstable perturbations undergo. The meridional tilt of the axes of troughs and ridges is an essential characteristic of atmospheric perturbations. Their tilt relative to the meridians assures the transport of zonal momentum and kinetic energy along them.

The Stability of Permanent, Horizontal, Isobaric Motion

When the air is in permanent, horizontal, isobaric motion, the atmosphere is said to be in a state of hydrodynamic equilibrium. The dynamic method which we employed (pp. 434–437) for the case of rectilinear isobars can be applied to the case of curvilinear isobars, provided we use a system of orthogonal curvilinear coordinates σ^1, σ^2, σ^3, fixed relative to the earth and having one (σ^1) of the three families of coordinate lines coincident with the lines of intersection between the isobaric surfaces and the equipotential surfaces of the gravity field. Let $Oxyz$ be a right-handed, rectangular Cartesian coordinate system of origin O, in which the axes are tangent to the coordinate lines passing through O; axis Ox points in the direction of the isobaric motion. We designate by $u \equiv u(\sigma^1, \sigma^2)$ the velocity of air along the isobars obtained by varying σ^1 (gradient wind), by R_y the radius of geodesic curvature, and by R_z the radius of normal curvature at O of isobar σ^1 considered as a line in the surface $\sigma^3 = \sigma_0^3$ passing through O. By then adopting without change the reasoning presented on pages 434–437, we find that the equilibrium between gravity, the pressure gradient, the centrifugal force, and the Coriolis force at point O, for a transverse displacement (r_y, r_z) from this point, is stable or unstable depending on whether [41]

$$Q(r_y, r_z) \equiv a_{yy}r_y^2 + 2a_{yz}r_y r_z + a_{zz}r_z^2 > \text{ or } < 0, \tag{75}$$

where

$$
\begin{aligned}
a_{yy} &\equiv 2\left(\omega_z + \frac{u}{R_y}\right)\left(2\omega_z - \frac{\partial u}{\partial y} + \frac{u}{R_y}\right) - \frac{\partial \Pi}{\partial y}\frac{\partial \Theta}{\partial y}, \\
a_{yz} &\equiv -2\left(\omega_z + \frac{u}{R_y}\right)\left(2\omega_y + \frac{\partial u}{\partial z} - \frac{u}{R_z}\right) - \frac{\partial \Pi}{\partial y}\frac{\partial \Theta}{\partial z}, \\
a_{zy} &\equiv -2\left(\omega_y - \frac{u}{R_z}\right)\left(2\omega_z - \frac{\partial u}{\partial y} + \frac{u}{R_y}\right) - \frac{\partial \Pi}{\partial z}\frac{\partial \Theta}{\partial y}, \\
a_{zz} &\equiv 2\left(\omega_y - \frac{u}{R_z}\right)\left(2\omega_y + \frac{\partial u}{\partial z} - \frac{u}{R_z}\right) - \frac{\partial \Pi}{\partial z}\frac{\partial \Theta}{\partial z},
\end{aligned}
\tag{76}
$$

with $a_{yz} \equiv a_{zy}$. We note that in the differential quotients on the right-hand sides of (76), dy and dz represent elements of arc along the coordinate lines σ^2 and σ^3 and that these elements of arc are not in general exact differentials [41].

There is an obvious analogy between the quadratic form (75) and equation (13) which holds in the case of geostrophic motion. In the case of isobaric motion, this form retains the dynamical significance and the interpretation on an energy basis of Kleinschmidt's form (see pp. 434–437). Moreover, we can apply the discussion of Kleinschmidt's quadratic form to the sign of this form. If we assume the vertical distribution of mass to be stable in the field of gravity, the state of isobaric motion is then stable at any point, whatever the transverse displacements from the point, with the exception of displacements close to the isentropic surface when

$$\nabla\Theta \cdot \operatorname{curl} \mathbf{U} \equiv \frac{\partial \Theta}{\partial y} \operatorname{curl}_y \mathbf{U} + \frac{\partial \Theta}{\partial z} \operatorname{curl}_z \mathbf{U} < 0,$$

where

$$\operatorname{curl}_x \mathbf{U} \equiv 2\omega_x, \qquad \operatorname{curl}_y \mathbf{U} \equiv 2\omega_y + \frac{\partial u}{\partial z} - \frac{u}{R_z},$$

$$\operatorname{curl}_z \mathbf{U} \equiv 2\omega_z - \frac{\partial u}{\partial y} + \frac{u}{R_y};$$

$\mathbf{U} \equiv \mathbf{W} + \mathbf{u}$ being the absolute velocity of the air.

When the coordinate surfaces $\sigma^3 = \text{const}$ are equipotential surfaces in the field of gravity, the z-axis coincides with the zenith direction at the origin. If we assume that the equigeopotential surfaces are spherical and concentric with the earth, $R_z = -r$, where r stands for the distance from the earth's center to the point under consideration. In this case, R_y represents the radius of curvature at O of the horizontal projection of the isobar obtained by varying σ^1; in synoptic meteorology R_y is "the radius of curvature R_{is} of the isobar" at this point, ($R_y \equiv R_{is}$). We note that $R_{is} > 0$ or < 0, depending on whether the circulation along the isobar is cyclonic or anticyclonic at the point considered. Since $2\omega_y + u/r$ is negligible compared to $\partial u/\partial z$, it is evident that the isobaric motion is unstable in the neighborhood of the isentropic surfaces when

$$\frac{\delta u}{\delta y} > f + \frac{u}{R_{is}}, \tag{77}$$

where $\delta u/\delta y$ has been defined by (35). This formula shows that the threshold value $f + u/R_{is}$ of the instability of isobaric motion is higher or lower than the threshold value f of the instability of geostrophic motion ($R_{is} = \infty$) depending on whether the curvature of the isobar is positive or negative. *Anticyclonic circulation thus favors hydrodynamic instability* [41].

When the isobar at O coincides with the parallel through this point, $R_{is} \equiv r \operatorname{ctn} \phi$, where ϕ is the latitude of O; here the limit of hydrodynamic instability is given by the approximate expression [22, 41]

$$\frac{\delta u}{\delta y} \cong 2\omega \sin \phi + \frac{u \tan \phi}{r}. \tag{78}$$

By virtue of the instability criterion (77) for a permanent, isobaric, horizontal current, cyclonic currents as a whole are more stable than anticyclonic currents. Let us assign an arbitrary value ($\delta u/\delta y$) to the transverse isentropic gradient $\delta u/\delta y$ of the isobaric current u. Let us suppose that it satisfies the condition most generally encountered, that is, $\delta u/\delta y < f$. The domain of stable currents will then be separated from the domain of unstable currents by an anticyclonic current of the curvature $1/R^*_{is} = (1/u)[(\delta u/\delta y) - f] < 0$. In this case, the geostrophic current ($R_{is} = \infty$), the limit between the domains of cyclonic and anticyclonic currents, will be located within the domain of stable currents composed of all cyclonic currents and of weakly anticyclonic currents ($|R_{is}| > |R^*_{is}|$). The domain of unstable flow contains only anticyclonic currents with a radius of curvature less than $|R^*_{is}|$.

Let us now admit, following Wippermann [46], the *existence of a transverse isentropic exchange* of air particles. When the current u is stable, this exchange can maintain itself only at the expense of the surrounding medium, and the displaced particles acquire an anticyclonic circulation with respect to the current u (see p. 442), thereby attenuating the curvature of the current u when it is cyclonic or reinforcing it when it is weakly anticyclonic ($|R_{is}| > |R^*_{is}|$). In this case, the current u, whether cyclonic ($R_{is} > 0$) or weakly anticyclonic ($R_{is} < 0$ with $|R_{is}| > |R^*_{is}|$) will be transformed progressively into an anticyclonic current whose radius of curvature will approach the limit $|R^*_{is}| \approx 10^6$ m. On the other hand, if the current u were unstable ($R_{is} < 0$ and $|R_{is}| < |R^*_{is}|$), the transversely displaced particles in the isentropic surfaces would acquire a cyclonic circulation (see p. 443) with respect to the current u, releasing energy of instability. The anticyclonic curvature of the unstable current u would thereupon diminish, that is, the current u would spontaneously become a current within the domain of stability. Summarizing, we may say that an anticyclonic current whose radius of curvature $|R_{is}| > |R^*_{is}|$ approaches the limit $|R^*_{is}|$ would thus appear to be a current of some persistence [46].

Inasmuch as hydrodynamic instability is a transitory state of ephemeral duration, it will not manifest itself unless its cause is of even less duration (*i.e.*, produced instantaneously); according to Kleinschmidt

[18], large-scale condensation is such a cause. The gradient $\delta u/\delta y$ in a cloud layer should be determined in surfaces of equal wet-bulb potential temperature rather than in surfaces of equal dry-bulb potential temperature. Inasmuch as the slope of the former is much more marked than that of the latter, it follows that $\delta u/\delta y$ undergoes, at the moment of condensation, a sudden increase which is capable of bringing about hydrodynamic instability ($\delta u/\delta y > f$). We then have $R_{is}^* > 0$ and, as a result, the current u will spontaneously become a cyclonic current of the stable domain ($0 < R_{is} \lesseqgtr R_{is}^*$) (cyclogenesis according to Wippermann [46]).

The Permanent Circular Vortex. Application to Tropical Cyclones

The problem of the stability of this state of motion has been treated in several different ways [2, 5, 6, 8, 9, 13–18, 21, 31]; we will consider it here as a special case of permanent, horizontal, isobaric motion. To this end we compare the atmosphere to a circular vortex around the polar axis and at some point O we adopt Kleinschmidt's coordinate system $OXYZ$, having axis OX tangent to the parallel through O and directed eastward, and axis OY perpendicular to the vortex axis and directed toward the earth's interior. Under these conditions, $dY = -dR$, $R_y = R$, $R_z = \infty$; where R is the radius of rotation from O; there follows from (76),

$$\left.\begin{aligned} a_{YY} &\equiv 2\left(\omega + \frac{u}{R}\right)\left(2\omega - \frac{\partial u}{\partial Y} + \frac{u}{R}\right) - \frac{\partial \Pi}{\partial Y}\frac{\partial \Theta}{\partial Y}, \\ a_{YZ} &\equiv -2\left(\omega + \frac{u}{R}\right)\frac{\partial u}{\partial Z} - \frac{\partial \Pi}{\partial Y}\frac{\partial \Theta}{\partial Z}, \\ a_{ZY} &\equiv -\frac{\partial \Pi}{\partial Z}\frac{\partial \Theta}{\partial Y}, \qquad a_{ZZ} \equiv -\frac{\partial \Pi}{\partial Z}\frac{\partial \Theta}{\partial Z}, \end{aligned}\right\} \tag{79}$$

where $a_{YZ} \equiv a_{ZY}$, and $u \equiv u(R, Z)$ represents the zonal velocity of the air. The discriminant a reduces here to

$$\begin{aligned} a &\equiv a_{YZ}^2 - a_{YY}a_{ZZ} \\ &\equiv 2\left(\omega + \frac{u}{R}\right)\frac{g_z}{\Theta}\frac{\partial \Theta}{\partial Z}\left[\frac{\delta u}{\delta Y} - 2\omega - \frac{u}{R}\right], \end{aligned} \tag{80}$$

where g_z is the absolute value of the component of gravity parallel to the earth's axis.

Since the inequality $\partial\Theta/\partial Z > 0$ generally holds in the atmosphere, the permanent circular vortex is stable or unstable depending on whether

$$\frac{\delta u}{\delta Y} < \text{or} > 2\omega + \frac{u}{R}. \tag{81}$$

The circulation along the parallels being cyclonic or anticyclonic as $u >$ or < 0, we observe that anticyclonic circulation favors the instability of the vortex. Consequently an easterly zonal circulation will become unstable more easily than a westerly one. Since the zonal circulation is easterly in tropical latitudes and westerly in temperate latitudes, and the Coriolis parameter increases with latitude, it is evident from (78) that the zonal circulation in tropical regions can reach the threshold of instability more easily than that of temperate regions. However, inasmuch as the isentropic surfaces in tropical latitudes are nearly horizontal, stabilization of the zonal circulation is favored there.

Finally it is easy to show, using criteria (81), that the permanent circular vortex is stable or unstable depending on whether its absolute angular momentum $\mathfrak{M} \equiv R(u + R\omega)$ increases ($\delta\mathfrak{M}/\delta R > 0$) or decreases ($\delta\mathfrak{M}/\delta R < 0$) toward the exterior of the vortex in the isentropic surfaces [2].

The state of neutral equilibrium ($\delta\mathfrak{M}/\delta R = 0$), characterized by the invariance of absolute angular momentum $\mathfrak{M}$ in the isentropic surfaces, would be the state of exchange equilibrium (*Austauschgleichgewicht*) according to Raethjen [27] and Kleinschmidt [18]. In other words it is that equilibrium condition toward which atmospheric air would tend if subjected to isentropic lateral mixing, Raethjen's *Gleitaustausch*, or Rossby's *lateral mixing*. If this condition prevailed, the lateral Reynolds stress T_x^y due to isentropic turbulence would be proportional to $\delta u/\delta y - f$ (neglecting the curvature term in (78)), where x represents the eastward tangent to the parallel and y the northward tangent to the meridian. However, this is true only if the isentropic turbulence is purely transverse. In reality the turbulent particles move in the isentropic surfaces parallel to the mean flow as well as perpendicular to it. Priebsch [25] has been able to show that the stress T_x^y is actually proportional to $\delta u/\delta y$ and *not* to $\delta u/\delta y - f$. As a result, the absolute angular momentum relative to the earth's axis of rotation is not an invariant property of isentropic exchange of air [44].

We observe that the permanent circular vortex satisfies an extremum principle [38] identical to that stated on page 436.

Moreover, the method we followed in studying the inertial oscillations of a geostrophic current (pp. 032–040) will naturally extend itself to cover the case of a stationary circular vortex [31]. We thus obtain the results which we had established earlier for the case of zonal geostrophic motion ($\omega_x \equiv 0$ or $\alpha \equiv 0, \pi$). Similarly, the equations of adiabatic perturbations of a permanent circular vortex can be derived in the same way as those for a zonal geostrophic current (pp. 444–446) provided cylindrical or spherical coordinates are used. This problem has recently been treated in terms of cylindrical coordinates, in a slightly different fashion, by Queney [26], who has in addition proposed a method for the simplification of the equations which differs from Charney's [4].

Let us further note that Fjørtoft [10] has recently taken up the study of the stability of stationary circular vortices with the aid of a new method based on the primary integral of the equations of motion (integral of the equation of mechanical energy) and utilizing the calculus of variations.

Finally, we consider a permanent circular vortex whose vertical axis z is located at latitude ϕ. If we designate by u the linear velocity of the vortex, $u > 0$

or < 0 depending on whether the vortex is cyclonic or anticyclonic relative to the earth. We shall assume that the vertical distribution of mass is stable. Then the vortex is unstable at any point for a transverse isentropic displacement from this point when, (80) and (81),

$$\frac{\delta u}{\delta R} + \frac{u}{R} + f < 0, \tag{82}$$

since the vorticity in the atmosphere is always cyclonic in a fixed, geocentric reference system ($u/R + f/2 > 0$, see equation (80) where $f/2$ must be substituted for ω). This being the case, to an isentropic displacement of radial component ΔR there corresponds an azimuthal motion of the displaced particle, whose velocity is given by, (7),

$$V_x = u - \left(f + \frac{\delta u}{\delta R} + \frac{u}{R}\right)\Delta R.$$

Here V_x denotes the particle's velocity along the parallel associated with the vortex. Consequently the cyclonic circulation, relative to the earth, of air particles subjected to a radial isentropic displacement toward the exterior of the vortex ($\Delta R > 0$), decreases or increases depending on whether the vortex is stable or unstable. It follows that *when the air particles in a vertically oriented, unstable, circular vortex undergo an outward radial, isentropic displacement, they release instability energy which reinforces their cyclonic circulation around the vertical axis of the vortex.* According to Sawyer [30], this mechanism plays an important role in the formation of tropical cyclones. The probable truth of this opinion is enhanced by the fact that at low latitudes the Coriolis parameter f is relatively small (10^{-5} sec^{-1}) so that condition (82) is more easily fulfilled there than in middle latitudes.

Inertial Oscillations of an Arbitrary Flow

Ertel [7] has given the equation of circular frequencies of the inertial oscillations of an air parcel in arbitrary motion. This more general problem has recently been taken up by W. L. Godson [11].

If the atmosphere is referred to a right-handed Cartesian system, $x^1x^2x^3$, chosen at random but at rest with respect to the earth, the equation of motion and the equation of continuity are, respectively,

$$\frac{d^2x^i}{dt^2} + 2\omega_{ki}\frac{dx^k}{dt} = -\Theta\frac{\partial\Pi}{\partial x^i} - \frac{\partial\Phi}{\partial x^i} = -S\frac{\partial P}{\partial x^i} - \frac{\partial\Phi}{\partial x^i} \quad (i, k = 1, 2, 3) \tag{83}$$

and

$$\frac{d}{dt}\left(\frac{\delta' x^1 \delta' x^2 \delta' x^3}{S}\right) = 0 \qquad \text{with } \delta' t \equiv 0,$$

in which $\omega_{ki} \equiv -\omega_{ik}$, are the antisymmetrical components of the rotation ω of the earth [41], and the repeated index k should be considered as a summation index (dummy index convention). In the general case considered here, S, Θ, P, Π are functions of x^i and of t, and Φ is a function of x^i. As in the case of geostrophic motion (see p. 435), let us associate to the equilibrium position $O(x_0^1, x_0^2, x_0^3)$ which a particle occupies at time t_0, the perturbed position

$$A(x^1 + \Delta x^1, x^2 + \Delta x^2, x^3 + \Delta x^3)$$

which this particle occupies at the later instant $t > t_0$ after receiving an impulse at O at time t_0. The unperturbed particle will occupy position $P(x^1, x^2, x^3)$ at time t.

The coordinate components Δx^i of the displacement $\mathbf{r} \equiv \overrightarrow{PA}$ should satisfy the variation equations deduced from (83), that is,

$$\frac{d^2\Delta x^i}{dt^2} + 2\omega_{ki}\frac{d\Delta x^k}{dt} = -\Delta\Theta\frac{\partial\Pi}{\partial x^i} - \Theta\,\Delta\frac{\partial\Pi}{\partial x^i} - \Delta\frac{\partial\Phi}{\partial x^i}, \tag{84}$$

with

$$\frac{\Delta S}{S} = \frac{\delta'\Delta x^i}{\delta' x^i} \equiv \operatorname{div} \mathbf{r}.$$

Let us recall that d/dt represents the individual total derivative following the motion of air with respect to the earth. The variation Δ applied to any scalar quantity can be broken down into a local variation Δ_l at P and a convective variation $\Delta x^k \frac{\partial}{\partial x^k}$ along $\overrightarrow{PA}$; we thus have $\Delta \equiv \Delta_l + \Delta x^k \frac{\partial}{\partial x^k}$. Assuming the perturbation to be adiabatic ($\Delta\Theta \equiv 0$) and assuming an absence of local variation in the geopotential Φ, equation (84) reduces to

$$L_{ik}(\Delta x^k) = -\Theta\frac{\partial\Delta_l\Pi}{\partial x^i}, \tag{85}$$

provided we set

$$L_{ik} \equiv \gamma_{ik}\frac{d^2}{dt^2} - 2\omega_{ik}\frac{d}{dt} + \sigma_{ik},$$

in which γ_{ik} ($\equiv 0$ or 1 depending on whether $i \neq k$ or $i \equiv k$) are the coefficients of the metric form in rectangular coordinates x^1, x^2, x^3 and

$$\sigma_{ik} \equiv \Theta\frac{\partial^2\Pi}{\partial x^i\partial x^k} + \frac{\partial^2\Phi}{\partial x^i\partial x^k} \equiv S\frac{\partial^2 P}{\partial x^i\partial x^k} - \frac{S^2}{C^2}\frac{\partial P}{\partial x^i}\frac{\partial P}{\partial x^k} + \frac{\partial^2\Phi}{\partial x^i\partial x^k} \equiv \sigma_{ki}$$

are the components of Ertel's stability tensor [7]. If we consider the perturbation to be small, we may consider the coefficients of the differential system (85) as being constants whose numerical values are those which these coefficients take at the point P at the instant t.

In general, we will designate by α_{ij} the elements of the determinant of the third order $\alpha \equiv \| \alpha_{ij} \|$ and by α^{ij} the algebraic minor of α relative to the element α_{ij}; we will then have $\alpha^{ij}\alpha_{ik} \equiv 0$ or α depending on whether $j \neq k$ or $j \equiv k$. With this in mind, let us now multiply the two terms of (85) by L^{ik} and perform the

summation with respect to the index i; we then have the normal differential system

$$L(\Delta x^k) = -L^{ik}\left(\Theta \frac{\partial \Delta_l \Pi}{\partial x^i}\right). \tag{86}$$

The general integral of the nonhomogeneous linear system (86) is composed additively of a particular integral of this system and the general integral of the homogeneous differential system

$$L(\Delta x^k) = 0, \qquad (k = 1, 2, 3) \tag{87}$$

in which

$$L \equiv \frac{d^6}{dt^6} + (\gamma^{ij}\sigma_{ij} + \gamma_{ij}f^i f^j)\frac{d^4}{dt^4} + (\gamma_{ij}\sigma^{ij} + \sigma_{ij}f^i f^j)\frac{d^2}{dt^2} + \sigma \qquad (i, j = 1, 2, 3)$$

with $f^k \equiv 2\omega_{ij}$, the index series (k, i, j) being derived from the series (1, 2, 3) by a rotating permutation. The f^k terms are nothing but the Coriolis parameters associated with the coordinate system $x^1x^2x^3$. Let us note that the elongations Δx^i of an inertial oscillation ($\Delta_l \Pi \equiv 0$) of the air particle under consideration satisfy the differential system (87). The characteristic equation

$$\nu_0^6 - \beta\nu_0^4 + \epsilon\nu_0^2 - \sigma = 0 \tag{88}$$

of this system is obtained in the same way that the characteristic equation (49) is obtained from the differential system (48). In equation (88) we have set

$$\beta \equiv \gamma^{ij}\sigma_{ij} + \gamma_{ij}f^i f^j \quad \text{and} \quad \epsilon \equiv \gamma_{ij}\sigma^{ij} + \sigma_{ij}f^i f^j.$$

Since equation (88) is cubic with respect to ν_0^2, it follows that in the atmosphere *a particle set into any type of motion can undergo, in general, three inertial oscillations of different periods* [7].

Let us now attempt to determine the three roots, ν_0^2, of equation (88). In order to do this let us substitute for the coordinate system $x^1x^2x^3$ the system xyz whose z-axis coincides with the zenith direction at the point P; let us then adopt the approximation allowed (p. 438) and, finally, let us introduce the geostrophic flow $\mathbf{u}(u_x, u_y, 0)$ associated with the arbitrary motion (83); then, by definition, we have

$$u_x \equiv -\frac{\Theta}{f}\frac{\partial \Pi}{\partial y}, \qquad u_y \equiv \frac{\Theta}{f}\frac{\partial \Pi}{\partial x}, \qquad u_z \equiv 0. \tag{89}$$

We will admit moreover that

$$\Theta \frac{\partial \Pi}{\partial z} + g = 0. \tag{90}$$

In (89) and (90) we have set $x \equiv x^1$, $y \equiv x^2$, $z \equiv x^3$, and $f^3 \equiv f \equiv 2\omega \sin\phi$ and $f^2 \equiv f^1 \cong 0$. To the approximation to which we have just consented, the equation of motion (83, $i \equiv 3$) in the vertical, $z \equiv x^3$, has been replaced by the equation of hydrostatic balance (90). This simplification is amply justified in the atmosphere. Let us note that in the system xyz, it is possible to consider the second derivatives of the geopotential Φ as negligible. Substituting (89) and (90) into the σ_{ij} expression, we obtain

$$\sigma \equiv \| \sigma_{ik} \| \equiv \begin{vmatrix} f\Theta \frac{\partial}{\partial x}\left(\frac{u_y}{\Theta}\right) & -f\Theta \frac{\partial}{\partial x}\left(\frac{u_x}{\Theta}\right) & \frac{g}{\Theta}\frac{\partial \Theta}{\partial x} \\ f\Theta \frac{\partial}{\partial y}\left(\frac{u_y}{\Theta}\right) & -f\Theta \frac{\partial}{\partial y}\left(\frac{u_x}{\Theta}\right) & \frac{g}{\Theta}\frac{\partial \Theta}{\partial y} \\ f\Theta \frac{\partial}{\partial z}\left(\frac{u_y}{\Theta}\right) & -f\Theta \frac{\partial}{\partial z}\left(\frac{u_x}{\Theta}\right) & \frac{g}{\Theta}\frac{\partial \Theta}{\partial z} \end{vmatrix}$$

with the symmetry relations

$$\frac{\partial}{\partial x}\left(\frac{u_x}{\Theta}\right) + \frac{\partial}{\partial y}\left(\frac{u_y}{\Theta}\right) = 0, \qquad f\Theta \frac{\partial}{\partial z}\left(\frac{u_x}{\Theta}\right) + \frac{g}{\Theta}\frac{\partial \Theta}{\partial y} = 0,$$

$$f\Theta \frac{\partial}{\partial z}\left(\frac{u_y}{\Theta}\right) - \frac{g}{\Theta}\frac{\partial \Theta}{\partial x} = 0,$$

and

$$\frac{\delta u_x}{\delta x} + \frac{\delta u_y}{\delta y} = 0, \tag{91}$$

in which we have set, (35),

$$\frac{\delta}{\delta x} \equiv \frac{\partial}{\partial x} - \left(\frac{\partial \Theta/\partial x}{\partial \Theta/\partial z}\right)\frac{\partial}{\partial z}, \qquad \frac{\delta}{\delta y} \equiv \frac{\partial}{\partial y} - \left(\frac{\partial \Theta/\partial y}{\partial \Theta/\partial z}\right)\frac{\partial}{\partial z}.$$

From the relation (91) we are able to deduce the existence of a stream function for geostrophic flow within the isentropic surfaces (Θ = const).

It is easy to show that, (36),

$$\sigma \equiv f^2\nu_s^2\left(\frac{\delta u_x}{\delta x}\frac{\delta u_y}{\delta y} - \frac{\delta u_x}{\delta y}\frac{\delta u_y}{\delta x}\right)$$

$$\equiv -f^2\nu_s^2\left[\left(\frac{\delta u_x}{\delta x}\right)^2 + \frac{\delta u_x}{\delta y}\frac{\delta u_y}{\delta x}\right] \approx 10^{-22} \text{ to } 10^{-21} \text{ sec}^{-6}$$

and

$$\epsilon \equiv \nu_s^2\nu_d^2 + f^2\Theta^2\frac{\partial(u_x/\Theta, u_y/\Theta)}{\partial(x, y)} \cong \nu_s^2\nu_d^2 \approx 10^{-12} \text{ sec}^{-4}$$

with

$$\nu_d^2 \equiv f\left[f + \left(\frac{\delta u_y}{\delta x} - \frac{\delta u_x}{\delta y}\right)\right] \approx 10^{-8} \text{ sec}^{-2},$$

in which $\delta u_y/\delta x - \delta u_x/\delta y$ represents the vertical component of vorticity determined in the isentropic surfaces (Θ = const) by the geostrophic current $\mathbf{u}(u_x, u_y, 0)$. Finally, we obtain

$$\beta \equiv \nu_s^2 + \nu_i^2 - \frac{f}{\Theta}\left(\frac{\partial \Theta}{\partial x}u_y - \frac{\partial \Theta}{\partial y}u_x\right) \cong \nu_s^2 \approx 10^{-4} \text{ sec}^{-2},$$

in which

$$\nu_i^2 \equiv f\left[f + \left(\frac{\partial u_y}{\partial x} - \frac{\partial u_x}{\partial y}\right)\right] \approx 10^{-8} \text{ sec}^{-2}.$$

The expressions ν_i^2 and ν_d^2 defined above generalize the corresponding expressions (37) and (40), respectively, which are valid in the case of a particle in geostrophic motion.

In the general case, as in the geostrophic case, we also have

$$\nu_d^2 \cong \nu_i^2 - \frac{N^2}{\nu_s^2}$$

in which

$$N^2 \equiv N_x^2 + N_y^2,$$

with

$$N_x \equiv f\frac{\partial u_x}{\partial z} \cong -\frac{g}{\Theta}\frac{\partial \Theta}{\partial y},$$

$$N_y \equiv f\frac{\partial u_y}{\partial z} \cong +\frac{g}{\Theta}\frac{\partial \Theta}{\partial x},$$

together define the baroclinity at point P.

In order to enable us to interpret the formulas conveniently, let us orient the horizontal axis x of the xyz system along the tangent to the isobar at P in the direction of the geostrophic flow $\mathbf{u}(u_x, u_y, 0)$; we then have [11]:

$\frac{\delta u_x}{\delta y}$, the transversely isentropic geostrophic wind shear, (perpendicular to the streamlines of geostrophic flow within the isentropic surfaces); this wind shear is cyclonic or anticyclonic depending on whether $\delta u_x/\delta y < 0$ or > 0;

$\frac{\delta u_y}{\delta x}$ $>$ or $<$ 0 depending on whether the curvature of streamlines of geostrophic motion in the isentropic surfaces is cyclonic or anticyclonic; and

$\frac{\delta u_x}{\delta x}$ $>$ or $<$ 0 depending on whether these streamlines are converging or diverging.

It follows from the order of magnitude and approximate values of the coefficients β, ϵ, and σ of equation (88), as well as from their classical expression as functions of the roots, that the largest root of this equation has a value in the neighborhood of ν_s^2. Dividing the first member of equation (88) by $\nu_0^2 - \nu_s^2$, we obtain Godson's approximate equation [11]

$$\nu_0^4 - \nu_d^2\nu_0^2 + C = 0 \qquad (92)$$

in which

$$C \equiv \sigma/\nu_s^2 \equiv -f^2\left[\left(\frac{\delta u_x}{\delta x}\right)^2 + \frac{\delta u_x}{\delta y}\frac{\delta u_y}{\delta x}\right] \approx 10^{-18} \text{ to } 10^{-17} \text{ sec}^{-4}.$$

If we refer to the equations of the inertial oscillations, derived from (85), it is apparent that the inertial oscillation corresponding to the root ν_s^2 is quasi-vertical (static stability) and that those corresponding to the two roots ν_0^2 of (92) are quasi-isentropic [11].

The nature of the roots of the biquadratic equation (92) depends on the sign of the discriminant

$$\nu_d^4 - 4C \equiv f^2\left[f^2 + \left(\frac{\delta u_y}{\delta x} + \frac{\delta u_x}{\delta y}\right)^2 + 4\left(\frac{\delta u_x}{\delta x}\right)^2 + 2f\left(\frac{\delta u_y}{\delta x} - \frac{\delta u_x}{\delta y}\right)\right].$$

In general, equation (92) admits of two real roots ($4C < \nu_d^4$), whose approximate values are ν_d^2 and C/ν_d^2. There are four cases to be considered:

I. $\nu_d^2 > 0$, $C > 0$: hydrodynamic stability regardless of the particular isentropic displacement at point P.

II. $\nu_d^2 < 0$, $C > 0$: hydrodynamic instability regardless of the particular displacement at point P.

III. $\left.\begin{matrix}\nu_d^2 < 0,\ C < 0\\ \nu_d^2 > 0,\ C < 0\end{matrix}\right\}$: hydrodynamic instability at P.

It should be noted that C can be positive only if $(\delta u_x/\delta y)(\delta u_y/\delta x) < 0$. In this case, a transversally isentropic, cyclonic shear (anticyclonic shear) of the geostrophic wind will necessarily correspond to a cyclonic (anticyclonic) curvature of the streamlines of geostrophic motion within the isentropic surface at P. The case of cyclonic geostrophic wind shear invariably corresponds to the stable type I (marked stability); the case of anticyclonic geostrophic wind shear corresponds to the unstable type II or to the stable type I (weak stability), but only if the absolute value of the anticyclonic vorticity $\delta u_y/\delta x - \delta u_x/\delta y < 0$ is smaller than the Coriolis parameter f.

Furthermore, C is necessarily negative if

$$(\delta u_x/\delta y)(\delta u_y/\delta x) > 0.$$

In this case, a transversally isentropic, anticyclonic (cyclonic) shear of the geostrophic wind will correspond to a cyclonic (anticyclonic) curvature of the streamlines of geostrophic motion in the isentropic surface at P.

The sign of the transversally isentropic geostrophic wind shear and the sign of the curvature of streamlines of geostrophic motion in isentropic surfaces both play preponderant roles; the divergence or convergence of these lines of motion, on the other hand, are without influence over the conditions leading to hydrodynamic stability or instability—only the absolute value $|\delta u_x/\delta x| \equiv |\delta u_y/\delta y|$ is decisive.

The biquadratic equation (92) admits of two conjugate imaginary roots when:

IV. $4C - \nu_d^4 > 0$: hydrodynamic instability regardless of the isentropic displacement which takes place at point P. This case can arise only when ν_d^2 is of an order of magnitude less than 10^{-8} sec^{-2}, that is, when the vorticity $\delta u_y/\delta x - \delta u_x/\delta y$ is anticyclonic, and when its absolute value is of the same order of magnitude as the Coriolis parameter f. The existence in the general case of a second type of total instability in the isentropic surfaces is thus not excluded. Let us note that the first type (case II) is none other than the one we met previously in our discussion of geostrophic motion (case II of Table II) and as a consequence the results obtained in the geostrophic case can be extended to the general case of any given motion.

Thus, the condition $\nu_d^2 < 0$ is a sufficient condition for instability, but is no longer (as in the geostrophic case) a necessary and sufficient condition. On the other hand, the condition $\nu_d^2 > 0$ is a necessary condition of stability but is no longer (as in the geostrophic case) a necessary and sufficient condition [11]. Nevertheless, it

can be said, in a general way, that the hydrodynamic stability increases or decreases depending on whether ν_a^2 increases or decreases. It is the instability corresponding to the weak positive values and to the negative values of ν_a^2 which seems to be of the greatest practical importance [12].

Godson has not only calculated the inertial orbits in the four cases discussed above [11] but has also made a statistical and synoptic study of the four corresponding types of stability and instability [12].

The hydrodynamic instability which accompanies the deepening of frontal cyclones appears in the atmosphere wherever the baroclinity is strongest and the static stability, simultaneously, is weakest (see pp. 438–440), that is, in the tropical air above the polar front zone. It is particularly with reference to the importance of hydrodynamic instability in the formation of cyclonic circulation that new synoptic studies, in greater number and on a larger scale, appear to be desirable.

STABILITY PROPERTIES OF LARGE-SCALE ATMOSPHERIC DISTURBANCES

By R. FJØRTOFT

*The Institute for Advanced Study**

Introduction

The large-scale motion of the earth's atmosphere is to the first approximation a solid rotation from west to east. Upon this are superimposed a more or less orderly zonal flow in the relative motion and the large-scale disturbances familiar in meteorology. In this article causes for the creation and maintenance of these disturbances will be discussed, excluding, however, the more or less permanent disturbances forced upon the atmosphere because of the earth's topographic inhomogeneity.

By the use of the phrase "disturbances in a zonal flow," a separation is implied between two components of the flow. This may seem artificial since the hydrodynamic equations are directly applicable to the total component of the flow. There are, however, several reasons for doing this: The immediate impression obtained by studying hemispherical weather maps is one of a more or less orderly zonal flow upon which are superimposed disturbances that behave to some degree as physical entities themselves. Further, the zonal flow and the disturbances undergo somewhat systematic changes, seemingly of great importance to weather. Therefore, by a separation of the atmospheric flow into some kind of orderly zonal flow and disturbances superimposed thereupon, one isolates at the outset certain phenomena which appear to be related to actual weather. Besides, this separation will enable one to deal satisfactorily with problems in which a detailed knowledge of the motion is unnecessary, as exemplified by the stability investigations carried out in the discussion of barotropic disturbances (pp. 460–463).

Granted that such a separation of the atmospheric flow may prove useful, it becomes important for quantitative treatment to express this separation in mathematical terms. How this should be done is to some extent arbitrary because there may be several ways of defining the orderly flow, and thereby the disturbances. In this article, the orderly flow will be characterized, for an arbitrary hydrodynamic element α, by the mean value of α at a fixed time along latitude circles:

$$\bar{\alpha} = \frac{1}{2\pi}\int_0^{2\pi} \alpha \, d\psi,$$

while the corresponding element in the flow of disturbances will be defined by

$$\alpha' = \alpha - \bar{\alpha}.$$

The flow therefore is composed of an orderly, axially symmetric motion and an irregular flow vanishing in the mean along zonal circles. The degree of irregularity may, however, vary widely. In this article it is assumed that all irregularities considerably smaller than the smallest-scale cyclones have already been smoothed out in some way. The corresponding turbulent stresses will be entirely neglected throughout this article.

As already pointed out above, the sum of the two components of flow must obey the hydrodynamic equations of motion. There must therefore exist a coupling between these two components. Actually, in many cases this coupling is so strong that a full understanding of what happens with one component cannot be achieved without taking into account simultaneous changes of the other.

It is an established procedure to separate the hydrodynamic equations into one set valid for the orderly motion and one for the irregular flow. To implement this process the equations will first be simplified by suppressing certain terms of minor importance. With the conventional simplification in the Coriolis acceleration, the equation of motion is

$$\rho\left[\frac{D\mathbf{v}}{dt} + f\mathbf{k}\times\mathbf{v} - \mathbf{g}\right] = -\nabla p,$$

where ρ is the density, f is the Coriolis parameter, $\mathbf{g}$ is the acceleration of gravity, $\mathbf{v}$ is the velocity, and p is the pressure. The coordinate system has been selected so that the x-axis is directed east, the y-axis north, and the z-axis upward; $\mathbf{i}$, $\mathbf{j}$, and $\mathbf{k}$ are unit vectors in the x, y, and z directions, respectively. By elimination of ∇p and substitution of $\varkappa = \ln\vartheta$ (where ϑ is the potential temperature) by means of the relationship $\nabla\rho - \Gamma\nabla p = -\rho\nabla\varkappa$, one obtains

$$\nabla\times\left[\frac{D\mathbf{v}}{dt} + f\mathbf{k}\times\mathbf{v}\right] = -\nabla\times\varkappa\mathbf{g}. \qquad (1)$$

The neglected term $-\nabla\varkappa\times[D\mathbf{v}/dt + f\mathbf{k}\times\mathbf{v}]$ is small compared with the others. Equation (1) is equivalent to

$$\frac{D\mathbf{v}}{dt} = -\nabla\gamma - f\mathbf{k}\times\mathbf{v} - \varkappa\mathbf{g}, \qquad (2)$$

where $\nabla\gamma$ is a certain laminar vector. It is easily understood that by introducing the simplification above, the effects from solenoids in horizontal planes have been neglected. Now let $Q(z)$ represent some standard distribution of density with height. The following approximate equation will then constitute the continuity equation:

$$\nabla\cdot Q\mathbf{v} = Q\nabla_h\cdot\mathbf{v}_h + \frac{\partial Qw}{\partial z} = 0. \qquad (3)$$

* This article is to some extent based upon work performed under contract N6-ori-139, Task Order I between the Office of Naval Research and The Institute for Advanced Study.

In this article only adiabatic processes will be considered. The physical equation is therefore

$$\frac{\partial \kappa}{\partial t} = -\mathbf{v}\cdot\nabla\kappa. \tag{4}$$

From the foregoing equations one obtains by separation into the mean and irregular flows:

$$\frac{\partial \bar{\mathbf{v}}}{\partial t} + \bar{\mathbf{v}}\cdot\nabla\bar{\mathbf{v}} = -\nabla\bar{\gamma} - f\mathbf{k}\times\bar{\mathbf{v}} - \bar{\kappa}\mathbf{g} - \overline{\mathbf{v}'\cdot\nabla\mathbf{v}'}, \tag{5a}$$

$$\nabla\cdot Q\bar{\mathbf{v}} = 0, \tag{5b}$$

$$\frac{\partial \bar{\kappa}}{\partial t} = -\bar{\mathbf{v}}\cdot\nabla\bar{\kappa} - \overline{\mathbf{v}'\cdot\nabla\kappa'}, \tag{5c}$$

and

$$\frac{\partial \mathbf{v}'}{\partial t} + \mathbf{v}'\cdot\nabla\mathbf{v}' = -\nabla\gamma' - f\mathbf{k}\times\mathbf{v}' - \kappa'\mathbf{g} - \bar{\mathbf{v}}\cdot\nabla\mathbf{v}' - \mathbf{v}'\cdot\nabla\bar{\mathbf{v}} + \overline{\mathbf{v}'\cdot\nabla\mathbf{v}'}, \tag{6a}$$

$$\nabla\cdot Q\mathbf{v}' = 0, \tag{6b}$$

$$\frac{\partial \kappa'}{\partial t} = -\bar{\mathbf{v}}\cdot\nabla\kappa' - \mathbf{v}'\cdot\nabla\bar{\kappa} + \overline{\mathbf{v}'\cdot\nabla\kappa'}. \tag{6c}$$

These equations reveal the coupling which must exist between the two components of the flow, as both components occur in each set of equations.

The Circular Vortex

According to the definitions above, the orderly flow may be considered as a pure zonal flow with velocity component $\bar{u}\mathbf{i}$, and a meridional flow with velocity $\bar{\mathbf{v}}_m = \bar{v}\mathbf{j} + \bar{w}\mathbf{k}$, which is identically the same in all meridional planes. The meridional component of (5) may be written

$$\frac{\overline{D\mathbf{v}_m}}{dt} = -\nabla\bar{\gamma} - \bar{\kappa}\mathbf{g} - f\mathbf{k}\times\bar{u}\mathbf{i}.$$

The approximate balance existing in the large-scale relative motion in the atmosphere gives, when $\nabla\bar{\gamma}$ is eliminated from this equation:

$$\frac{\partial \bar{u}}{\partial z} = -\frac{g}{\bar{f}}\frac{\partial \bar{\kappa}}{\partial y}. \tag{7}$$

This is the so-called thermal wind equation applied to the mean flow.

One may study the axially symmetric meridional motions in a qualitative way by the method of velocity circulation used primarily by V. Bjerknes [4] and Høiland [16]. If $\nabla\bar{\gamma}$ is eliminated from the foregoing equation by taking the circulation along some arbitrary closed curve in a meridional plane, and the resulting equation differentiated once with respect to time, one gets

$$\frac{d}{dt}\oint \frac{\overline{D\mathbf{v}_m}}{dt}\cdot\delta\mathbf{r} = -\oint \frac{\partial \bar{\kappa}}{\partial t}\,\mathbf{g}\cdot\delta\mathbf{r} - \oint f\frac{\partial \bar{u}}{\partial t}\,\mathbf{j}\cdot\delta\mathbf{r}. \tag{8}$$

The expression for $\partial\bar{u}/\partial t$ is obtained from the zonal component of (5a):

$$\frac{\partial \bar{u}}{\partial t} = -\bar{\mathbf{v}}_m\cdot(\nabla\bar{u} - f\mathbf{j}) - \overline{\mathbf{v}'\cdot\nabla u'}. \tag{9}$$

Substituting this expression for $\partial\bar{u}/\partial t$ in (8) and likewise for $\partial\bar{\kappa}/\partial t$ from (5c), one gets

$$\frac{d}{dt}\oint \frac{\overline{D\mathbf{v}_m}}{dt}\cdot\delta\mathbf{r} = \oint \bar{\mathbf{v}}_m\cdot[f\nabla\bar{u}\mathbf{j} - f^2\mathbf{j}\mathbf{j} + \nabla\bar{\kappa}\mathbf{g}]\cdot\delta\mathbf{r} + \oint\overline{\mathbf{v}'\cdot\nabla\kappa'}\mathbf{g}\cdot\delta\mathbf{r} + \oint f\overline{\mathbf{v}'\cdot\nabla u'}\mathbf{j}\cdot\delta\mathbf{r}. \tag{10}$$

A study of the first integral on the right-hand side of this equation leads to the conditions which must exist if in a pure, axially symmetric motion the meridional circulations should accelerate or decelerate, in other words to the now well-known stability criteria for a circular vortex for vortex-ring perturbations. It will be assumed in this article that all orderly flows which are treated are stable in this sense. Most likely this is usually the case in the atmosphere.

The remaining terms on the right-hand side of (10) represent the effects upon the acceleration of the meridional circulations which are due to the disturbances. The character of the resulting forced circulations will now also depend essentially upon the stability properties of the circular vortex for vortex-ring perturbations. Briefly, one may say that the presence of effects changing the fields of mass and velocity in the orderly zonal flow, other than effects of the meridional circulations themselves, will generally tend steadily to destroy the balance in the meridional motions. Because of the stability of the circular vortex the resulting added meridional circulations will act to restore the equilibrium, an equilibrium which will, however, be different from the original one. If the stability is large enough, the whole development may be thought of as one which goes through different equilibrium stages by smoothing out over sufficiently large periods the relatively high frequency oscillations superimposed upon this trend. The simplifications following from such a procedure are essentially the same as those introduced by the systematic use of the condition of quasi-geostrophic motion [7, 12]. With the simplifications above, A. Eliassen [11] has studied the forced meridional circulations produced by given sources of heat and angular momentum.

To see in a qualitative fashion how the irregular flow affects the mean meridional circulations one may use the simplifications mentioned above in connection with the circulation integrals in (10). One then obtains

$$\oint \bar{\mathbf{v}}_m\cdot[f\nabla\bar{u}\mathbf{j} - f^2\mathbf{j}\mathbf{j} + \nabla\bar{\kappa}\mathbf{g}]\cdot\delta\mathbf{r} = -\oint\overline{\mathbf{v}'\cdot\nabla\kappa'}\mathbf{g}\cdot\delta\mathbf{r} - \oint f\overline{\mathbf{v}'\cdot\nabla u'}\mathbf{j}\cdot\delta\mathbf{r}. \tag{11}$$

It will now be assumed that $\nabla\bar{u}$ and $\partial\bar{\kappa}/\partial y$ are small enough to be neglected where they occur in (9) and (11). It is further assumed that $\partial\bar{\kappa}/\partial z \geqq 0$, which is

necessary to insure the stability of the circular vortex in the present case. Equations (9) and (11) now reduce to

$$\frac{\partial \bar{u}}{\partial t} = f\bar{v} - \overline{\mathbf{v}'\cdot\nabla u'}, \tag{12}$$

$$-\oint f^2\bar{v}\,\delta y - \oint g\frac{\partial \bar{\kappa}}{\partial z}\bar{w}\,\delta z = \oint \overline{\mathbf{v}'\cdot\nabla\kappa'}g\,\delta z - \oint f\overline{\mathbf{v}'\cdot\nabla u'}\,\delta y. \tag{13}$$

Let it now be assumed that the path of integration consists of the sides of a "rectangle" bounded below by the earth's surface and with the top at about tropopause height (Fig. 1). The direction of integration is indicated by arrows. With subscripts from 1 to 4 denoting average values along the sides of the rectangle correspondingly labelled, (13) may be written

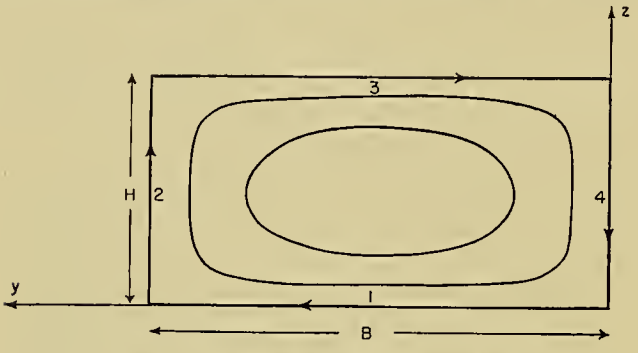

Fig. 1.—Idealized meridional circulation.

$$f^2(\bar{v}_3 - \bar{v}_1)B + g\frac{\partial \bar{\kappa}}{\partial z}(\bar{w}_2 - \bar{w}_4)H = g(\overline{\mathbf{v}'\cdot\nabla\kappa_2'} - \overline{\mathbf{v}'\cdot\nabla\kappa_4'})H + f(\overline{\mathbf{v}'\cdot\nabla u_3'} - \overline{\mathbf{v}'\cdot\nabla u_1'})B. \tag{14}$$

Here, B and H are the lengths of the sides of the rectangle. Suppose further that the rectangular-shaped boundary is a streamline in a corresponding simple cellular meridional motion, in which $\bar{v}$ and $\bar{w}$ are derived from a stream function

$$\psi_a \sim \sin\frac{\pi y}{B}\sin\frac{\pi z}{H}. \tag{15}$$

This implies that for the present the atmosphere is treated as incompressible. It may be anticipated, however, that the results to be obtained will also roughly apply to cellular motions whose kinematics are essentially the same as in this most simple cellular motion.

By deriving $\bar{v}$ and $\bar{w}$ from (15) and forming the averages $\bar{v}_1$, $\bar{v}_3$, $\bar{w}_2$, and $\bar{w}_4$, one obtains

$$(\bar{w}_4 - \bar{w}_2)B = (\bar{v}_3 - \bar{v}_1)H. \tag{16}$$

If one does not think of the velocities in this formula as averages along the sides of the rectangular boundary, but rather as averages over the whole region of the velocities in the ascending and descending motions, and in the north and south motions, the formula simply states the well-known continuity principle that the ratio between the magnitude of the vertical and horizontal velocities is proportional to the ratio between the vertical and horizontal scale of the motion. By a suitable choice of the integration curve in the circulation integrals given above, one could therefore also apply (16) to cellular motions of a much more general character than the one determined from (15). In view of (16), (14) may now be written

$$f(\bar{v}_3 - \bar{v}_1)\left(f^2 + g\frac{\partial \bar{\kappa}}{\partial z}\frac{H^2}{B^2}\right) = fg(\overline{\mathbf{v}'\cdot\nabla\kappa_2'} - \overline{\mathbf{v}'\cdot\nabla\kappa_4'})\frac{H}{B} + f^2(\overline{\mathbf{v}'\cdot\nabla u_3'} - \overline{\mathbf{v}'\cdot\nabla u_1'}). \tag{17}$$

Taking likewise an average of (12) along the horizontal sides of the rectangle, one obtains by subtraction

$$\frac{\partial}{\partial t}(\bar{u}_3 - \bar{u}_1) = f(\bar{v}_3 - \bar{v}_1) - (\overline{\mathbf{v}'\cdot\nabla u_3'} - \overline{\mathbf{v}'\cdot\nabla u_1'}).$$

Substituting here for $f(\bar{v}_3 - \bar{v}_1)$ from (17), one obtains

$$\frac{\partial}{\partial t}\left(\frac{\bar{u}_3 - \bar{u}_1}{H}\right) = \left[\frac{g\dfrac{\partial \bar{\kappa}}{\partial z}\dfrac{H^2}{B^2}}{f^2 + g\dfrac{\partial \bar{\kappa}}{\partial z}\dfrac{H^2}{B^2}}\right]\left[\frac{\overline{\mathbf{v}'\cdot\nabla u_1'} - \overline{\mathbf{v}'\cdot\nabla u_3'}}{H}\right] + \left[\frac{f^2}{f^2 + g\dfrac{\partial \bar{\kappa}}{\partial z}\dfrac{H^2}{B^2}}\right]\left[\frac{g}{Bf}(\overline{\mathbf{v}'\cdot\nabla\kappa_2'} - \overline{\mathbf{v}'\cdot\nabla\kappa_4'})\right]. \tag{18}$$

This formula now determines, as a function of two terms, the time rate of change in the vertical wind shear of the mean zonal flow: The first term involves the wind shear that would directly result from the dynamic effects of the irregular motion; the second, the mean meridional temperature gradient resulting directly from the thermal effects of the disturbances. However, it is seen that only fractions of these quantities are effective in building up the resulting shear since they are multiplied by factors smaller than unity. This is clearly a result of the interference with the effects resulting from the forced meridional circulations, and could have been obtained by more direct considerations. The formula given above, however, may serve as a rough indicator of how this interference depends upon the stability of the circular vortex and the horizontal and vertical scales of the motion. In the present discussion it will only be pointed out how the dynamically conditioned increase in the wind shear becomes more and more compensated when the vertical stability goes to zero, or when H/B becomes smaller, while at the same time the thermally conditioned increase in wind shear becomes correspondingly more important. The relative importance, in regard to the general circulation, of the dynamic effects of the disturbances on the one hand, and the thermal effects on the other, naturally depends also upon the relative magnitudes of the terms $\overline{\mathbf{v}'\cdot\nabla u'}$ and $\overline{\mathbf{v}'\cdot\nabla\kappa'}$ and their distribution. This is intimately connected with the problems to be treated in the following sections.

Baroclinic Disturbances

One way of classifying atmospheric disturbances is with respect to the sources of energy which are at their disposal. The energy equation, when integrated over an isolated volume τ of the atmosphere, is obtained from (2) and (3) and becomes

$$\int Q\tfrac{1}{2}\mathbf{v}^2\,d\tau = \int Q\varkappa gz\,d\tau + \text{const.}$$

Substituting here $\mathbf{v} = \bar{u}\mathbf{i} + \bar{\mathbf{v}}_m + \mathbf{v}'$, one arrives at

$$\int Q\tfrac{1}{2}\mathbf{v}'^2\,d\tau = \int Q\varkappa gz\,d\tau - \int Q\tfrac{1}{2}\bar{u}^2\,d\tau + \text{const},$$

having neglected the relatively much smaller kinetic energy contained in the mean meridional circulations. Applying the same approximation, the time rate of change of this equation becomes, in view of (5) and (6),

$$\frac{d}{dt}\int Q\tfrac{1}{2}\mathbf{v}'^2\,d\tau = \int Q\varkappa' w' g\,d\tau - \int Q\frac{\partial\bar{u}}{\partial y}u'v'\,d\tau - \int Q\frac{\partial\bar{u}}{\partial z}u'w'\,d\tau. \tag{19}$$

Consequently, one may classify disturbances into three categories according to whether the main source of energy is potential, kinetic, or both. In this section the first one will be considered.

Clearly, it is the correlation between the fluctuations in temperature and vertical velocity which will be decisive in determining whether potential energy shall be a source or sink for the disturbances. It is in accordance with synoptic experience that in most cases cold air masses sink relative to the warmer ones. It is therefore to be expected that potential energy is, at least partly, an important factor in creating and maintaining the large-scale disturbances. In order to understand how a positive correlation between the fluctuations of temperature and vertical velocity may be brought about, one may write

$$\varkappa' = -\mathbf{l}\cdot\nabla\bar{\varkappa} = -K\mathbf{v}'\cdot\nabla\bar{\varkappa}, \qquad (K > 0).$$

Here, $\mathbf{l}$ is a kind of mixing length, and a positive correlation has been assumed between $\mathbf{l}$ and $\mathbf{v}'$. Consequently, one has

$$\int Q\varkappa' w' g\,d\tau = -K\int Q(\mathbf{v}'\cdot\nabla\bar{\varkappa})w' g\,d\tau = -K\int Qv'w'\frac{\partial\bar{\varkappa}}{\partial y}g\,d\tau - K\int Qw'^2\frac{\partial\bar{\varkappa}}{\partial z}g\,d\tau.$$

Having assumed vertical stability, it is therefore seen that as requirements for potential energy to be fed into the disturbances (*i*) horizontal temperature gradients must exist, and (*ii*) the slope of the streamlines in the meridional planes, w'/v', must be of the same sign as the slope $(-\partial\bar{\varkappa}/\partial y)/(\partial\bar{\varkappa}/\partial z)$ of the isentropic surfaces of the mean flow, but have a smaller magnitude. This last requirement may also be stated as saying that in the identity $\mathbf{v}'\cdot\nabla\bar{\varkappa} = v'\partial\bar{\varkappa}/\partial y + w'\partial\bar{\varkappa}/\partial z$ there must be a tendency for the vertical transport of entropy to compensate the horizontal transport. The latter, however, has to be the dominating effect, so that approximately $\mathbf{v}'\cdot\nabla\bar{\varkappa} = v'\partial\bar{\varkappa}/\partial y$.

For reasons of continuity it is to be expected that for decreasing horizontal dimensions of the disturbances the magnitude of the vertical velocities will increase relative to the horizontal velocities. It would therefore not be surprising if, for sufficiently small horizontal dimensions of the disturbances, w'/v' would exceed the values for which a conversion of potential energy into kinetic energy of the disturbances could take place. This effect will now be studied in more detail. To obtain results comparable with others which will be referred to at the end of this section, an incompressible atmosphere will be considered, bounded by two horizontal rigid planes at distance h apart. Also it will be assumed that

$$\frac{\partial u}{\partial y} = \frac{\partial v}{\partial y} = \frac{df}{dy} = 0; \qquad \frac{d^2u}{dz^2} = 0.$$

By eliminating $\nabla_h\gamma$ from the horizontal component of (2), one now obtains

$$\left(\frac{\partial}{\partial t} + u\frac{\partial}{\partial x}\right)\frac{\partial v}{\partial x} = -f\frac{\partial u}{\partial x} = f\frac{\partial w}{\partial z}. \tag{20}$$

Let it be assumed that instantaneously v and its derivatives may be obtained from the identity

$$v = \text{const}\cdot\sin\frac{2\pi}{L}\left[x - u\left(\frac{h}{2}\right)t\right],$$

representing instantaneously a simple wave propagating with a speed given by the value of u halfway between the boundaries. By substituting into (20), one obtains

$$-\frac{4\pi^2}{L^2}\frac{du}{dz}\left(z - \frac{h}{2}\right)v = f\frac{\partial w}{\partial z}.$$

Applying the boundary condition $w = 0$ for $z = 0$, one obtains by integration between $z = 0$ and the height $h/2$ where w reaches its maximum value:

$$\frac{w_{z=h/2}}{v} = \frac{\pi^2 h^2}{2L^2 f}\frac{du}{dz}.$$

Applying now the condition (*ii*) above to $w_{z=h/2}/v$, one obtains

$$\frac{\pi^2 h^2}{2L^2 f}\frac{du}{dz} < -\frac{\partial\varkappa/\partial y}{\partial\varkappa/\partial z},$$

or, by substitution from the thermal wind relationship $du/dz = -(g/f)(\partial\varkappa/\partial y)$:

$$\frac{L^2}{h^2} > \frac{\pi^2}{2f^2}\left(g\frac{\partial\varkappa}{\partial z}\right). \tag{21}$$

This now constitutes approximately the restriction on the horizontal scale of the disturbances if potential energy is to be converted into kinetic energy of the disturbances.

It will now be shown how one may express the conditions for a positive correlation between $\varkappa'$ and w'

in terms of the horizontal fields of velocity and temperature only. The conclusions arrived at are very much like those of Bjerknes and Holmboe [3]. The line of argument followed below is in some respects similar to that of Sutcliffe [26, 27]. (See also [8] and the article by J. G. Charney in this Compendium.[1])

From (2) one finds the vorticity equation in the vertical component to be

$$\frac{\partial \zeta}{\partial t} + \mathbf{v}_h \cdot \nabla \zeta + \beta v + f \nabla_h \cdot \mathbf{v} = 0,$$

when the presumably small terms

$$w(\partial \zeta / \partial z) + \zeta \nabla_h \cdot \mathbf{v} + \nabla_h w \times (\partial \mathbf{v} / \partial z) \cdot \mathbf{k}$$

are neglected. In this equation ζ is the vorticity and β is the variation of the Coriolis parameter with latitude. Let α^* be defined from $\alpha^* \int_0^\infty Q\, dz = \int_0^\infty Q\alpha\, dz$, where Q is now supposed to be the standard density in some isothermal atmosphere.[2] The term α^* will represent the mean, in the vertical, of α with respect to mass. Taking this mean of the vorticity equation, one obtains, by virtue of the continuity equation (3) and the boundary conditions $Qw = 0$ for $z = 0, z = \infty$,

$$\frac{\partial \zeta^*}{\partial t} + \mathbf{v}_h^* \cdot \nabla \zeta^* + \beta v^* + [(\mathbf{v}_h - \mathbf{v}_h^*) \cdot \nabla (\zeta - \zeta^*)]^* = 0. \tag{22}$$

In this equation the last term depends upon the existence of vertical wind shears, or in consequence of the thermal wind equation, upon the horizontal temperature gradients. It must therefore be this term that provides for the effects responsible for conversion of potential into kinetic energy. For a rough estimate of this term one may assume $d^2\mathbf{v}_h/dz^2 = 0$. From the thermal wind equation this implies that $\nabla_h \varkappa = \nabla_h \varkappa^*$. Equation (22) now takes the form

$$\frac{\partial \zeta^*}{\partial t} = -\mathbf{v}_h^* \cdot \nabla \zeta^* - \beta v^* - \mathbf{v}_T \cdot \nabla \zeta_T, \tag{23}$$

where

$$\mathbf{v}_h^* = \mathbf{v}_{z=0} + \mathbf{v}_T,$$

$$\mathbf{v}_T = H \frac{d\mathbf{v}_h}{dz} = -\frac{gH}{f} \nabla \varkappa^* \times \mathbf{k}, \tag{24}$$

and H = height of the homogeneous atmosphere. By taking the mean in the vertical of the physical equation (4), one further obtains

$$\frac{\partial \varkappa^*}{\partial t} = -\mathbf{v}_h^* \cdot \nabla \varkappa^* - \left(w \frac{\partial \varkappa}{\partial z} \right)^*. \tag{25}$$

To these equations one may add

$$\nabla \cdot \mathbf{v}_h^* = 0, \qquad \nabla \cdot \mathbf{v}_T = 0, \tag{26}$$

of which the first is exactly true owing to the definition of $\mathbf{v}_h^*$, and the second approximately true because of the identity (24).

It may be inferred from (22) that, under the foregoing assumptions, vorticity in the vertical-mean motion can vary individually only as a result of an advection of the vorticity of the thermal wind by the thermal wind $\mathbf{v}_T$. It is also apparent that if in the thermal wind field there is a transport of cyclonic thermal wind vorticity into regions of high vorticities in the actual motion, these vorticities will intensify. This corresponds to one of the rules developed by Sutcliffe for the sea-level motion [26, p. 205]. Applied to troughs which are symmetrical with respect to meridians, this leads, as Fig. 2 illustrates, to the synoptically well-known rule that troughs in the upper-air flow pattern intensify if troughs in the temperature patterns lag behind the troughs in the streamline patterns. A similar rule applies to ridges. It should be noted that these intensifications cannot be a result of the solenoids in horizontal planes, since these were neglected in the derivation of (2). The corresponding increase in the kinetic energy must have resulted from a conversion of potential energy. With reference to the discussion earlier in this section, it may therefore be concluded that, under the conditions mentioned above, the cold air must be subsiding relative to the warmer air, and further that the temperature changes due to the vertical motions can only partly compensate the advective changes. This rather definite knowledge of the three-dimensional flow structure based only upon a knowledge of the structure of the horizontal temperature and flow patterns is noteworthy. Clearly, nothing could in principle prevent a horizontal flow as illustrated in Fig. 2 from having any distribution of vertical velocities initially. This seeming discrepancy is due to the specific use which has been made of the conditions for quasi-geostrophic motion, which actually may be interpreted as effecting a smoothing similar to the one mentioned under the study of the mean meridional motions. As there, the success of such a smoothing, and therefore of the specific use of the conditions for quasi-geostrophic motion, depends upon the stability of the noise motion which is superimposed upon the "geostrophically" conditioned trend.

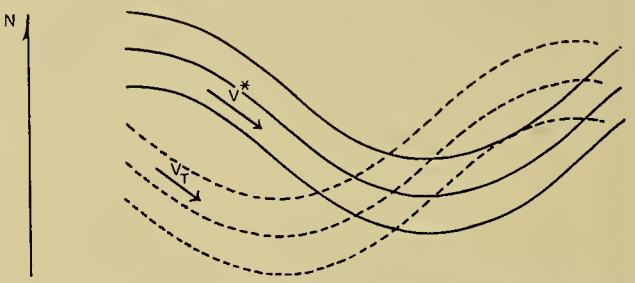

FIG. 2.—Flow pattern (solid lines) and temperature pattern (dashed lines) in an intensifying trough.

The question may now be raised as to what are the different mechanisms leading to the conditions mentioned above, under which potential energy can be converted into kinetic energy of the disturbances. Ad-

1. "Dynamic Forecasting by Numerical Process" by J. G. Charney, pp. 470–482.

2. The assumption of isothermalcy is not necessary, but convenient.

mitting that several such mechanisms may exist, the discussion here will be confined to the self-exciting one, by means of which small disturbances may amplify because of an instability of the underlying basic zonal flow. A theoretical attack on the problem of waves in a baroclinic atmosphere was first undertaken in the Norwegian polar front school of meteorology, principally by H. Solberg [25] (in addition, see [2, 5]). Waves were examined on an inclined surface of discontinuity separating two barotropic layers. Thus, all the baroclinity was considered as concentrated in a surface of discontinuity. In principle, however, with regard to the possibility of converting potential into kinetic energy, there is no difference between such a basic flow and one with continuously distributed baroclinity. In contrast to the pure, polar front waves, which may possibly feed also upon the kinetic energy of the basic current, are the baroclinic waves for a horizontally uniform basic flow, first examined by Charney [6]. The essential stability properties of these waves may be found easily by means of equations (23)–(26), if one neglects the vertical transport of potential temperature. As remarked in an earlier connection, and confirmed by the more rigorous solutions [10; 14, pp. 46–51], this approximation will be justified for the relatively large wave lengths. The adiabatic equation (3) may then be written

$$\left(\frac{\partial}{\partial t} + u^* \frac{\partial}{\partial x}\right) \varkappa^* + \frac{\partial \varkappa^*}{\partial y} v^* = 0, \tag{27}$$

or, by differentiation with respect to x and use of (24),

$$\left(\frac{\partial}{\partial t} + u^* \frac{\partial}{\partial x}\right) v_T - u_T \frac{\partial v^*}{\partial x} + \frac{\partial v_T}{\partial y} v^* + \frac{\partial u^*}{\partial x} v_T = 0.$$

Let it now be assumed by way of example that

$$\frac{\partial v^*}{\partial y} = \frac{\partial v_T}{\partial y} = 0,$$

so that the results arrived at may be said to apply approximately to disturbances whose scale in the y-direction is large compared with the scale in the x-direction. It follows then from (26) that $\partial u^*/\partial x = \partial u_T/\partial x = 0$. With the assumption of no horizontal shear for the zonal flow, u^* and u_T will now have to be independent of x and y. It is also easily understood that neither can they depend upon time. Equations (23) and (25) now reduce to

$$\left[\left(\frac{\partial}{\partial t} + u^* \frac{\partial}{\partial x}\right) \frac{\partial}{\partial x} + \beta\right] v^* + \left(u_T \frac{\partial^2}{\partial x^2} - \frac{\partial}{\partial x}\right) v_T = 0, \tag{28}$$

$$u_T \frac{\partial}{\partial x} v^* - \left(\frac{\partial}{\partial t} + u^* \frac{\partial}{\partial x}\right) v_T = 0.$$

Suppose

$$v^* \sim \exp\left[i(\mu x + \omega t)\right]$$

and

$$v_T \sim \exp\left[i(\mu x + \omega t)\right]$$

to be solutions of (28). By substitution into (28) one gets as the condition that v^* and v_T do not vanish identically,

$$\omega = -\mu u^* + \frac{\beta}{2\mu} \pm \sqrt{\left(\frac{\beta}{2\mu}\right)^2 - \mu^2 u_T^2}.$$

When the square root becomes imaginary, and the negative sign is taken, v^* and v_T will increase exponentially. When the substitution for u_T is made from (24), the criterion for stability and instability therefore becomes

$$\left(\frac{\beta}{2\mu}\right)^2 - \mu^2 H^2 \left(\frac{du}{dz}\right)^2 \begin{matrix} < 0 & \text{(unstable)} \\ > 0 & \text{(stable).} \end{matrix} \tag{29}$$

Formula (29) reveals the high degree of instability of a horizontally uniform current in a baroclinic atmosphere. This result is common to all the different studies of baroclinic waves, which otherwise differ widely both with respect to the manner of formulating the problem of instability, and with respect to some of the conclusions obtained [1; 6; 10; 14, pp. 35–51]. Below is a summary of some of the assumptions and conclusions.

Charney

Assumptions:

1. Geostrophic approximation.
2. Compressibility.
3. Infinite atmosphere.
4. Vertical stability.

Conclusion:

All waves, at least down to about 1200 km, are unstable for a sufficiently large meridional temperature gradient.

Eady

Assumptions:

1. Geostrophic assumption.
2. Incompressibility.
3. Vertical stability.
4. Inertia effects of inhomogeneity neglected:

$$Q\left(\frac{D\mathbf{v}}{dt} + f\mathbf{k} \times \mathbf{v}\right) = \text{const}\left(\frac{D\mathbf{v}}{dt} + f\mathbf{k} \times \mathbf{v}\right).$$

5. Constant Coriolis parameter: $df/dy = 0$.
6. (*a*) Finite atmosphere bounded by two rigid walls at distance h apart.
   (*b*) Infinite atmosphere.

Conclusions from assumption (6) are:

(*a*) All waves are unstable[3] if and only if

$$\left(\frac{L}{h}\right)^2 > \frac{\pi^2}{2f^2}\left(g\frac{\partial \bar{\kappa}}{\partial z}\right).$$

(*b*) No waves are unstable unless a layer of smaller vertical stability is underlying one of greater stability.

3. Compare with the result obtained on p. 457.

FJØRTOFT

Assumptions:

1. Incompressibility.
2. Vertical stability zero.
3. Constant Coriolis parameter: $df/dy = 0$.
4. Finite atmosphere bounded by horizontal walls at distance h apart.

Conclusion:

All waves are unstable if and only if

$$\left(\frac{L}{h}\right)^2 > \frac{\pi^2}{2f^2}\left(\frac{du}{dz}\right)^2.$$

It may be remarked that Eady's second conclusion will no longer hold if the simplification mentioned in his fourth assumption is not made, in other words, even the infinite atmosphere with uniform vertical stability will be unstable if account is taken of the fact that density diminishes to zero for increasing heights. The appearance of a stabilizing influence from the vertical shear for short wave lengths in Fjørtoft's conclusion is due to effects to be discussed at the end of the following section. This stabilizing effect could not possibly appear in the other studies because there $(\omega + 2\pi u/L)^2$ was neglected compared with f^2 [14, pp. 41–42].

Barotropic Disturbances

In the case of barotropy there can be no vertical wind shear in the state of quasi-balance which characterizes the motions with which this article is concerned. Equations (18) and (21) therefore reduce to

$$\frac{D\zeta_{abs}}{dt} = 0; \qquad \nabla\cdot\mathbf{v} = 0, \tag{30}$$

with the asterisks now dropped as superfluous. These equations represent the classical equations for conservation of vorticity in a two-dimensional nondivergent flow of a nonviscous fluid. The fundamental investigation of wave motions in such flows was carried out by Rayleigh [22]. Although in the studies of polar front waves the destabilizing effects of a gliding discontinuity were considered to be important, it has not been until recently that barotropic phenomena in their full and complex generality have been taken up for systematic investigations, primarily by the Chicago school of meteorology. Starting with Rossby's work on planetary waves [24], in which the specific importance of the variability of the Coriolis parameter was discovered, a series of papers have followed in which different barotropic phenomena have been discussed. Briefly, one may say that while some of them, apart from the modifications following from the spherical shape of the earth, are analogous to the classical works by Rayleigh, others represent original investigations as exemplified by those treating stationary solutions of the nonlinear vorticity equation [9, 13, 17, 20]. The mathematical solution of (30) involves, of course, all the difficulties connected with the solution of nonlinear equations. The difficulties may even be very great for the linearized equations, particularly when there is a variable zonal current [18]. It is, however, possible and also useful to obtain an understanding of several of the most important barotropic phenomena by direct physical considerations [14, pp. 15–35]. In the following discussion this kind of argument will be used. We will make the purely formal simplification of assuming that the horizontal motion takes place as if on a circular disk; however, f will be kept a variable parameter.

One of the physical principles which may be used for a general discussion of some barotropic phenomena is the conservation of total angular momentum:

$$\int uR\, dF = \text{const.} \tag{31}$$

Here R is the distance from the pole, and dF a surface element in the plane of motion. By introducing the velocity circulation $c = \int_0^{2\pi} uR\, d\psi$ along zonal circles, (31) becomes equivalent to

$$\int c\, dF = \text{const.} \tag{32}$$

Another equivalent expression can easily be shown to be [14, p. 21]

$$G = \int \zeta_{abs}(R_0, \psi_0)R^2\, dF = \text{const.} \tag{33}$$

Here, ζ_{abs} is represented as a function of Lagrangian coordinates, and is therefore independent of time because the absolute vorticity is conserved, and R represents the generally time-variable radial positions of the fluid particles. Equation (33) is now a condition which restricts all future radial positions. In Fig. 3

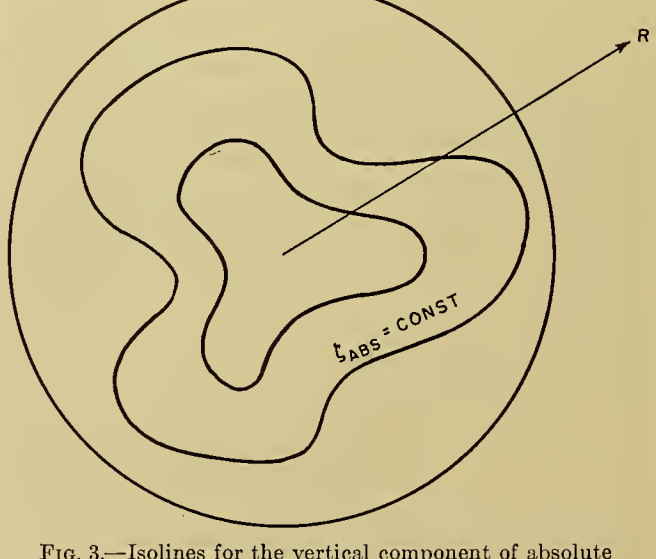

FIG. 3.—Isolines for the vertical component of absolute vorticity.

the irregular lines are curves of equal absolute vorticity for the case that ζ_{abs} varies monotonically from one isoline to the other. Clearly, a necessary and sufficient condition for having a pure zonal flow is that the lines

of equal vorticity have a zonal distribution. The motion corresponding to the vorticity distribution in Fig. 3 is therefore certainly not zonal. It may now be inferred from (33) that neither can it be so at any later time. The reason for this is that by varying the positions of the fluid particles, G assumes an extreme value if and only if the lines of equal vorticity are zonal. In the present case this extremum would be either an absolute minimum or maximum. Therefore, the isolines of ζ_{abs} could not possibly become zonal unless at the same time G varied in contradiction to (33). Thus, at all times one must have

$$\int \zeta'^2 \, dF \geqq m, \qquad (m > 0), \tag{34}$$

where a prime again has been used to indicate deviations from zonal means. With possible exceptions for some singular cases, it can be shown that (34) must be true for a quite general distribution of vorticities.

A problem of considerable interest is involved in the question as to what will happen in a barotropic atmosphere left with a certain distribution of vorticities that do not correspond to a motion which is stationary, either absolutely or with respect to a coordinate system rotating at a constant speed. Will the structure of the subsequent motion tend to approach a more or less definite limit, or will different structures be repeated more or less periodically? Synoptic experience is probably most in favor of the first point of view, though there have been attempts to interpret some cycles in the general circulation on a strictly barotropic basis. In favor of the first point of view one can at least say with certainty that theoretically no oscillations in the strict sense are possible. This is because in a purely oscillatory motion the fluid particles would simultaneously have to reassume earlier positions, but with different velocities. However, this is impossible because, according to the conservation of vorticity, the positions of the fluid particles determine uniquely the vorticity distribution which in turn determines the velocities.

From the condition $\int \zeta'^2 \, dF + \int \bar{\zeta}_{abs}^2 \, dF = \text{const}$, there is also an upper limit to $\int \zeta'^2 dF$, so that (34) may be extended to

$$M \geqq \int \zeta'^2 \, dF \geqq m, \qquad (m > 0). \tag{35}$$

Returning now to the kind of vorticity distributions which are illustrated in Fig. 3, it will be assumed as a particular case that the vorticity distribution deviates only slightly from a zonal one. The corresponding flow is a zonal flow upon which there are superimposed small disturbances. The time-invariant value of G will now be but slightly different from a maximum or minimum value, which implies that no change in the vorticity pattern from the nearly zonal one to one characterized as in Fig. 3 can take place without necessarily changing the value of G. The proof for this is simply the reversal of the one stating that it was not possible to come arbitrarily near to a zonal distribution. The corresponding zonal flow is, therefore, stable in this case. Let $\bar{\zeta}_0 + f$ and ζ_0' be the initial vorticities in the mean zonal flow and in the disturbances. An expression and criterion for the present stability is

$$M \geqq \int \zeta'^2 \, dF \geqq m, \qquad (m > 0), \tag{36a}$$

$$M \to 0 \quad \text{when} \quad \int \zeta_0'^2 \, dF \to 0, \tag{36b}$$

if

$$\bar{\zeta}_0 + f \quad \text{varies monotonically with latitude.} \tag{36c}$$

It should be mentioned that the result which has been found that polar anticyclones are always unstable in a barotropic atmosphere [23] cannot be true if (36) is true. That is because anticyclones may exist for which condition (36c) still may be true.

Suppose now again that the absolute vorticity for the mean zonal flow varies monotonically with latitude and consider the possible changes in the mean zonal flow which will result from the meridional exchange of air. It may be assumed, in accordance with the most frequent conditions, that $d(\bar{\zeta}_0 + f)/dy > 0$. One has

$$\bar{u} = \frac{c}{2\pi R} = \frac{1}{2\pi R} \int_F \zeta \, dF,$$

where F is the area north of the latitude circle which is being considered. Since equal areas of fluid are going in and out of a latitude circle, $\bar{u}$ will have to decrease or increase according as the vorticities leaving the circle are replaced by vorticities of lower or higher magnitudes, respectively. Now, each fluid particle is assigned a certain absolute vorticity $\bar{\zeta}_0 + f + \zeta_0'$ which is moving with the particle. The effect of this transport may be considered as a separate effect from those of the transport of $\bar{\zeta}_0 + f$ and of ζ_0'. As to the first effect it is easily understood that because $\bar{\zeta}_0 + f$ is increasing northwards, air streaming out of a zonal circle will have to be replaced by air with lower value of the absolute vorticity. This effect, when considered alone, will therefore amount to a decrease in c at all latitudes. This is in conflict with the principle of the conservation of total angular momentum, equation (32). It can, therefore, immediately be inferred that the effect from the transport of the initial irregular vorticities must be to compensate exactly this loss in angular momentum, that is, to create in the mean a compensating westerly flow [14, p. 28]. In consequence of this it may be concluded that, in the mean at least, the air with positive ζ_0' has to be transported to the north, and that with negative ζ_0' to the south. In the special case of a stationary flow pattern, as for instance for the Rossby waves, the two effects compensate each other exactly at each latitude. In other cases, however, one can only expect that the compensation is accomplished after integration over all latitudes. It has been assumed by Kuo [19] that the effect of the transport

of the irregular vorticities will be the dominating one at middle latitudes, resulting there in an increase of the westerlies. However, the arguments used are not convincing, and without carrying out numerical calculations nothing certain can be said with respect to the resulting changes in the mean zonal flow. Preliminary calculations [15] seem to indicate that rather than increasing the westerlies at middle latitudes, the tendency under certain conditions may as well be to decrease the westerlies at middle latitudes and increase them in belts to the north and south, particularly to the north.

In a barotropic atmosphere the energy equation reduces to

$$\int \tfrac{1}{2}\mathrm{v}'^2\,dF = -\int \tfrac{1}{2}\bar{u}^2\,dF + \text{const.}$$

Consequently, there is an upper bound to the kinetic energy of the disturbances. In the case where ζ_{abs} varied monotonically from one isoline of vorticity to the next it was found that there must be a lower bound to $\int \zeta'^2\,dF$ which is different from zero. The same must, therefore, be the case for the kinetic energy of the irregular flow. Thus, in this case

$$A \geqq \int \tfrac{1}{2}\mathrm{v}'^2\,dF \geqq a, \qquad (a > 0). \tag{37}$$

The stability under condition (36c) therefore does not imply that the disturbances are entirely damped out. Whether the total kinetic energy of the disturbances will increase or decrease is usually difficult to ascertain and will depend upon the character of the changes in $\bar{u}$. Writing

$$\begin{aligned}\tfrac{1}{2}\int (\mathrm{v}'^2 - \mathrm{v}_0'^2)\,dF &= -\tfrac{1}{2}\int (\bar{u}^2 - \bar{u}_0^2)\,dF \\ &= -\int \frac{\bar{u}_0}{R}(\bar{u}R - \bar{u}_0 R)\,dF - \tfrac{1}{2}\int (\bar{u} - \bar{u}_0)^2\,dF,\end{aligned} \tag{38}$$

one finds easily [14, p. 23] by using condition (31) in the form

$$\int (\bar{u}R - \bar{u}_0 R)\,dF = 0 \tag{39}$$

that $\bar{u}$ has to decrease where $\bar{u}_0/R$ is large and increase where $\bar{u}_0/R$ is small, if the kinetic energy of the disturbances is to increase. Particularly if one has to do with small disturbances in a zonal flow, the upper bound to the changes in $\bar{u}$ which can be caused by a transport of the initial irregular vorticities is also a small quantity. In order to find necessary conditions for real instability one has therefore to investigate the effect from the transport of $\bar{\zeta}_0 + f$. It was found earlier that $\bar{u}$ would decrease if $d(\bar{\zeta}_0 + f)/dy > 0$. By similar arguments one will find that $\bar{u}$ on the other hand has to increase where $d(\bar{\zeta}_0 + f)/dy < 0$. So, the necessary conditions for real instability will be that

$$\begin{aligned}&\frac{d}{dy}(\bar{\zeta}_0 + f) > 0 \quad \text{where } \frac{\bar{u}_0}{R} \text{ is large,} \\ &\frac{d}{dy}(\bar{\zeta}_0 + f) < 0 \quad \text{where } \frac{\bar{u}_0}{R} \text{ is small.}\end{aligned} \tag{40}$$

The trivial case with solid rotation in the mean flow, $\bar{u}_0/R = \text{const}$, implies, of course, according to (38) and (39), that $\int \tfrac{1}{2}\mathrm{v}'^2\,dF$ at most can remain constant in time, but will decrease if some changes in $\bar{u}$ result.

Hitherto, the most complete mathematical treatment of barotropic waves in a basic flow which is unstable in the above sense has been undertaken by Kuo [18]. This instability is fundamentally the same as the one occurring when a gliding discontinuity exists. However, by treating the realistic case with a continuous shear and including the variation of the Coriolis parameter, two important modifications result:

1. As results of an assumed continuous shear under average atmospheric conditions:

a. All waves below approximately 300 km are stable.

b. An intermediate wave length of maximum instability exists.

2. As a result of the inclusion of $df/dy \neq 0$, the longest waves become stable.

It is important to notice that the most unstable waves of the type discussed above are relatively long waves compared with the most unstable baroclinic waves [10; 14, p. 50].

How can the stability occurring for short waves mentioned above be understood? It was previously seen that provided conditions (40) were fulfilled the kinetic energy of the disturbances would necessarily increase as a result of a transport of $\bar{\zeta}_0 + f$. Therefore, when the shortest waves become stable this can only be a result of the transport of the initial irregular vorticities, ζ_0', which furthermore must tend to be the dominating effect for the shortest wave lengths. An understanding of the stabilizing influence arising from the transport of irregular vorticities may be obtained in the following way: Suppose a wavelike disturbance with untilted troughs and ridges to exist initially in a nonuniform zonal current. The instantaneous transport of the irregular vorticities is accomplished by a component $\bar{u}_0\mathbf{i}$ of the mean flow and a component $\mathbf{v}_0'$ of the irregular flow. When small disturbances are considered, or disturbances in which $\mathbf{v}_0'$ is essentially parallel to the lines $\zeta_0' = \text{const}$, only the transport by the first component has to be considered. It is now obvious that if the angular velocity $\bar{u}_0/R$ varies with latitude, the lengths of the lines $\zeta' = \text{const}$ have to increase as a result of this transport. On the other hand, the areas enclosed by these lines are conserved as are also the values of ζ' because the effects of the transverse displacements of the vorticities $\bar{\zeta}_0 + f$ are disregarded in this connection. Consequently, it follows from Stokes' theorem that the velocity circulation for the disturbances taken along the closed curves $v\zeta' = \text{const}$, which approximately are also streamlines for $\mathbf{v}'$, must remain

constant. But since the lengths of the streamlines for v' increase, the average intensity of $|v'|$ must decrease correspondingly. When this stabilizing influence dominates the destabilizing influence from the transverse transport of vorticities of the basic flow, which can be shown to be the case for the shortest waves [14, p. 31], kinetic energy must flow from the disturbances to the mean flow so that in accordance with what was said above, $\bar{u}$ will have to increase where $\bar{u}/R$ is large and decrease where $\bar{u}/R$ is small.

Combined Baroclinic and Barotropic Disturbances

While there is enough evidence for the importance both of baroclinic and barotropic effects, there must be a limit to the extent to which phenomena can be explained purely barotropically or baroclinically. In general, one must expect that barotropic and baroclinic effects either add together in a more or less simple fashion, or they may be coupled to such a degree that the consideration of both effects simultaneously may give rise to entirely new types of phenomena.

The only studies until now on waves for which both potential and kinetic energy are possible sources for the growth of the disturbance are those on polar front waves. Because of the complexity in the solutions for these waves one does not know whether the one or the other of these two possible sources is the more important, although the shearing instability has been interpreted as the decisive one, seemingly, however, without any convincing justification. The unstable baroclinic waves treated in this article have accordingly been looked upon as physically entirely different waves. It is the writer's opinion that this probably is not true. Further investigations on this subject can be carried out with relative ease when the quasi-geostrophic approximation is made. Relatively simple equations appropriate for the most simple polar front model have been worked out by Phillips [21].

It is not unlikely that the study of an atmosphere where typical barotropic and baroclinic effects are operating in full generality may contribute considerably to a further understanding of the behavior of the atmosphere. For this purpose equations (23) and (25), or essentially similar equations, may prove useful, at least for theoretical investigations, because of their great simplicity and generality.

THE QUANTITATIVE THEORY OF CYCLONE DEVELOPMENT

By E. T. EADY

Imperial College of Science and Technology

Introduction

The title of this article indicates its principal theme but not its full scope, for although we shall explain the method of formulating and solving certain theoretical problems and shall interpret the answers in terms of the initial stages of development of extratropical cyclones and anticyclones, our analysis has also a wider significance. Not only does a fundamentally similar theoretical analysis apply to a wide variety of development problems (including, for example, the development of "long" waves as well as the shorter "frontal" waves and even phenomena due primarily to ordinary convective instability) so that a comprehensive analysis is desirable, but this analysis gives results of primary importance in the theory of development *in general*, that is, from the point of view of the general forecasting problem. We shall infer from our results that there exist, in general, certain ultimate limitations to the possibilities of weather forecasting. Certain apparently sensible questions, such as the question of weather conditions at a given time in the comparatively distant future, say several days ahead, are *in principle* unanswerable and the most we can hope to do is to determine the relative *probabilities* of different outcomes. The full significance of our theoretical problems becomes apparent only when it is clear what *kind* of question we should attempt to answer.

The science of meteorology is a branch of mathematical physics; it can be fully understood only in a quantitative manner. Moreover, all the practical questions we should like to answer are of a quantitative character. Having discovered the relevant equations of motion, we ought to aim at obtaining significant integrals (more precisely, solutions of significant boundary-value problems) which may be applied directly to practical problems. In order to obtain tractable problems, and at the same time to see clearly what we are doing (*i.e.*, "to see the wood for the trees"), we may, for a first analysis, simplify the equations by omitting all factors not vitally affecting the nature of the answer. Later we may refine our solutions by taking into account factors previously omitted (*e.g.*, by the method of successive approximations), thereby testing whether we have in fact included all the vital factors. This is a procedure with which we are familiar and, however laborious it may be in practice, it introduces no new difficulty in principle. The really serious difficulty is to discover what kind of problem ought to be solved, for this difficulty arises as soon as we consider the question of the stability of atmospheric motion. Observation suggests that the motion may, at least sometimes, be unstable, and we shall infer from subsequent analysis that instability (to a greater or less degree) is a *normal* feature of atmospheric motion.

It is important to be quite clear as to the meaning of the term "unstable" when applied to a system of fluid motion. If we suppose the initial field of motion to be given, the final field of motion, after a given interval of time, is determined precisely by the equations of motion, continuity, radiation, etc., together with the appropriate boundary conditions. If we consider a slightly different (perturbed) initial state, the new final state, after the same interval of time, will be determined in a similar manner. The stability or instability of the motion depends on the behaviour of the resulting change (perturbation) in the final state as the time interval is increased. If the final perturbation remains small for all time for *all* possible initial perturbations, the motion is stable. If, on the other hand, the perturbation in some or all regions grows (initially) at an exponential rate for *any* possible initial perturbation, the motion is unstable. There is an intermediate case, conveniently described as *neutral* stability, when the perturbations grow linearly or according to a low-degree power law, but this need not concern us here.

The practical significance of a demonstration that the motion is unstable is clear, for in practice, however good our network of observations may be, the initial state of motion is never given precisely and we never know what small perturbations may exist below a certain margin of error. Since the perturbation may grow at an exponential rate, the margin of error in the forecast (final) state will grow exponentially as the period of the forecast is increased, and this possible error is unavoidable whatever our method of forecasting. After a limited time interval, which, as we shall see, can be roughly estimated, the possible error will become so large as to make the forecast valueless. In other words, the set of all possible future developments consistent with our initial data is a divergent set and any direct computation will simply pick out, arbitrarily, one member of the set. Clearly, if we are to glean any information at all about developments beyond the limited time interval, we must extend our analysis and consider the properties of the set or "ensemble" (corresponding to the Gibbs-ensemble of statistical mechanics) of all possible developments. Thus long-range forecasting is necessarily a branch of statistical physics in its widest sense: both our questions and answers must be expressed in terms of *probabilities*.

There are two important connections between these general considerations and subsequent analysis. Firstly, this analysis will show the existence of at least one type of large-scale unstable disturbance in a simplified but typical system, and we shall infer that instability is a

normal feature of atmospheric motion. Although the unstable disturbances are continually tending to establish a new stable state, radiative processes are continuously tending to restore the initial system, which therefore remains *permanently* unstable. Secondly, for such a system the study of the ensemble of all possible perturbations is relatively simple. In each system there exists a disturbance of maximum growth-rate (so that we can determine the growth of the margin of error and estimate the limited time interval referred to above) which eventually becomes dominant in subsequent developments by a process analogous to Darwinian natural selection. Almost any initial disturbance tends eventually to resemble the dominant, which is therefore the most probable development. The "ensemble" possesses at least *some* strongly marked statistical properties which may be utilised to extend the range of forecasts. In spite of inaccuracies due to oversimplification this result is practically significant. The disturbances referred to are approximations to nascent cyclones, long waves, etc.; were it not that "natural selection" is a very real process, weather systems would be much more variable in size, structure, and behaviour.

The Basic Equations

We shall regard as basic equations the three dynamical equations, the thermal equation, and the equation of continuity; others, such as the gas laws and the laws of radiation, will be regarded as subsidiary. The number of dependent variables we need, or that we find it convenient to use, depends on the nature of the problem and the degree of accuracy aimed at. In the problems with which we shall be concerned it is possible to express the basic equations in terms of the three components of velocity, pressure, and entropy (or density) alone so that the five basic equations, together with appropriate boundary conditions, form a complete set. Clearly these equations can be appropriate only for a limited range of problems when certain approximations are justified; we shall in fact make further approximations, our aim being to retain only those terms which are of prime importance in the range in which we are interested.

A completely realistic theory of the stability of atmospheric motion should deal with nonsteady initial conditions, but for simplicity we shall confine our attention to the case in which the initial motion is steady, and in fact we shall be concerned mainly with rectilinear horizontal motion. Our analysis will be approximately true even when the very-large-scale distribution is slowly changing.

The relative importance of the terms in our equations depends partly on the scale of the phenomena with which we are concerned. Here we are interested in disturbances of the order of magnitude of nascent cyclones, say 1000 km in horizontal extent and occupying a large part (or the whole depth) of the troposphere. From our point of view ordinary or gravitational convection, originating from static instability (*i.e.*, superadiabatic lapse rate), and ordinary turbulence of frictional or convective origin are small-scale phenomena. The epithet "ordinary" is appropriate in each case because the disturbances whose nascent form we are studying may be regarded as elements of a large-scale convective process and this process, regarded statistically, is a kind of large-scale turbulence. From our point of view the significance of small-scale turbulence, including ordinary convection, lies in its statistical properties, such as ability to transport heat, momentum, etc. Now frictionally induced turbulence is most effective near the earth's surface, and rough calculations (which we have not space to describe) using empirical estimates of skin friction indicate that frictional dissipation of energy usually has a relatively small effect on the development of large-scale disturbances (especially over a sea surface) in their *nascent* stage, provided the unstabilising factors are not too weak. Since we are most interested in those regions where the unstabilising factors are relatively strong, we may obtain a useful first approximation during the nascent stage if we neglect the frictional terms in the equations of motion. It is not possible to neglect frictional terms throughout the whole life-history of a disturbance because in the long run the kinetic energy destroyed by friction must equal that generated as a result of instability.

Surface friction transports heat vertically through a shallow layer, but since we are interested in the behaviour of deep layers this effect will be neglected. Moreover, surface turbulence is partly convective in origin, and we may regard shallow convection as included in this argument. But sometimes (*e.g.*, in strong polar outbreaks) deep and widespread convection transports heat to great heights at a great rate. We shall ignore this possible complication and concentrate our attention on systems in middle and high latitudes which are statically stable in their initial stages.

Just as, in the long run, we cannot ignore skin friction so, in the long run, we cannot ignore radiative processes. Large-scale turbulence (the statistical aspect of our disturbances) appears to be a major factor in transporting heat poleward to compensate the unbalanced radiation flux. But during the nascent stage, development (measured by the time for growth of the disturbance by a given factor) is relatively rapid and it is precisely for this reason that we are able to neglect frictional terms. Hence it is reasonable to suppose that in the nascent stage we may, for a first approximation, neglect the change in the radiation balance caused by the disturbance and use for our thermal equation the adiabatic equation.

Consider first the case of unsaturated air. To a close enough approximation the entropy of dry air is measured, in suitable units, by $\Phi \equiv (1/\gamma) \ln p - \ln \rho$, where p = pressure, ρ = density, γ = specific heat ratio, and Φ is conserved during the motion. In this case we shall define the static stability, which measures the restoring force due to gravity on a particle displaced vertically, as $\partial\Phi/\partial z$ (z = vertical coordinate). Now consider the case of saturated air in contact with a cloud. The static stability is now measured by the difference

between the actual entropy lapse and that of the appropriate wet-adiabatic. Thus there is a sharp, and usually a large, reduction in static stability when air becomes saturated. The effective horizontal entropy gradients are also modified as a result of saturation, but to a much smaller extent. Normally a cloud mass behaves, to a sufficiently close approximation, as if the air were unsaturated except for the appropriate modification in static stability.

Our equations are complicated by the fact that air is a compressible fluid, but it is clear that this feature is not, for our purposes, a significant one. We are concerned essentially with a particular type of "vibration" problem though our disturbances have mathematically complex wave velocities. The moduli of these wave velocities are in all cases, as our calculations verify, small compared with the velocity of sound. It is not surprising therefore that the forces associated with compressibility are negligible, that is, that the air behaves *dynamically* as if it were incompressible. The static effect of compressibility, involving a large change of density with height, is a complication which prevents atmospheric motion from being quite the same as that of an incompressible fluid. Nevertheless, even for deep disturbances, the behaviour differs little from that of an incompressible fluid of similar mean density: the modifications are essentially of the nature of distortions of wave structure without much change in more significant features like growth rate. We shall therefore confine our attention to "equivalent" incompressible fluid systems. Our results are, of course, more directly applicable to analogous oceanographic problems.

Lack of space prevents a discussion of these points in mathematical terms. It has been shown elsewhere [3] that the basic equations may be further simplified by the elimination of the pressure field, so that we have finally four equations connecting the four dependent variables V_x, V_y, V_z (velocity components), and Φ (entropy). But our present concern is the physical interpretation and practical significance of certain calculations rather than the calculations themselves.

The General Theory of the Instability of Fluid Motion

The various types of instability occurring in dynamical meteorology merge into one another so that most systems encountered in practice are, to a greater or less degree, hybrid. Nevertheless it is not only simpler but theoretically more instructive to consider certain ideal limiting cases where one or another unstabilising factor acts alone. Four simple types of instability will interest us:

1*a*. Gravitational instability (ordinary convection or static instability).

1*b*. Centrifugal instability (dynamic instability).

2*a*. Baroclinic instability (with thermal wind).

2*b*. Helmholtz instability (at a velocity discontinuity).

Instability of type 1*a* is, in middle and high latitudes, nearly always a small-scale phenomenon, but in low latitudes a modified form, taking into account the rotation of the earth, is intimately concerned with the development of tropical cyclones.

Instability of type 1*b* has been the subject of much recent investigation, usually under the heading "dynamic instability," but despite its theoretical importance it is probably rare for large-scale motion. The name "centrifugal" has been preferred to "dynamic" because it is more descriptive and less confusing—other types of instability may reasonably be called "dynamic."

Instability of type 2*a* is probably the most important, on a large scale, in middle and high latitudes. It is to this type that our earlier remarks regarding the normality of instability and the existence of "natural selection" directly apply.

Instability of type 2*b* was investigated by Helmholtz and Rayleigh for nonrotating barotropic fluids. The Norwegian wave theory of cyclones was a partially successful attempt to extend the theory to rotating barotropic fluids.

Although we shall choose our initial systems so that only one type of instability is in question, the same general method of analysis applies in every case. Using the method of small perturbations, we obtain a set of simultaneous, linear, partial differential equations involving the perturbations as dependent variables. By elimination we obtain a partial differential equation with only one dependent variable and look for simple solutions satisfying appropriate boundary conditions. Usually these solutions involve only circular or exponential functions in the horizontal (x and y directions) and all contain the factor $e^{\theta_1 t}$ where t represents time and θ_1 is a constant called the growth rate. For θ_1 to be real we usually have to use a moving coordinate system. Fortunately these solutions for unstable waves are, practically, the most important ones and the disturbance of maximum growth rate, when it exists, is probably dominant relative to one of *arbitrary* initial structure. In any case a study of these particular solutions enables us to *understand* the process of breakdown of the initial system and to estimate the relative importance of various factors.

The method of analysis outlined above is necessary if we require precise results and is the only one which is completely unequivocal. But it is mathematical in form and usually rather involved so that significant physical principles, which give us insight into our problems and immediately suggest generalisations, tend to be obscured. Now, except that our interest is centred in the unstable region, we are concerned with what are essentially vibration problems and we may expect to find that energy considerations are of paramount importance. For, by the law of conservation of energy, the kinetic energy associated with any perturbation must be equal to the decrease in "potential" energy of the system, and a necessary condition for instability is that it should be possible to find displacements which will decrease "potential" energy; the condition will be sufficient only if these displacements are consistent with all the equations of motion and boundary conditions. More precisely, using Rayleigh's method, we

may express separately the changes in kinetic and "potential" energy in terms of arbitrary displacements of the form $\delta x = e^{\theta_1 t}\delta x_0(x, y, z)$, etc. The kinetic energy change contains the factor θ_1^2, while the "potential" energy change does not, so that the law of conservation of energy gives an expression for θ_1^2 in terms of the displacements. The possible simultaneous values of the displacements are restricted (or constrained) by the equations of motion and we can to some extent delimit possible values of θ_1^2 by considering only some of the constraints, as in somewhat analogous problems in dynamics. In the present instance we consider only the equation of continuity and one momentum equation (and suitable boundary conditions) and then apply algebraic inequality theory to our undetermined displacements. We thereby obtain an *upper* bound to the possible value of θ_1^2 (corresponding to *negative* square of frequency) just as in dynamics we obtain a lower bound to frequency (squared) by considering a less constrained system.

The value of the foregoing, described in more detail elsewhere [3], derives partly from the fact that we can treat a wider variety of problems than we can by complete solution, while the value of θ_1^2 (maximum) thereby obtained is usually not much greater than the true value of θ_1^2. But its greatest usefulness is that it makes the process of breakdown of unstable systems immediately intelligible. If we take into account only our limited set of constraints, it is immediately evident what kind of displacement field is necessary for a release of "potential" energy. It is of course essential that the term "potential" energy be correctly interpreted. For our purpose it comprises *all* forms of energy other than the kinetic energy of the perturbation and therefore includes, besides gravitational potential energy, the organised kinetic energy of the mean flow (smoothed of harmonic variation). This distinction between two kinds of kinetic energy change is justified by their different roles in the turbulent motion which is the ultimate state in practice: turbulent energy may arise either from a decrease in gravitational potential energy or from a decrease in kinetic energy of the mean motion. We may classify our systems according to whether the "potential" energy source is (*a*) static (gravitational) or (*b*) dynamic (kinetic). Now the displacement field is merely the nascent form of a process of overturning and we shall need to consider only two possibilities: (1) overturning in a *vertical* plane; (2) overturning in a *quasi-horizontal* plane. Thus we may also classify our systems according to the kind of overturning associated with instability. In our list of four simple types of instability we anticipated their classification from both points of view. Let us consider the characteristics of these systems.

1*a*. *Gravitational Instability.* We consider barotropic conditions, so that initially there is no wind change with height, and for simplicity we suppose that $d\Phi/dz = B$, where B is constant. If, to begin with, we neglect the rotation of the earth, then "potential" energy exists only in gravitational potential form. Suppose that two small parcels of air of equal potential volume were slowly interchanged. Then since potential density would depend only on entropy, we should obtain, if B were negative, a net release of energy for *any* two parcels at different levels, while if B were positive no interchange could release potential energy. Clearly the constraints associated with the continuity equation cannot alter this result—the overturning process is equivalent to a set of such interchanges of different amplitudes. Since horizontal motion does not affect potential energy we need consider only vertical overturning; calculations by the energy method give $\theta_1^2 \leq -gB$, where g = gravitational acceleration. Of course in this simple case it is easy to obtain complete solutions, representing the nascent stage of Bénard cells, and calculations show that θ_1^2 (maximum) is nearly attained for narrow deep cells, where little energy is wasted in horizontal motion. We shall postpone the extension to large-scale convection, where the rotation of the earth is considered, since this is really a combination of types 1*a* and 1*b*.

1*b*. *Centrifugal Instability.* We shall suppose the motion to be barotropic and horizontal with the initial velocity V_x a function of y only. For simplicity we take dV_x/dy constant and, to begin with, we put $B = 0$ (isentropic conditions). Then "potential" energy exists only in the "kinetic" form. Let us consider the change due to overturning in the (vertical) y, z plane. Filaments of air in the x-direction move as a whole and we easily derive from the equations of motion that, during displacement, $\delta V_x = f\delta y$, where f is the Coriolis parameter. If the x-axis is directed toward the east, this corresponds to constancy of absolute angular momentum. But for our purposes, where a mean value of f is used, the orientation of the x-axis is arbitrary. A simple calculation shows that potential energy is released only if $dV_x/dy > f$, corresponding to negative absolute vorticity, and the energy method gives $\theta_1^2 \leq f(dV_x/dy - f)$. Although values of dV_x/dy *near* the critical value are sometimes observed in narrow bands, it is doubtful whether centrifugal instability ever occurs on a large scale except perhaps in low latitudes. The rotation of the earth, normally at least, has a stabilising effect so far as *vertical* overturning is concerned.

Similar results are obtained if, instead of rectilinear motion, we consider a barotropic circular vortex (with no motion relative to the earth as a special case). The condition for instability is again negative absolute vorticity.

We may note that in both the foregoing cases maximum instability occurs for shallow, flat, cells since "potential" energy changes depend only on horizontal motion (no energy is wasted in vertical motion).

1*ab*. *Gravitational-Centrifugal Instability.* It is easy to combine the results of the previous sections for a system in which neither B nor dV_x/dy vanishes. There is instability if either B or $(f - dV_x/dy)$ is negative, for the cells may be either so deep that centrifugal stability is negligible or so shallow that static stability is negligible. The important practical case is that of no motion (special case of circular vortex) with $B < 0$. Instability occurs for disturbances which are sufficiently

deep relative to their breadth, the condition being that there should be a *net* release of "potential" energy. In low latitudes not only is $-B$ sometimes (temporarily) relatively large but the stabilising effect of the earth's rotation is small, so that convection cells of relatively enormous diameter (nascent hurricanes) can develop.

In general, maximum growth rate corresponds either to very deep or to very shallow cells but this result is not of great significance because practical systems are very inhomogeneous.

2*a*. *Baroclinic Instability.* We suppose the initial motion to be rectilinear and take the initial velocity V_x to be a function of z only. For equilibrium this implies a horizontal gradient of entropy $A \equiv \partial\Phi/\partial y$, where, approximately ($A$ not too small), $dV_x/dz = -gA/f$. For simplicity we suppose A to be constant. Pure baroclinic instability should correspond to $B = 0$, but it will be convenient to consider directly the more general case $B \neq 0$. In practice we usually have (at least in the mean) $B > 0$, and this is the only case we need examine, for when $B < 0$ the system is obviously unstable. The isentropic surfaces have an angle of slope $\alpha(<\pi/2)$ given by $\tan\alpha = |A/B|$ and in practice we normally have $\tan\alpha \ll 1$.

Consider first the change in gravitational potential energy resulting from interchange of parcels of air in the manner of subsection 1*a*. The result is no longer independent of the y-displacement. If the direction of displacement lies outside the acute angle α, there is an increase of energy, but if it lies inside, energy is released. There is zero change for displacement either along the isentropic surfaces or horizontally, and calculation shows that maximum release of energy occurs (approximately, assuming $\alpha \ll \pi/4$) for displacement in the direction of the bisector of α (in the y, z plane), which we shall call the s-axis. Now consider the change in kinetic "potential" energy. If the overturning were in the vertical plane, this would occur in the manner of subsection 1*b*, with increase of energy. But if overturning occurs in the x, s plane (*i.e.*, quasi-horizontally), with the perturbations varying harmonically in the x-direction, there is no change in the mean motion and no change of energy (correct to the appropriate order of small quantities). Hence our energy method gives instability in *all* cases and on calculation:

$$\theta_1^2 \leq -g_s B_s \approx \frac{1}{4}\frac{f^2}{h^2} \qquad (h^2 >> 1),$$

where g_s and B_s are the components of gravity and entropy gradient, respectively, along the s-axis (note analogy to 1*a*) and h^2 is the Richardson number defined by $h^2 = gB/(dV_x/dz)^2$.

This result is of course provisional but, as in other cases, is verified by complete solution. With artificial (but physically possible) boundary conditions we can obtain nearly the maximum value of θ_1, but a more realistic model gives $\theta_1 \approx 0.31\, f/h$. The reduction in the coefficient from 0.5 to 0.31 is due to the additional constraints imposed by the boundary conditions, as a result of which displacements cannot everywhere be in the optimum s-direction: for one particular wave length (more precisely, for one ratio of horizontal to vertical "wave length"), the displacements are as near optimum as possible and it is to this dominant wave that the coefficient 0.31 applies. Longer waves grow more slowly while very short waves are stable. Thus there is "natural selection" for one particular wave structure. It has been shown elsewhere how, by considering compound systems containing a region where h^2 is a minimum, realistic models of both nascent wave cyclones and long waves may be constructed. Briefly, the smaller disturbances develop in frontal regions, where cloud masses reduce the effective static stability and therefore also h^2. The long waves occupy the whole troposphere, and secondary modifications, caused by constraints associated with the variability of the Coriolis parameter, are then significant.

1*ab*. *Generalised Vertical-Overturning Instability.* We may consider from the point of view of *vertical* overturning an initial system similar to that of subsection 2*a*, but it will be convenient to generalise by supposing V_x to vary with y as well as with z. Then using the same general method as before, we obtain

$$2\theta_1^2 \leq -\left[gB + f\left(f - \frac{dV_x}{dy}\right)\right] + \sqrt{\left[gB + f\left(f - \frac{dV_x}{dy}\right)\right]^2 + 4\left[(gA)^2 - gBf\left(f - \frac{dV_x}{dy}\right)\right]},$$

where the surd has always to be taken as positive. This is the general formula for vertical overturning, including the examples previously given as special cases. If either $B < 0$ or $dV_x/dy > f$, the system is certainly unstable. If neither condition is satisfied, we require for instability $(gA)^2 > gBf(f - dV_x/dy)$, which is equivalent to $1/h^2 > [1 - (1/f)(dV_x/dy)]$. In the important special case when dV_x/dy vanishes, this condition becomes simply $h^2 < 1$, equivalent to the well-known condition of negative absolute vorticity in the isentropic surfaces.

2*b*. *Helmholtz Instability.* Consider the system of two barotropic air masses with uniform horizontal motion $V_x = U_1$ in one, and $V_x = U_2$ in the other, separated by a vertical "front" at the x, z plane. If the earth were not rotating, we could apply the well-known results of Helmholtz (complete solutions) which show this system to be unstable for *all* perturbation wave lengths, growth-rate being inversely proportional to wave length, but it is instructive to apply the energy method. Helmholtz's solutions involve only horizontal motion, associated with corrugation of the "front," so we need consider only *horizontal* overturning. The "potential" energy is entirely "kinetic" and the manner of its release is clear from the flow pattern, obtained by considerations of continuity and boundary conditions alone. Outside the y-limits to which the corrugations of the "front" extend, the mean motion is unaltered, but inside these limits there is a change in the

mean flow of each air mass (in opposite directions) resulting in a decrease in organised kinetic energy (see Fig. 1).

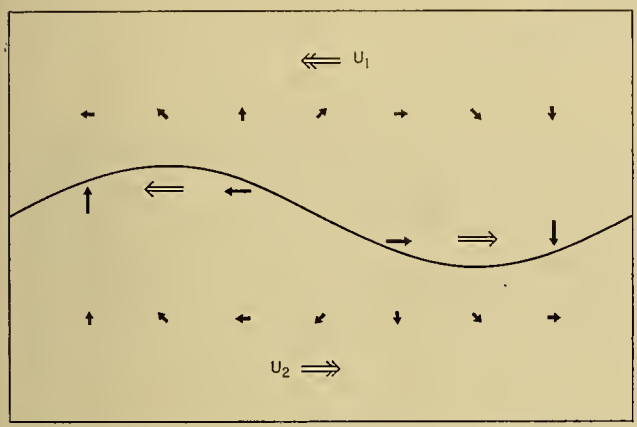

FIG. 1.—Helmholtz waves. Arrows with a single head and a single shaft denote perturbation velocities; those with a single head and double shaft, perturbation mean velocities; those with a double head and a double shaft, initial velocities.

Now, as we have seen, the earth's rotation has a stabilising effect only when there is *vertical* overturning. Hence we should expect results similar to those mentioned above when the earth's rotation is taken into account. Complete solution of the problem confirms this, and $\theta_1^2 = (\lambda^2/4)(U_1 - U_2)^2$, where $2\pi/\lambda$ is the wave length for a rotating, as well as for a nonrotating, system.

In practice, B is usually strongly positive so that any vertical motion would decrease the net release of "potential" energy. Moreover, frontal surfaces are not usually vertical and in general the boundary conditions cannot be satisfied by purely horizontal motion. Hence a sloping front is less unstable than a vertical one. Since the unstabilising effect of a velocity discontinuity is inversely proportional to the wave length, whereas the stabilising effect of static stability is independent of the scale of motion, it follows that only waves shorter than a critical wave length are unstable. Very short waves are always unstable because static stability may be neglected.

Future Developments

The discussion above is merely an outline of elementary principles. Although our analysis shows that the equations of dynamical meteorology are by no means intractable from the point of view of computing future developments, the results so far obtained are only of limited applicability. Our calculations give only the initial form of the most probable (dominant) new development and we need to compute the further development when the perturbations are no longer small. As the period of the forecast is extended, analytical methods become increasingly involved and clumsy and sooner or later we have to resort, at least partly, to numerical methods. An adequate degree of accuracy is practically attainable only with the use of computing machines, and electronic large-memory computers will play an important part in extending and generalising the elementary theory.

The development of numerical methods, even to the extent of a direct attack using observed data, does not absolve us from the necessity of understanding the precise significance of our solutions. Not only do we have to know how and where to approximate, but the reliability of our solutions varies with time, place, and forecast period. In fact for long forecast periods what is significant is not the detail, which is usually partially, perhaps entirely, accidental (*i.e.*, dependent on minutiae below the margin of error), but the general nature (*e.g.*, persistently settled or unsettled) of the majority of possible solutions. We need to develop the statistical theory referred to earlier. Not all the questions about future weather we should like to answer are in fact answerable, but it may well be that the growth of uncertainty in some directions is compensated by statistical regularity in others.

DYNAMIC FORECASTING BY NUMERICAL PROCESS

By J. G. CHARNEY

*The Institute for Advanced Study**

Introduction

As meteorologists have long known, the atmosphere exhibits no periodicities of the kind that enable one to predict the weather in the same way one predicts the tides. No simple set of causal relationships can be found which relate the state of the atmosphere at one instant of time to its state at another. It was this realization that led V. Bjerknes in 1904 [1] to define the problem of prognosis as nothing less than the integration of the equations of motion of the atmosphere. But it remained for Richardson [12] to suggest in 1922 the practical means for the solution of this problem. He proposed to integrate the equations of motion numerically and showed exactly how this might be done. That the actual forecast used to test his method was unsuccessful was in no sense a measure of the value of his work. In retrospect, it becomes obvious that the inadequacies of observation alone would have doomed any attempt however well conceived, a circumstance of which Richardson was aware. The real value of his work lay in the fact that it crystallized once and for all the essential problems that would have to be faced by future workers in the field and that it laid down a thorough groundwork for their solution.

For a long time no one ventured to follow in Richardson's footsteps. The paucity of the observational network and the enormity of the computational task stood as apparently unsurmountable barriers to the realization of his dream that one day it might be possible to advance the computation faster than the weather. But with the increase in the density and extent of the surface and upper-air observational network on the one hand, and the development of large-capacity high-speed computing machines on the other, interest has revived in Richardson's problem and attempts have been made to attack it anew.

These efforts have been characterized by a devotion to objectives more limited than Richardson's. Instead of attempting to deal with the atmosphere in all its complexity, one tries to be satisfied with simplified models approximating the actual motions to a greater or lesser degree. By starting with models incorporating only what are thought to be the most important of the atmospheric influences, and by gradually bringing in others, one is able to proceed inductively and thereby to avoid the pitfalls inevitably encountered when a great many poorly understood factors are introduced all at once.

A necessary condition for the success of this stepwise method is, of course, that the first approximations bear a recognizable resemblance to the actual motions. Fortunately, the science of meteorology has progressed to the point where one feels that at least the main factors governing the large-scale atmospheric motion are known. Thus integrations of even the linearized barotropic and thermally inactive baroclinic equations have yielded solutions bearing a marked resemblance to reality. At any rate, it seems clear that the models embodying in mathematical form the collective experience and the positive skill of the forecaster cannot fail utterly. This conviction has served as the guiding principle in the work of the meteorology project at The Institute for Advanced Study with which the writer has been connected.

The Geostrophic Approximation

In the selection of a suitable first approximation, Richardson's discovery that the horizontal divergence was an unmeasurable quantity had to be taken into account. Here a consideration of forecasting practice gave rise to the belief that this difficulty could be surmounted: forecasts were made by means of geostrophic reasoning from the pressure field alone—forecasts in which the concept of horizontal divergence played no part. And indeed, this belief was substantiated when it was shown by Charney [2] and Eliassen [7] that the geostrophic approximation could be used to reduce the equations of motion to a single dynamically consistent equation in which pressure appears as the sole dependent variable.

If, in addition to the geostrophic approximation, one makes the assumptions that frictional and nonadiabatic effects may be ignored, the equations of motion are found to be contained in the statement that the potential temperature and the potential vorticity, as defined by Rossby [13], are conserved, and that both the quasi-hydrostatic and the geostrophic approximations may be used for evaluating the terms involving density and horizontal velocity in the conservation equations. A partial justification for this procedure was given by the author [2], but the ultimate test must depend upon comparison of theory with observation.

The potential vorticity is defined as specific volume times the scalar product of the absolute vorticity and the entropy gradient. For the large-scale atmospheric motions the isentropic surfaces are quasi-horizontal, and we may to a first approximation replace the absolute vorticity and entropy gradient by their vertical components. The pressure equation then becomes [3]

$$\left[\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{f(\zeta_g+f)}{g\partial \ln\theta/\partial z}\left(\frac{\partial^2}{\partial z^2}+\alpha\frac{\partial}{\partial z}+\beta\right)\right]\frac{\partial p}{\partial t}=\gamma \quad (1)$$

in a rectangular coordinate system with x pointing

east, y north, and z upwards. The quantity f is the Coriolis parameter $2\Omega \sin \phi$, with Ω the angular speed of the earth's rotation and ϕ the latitude; p is the pressure; α, β, and γ are functions of p and its space derivatives; θ is the potential temperature, and ζ_g is the geostrophic vorticity:

$$\zeta_g \approx \frac{1}{\rho f}\left(\frac{\partial^2 p}{\partial x^2} + \frac{\partial^2 p}{\partial y^2}\right) \equiv \frac{1}{\rho f}\nabla_h^2 p, \tag{2}$$

where ∇_h is the horizontal operator, ρ the density, and the symbol "$\approx$" denotes approximate equality. For simplicity of presentation, the curvature of the earth is here ignored.

Equation (1) is elliptic or hyperbolic in the pressure tendency according as the factor multiplying the z-derivative terms is positive or negative. Since this factor has the same sign as the approximate potential vorticity, $\rho^{-1}(\zeta_g + f)\partial \ln \theta/\partial z$, we may infer that the elliptic or hyperbolic character of (1) is preserved at a material point. Thus we are assured that if (1) is everywhere elliptic initially it will remain so. On the other hand, if (1) is elliptic at some points and hyperbolic at others it will retain this property. In the latter case the integration problem becomes exceedingly complicated. Moreover, it is not known if, or to what extent, the geostrophic approximation applies when the potential vorticity is negative. Fortunately, however, negative potential vorticities occur rarely, and then only locally, and we may therefore be justified in assuming at the start that equation (1) is elliptic everywhere and for all time. (In the more general case, where the isentropic surfaces are not assumed quasi-horizontal, it can also be proved that the pressure-tendency equation is and remains a second order elliptic differential equation if the potential vorticity is initially positive everywhere.)

We may envisage a solution of equation (1) by the following procedure. Assuming that p is known at time t, we evaluate its coefficients and nonhomogeneous terms at time t and solve for $\partial p/\partial t$ by a relaxation method (Southwell [14]). The boundary conditions are that there shall be no influx or efflux of mass through the bottom or top of the atmosphere, translated into equivalent conditions on the pressure tendency. Having obtained $\partial p/\partial t$ we calculate the pressure at time $t + \Delta t$ from

$$p(t + \Delta t) = p(t) + \Delta t\, \partial p/\partial t.$$

The sequence of steps is then iterated to give $p(t + 2\Delta t)$, $p(t + 3\Delta t)$, etc.

As computing machinery for calculations of such great complexity have not yet been available, more simplified atmospheric models have been devised to test the validity of some of the basic assumptions. These will now be described.

Advective Models

The General Case. A first simplification is obtained by ignoring the effect of vertical motion on the change in potential temperature. Although this assumption is more questionable than those already made, one cannot ignore the fact that the advective hypothesis has been used with a degree of success in present-day synoptic practice. Hence, in accordance with the plan of utilizing the results of synoptic experience in the construction of models, we shall investigate the form taken by the equations of motion under this hypothesis.

First, by way of further justification, we shall show by means of scale considerations that the term $u\partial \ln \theta/\partial x + v\partial \ln \theta/\partial y$ is usually larger in order of magnitude than $w\partial \ln \theta/\partial z$ in the adiabatic equation,

$$\frac{d \ln \theta}{dt} = \frac{\partial \ln \theta}{\partial t} + u\frac{\partial \ln \theta}{\partial x} + v\frac{\partial \ln \theta}{\partial y} + w\frac{\partial \ln \theta}{\partial z} = 0, \tag{3}$$

in which u, v, and w are the x, y, and z velocity components, respectively.

From the geostrophic and thermal wind equations we have

$$u\frac{\partial \ln \theta}{\partial x} + v\frac{\partial \ln \theta}{\partial y} \approx \frac{f}{g}\left(u\frac{\partial v}{\partial z} - v\frac{\partial u}{\partial z}\right),$$

and from the vertical vorticity and continuity equations

$$\begin{aligned}\frac{1}{\zeta + f}\left(\frac{\partial}{\partial t} + u\frac{\partial}{\partial x} + v\frac{\partial}{\partial y}\right)(\zeta + f) \\ \approx -\left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y}\right) \approx \frac{1}{\rho}\frac{\partial(\rho w)}{\partial z} \sim \frac{\partial w}{\partial z}.\end{aligned} \tag{4}$$

The symbol "$\sim$" denotes equality in order of magnitude only.

Assuming a sinusoidal dependency, with wave lengths l_x, l_y, and l_z,

$$\begin{aligned} u &= U \exp\,[2\pi i(x/l_x + y/l_y + z/l_z)] \\ v &= V \exp\,[2\pi i(x/l_x + y/l_y + z/l_z)] \\ w &= W \exp\,[2\pi i(x/l_x + y/l_y + z/l_z)], \end{aligned}$$

where $U \sim V$ and $l_x \sim l_y$, and noting that each term on the left-hand side of (4) has the same order of magnitude, we obtain

$$\left|\frac{w\partial \ln \theta/\partial z}{u\partial \ln \theta/\partial x + v\partial \ln \theta/\partial y}\right| \sim \frac{l_z^2}{l_x^2}\frac{\nu_b^2}{\nu_i^2},$$

where $\nu_i \equiv f$ is the frequency of a horizontal inertial oscillation and $\nu_b^2 = g\partial \ln \theta/\partial z$ is the frequency of a buoyancy oscillation. For the large-scale motions in middle latitudes l_x, $l_y = 2 \times 10^6$ to 6×10^6 m; $l_z = 10^4$ m to 2×10^4 m; $\nu_i \approx 10^{-4}$ sec^{-1}; and $\nu_b \approx 10^{-2}$ sec^{-1}. Hence the above ratio varies between 0.03 and 1. For a typical large-scale system (l_x, $l_y = 4 \times 10^6$ m; $l_z = 1.5 \times 10^4$ m) its value is about 0.14. We note, however, that the advective hypothesis is less valid in the stratosphere where the buoyancy frequency ν_b is several times greater than 10^{-2} sec^{-1}.

The following derivation of the geostrophic-advective equations is due substantially to Fjørtoft [5], although it is much in the spirit of Sutcliffe's work [15].

If the thermal wind equation

$$\frac{\partial \mathbf{v}_g}{\partial z} \approx \frac{g}{f}\mathbf{k} \times \nabla_h \ln \theta, \tag{5}$$

in which $\mathbf{v}_g$ is the geostrophic wind and $\mathbf{k}$ is the vertical

unit vector, is integrated from the ground to the level z, fixed with respect to time, we obtain

$$\mathbf{v}_g = \mathbf{v}_{g0} + \frac{g}{f}\int_0^z \mathbf{k} \times \nabla_h \ln\theta \, dz \tag{6}$$

and, by differentiating with respect to t and taking the curl,

$$\frac{\partial \zeta_g}{\partial t} = \frac{\partial \zeta_{g0}}{\partial t} + \frac{g}{f}\nabla_h^2 \int_0^z \frac{\partial \ln\theta}{\partial t} dz, \tag{7}$$

since the variability of f may be ignored in the differentiation. To eliminate $\partial\zeta_{g0}/\partial t$ we proceed as follows: If we define

$$\bar{\alpha} \equiv \frac{\int_0^\infty \frac{\rho}{\zeta_g + f}\alpha \, dz}{\int_0^\infty \frac{\rho}{\zeta_g + f} dz}, \tag{8}$$

equation (7) becomes, by integration with respect to z,

$$\overline{\frac{\partial \zeta_g}{\partial t}} = \frac{\partial \zeta_{g0}}{\partial t} - \frac{g}{f}\overline{\nabla_h^2 A}, \tag{9}$$

where

$$A \equiv -\int_0^z \frac{\partial \ln\theta}{\partial t} dz. \tag{10}$$

Utilizing the relationship [2, eq. 68]

$$\overline{\frac{\partial \zeta_g}{\partial t}} = -\overline{\mathbf{v}_g \cdot \nabla_h(\zeta_g + f)}, \tag{11}$$

which may also be derived directly by vertical integration of (4), we eliminate $\partial\zeta_{g0}/\partial t$ between (7) and (9) to obtain

$$\frac{\partial \zeta_g}{\partial t} = -\overline{\mathbf{v}_g \cdot \nabla_h(\zeta_g + f)} + \frac{g}{f}(\overline{\nabla_h^2 A} - \nabla_h^2 A). \tag{12}$$

It now becomes convenient to replace z by p as the vertical coordinate. The geopotential $\Phi = gz$ may then be introduced as a dependent variable in place of p, and, with slight approximation, the local and horizontal derivatives may be replaced by derivatives in an isobaric surface. The latter are denoted by the subscript p. For the large-scale systems in which we are primarily interested (since only for these is the geostrophic approximation valid), f is usually several times greater than ζ_g, and the mean defined by (8) may be replaced by the simple average with respect to pressure. Then, since

$$\zeta_g \approx f^{-1}\nabla_p^2 \Phi,$$

equation (12) becomes

$$\nabla_p^2\left(\frac{\partial \Phi}{\partial t} + A - \bar{A}\right) = \bar{J}_p\left(\frac{1}{f}\nabla_p^2\Phi + f, \Phi\right), \tag{13}$$

where J_p is the Jacobian operator defined by

$$J_p(\alpha, \beta) \equiv \frac{\partial\alpha}{\partial x}\frac{\partial\beta}{\partial y} - \frac{\partial\alpha}{\partial y}\frac{\partial\beta}{\partial x}, \tag{14}$$

and

$$A \equiv -\frac{1}{g}\int_p^{p_0} \frac{\partial \ln\theta}{\partial t}\frac{dp}{\rho} \tag{15}$$

with p_0 the surface pressure. We now introduce the advective hypothesis,

$$\frac{\partial \ln\theta}{\partial t} \approx -\mathbf{v}_g \cdot \nabla_p \ln\theta, \tag{16}$$

so that

$$\begin{aligned} A &\approx \frac{1}{g}\int_p^{p_0} \mathbf{v}_g \cdot \nabla_p \ln\theta \frac{dp}{\rho} \\ &\approx \frac{1}{fg}\int_p^{p_0} J_p\left(\frac{\partial\Phi}{\partial p}, \Phi\right) dp, \end{aligned} \tag{17}$$

with the result that all quantities in (13) are expressed in terms of Φ and its derivatives.

The numerical integration of (13) is simpler than that of the general quasi-geostrophic equation. One solves the two-dimensional Poisson's equation

$$\nabla_p^2 S = \bar{J}_p \tag{18}$$

and determines the field of $\partial\Phi/\partial t$ from

$$\frac{\partial \Phi}{\partial t} = S - A + \bar{A}. \tag{19}$$

There are a number of methods, both analytic and numerical, by which (18) can be solved. The best for hand calculation is probably the relaxation method of Southwell [14] as it is rapid and can be used with any type of boundary. However this method is not always suitable for automatic machine computation as it makes large memory demands. It has been found best for a machine with a small internal and large external memory to use the analytic solution expressed in terms of a Green's function G:

$$S = \iint G(x, y, x', y')\bar{J}\, dx'dy', \tag{20}$$

where the integral extends over the forecast area and $\bar{J}$ is regarded as a function of x' and y'. The function G is a solution of the homogeneous equation $\nabla_p^2 G = 0$, satisfying the same condition as S on the boundary. Finally we mention that one may also use an "analogy" device, consisting of a physical system whose equilibrium state is governed by an equation having the same form as (18). The physical magnitude $\bar{J}$ appearing in (18) is varied at will and the magnitude S determined by measurement from the resulting equilibrium configuration.

A Simplified Version. While (13) is already a considerable simplification of the quasi-geostrophic equation, it still presents appreciable difficulties for numerical integration. Further simplifications will therefore be considered. The first is based on the observation that the isolines of temperature and potential temperature in large-scale systems are approximately parallel at all levels, that is,

$$\frac{1}{\rho}\nabla_p \ln\theta = \frac{\pi(p)}{\bar{\rho}}\nabla_p \ln\bar{\theta} \tag{21}$$

where the bar refers to a fixed isobaric surface $\bar{p}$. If $\bar{\mathbf{v}}_g$, $\bar{\rho}$, $\bar{T}$, and $\bar{\theta}$ are the velocity, density, temperature,

and potential temperature respectively at this level,

$$\mathbf{v}_g = \bar{\mathbf{v}}_g + \int_{\bar{p}}^{p} \frac{\partial \mathbf{v}_g}{\partial p}\, dp = \bar{\mathbf{v}}_g + \sigma \mathbf{v}', \tag{22}$$

where

$$\mathbf{v}' = -R\bar{T}f^{-1}\nabla_p \ln \bar{\theta} \times \mathbf{k}, \tag{23}$$

and

$$\sigma = [\mu(p) - \mu(\bar{p})]/\bar{p}; \qquad \mu(p) \equiv \int_{p}^{p_0} \pi(p)\, dp. \tag{24}$$

Similarly we find

$$A = (g\bar{\rho})^{-1}\mu(p)\mathbf{v}_g \cdot \nabla_p \ln \bar{\theta},$$
$$\bar{A} = (g\bar{\rho})^{-1}\bar{\mu}\,\bar{\mathbf{v}}_g \cdot \nabla_p \ln \bar{\theta},$$

where $\bar{\mu}$ is the pressure average of $\mu(p)$. If the level $\bar{p}$ is chosen so that $\mu(\bar{p}) = \bar{\mu}$, it is easily found that (13) becomes

$$\nabla_p^2 \frac{\partial \Phi}{\partial t} = J_p\left(\frac{1}{f}\nabla_p^2\Phi + f, \Phi\right) + (R\bar{T})^2\,\overline{\sigma^2} J_p\left(\frac{1}{f}\nabla_p^2 \ln\theta, \ln\theta\right) \tag{25}$$

at this level. The variations in $\ln\theta$ are determined from

$$\frac{\partial \ln\theta}{\partial t} = -\bar{\mathbf{v}}_g \cdot \nabla_p \ln\theta = \frac{1}{f} J_p(\ln\theta, \Phi). \tag{26}$$

The two equations above are sufficient to determine the motion. Their advantage lies in the fact that the problem has been reduced to a purely two-dimensional one: no vertical integrations are required and the initial data need consist only of the height and temperature distribution in the surface $\bar{p}$.

An empirical study of the function $\mu(p)$ gave for $\overline{\sigma^2}$ the approximate mean value 0.14, and the value 600 mb for $\bar{p}$ in winter. In a specific situation $\overline{\sigma^2}$ and $\bar{p}$ seemed to be somewhat influenced by the height of the tropopause, indicating that the position of the tropopause exerts an influence at least on the kinematics of the atmospheric motion.

The Barotropic Model. The barotropic model results from a further simplification of (25). If one assumes that the thermal wind $\sigma\mathbf{v}'$ in (22) is proportional to $\bar{\mathbf{v}}_g$, implying that the isobars are parallel at all heights,

$$\mathbf{v}_g = \left(1 + \sigma\left|\frac{\mathbf{v}'}{\bar{\mathbf{v}}_g}\right|\right)\bar{\mathbf{v}}_g, \tag{27}$$

and equation (25) becomes

$$\nabla_p^2 \frac{\partial \Phi}{\partial t} = J_p\left(\frac{1}{f}\nabla_p^2\Phi + f, \Phi\right) + \left|\frac{\mathbf{v}'}{\bar{\mathbf{v}}_g}\right|^2 \overline{\sigma^2} J_p\left(\frac{1}{f}\nabla_p^2\Phi, \Phi\right) \tag{28}$$

at the level $\bar{p}$. This equation may also be written

$$\frac{\partial \zeta_g}{\partial t} + K\mathbf{v}_g \cdot \nabla_p \zeta_g + v_g \frac{df}{dy} = 0, \tag{29}$$

where

$$K = 1 + \left|\frac{\mathbf{v}'}{\bar{\mathbf{v}}_g}\right|^2 \overline{\sigma^2},$$

in which form it is seen to be practically identical with the so-called "equivalent-barotropic" equation derived by the author [3, p. 384]. The quantity $|\mathbf{v}'/\bar{\mathbf{v}}_g| \approx R\,|\nabla_p\bar{T}/\nabla_p\Phi|$ has been found to have the average value 1.25 and consequently $K = 1 + (1.25)^2(0.14) = 1.22$, which agrees well with the value $K = 1.25$ given in the author's paper just mentioned. Defining p^* by $\mathbf{v}_g(p^*) = K\bar{\mathbf{v}}_g$ and multiplying (29) by K, we obtain

$$\frac{\partial \zeta_g^*}{\partial t} + \mathbf{v}_g^* \cdot \nabla_p \zeta_g^* + v_g^* \frac{df}{dy} \approx \left(\frac{d}{dt}\right)_{p^*}(\zeta_g^* + f) = 0, \tag{30}$$

where the asterisks denote quantities at the level p^*. Hence from (4) we see that p^* is the level of nondivergence and that the vertical component of absolute vorticity $\zeta_g + f$ is conserved at this level. The value of p^* is about 100 mb less than that of $\bar{p}$, or about 500 mb.

The foregoing remarks reveal clearly the exact sense in which the barotropic atmosphere may be considered an approximation to the real atmosphere.

Kibel's Method. In 1940, I. A. Kibel [9] proposed a numerical method for forecasting surface pressure and temperature changes on the basis of the geostrophic hypothesis[1] by assuming that the lapse rate of temperature is everywhere constant, that is,

$$T(x, y, z) = T_0(x, y) - \gamma z, \tag{31}$$

and that the temperature T_H at a fixed upper level is advected with the wind:

$$\frac{\partial T_H}{\partial t} + \mathbf{v} \cdot \nabla T_H = 0. \tag{32}$$

The latter approximation holds at the tropopause where it is considered to be a consequence of the property that the tropopause is a discontinuity surface of the second kind at which the lapse rate of temperature is approximately zero. With $\mathbf{v} = \mathbf{v}_g + \mathbf{v}'$, where $\mathbf{v}'$ is the geostrophic deviation, the adiabatic equation at the ground becomes

$$\frac{\partial T_0}{\partial t} - \frac{RT_0}{fp_0} J(T_0, p_0) + \mathbf{v}_0' \cdot \nabla_h T_0 - \frac{RT_0}{c_p p_0}\left(\frac{\partial p_0}{\partial t} + \mathbf{v}_0' \cdot \nabla_h p_0\right) = 0, \tag{33}$$

where c_p is the specific heat of dry air at constant pressure. Similarly, equation (32) becomes

$$\frac{\partial T_0}{\partial t} - \frac{RT_H}{fp_H} J(T_0, p_H) + \mathbf{v}_H' \cdot \nabla_h T_0 = 0. \tag{34}$$

Noting that

$$p = p_0 \exp\left(-\frac{g}{R}\int_0^z \frac{dz}{T_0 - \gamma z}\right), \tag{35}$$

we obtain the thermal wind equation

$$\frac{\nabla_h p}{\rho} = \frac{RT_H}{p_0}\nabla_h p_0 + \frac{gz}{T_0}\nabla_h T_0 \tag{36}$$

1. A somewhat simplified account of Kibel's method by B. I. Isvekov has been translated into English. See "Professor I. A. Kibel's Theoretical Method of Weather Forecasting." *Bull. Amer. meteor. Soc.*, 27:488–497 (1946).

and the relationship

$$\frac{1}{\rho}\frac{\partial p}{\partial t} = \frac{RT_H}{p_0}\frac{\partial p_0}{\partial t} + \frac{gz}{T_0}\frac{\partial T_0}{\partial t}, \tag{37}$$

from which it follows that (34) may be written

$$\frac{\partial T_0}{\partial t} - \frac{RT_H}{fp_0} J(T_0, p_0) + \mathbf{v}'_H \cdot \nabla_h T_0 = 0. \tag{38}$$

If the winds are assumed geostrophic, (33) and (38) combine to give

$$\left.\begin{aligned} \frac{\partial p_0}{\partial t} &= -\alpha J(T_0, p_0) \\ \frac{\partial T_0}{\partial t} &= \beta J(T_0, p_0) \end{aligned}\right\}, \tag{39}$$

where

$$\alpha = \frac{c_p}{f}\left(1 - \frac{T_H}{T_0}\right); \qquad \beta = \frac{RT_H}{fp_0}.$$

These are Kibel's equations for the first approximation. Their integration becomes especially simple if it is observed that in virtue of (39)

$$\frac{\partial}{\partial t}(\alpha T_0 + \beta p_0) = 0,$$

so that

$$\theta = \alpha T_0 + \beta p_0 \tag{40}$$

is independent of time, and

$$\left.\begin{aligned} \frac{\partial p_0}{\partial t} &= J(p_0, \theta) \\ \frac{\partial T_0}{\partial t} &= J(T_0, \theta) \end{aligned}\right\}. \tag{41}$$

These equations imply that the fields p_0 and T_0 are propagated along lines of constant θ with a velocity numerically equal to $|\nabla_h \theta|$. They may also be interpreted to state that the surface pressure and temperature are steered along the contour lines of the isobaric surface located at approximately the height $Z = \alpha T_0/(\alpha\gamma + g\beta\rho_0)$ and with a velocity given by the wind at this level multiplied by $(\alpha\gamma + g\beta\rho_0)f/g$. In practice, the constants α and β are determined empirically rather than from their formulas.

In 1948 Lettau [10] observed that Kibel's equations of first approximation are very similar to a set derived by Exner in 1906 [8] under similar assumptions. In place of Kibel's tropopause condition, Exner assumed that there exists a level H at which the pressures do not change. If H is identified with Z, Exner's equations become nearly identical with Kibel's.

Equations (39) give zero pressure tendency at a pressure center, where $\partial p_0/\partial x = \partial p_0/\partial y = 0$. For an estimate of the tendency at a center Kibel proceeds to a second approximation. As the derivation is omitted in both Kibel's and Isvekov's papers, it will be supplied here.

The geostrophic deviation

$$u' \approx -\frac{1}{f}\left(\frac{\partial v}{\partial t} + u\frac{\partial v}{\partial x} + v\frac{\partial v}{\partial y}\right)$$

$$v' \approx \frac{1}{f}\left(\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y}\right)$$

is further approximated by substituting the geostrophic wind components $u_g = -\rho^{-1}f^{-1}(\partial p/\partial y)$, $v_g = \rho^{-1}f^{-1}(\partial p/\partial x)$ for u and v. Ignoring small terms and using (36) and (37), one obtains, when $\partial p_0/\partial x = \partial p_0/\partial y = 0$,

$$\left.\begin{aligned} u'_H - u'_0 = &-\frac{R(T_H - T_0)}{f^2 p_0}\frac{\partial^2 p_0}{\partial x \partial t} - \frac{gH}{f^2 T_0}\frac{\partial^2 T_0}{\partial x \partial t} \\ &- \frac{g^2H^2}{f^3 T_0^2} J\left(T_0, \frac{\partial T_0}{\partial x}\right) - \frac{gHRT_H}{f^2 p_0 T_0} J\left(T_0, \frac{\partial p_0}{\partial x}\right), \\ v'_H - v'_0 = &-\frac{R(T_H - T_0)}{f^2 p_0}\frac{\partial^2 p_0}{\partial y \partial t} - \frac{gH}{f^2 T_0}\frac{\partial^2 T_0}{\partial y \partial t} \\ &- \frac{g^2H^2}{f^3 T_0^2} J\left(T_0, \frac{\partial T_0}{\partial y}\right) - \frac{gHRT_H}{f^2 p_0 T_0} J\left(T_0, \frac{\partial p_0}{\partial y}\right) \end{aligned}\right\}. \tag{42}$$

Evaluating $\partial^2 p_0/\partial x \partial t$ and $\partial^2 p_0/\partial y \partial t$ from (39) and substituting in (33) and (38) we obtain, by elimination of $\partial T_0/\partial t$,

$$\frac{\partial p_0}{\partial t} = B\left[\frac{\partial T_0}{\partial x} J\left(T_0, \frac{\partial \tilde{\theta}}{\partial x}\right) + \frac{\partial T_0}{\partial y} J\left(T_0, \frac{\partial \tilde{\theta}}{\partial y}\right)\right], \tag{43}$$

where

$$\left.\begin{aligned} \tilde{\theta} &= \tilde{\alpha} T_0 + \beta p_0 \\ \tilde{\alpha} &= \left(\frac{\gamma_a}{\gamma}\right)^2 \alpha \Big/ \left(2\frac{\gamma_a}{\gamma} + \frac{T_0}{T_H} - 1\right) \\ B &= \frac{c_p p_0 \alpha}{RT_0 f}\left(2\frac{\gamma_a}{\gamma} + \frac{T_0}{T_H} - 1\right) \end{aligned}\right\}, \tag{44}$$

and γ_a is the dry-adiabatic lapse rate. Making the approximation $\tilde{\theta} \approx \theta$, it is possible to deduce the consequence that the surface pressure decreases when the θ contours at the steering level Z diverge over the center in the direction of the wind. Conversely, if the contours converge, the surface pressure increases.

In view of the nature of the assumptions made, Kibel's first and second approximations cannot serve as a substitute for the general advective geostrophic equations. There have been references to higher approximations, but the articles unfortunately were not available to the writer.

The Linearized Barotropic Model

The nonlinearity of the quasi-geostrophic equations makes it difficult to study their properties. However, many of the essential properties of the nonlinear motions are preserved in the linearization. Thus, for example, boundary conditions will often be qualitatively the same for both and the numerical technique of integration used for the one can be used for the other. In this manner it is often possible to obtain semi-

quantitative estimates of the convergence criteria for the nonlinear difference equations—estimates that would be difficult if not impossible to obtain by any other means. Also, the study of linearized counterparts may be undertaken for the physical insight they give into the nature of the dynamical processes at work in the atmosphere—without which insight, numerical forecasting is at best a haphazard affair.

One problem to which at least a partial answer is required is the determination of the speeds at which influences propagate in the atmosphere. The elliptic character of (1) demands that the boundary conditions be known as functions of time along vertical surfaces surrounding the forecast region, as well as at the ground and at the "top" of the atmosphere. Since such conditions cannot be known, there appears to be a basic indeterminacy in the problem of forecasting for a limited region. The reason for this indeterminacy is that the introduction of the geostrophic approximation effectively filters out the sound and gravity waves whose finite speeds place an upper limit on the rate of propagation of a disturbance. Thus disturbances propagate instantaneously in quasi-geostrophic motion, and effects from the boundaries are felt immediately at every point in the region they enclose. One feels that since sound and gravity motions interact negligibly with the large-scale systems, the solution to the difficulty must be found in the quasi-geostrophic equations themselves. Let us, therefore, examine these equations in their linearized form.

As we shall be concerned primarily with horizontal propagation it will be permissible to treat the motion barotropically, for it has already been shown that the horizontal motion of a barotropic atmosphere approximates the actual motion at a certain mean level.

For small perturbations on a constant zonal current U, the barotropic equation (30) becomes

$$\nabla_h^2\left(\frac{\partial\Phi}{\partial t}+U\frac{\partial\Phi}{\partial x}\right)+\beta\frac{\partial\Phi}{\partial x}=0. \tag{45}$$

The quantity $\beta = df/dy$ will be given the constant value corresponding to the mean latitude 45°. Equation (45) admits of the plane wave solution

$$\Phi = \exp\left[i(kx+\mu y-\nu t)\right] \tag{46}$$

in which the frequency ν is related to the wave numbers $k = 2\pi/l_x$ and $\mu = 2\pi/l_y$ by

$$\nu = kU-\frac{\beta k}{k^2+\mu^2}. \tag{47}$$

The group velocity components c_{gx} and c_{gy} are

$$\left.\begin{aligned} c_{gx} &= \frac{\partial\nu}{\partial k} = U+\beta\frac{k^2-\mu^2}{(k^2+\mu^2)^2}\\ c_{gy} &= \frac{\partial\nu}{\partial\mu} = \frac{2\beta k\mu}{(k^2+\mu^2)^2}\end{aligned}\right\}. \tag{48}$$

Now it may be shown that the kinetic energy E of a point disturbance obeys approximately the law

$$\frac{\partial E}{\partial t}+\frac{\partial}{\partial x}(c_{gx}E)+\frac{\partial}{\partial y}(c_{gy}E)=0, \tag{49}$$

which states that the energy of the disturbance associated with a given area in the x, y plane will not change with time when each point of the area moves with the local group velocity given by (48). Since an arbitrary initial disturbance may be regarded as a sum of point disturbances, we may state that no influence is propagated faster than the maximum group velocity. An inspection of (48) shows that for increasing l_x and l_y the group velocities as well as the phase velocities become arbitrarily large. However, the magnitudes of l_x and l_y are limited by the finiteness of the earth's surface, and even this limitation is scarcely realistic, for the extent of the motions with which we are concerned is far less than world-wide. To obtain a better estimate of the maximum group velocities, we first provide for the finiteness of the earth by assuming x to have a period equal to the circumference of the 45° latitude circle. If the unit of distance is taken as the radius of this circle and the unit of time as one day, k becomes an integer representing the number of waves encircling the earth and $\beta = 2\pi$.

A typical spectrum determined by Fourier analysis of the v component of the velocity at 45°N for 0300Z on January 11–13, 1946 at 500 mb is shown in Fig. 1,

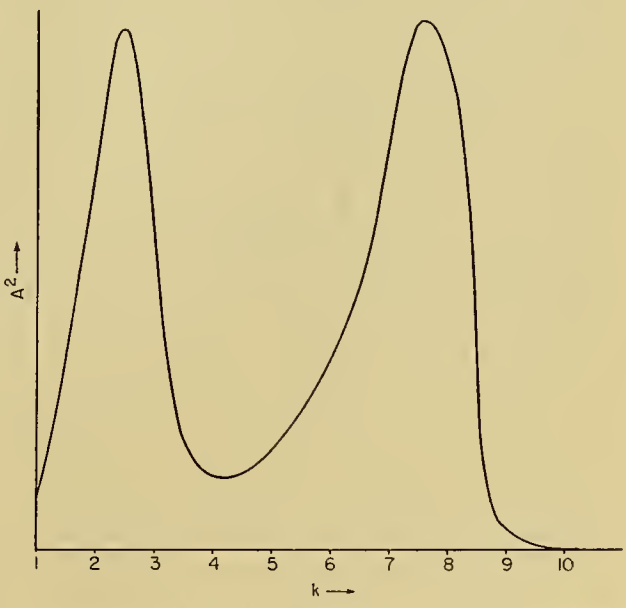

FIG. 1.—Mean spectral distribution of the kinetic energy of the north-south motion at 500 mb and 45° N for 0300Z, January 11, 12, and 13, 1946.

in which the square of the amplitude, A^2, measuring the kinetic energy of the north-south motion, is plotted against k. One energy maximum occurs at $k = 2.5$, corresponding to a wave length of 144° long. at 45° lat., and the other at $k = 7.5$, corresponding to a wave length of 48° long. The first maximum is associated with the very long wave quasi-stationary disturbances which, as Charney and Eliassen [4] have shown, are produced mainly by topographical action. As we are

not here concerned with these disturbances, we may assume a cutoff in the wave number at $k = 4$. The maximum value of c_{gx} then occurs at $\mu = 0$ and is equal to $U + \beta/k^2$ or $(U + 22.5)$ deg long. day^{-1}, and the minimum value occurs at $\mu^2 = 3k^2$ and is equal to $U - \beta/8k^2 = (U - 2.8)$ deg long. day^{-1}. Since it is also unrealistic to take $\mu = 0$, we shall suppose that $\mu \geq 4$ also, in which case max c_{gx} and min c_{gx} are equal to $U \pm \beta/8k^2 = (U \pm 2.8)$ deg long. day^{-1}. The corresponding values of max and min c_{gy} occur at $\mu = \pm k$ and are equal to ± 11.2 deg long. day^{-1} for k, $\mu \geq 4$.

These group velocity estimates can be regarded only as approximations in the asymptotic sense; they are accurate only for large values of time. Moreover, the derivation of the energy propagation equation (49) presupposes a continuous variation of frequency, whereas the frequencies are here restricted to discrete values by the finiteness of the earth. The following alternative approach to the problem avoids these difficulties.

If we assume a sine dependency on the y-coordinate ($\partial^2\Phi/\partial y^2 = -m^2\Phi$), equation (45) becomes

$$\frac{\partial^2}{\partial x^2}\left(\frac{\partial \Phi}{\partial t} + U\frac{\partial \Phi}{\partial x}\right) - m^2\frac{\partial \Phi}{\partial t} + (\beta - Um^2)\frac{\partial \Phi}{\partial x} = 0. \quad (50)$$

Its solution may be written [3]:

$$\Phi(x, t) = \Phi(x - Ut, 0) + \int_{-\pi}^{+\pi} I_{m^2}(x - Ut - \alpha, t)\Phi(\alpha, 0)\, d\alpha, \quad (51)$$

where

$$I_{m^2} = \frac{1}{2\pi}\sum_{-\infty}^{+\infty}(e^{-i\nu t} - 1)e^{ikx}, \quad (52)$$

and

$$\nu = -\frac{\beta k}{k^2 + m^2}. \quad (53)$$

The "influence function" $I_{m^2}(x, t)$ is shown in Fig. 2 for $m^2 = 18$ and $t = 1$. This function is seen to become very small as the absolute value of x is increased. Let us assume that it is negligible for $x > x_1$ and $x < -x_2$. Then the upper and lower limits of integration may be replaced by $x - Ut - x_1$ and $x - Ut + x_2$, respectively. This means that with respect to the mean zonal current, influences propagate eastward with a speed less than x_1 degrees per day and westward with a speed less than x_2 degrees per day. From the figure, one may estimate $x_1 \approx 25°$ and $x_2 \approx 40°$. These estimates for the influence velocities are greater than those obtained for the group velocities because no restrictions have been placed on the energy spectrum of the initial disturbance $\Phi(x, 0)$. Influences from only very long wave disturbances propagate rapidly, and it is likely that a disturbance with most of its energy lying in the middle and short wave length region of the spectrum would again be found to have influence velocities more in conformity with those given by the extreme group velocities.

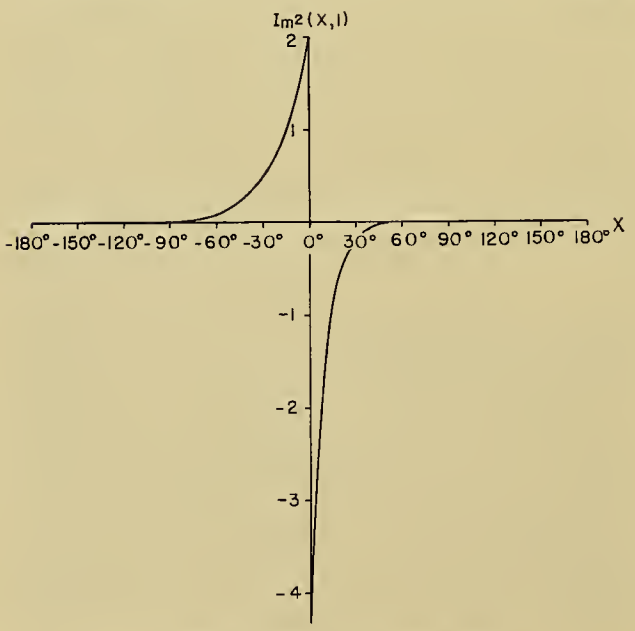

FIG. 2.—Influence function for $m^2 = 18$, $t = 1$.

In summary, one may say that influences have a maximum rate of propagation not much in excess of U (the particle speed) and a minimum rate not much less than U, so that the propagation relative to the ground is eastward. These conclusions have been borne out by several recent integrations of the nonlinear barotropic equations.

The solution for the linearized barotropic equations given by (51) has a certain value in itself. It has been used with some success for forecasting the actual wave-like perturbations of the westerlies [4]. The initial distribution of Φ along a fixed latitude was determined from the 500-mb map, and the integral in (51) was evaluated by means of Simpson's rule. It was shown that the topographical motions become quasi-stationary when $m^2 = 18$, so that the relative variation in the height of an isobaric surface at a fixed latitude could be predicted for a 24-hr period without taking these motions into account. Frictional effects were likewise found to be negligible in forecasts for so short a period. These results have been taken to justify the neglect of topography and friction in first attempts at the integration of the nonlinear barotropic equations.

It has also been shown [3] that influences are propagated at an effectively finite speed in the vertical direction. The maximum vertical group velocity for small plane wave disturbances in a baroclinic atmosphere with fronts perpendicular to the x, z plane has been calculated at approximately ± 4.5 km day^{-1} at 45° lat. Thus in principle it is unnecessary to know the entire vertical structure of the atmosphere initially in order to predict the motion of the lower layers for short periods. This result is perhaps of no great practical importance for numerical computation, since the low energy of the very high level motions renders their influence negligible in any case. It does, however, have a theoretical significance in stating a property of the atmospheric motion that has not generally been recognized. It is this property which may constitute the most serious criticism of the advective model. According to equation (19) the calculation of the geopotential

tendency $S - \bar{A}$ at a point on the ground requires a knowledge of the potential temperature advection throughout the entire vertical column above the point, in contradiction of what has just been stated; and here there is no compensation mechanism that effectively limits the spread of influences as in the case of the geostrophic approximation. It is thus possible that the advective assumption imposes a physically untenable constraint on the atmosphere.

Computational Stability

Once the physical problem of determining the equations of motion and the boundary conditions has been solved, there arises the purely mathematical problem of approximating the solution of the continuous equations by finite-difference methods. Here it may come as a surprising fact that no matter how small one chooses the space and time increments for the finite-difference equations, one has no guarantee that the finite-difference solution will approximate the continuous solution. This phenomenon, first discovered in 1928 by Courant, Friedrichs, and Lewy [6] will be illustrated for the one-dimensional wave equation

$$\frac{\partial^2 \varphi}{\partial t^2} = c^2 \frac{\partial^2 \varphi}{\partial x^2}, \tag{54}$$

whose finite-difference analogue for centered differences may be written

$$\frac{\varphi(x, t + \Delta t) + \varphi(x, t - \Delta t) - 2\varphi(x, t)}{(\Delta t)^2} = c^2 \frac{\varphi(x + \Delta x, t) + \varphi(x - \Delta x, t) - 2\varphi(x, t)}{(\Delta x)^2}. \tag{55}$$

Because of the linearity of (55) we may suppose that the solution is represented by a Fourier series. The long wave length components will be accurately expressed by the solution of (55), but there will inevitably be a distortion of the components whose wave lengths are of the order of Δx. This distortion will be harmless if Δx is small compared with the wave lengths of the physically relevant components and if the small wave length components do not amplify. However, when such an amplification occurs, it does so with exponential rapidity and quickly makes nonsense of the entire solution.

Let us, therefore, consider a Fourier component of the form $\exp[i(kx - \nu t)]$. Substitution in (55) gives

$$\frac{e^{-i\nu\Delta t} + e^{i\nu\Delta t} - 2}{(\Delta t)^2} = c^2 \frac{e^{ik\Delta x} + e^{-ik\Delta x} - 2}{(\Delta x)^2} = -\frac{4c^2}{(\Delta x)^2} \sin^2 \frac{k\Delta x}{2},$$

and, if we set $\omega = e^{-i\nu\Delta t}$,

$$\omega^2 - 2\left(1 - 2c^2 \left(\frac{\Delta t}{\Delta x}\right)^2 \sin^2 \frac{k\Delta x}{2}\right)\omega + 1 = 0. \tag{56}$$

The small error will cause no difficulties if it does not amplify, that is, if $|\omega| \leq 1$. If the two roots of (56) are complex, the square of their common absolute value is given by their product, which by (56) is equal to unity. If the roots are real, one of them must exceed unity in absolute value. Hence the condition for computational stability is that the roots be complex, that is, that the discriminant of (56) be negative. This leads to the condition

$$\frac{\Delta x}{\Delta t} \geq c \sin \frac{k\Delta x}{2},$$

or, since k must be presumed to have any value,

$$\frac{\Delta x}{\Delta t} \geq c. \tag{57}$$

Thus, no matter how small Δx and Δt are chosen independently, the solution of the finite-difference equation will not approximate the continuous solution unless (57) is satisfied. A geometrical interpretation of this criterion has been given by the author in a previous article [3].

Now it may be shown that whenever equations of motion permitting physical propagations are used, the condition (57) must be satisfied for c, the greatest propagation speed. Although Richardson [12] effectively excluded sound waves with the hydrostatic approximation, he did not exclude external gravity waves whose speeds are nearly as great as those of sound, about 300 m sec^{-1}. He chose Δx to be about 200 km; consequently his Δt should have been smaller than 200,000/300 sec or 20 min. In point of fact he chose 6 hr. Hence, a direct application of his method would inevitably have led to computational instability.

By employing the quasi-geostrophic equations one avoids the difficulty of having to choose time increments so small as to be meaningless in relation to the meteorologically significant motions. Nevertheless, the space and time increments cannot be chosen arbitrarily. To show this, let us again consider equation (45).

If we use centered differences, its finite-difference analogue may be written

$$D^2\left[\frac{\Phi(x, y, t + \Delta t) - \Phi(x, y, t - \Delta t)}{2\Delta t} + U\frac{\Phi(x + \Delta s, y, t) - \Phi(x - \Delta s, y, t)}{2\Delta s}\right] = \beta(\Delta s)^2 \frac{\Phi(x + \Delta s, y, t) - \Phi(x - \Delta s, y, t)}{2\Delta s}, \tag{58}$$

where Δs is the space increment and the finite-difference operator D^2 is defined by

$$D^2\psi \equiv \psi(x + \Delta s, y, t) + \psi(x, y + \Delta s, t) + \psi(x - \Delta s, y, t) + \psi(x, y - \Delta s, t) - 4\psi(x, y, t). \tag{59}$$

Consider a Fourier component of the form $\exp[i(kx + \mu y - \nu t] \equiv \omega \exp[i(kx + \mu y)]$. Substitution in (58) gives

$$\omega^2 + 2ai\omega - 1 = 0,$$

where

$$a = \left[U + \frac{\beta(\Delta s)^2/4}{\sin^2 \frac{k\Delta s}{2} + \sin^2 \frac{\mu \Delta s}{2}} \right] \frac{\Delta t}{\Delta s} \sin k\Delta s.$$

The condition for stability, $|\omega| \leq 1$, is then found to be $a \leq 1$, and we obtain

$$\frac{\Delta s}{\Delta t} \geq U \sin k\Delta s + \frac{(1/4)\beta(\Delta s)^2 \sin(k\Delta s)}{\sin^2 \frac{k\Delta s}{2} + \sin^2 \frac{\mu \Delta s}{2}}.$$

An upper bound for the first term on the right-hand side is U. The second term increases with decreasing k and μ, and we may evaluate it by assuming $k\Delta s$ and $\mu\Delta s$ to be small, thus obtaining the upper bound $\beta\Delta s k(k^2 + \mu^2)^{-1}$. Let us now assume that (58) is to be solved for a rectangular region with sides L_x and L_y parallel to the x- and y-axes, respectively. Then k and μ must be greater than $2\pi/L_x$ and $2\pi/L_y$, respectively, and the stability condition becomes

$$\frac{\Delta s}{\Delta t} \geq U + \frac{\beta \Delta s}{4\pi} \frac{L^2}{L_x}, \tag{60}$$

where L is the square harmonic mean,

$$[1/2(L_x^{-2} + L_y^{-2})]^{-\frac{1}{2}},$$

of L_x and L_y.

If Δs is small compared to the dimensions of the rectangular area, the second right-hand term will be small, and we obtain the result that the ratio of the space to the time increment must be greater than the particle velocity. It is shown in reference [5] that a stability condition closely analogous to (60) holds for the general nonlinear barotropic equation.

Integration of the Nonlinear Barotropic Equation

In the following section a description will be given of a method that has been used to integrate the barotropic equation (30).

Equation of Motion. The nondivergence level p^* is taken to be 500 mb. If the spherical surface of the earth is mapped conformally onto a plane and the geopotential Φ of the 500-mb surface is used as dependent variable, the correct form of (30) for a spherical earth becomes

$$m^2 \nabla_p^2 \frac{\partial \Phi}{\partial t} = m^2 J_p \left(\frac{m^2}{f} \nabla_p^2 \Phi + f, \Phi \right),$$

or

$$\nabla_p^2 \frac{\partial \Phi}{\partial t} = J_p \left(\frac{m^2}{f} \nabla_p^2 \Phi + f, \Phi \right), \tag{61}$$

where ∇_p^2 and J_p are to be interpreted as operators in the plane, and m is the scale factor of the mapping.

Except for the factor m^2/f, the left-hand side of (61) is the change in absolute vorticity and the right-hand side is the negative of the absolute vorticity advection. The equation therefore asserts that the vertical component of absolute vorticity is individually conserved.

The Conformal Map. The stereographic projection has the advantage that it is the map on which hemispheric data are usually plotted and analyzed and that, in comparison with the Mercator projection, it has much less distortion at high latitudes so that a square lattice represents more nearly equal areas on the earth. If ϕ is the latitude, a the radius of the earth, and the radius of the equator on the map is chosen as the unit of distance, the scale factor for the stereographic projection is $m = 2a^{-1}(1 + \sin\phi)^{-1}$.

Boundary Conditions. Since data are lacking for the entire earth and as the geostrophic approximation does not hold in the vicinity of the equator, the integration must be performed for a restricted area. The problem then arises of determining the boundary conditions. It is not a serious difficulty that these conditions are not actually known as functions of time, since we already know that influences from the boundary will not propagate inwards at a rate much greater than the particle velocity. One has only to choose the boundary sufficiently far from the area for which the forecast is desired. However, it is still important to assign artificial boundary conditions that are dynamically correct, for experience has shown that if the conditions assigned are not physically possible, computational instabilities arise which propagate faster than the physical disturbances.

If one wishes to solve (61) for the initial tendencies only, it is sufficient to prescribe $\partial\Phi/\partial t$ on the boundaries. This may be done by first making a crude forecast of $\partial\Phi/\partial t$, say by extrapolation from the observed 12-hr height change, or, more roughly, by setting $\partial\Phi/\partial t$ equal to 0. But in forecasting for a finite time interval, it is not sufficient to specify $\partial\Phi/\partial t$, and therefore Φ, for all time. For this case one may show [5] that if fluid is flowing into the forecast region both the flux of vorticity and Φ must be specified, whereas if fluid is flowing out of the region, only Φ need be prescribed. Since the specification of Φ determines the normal velocity at the boundary, one has only to specify the vorticity in addition to Φ where fluid is entering.

Method of Solution. The method to be followed in the solution of (61) will depend on the types of computing instruments available. It may be of some interest to describe briefly the integration procedure used by the writer in collaboration with R. Fjørtoft and J. von Neumann [5].

With the notation $\xi = \nabla_p^2 \Phi$ the basic equation (61) may be replaced by the system

$$\eta = m^2 f^{-1} \xi + f, \tag{62}$$

$$\partial\xi/\partial t = J_p(\eta, \Phi), \tag{63}$$

$$\nabla_p^2(\partial\Phi/\partial t) = \partial\xi/\partial t, \tag{64}$$

with the boundary conditions

$$\partial\Phi/\partial t = 0; \tag{65}$$

$$\partial\xi/\partial t = 0, \quad \text{if} \quad d\Phi/ds < 0, \tag{66}$$

where s is the tangential coordinate along the boundary, directed so as to keep the interior domain always on the right.

For simplicity in computation, a rectangular area with sides μ and ν is chosen, and a rectangular lattice is defined by the coordinates

$$x = (\mu/p)i, \qquad (i = 0, 1, \cdots, p),$$
$$y = (\nu/q)j \qquad (j = 0, 1, \cdots, q),$$

in which the boundary lines are $i = 0, i = p,$ and $j = 0$, $j = q$. If Φ_{ij}, ξ_{ij}, η_{ij}, J_{ij}, $(\partial\Phi/\partial t)_{ij}$, $(\partial\xi/\partial t)_{ij}$ denote the finite-difference approximations to Φ, ξ, η, J_p, $\partial\Phi/\partial t$, $\partial\xi/\partial t$ at the points (i, j), the procedure is as follows: From the initial values of Φ_{ij} one determines first ξ_{ij}, then η_{ij}, and finally J_{ij}. The values of $(\partial\xi/\partial t)_{ij}$ are then immediately found from (63):

$$(\partial\xi/\partial t)_{ij} = J_{ij}(\eta_{ij}, \Phi_{ij}).$$

To obtain $(\partial\Phi/\partial t)_{ij}$ one has to solve the finite-difference analogue of (64), that is,

$$D^2(\partial\Phi/\partial t)_{ij} = (\Delta s)^2(\partial\xi/\partial t)_{ij}, \tag{67}$$

where D^2 is defined by (59) and $\Delta s = \mu/p = \nu/q$ is the grid interval. On the assumption that Φ does not vary on the boundary $(\partial\Phi/\partial t = 0)$ the solution is found to be

$$\left(\frac{\partial\Phi}{\partial t}\right)_{ij} = -\frac{(\Delta s)^2}{pq}\sum_{l=1}^{p-1}\sum_{m=1}^{q-1}\sum_{r=1}^{p-1}\sum_{s=1}^{q-1} \cdot \left(\sin^2\frac{\pi l}{2p} + \sin^2\frac{\pi m}{2q}\right)^{-1} \cdot J_{rs}\sin\frac{\pi lr}{p}\sin\frac{\pi ms}{q}\sin\frac{\pi li}{p}\sin\frac{\pi mj}{q}. \tag{68}$$

In the actual computation, the functions $S_u = \sin(\pi u/p)$ and $T_v = \sin(\pi v/q)$ need only to be tabulated for integral values of u from 0 to $p/2$ and for v from 0 to $q/2$, the functions for other values of the arguments being given by

$$S_{-u} = S_{u+p} = -S_u; \qquad T_{-v} = T_{v+q} = -T_v.$$

This is a decided advantage in a machine with a limited storage capacity for numbers. Had an arbitrary area rather than a rectangular one been selected, the solution would be given by the finite-difference form of (20). Instead of storing the $(p + q)/2$ sines, one would then have to store the $p^2q^2/2$ independent values of a symmetric Green's function.

Having determined the quantities $(\partial\xi/\partial t)_{ij}$, $(\partial\Phi/\partial t)_{ij}$ the time extrapolation is performed by means of the formulas

$$\xi_{ij}^{t+\Delta t} = \xi_{ij}^{t-\Delta t} + 2\Delta t(\partial\xi/\partial t)_{ij}^{t},$$
$$\Phi_{ij}^{t+\Delta t} = \Phi_{ij}^{t-\Delta t} + 2\Delta t(\partial\Phi/\partial t)_{ij}^{t},$$

and the entire process is repeated a required number of times. In the first step, uncentered time differences must, of course, be used.

A number of 24-hr integrations have been carried out by this method on the Eniac[2] [5]. The space interval Δs was chosen to be eight degrees of longitude at 45° on the map and the time intervals 1, 2, and 3 hr were used on different occasions. The results indicated that the space interval was too large—about one-half its value seems to be recommended for future work—whereas even three hours was not too long for the time interval.

Figure 3 shows the results of one such integration. A strip two grid intervals in width at the top and side borders and one grid interval in width at the lower border of each diagram has been excluded to eliminate spurious boundary influences from the forecast. The forecast is seen to be fairly good in regions where adequate data were available. The major discrepancy occurred south of Greenland. In order to ascertain whether the discrepancy was due to the effect of baroclinicity, the 500-mb tendencies were calculated by means of the general advective equations (18) and (19), and to obtain a comparison with observation the computed tendency field was translated in the direction of the mean current for 24 hr with the speed of the trough to give a 24-hr change. The results are shown in Fig. 4.

Objective Analysis

After the initial data were assembled and put on punch cards, the time required for the Eniac to produce a 24-hr forecast using 2-hr time intervals was approximately 24 hr of continuous operating time. However, this time is likely to be considerably reduced by machines with a greater memory capacity. It has been estimated that the time required for the electronic computer at The Institute for Advanced Study, with a memory capacity for 1024 forty-digit binary numbers, will be about ½ hr. It is thus not entirely quixotic to contemplate the preparation of numerical forecasts for practical use in the near future. It then becomes obvious that if the high speed and high capacity of the machines are to be used to greatest advantage, there must be an equally rapid method of preparing the data received by teletype, radio, and telegraph in a form accessible to the machine. Under present conditions the data must first be plotted and subjectively analyzed, both of which operations are now painfully slow. J. von Neumann and H. A. Panofsky have therefore suggested that weather reports be translated into initial data by purely objective methods. As Panofsky [11] has shown, the pressure field may be approximated by an nth order polynomial of the form

$$p(x, y) = \sum_{i,j} a_{ij}x^iy^j \qquad (i + j \leq n)$$

by the method of least squares, provided the number of coefficients a_{ij} is less than the number of points at which p is known. The degree of the polynomial is determined by the amount of smoothing desired. For relatively small areas a third-degree polynomial is held to be adequate.

One can easily envisage a process whereby the machine is instructed in advance to take note of the data at a set of fixed observation points, to perform the

2. The Electronic Numerical Integrator and Computer of the Ballistic Research Laboratories, U. S. Army Proving Ground, Aberdeen, Maryland.

polynomial interpolation, and to calculate the initial data at the points of a predetermined grid. Given the mechanical means for the accomplishment of this program, there would, of course, remain other problems to be solved, not the least of which would be the devising of an objective technique for the location and elimination of errors in the raw data.

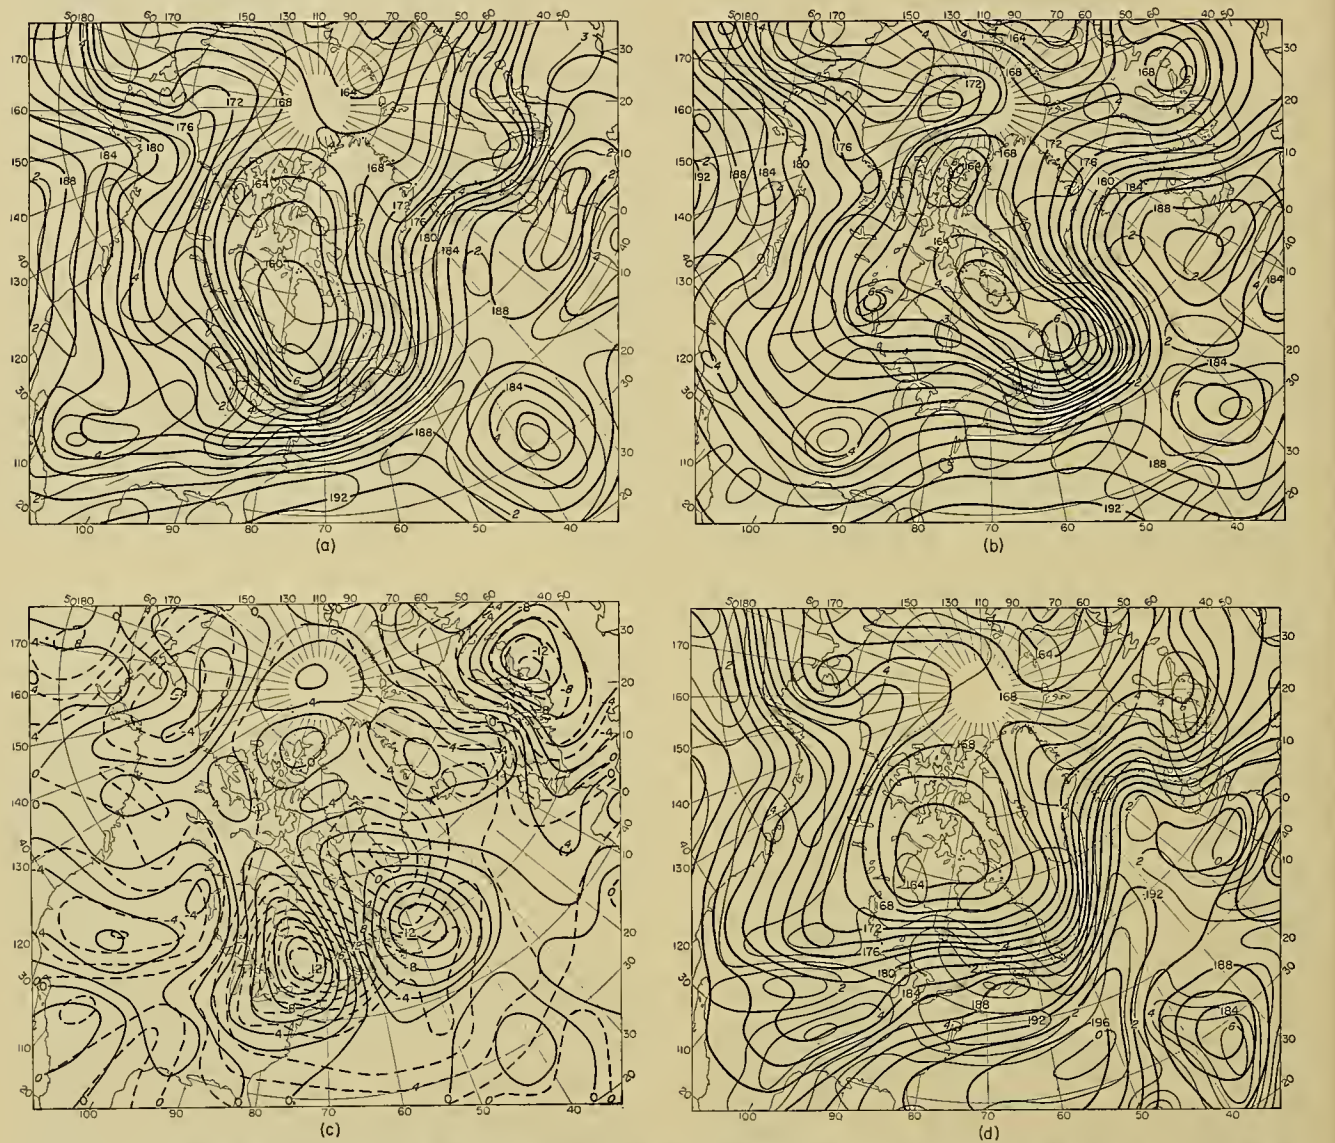

FIG. 3.—Forecast of January 30, 1949, 0300 GMT: (*a*) observed z (heavy lines) and $\zeta + f$ (light lines) at $t = 0$; (*b*) observed z and $\zeta + f$ at $t = 24$ hr; (*c*) observed (continuous lines) and computed (broken lines) 24-hr height change; (*d*) computed z and $\zeta + f$ at $t = 24$ hr. The height unit is 100 ft and the unit of vorticity is $\frac{1}{3} \times 10^{-4}$ sec^{-1}.

Use of the Primitive Equations

The discussion so far has dealt exclusively with the quasi-geostrophic equations as the basis for numerical forecasting. Yet there has been no intention to exclude the possibility that the primitive Eulerian equations can also be used for this purpose. The outlook for numerical forecasting would indeed be dismal if the quasi-geostrophic approximation represented the upper limit of attainable accuracy, for it is known that it applies only indifferently, if at all, to many of the small-scale but meteorologically significant motions. We have merely indicated two obstacles that stand in the way of the application of the primitive equations: First, there is the difficulty raised by Richardson that the horizontal divergence cannot be measured with sufficient accuracy; moreover, the horizontal divergence is only one of a class of meteorological unobservables which also includes the horizontal acceleration. And second, if the primitive Eulerian equations are employed, a stringent and seemingly artificial bound is imposed on the size of the time interval for the finite-difference equations. The first obstacle is the more formidable, for the second only means that the integration must proceed in steps of the order of fifteen minutes rather than two hours. Yet the first does not

seem insurmountable, as the following considerations will indicate.

It is very probable that the state of the motion at any given time will depend continuously upon the

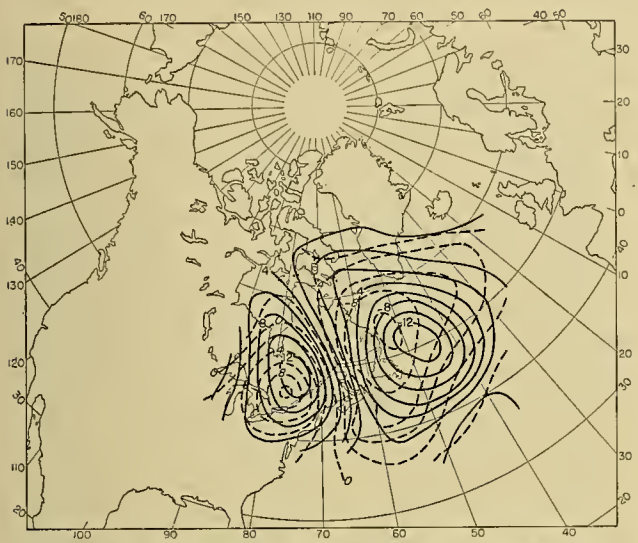

FIG. 4.—The broken lines represent the 24-hr height change computed by translating the baroclinically computed tendency field for 0300 GMT, January 30, 1949 in the direction of the mean current and with the speed of the trough. The solid lines represent the observed 24-hr height change.

initial motion; if the initial conditions are varied slightly, the motion at a subsequent time will vary slightly. Thus if the initial distribution of pressure, temperature, and horizontal wind is known to a relatively high degree of accuracy, the final distribution of these quantities will also be accurately determined and this will be true for whatever initial values are assigned to the unobservables.

To elaborate, let us consider two motions whose velocity components u, v, w and u', v', w' result from the slightly differing initial velocities u_0, v_0, w_0 and u_0', v_0', w_0'. If dm is the element of mass, the integral

$$I = \iiint \tfrac{1}{2}[(u - u')^2 + (v - v')^2 + (w - w')^2]\, dm$$

over the forecast region is a measure of error in the motion when u_0, v_0, w_0 are regarded as correct. We shall assume that u_0', v_0', w_0' are measured with such accuracy that I_0, the initial value of I, is small in comparison with the initial kinetic energy

$$\iiint \tfrac{1}{2}(u_0^2 + v_0^2 + w_0^2)\, dm.$$

Now let us assume that the differences $u - u'$, $v - v'$, $w - w'$ remain fairly small in comparison to u, v, w but allow for the possibility of a relative increase. The differences will then satisfy the linearized perturbation equations for the mean flow u, v, w and reduce to $u_0 - u_0'$, $v_0 - v_0'$, $w_0 - w_0'$ for $t = 0$. If this perturbation motion is stable so that the kinetic energy does not increase with time, the error I will also not increase and the motion u', v', w' will continue to be a good approximation. In practice, when forecasting for a *limited* region, the kinetic energy of the difference motion might conceivably increase as a result of work done at the boundaries or by advection of kinetic energy at the boundary. But in view of what is known about influence velocities one can say that it cannot possibly increase by more than the kinetic energy contained in that region, lying outside the forecast area, from which influences can reach the boundary in the forecast time. Hence, if the kinetic energy within this region is not many times larger than the kinetic energy within the forecast region, the above conclusions still apply. If the difference motion is unstable, the question of the utility of the primitive equations is not easily decided. It is certainly not obvious that dynamic instability necessarily implies their inutility. If, for example, the original motion is a small perturbation on an unstable steady flow with u, v, w, and u', v', $w' \sim e^{\nu t}$ (ν a positive number), the error I will increase exponentially; but the kinetic energy of the actual motion will also increase exponentially in the same proportion so that the relative error will remain constant.

J. C. Freeman and the writer[3] have carried out a numerical integration of the Eulerian equations for small perturbations in a barotropic atmosphere, taking care to satisfy the Courant-Friedrichs-Lewy stability criterion. Had the quasi-geostrophic equation been used, the motion would have consisted only of generalized Rossby waves; instead, the computed motion was found to consist of two superimposed parts, the first nearly identical to the Rossby motion and the second a gravitational wave motion of much smaller amplitude. Because of the necessarily erroneous values used for the acceleration and divergence (these were assumed to be identically zero initially), the changes in the velocity occurring after the first few time steps were quite incorrect. But there soon took place an adjustment of a kind that the motion at no time was found to deviate appreciably from the quasi-geostrophic. The function of the acceleration and divergence fields lay apparently in the mechanism by which the quasi-geostrophic balance was maintained. In a manner of speaking, the gravity waves created by the slight unbalance served the telegraphic function of informing one part of the atmosphere what the other part was doing, without themselves influencing the motion to any appreciable extent. Thus it mattered little that the initial error in the unobservables changed the character of the gravitational waves; only their existence was important.

The question arises whether the unobservables in the baroclinic atmosphere play an analogous role. This question is again not easily answered: in the case of barotropic motion, gravity waves are of the external type which move with the Newtonian velocity of sound; whereas in the baroclinic atmosphere they may be of the internal type—for which the speeds and frequencies are smaller—and might conceivably interfere with the large-scale motions.

In the last analysis, the feasibility of using the primitive equations will be decided only when numerical integrations have been carried out. For this purpose

3. Unpublished report, Meteorology Project, The Institute for Advanced Study, Princeton, New Jersey.

it is more convenient to use pressure as an independent variable in place of height. The complete equations of motion in this variable are given by Eliassen [7]. Under the hydrostatic and adiabatic assumptions they become

$$\frac{d\mathbf{v}}{dt} = \frac{\partial \mathbf{v}}{\partial t} + \mathbf{v}\cdot\nabla_p\mathbf{v} + \omega\frac{\partial \mathbf{v}}{\partial p} = -\nabla_p\Phi - 2\Omega\sin\phi\mathbf{k}\times\mathbf{v}, \quad (67)$$

$$\frac{\partial\Phi}{\partial p} = -\frac{1}{\rho}, \quad (68)$$

$$\nabla_p\cdot\mathbf{v} + \frac{\partial\omega}{\partial p} = 0, \quad (69)$$

$$\frac{\partial \ln\theta}{\partial t} + \mathbf{v}\cdot\nabla_p \ln\theta + \omega\frac{\partial \ln\theta}{\partial p} = 0, \quad (70)$$

where $\mathbf{v}$ is the horizontal velocity and $\omega = dp/dt$. The boundary conditions at the ground and at the upper limit of the atmosphere are, respectively,

$$\frac{d\Phi}{dt} = \frac{\partial\Phi}{\partial t} + \mathbf{v}\cdot\nabla_p\Phi - \frac{\omega}{\rho} = 0, \quad (71)$$

and

$$\frac{dp}{dt} = \omega = 0. \quad (72)$$

In the process of numerical computation, the time increment in $\mathbf{v}$ is determined from (67) and ω is found by integrating (69) and taking account of (72):

$$\omega = -\int_0^p \nabla_p\cdot\mathbf{v}\,dp. \quad (73)$$

The time increment in $\ln\theta$ is obtained from (70) and that of Φ is obtained as follows: Combining (73) with (71), we find for the surface height tendency

$$\left(\frac{\partial\Phi}{\partial t}\right)_0 = -\mathbf{v}_0\cdot(\nabla_p\Phi)_0 - \frac{1}{\rho_0}\int_0^{p_0}\nabla_p\cdot\mathbf{v}\,dp, \quad (74)$$

and from the relation

$$\frac{\partial \ln\theta}{\partial t} = -\rho\frac{\partial}{\partial p}\frac{\partial\Phi}{\partial t},$$

we derive by integration

$$\frac{\partial\Phi}{\partial t} = \left(\frac{\partial\Phi}{\partial t}\right)_0 + \int_{p_0}^p\left(\mathbf{v}\cdot\nabla_p\ln\theta + \omega\frac{\partial\ln\theta}{\partial p}\right)\frac{dp}{\rho}. \quad (75)$$

As $(\partial\Phi/\partial t)_0$ is known from (74), $\partial\Phi/\partial t$ is then immediately determined.

Since ω is very nearly equal to w, one would begin by assuming $d\mathbf{v}/dt$, $\nabla_p\cdot\mathbf{v}$, and ω to be 0 and then trust the compensation mechanism to yield a correct forecast. In six hours, the time interval used by Richardson, twenty-four time extrapolations of fifteen minutes each will have been performed, during which time there would presumably be ample opportunity for this mechanism to operate.

Nonadiabatic and Frictional Effects

Nonadiabatic and frictional effects have been ignored in the body of the discussion only because it was thought that one should first seek to determine how much of the motion could be explained without them. Ultimately they will have to be taken into account, particularly if the forecast period is to be extended to three or more days.

Condensation phenomena appear to be the simplest to introduce: one has only to add the equation of continuity for water vapor and to replace the dry by the moist-adiabatic equation. Long-wave radiational effects can also be provided for, since our knowledge of the absorptive properties of water vapor and carbon dioxide has progressed to a point where quantitative estimates of radiational cooling can be made, although the presence of clouds will complicate the problem considerably.

The most difficult phenomena to incorporate have to do with the turbulent transfer of momentum and heat. A great deal of research remains to be done before enough is known about these effects to permit the assigning of even rough values to the eddy coefficients of viscosity and heat conduction. Owing to their statistically indeterminate nature, the turbulent properties of the atmosphere place an upper limit on the accuracy obtainable by dynamical methods of forecasting, beyond which we shall have to rely upon statistical methods. But it seems certain that much progress can be made before these limits are reached.

ENERGY EQUATIONS

By JAMES E. MILLER

New York University

The concept of energy has two applications in meteorological problems: it facilitates the analysis of many atmospheric processes, and it makes possible a treatment of temperature changes associated with air motion. While many analyses that are facilitated by the energy concept can be accomplished without it, the relation between characteristics of the air motion and temperature changes following the motion is essentially an energy transformation and should be so treated.

The following discussion of atmospheric-energy equations is based primarily upon the work of Reynolds [11], with extensions and interpretations suggested by the work of many others, especially Margules [6, 7, 8], Richardson [12], and Ertel [4]. The mathematical analysis, which is presented in outline form here, can be found more fully developed, though with a few slight differences in approach, in a recent paper [9].

The Concept of Energy

When discussing energy one must define the system with which the energy is identified. A system may be the gas in a cylinder; it may be a certain interconnected series of rods, wheels, and gears in a mechanical device; it may be an electronic circuit; and it may be a part of a fluid. In the most general sense, a system is a portion of space with prescribed boundaries.

When a body moves through a distance d, opposite to the direction of a force F that is acting on the body, it is said to have done work equal in amount to the product $F \times d$. An insulated system is one that can do work or have work done on it, but is restrained from any other interaction with its environment. Energy, then, is that property of an insulated system which decreases when the system does work and increases when work is done on the system, the amount of increase or decrease being equivalent to the work done.

Different kinds of work are associated with changes of different forms of energy: When a gas system expands, its thermal energy decreases; when the gas is lifted in a gravitational field, its potential energy increases. The change of any form of energy in an insulated system can be identified from the work that accompanies the change. The change can be correlated with measurable properties of the system in a series of suitably controlled experiments and expressed as a mathematical function of those properties. It is assumed that the functions for various forms of energy, though established by a necessarily limited number of experiments, can be used to calculate energy changes in all circumstances—in noninsulated systems of any configuration and in complex processes where many different energy forms are changing simultaneously.

If the concept of energy went no further than the preceding discussion, it would have no value whatsoever; "energy change" would simply be a synonym for "work." There is one additional characteristic of energy that gives the concept its real importance. No exception has ever been found to the rule that energy changes can be expressed in terms of changes of the state parameters of a system, such as temperature, velocity, and position, regardless of how those changes take place. Thus, a change of thermal energy can be expressed in terms of the temperature change, and has the same value regardless of the intermediate states of the system. A similar statement cannot, in general, be made about work.

How, then, can the change of energy, as defined, be independent of intermediate states whereas work is not? It is true that, for an insulated system, both energy change and total work are completely determined by the initial and final states of the system. But for a system that can interact with its environment in other ways besides the performance of work, part of the energy change may be associated with a flow of energy into or out of the system. A gas that is being heated while it is expanding against external pressure will experience a change of thermal energy determined by its initial and final temperatures, while the work and the energy added through the boundary may have many different values, so long as their sum equals the energy change in the system.

Now if a system is restrained from the performance of work, but is not restrained from other external actions, a certain form of energy may flow through the boundary into the system. The increase in the amount of that energy form present in the system can be detected from changes of the parameters that enter into the corresponding energy function. Such changes, associated with energy flux alone, can be correlated with measurable properties on the boundary surface in a series of controlled experiments and expressed as mathematical functions of the boundary properties. It is assumed that these functions can be used to compute energy flux in all circumstances.

The preceding definitions of work, energy, and energy flux, and the empirical evidence that they can always be applied consistently to natural processes, lead to a general law of energy, which is expressed here in terms of changes with time:

$$\begin{bmatrix}\text{Rate of increase of energy in the system}\end{bmatrix} = \begin{bmatrix}\text{Rate at which energy is added through the boundary}\end{bmatrix} - \begin{bmatrix}\text{Rate at which work is done by the system}\end{bmatrix}. \quad (1)$$

The First Law of Thermodynamics

The special form of the energy law that is most commonly used in meteorological analysis is the "first law of thermodynamics":

$$\frac{d}{dt}(c_v T + L) = Q^I + Q^L + \alpha p_{ki} \frac{\partial v_i}{\partial x_k}. \quad (2)$$

Written in this way, the law can be applied to a very small system containing moist air and moving at the velocity of the air. The air is subject to viscous forces, but its thermal-energy function is assumed to be the same as that for a perfect gas. The operator d/dt is the rate of change following the motion of the system or the air; c_v is the specific heat of the mixture at constant volume; T is the absolute temperature; and $d(c_vT)/dt$ is the rate of change of thermal energy per unit mass. The rate of change of latent-heat energy, per unit mass, of water within the system is dL/dt. It is not necessary to establish a zero point for either thermal energy or latent-heat energy, because only their rates of change appear in (2).

The term Q^I on the right-hand side of equation (2) represents the rate at which thermal energy, per unit mass, is added by radiation or molecular conduction through the boundary of the system; and Q^L represents the rate at which latent-heat energy, per unit mass, is added by the net flux of water through the boundary.

The last term represents the rate of work, per unit mass, done on the system by relative motion against the molecular stresses. It is written with the aid of tensor notation which, despite its convenience in a term of this nature, is not widely used in meteorology. The indices i and k may have the values 1, 2, or 3, corresponding to the three directions of a Cartesian coordinate system; thus, x_i or x_k may be x_1, x_2, or x_3. The velocity components v_i or v_k may be v_1, v_2, or v_3, corresponding to the directions of the x_1, x_2, or x_3 axes, respectively. The general derivative $\partial v_i/\partial x_k$ stands for any one of nine different derivatives:

$$\frac{\partial v_i}{\partial x_k} = \frac{\partial v_1}{\partial x_1}, \frac{\partial v_1}{\partial x_2}, \frac{\partial v_1}{\partial x_3}, \frac{\partial v_2}{\partial x_1}, \frac{\partial v_2}{\partial x_2}, \frac{\partial v_2}{\partial x_3}, \frac{\partial v_3}{\partial x_1}, \frac{\partial v_3}{\partial x_2}, \frac{\partial v_3}{\partial x_3}.$$

The specific volume of the mixture in the system is α, and p_{ki} is the molecular stress tensor.

The components of p_{ki} are given by the expression

$$p_{ki} = p_{ik} = -\delta_{ik}\left(p + \frac{2}{3}\mu\frac{\partial v_j}{\partial x_j}\right) + \mu\left(\frac{\partial v_i}{\partial x_k} + \frac{\partial v_k}{\partial x_i}\right), \quad (3)$$

where p is the pressure; δ_{ik} is a unit tensor of value 1 when $i = k$ and of value 0 when $i \neq k$; μ is the coefficient of molecular viscosity; and j is an index with the value 1, 2, or 3. In the tensor notation, repetition of an index within a term means that the term is summed over all values of the index. Thus,

$$\frac{\partial v_j}{\partial x_j} = \sum_{j=1}^{3}\frac{\partial v_j}{\partial x_j} = \frac{\partial v_1}{\partial x_1} + \frac{\partial v_2}{\partial x_2} + \frac{\partial v_3}{\partial x_3},$$

which is the three-dimensional velocity divergence. Any component of p_{ki} is a force per unit area, acting in the plane perpendicular to the x_k-axis. If it is regarded as acting on the fluid lying to the negative side of that plane, then the force is positive in the x_i-direction. If the velocity gradients are vanishingly small, or if the fluid is nonviscous ($\mu = 0$), p_{ki} reduces to the negative of the pressure, p:

$$p_{12} = p_{21} = p_{13} = p_{31} = p_{23} = p_{32} = 0,$$
$$p_{11} = p_{22} = p_{33} = -p.$$

Both i and k are repeated in the last term of (2), and hence

$$\alpha p_{ki}\frac{\partial v_i}{\partial x_k} = \sum_{\substack{i=1\\k=1}}^{3}\alpha p_{ki}\frac{\partial v_i}{\partial x_k}.$$

When this term is summed, expanded, and rearranged, there is obtained:

$$\alpha p_{ki}\frac{\partial v_i}{\partial x_k} = -\alpha p\frac{\partial v_j}{\partial x_j} + \mu\left[\begin{array}{c}\text{Sum of squares of terms}\\ \text{involving derivatives}\\ \text{of velocity components}\end{array}\right],$$

where $\partial v_j/\partial x_j$, the velocity divergence, is equivalent to $\delta_{ik}\,\partial v_i/\partial x_k$. According to the equation of continuity,

$$\frac{\partial v_j}{\partial x_j} = \frac{1}{\alpha}\frac{d\alpha}{dt}. \quad (4)$$

Therefore,

$$\alpha p_{ki}\frac{\partial v_i}{\partial x_k} = -p\frac{d\alpha}{dt} + \mu[\text{Sum of squares}]. \quad (5)$$

The first term on the right, $-p\,d\alpha/dt$, is the rate of work by expansion, and the second term is the rate of work by relative motion against viscous stresses. The latter term, Stokes' "dissipation function," is always positive because both μ and the sum of squares are positive.

The first law of thermodynamics has been established by many experiments, controlled and interpreted with a philosophy of the energy concept similar to that presented in the first part of this paper. The earliest statement of an energy law, by Leibnitz in 1693, dealt not with thermal energy but with kinetic and potential energies (the "live" and "dead forces"). This energy law can be established by a mathematical transformation of Newton's second law of motion, and its validity rests upon the validity of the law of motion.

The Law of Kinetic Energy

Newton's second law, for a compressible viscous fluid on the rotating earth, can be expressed as follows:

$$\left.\begin{aligned}\frac{dv_1}{dt} + (2\omega\cos\phi)v_3 - (2\omega\sin\phi)v_2 &= \alpha\frac{\partial p_{k1}}{\partial x_k},\\ \frac{dv_2}{dt} + (2\omega\sin\phi)v_1 &= \alpha\frac{\partial p_{k2}}{\partial x_k},\\ \frac{dv_3}{dt} - (2\omega\cos\phi)v_1 &= \alpha\frac{\partial p_{k3}}{\partial x_k} - g,\end{aligned}\right\} \quad (6)$$

where ω is the angular velocity of the earth's rotation; ϕ, the latitude; and g, gravity. The x_1-axis is directed toward east; the x_2-axis toward north; and the x_3-axis toward the zenith. When the first equation is multiplied by v_1, the second by v_2, the third by v_3, and the resulting equations are added, the Coriolis terms disappear, and the result is

$$\frac{d}{dt}\left(\frac{v_i^2}{2}\right) = \alpha v_i\frac{\partial p_{ki}}{\partial x_k} - v_3 g,$$

in which $v_i^2 = v_1^2 + v_2^2 + v_3^2$. The first term on the

right is recognized as the rate of work, per unit mass, done on a small volume of the fluid as a result of its motion in the direction of the net molecular stress acting on the volume. It can be transformed to

$$-\alpha p_{ki}\frac{\partial v_i}{\partial x_k}+\alpha\frac{\partial}{\partial x_k}(v_i p_{ki}),$$

and the last term, $-v_3 g$, can be written $-d(gx_3)/dt$, neglecting the variations of gravity. The equation then becomes

$$\frac{d}{dt}\left(\frac{v_i^2}{2}+gx_3\right)=-\alpha p_{ki}\frac{\partial v_i}{\partial x_k}+\alpha\frac{\partial}{\partial x_k}(v_i p_{ki}). \quad (7)$$

Note that, because of the summation convention, each term on the right is summed over the three values of i and k.

This equation, though established by a mathematical transformation of the equations of motion, is interpreted as a special form of the general energy law, equation (1). It will be applied to the same system to which the first law of thermodynamics is applied: a very small volume containing a mixture of air and water vapor. The term $v_i^2/2$ is known as the kinetic energy and gx_3 as the potential energy, both per unit mass. Such interpretation is consistent with the energy concept, for these functions are determined by the system's state and not by its history, and their total increase is equivalent to work done on the system.

For simplicity the following symbols will be used in writing the energy equations:

$$\left.\begin{aligned} I &= c_v T, \quad \text{the thermal energy} \\ K &= v_i^2/2, \quad \text{the kinetic energy} \\ P &= gx_3, \quad \text{the potential energy} \end{aligned}\right\}\ \text{per unit mass}$$
$$M=\alpha p_{ki}\frac{\partial v_i}{\partial x_k}. \quad (8)$$

Equations (2) and (7) then become

$$\frac{d}{dt}(I+L)=[Q^I+Q^L]_A-[-M]_W, \quad (9)$$

$$\frac{d}{dt}(K+P)=-\left[M-\alpha\frac{\partial}{\partial x_k}(v_i p_{ki})\right]_W. \quad (10)$$

The subscripts A and W indicate that the preceding terms in brackets represent energy added to the system or work done by the system, respectively. Since P is understood to mean g times a distance along a line directed opposite to gravity, there is no required orientation of the axes in equations (9) and (10).

The rate of work represented by M contributes to an increase of the sum of thermal and latent-heat energies, and simultaneously takes the same amount from the sum of kinetic and potential energies. It represents an energy transformation through the mechanism of molecular stress, and hence it will be called the molecular transformation function.

Energy equations that may be useful in meteorological problems will be derived from the basic equations (9) and (10) by purely mathematical methods, with the aid of certain simplifying assumptions about the physical properties of the moist air. Before this analysis is begun, a few remarks about the basic equations are in order.

Remarks on the Basic Energy Laws

Equations (6), upon which (10) is based, express Newton's second law of motion in a coordinate system that rotates with the earth. The rotational terms, such as $(2\omega\cos\phi)v_3$, vanish during the derivation of the energy equation, so that the velocity v_i and the rate of change d/dt in equation (10) may be measured in any Cartesian system, whether fixed, rotating, or moving at constant speed. It is customary to refer both (9) and (10) to a Cartesian coordinate system which is instantaneously fixed in the rotating earth, but which also follows the small air system so that two axes always lie in a plane tangent to the earth's surface. The magnitudes of terms in (10) may be different in other coordinate systems. For example, if a 1-g air particle, moving from east to west at 20 m sec^{-1} on the earth's equator, is brought to rest, it loses 2×10^6 ergs of kinetic energy in the commonly used coordinate system; but it gains 90×10^6 ergs in a nonrotating coordinate system. There is a compensating difference in the work in the two coordinate systems. In the former, the air particle performs work in the amount 2×10^6 ergs; in the latter, work is done on it in the amount 90×10^6 ergs.

The terms $\alpha\,\partial p_{ki}/\partial x_k$ in (6) are supposed to represent all body forces, per unit mass, on a small fluid element, with the exception of gravity. Whether they do or not depends upon the accuracy of the expressions for the stress tensor in (3). These expressions are presumed to be correct, but they have been verified experimentally for only a few special cases.

There is a further uncertainty about the equations that is of particular concern to the meteorologist. It is well known that the observed velocity of air motion varies with the type of instrument used. Fluctuations of the velocity in space and time cause a large, sluggish anemometer to react differently from a small, sensitive one. The same sort of scale effect is certainly present in measurements of temperature, pressure, and other properties. This situation poses a problem: How shall the properties be measured in order that the equations will be satisfied?

It can be shown logically that the equations (6), with the stress represented by (3), if correct at all, are strictly correct only in a certain scale domain with time and space periods greater than the molecular periods but smaller than the periods of the smallest turbulent fluctuations [11]. This conclusion presupposes that there is a lower limit to the periods of turbulent fluctuations of the various properties. If the conclusion is correct for the equations of motion, it is also correct for equation (10) and presumably for equation (9).

The latter equation, the first law of thermodynamics, is generally applied only to a stationary, homogeneous fluid whose changes of state take place very slowly. The

equation, which has been limited here to a system small enough to be considered homogeneous, will later be integrated for large, nonhomogeneous systems. Whether the fluid is stationary does not seem to make any difference. If it moves, so that the system contains kinetic energy, the changes of this energy form are completely accounted for in equation (10); and transformations of kinetic into thermal energy are accounted for by the transformation function M, common to both equations.

Equation (9) contains some terms that are not always found in expressions of the first law of thermodynamics. In the first place, the heat released in phase changes is frequently included in a general Q term, implying that the latent heat is supplied by some source outside the system. In equation (9) the latent-heat energy L and its net flux Q^L are written specifically, in order to make a clear distinction between energy transformations within the system and flux of energy across the boundary.[1]

In the second place, equation (9) includes, within the function M, not only the expansional work but also Stokes' dissipation function, which represents work done in relative motion against viscous forces. Since this function usually has a magnitude much smaller than that of expansional work, its neglect is of no consequence in most meteorological problems. But if it is omitted from a discussion of energy transformations, there can be no explanation of the frictional conversion of kinetic energy into thermal energy [14].

The General System

The basic energy equations can be integrated for a large, nonhomogeneous system, whose boundary surface has any shape and moves and changes shape in any prescribed manner, by the following procedure. Each equation is transformed to apply to a unit volume instead of a unit mass and is integrated over the volume of the large system, yielding an equation for the local rate of change of the energy. A term representing energy flux through the boundary surface, associated with the arbitrary and variable motion of the surface, is added to both sides of each equation. The equations then give the rate of change of energy following the large, irregularly shaped, irregularly moving system, the shape of whose boundary may also be changing. This procedure will be illustrated by the transformation of equation (10).

The equation of continuity (4) in the form

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x_k}(\rho v_k) = 0,$$

where ρ is the density of the small volume of moist air, is multiplied through by $K + P$. Equation (10) is multiplied through by ρ and the resulting two equations are added; each term in the sum now refers to a unit volume. When this equation is integrated over the volume of the large system, there results

$$\frac{\partial}{\partial t}(K^* + P^*) = -\left[\int_\sigma v_n \rho(K + P)d\sigma\right]_A - \left[M^* - \int_\sigma v_i p_{ni}\, d\sigma\right]_W. \tag{11}$$

Here an asterisk indicates that a term has been multiplied by ρ and integrated over the volume; thus, $K^* = \int_v \rho K\, dV$. Two volume integrals on the right-hand side of the equation have been transformed to surface integrals by the divergence theorem. An element of the boundary surface is $d\sigma$; the component of air motion normal to the boundary and directed outward from the system is v_n ; and the three components of the stress tensor acting in a plane tangent to the boundary surface are p_{ni} .

Finally, the net flux of the energy $K + P$ into the system through the boundary surface, associated with the normal, outwardly directed velocity V_n of the surface, is written as a surface integral. The rate of change following the system is, then, the local change plus the net flux due to the motion of the system's boundary surface:

$$\frac{D}{Dt}(K^* + P^*) = \frac{\partial}{\partial t}(K^* + P^*) + \int_\sigma V_n \rho(K + P)d\sigma, \tag{12}$$

and (11) becomes

$$\frac{D}{Dt}(K^* + P^*) = \left[\int_\sigma u\rho(K + P)d\sigma\right]_A - \left[M^* - \int_\sigma v_i p_{ni}\, d\sigma\right]_W, \tag{13}$$

where u is equal to $V_n - v_n$, or the velocity of the boundary relative to the velocity of the air.

Similarly, equation (9) becomes

$$\frac{D}{Dt}(I^* + L^*) = \left[\int_\sigma [u\rho(I + L) - q_n^I - q_n^L]d\sigma\right]_A - \left[-M^*\right]_W, \tag{14}$$

where q_n^I and q_n^L are the components of the fluxes q_k^I and q_k^L of thermal energy and latent-heat energy at the boundary surface, and are directed normal to the surface out of the system. The fluxes q_k^I and q_k^L , whose units are energy per unit area and time, are defined in terms of Q^I and Q^L :

$$\rho Q^I = -\frac{\partial}{\partial x_k}(q_k^I) \quad \text{and} \quad \rho Q^L = -\frac{\partial}{\partial x_k}(q_k^L). \tag{15}$$

For example, the part of q_k^I associated with molecular conduction is $-c\,\partial T/\partial x_k$, where c is a constant, and the net inward flux per unit volume is $c\,\partial^2 T/\partial x_k{}^2$, a summation over the three values of k.

1. The term L can be expanded into $h_{vs}w_v + h_{ls}w_l$, where h_{vs} and h_{ls} are the latent heats of sublimation and freezing, and w_v and w_l are the mass proportions of water vapor and liquid water to the total mass of moist air. This method of representation is not completely satisfactory because the system, stipulated to consist of moist air only, may also contain some liquid water and ice.

Addition of (13) and (14) gives a total-energy equation:

$$\frac{D}{Dt}(I^* + L^* + K^* + P^*) = \left[\int_\sigma [u\rho(I + L + K + P) - q_n^I - q_n^L]d\sigma\right]_A - \left[-\int_\sigma v_i p_{ni} d\sigma\right]_W. \quad (16)$$

The important effect of adding the equations is the elimination of M^*, the only term on the right-hand side of the equations that depends upon processes within the system. By means of equation (16), it is possible to compute the change of total energy from measurements on the boundary, without any knowledge of processes within the system. If there is no work or energy flux at the boundary, the right side of (16) is zero, and the equation then expresses a law of conservation of energy.

The energy equations are sometimes derived in an order different from that followed here. The principle of conservation of energy is accepted as the basic law, and a total-energy equation in a form similar to (16) is written immediately. The law of kinetic energy is derived from the equations of motion, as is done here, and then the first law of thermodynamics follows upon subtraction of the kinetic-energy law from the total-energy law [15]. In contrast, the procedure used here is, first, the formulation of the law of kinetic energy and the first law of thermodynamics; and second, a statement of the total-energy law derived by combining the two. This procedure is considered more logical because one cannot write the necessary energy and work functions in the total-energy law without recourse to the experimental evidence embodied in the two special laws.

Effects of Averaging Processes

The scale domain of nonturbulent variations, the domain for which the energy equations are presumably valid, may be defined as follows: If instrumental measurements of a property are not appreciably affected by decrease in size and increase in response of the instrument, the property is being measured in a scale domain below the scale of the smallest turbulent fluctuations of that property.

Meteorological measurements of the various physical properties are made with instruments whose size and period of response are certainly greater than the size and period of the smallest turbulent fluctuations. Suppose several anemometers of varying size and response were mounted near each other in the atmosphere. The largest, most insensitive anemometer would indicate a fluctuation of velocity with time; the next more refined instrument would indicate more rapid fluctuations superimposed on those detected by the first instrument; and so on, down the scale. According to the postulate of a scale domain smaller than the smallest fluctuations, all anemometers smaller and more sensitive than a certain anemometer would give indications that were essentially identical in period and amplitude. The velocities indicated by these anemometers are the velocities that are supposed to satisfy the equations of motion and energy. Experimental studies suggest that the anemometers should be at least smaller than one centimeter in diameter and should react to velocity changes within at least one second [3].

Because the terms in the basic energy equations cannot be correctly evaluated by ordinary meteorological observations, it is no great exaggeration to say that the equations are not very useful for meteorological purposes. The equations can be rendered more useful by an analysis that will now be demonstrated; but, as will be seen, the analysis introduces new terms whose evaluation has long been a subject for speculation, postulation, and experimentation.

A property s will be separated into a mean value $\bar{s}$ and a deviation s' from the mean:

$$s = \bar{s} + s'. \quad (17)$$

The mean value is defined by a space-time integral:

$$\bar{s} = \frac{\int_V \int_t s\, dt\, dV}{Vt}, \quad (18)$$

where V is the volume of the space occupied by the instrument, and t is the period for which the instrument, because of its inertia, automatically averages the reading. If the mean value is defined arbitrarily for a selected volume and a selected period, the averaging can be carried out by numerical methods. Thus, any set of observations of s, at different points and different times, may be converted into a mean value over a selected volume and period by calculation of the integral in (18). Whether the averaging is done automatically by the instrument, or by numerical methods, or by both, $\bar{s}$ refers to a central point and time in V and t, and it is a continuous function of space and time. The values of $\bar{s}$ at nearby points and times are determined in overlapping volumes and periods.

The various properties s are replaced in the equations by $\bar{s} + s'$ and the individual terms of the equations are averaged by an integral of the form (18). It is assumed that $\overline{s'}$, the average value of s' for the same space-time as $\bar{s}$, is negligible; and that, therefore, $\bar{\bar{s}}$, which represents the average of the continuously varying $\bar{s}$ in the same space-time, is equivalent to the value of $\bar{s}$ at the center of the space-time.[2] Further, for the sake of simplification, it is assumed that $\rho = \bar{\rho}$, or that the density fluctuations are negligible; but this does not necessarily mean that the fluid is incompressible. The consequences of the assumptions are, for example,

$$\overline{v_i'} = 0, \quad \overline{\rho v_i'} = 0, \quad \overline{p_{ki}'} = 0, \quad \bar{\bar{v}}_i = \bar{v}_i,$$

$$\overline{\rho v_i} = \rho \bar{v}_i, \quad \overline{\frac{\partial}{\partial x_k}(\rho \bar{v}_i v_k')} = 0, \quad \text{etc.}$$

2. Note that $\overline{s'}$ is not the average value of deviations from a fixed mean, because $\bar{s}$ also varies from point to point; thus, $\overline{s'} = 0$ does not follow from the definitions but must be stated as an assumption.

Hesselberg [5] has defined the mean velocity by the formula:

$$\bar{u}_i = \frac{\int_V \int_t \rho v_i \, dt \, dV}{\int_V \int_t \rho \, dt \, dV},$$

as a consequence of which $\overline{\rho u_i'}$ is automatically zero whether ρ' is negligible or not. Energy equations written for this density-weighted mean velocity are similar in form to the ones that follow, but many of the terms have different meanings and values. The choice of the averaging formula for the velocity should be determined finally by the instrumental technique that is used in measuring v_i. If the instrument responds directly to the momentum ρv_i, then it measures the $\bar{u}_i$ of Hesselberg's formula. If it responds directly to the velocity v_i, then it measures $\bar{v}_i$ and formula (18) should be used. If ρ' is truly negligible or is not correlated with velocity components, the two formulas are identical.

Energy Equations for Averaged Properties

The process of analysis for averaged properties is applied to the first law of thermodynamics as follows. By combination with the equation of continuity, equation (9) is transformed to apply to a unit volume:

$$\frac{\partial}{\partial t}(\rho I + \rho L) + \frac{\partial}{\partial x_k}(v_k \rho I + v_k \rho L) = \rho Q^I + \rho Q^L + \rho M. \tag{19}$$

Then v_k is replaced by $\bar{v}_k + v_k'$, and the terms are averaged by formula (18) over the space and time pertaining to $\bar{v}_k$:

$$\frac{\partial}{\partial t}(\rho \bar{I} + \rho \bar{L}) + \frac{\partial}{\partial x_k}(\bar{v}_k \rho \bar{I} + \bar{v}_k \rho \bar{L} + \overline{\rho v_k' I} + \overline{\rho v_k' L}) = \rho \bar{Q}^I + \rho \bar{Q}^L + \rho \bar{M}, \tag{20}$$

Now,

$$\bar{M} = \alpha \bar{p}_{ki} \frac{\partial \bar{v}_i}{\partial x_k} + \overline{\alpha p_{ki}' \frac{\partial v_i'}{\partial x_k}} + \overline{\alpha p_{ki}' \frac{\partial \bar{v}_i}{\partial x_k}} + \overline{\alpha \bar{p}_{ki} \frac{\partial v_i'}{\partial x_k}}, \tag{21}$$

in which the last two terms are assumed to be negligible. The first two terms on the right will be indicated by M_m and M_e, respectively. The energy equation is integrated over the total volume of the arbitrary system and becomes finally

$$\frac{D}{Dt}(\bar{I}^* + \bar{L}^*) = \left[\int_\sigma [\bar{u}\rho(\bar{I} + \bar{L}) - \overline{\rho v_n'(I + L)} - \bar{q}_n^I - \bar{q}_n^L] \, d\sigma\right]_A - [-M_m^* - M_e^*]_W, \tag{22}$$

where $\bar{u}$ is the normal velocity of the boundary surface relative to $\bar{v}_n$, or $V_n - \bar{v}_n$.

The term $\bar{u}\rho(\bar{I} + \bar{L})$ is the flux of the averaged thermal and latent-heat energies at the velocity of the boundary relative to the averaged air velocity. The flux $\overline{\rho v_n'(I + L)}$, averaged locally before integration over the surface, is associated with the "eddy" velocity of the air, v_n', normal to the surface; it can be called the eddy flux of thermal and latent-heat energies. The terms $\bar{q}_n^I$ and $\bar{q}_n^L$ are averaged values of the fluxes that appear in the thermal-energy equation (14); $\bar{q}_n^I$, for example, consists in part of molecular conduction proportional to the gradient of the mean temperature:

$$\bar{q}_n^I = -c \frac{\partial \bar{T}}{\partial x_n} + \text{flux of radiant energy},$$

where x_n is a coordinate normal to the surface and directed outward. The last terms, M_m^* and M_e^*, are the volume integral of the molecular transformation function: M_m^* for averaged stresses and velocity, M_e^* for deviations of stresses and velocity from their averaged values.

There are two alternate ways of deriving an energy equation for averaged properties from the equations of motion: The equations may be averaged first and then converted into an equation for the kinetic energy of averaged motion alone; or they may be converted into an energy equation and then averaged, yielding an equation for kinetic energies of both averaged and eddy motions. The difference between these two equations is the equation for the kinetic energy of eddy motions alone.

In the first method, the equations (6) are converted to the momentum form by combining each of them with the equation of continuity. The velocities and stresses are replaced with their averaged values and deviations, and the terms of the equations are averaged by formula (18). These three equations are multiplied by $\bar{v}_1$, $\bar{v}_2$, and $\bar{v}_3$, respectively; the averaged form of the equation of continuity is multiplied by $-\bar{v}_i^2/2$; and all four equations are added together. The final result is

$$\frac{\partial}{\partial t}\left(\rho \frac{\bar{v}_i^2}{2} + \overline{\rho g x_3}\right) + \frac{\partial}{\partial x_k}\left(\bar{v}_k \rho \frac{\bar{v}_i^2}{2} + \overline{\bar{v}_k \rho g x_3}\right) = \bar{v}_i \frac{\partial T_{ki}}{\partial x_k} + \bar{v}_i \frac{\partial \bar{p}_{ki}}{\partial x_k}. \tag{23}$$

The symbol T_{ki} stands for the "eddy stress" tensor:

$$T_{ki} = T_{ik} = -\overline{\rho v_i' v_k'}. \tag{24}$$

This term, though it arises from the averaging of the accelerational term, is customarily regarded as a stress against the mean motion, acting in the x_i-direction in a plane normal to the x_k-axis, on the fluid lying to the negative side of the plane.

Equation (23) is transformed into an equation valid for a general system by the method already described, and it becomes

$$\frac{D}{Dt}(K_m^* + \bar{P}^*) = \left[\int_\sigma \bar{u}\rho(K_m + \bar{P}) \, d\sigma\right]_A - \left[M_m^* + E^* - \int_\sigma \bar{v}_i(\bar{p}_{ni} + T_{ni}) \, d\sigma\right]_W, \tag{25}$$

where $K_m = \bar{v}_i^2/2$, the kinetic energy, per unit mass, of the averaged motion; $\bar{P} = \overline{gx_3}$, which, incidentally, is equivalent to the unaveraged gx_3 or P; and E is the "eddy-transformation function":

$$E = \alpha T_{ki} \frac{\partial \bar{v}_i}{\partial x_k}. \tag{26}$$

The other terms and their superimposed symbols have the same meanings as in the preceding analyses.

In the second method of deriving a kinetic-energy equation for averaged properties, the starting point is the basic equation of kinetic energy (10), transformed for a unit volume. Again, v_i and p_{ki} are replaced with $\bar{v}_i + v_i'$ and $\bar{p}_{ki} + p_{ki}'$, and the terms are averaged. The resulting equation contains the kinetic energy of eddy motions as well as averaged motion. When equation (23) is subtracted from this equation, there is obtained, after transformation to the general system,

$$\frac{D\bar{K}_e^*}{Dt} = \left[\int_\sigma (\bar{u}\rho\bar{K}_e - \rho\overline{v_n' K_e})\, d\sigma\right]_A - \left[M_e^* - E^* + \int_\sigma \overline{v_i' p_{ni}'}\, d\sigma\right]_W, \tag{27}$$

where $K_e = v_i'^2/2$ and $\bar{K}_e = \overline{v_i'^2/2}$. The function E^* appears with opposite signs in (25) and (27). This explains why E has been called the eddy-transformation function; when positive, it decreases the energy of the mean motion and increases the energy of the eddy motion. It is analogous to the molecular transformation function M.

Applications of the General Energy Equations

Equations (22), (25), and (27) constitute an array of general energy equations for atmospheric processes. Many different special equations can be obtained from them. For example, if turbulent fluctuations are nonexistent ($v_i' = v_k' = p' = p_{ki}' = 0$), if the system's boundary everywhere moves with the air, and if the system is homogeneous, equation (27) vanishes, and (22) and (25) can be reduced to the basic equations (9) and (10).

If one wishes to establish a criterion for the increase of eddying motion, one starts with equation (27) and modifies it according to whatever conditions may be assumed. Richardson's criterion [12], however, cannot be derived from that equation because of the omission of terms involving density fluctuations. One such term omitted from (27) is $-\int_V g\overline{\rho' v_3'}\, dV$. If this term[3] is included and if, following Richardson, one assumes that the boundary work and flux terms and the term M_e^* are negligible, then (27) becomes

$$\frac{D\bar{K}_e^*}{Dt} = E^* - \int_V g\overline{\rho' v_3'}\, dV. \tag{28}$$

Richardson's number is the ratio

$$Ri = \frac{\int_V g\overline{\rho' v_3'}\, dV}{E^*}.$$

According to the assumptions that are usually made in applications of Richardson's criterion, the ratio reduces to the stability divided by the square of the vertical shear; when this ratio is less than a critical value Ri_{crit}, turbulence is supposed to increase. Richardson assumed that $Ri_{\text{crit}} = 1$.

It will not be argued that the terms involving ρ' are negligibly small, for they very well may not be. They have been omitted from the equations developed here solely to permit a discussion of the general aspects of the equations without too much involvement with details. But the fact that this omission eliminates the possibility of deriving Richardson's criterion from the equations may not be a serious fault. The criterion depends upon the term $g\overline{\rho' v_3'}$ being positive and different from zero; in other words, upon a positive correlation between density and vertical velocity. There is no experimental evidence that such correlation is to be expected. The occasional examples cited in support of the criterion are more qualitative than quantitative; according to Sutton [16], "some support can be found for almost any value of Ri_{crit} between 0.04 and 1."

Richardson's criterion appears to be qualitatively correct, because observations show that turbulence tends to be suppressed in a stable layer and to be increased when the vertical wind shear is great. The qualitative success may be explained without considering the term $g\overline{\rho' v_3'}$. Suppose (27) is applied to a homogeneous system, and all terms are dropped except the following:

$$\frac{D\bar{K}_e^*}{Dt} = -M_e^* + E^*. \tag{29}$$

The first term on the right represents the dissipation of eddy energy into thermal energy; it is probably negative most of the time so that it consistently acts to decrease the eddy energy by converting it into thermal energy. The second term E^*, for the frictional layer, is essentially the volume integral of

$$\rho E = -\rho\overline{v_1' v_3'}\frac{\partial \bar{v}_1}{\partial x_3} - \rho\overline{v_2' v_3'}\frac{\partial \bar{v}_2}{\partial x_3}, \tag{30}$$

where the x_3-axis is vertical. According to empirical evidence, the eddy-transformation function E is predominantly positive, so it consistently acts to increase the eddy energy at the expense of the energy of mean motion. The magnitude of E increases with increasing vertical wind shear, $\partial\bar{v}_1/\partial x_3$ and $\partial\bar{v}_2/\partial x_3$; thus, the eddy energy tends to increase with increasing shear. Its magnitude increases also with increasing v_3'; but this fluctuation of the vertical velocity tends to be damped

3. Calder [2] derives the kinetic-energy equations for mean and eddy motion by a procednre similar to that followed here, bnt he retains this one term involving ρ'. His arguments for retaining it appear logical, but it would seem that the arguments apply equally to some of the terms that he does not retain.

out when the stability is great. Hence, with smaller stability v_3' is greater on the average, E is greater, and the eddy energy tends to increase with decreasing stability.

The array of general energy equations may be combined in four ways: any two or all three may be added together. When all three are combined, a total-energy equation is obtained:

$$\frac{D}{Dt}(\bar{I}^* + \bar{L}^* + \bar{K}_m^* + \bar{P}^* + \bar{K}_e^*) = \left[\int_\sigma [\bar{u}\rho(\bar{I} + \bar{L} + \bar{K}_m + \bar{P} + \bar{K}_e) - \rho\overline{v_n'(I + L + K_e)}]\, d\sigma\right]_A - \left[-\int_\sigma [\bar{v}_i(\bar{p}_{ni} + T_{ni}) + \overline{v_i' p_{ni}'}]\, d\sigma\right]_W. \tag{31}$$

If no energy flux or work occurs at the boundary surface, the total energy within the system remains unchanged. This is the law of conservation of energy.

Margules' models of energy transformations in the atmosphere were based upon an equation which can be obtained from (31) by neglecting turbulent fluctuations and boundary activity:

$$\frac{D}{Dt}(I^* + L^* + K^* + P^*) = 0. \tag{32}$$

Margules computed the changes of latent-heat, potential, and thermal energies for closed, stationary systems which progressed, in certain special ways, from a state of instability to a state of stability. He was then able to compute the associated change of kinetic energy by means of (32). His masterful analysis of the models has deeply influenced meteorological thought on atmospheric-energy transformations. Margules, however, was apparently well aware that his models were far from realistic and that, at best, they provided nothing more than general suggestions of the source of atmospheric motions. Furthermore, Spar [13] has investigated the energy changes in two deepening cyclones and has stated that the results "lend no support to Margules' energy theory of cyclones."

To reduce the total-energy equation to Bjerknes' generalization of Bernoulli's equation [1], one must omit a number of terms and undo most of the analysis that produced the total-energy equation. Turbulent fluctuations, viscous stresses, and latent-heat energy are omitted; and the equation is applied to a system consisting of a small volume of air moving at the air velocity, instead of a large volume moving arbitrarily. With these conditions, equation (30) reduces to

$$\frac{\partial}{\partial t}[\rho(I + K + P + p\alpha)] - \frac{\partial p}{\partial t} = -\frac{\partial}{\partial x_k}[\rho v_k(I + K + P + p\alpha)]. \tag{33}$$

After application of the equation of continuity this becomes, for a steady pressure distribution,

$$c_v T + \frac{v_i^2}{2} + g x_3 + p\alpha = \text{const}, \tag{34}$$

along a trajectory.

The eddy flux of thermal and latent-heat energies is the first of the following three eddy terms from the right side of (31):

$$-\rho\overline{v_n'(I + L)} - \rho\overline{v_n' K_e} + \overline{v_i' p_{ni}'}.$$

It differs from the expression for the vertical eddy flux of heat derived by Montgomery [10], partly because he defined the mean velocity by Hesselberg's formula, and partly because he combined the pressure part of the work term $\overline{v_i' p_{ni}'}$ with the flux term. The first difference is unimportant if $\rho = \bar{\rho}$. As for the second difference, the term $\overline{v_i' p_{ni}'}$ becomes either $-\overline{v_n' p'}$ or $-\overline{v_n'}\,\overline{p}$ (since $\overline{v_n'}\,\overline{p} = 0$) if the viscous stresses are ignored; and this, combined with the flux, gives Montgomery's expression for the x_3-direction:

$$-\rho\overline{v_3'(I + L + p\alpha)} = -\rho\overline{v_3' h_t},$$

where $h_t = I + L + p\alpha$. For dry air, $h_t = h = c_v T + p\alpha$, the enthalpy.

The preceding examples are only a small sample of the numerous studies of atmospheric energy. Many others can be found without difficulty in the literature. Since no general approach to the philosophy of atmospheric energy has been adopted by meteorologists, the problems discussed in the literature may sometimes seem to have very little to do with the energy laws discussed here. It is unfortunate that the experimentally determined facts are not always kept distinct from the definitions, assumptions, and speculations. If this distinction were preserved, the work of different investigators could be more readily fitted into a single philosophy.

The general energy equations permit the use of averaged values of velocity and stresses, but they require also a knowledge of eddy terms that are not measured directly. These terms have been the subject of many investigations during the past forty years. The most common approach to their evaluation seems to be guided by their analogy to terms associated with molecular motions. The molecular stress p_{ki} is a function of the pressure p, viscosity μ, and velocity gradients. By analogy, one might wish to express the eddy stress T_{ki} by a similar formula in terms of an "eddy pressure" [12], "eddy viscosity," and gradients of the averaged velocity. The molecular flux of heat is a function of a coefficient of heat conduction and the temperature gradient; and by analogy, the eddy flux of thermal energy may be expressed in terms of a coefficient of eddy conduction and the gradient of mean temperature:

$$\overline{v_k' I} = -C\frac{\partial \bar{I}}{\partial x_k}.$$

The trouble with the analogy is that the coefficients of eddy viscosity and thermal conductivity are too variable and unpredictable, and are not positive at all times;

while the corresponding coefficients on the molecular scale are established physical properties, varying in a predictable manner when other properties vary.

It is apparent, then, that the general energy equations cannot be applied successfully to the real atmosphere until more is known about the eddy terms. The problem of these terms can be formulated more effectively if their mutual relationship, as shown by general equations, is taken into consideration. For example, whether eddy flux of thermal energy, $-\overline{\rho v_k' c_v T}$, or eddy flux of enthalpy, $-\overline{\rho v_k'(c_v T + p\alpha)}$, should be called the eddy flux of heat does not appear to be an important question. The latter, however, combines the flux of a property recognized as energy with an eddy term recognized as work, and there may be some point in maintaining the distinction between energy and work.

It is well known from observations that changes of potential and thermal energies, and sometimes latent-heat energies, are ten to a hundred times greater than changes of kinetic energy in the atmosphere. This difference in magnitudes evidently is caused by some property of the atmosphere, but the energy equations give no clue to the nature of the property. Neither do the equations give any clue as to which factors are most important in determining changes of kinetic energy. The equations, being in differential form, represent relationships between instantaneous rates, but they tell nothing about the relative magnitudes of the various rates of work, flux, and changes of energy. The solution to the problem lies in conditions that are not reflected in the equations; specifically, it lies in the initial and boundary conditions.

For example, increasing kinetic energy of the mean motion in the air near the surface of the earth may lead, because of perturbations set up by the roughness of the surface, to an increasing value of the eddy transformation function E. This effect, as can be seen from the energy equations, results in a more rapid transformation of the mean kinetic energy into eddy kinetic energy, so that the mean energy may approach a limiting value. But the increasing eddy energy implies greater turbulent fluctuations, hence stronger gradients of the unaveraged motion, and hence an increasing value of the molecular transformation function M_e. As this function increases, the eddy energy is more rapidly transformed into thermal energy. The net results are that the mean and eddy kinetic energies may approach limiting values where energy is supplied by some source to the mean motion and degraded finally to thermal energy.

The energy equations, however, quite clearly do not tell the whole story. Some additional guiding principles are required to permit a complete solution to problems of this kind. Classical thermodynamics has such guiding principles—for example, the second law. There should be more attempts to formulate the necessary principles in studies of atmospheric energy.

ATMOSPHERIC TURBULENCE AND DIFFUSION

By O. G. SUTTON

Military College of Science, Shrivenham, England

THE AERODYNAMICAL BACKGROUND

The Nature of Turbulent Flow. A particle in a stream of fluid can never follow a perfectly smooth path because of minute random disturbances arising from the molecular structure of the fluid (Brownian motion), but observation shows that, in certain circumstances, oscillations appear in the path which are much too large to be ascribed to molecular agitation. Such irregularities must imply the existence of rapid and apparently random fluctuations in the velocity of the stream, constituting a permanent and characteristic feature of this type of flow. Turbulence can hardly be defined in a strict mathematical sense, but is generally understood to imply a motion characterized by a continuous succession of such finite disturbances and in this sense nearly all natural motion, whether of water or of air, is turbulent. Only exceptionally is there found in nature a truly nonturbulent or laminar flow, in which the only random disturbances are the infinitesimal fluctuations due to molecular agitation.

Anemometer records show that in general, and especially in the lower layers of the atmosphere, the wind is highly turbulent, the velocity being a complex of oscillations of duration varying from a fraction of a second to many minutes and of an amplitude which is often a substantial fraction of the average speed. Similar irregular oscillations are shown by direction indicators, so that the speed of the wind changes not only from instant to instant but also from point to point of space. A complete specification of the velocity field over even a limited portion of the atmosphere is in practice unattainable and, to make progress, attention must be concentrated upon mean values and other statistical functions of the velocity. The study of atmospheric turbulence is chiefly concerned with the analysis of the mean distribution of momentum, heat and suspended matter in, and as a result of, this highly complex and rapidly changing field.

Air flow near the surface of the earth, the region in which atmospheric turbulence is of greatest importance, resembles in many respects turbulent motion in long straight pipes or near solid boundaries, as in wind tunnels, and aerodynamics thus affords a natural and convenient starting point for the meteorological problem. The earliest recognition of two distinct types of flow—laminar and turbulent—seems to have been made by Hagen about 1839, but the detailed and systematic study of turbulence undoubtedly opens in 1883 with the famous experiments of Osborne Reynolds [49] on the flow of water through long straight glass tubes. Reynolds, by the simple device of making the flow visible by a thin stream of dye, was able to demonstrate that the transition from an orderly rectilinear motion (laminar flow) in which the thread of dye remains intact from inlet to outlet, to a disorderly or turbulent flow, evinced by the rapid disintegration of the filament of dye, takes place when the Reynolds number $\bar{u}d/\nu$ ($\bar{u}$ = mean speed, d = tube diameter, ν = kinematic viscosity) exceeds a certain value. At the same time other properties of the flow are changed, in particular the distribution of mean velocity across the pipe. In the laminar state the velocity profile is parabolic from the wall to the centre, but in turbulent flow the velocity is almost uniform over a central core, declining sharply to zero in a very thin layer adjacent to the wall itself. Such a change is easily accounted for in general terms. In laminar flow the only intermingling of adjacent layers of fluid is that due to molecular agitation (viscosity, conduction, diffusion), but in turbulent motion the fluid elements, because they follow extremely tortuous paths, transfer momentum, heat and matter freely from one layer to another and thus tend to smooth out local differences in velocity, temperature and concentration of suspended matter. In other words, the principal effect of the turbulence is to cause enhanced *mixing*, and it is this aspect which is of paramount importance in meteorology. Very similar features are found in flow near solid surfaces. When a uniform stream of air meets a solid body, the influence of viscosity is felt only in the immediate vicinity of the surface, in the so-called *boundary layer*, a very shallow region characterized by large velocity gradients. Flow in such layers may be laminar, partly laminar and partly turbulent, or wholly turbulent. In a laminar boundary layer the velocity increases fairly regularly from the wall to the free stream, but in a turbulent boundary layer the velocity profile is much more uniform over the greater part of the layer, decreasing sharply to zero on approaching the wall itself. The effect of the turbulence is to bring down elements of fast-moving air from the free stream to the wall and, conversely, to remove the retarded air at the wall into the free stream so that, except in the immediate vicinity of the surface, the velocity gradient is much reduced compared with that found in laminar flow.

These observations have their counterparts in natural flow near the ground, but here the problem is much complicated by two extremely important differences. Laboratory investigations at low speeds deal almost exclusively with fluids in which marked density differences do not exist and for which the effects of gravity on the flow are negligible. The maintenance of the turbulent state calls for a continuous supply of energy to be used in moving elements of the fluid from one level to another. If the lower layers of the fluid considerably exceed in density those above, the work which has to be done against the gravitational field in lifting masses of

fluid from lower to higher levels must reduce the intensity of the turbulence and may ultimately cause a transition to laminar flow. On the other hand, a fluid in which density increases with height is favourable to the formation of upward currents and therefore to the maintenance and the growth of turbulence. The atmosphere is a fluid whose lower boundary is subjected to strong heating and cooling, especially in clear weather, so that near the ground the turbulence of the wind tends to rise to a maximum in the mid-hours of a sunny day, when there is usually a pronounced superadiabatic lapse rate in the lowest layers, and to diminish or even die away completely during a clear night, when the radiative cooling of the ground creates a marked inversion of temperature gradient in the lowest layers. The gradient of temperature in the vertical is thus to be regarded as a factor exerting a powerful control on the turbulence of the wind. A second difficulty peculiar to meteorology arises from the variable nature of the surface over which the air flows. Provided that the obstacles which cover a surface are not too large and are evenly distributed, aerodynamic investigations have indicated a rational method of allowing for their effects, and the same concepts have been applied with considerable success in many problems of atmospheric motion, but in meteorology cases frequently arise in which the surface irregularities are too large or too unevenly distributed to be treated in this way. This is especially the case, for example, in considering the diffusion of atmospheric pollution in built-up areas.

Mathematical Treatment. It is generally accepted that in any fluid motion the component velocities u, v and w, along axes of x, y and z respectively, satisfy the Navier-Stokes equations, that is, three relations of the type

$$\rho\left(\frac{\partial u}{\partial t}+u\frac{\partial u}{\partial x}+v\frac{\partial u}{\partial y}+w\frac{\partial u}{\partial z}\right) = -\frac{\partial p}{\partial x}+\mu\left(\frac{\partial^2 u}{\partial x^2}+\frac{\partial^2 u}{\partial y^2}+\frac{\partial^2 u}{\partial z^2}\right)+\rho X,$$

where ρ is the density, p is the pressure, μ is the dynamic viscosity and X the x-component of any external force. To these must be added the equation of continuity, which expresses the conservation of mass. Exact solutions of this set of nonlinear equations are known only for certain special cases which have little or no interest for meteorology.

The mean velocities which appear so prominently in studies of turbulence are usually averages over an interval of time (T), that is, they are defined by the relations

$$\bar{u}=\frac{1}{T}\int_{t-\frac{1}{2}T}^{t+\frac{1}{2}T} u\,dt, \qquad \bar{v}=\frac{1}{T}\int_{t-\frac{1}{2}T}^{t+\frac{1}{2}T} v\,dt,$$

$$\bar{w}=\frac{1}{T}\int_{t-\frac{1}{2}T}^{t+\frac{1}{2}T} w\,dt,$$

in which case the fluctuations or eddy velocities u', v' and w' are defined by

$$u=\bar{u}+u', \quad v=\bar{v}+v', \quad w=\bar{w}+w'.$$

If the interval of time T is sufficiently long, it may be asserted that

$$\bar{u}'=\bar{v}'=\bar{w}'=0.$$

The effect of viscosity is to set up in the fluid a system of stresses, namely three normal stresses p_{xx}, p_{yy} and p_{zz} defined by

$$p_{xx}=-p+2\mu\frac{\partial u}{\partial x}, \qquad p_{yy}=-p+2\mu\frac{\partial v}{\partial y},$$

$$p_{zz}=-p+2\mu\frac{\partial w}{\partial z},$$

and three tangential stresses, p_{xy}, p_{yz}, p_{zx} defined by

$$p_{xy}=\mu\left(\frac{\partial u}{\partial y}+\frac{\partial v}{\partial x}\right), \qquad p_{yz}=\mu\left(\frac{\partial v}{\partial z}+\frac{\partial w}{\partial y}\right),$$

$$p_{zx}=\mu\left(\frac{\partial w}{\partial x}+\frac{\partial u}{\partial z}\right).$$

Introducing these stresses into the equations of motion, we have three equations of the type

$$\rho\frac{\partial u}{\partial t}=\frac{\partial}{\partial x}(p_{xx}-\rho u^2)+\frac{\partial}{\partial y}(p_{xy}-\rho uv)+\frac{\partial}{\partial z}(p_{zx}-\rho uw)+\rho X. \tag{1}$$

Putting $u=\bar{u}+u'$, etc., and taking means, we have

$$\rho\frac{\partial \bar{u}}{\partial t}=\frac{\partial}{\partial x}(\bar{p}_{xx}-\rho\bar{u}^2-\rho\overline{u'^2})+\frac{\partial}{\partial y}(\bar{p}_{xy}-\rho\bar{u}\bar{v}-\rho\overline{u'v'})+\frac{\partial}{\partial z}(\bar{p}_{zx}-\rho\bar{u}\bar{w}-\rho\overline{u'w'})+\rho X, \tag{2}$$

and analogous equations for the y- and z-components. The only formal change which has occurred is that in equations (2) certain additional terms, depending upon the eddy velocities, have been added to the original viscous stresses. These additional terms, called the *Reynolds stresses*, are the mathematical expression of the effect of the velocity fluctuations in transporting momentum across a surface in the fluid, just as the original stresses represent the effect of the molecular agitation in transporting momentum by viscosity. In general, the Reynolds stresses are considerably greater than the corresponding viscous stresses, and it is usually possible to ignore the latter in problems of atmospheric turbulence.

No general method has yet been evolved for expressing the Reynolds stresses in terms of the velocity components and their spatial derivatives by exact analysis, and this constitutes the principal difficulty in proceeding further along these lines. The study of a special case, however, suggests semi-empirical methods by which progress can be made despite the formidable difficulties of the complete problem.

Flow Near a Boundary. Consider a steady flow in

which the mean motion has the same direction at all points and in which the turbulence, specified by the mean squares of the oscillations, is uniform in all directions. Such conditions are approached fairly closely in motion very near a plane solid boundary, such as the surface of the earth. In the notation of the previous section, if x be in the direction of mean flow and z distance normal to the surface ($z = 0$),

$$\bar{u} = \bar{u}(z), \quad \bar{v} = \bar{w} = 0.$$

If we introduce the eddy shearing-stress $\tau = -\rho\overline{u'w'}$, the equations of motion reduce to the single equation

$$\frac{\partial \tau}{\partial z} = \frac{\partial \bar{p}}{\partial x},$$

in which molecular terms have been neglected. If the pressure gradient $\partial\bar{p}/\partial x$ is invariable throughout the shallow layer concerned,

$$\tau = \tau_0 + z\,\frac{\partial \bar{p}}{\partial x},$$

where τ_0 is the value of τ as $z \to 0$.

In many aerodynamical problems the pressure gradient is effectively zero, and in micrometeorological applications $\partial\bar{p}/\partial x$ is usually small compared with τ_0/z. For moderate values of z the shearing stress τ may thus be considered invariable with height and equal to the value at the surface, τ_0. This assumption is almost always made in problems of turbulence near the ground. For a more detailed examination of the meteorological problem the reader should consult papers by Ertel [17] and Calder [6], who conclude that in the atmosphere the constancy of τ with height may usually be safely assumed for values of z not exceeding about 25 m. In this special case the transport of momentum across any horizontal plane is effectively measured by the eddy shearing-stress $-\rho\overline{\bar{u}'\bar{w}'}$, that is, by a quantity involving the correlation between the eddy velocities u' and w'. The existence of this correlation expresses the fact that gusts or positive values of u' are more frequently associated with downward-moving air, and lulls (negative u') with upward-moving air, than vice versa.

The form of the profile of mean flow, however, cannot be deduced unless some further hypothesis is introduced. The earliest attempt to frame such a hypothesis appears to have been that of Boussinesq [3] in 1877. There is an obvious analogy between the action of the velocity fluctuations in a turbulent fluid and the motion of the molecules in a gas, which suggests that the effects produced by the turbulence may be ascribed to the movements of discrete masses of fluid, called *eddies*, from one level to another. In the corresponding problem in purely laminar flow the shearing stress is $\mu\,\partial u/\partial z$, which suggests that, on this analogy, the Reynolds stress may be expressed as the product of the gradient of mean velocity and a virtual viscosity, that is,

$$\tau = -\rho\overline{u'w'} = A\,\partial\bar{u}/\partial z = K\rho\,\partial\bar{u}/\partial z. \quad (3)$$

The quantity A, called an interchange coefficient (*Austauschkoeffizient*), corresponds to the dynamic viscosity μ, and the quantity K, called the eddy viscosity, corresponds to the kinematic viscosity ν. It is obvious that the same concept can be applied equally well to the transport by turbulence of heat or suspended matter, by defining in a similar fashion the eddy conductivity and the eddy diffusivity. This simple but powerful concept has had a much greater influence on dynamical meteorology than on other branches of fluid motion. As an initial assumption it is natural to suppose that A and K behave exactly like their molecular counterparts, that is, are true constants and thus independent of position in the field. If this were strictly true, turbulent motion would be simply an enlarged copy of laminar flow, which is far from being the case. This hypothesis is now abandoned, but it should be recognized that in meteorology it has played an invaluable part in bringing to prominence the enormous difference in magnitude between molecular and turbulent transport. The magnitudes usually quoted in meteorological literature for K are 10^3, 10^4 or 10^5 cm^2 sec^{-1}, which should be contrasted with the kinematic viscosity of air, which is of the order of 10^{-1} cm^2 sec^{-1}.

The Mixing-Length Hypothesis. It was soon recognized, especially by workers in aerodynamics, that the eddy viscosity itself was likely to prove too complicated as a starting point for the analysis of turbulent flow. An attempt to improve the treatment without entirely abandoning the analogy with molecular theory was made by Prandtl [44] in 1925. This has proved extremely fruitful although, like many other theories of turbulence, it is semi-empirical, and intuitive rather than analytical.

Measurements of turbulent flow indicate that the virtual stresses set up by the turbulence are approximately proportional to the square of the mean velocity. It is convenient to define an auxiliary reference velocity u_*, known as the friction velocity (*Schubspannungsgeschwindigkeit*) for which this relation is exact, that is,

$$u_*^2 = \tau/\rho = \overline{u'w'}.$$

Thus u_* is a quantity of the same order of magnitude as the eddy velocities (that is, in most meteorological applications u_* is about $\frac{1}{10}$ of the mean speed, the exact value depending on the nature of the terrain). A list of typical values of u_* has been given by Sutton [63]. Prandtl then introduces a characteristic quantity l, called the *mixing length* (*Mischungsweg*), defined by

$$u_* = l\,\partial\bar{u}/\partial z,$$

so that

$$K = u_* l = l^2\,\partial\bar{u}/\partial z.$$

Thus l is a length which resembles, but is very much greater than, the free path of the kinetic theory of gases.[1] It may be interpreted in a general way as the distance which an eddy moves from its point of departure from the mean motion until it mixes again with the

1. Compare $\nu = \frac{1}{3}c\lambda$, where c = molecular velocity, λ = free path.

main body of the fluid. A mass of fluid leaving a layer z in which it has acquired the mean motion $\bar{u}(z)$, and moving a vertical distance l while conserving its momentum, will give rise to the fluctuation

$$\bar{u}(z + l) - \bar{u}(z) \approx l\, \partial\bar{u}/\partial z$$

at the new level. Thus $l\, \partial\bar{u}/\partial z$ may be regarded as representing either an eddy velocity or the friction velocity.

A somewhat different method [22] of introducing a characteristic length is as follows: Suppose that $E(z)$ is any transferable property, such as momentum, temperature or concentration of suspended matter, whose mean value is constant over any (x, y) plane and which is supposed to be conserved during a transfer from the plane $z = z_1$ to $z = z_2$. The mean rate at which $E(z)$ is transported across a unit area of an (x, y) plane is

$$q = -\overline{w'[E(z_2) - E(z_1)]} \approx -\overline{w'(z_2 - z_1)}\, \partial\bar{E}/\partial z.$$

If a length l be defined such that

$$l\sqrt{\overline{w'^2}} = \overline{w'(z_2 - z_1)},$$

the rate of transfer is

$$q = -l\sqrt{\overline{w'^2}}\, \partial\bar{E}/\partial z.$$

Applying this to the transfer of momentum, in which $E = \rho u$ and $q = -\tau$, we have

$$\tau = \rho l\sqrt{\overline{w'^2}}\, \partial\bar{u}/\partial z,$$

and so

$$K = l\sqrt{\overline{w'^2}}.$$

The advantages to be gained by such dissections are not immediately obvious, since the analysis gives no clue to possible variations of l with any of the variables. In practice, the introduction of the mixing length has proved very useful, since it has been found that only very simple assumptions regarding l are required to obtain a satisfactory mathematical representation of many complex phenomena. It is doubtful if it is possible to assign a definite physical meaning to the mixing length, but broadly it is clear that l is a measure of the average "size" of the eddies responsible for the mixing, or equally, a rough indication of the average depth of the layers over which mixing takes place.

Velocity Profile Near a Boundary. When a turbulent stream flows over a smooth surface, three regions of motion can be distinguished:

1. A shallow zone of laminar flow immediately adjacent to the wall in which the shearing stress is chiefly due to viscosity ("laminar sub-layer").
2. The turbulent boundary layer proper, lying above the laminar sub-layer, in which the Reynolds stress is at least as important as the viscous stress.
3. The main body of the turbulent fluid, lying above the boundary layers, in which viscosity plays a negligible part.

A surface whose irregularities are large enough to prevent the formation of a laminar sub-layer is said to be "aerodynamically rough."

Smooth Surface. We consider again motion in a shallow layer in which τ (and hence u_*) is invariable with height and in which the mean velocity $(\bar{u})$ is a function of z only. If the velocity profile be assumed to depend only upon l, ν, u_* and the independent variable z, it follows that the dimensionless ratio $\bar{u}/u_*$ must be expressible as a function of l/z and u_*z/ν, since these are the only nondimensional ratios which can be formed from these variables. If, in addition, the scale of the mixing is assumed to be proportional to distance from the boundary, that is, $l = kz$, where k is a pure number (Kármán's constant), the definitions of u_* and of τ lead to the first-order differential equation,

$$\frac{d\bar{u}}{dz} = \frac{u_*}{l} = \frac{u_*}{kz},$$

whence

$$\frac{\bar{u}}{u_*} = \frac{1}{k} \ln\left(\frac{u_*z}{\nu}\right) + \text{const}, \tag{4}$$

where the "constant" is to be determined by a suitable boundary condition. The usual requirement that $\bar{u} = 0$ on $z = 0$ cannot be satisfied, but Nikuradse has shown that equation (4) agrees closely with observations made on flow in smooth pipes in the form,

$$\frac{\bar{u}}{u_*} = \frac{1}{0.4} \ln\left(\frac{u_*z}{\nu}\right) + 5.5 \approx 2.5 \ln\left(\frac{9u_*z}{\nu}\right), \tag{5}$$

that is, $k = 0.4$ and the velocity vanishes on the plane $z = \nu/9u_*$, the equation having no meaning for smaller values of z.

Rough Surface. It is a well-established experimental fact that in the case of an aerodynamically rough surface, the influence of viscosity is negligible, in which case the solution of equation (3) may be written

$$\frac{\bar{u}}{u_*} = \frac{1}{k} \ln\frac{z}{z_0}, \tag{6}$$

where z_0 is another constant of integration. This form of the equation implies that $\bar{u} = 0$ on $z = z_0$ (the equation having no meaning for smaller values of z), so that z_0, usually termed the *roughness length*, is a quantity which may be regarded as specifying, in some manner, the effect of the irregularity of the surface on the mean flow. This is borne out by the fact that, for pipes whose interior surface is uniformly roughened with fine grains of sand, it has been found that a definite relation exists between the roughness length and the size of the irregularities ($z_0 \approx \frac{1}{30}$ of the average diameter of the grains). Schlichting [56] has gone further and has shown that a surface may be regarded as smooth if $u_*z_0/\nu < 0.13$ and fully rough if $u_*z_0/\nu > 2.5$.

The analysis above appears to be adequate if the layer concerned is very shallow, but since it implies that the effect of the irregularities is equally felt at all distances above the surface it cannot be applied, without care, to the deeper layers met with in most meteorological applications. An alternative treatment of the rough-surface problem, due to Rossby and Mont-

gomery [55], appears to be more appropriate for such cases. Rossby and Montgomery assume that

$$l = k(z + z_0),$$

which expresses the intuitive conception that the effects of the irregularities are most strongly felt in the immediate vicinity of the surface and hardly at all at the greater heights. Equation (3), with this form for l, yields

$$\frac{\bar{u}}{u_*} = \frac{1}{k} \ln \left(\frac{z + z_0}{z_0} \right), \tag{7}$$

using the boundary condition $\bar{u} = 0$ on $z = 0$. Thus theoretically, the profile of mean velocity over a rough surface is fully determined provided both u_* and z_0 are known (k being regarded as a universal constant). These may be combined to form the quantity termed by Sutton [63, 65] the *macroviscosity*, defined by $N = u_* z_0$. The introduction of this quantity enables a single profile, applicable to both smooth and rough surfaces, to be obtained, thus overcoming the difficulty felt in the free use of equations (6) and (7), that neither of these tends to the smooth-surface form (5) as $z_0 \to 0$. The generalized profile is

$$\frac{\bar{u}}{u_*} = \frac{1}{k} \ln \left(\frac{u_* z}{N + \nu/9} \right),$$

corresponding to $l = kz$, or

$$\frac{\bar{u}}{u_*} = \frac{1}{k} \ln \left(\frac{u_* z + N}{N + \nu/9} \right)$$

if $l = k(z + z_0)$. As z_0 (and hence N) tends to zero these equations tend to the smooth-surface form, but in most meteorological applications N is of the order of 10 to 10^3 cm^2 sec^{-1} and is thus much greater than ν. Schlichting's criteria may be written

$$\text{smooth flow: } N < 0.13\nu \approx 0.02 \text{ cm}^2 \text{ sec}^{-1},$$

$$\text{rough flow: } N > 2.5\nu \approx 0.4 \text{ cm}^2 \text{ sec}^{-1}.$$

Power-Law Profiles. A somewhat less satisfactory representation of the flow near a boundary is obtained by the use of power laws, but this type of profile is often much easier to handle mathematically than the logarithmic profile. The usual form of the profile near a smooth surface is

$$\bar{u} = \bar{u}_1 (z/z_1)^p, \tag{8}$$

where $\bar{u}_1$ is the mean wind speed at height z_1 and p is a positive number whose value for moderate Reynolds numbers is about $\frac{1}{7}$. If $\tau/\rho = K \, \partial\bar{u}/\partial z$ is invariable with height, it follows that

$$K = K_1 (z/z_1)^{1-p}, \tag{9}$$

where K_1 is the value of K at $z = z_1$. Equations (8) and (9) constitute the so-called "conjugate power-laws" of Schmidt.

The Vorticity-Transport Hypothesis. The preceding analysis is based essentially upon the hypothesis that momentum is conserved during the motion of an eddy, and for this reason the Prandtl treatment is often referred to as the "momentum-transport theory." From the aspect of exact hydrodynamical theory this hypothesis is questionable, since it involves the assumption that the pressure fluctuations do not affect the transfer of momentum. An alternative hypothesis, in many ways more attractive, is that *vorticity* is conserved and this forms the basis of Taylor's treatment of the problem [72]. Space does not allow an adequate discussion of the matter here, nor, in the present state of development of the theory of atmospheric turbulence, are the differences between the two theories of major importance for meteorology, except perhaps in one respect. According to the momentum transport theory, the rate at which momentum is communicated to unit volume of the fluid by turbulence is

$$\frac{\partial \tau}{\partial z} = \rho \frac{\partial}{\partial z} \left\{ K(z) \frac{\partial \bar{u}}{\partial z} \right\},$$

whereas on the vorticity transport theory,

$$\frac{\partial \tau}{\partial z} = \rho K(z) \frac{\partial^2 \bar{u}}{\partial z^2}.$$

These two forms are equivalent if, and only if, $K(z) =$ constant. For further details the reader is referred to Taylor's original papers, or to the accounts given by Brunt [4] and Goldstein [22]; the latter gives considerable detail as regards tests on the laboratory scale. An illuminating discussion, chiefly from the standpoint of the experimental worker, of the validity of the various hypotheses which have been advanced in the last two or three decades in order to develop further the Reynolds theory of stresses has been given by Dryden [14]. When the predictions of the various theories are compared with the results of accurate measurements made in turbulent boundary layers, the disquieting conclusion is reached that all such theories fail at some point or other. Considerable doubt is now thrown on the validity of the mixing-length idea and even on the fundamental hypothesis that the eddy velocities and the turbulent shear-stresses are directly related to the mean velocity and its derivatives at a point (equations (3) above). These considerations may perhaps indicate that one fruitful period of development in the theory of turbulence is drawing to its close, and that the time is now ripe for advances along quite different lines.

Statistical Theories of Turbulence. One such fundamentally different approach to the general problem is that of the so-called "statistical" theory of turbulence, initiated by Taylor [73] in 1920 and later expanded by him in a remarkable series of papers in 1935 [74]. Subsequent developments were made by Kármán and Howarth [32] and an account of the position reached by 1943 has been given by Dryden [15].

All theories of turbulence are necessarily statistical in some sense or other, but whereas the theories described in the first part of this article start with a measured distribution of mean velocity and mean pressure and relate these to the virtual stresses, the methods about to be described originate in the statistical properties of the fluctuations and seek to establish exact

relations between these properties and the mean motion. The two approaches have their counterparts in molecular theory, one being analogous to the kinetic theory of the elastic sphere models while the other has certain affinities to the statistical mechanics of an assembly of molecules.

In his initial (1920) contribution Taylor considered what statistical properties of a fluctuating field of flow are required to determine the diffusion of a group of particles suspended in the medium. If the turbulence is statistically uniform and steady ($\overline{u'^2}$ independent of locality and time), the spread of a cluster of particles over a plane is given by

$$\overline{X^2} = 2\overline{u'^2} \int_0^T \int_0^t R(\xi)\, d\xi\, dt,$$

where X is the distance travelled by a particle in time T and $R(\xi)$ is the correlation coefficient between the fluctuating velocities which affect a particle at times t and $t + \xi$. Taylor's theorem means, in effect, that a knowledge of the mean eddying energy and of the correlation $R(\xi)$ specifies completely the diffusion in such a field. The application of this result to meteorological problems is considered later. The analysis also indicates a length l_1, analogous to the mixing length but independent of any model, defined by

$$l_1 = \sqrt{\overline{u'^2}} \int_0^\infty R(\xi)\, d\xi,$$

which is finite if $R(\xi)$ tends to zero in a suitable manner as $\xi \to \infty$.

Another way of representing such a field utilises the correlation $R(y)$ between velocities at points separated by a variable distance y. The length L defined by

$$L = \int_0^\infty R(y)\, dy$$

is called the "scale of the turbulence" and may be regarded as a measure of the average size of the eddies which constitute the pattern of flow. Evidence presented later suggests that in meteorological problems L has no effective upper bound or, in other words, that in atmospheric diffusion, account must be taken of eddies ranging from the minute convectional whorl to full-size disturbances which affect the general circulation of the atmosphere.

In later development of this theory attention has been particularly concentrated upon the problem of the decay of disturbances (*e.g.*, downstream of a grid in a pipe), especially in isotropic turbulence, for which Taylor has introduced another important length λ called the "microscale of turbulence" and defined by

$$1/\lambda^2 = \lim_{y \to 0} \left\{ \frac{1 - R(y)}{y^2} \right\}.$$

The microscale of turbulence indicates the average size of the small eddies which are responsible for the greater part of the dissipation of energy, and is also related to the curvature of the $R(y)$ curve at the origin.

Later Developments; Kolmogoroff's Theory. The most striking advances in the statistical theory of turbulence since 1941 are due to Kolmogoroff [34], Onsager [37], Weizsäcker [79], and Heisenberg [25]. These theories have many points of resemblance, and the most promising appears to be that advanced by Kolmogoroff, whose work has been well summarized in English by Batchelor [1].

Kolmogoroff's basic conception is that, at very high Reynolds numbers, all turbulent motion has the same sort of small-scale structure, although the mean flow may differ widely from situation to situation, and that the motion caused by the small eddies is isotropic and statistically uniform. A turbulent flow may be thought of as giving rise to a spectrum of oscillations whose wave lengths vary in scale from those characteristic of the mean flow to a lower limit below which the motion is entirely laminar. Within this spectrum, energy is continually being transferred from one length scale to another by the generation, from any given band of oscillations, of a set of smaller oscillations, and so on, until it is no longer possible to form smaller eddies. Thus the process may be thought of as one in which energy from the mean motion is fed into the long-wave end of the spectrum by the largest eddies and passed down the spectrum in the direction of decreasing wave length, until ultimately it is absorbed into the random heat motion of the molecules by viscosity. Kolmogoroff then puts forward two similarity hypotheses: (1) that the statistical characteristics can depend only on the mean energy dissipation per unit mass of fluid (ϵ) and on viscosity; (2) that the statistical characteristics of the motion due to the larger eddies are independent of viscosity and depend only upon the energy dissipation ϵ. From these plausible hypotheses it is possible, by arguments chiefly of a dimensional character, to make certain definite predictions about the properties of the mean flow, and in particular, to show that as the Reynolds number increases without limit, the coefficient of correlation between fluctuations at points distance y apart tends to the form $1 - Ay^{2/3}$ (A = constant), provided that y is small compared with the scale of the turbulence. Wind-tunnel measurements so far have provided excellent confirmation of deductions made from Kolmogoroff's hypotheses and there is little doubt that the theory constitutes a powerful tool for the resolution of many complex problems, and one which should especially appeal to meteorologists because of the emphasis laid upon the passage of energy from disturbances of one size to another. An account of this and other theories, together with some promising new developments, has recently been given by Kármán [31], who considers that the principal aim of the present period is to find the laws which govern the shapes of either the correlation or the spectrum functions.

We now pass from these theoretical and laboratory studies to detailed consideration of the meteorological problem.

PHYSICAL FEATURES OF ATMOSPHERIC TURBULENCE

Experimental investigations into atmospheric turbulence may be conveniently divided into: (1) those dealing with localized effects, usually in shallow layers near the ground, in which the consequences of the earth's rotation may be disregarded; (2) those relating to larger-scale processes, usually in the so-called "friction layer" or "planetary boundary-layer" (Lettau), extending from the surface to the level at which the geostrophic velocity is attained (*c.* 500 m); and (3) those concerned with the atmosphere as a whole.

The Temperature Field. The most direct manifestation of atmospheric turbulence is the presence of fluctuations in the wind, but in view of the controlling influence of temperature gradient, it is convenient to begin by discussing the temperature field near the ground. Accurate continuous observations of temperature differences between various heights extending from 2.5 cm to 87.7 m have been tabulated and analysed for southern England by Johnson [28], Best [2], Johnson and Heywood [30], and by Flower [19] for Ismailia, Egypt, while Ramdas [48] has given mean values of air temperature at various levels from 2.5 cm to 10.6 m at maximum- and minimum-temperature epochs at Poona, India. From these investigations there emerges the now familiar picture of the temperature field in the lowest 100 m. In clear weather there is a well-marked diurnal variation of temperature gradient, with superadiabatic lapse rates during the hours of daylight and pronounced inversions at night. With overcast skies, and especially with strong winds, the gradient remains close to the adiabatic lapse rate both day and night.

The gradient of temperature near the ground is subject to such large variations with locality and season, time of day and height above the surface that it would be misleading to attempt to give representative values here. Very large gradients, as high as thousands of times the adiabatic lapse rate, are a persistent feature of the temperature field in the first few centimetres above the ground, especially in summer, but the sharp curvature in the temperature-height curve is confined to the first few metres. Sheppard [60] states that on the average the daytime fall of temperature is roughly proportional to the logarithm of the height, but more detailed investigations by Deacon [12] indicate that, in general, the gradient of temperature is inversely proportional to a power of the height over the first 17 m, the index being greater than unity during lapse conditions and less than unity in inversions.

In warm weather the temperature of the air near the ground shows rapid fluctuations of considerable amplitude, as much as several degrees centigrade. Schmidt [58] gives observations by Robitzsch which show that these oscillations have a well-marked diurnal variation in phase with the temperature gradient, the fluctuations tending to die away as the lapse rate approaches the adiabatic value. Sutton [64], from an examination of records obtained in clear warm weather, has found that in these conditions the oscillations decrease as $z^{-0.4}$ over the range 7 m $\leqq z \leqq$ 45 m, but this is an isolated result and a complete picture of the variation with height does not exist at present. During the inversion period the gradient shows large long-period fluctuations unlike those met with in daytime.

There is much less information concerning temperature gradients over the ocean, but data have been given by Wüst [80], Johnson [29], Montgomery [35], Craig [10], Emmons [16], and Sverdrup [71]. Because of the relatively small effects of insolation and long-wave radiation on the sea, the gradients are much less than those found over land and diurnal effects are hardly noticeable, except in shallow landlocked waters.

The exploration of the mean temperature field near the ground is thus virtually complete except in one important respect. It has now become clear that radiation, especially in the longer wave lengths, is quite as important as convection in the problem of heat transfer, and systematic simultaneous records of both temperature gradient and radiative flux are needed to complete the picture of the thermal structure of the lower atmosphere.

The Velocity Field. Following the lead given by the theory of the turbulent boundary layer in aerodynamics, it has now been shown conclusively by many workers that the profile of mean velocity near the ground in conditions of small temperature gradient is adequately represented by a logarithmic law (*e.g.*, of the type proposed by Rossby and Montgomery, equation (7)), provided that the vegetation cover is not too high. For profiles measured above long grass it is necessary to use an empirical modification of the equation, namely

$$\frac{\bar{u}}{u_*} = \frac{1}{k} \ln\left(\frac{z-d}{z_0}\right) \qquad (z \geqq z_0 + d),$$

where d is a zero-plane displacement, of the order of the depth of the layer of air trapped among the plants. Model has used the same equation for the wind profile over the sea.

The most significant feature of the work referred to above is that which emerges from the detailed investigations of Sheppard [61], Paeschke [38], Deacon [12] and others. In conditions of small temperature gradient, air flow near the ground is identical with that observed in the turbulent boundary layer of a fully rough surface in the laboratory, despite the great differences in scale. Sheppard has shown that the Kármán constant k has much the same value as in wind-tunnel work, while Deacon has provided good evidence that the aerodynamical theory of the roughness length is equally appropriate for natural surfaces.

The real difficulties and complexities of the meteorological problem begin to appear when the temperature gradient differs from the adiabatic lapse rate. The general high level of turbulence during the superadiabatic lapse-rate period promotes a free exchange of momentum between higher and lower levels, while the reverse holds during inversions. Thus, in general, the velocity gradient exhibits a diurnal variation, being small in daytime and large at night, but this is not all. Thornthwaite and Kaser [78] and, more recently, Deacon [12] have shown that for nonadiabatic gradients

the $\bar{u}$, ln z plots are no longer linear, but are convex to the $\bar{u}$-axis in the lapse period and concave to the same axis in the inversion period. Deacon concludes that, in all conditions,

$$d\bar{u}/dz = az^{-\beta} \qquad (z \leqq 13 \text{ m})$$

(a independent of z), with $\beta > 1$ for superadiabatic gradients, $\beta = 1$ for the adiabatic lapse rate and $\beta < 1$ for inversions. Thus the logarithmic profile is valid only for adiabatic gradients, and for other conditions Deacon proposes the profile

$$\frac{\bar{u}}{u_*} = \frac{1}{k(1-\beta)}\left[\left(\frac{z}{z_0}\right)^{1-\beta} - 1\right] \qquad (z \geqq z_0),$$

where z_0, as usual, is the roughness length.

For many applications, and particularly those dealing with diffusion, the logarithmic profile makes the relevant differential equations difficult to handle, and in such problems a simple power law, $\bar{u} = \bar{u}_1(z/z_1)^p$, is usually employed as an approximation. This is fairly satisfactory except near a rough surface, where a modification has to be introduced to allow for the effect of the irregularities (*v.* Calder [7] and Sutton [65]). When a law of this type is adopted the effect of temperature gradient is shown by variations in the index p. Values of p ranging from 0.01 (large lapse rate) to 0.77 (large inversion) have been given (Brunt [4], Frost [20]), and it is generally accepted that the value $p = 1/7$ is appropriate for small gradients, except very near the ground or over very high vegetation. For conditions very near the ground ($z < 2$ m), the evidence shows that the logarithmic profile can be assumed without serious error for all except the largest gradients by allowing the roughness length and the Kármán constant to vary with temperature gradient, but if deeper layers are involved, the departure of the velocity profile from the logarithmic form must be taken into account.

The profile of mean velocity near the surface has now been thoroughly explored, but the same cannot be said about the eddy velocities. One of the great difficulties in dealing with atmospheric turbulence compared with that found in wind tunnels is that the natural wind is made up of fluctuations of widely different periods, and the interval of measurement and the response characteristics of the anemometer must always be taken into account, particularly in problems of diffusion. The most reliable data on the velocity fluctuations relate to what Scrase [59] has called "intermediate-scale turbulence," mean values over intervals of the order of a few minutes. It was early demonstrated by Taylor and later confirmed by Scrase [59] and Best [2] that such turbulence is anisotropic near the ground, with the cross-wind component about 50 per cent greater than either the downwind or vertical component at about 2 m over downland in conditions of small lapse rate. Best [2] has given a reasonably complete picture of the behaviour of the three components near the ground by making use of the bi-directional vane, and he concludes that the anisotropy is likely to be negligible at heights greater than about 25 m.

As would be expected, the eddy velocities obey the Maxwell law of frequency distribution, and Best has given the precise formula. Best also examined the variation of the fluctuations with height and found that both the lateral and vertical components increase slowly from 25 cm to 5 m and presumably begin to decrease at higher levels. For winds blowing over the sea there is still less information, but all three components of gustiness are much reduced compared with those over land, probably to about one half.

At the present time, much remains to be learnt concerning the structure of turbulence near the ground. While it is known that the amplitude of the oscillations shows a continuous decrease as the temperature gradient changes from lapse to inversion, it is impossible to quote reliable laws, even empirical, which express this fact quantitatively. There is very little information on the distribution of energy among the fluctuations; Brunt [4] has deduced from the work of Scrase that near the ground and in conditions of small lapse rate most of the eddying energy is associated with oscillations of periods less than five seconds, but a complete picture of the eddy spectrum is not yet available.

The Humidity Field. Investigations into the propagation of high-frequency electromagnetic waves over the surface of the earth have directed attention to the study of water-vapour gradient in the atmosphere, and fairly detailed accounts have been given by Sheppard [60] and Burrows and Attwood [5]. In the daytime, vapour pressure in the lower layers decreases with height even over ground which appears dry, but during the inversion period the gradient may change sign (vapour pressure increasing with height), often with the formation of dew. Sheppard concludes that in the main the vapour-pressure profile conforms fairly closely to a logarithmic law up to 100 m at least, and that there is no marked diurnal variation. Information concerning the distribution of water vapour over the sea is to be found in the papers by Craig, Emmons and Sverdrup cited above.

The Transference of Momentum, Heat and Water-Vapour in the Vertical. In Reynolds theory the transport of momentum by turbulence across a horizontal plane is expressed by the eddy shearing stress $\tau = -\rho\overline{u'w'}$, if the molecular term is disregarded. In the surface layers, it is customary to assume that τ is virtually independent of height and therefore equal to its value at the surface, τ_0. The frictional effect of the ground may also be expressed by means of the skin-friction coefficient C_D by writing

$$\tau_0 = \tfrac{1}{2}C_D\rho\bar{u}^2,$$

where $\bar{u}$ is the mean velocity at some fixed height.

Laboratory investigations show that the skin-friction coefficient of a fully rough surface is virtually independent of the viscosity of the fluid, and in these small-scale experiments C_D usually varies between 10^{-3} and 10^{-2}. Taylor [75], by measuring the approach to the gradient wind in the friction layer from pilot-balloon observations, found C_D for downland to be about 5×10^{-3}, and very similar values were found by Sutcliffe [62], using a somewhat different method.

Hence there is no essential difference between laboratory and open-air results as regards the magnitude of the skin friction.

Direct observations of the eddy shearing stress are few. Sheppard [61] measured τ_0 by observing the deflection of a small plate floating on oil in a streamlined wooden surround placed at the centre of a large concrete surface. For this unusually smooth terrain he found C_D to be about 2×10^{-3} in conditions of small lapse rate. A table of values of C_D, based chiefly on data given by Sheppard and Deacon, has been published by Sutton [63]. The range is from $C_D = 2 \times 10^{-3}$ for a very smooth surface to $C_D = 4 \times 10^{-2}$ for a field of fully grown root crops.

Scrase [59] determined the Reynolds stress at two levels by the direct evaluation of $-\rho\overline{u'w'}$ from ciné records of the motions of light vanes over downland and found, disconcertingly, a fourfold increase of τ with height over the interval 1.5 m–19 m in conditions of small temperature gradient. Thus the only direct observation yet made of the Reynolds stress in the atmosphere does not support the theoretical deduction of invariability with height, and the discrepancy has still to be explained.

Some data relating to superadiabatic lapse rate and inversion conditions have been given by Sheppard [61], who shows that if the Kármán constant k in the logarithmic profile be allowed to vary with temperature gradient, C_D may be regarded as approximately constant for any given terrain. Since it is now clear that the logarithmic law can hold only for gradients near the adiabatic lapse rate, this conclusion loses some of its force. A complete investigation of the drag of the surface or of the transfer of momentum in large temperature gradients has not yet been made.

In the analogous problem of heat flux, the situation is complicated by influences not directly due to turbulence. The balance of heat exchange near the ground involves short-wave radiation (direct, diffuse and reflected), long-wave radiation from the ground and the atmosphere, heat absorbed by the soil and vegetation and by evaporation from the ground or released by the formation of dew, and finally the flux associated with turbulence, that is, by convection, either natural or forced. It is not yet possible to give representative values for all these components, but a recent contribution by Pasquill [39], giving very complete data for a few selected occasions, makes it clear that the flow of heat caused by outgoing long-wave radiation can be as large as, or even greater than, the turbulent flux.

In conditions of calm warm weather Sutton [64], using data for southern England, has shown that in the hours around noon the net upward flux of heat (q) in the lowest 100 m is expressed by

$$q = 3 \times 10^{-3} - 5.4 \times 10^{-8} z \qquad (\text{g cal cm}^{-2} \text{ sec}^{-1}),$$

where the height z is measured in centimetres. This means that near the ground the heat flux, like the eddy shear-stress, is invariable with height during the hottest part of the day, the average value being about 3×10^{-3} g cal cm^{-2} sec^{-1}. A very similar estimate has been made by Priestley and Swinbank [47] from different data, and the figure is also supported by Pasquill's measurements [39], while Sutton [64] has pointed out that the estimate agrees with laboratory data on the loss of heat by natural convection from a small horizontal plate maintained at a constant temperature.

The upward flux of water vapour is the rate of evaporation from the surface, and will be dealt with at greater length in the discussion of small-scale diffusion processes.

To summarize generally what has been achieved in the determination of the physical features of atmospheric turbulence, it may be said that as regards mean properties, the picture is reasonably complete. The outstanding need at present is for a systematic investigation of the fluctuations themselves, and especially the distribution of energy among the various wave lengths, and the correlations between fluctuations in different planes or of different entities. Recent developments in electronic methods should enable many of these problems to be solved.

ANALYSIS OF LARGE-SCALE PROCESSES

The initial successes of the theory of atmospheric turbulence came in the pioneer work of Taylor, Ekman, Schmidt and Richardson on large-scale phenomena such as the approach of the wind in the friction layer to the geostrophic velocity, the propagation of the diurnal wave of temperature from the surface, and the large-scale diffusion of water vapour and pollution. These are the "classical" problems of atmospheric turbulence; they are usually dealt with at length in textbooks of dynamical meteorology and for this reason only a brief account will be given here.

If we consider first the slowing down of the free-stream (geostrophic) velocity by the friction of the earth, the effect of turbulence on the transport of momentum may be expressed quite generally by the introduction of virtual stresses τ_{xz} and τ_{yz}. If $\bar{u}$ and $\bar{v}$ are the components of the mean velocity, assumed horizontal, along axes pointing east and north respectively, equations (2), neglecting any change of pressure gradient with height, become

$$\frac{\partial \bar{u}}{\partial t} - 2\omega\bar{v} \sin\phi = -\frac{1}{\rho}\frac{\partial p}{\partial x} + \frac{1}{\rho}\frac{\partial \tau_{xz}}{\partial z},$$

$$\frac{\partial \bar{v}}{\partial t} + 2\omega\bar{u} \sin\phi = -\frac{1}{\rho}\frac{\partial p}{\partial y} + \frac{1}{\rho}\frac{\partial \tau_{yz}}{\partial z}.$$

The terms involving $\omega \sin\phi$ (ω= angular velocity of earth, ϕ = latitude) are the Coriolis accelerations.

The component eddy stresses τ_{xz} and τ_{yz} must vanish or become small at the top of the friction layer, but apart from this there is no a priori knowledge of their behaviour, and the equations can be solved only when some additional information is deduced or postulated concerning these stresses. An obvious first step is to adopt the analogy with molecular theory by expressing the shear stresses as the product of a constant virtual viscosity and the velocity gradient. The solution obtained in this way is usually displayed as the familiar

"Ekman spiral," a graph of $\bar{u}$ against $\bar{v}$ with the geostrophic velocity as the limit point.

Although the assumption of a constant eddy viscosity (K) or exchange coefficient ($A = K\rho$) can be no more than a crude first approximation, the Ekman spiral undoubtedly gives a picture of the approach to the geostrophic wind which is easily grasped and which, except near the surface, does not depart too far from the truth. The most striking feature of this early work is that the concept of eddy viscosity implies values of K at least ten-thousand or a hundred-thousand times greater than the kinematic viscosity of air.

In the corresponding problem of the transport of heat by eddies, the assumption of a constant eddy conductivity leads to the familiar equation

$$\frac{\partial T}{\partial t} = K \frac{\partial^2 T}{\partial z^2},$$

where T is absolute temperature (Brunt [4]). If the diurnal variation of surface temperature be given by

$$T = T_0 + B \sin qt,$$

the solution which expresses the progress of the diurnal wave upwards is

$$T = T_0 + Be^{-bz} \sin (qt - bz), \qquad (10)$$

where $b = \sqrt{q/2K}$. This solution has been used by Schmidt and Taylor for the analysis of the Eiffel Tower observations and by Johnson [28], Best [2], and Johnson and Heywood [30] in a very detailed examination of the temperature field up to 100 m above the surface. These early researches indicated values of K, the eddy conductivity, of the same order of magnitude as those found for the eddy viscosity.

Finally, if $\bar{\chi}$ represents the mean concentration or mass per unit volume of some easily identified constituent of the atmosphere, such as water vapour, smoke or dust, the assumption of a constant eddy diffusivity leads to Fick's equation

$$\frac{D\bar{\chi}}{Dt} = K\nabla^2\bar{\chi},$$

where D denotes "differentiation following the motion" and ∇^2 is the Laplace operator. For moderate distances of travel, say not exceeding a few hundred metres, the values obtained for the eddy diffusivity are of the same order of magnitude as those found for the turbulent transport of momentum and heat.

The picture of eddy diffusion given by this early work is consistent and convincing—the atmosphere behaves like a gas of greatly enhanced viscosity, conductivity and diffusivity, and the analogy is reinforced by the fact that all three coefficients appear to have much the same order of magnitude. Detailed examination of the results, however, reveal discrepancies which are far too serious to be ignored or ascribed to errors of measurement. Best [2] and Johnson and Heywood [30], by applying the solution (10) to a succession of shallow layers, showed that to explain the observations the "constant" eddy conductivity must be made to increase rapidly with height, especially in clear summer weather. The solution (10) indicates that the phase of the diurnal wave should change linearly with height, whereas Best found that in reality the change of phase with height is relatively slow, being approximately as the one-fifth root of the height. Cowling and White [9] made a searching analysis of the Leafield temperature results and concluded that the eddy conductivity must vary with height and have a diurnal variation, and they found additional support for a conclusion reached by Chapman in 1925 that the temperature field near the surface cannot be explained on the basis of eddy conduction alone, and that some other factor (possibly radiation) must play an important part. Richardson [52] obtained equally striking results in a series of notable researches on the large-scale diffusion of matter. If the eddy diffusivity were truly constant, the scatter of matter originally concentrated at a point would follow the law deduced by Einstein for Brownian motion, namely

$$\sigma^2 = 2Kt,$$

where σ is the standard deviation of the distances travelled by the particles in time t. By applying this equation to processes ranging from the drift of thistledown over a few metres to the scatter of free balloons and volcanic dust over many kilometres, Richardson demonstrated that K in this equation must increase indefinitely with the distance travelled, values as high as 10^8 cm^2 sec^{-1} being found for the longer distances.

The recognition of the fact that the mixing processes of the atmosphere cannot be regarded as a kind of enlarged version of molecular diffusion marks the beginning of the modern phase of the theory of atmospheric turbulence. Obviously, if the concepts of eddy viscosity, conductivity and diffusivity are to be retained, it is no longer possible to regard these coefficients as independent of position in the field, but the next step in the development of the theory is by no means obvious. To fix ideas, consider the relatively simple problem of the diffusion of smoke from a continuous source at ground level, a matter of importance in the military problem of the screening of targets and for which the experimental results are known to a high degree of accuracy for conditions of small temperature gradient and moderate distances of travel (Sutton [67]). The solution of Fick's equation for a steady continuous point source is

$$\bar{\chi}(x, y, z) = \frac{Q}{4\pi Kr} \exp\left\{-\bar{u}\frac{(y^2 + z^2)}{4Kr}\right\},$$

where $r = \sqrt{x^2 + y^2 + z^2}$ is the distance from the source Q; x, y and z are measured downwind, across wind and vertically; and $\bar{u}$ is the constant mean wind (Roberts [54]). Thus the concentration of smoke on the axis of the cloud ($y = z = 0$) should decrease inversely as $1/x$, but the measurements show that the actual decrease is as $1/x^{1.76}$ in conditions of small temperature gradient. Hence K must be made to increase with distance from the source if the measured concen-

trations are to be made to agree with the mathematical solution. There are obvious difficulties in ascribing physical reality to a quantity whose value depends on the distance of the sampling point from an arbitrary point in space and any variation in K must be regarded, more rationally, as an expression of the fact that (as Richardson puts it) in a turbulent fluid the average rate of separation of a pair of marked particles is a function of their distance apart, a type of diffusion quite unlike that contemplated in the kinetic theory of gases. In particular, it does not seem possible to assign any upper limit to the "size" of eddy which can take part in atmospheric diffusion, and there is no definite "scale" of atmospheric turbulence.

The most natural and acceptable form of variation of K is to allow the coefficient to increase with the depth of the layer under consideration. The mathematical technique required for the solution of diffusion problems is considerably simplified if the interchange coefficients are assumed to vary as a simple power of the height. The problem of the approach of the wind in the friction layer to the geostrophic velocity has been dealt with very thoroughly by Köhler [33] for the case $K \propto z^m$, $m \geqq 0$. The solution involves Bessel functions and the results show a fair measure of agreement with observation. Rossby and Montgomery have also discussed the same problem by making the reasonable assumption that the mixing length (and hence the eddy viscosity) first increases linearly with height in a relatively shallow surface layer (thickness about 100 m) and then decreases slowly so as to allow a small "residual turbulence" at the top of the friction layer.

In the problem of heat transfer Brunt [4], following the lines of Taylor's early work, has shown that if T be the absolute temperature of the air at height z, the equation of eddy conduction is

$$\rho \frac{\partial T}{\partial t} = \frac{\partial}{\partial z}\left\{K\rho\left(\frac{\partial T}{\partial z} + \Gamma\right)\right\},$$

where Γ is the adiabatic lapse rate. This implies that the net turbulent flux of heat across a horizontal surface is proportional to the difference between the existing lapse rate and the dry-adiabatic lapse rate, so that in a stable atmosphere, the flow of heat due to eddy motion is downwards, and the ultimate effect of mixing is to produce an atmosphere with constant lapse rate equal to the adiabatic value. This equation and the conclusions drawn from it have been the subject of much discussion in recent years, but this aspect will be dealt with at greater length in the section dealing with convection.

From the purely mathematical aspect the equation of conduction with K variable has been well explored; Haurwitz [24] has given the solution for ρ = constant, $T = T_0 + B \sin qt$ on $z = 0$, $K = a_0 + a_1 z$ (a_0, a_1 constant) in terms of ker and kei functions, and Köhler [33] has published a very thorough treatment of the case in which $K \propto z^m$, $m \geqq 0$, the solution in this case being expressed in terms of Bessel functions of imaginary argument. The implications of this work are considered later.

Turbulence in the General Circulation. In 1921, Defant [13] introduced a picture of the depressions and anticyclones of the synoptic meteorologist as "eddies" in the general circulation, a theory which leads to the concept of *Grossturbulenz* (Lettau), the transport of heat, momentum and water vapour on a planetary scale. A clear account of this work is to be found in Chapter XII of Lettau's *Atmosphärische Turbulenz*. Lettau adopts the ordinary interchange coefficient theory of turbulent transport and by consideration of the deviations from the geostrophic wind finds, for example, that the meridional component of the *Grossaustausch* is of the order of 10^8 g cm^{-1} sec^{-1}, with a "mixing length" of the order of several degrees of longitude.

A very different approach, not involving mixing-length concepts is that given by Priestley [46] in a recent paper in which he develops a method whereby the meridional flux of heat, water vapour and momentum can be evaluated from upper-air soundings. From a preliminary survey Priestley concludes that the atmospheric eddy flux of heat is of the magnitude required to equalize the heat losses and gains in adjacent zones of the earth and atmosphere as a whole, and that the zonal stresses arising from deep meridional currents can maintain wide zonal circulations against the effects of surface friction.

Richardson's investigations into large-scale diffusion have already been mentioned; in 1932 Sutton [66], by means of a semi-empirical theory, showed that in a turbulent medium the Einstein law of molecular diffusion (Brownian motion) should be replaced by the equation

$$\sigma^2 = C^2(\bar{u}t)^m. \tag{11}$$

Here C is a generalized coefficient of diffusion and m is a constant whose value is about 1.75. This equation is certainly satisfied for diffusion over distances of the order of a few hundred metres, and Richardson's data, re-analysed on the basis of this equation, indicate a strong probability that the law is valid also for distances of the order of hundreds of kilometres. In assessing the value of this conclusion it should be borne in mind that the data on which it is based are extremely crude for the greater distances, but the evidence available so far is that a law of the type (11) is capable of representing atmospheric diffusion, to a first approximation at least, over a very wide range.

It will be evident from the discussion above that although the broad features of many large-scale atmospheric processes can be explained reasonably well by the simpler forms of turbulence theory, as yet little has been attempted in the way of detailed analysis. Many opportunities present themselves here. The recent brilliant American work[2] on the structure of thunderstorms has directed the attention of meteorologists to the problems of free jets and of the general mechanism of the entrainment of air by turbulent mixing on the boundary of a thermal current. Much remains to be

2. Described in *The Thunderstorm* by H. R. Byers and others, Supt. of Documents, Washington, D. C., 1949.

explained concerning the details of large cellular convective motion, first studied in the laboratory by Bénard and investigated mathematically by Rayleigh, Jeffreys and others. The whole problem of turbulence in the upper atmosphere has recently arisen in an acute form in relation to the design of large aircraft. Finally, the applicability of the Reynolds process of averaging in dealing with major atmospheric motions is still uncertain and it is here, perhaps more than anywhere else, that the statistical theories are likely to make the most decisive contributions.

SMALL-SCALE DIFFUSION PROCESSES

Because of their importance in military operations and in studies of atmospheric pollution, specialized problems relating to the spread of suspended matter (smoke and gas) over distances of the order of a few kilometres have been the subject of intensive research, both practical and theoretical. In experimental investigations a measure of control is possible, and the data on diffusion thus obtained are among the most reliable and accurate in micrometeorology. A summary of the properties of continuously generated smoke clouds, based on extensive trials conducted at Porton, England, has been given by Sutton [67]; these refer exclusively to conditions of small temperature gradient and, as yet, no corresponding set has been published for inversions or for conditions of a superadiabatic lapse rate.

Concurrently with the experimental work, there has been a great deal of activity on the theoretical side, with the result that a workable but semi-empirical theory of turbulent diffusion has been built up and verified for conditions of neutral equilibrium (adiabatic lapse rate). This work will now be summarized briefly.

Properties of Continuously Generated Clouds in Conditions of Small Temperature Gradient. The smoke cloud from a continuous point-source stretches downwind in a long cone, and measurements of concentration taken at fixed points are to some extent dependent upon the period of sampling. This is because the natural wind is made up of fluctuations of all periods, and the "instantaneous" aspect of the cloud, being mainly influenced by the small-scale eddies, differs considerably from the "time-mean" aspect. The narrow "instantaneous cone" swings slowly over a wider front and is contained within an enveloping "time-mean cone." The properties which have been measured almost invariably refer to the "time-mean" aspect, that is, the concentrations at fixed points are averages over periods of time of not less than three minutes.

For a continuously generated cloud, the concentration of smoke at any point is directly proportional to the strength of the source and approximately inversely proportional to the mean wind speed, while the cross-wind and vertical distributions of concentrations are approximately of the "normal law of error" type. From the point of view of the mathematician, the results of greatest importance are: The central or peak concentration in the cloud from a continuous point-source decays as $1/x^{1.76}$ (x = distance downwind) and as $1/x^{0.9}$ in the cloud from an infinite cross-wind continuous source, and the maximum concentrations at $x = 100$ m in a mean wind of 5 m sec^{-1} are

point-source of 1 g sec^{-1} ..... 2 mg m^{-3}

infinite line-source of 1 g sec^{-1} m^{-1}.... 35 mg m^{-3}.

The fundamental problem for the mathematical physicist is to find means whereby these properties can be derived from measurements of the relevant meteorological factors, such as the profile of mean velocity, gustiness and temperature gradient.

Theoretical Aspects. The general equation of diffusion in a turbulent medium is

$$\frac{\partial \bar{\chi}}{\partial t} + \bar{u}\frac{\partial \bar{\chi}}{\partial x} + \bar{v}\frac{\partial \bar{\chi}}{\partial y} + \bar{w}\frac{\partial \bar{\chi}}{\partial z} = \frac{\partial}{\partial x}\left(K_x \frac{\partial \bar{\chi}}{\partial x}\right) + \frac{\partial}{\partial y}\left(K_y \frac{\partial \bar{\chi}}{\partial y}\right) + \frac{\partial}{\partial z}\left(K_z \frac{\partial \bar{\chi}}{\partial z}\right), \tag{12}$$

where $\bar{\chi}$ is the mean concentration of smoke, the density of the air being supposed constant. It is convenient to take axes in which x is measured in the direction of the mean wind, y across wind and z vertically, so that $\bar{v} = \bar{w} = 0$. For these localized problems the mean wind may be supposed to vary only with height.

Two-Dimensional Problems. In the case of a long line source across wind, or an area source in which lateral edge effects are negligible, equation (12), neglecting downwind diffusion in comparison with vertical diffusion, reduces to

$$\bar{u}(z)\frac{\partial \bar{\chi}}{\partial x} = \frac{\partial}{\partial z}\left(K_z \frac{\partial \bar{\chi}}{\partial z}\right)$$

for the steady state. To deal further with this equation means that $\bar{u}(z)$ and K_z must be known explicitly. We shall consider here only power-law formulations; so far no solutions have been published in which $\bar{u}$ is expressed in terms of ln z. Most investigations assume the Schmidt "conjugate power-law" relation, that is, if $\bar{u} = \bar{u}_1(z/z_1)^p$, then $K = K_1(z/z_1)^{1-p}$, but since this is equivalent to the assumption that the eddy shearing-stress $\tau = K\rho\, d\bar{u}/dz$ is invariable with height, the resulting equation can hold only in a relatively shallow layer ($z \leqq 25$ m) near the surface. This limitation is of importance in questions dealing with the variation of humidity profile in air passing from sea to land (*v.* Booker), and results obtained in investigations which assume the conjugate power-law relation to hold in deeper layers must be regarded with considerable doubt, and any close agreement with observation to be a matter of chance rather than of sound reasoning.

With the conjugate power-law relation, the two-dimensional steady-state equation becomes

$$\frac{\bar{u}_1}{K_1} z_1^{1-2p}\frac{\partial \chi}{\partial x} = z^{-p}\frac{\partial}{\partial z}\left(z^{1-p}\frac{\partial \chi}{\partial z}\right). \tag{12a}$$

By a suitable change of variables this equation may be converted to the form

$$\frac{\partial \chi}{\partial x} = \frac{1-2p'}{z}\frac{\partial \chi}{\partial z} + \frac{\partial^2 \chi}{\partial z^2}; \qquad p' = p/(2p+1),$$

(W. G. L. Sutton [70]), which will be recognized as a generalization of the classical equation for the conduction of heat in a solid. This is probably the most useful way of regarding the equation, for the boundary conditions which occur in problems of atmospheric diffusion are entirely analogous to those familiar in the theory of heat flow. Solutions of this equation for various types of boundary conditions (chiefly those which arise in the problem of evaporation) have been discussed in considerable detail by W. G. L. Sutton [70], who based his analysis on Goursat's treatment of the equation of conduction of heat. Jaeger [27] has recently given an elegant and concise discussion of the diffusion equation by the method of the Laplace transform.

The boundary conditions for the problem of the steady continuous infinite cross-wind line-source of smoke are easily specified; the concentration tends to zero at infinity and increases without limit as the line of emission is approached, while the effect of the earth's surface is represented by the condition that there is no net flow across the plane $z = 0$. The solution is then easily obtained as

$$\bar{\chi}(x, z) = \frac{\text{const}}{\bar{u}_1^{1/(1+2p)}\, x^{(p+1)/(2p+1)}} \cdot \exp\left\{\frac{-\text{const}\ \bar{u}_1^{2p/(1+p)}\, z^{(1+2p)}}{x}\right\}, \tag{13}$$

in which the various "constants" are easily determined by the "continuity" condition.

In the problem of evaporation from a free-liquid or saturated area on the plane $z = 0$, of infinite extent across wind and of finite length downwind, the boundary conditions are not as obvious. In his treatment of the problem O. G. Sutton [68] introduced the condition that the vapour concentration attains the saturation value (χ_s) at all points on the wetted area, so that the problem of evaporation becomes that of finding the strength of the area source which will maintain this constant concentration on the surface despite the removal of vapour by the turbulent air stream above. The solution of the problem constituted by equation (12a) and the boundary conditions can then be obtained as an incomplete gamma function, namely,

$$\bar{\chi}(x, z) = \chi_s\left[1 - \text{const} \cdot \Gamma\left(\frac{\text{const}\ \bar{u}_1^{2p/(1+p)}\, z^{1+2p}}{x},\ \frac{p}{2p+1}\right)\right], \tag{14}$$

from which the total rate of evaporation can be found by integrating the local rate of evaporation $\left[K_z \frac{\partial \bar{\chi}}{\partial z}\right]_{z=0}$ over the area (see W. G. L. Sutton [70], Jaeger [27], Frost [21], Pasquill [40]).

Three-Dimensional Problems. For problems involving point or short line sources, or areas finite across wind, the term $\frac{\partial}{\partial y}\left(K_y \frac{\partial \bar{\chi}}{\partial y}\right)$ must be retained. So far very little progress has been made with these problems. In the first place, the form for K_y cannot be settled as easily as that for K_z, since there is no resultant shear-stress across wind and hence no counterpart of the "conjugate power-law" theorem. It is hardly possible to consider K_y as a function of y, that is, dependent upon distance from an arbitrary axis, and K_y must therefore be made a function of height (z). This, however, introduces considerable mathematical difficulties. It is known, for example, that a solution satisfying the boundary conditions for a continuous point-source can easily be found (in the usual exponential form) if both K_y and $\bar{u}$ are constant or if K_y and $\bar{u}$ are proportional to the same power of z, but these solutions do not agree with the experimental data. In the problem of evaporation, a formal solution for K_y, K_z and $\bar{u}$ constant, applicable to a rectangular area, can be found in terms of Mathieu functions, and Davies [11] has investigated the case in which K_y and $\bar{u}$ are proportional to the same power of z for an area of parabolic shape, but the solution for K_y proportional to an arbitrary power of z, applicable to a closed area, has not been found. There is need for a detailed pure mathematical examination of this type of equation, and progress in this branch of atmospheric diffusion is bound to be slow until such an investigation has been made.

Formulas for K_z, Statistical Theory. In applying the analysis described above to specific problems, it is usually assumed that the velocity profile is known to a high degree of accuracy, and that from this, the value of the friction velocity u_* can be found for any given mean velocity. Since

$$K_z = \frac{\tau/\rho}{d\bar{u}/dz} = \frac{u_*^2}{d\bar{u}/dz},$$

it follows that K_z is also known explicitly at all points in the layer in which the shearing stress is constant. Thus the two-dimensional problem of diffusion depends essentially on the accurate determination of the velocity profile near the surface, the underlying assumption being that the diffusion of mass by eddy motion is identical with that of the diffusion of momentum.

This method, initiated by Sutton, has been followed by Calder [7] in a very exact study of two-dimensional diffusion over surfaces covered by both short and long grass. Calder uses the logarithmic profile to determine the roughness length, friction velocity and zero-plane displacement (for the long-grass case), but in the equation (12a) he replaces the logarithmic profile by an approximate power-law profile and uses solutions (13) and (14) above. The theoretical results are in very good agreement with the observational data. The method cannot be used for three-dimensional problems, and for such problems recourse must be had to the statistical approach devised by Sutton [67].

This theory is based upon Taylor's "Diffusion by Continuous Movements" [73], using as the starting point the correlation coefficient $R(\xi)$ between eddy velocities at different times. For flow over a smooth surface, dimensional arguments indicate that $R(\xi)$ may be represented by

$$R(\xi) = \left(\frac{\nu}{\nu + \overline{u'^2}\,\xi}\right)^n, \tag{15}$$

where ν is the kinematic viscosity of the air and n is a parameter expressing the degree of turbulence in the fluid. The value of n is found from observations of the velocity profile. Using mixing-length concepts, an explicit power-law form for K_z can then be found, which when inserted in the equation of diffusion leads to results in excellent agreement with observation from a smooth saturated surface (Sutton [68], Pasquill [40]). For diffusion over rough surfaces, the kinematic viscosity in (15) must be replaced by the macroviscosity $N = u_* z_0$; the resulting expressions are then in good agreement with observation (Sutton [65]).

For three-dimensional problems Sutton abandons the mixing length *cum* differential equation approach and proceeds by finding expressions which satisfy Taylor's equation

$$\sigma^2 = 2\overline{u'^2} \int_0^T \int_0^t R(\xi)\, d\xi\, dt,$$

the boundary conditions and the equation of continuity. For this purpose it is necessary to introduce generalized diffusion coefficients C_y and C_z, which are found as explicit functions of the mean gustiness, the parameter n occurring in the velocity profile, and either the kinematic viscosity or the macroviscosity, according as the underlying surface is smooth or rough. The expression for the concentration from a line-source obtained in this way is not quite as accurate as that derived from the differential equation, but is adequate for many purposes, and the method has the advantage of providing a simple solution for the point-source problem where, as yet, the mixing length *cum* differential equation approach has failed. Recently, Sutton [69] has extended this work to cover the case of an elevated source such as a factory chimney.

Detailed Study of Evaporation. The work described above has shown that the rate of evaporation from a small saturated or free-liquid area can be calculated with considerable accuracy, at least in conditions of neutral vertical equilibrium and provided that edge losses can be disregarded. Since the mean rate of evaporation decreases with the length of the area downwind, and also because it is uncertain if a small area can reflect adequately the effect of changing stability (Sutton [67]), it is extremely doubtful if the conventional "evaporimeter" or "evaporation tank" is of any real use in assessing the rate of evaporation from areas of moderate size, such as reservoirs or small lakes.

For the estimation of evaporation from natural surfaces without the aid of evaporimeters, two methods are possible. One, initiated by Ångström for lakes and later applied by Penman [42] to land, depends upon an accurate evaluation of the remaining terms in the equation for heat balance. No knowledge of the process of turbulent transport is required. The second method, used by Sverdrup and others for evaporation from the sea and by Thornthwaite and Holzman [77] for land, uses the theory of eddy diffusion to evaluate the flux of water vapour from the wind and water-vapour profiles. This procedure has been subjected to a critical examination by Pasquill [41], who concludes that the Thornthwaite-Holzman formula

$$E = \frac{\rho k^2 (q_1 - q_2)(u_2 - u_1)}{(\ln z_2/z_1)^2}$$

(E = rate of evaporation, q_1 , q_2 and u_1 , u_2 = specific humidities and mean velocities at heights z_1 and z_2 , ρ = air density, k = Kármán's constant ≈ 0.4) is valid for conditions of neutral equilibrium and may be used in other conditions if errors up to about 20 per cent in the rate of evaporation can be tolerated.

Space does not permit more than a brief mention here of the large amount of work which has been done on evaporation from the ocean, but some reference should be made to the "evaporation coefficient" of Montgomery [35], defined as

$$\Gamma = -\frac{1}{e_s - e_a} \frac{de}{d(\ln z)},$$

where e_s = vapour pressure at the surface and e_a = vapour pressure at a standard height. The rate of evaporation from the sea surface is then

$$E = \rho k \gamma_a \Gamma (q_s - q_b) W_a,$$

where k is Kármán's constant, $\gamma_a = u_*/W_a$, where W_a = velocity at height a, and q_s and q_b are the specific humidities at heights a and b. Sverdrup [71] has shown that with certain assumptions $\Gamma = 1/\ln\left(\frac{b + z_0}{z_0}\right)$, where z_0 is the roughness length, and has made a critical examination of the validity of Montgomery's concept.

Richardson's Diffusion Theory and Its Relation to Recent Developments. We conclude this short summary of the diffusion problem by mention of some work by Richardson which may prove to be of considerable significance. In 1926, Richardson [50], showed in his "Distance-Neighbour Graph" theory, that if l is the projection of the separation of a pair of marked particles on a fixed direction, and q is the "number of neighbours per unit of l,"

$$q(l) = \int_{-\infty}^{\infty} \chi(x)\chi(x + l)\, dx,$$

where χ is the concentration. The equation of diffusion then becomes

$$\frac{\partial q}{\partial t} = \frac{\partial}{\partial l}\left\{F(l) \frac{\partial q}{\partial l}\right\},$$

where $F(l)$ is a kind of diffusion coefficient. If l_0 is the initial value of l, and l_1 its value t seconds later,

$$F(l_0) = \frac{(\text{mean of } (l_1 - l_0)^2 \text{ for all pairs})}{2t}.$$

Observations by Richardson and Stommel [53] on small objects floating in water indicate that

$$F(l) \approx 0.07 l^{1.4}.$$

This is a result of considerable importance, because the recent statistical theories of Weizsäcker and Heisen-

berg (page 497) predict a similar law of diffusion. It is possible that here is the first indication of developments of considerable importance for meteorology.

Further progress in the study of small-scale processes, so important for many aspects of civilized life, depends on a number of factors. Micrometeorology demands measurements whose accuracy approaches that attained in the laboratory, and for which the development of specialized instruments, highly sensitive and yet sufficiently robust to be used in the open, is imperative. On the mathematical side it must be admitted that present theories, although often astonishingly successful for limited classes of problems, are unsatisfactory in that they involve a large element of empiricism, and rigour has often been sacrificed for simplicity of treatment. There is, in particular, a need to examine both practically and theoretically the basic assumptions of the various theories, such as the form of the various correlation functions and of the eddy spectrum over a wider range of conditions. The characteristic meteorological problem, that of diffusion in large density gradients, is still unsolved and is likely to remain so until further progress has been made in the dynamics of stratified fluids. Some of the attempts to solve this, perhaps the most difficult problem in turbulence, are discussed in the next section.

PROBLEMS ARISING FROM CHANGES IN THE DENSITY GRADIENT

Much, if not most, of the preceding work could be fairly described as a straightforward application of the aerodynamical theory of the turbulent boundary layer to meteorology. The feature which sharply differentiates the meteorological problem from those of normal aerodynamics is undoubtedly the influence of the density gradient on the nature of the flow. In other words, the meteorologist must take into account the effects of the gravitational field, and there is very little in the way of wind-tunnel investigation to guide him here.

The Richardson Criterion. The basic result in the theory of turbulence in a gravitational field is that of Richardson [51], who enunciated the criterion that the kinetic energy of the eddying motion will increase or decrease if the rate at which energy is extracted by the Reynolds stresses exceeds or falls below that at which work has to be done against gravity by the turbulence. From this, it is easy to show that turbulence will increase or die away according as the Richardson number

$$Ri = \frac{g\left(\frac{\partial T}{\partial z} + \Gamma\right)}{T\left(\frac{\partial \bar{u}}{\partial z}\right)^2}$$

(T = absolute temperature of the environment) is less or greater than the ratio of the eddy viscosity to the eddy conductivity. If these two coefficients are supposed identical, we have

turbulence increases if $Ri < 1$,

turbulence decreases if $Ri > 1$,

that is, the critical value (Ri_{crit}) of the Richardson number is unity.

In his derivation of this criterion Richardson limited its application to a system possessing a very small amount of turbulence ("just-no-turbulence"). The matter has since been the subject of intensive investigations, chiefly theoretical. Taylor [76] and Goldstein [23] showed that in the case of an inviscid incompressible fluid with a linear velocity profile and a continuous density distribution, $Ri_{crit} = 0.25$, but the most detailed and realistic investigation is that of Schlichting [57] on the decay of turbulence in the boundary layer of a smooth flat plate. Schlichting found that Ri_{crit} varied between 0.041 and 0.029, depending on the inertia effects of the density distribution, a result which was later confirmed by Reichardt in the Göttingen "hot-cold" wind tunnel. Recently, a detailed investigation of the mathematical aspects of Richardson's derivation has been made by Calder [8], who finds that the inclusion of certain terms, neglected by Richardson because of his assumption of "just-no-turbulence," changes the form of the criterion to $Ri_{crit} = 1 - \delta$, $\delta > 0$, but he was unable to give a definite value for δ, except that δ must be small if the initial degree of turbulence is small.

There have been several attempts to ascertain the value of Ri_{crit} in the atmosphere [63]. Durst agrees with Richardson in finding $Ri_{crit} = 1$, but Paeschke [38] concludes that the Schlichting value, $Ri_{crit} = 0.04$, is appropriate. Some of the best evidence is that assembled by Deacon [12] who proposes $Ri_{crit} = 0.15$ for conditions near the ground, while for the free atmosphere Petterssen and Swinbank [43] suggest $Ri_{crit} = 0.65$. It is evident from these results that at the present time the question of the exact value of the critical Richardson number (if indeed it exists) is one of the most open in meteorology.

The Heat Flux Equation and the Problem of Convection. It has been known for some time that the early assumption of the identity of the coefficients of eddy viscosity (K_M) and eddy conductivity (K_H) is open to considerable doubt; thus although in the lower layers of the atmosphere the transfer of momentum can be explained by taking $K_M \propto z^m$, where $0 \leqq m \leqq 1$, the propagation of the diurnal temperature wave in warm weather seems to require $K_H \propto z^{m'}$, where $1 \leqq m' \leqq 2$. These conclusions are based upon the assumption that the eddy flux of heat is proportional to the gradient of potential temperature (Taylor) or to the difference between the observed gradient and the adiabatic lapse rate (Brunt). Ertel [18], in a series of papers, questions this assumption because it neglects buoyancy effects, and concludes that the flux is more likely to be proportional to the gradient of temperature itself, a result which in turn has been criticized by Prandtl [45] on the grounds that the analysis can only be valid for occasions of calm or light winds and large lapse rates.

Ertel's main conclusion is supported by the later work of Priestley and Swinbank [47], who consider that the flux of heat has the form

$$q = \rho c_p \left\{ -\overline{w'l}\left(\frac{\partial T}{\partial z} + \Gamma\right) + \overline{w'T''} \right\},$$

where w' is the vertical component of the eddy velocity and T'' is the temperature anomaly of the eddy at the beginning of its upward motion. The first term in the brackets is that derived in the classical theory, but the second term is independent of the gradient of potential temperature and depends essentially on the existence of a correlation between the vertical velocity and the initial temperature of the eddy, which need not be that of the layer from which it came. The second term is therefore due entirely to buoyancy, whereas the first term could arise if the air were forced upwards by purely dynamical means. Unfortunately, the term $\overline{w'T''}$ cannot be isolated from the general heat flux and measured separately, and its magnitude can only be inferred from arguments of a general nature, but the theory does give a fairly satisfactory explanation of certain large-scale phenomena, such as the superadiabatic lapse rates of the higher regions of the troposphere in clear non-subsiding air. The same problem has recently been considered by Montgomery [36].

The problem of natural convection, that is, of heat transport due to the upward motion of the air in calm or very light wind conditions has been considered by Sutton [64], who, starting from the assumption that the vertical flux of heat is proportional to the difference between the observed temperature gradient and the adiabatic lapse rate, shows that the observations then necessarily imply a very rapid increase of K_H with height (as $z^{1.75}$) in hot, clear weather. On the assumption that the intensity of the turbulent upward currents is determined by the balance between their dissipation into smaller eddies and their rate of loss of potential energy, Sutton shows that certain simple relations must exist between the eddy velocity, the mixing length for heat transfer, the temperature gradient, the temperature oscillations and the eddy conductivity, provided that the upward flux of heat does not vary with height. These relations are in harmony with Johnson and Heywood's observations of the temperature field during the mid-hours of a clear summer day. Sutton also showed that a model of convection in which the ground is assumed to act as a plane instantaneous source of heat at intervals of the order of half-a-minute or so could provide an explanation of the temperature field found near the ground in warm weather. This implies that the typical convectional eddy behaves like a "bubble" which rises because of its buoyancy and grows by entraining cold air by turbulent mixing as it moves.

From this brief survey it will be seen that the solution of the problem of the transfer of heat from the ground to the air, or vice versa, is still far from complete. At the present time the main need is for accurate observations of elements such as the temperature and wind oscillations and their correlations (and hence the eddy flux) and the radiative flux. On the credit side, it appears to be fairly well established that in conditions of high lapse rate there is a significant difference between the rate of transport of heat and momentum near the ground, even when radiation is taken into account (Pasquill), but a complete explanation of the temperature field in both unstable and stable conditions is still to seek. When buoyancy effects are small compared with purely frictional effects, that is, in the problem of forced convection, it seems that there is little difference in the transport of heat and momentum by eddy motion.

The Diffusion of Matter and Other Studies in Non-adiabatic Gradients. Among the early attempts to extend the theory of diffusion to nonadiabatic gradients is that of Rossby and Montgomery [55], who, in effect, take the mixing length to be given by

$$l = kz/\sqrt{1 + \sigma Ri},$$

where σ is a "constant." This expression was used by Sverdrup in a study of turbulence over a snow field; his observations indicate that the value of σ is about 11. In a later contribution Sverdrup examined Best's velocity profiles in the light of this relation and found a large increase in σ as conditions changed from instability to stability. This work was later extended by Holzman [26], who suggested that

$$l = kz\sqrt{1 - \sigma_1 Ri},$$

where σ_1 is another constant so that $l = 0$ when $Ri = 1/\sigma_1$, when turbulence should be extinguished.

The Rossby-Montgomery and Holzman formulations have been subjected to a critical examination by Deacon [12], who finds that the Holzman expression agrees well with observations, σ_1 being independent of both roughness and stability, with a mean value about 7. This implies that the turbulent mixing-length becomes negligibly small if Ri is about 0.14.

Deacon [12] has applied these studies to an examination of two-dimensional diffusion in nonadiabatic gradients (chiefly superadiabatic lapse rates), using data on the travel of gas obtained at the Experimental Station, Alberta, Canada. The results show a certain measure of agreement with the theory, except in very large lapse rates, in which the experimental data are rather irregular.

To sum up, it is clear that a satisfactory theory of diffusion in large inversions and large lapse rates has yet to emerge, and this is particularly true for three-dimensional problems. It is unfortunate that the theory is most deficient where the need is greatest, that is, in conditions of large inversions, when even small sources of pollution can produce high concentrations, and the problem is one which should receive urgent attention from meteorologists if only because of its importance in the life of highly industrialized communities.

ATMOSPHERIC TIDES AND OSCILLATIONS

By SYDNEY CHAPMAN

Queen's College, Oxford, England

The oscillations considered in this article are those of world-wide character, on a scale greater than that of the ordinary local or regional weather distributions. It is convenient to call them "tides" even when their origin is thermal and not gravitational.

Most of our information concerning these tides comes from the barometer, which shows an excess or deficit of pressure as the motion heaps up the air or draws it away above a locality.

GRAVITATIONAL TIDES

The sea tides, with their twice-daily rise and fall, have been known since the dawn of history. The time of high tide advances from day to day in evident association with the moon's moiton. Our understanding of this goes back to Newton [85*a*], who showed how, on the basis of his laws of mechanics, a universal inverse-square "gravitational" attraction between all material particles would explain the weight that makes bodies near the earth fall towards it, explain the planetary motions, and also, less simply, the sea tides.

The gravitational attraction exerted by the sun on a particle of the earth is GS/r^2 per unit mass, where G denotes the gravitational constant, S the sun's mass, and r the distance from the sun's centre O to the terrestrial particle. On the average this force provides the orbital centripetal acceleration $\omega^2 r$ towards the sun, where ω denotes the orbital angular velocity of the earth (2π per year). The average values of these accelerations are those at the earth's centre C, for which $r = r_0$, where $r_0 = OC$. Hence $GS/r_0^2 = \omega^2 r_0$ or $\omega^2 = GS/r_0^3$.

But the gravitational attraction is greater, and the centripetal acceleration less, over the hemisphere nearer the sun, than at the earth's centre, leaving a distribution of unbalanced force over this hemisphere, directed sunwards (at most places obliquely upwards, partly acting against the earth's pull). Over the opposite hemisphere the gravitational acceleration is too weak to supply the whole centripetal acceleration, and there is a distribution of unbalanced acceleration away from the sun, here also obliquely upward, partly against the earth's pull. Particles free to move, like those of the sea water or air, will do so under the action of these unbalanced forces; the water surface will tend to become spheroidal, with its long axis along the line OC joining the centres of the sun and earth.

If the earth did not rotate relative to this line, such a steady distribution of level would actually be attained. It is called the *equilibrium solar tide*. This is proportional to the gradient along OC, at C, of the unbalanced acceleration $\omega^2 r - GS/r^2$, that is, to $\omega^2 + 2GS/r_0^3$ or $3GS/r_0^3$.

The moon exerts a similar tidal influence, proportional to $3\ GM/r_1^3$, where M and r_1 denote the moon's mass and distance (from C); M/S and r_1/r_0 are both very small, but it turns out that the lunar tidal action is 2.4 times as great as the solar, and on this account the moon chiefly governs the sea tides, though the sun at different epochs in the month adds to or reduces the lunar tides.

In the eighteenth century Newton's successors extended his planetary theory to explain the motions in the solar system in almost every detail. They began also to develop the theory of the tides. Laplace [74*a*] recognized the powerful influence of the earth's rotation on the tides, which are a dynamical, not statical, phenomenon. The "equilibrium tide" is only a theoretical conception providing a convenient standard of comparison for the real tides.

Laplace developed his tidal theory in a series of remarkable memoirs, later summarized in his *Mécanique céleste*. He restricted his analysis for the most part to the idealized case of an ocean of uniform depth covering the whole earth. Hence his results have only a limited application to the actual sea tides, which are complicated by the irregular outlines and interconnections of the oceans, and by their nonuniform depth. These complications present problems with which tidal theorists still wrestle arduously.

Laplace showed that his ideal ocean tides might be greater or less than the equilibrium tides, according to the depth of the ocean; and also that they might not be "direct," with high tide "under" the tide-producing body, and also on the other hemisphere: they might be "reversed," with low tides at points on the earth nearest to and farthest from the tide-producing body, and high tides intermediate between them.

THE ATMOSPHERIC TIDES S_n, L_n

Newton realized that the tidal forces must act on the atmosphere as well as on the seas. The lack of lateral boundaries renders the atmosphere a better subject for Laplace's idealized theory. This theory treated the sea water as incompressible, but he showed that the theory could be adapted surprisingly well to the compressible air if its temperature were assumed uniform, and unchanged throughout the compressions and rarefactions accompanying the air tides—that is, if the changes of air density were supposed to take place isothermally. On this basis he calculated the air tides for an atmosphere agreeing in total mass and average temperature with the actual atmosphere, and showed that the tides would be *direct*, that is, the air would be heaped up with high pressure under the tide-producing body, and on the opposite side of the earth.

Thus the tide should produce a twice-daily variation

of atmospheric pressure as recorded by the barometer, invented by Torricelli at about the time of Newton's birth. Already in the seventeenth century [21] the value of this instrument in the study of weather began to be realized, and in Newton's lifetime it became known that the barometric changes in the tropics are quite different from those in temperate latitudes. Instead of the mercurial height varying through several centimetres, as it does in temperate latitudes because of the irregular weather changes, the tropical barometer is almost steady except when hurricanes sweep the region. It shows, however, a small rise and fall twice daily, with a range of about 2 mm, almost as simple and regular as the tidal changes of sea level; but unlike these, the times of high pressure show no perceptible change throughout the month; they recur daily at nearly the same local *solar* time, about 10:00 A.M. and 10:00 P.M. This is illustrated in Fig. 1, which shows the barometric changes at Batavia and Potsdam (on different scales) for the same few days [14].

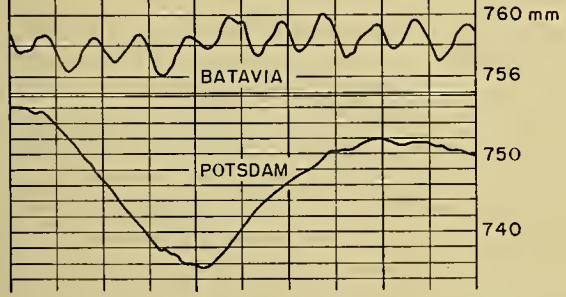

FIG. 1.—Barometric variations (on different scales) at Batavia and Potsdam, November 5–9, 1927.

This regular twice-daily barometric change is clearly due to the sun, so the "tidal" régime of the atmosphere differs greatly from that of the oceans, where the moon is the controlling agent. The moon's effect on the barometer is very small, though it can be determined with much labor from sufficient data.

The solar semidiurnal barometric variation is our chief indication of the greatest world-wide oscillation of the atmosphere. For brevity, this oscillation, with its associated barometric and wind changes, will be denoted by the symbol S_2, in which S signifies *solar*, and the suffix 2 indicates the number of its cycles or swings per day. Similarly, S_n will denote an oscillation whose barometric and other changes at each place are repeated n times each mean solar day, and L_n one with n repetitions in each mean *lunar* day.

The moon's capacity to exert any appreciable dynamical influence on the atmosphere lies solely in its tidal force, so potent on the oceans. The harmonic development of the lunar tidal potential [58] clearly indicates the values of n to be expected, and their relative importance in the lunar tidal force; for the chief term n equals 2, as in the sea tides, and there are two other terms for which n differs only slightly from 2; these increase or decrease the main semidiurnal tide according as the moon is nearer to or farther from the earth. There is also a term for which n is nearly equal to unity, but this depends on the moon's declination (namely, its angular "distance" from the equatorial plane) and is reversed in sign twice monthly as the moon moves northward or southward across the equator. This oscillation L_1 has not been detected in the barometric records [30].

THE SEARCH FOR THE LUNAR ATMOSPHERIC TIDE L_2

The Tide at Paris. Laplace's theory [74*a*] indicated a "direct" lunar tidal variation of the barometer with a range in the tropics of half a millimetre. He considered that such a change, though small, should be determinable from a considerable series of tropical readings; but no such series was available to him in 1823, when he developed an active interest in the air tide, an interest which he maintained for the rest of his life. Instead, he was able to obtain from Bouvard, of the Paris observatory,[1] an eight-year series (October 1, 1815 to October 1, 1823) of barometric readings made daily at 9, 12, 15, and 21 hours. He used only part of the three daytime readings, 4752 in all, and from these, by a well-designed method, he sought to compute the lunar semidiurnal tide L_2. He calculated its range as 0.054 mm, and the lunar times of maximum pressure as 3^h19^m after upper or lower transit. He attached limited significance to this result, after calculating the probability [74*c*] that it was not merely due to chance, that is, to the continual irregular "weather" variations of the barometer. He asserted that to determine so small a variation from such data with adequate certainty would require at least 40,000 observations.

Bouvard [74*f*] in 1827 repeated Laplace's calculation with four more years' data (in all, twelve years, January 1, 1815 to January 1, 1827), and from 8940 readings found a lunar tidal range of 0.0176 mm, with maxima at 2^h8^m and 14^h8^m. The great difference from Laplace's result confirmed the inference that the data used were still far too few.

In 1843 Eisenlohr [60] renewed the attempt with twenty-two years' data (1819–1840), using all the four daily readings. Unfortunately he departed from Laplace's excellent method of computation, which involved only *differences* between readings on the same day, thus eliminating the influence of the large changes of pressure from day to day. Eisenlohr rearranged his data according to the nearest lunar hour (0 to 23) at the time of each reading; with unlimited data this method would be satisfactory, showing the complete average change of the barometer according to lunar time. But with his limited data, the number of readings per lunar hour ranged from 1302 to 1377, and the hourly means

1. In references [28, 29] the source of Laplace's data for the air tide was wrongly given as Brest, through confusion with his use of Brest sea-level data for comparison with his theory of sea tides. It may also be added that in the translation of (Vols. 1–4 only, of) Laplace's great work, by N. Bowditch, ref. [74*a*] is to be found on pp. 793–801 of Vol. 2 (Boston, 1832).

were unequally affected by the great weather variations of pressure. They showed a quite irregular variation from hour to hour. Thus his laborious effort, in many ways well planned, was fruitless. He concluded that his data were insufficient to determine L_2, and hence that the attempts by Laplace and Bouvard were still less adequate. He urged that *hourly* readings of the barometer should be taken, so that in time, from a long series, L_2 might be determined.[2]

The Tropical Lunar Air Tide. When Eisenlohr wrote (1843), L_2 had already been determined from tropical pressure data, though the result was not published until 1847 [91]. Around 1840, several British colonial observatories, magnetic and meteorological, were set up under Sabine's leadership. In 1842 the director (Lefroy) of the St. Helena observatory successfully used his seventeen months' (August 1840 to December 1841) bihourly week-day barometric readings to determine L_2. His successor Smythe, with Sabine, confirmed the determination from three more years' data, October 1842 to September 1845. Sabine even attempted to find how the air tide varies with the lunar distance [91].

In 1852 the director (Elliot) of the Singapore observatory determined L_2 there [61] from five years' data, 1841 to 1845.

Later, when the Batavia observatory was established in 1866, these results stimulated its directors [22, 23, 96–99] to determine L_2 from their hourly barometric data, recorded photographically. Bergsma published the first results, for 1866 to 1868, in 1871. By 1905, L_2 at Batavia was really well determined from 350,000 observations covering forty years.

The Lunar Air Tide Outside the Tropics. Laplace [74*a*, *c*] stressed the need, in deriving results from observations, to determine the probability that the error lies within narrow known limits; without so doing, he said, one risks presenting the effects of irregular causes as laws of nature, "as has often happened in meteorology." This need has been overlooked or neglected by a multitude of those who, before and since his time, have vainly sought for lunar *monthly* meteorological variations. Eisenlohr, from 1833, was among these; but only a few of them have, like him, engaged in the more hopeful but still perilous search for lunar *daily* meteorological variations, in particular for L_2. Of these few, some, like Kreil in 1841, or later Bouquet de la Grye, used quite inadequate data[3]—for one year only, or even for five years, like Neumayer [84], who in 1867 failed to obtain consistent results from five years' hourly data (1858 to 1863) for Melbourne (lat 38°S). Even Airy [1], who used 180,000 hourly values for Greenwich (for twenty years, 1854 to 1873) unwisely concluded in 1877 that "we can assert positively that there is no trace of lunar tide in the atmosphere." Börnstein [24][4] in 1891 used only four years' data for Berlin and Vienna and Hamburg; for Keitum (lat 55°) he used ten years' hourly data (1878 to 1887), but found "no trace of a semidiurnal variation such as a lunar tide would produce"; he thought, however, he had found a definite lunar *diurnal* variation (not, like L_1, reversed fortnightly; see p. 511). Bartels [12] in 1927 showed that these conclusions completely misinterpreted the actual results that Börnstein had obtained, and that his supposed lunar diurnal variation was a purely chance effect, whereas L_2 was contained in his curves, though it was ill-determined. The misinterpretation sprang directly from the neglect of Laplace's advice to consider the probable accuracy of the results.

Morano [83] in 1899 used four years' data (1891 to 1894) for Rome (lat 42°N), although Neumayer [84] had failed, by the same method applied to five years' data for Melbourne, in a rather lower latitude, to obtain a reliable result. The validity of Morano's result, which is probably near the true value of L_2 at Rome, remained uncertain.

In 1918 a new attempt [28] succeeded in determining L_2 from the Greenwich hourly data, by then available for sixty-four years. Two-thirds of the material was rejected; the only days used were those on which the barometric range did not exceed 0.1 in. This was the first certainly valid nontropical determination of L_2.

This investigation was planned and undertaken with guidance [27], in a very simple way, from the theory of random errors. According to this theory, if a single observation is subject to an accidental error e, the probable random error of the sum of N such (independent) observations is $e\sqrt{N}$, and that of their mean is $e/\sqrt{N}$. The moon produces a systematic (though very small) semidiurnal variation of the barometer; if this is combined from N lunar days' observations (each in the form of a sequence of lunar hourly values), by forming the sum of the values for each lunar hour, the sequence of sums will contain N times the lunar daily variation. It will, however, be affected also by the other causes of variation, particularly, outside the tropics, by the succession of cyclones and anticyclones. If these produce an average random departure e of any hourly value from the long-term barometric mean, they will contribute to each lunar hourly sum of N hourly values a random contribution of the order $e\sqrt{N}$. As N is increased, the regular lunar daily variation in the lunar hourly sequence of sums will increase proportionately to N, and the random contributions will increase, but proportionately only to $\sqrt{N}$. Thus, although e greatly exceeds the range of the lunar air tide at Greenwich, the systematic tidal effect will altogether overpower the random contribution if N is taken large enough. In the sequence of lunar hourly *means*, L_2 is independent of N, whereas the random errors are of the order $e/\sqrt{N}$.

As the Greenwich data were used only for days of barometric range 0.1 in. or less, the average random departures e from each day's *mean* might be estimated as 0.01 in. Since N was 6457, $e/\sqrt{N}$ would be about 0.00012 in.

2. Not until 1945 was a further and successful attempt made to determine L_2 at Paris. The results are not yet published.

3. The method of computation is also important, as well as the amount of data, for the success of a determination.

4. See also [12, pp. 39, 40].

Figure 2 (full line) shows the mean lunar daily variation of Greenwich pressure obtained [28] from these N days, by a method of rearrangement of solar hourly values according to lunar time. Happily, this method avoided a pitfall, then unsuspected but afterwards disclosed by Bartels [12], associated with the use of selected barometrically "quiet" days [41].

The total range of pressure in Fig. 2 is less than 0.001 in., and the change from one lunar hour to the next averages about 0.00015 in. This exceeds the average random error in Fig. 2, namely, 0.00010 in., and the *systematic* nature of the lunar daily variation is clearly manifest. Apart from its meteorological and dynamical interest, this determination has great *statistical* interest as a remarkable illustration of the "law of combination of random errors"—an example confirmed by many later air-tide determinations, most notably by that of the tidal variation of air temperature at Batavia [36]. (See p. 519.)

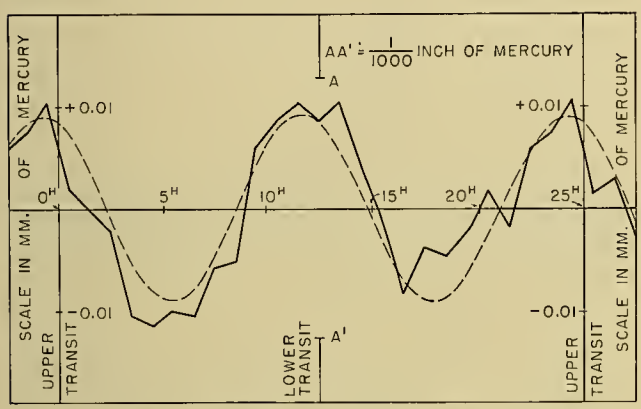

FIG. 2.—The average lunar daily variation (full line) of barometric pressure at Greenwich, computed from 6457 days' hourly data, 1854–1917; the broken line shows the lunar semidiurnal component of the variation.

Harmonic Analysis and the Harmonic Dial: Units. In Fig. 2 the broken curve represents the lunar semidiurnal harmonic (or Fourier) component obtained by harmonic analysis of the calculated variation (full line). This component curve represents the type of variation due to the moon, and the difference between the two curves must be ascribed to random variation due to weather.

Any variation which is periodic in an interval T can be harmonically analyzed and represented as a sum of harmonic terms,

$$\Sigma\, c_n \sin(n\theta + \gamma_n), \tag{1}$$

where $n = 1, 2, \ldots$ and θ denotes time reckoned in angle at the rate 360° per interval T. The integer n is the *order* of the harmonic, c_n and γ_n are its *amplitude* and *phase*. This harmonic has maxima at the time $\theta = (90° - \gamma_n)/n$ and at intervals T/n thereafter throughout the period T.

In the case of a solar or lunar daily variation, T signifies a (mean) solar or lunar day, and θ signifies solar time t at the rate 15° per mean solar hour, or lunar time τ at the rate 15° per mean lunar hour. It is convenient to reckon t from local mean midnight, and τ from local lower mean lunar transit. It is also convenient to denote the nth harmonic (S_n or L_n) by the distinctive notations:

$$s_n \sin(nt + \sigma_n) \tag{2}$$

for S_n, and for L_n,

$$l_n \sin(n\tau + \lambda_n). \tag{3}$$

The only harmonics yet detected in the lunar air tide (see p. 511) are the second ($n = 2$) and the two for which n differs only slightly from 2; the other harmonics obtainable by analysis of the full-line curve in Fig. 2 represent only residual accidental error.

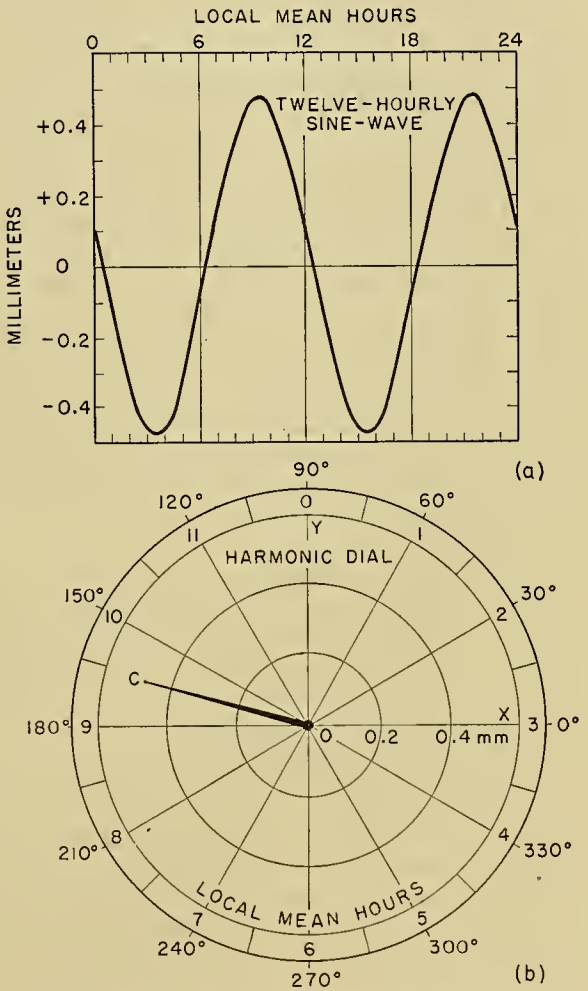

FIG. 3.—The solar semidiurnal component (S_2) of the daily barometric variation at Washington, D. C., *represented* (Fig. 3*a*, above) by a graph, *specified* (Fig. 3*b*, below) by a harmonic dial.

In this article l_2, for the lunar tidal variation of *barometric pressure*, will be expressed either in micrometres (μm) of mercury (1 μm = 10^{-6}m = 0.001 mm) or in microbars (1 microbar = 0.001 mb or 1 dyne cm^{-2}, or 0.00075 mm of mercury). The unit of *speed* used for l_2, the amplitude of the lunar tidal wind variation associated with L_2, will be 1 cm sec^{-1} (= 0.036 km hr^{-1}). In graphical illustrations showing both S_2 and L_2, the

scale values for the pressure and speed variations associated with S_2 will be ten times greater than for L_2.

A harmonic variation such as the nth term of (1) can be graphically represented by a curve, for example, the broken line for L_2 in Fig. 2 or the curve for S_2 in Fig. 3*a*;[5] or it may be specified by a diagram which indicates the amplitude c_n and phase γ_n, as in Fig. 3*b* [16]. This shows an origin O, a phase-reference line OX, and a line OC whose length, on the amplitude scale marked along OX, represents c_n (in this case s_2), and whose direction indicates, by the angle XOC, reckoned anticlockwise, the phase γ_n (in this case σ_2). A circle may be drawn with O as centre, and graduated, as in Fig. 3*b*, to show the phase angle.

A perpendicular axis OY may also be added, and the circle may also be graduated (clockwise from OY) in *time* measure $\varphi = n\theta$, at the rate 360° per interval T/n. For Fig. 3*b*, $n = 2$, so that T/n is half a solar day or twelve solar hours, and the time measure is therefore 30° per solar hour (or in a similar diagram for L_2, 30° per mean lunar hour, reckoned as 24 per lunar day). On this graduation, OC points to the time given by $n\theta = 90° - \gamma_n$, at which the harmonic variation has its first maximum in the interval T. When $n = 2$, the diagram corresponds to an ordinary clock face, on which each hour corresponds to 30°; OC points to the times of maxima, morning and afternoon. When $n = 1$, the diagram may be likened to a 24-hour dial. When $n = 3$ or $n = 4$, the diagram will show only eight or six hours on its face or rim, at intervals of 45° or 60° respectively. Because of this alternative interpretation of the diagram, as a clock face indicating the amplitude and time(s) of maximum, the diagram is appropriately called a *harmonic* dial [30].

Any part of a harmonic dial not needed in a particular case may be omitted; so also can the line OC if its end C is shown. This is useful when, as in Fig. 4, several determinations of a harmonic are to be shown on one dial. Figure 4 shows forty dial points [12], each representing the determination of L_2 in Batavia pressure for one of the forty years 1866 to 1905.

The Probable Error. More than a century after Laplace's pioneer attempt to assess the reliability of his determination of L_2 [74*c*, *d*], Bartels [11, 12] in 1926 applied the theory of errors in a plane to assess the uncertainty of the mean of a number of independent determinations of a periodic variation such as L_2, conveniently represented by dial points as in Fig. 4. He showed how to determine the *probable error ellipse* centred on the dial point C for the mean determination. When, as in Fig. 4, the individual dial points are symmetrically distributed around C, the ellipse becomes the *probable error circle*, as there shown. Its radius r is calculated, according to the theory of errors, from the distances d of the individual dial points from C. When, as in Fig. 4, the individual dial points are of equal weight, $r = 0.939\bar{d}$, where $\bar{d}$ denotes the mean value of d.

The probability that any individual dial point will fall within a distance d from C is $1 - e^{-(x/r)^2}$, where $x = 0.833d$. When $d = r$, this probability is ½, signifying that half the points are likely to fall within the probable error circle. This chance is reasonably well exemplified in Fig. 4, where nineteen of the forty points lie within the circle.

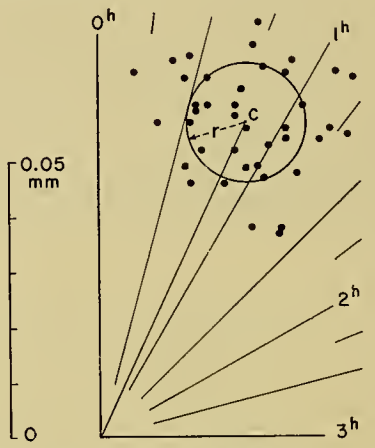

FIG. 4.—Harmonic dial showing the forty dial points for determinations of L_2, the lunar semidiurnal air tide in Batavia barometric pressure, for each of the years 1866–1905. Their centroid is the point C, specifying the forty-year mean of L_2. The circle with C as centre is the probable-error circle for any of the forty yearly dial points.

The circle indicates the probable error r of each of the forty yearly determinations of L_2; that of the 40-year mean is $r/\sqrt{40}$, as might be indicated on a separate dial showing only C and its own probable error circle.

A determination may be considered reasonably good if the length of its dial vector is at least three times its probable error. For L_2 at Batavia, each yearly determination satisfies this criterion, as there r is 0.011 mm, and l_2 ranges from about 0.045 to 0.078; for the 40-year mean value, $l_2 = 0.062$ and $r = 0.0016$, so that $l_2/r = 39$.

The uncertainty in the *amplitude* of a harmonic variation may be regarded as corresponding, in the sense explained above, to its r, and that of the *phase* to the angle $\sin^{-1}(r/l)$ subtended at O by half the probable error circle. Thus the phase uncertainty will be greater, for a given value of r, the smaller the amplitude l; for the "yearly" probable error circle shown in Fig. 4, the phase uncertainty is ±10°, or ±20 minutes of (lunar) time; for the 40-year mean it is only three minutes of time.

Methods of Computation of L_2. Several different methods have been used to determine L_2 from barometric records at various stations. In a few cases lunar hourly readings were taken, or measured from barographs, or interpolated between the solar hourly measures. This is quite unnecessary; the solar hourly values fully suffice if properly used. Where only a few readings

5. For the solar semidiurnal component variation of barometric pressure at Washington, D. C.; Fig. 3*a* is the graph of $s_2 \sin(2t + \sigma_2)$.

per day are available, a method depending on the differences between them, thus eliminating their absolute values, is desirable. Laplace [74], and in recent years also Bartels [17], used such a method. Almost all determinations other than those on the early Paris data have been based on hourly values, or (better, as Bartels urged [17]) on bihourly values, which give almost equal accuracy with much less labour [53].

In most of the determinations up to about 1935 the lunar day was taken as the basis, and the observations were rearranged according to lunar time (actual, not mean). Usually, though not always, the solar daily variation was removed before or after the retabulation. It is very important to remove, or allow for, any non-periodic change of pressure in the course of each day. This was only gradually realized [29, 32, 51, 54].

In 1917 reasonably certain determinations of L_2 had been made at only three stations [22, 23, 61, 91, 96–99]; it is now known at over sixty-five stations [12, 17, 28–46, 48–57, 88, 89]. More than half of these determinations have been made by the method [54] that now seems most suitable where hourly or bihourly data are available. The method is based on *solar* daily sequences of twenty-five hourly or (better) thirteen bihourly values, the last value for each day, which is also the first for the next day, being added so that the aperiodic change in the day can be removed. The daily sequences are separated in twelve lunar-phase groups, using tables [19, 20] constructed by Bartels and Fanselau for this purpose. The grouping is *facilitated* if each daily sequence of twenty-five or thirteen (three-figure) values, with its identifying and lunar-classification data, is entered on a punched card, using Hollerith sorting and adding machines in the later work; but these devices are not *necessary* for the application of the method. A practical description of the method, with examples, including the probable-error computation, is available [103]. The solar daily component variations S_n are computed in the course of the work, and are thus available for comparison with L_2 from the same material.

The determination of these variations, and especially of L_2, from the records of air pressure, wind, and temperature, may be likened to the extraction of a rare constituent from a great mass of crude ore—or of a needle from a haystack! It is an example of the unexhausted value of the long series of meteorological (as also of magnetic) data garnered at many observatories decade after decade. There is great need and scope for such work on many series of data not yet dealt with.

THE LUNAR ATMOSPHERIC TIDE L_2

Geographical Distribution: Annual Mean. Figure 5 indicates the annual mean value of L_2 so far as results are now available [47, 57]. The world map shows arrows which in direction and length (on the scales given) represent the dial vector for L_2 at the point corresponding to the *centre* of the arrow shaft. All the stations lie between 60°N and 40°S; there are large areas in this belt, however, where L_2 is not known—notably Central Asia, the western Pacific, and parts of South America. Some determinations made for Russian stations may have been omitted because the literature is not accessible. It is to be hoped that these gaps will gradually be filled, and the limits of our knowledge pushed polewards, using the improved computing methods [54, 103] mentioned in the foregoing section.

If the lunar air tide were in phase with the tidal force, all the arrows in Fig. 5 would be upright; actually most of them point to the right, implying a lag of high atmospheric tide (by about half an hour on the average) after lunar transit; but some well-determined arrows point leftward, as at Mauritius and Kimberley, and at the five north European stations, where high tide definitely precedes the lunar transit. Later diagrams (*e.g.*, Figs. 8, 10) indicate the uncertainties of amplitude and phase at several stations.

The L_2 component of lunar tidal *force* decreases steadily polewards from the equator, and on the whole so do the arrow-lengths representing l_2 in Fig. 5; but there are several departures from this regularity, definitely not due to errors in the determinations. The abnormalities in the distribution of L_2 are illustrated (rather tentatively, so far as the data will allow) in Fig. 6, which shows lines of equal amplitude l_2; where the lines are ill-determined they are drawn "broken." There is a belt of specially *high* tidal amplitude across the South Indian Ocean; and along the west coast of North and South America l_2 is abnormally low. Also at Buenos Aires, on the east coast, l_2 is much less than at Melbourne, in nearly the same latitude.

The remarkable anomaly of the small lunar air tide near the northwestern American coast is illustrated in Fig. 7 [46, 47, 57], which gives the distribution of L_2 over North America as in Fig. 5, but on a larger scale and with additional details (*cf.* the next section).

The Annual Variation of L_2. The lunar tidal *force* undergoes no regular *annual* variation, though it includes a semimonthly change of L_2 inseparable [30] from a semiannual change of S_2. Nevertheless, L_2, unlike the sea tides, varies notably in the course of each year. This must be due to a large-scale annual change in our atmosphere, the system on which the lunar tidal force acts.

World meteorological charts of isotherms and isobars show marked seasonal changes of distribution—seasonal in the sense that on the whole, as the sun crosses the equator northward or southward, these changes alternate, the summer state of one hemisphere being approximately reproduced in the other hemisphere in its summer. The lunar air tide is not seasonal in this sense; its main changes of l_2 and λ_2 occur simultaneously in both hemispheres.

Figure 8 (*a*, *b*) illustrates this in one way, 8*a* (above) showing l_2, and 8*b* (below) showing λ_2, for the *D* (December solstitial) group of four months November to February. The black dots indicate l_2 and λ_2 for about fifty stations, in the latitudes to be read on the scales of the abscissas; the lines centred on these dots indicate the uncertainty of l_2 and λ_2, in the manner described in the foregoing sections. The curved lines indicate the

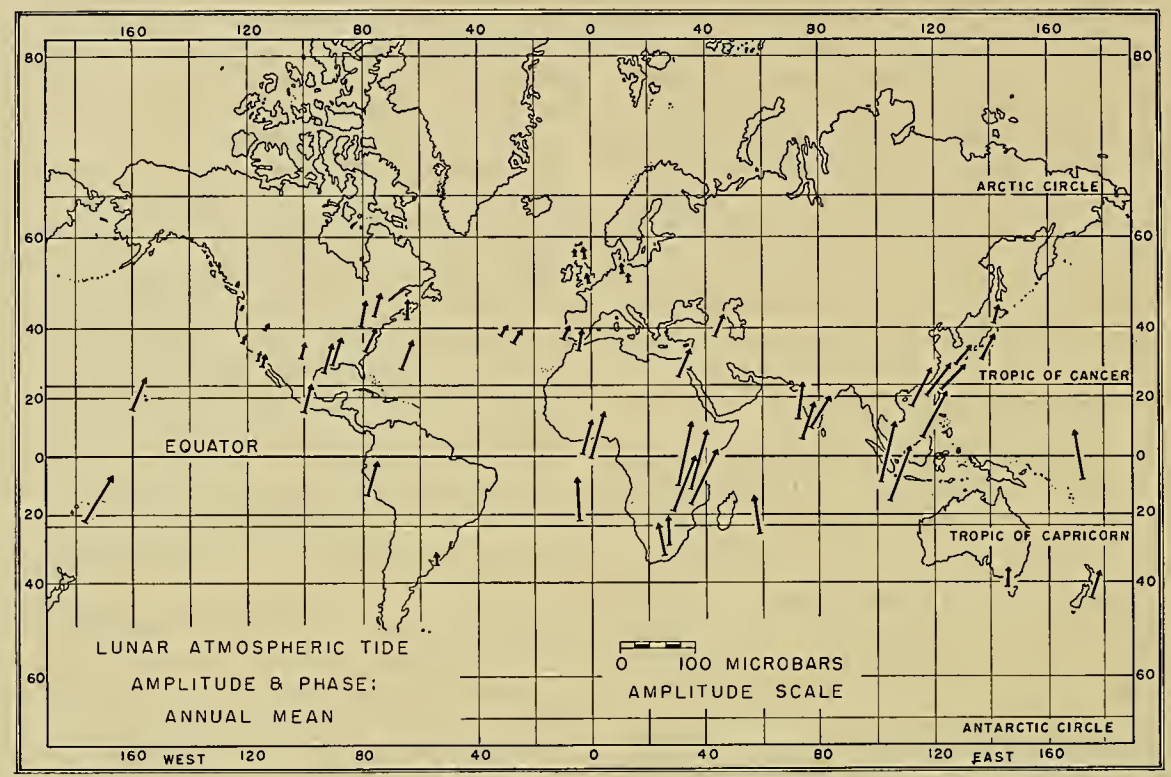

FIG. 5.—Geographical distribution of the annual mean lunar semidiurnal air tide L_2 in barometric pressure, indicated by dial vectors, each referring to the place at the mid-point of the arrow, whose length gives the amplitude l_2 on the scale shown, and whose direction gives the time of high air tide, as shown on a local mean lunar clock.

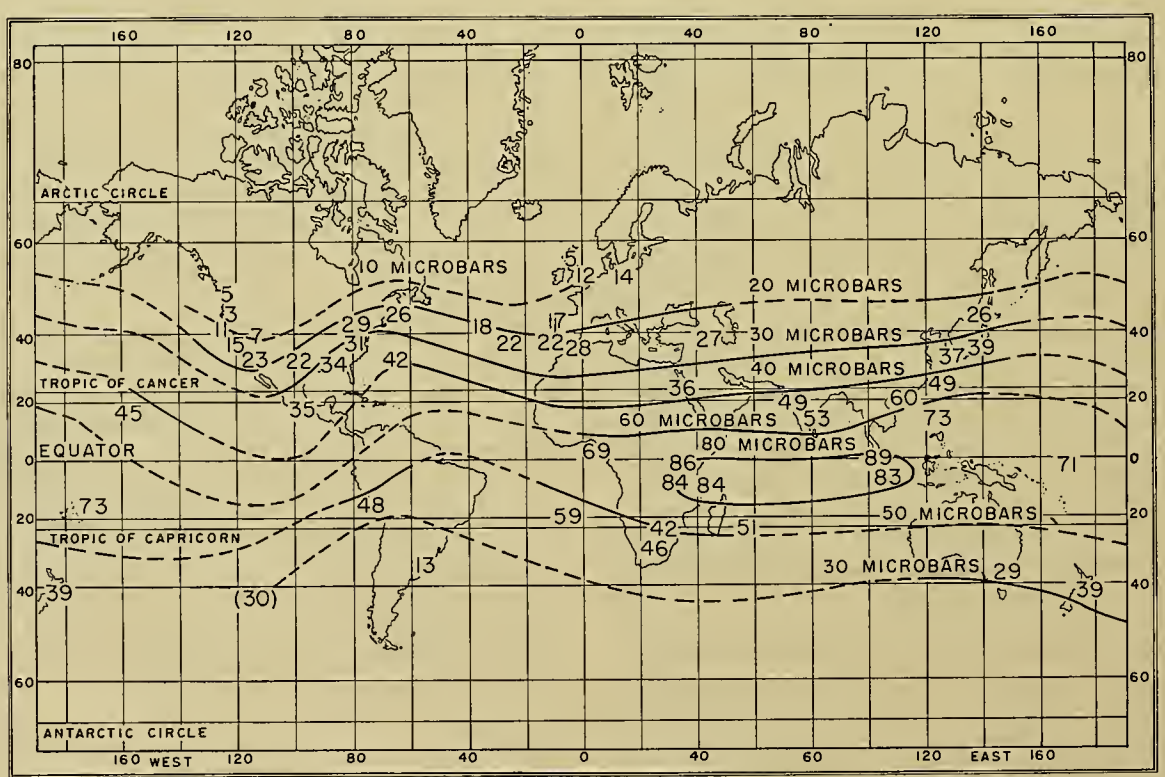

FIG. 6—Tentative lines (broken where only weakly determined) of equal amplitude l_2 (in microbars) of the annual mean lunar semidiurnal air tide L_2 in barometric pressure. The numbers (other than those, 10, 20, . . . , 80, followed by the word "microbar," which show the value of l_2 for each line) show local values of l_2.

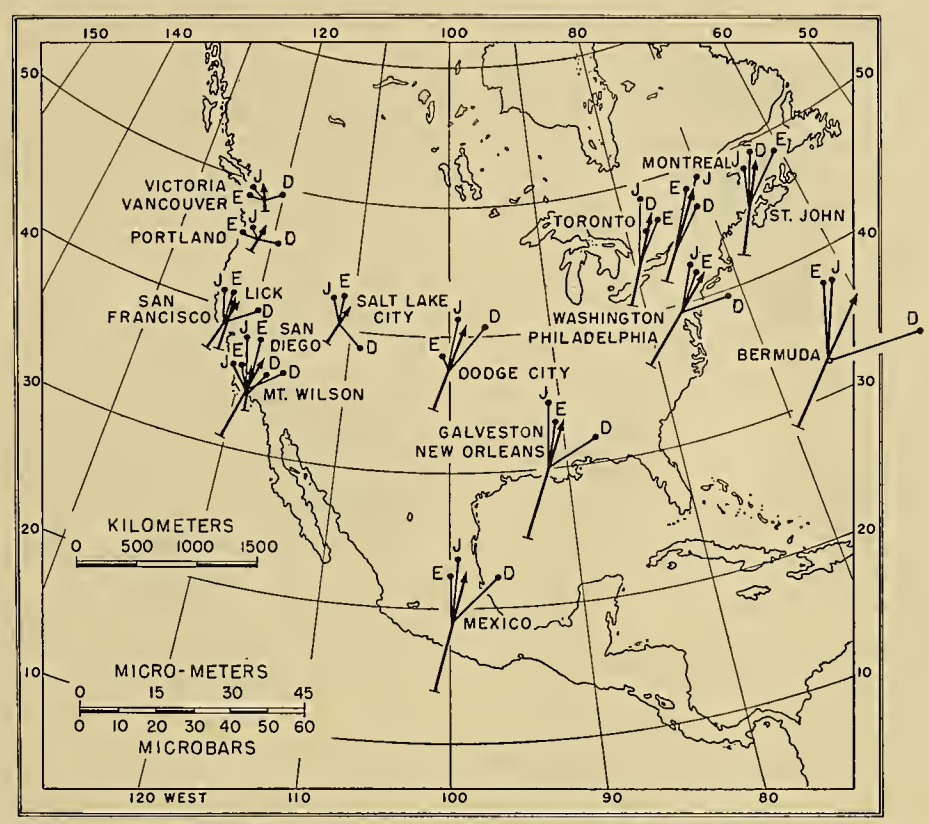

FIG. 7.—The distribution of L_2, the lunar semidiurnal air tide in barometric pressure, over North America, as shown by arrows, each of which specifies the annual mean L_2 at the point at its centre. The lines diverging from the centres of the arrows are the forward halves of corresponding arrows specifying the mean L_2 for groups of four months, J (May to August), D (November to February), and E (March, April, September, October).

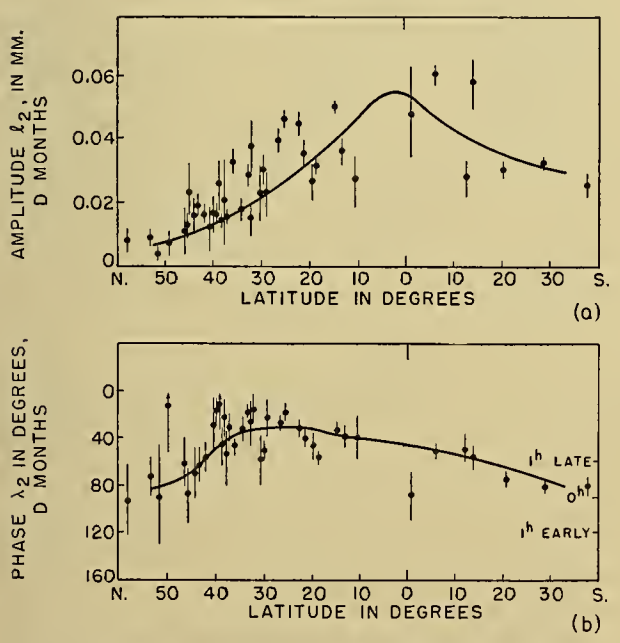

FIG. 8.—The dots indicate the latitude and the values of the amplitude l_2 (Fig. 8*a*, above) and phase λ_2 (Fig. 8*b*, below) of the lunar semidiurnal air tide in barometric pressure in the mean of the D months (November to February), at various stations. The vertical lines indicate the probable range of uncertainty of the determinations. The curves are drawn through points giving the mean l_2 or λ_2 for gronps of stations within narrow ranges of latitude.

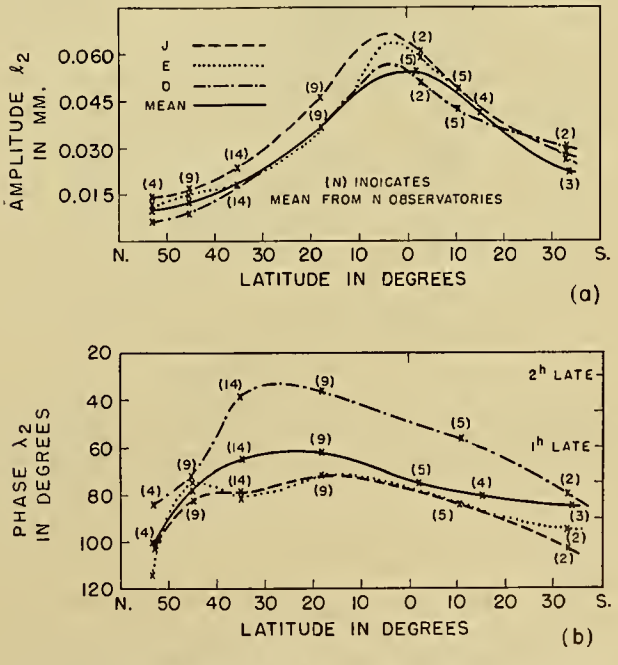

FIG. 9.—Curves showing the average dependence on latitude of the amplitude l_2 (Fig. 9*a*, above) and phase λ_2 (Fig. 9*b*, below) of the lunar semidiurnal air tide in barometric pressure, for the mean of the year and for groups of months J (May to August), D (November to February), and E (March, April, September, October). The curves are drawn through (or near to) points (×) each giving the mean l_2 or λ_2 for a group of stations (the number of stations is indicated beside each point) within a moderate range of latitude.

average l_2 or λ_2 as a function of latitude. They are obtained by forming means of l_2 or λ_2 for groups of stations within fairly small ranges of latitude. For several stations the black dot is "off" the mean curve by more than the length of its uncertainty line. Some such departures are to be expected from the laws of chance, but some certainly indicate that L_2 does not depend on latitude only, as was pointed out in the preceding section.

Similar mean curves of l_2 and λ_2 as functions of latitude are given in Fig. 9 for the annual mean of L_2, and for the group means for the D group of months (as in Fig. 8), the J (June solstitial) group May to August, and the E (equinoctial) group March, April, September, October. The individual values of l_2 and λ_2 with their uncertainty lines are not shown.

The outstanding feature of the annual change is the increased lag of high tide, by about an hour, in the D group as compared with the J and E groups. The amplitude is on the whole greatest in the J group of months.

Both these features of L_2 are illustrated in Fig. 7, for the region of North America. Besides the annual mean dial arrow for several United States and Canadian stations, Fig. 7 gives the forward halves of the dial arrows for the J, E, D groups of months. Not every station shows the two features just described, but this may be partly due to the accidental errors affecting all these determinations—errors about $\sqrt{3}$ times as great as for the annual means.

Figure 10*a* shows this annual change of L_2 in another way for a single station, Taihoku, Formosa [43]. It shows the dial points and their probable error circles for the annual mean L_2 (marked Y for year) and for the three groups of months J, E, D.

The annual change is, however, not fully shown by such means for four-monthly groups. It is better, where adequate data are available, to determine L_2 for each

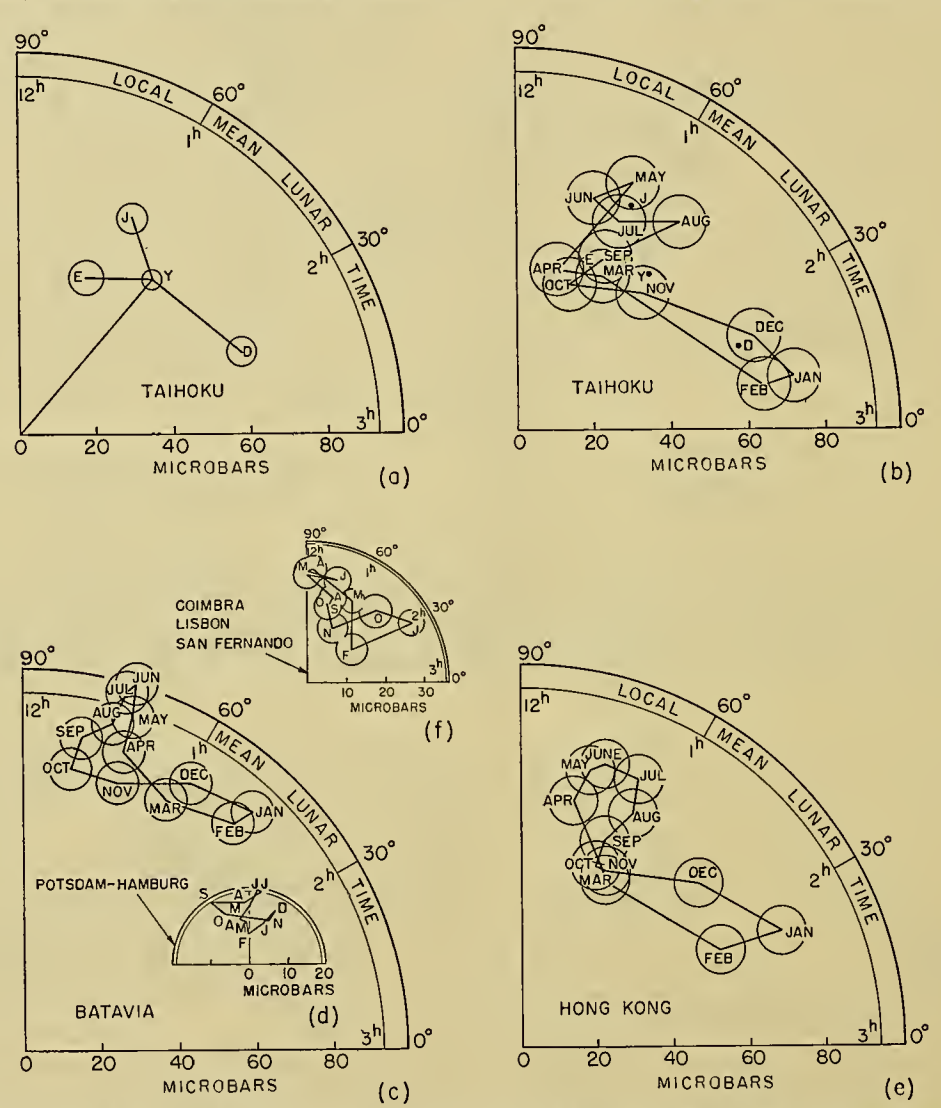

Fig. 10.—Harmonic dials (with probable error circles) indicating the annual change of the lunar semidiurnal air tide in barometric pressure. (*a*) Annual (Y) and J, E, D four-monthly determinations for Taihoku, Formosa (1897–1932). Also sets of twelve monthly mean dial points for (*b*) Taihoku (1897–1932), (*c*) Batavia (1866–1895), (*d*, inset) mean of Potsdam (1893–1922) and Hamburg (1884–1920), (*e*) Hong Kong (1885–1912), and (*f*, in centre) the mean of Coimbra, Lisbon, and San Fernando.

of the twelve calendar months (for many years). Figures 10*b*, *c*, *d*, *e*, *f* show sets of twelve dial points, one for each month, for (*b*) Taihoku [43], (*c*) Batavia [22, 23, 96–99], (*d*, inset in *c*) Potsdam and Hamburg [12] combined, (*e*) Hong Kong [29], and (*f*) the three Iberian-peninsular stations Coimbra, Lisbon, and San Fernando combined (using 112 years' data in all) [57]. Similar diagrams have been drawn for several other stations. Their most remarkable feature is the large lag of high tide, by nearly two hours, in January and February as compared with some of the *J* and *E* months. This is shown as well by the southern station Batavia as by the other (northern) stations.

The Lunar Tidal Variation of Temperature. The heating of the atmosphere by moonlight is quite negligible, but the moon nevertheless does produce a lunar semidiurnal variation of the air temperature, as a secondary consequence of its mechanical tidal action. The changes of air density accompanying the tidal variation of pressure will be different according as they take place isothermally or adiabatically, or in some intermediate way between these extremes. A similar question arises in the theory of sound waves. Newton [85*b*], who first calculated the speed of sound, assumed that the density variations are isothermal, and obtained a result that disagreed with his measurements. Laplace [74*f*] realized that the density variations are too rapid to allow the heat of compression to be conducted away during the brief period of each oscillation, and the assumption that the variations are adiabatic led him to the correct formula for the speed of sound.

The lunar atmospheric tide is a double tidal wave travelling round the earth each lunar day; the period is long—half a lunar day—but the distance between the places of high and low pressure, or condensation and rarefaction, is also great (except near the poles). Calculation shows that the density changes must be adiabatic as regards heat flow (either horizontal or vertical) *in the atmosphere* (except at very great heights—of the order 120 km—where the thermal conductivity of air is much increased owing to the long molecular free paths). The only possibility of the tidal oscillation being nearly isothermal is by interchange of heat with the liquid under surface (the solid earth does not conduct sufficiently to modify the tidal adiabatic temperature variations near ground level).

The adiabatic nature of the tidal air wave has been tested by determining the lunar semidiurnal variation of air temperature at Batavia, from sixty-two years' bihourly observations. Figure 11 shows the resulting dial vector with its probable error circle, within which lies the point *C* that corresponds to the adiabatic temperature variation, calculated from the known pressure variation L_2. Thus the determined and calculated temperature variations agree within the margin of accuracy of the determination [36].

It would be of interest to compute the lunar semidiurnal variation of air temperature from a long series of records from the windward side of some small flat tropical island in a great ocean. This would throw light on the degree of interchange of heat between air and sea. Bartels has suggested that it might prove advantageous, in such a study, to use only the night variations of air temperature, if these were less variable from day to day than the daytime values.

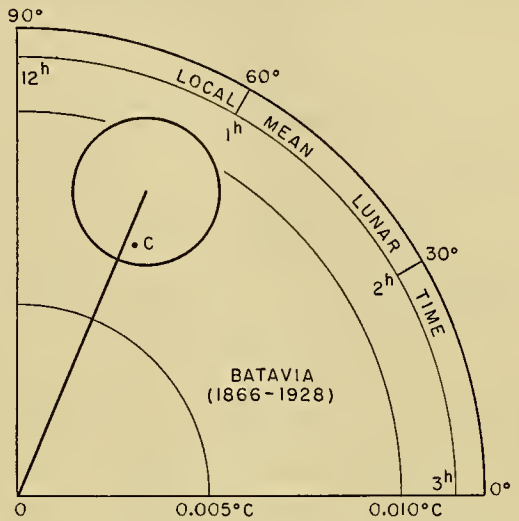

FIG. 11.—Harmonic dial specifying (with probable-error circle) the lunar semidiurnal tidal variation of *air temperature* at Batavia. The point *C* represents the variation calculated from the lunar semidiurnal variation of *barometric pressure* at Batavia, on the assumption that the density variations are adiabatic.

The Lunar Tidal Wind Currents. The tidal variations of sea level are accompanied by tidal currents (superposed on any other motions present, such as those in the Gulf Stream). Similarly in the atmosphere the L_2 pressure variation must be accompanied by tidal *wind* variations. These are best determined from bihourly values of the east-west and north-south component wind speeds. Only a few observatories, such as Mauritius and Bombay, have published such data, calculated from the usual wind records of direction and total speed. For this reason but little work has been done on the daily wind variations, whether solar or lunar. The only available *lunar* results are illustrated in Fig. 12*a* [47], which shows the L_2 dial vectors, with probable error circles, for the eastward and northward wind speeds at Mauritius, from sixteen years' observations (1916, 1917, 1920–33). The ratio l/r (see p. 514) is less than three, so that the determinations should be strengthened by using more data (which are available for Mauritius); similar investigations should be made also for other stations.

Figure 12*b* [47] shows in a similar way the dial vectors for the S_2 (solar semidiurnal) variations of east and north wind speed at Mauritius, derived from the same data, the amplitude scale being ten times less open than in Fig. 12*a*.

The ratios of the solar to the lunar amplitudes are of the order 20, rather greater than for the S_2 and L_2 pressure variations, for which at Mauritius the ratio is 17. The amplitude of the L_2 wind variations, about 1 cm sec^{-1}, is of the right order of magnitude according to the mathematical theory of these oscillations.

Figures 13*a*, *b* [47] show the actual wind-speed vectors due to the S_2 and L_2 wind variations at each hour of either half of the solar or lunar day (this diagram, of course, is not a dial diagram like Fig. 12). These wind velocities are superposed on any other local winds pres-

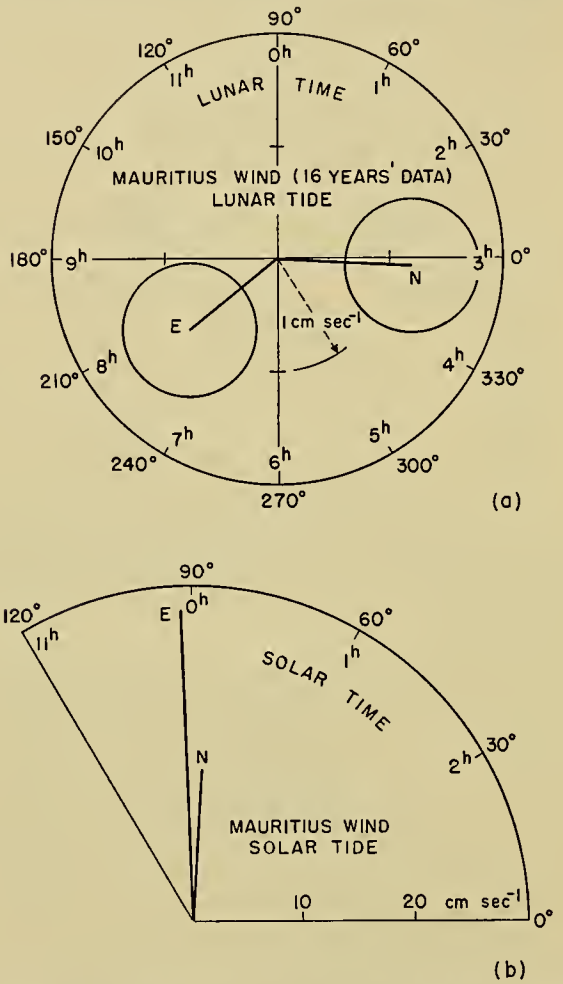

Fig. 12.—(*a*) Harmonic dial (with probable-error circles) for the annual mean *lunar* semidiurnal variations in the northward and eastward components of wind velocity at Mauritius, from about 16 years' bihourly data. (*b*) Harmonic dial for the corresponding annual mean *solar* semidiurnal variations. Note the tenfold scale difference between the two diagrams.

ent. The speed scale in Fig. 13*a* (lunar) is ten times more open than that for Fig. 13*b* (solar). The diagram Fig. 13*a* is, of course, not well determined.

The corresponding semidiurnal paths of Mauritius air particles due to these oscillations are similar in form and orientation to the ellipses of Fig. 13, which will represent these paths if all the time marks are advanced by three hours, and if the speed-scale is changed to a length-scale $T/2\pi$ times as great, where T denotes the duration in seconds of the (solar or lunar) half day. This factor is 6876 for the solar diagram 13*b*, and 7114 for the lunar diagram Fig. 13*a*. The distance scales are indicated on the left of each diagram. The extreme departure of any air particle from its mean position, at Mauritius, owing to these oscillations, is about 23 km for S_2 and about 1 km for L_2.

The Lunar Tidal Rise and Fall of the Ionospheric Layers. It has long been inferred from the evidence of the geomagnetic variations that there are horizontal lunar tidal currents in the ionosphere, the ionized electrically conducting region of the high atmosphere, containing at least two distinct layers, the E-layer at about 100 km height, and the F-layer at about 250 km. The first direct determination of the lunar tidal rise and fall of the high atmosphere was made in 1939 by Appleton

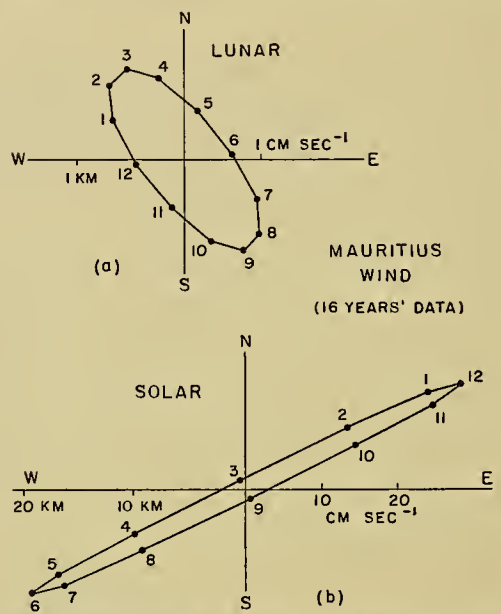

Fig. 13.—Diagrams based on Fig. 12, showing in plan the wind velocities at each lunar or solar hour (morning and afternoon) associated with the lunar and solar semidiurnal variations of wind at Mauritius. The velocity at each hour is represented (on the scale shown at the right) by the line (not drawn) from the center of the diagram to the numbered point for that hour. The diagrams also illustrate the corresponding *paths* of an air particle at Mauritius due to these wind variations, if the hour-numbers are increased by three; the distance scales are shown on the left of each diagram. Note the tenfold scale difference between the two diagrams.

and Weekes [6], who found from hourly radio measurements of the height of the E-layer above Cambridge, England, throughout several weeks, a lunar semidiurnal (L_2) variation of height of the E-layer amounting to 1 km above and below the mean level. This remarkable result is illustrated in Fig. 14, which shows eleven dial points each representing a determination from a period of twelve to fourteen days, between August 1937 and July 1938. The cross shows the mean dial point, and the probable error circle indicates the uncertainty of any one of the eleven points. The radius r for the mean point is $1/\sqrt{11}$ times less than this uncertainty, so that the determination is a good one.

Martyn [76–79] has lately examined the lunar tidal variations in the heights of the E- and F-regions, using the less accurate data available from routine recording at various ionospheric observatories throughout the

world.[6] Martyn finds at latitudes 35°S and 27°S a lunar variation in the height of the E-region which is opposite in phase to that found by Appleton and Weekes in the higher latitude of England. Martyn also finds lunar variations in both the heights and electron densities of the F-region. Near the magnetic equator these variations are very much larger than the already large variations found in the E-region. At Huancayo (Peru) the total tidal variation at certain hours and seasons amounts to some 60 km in height and 20 per cent in electron density. These variations concern the layers of electrons and ions interspersed among the neutral molecules of the high atmosphere. Their relation to the tidal oscillations of the main body of air requires consideration of electrodynamic as well as of hydrodynamic forces. There is no doubt that when the theory of these variations is fully understood the observational results will provide important and interesting information about the lunar atmospheric tide at high levels.

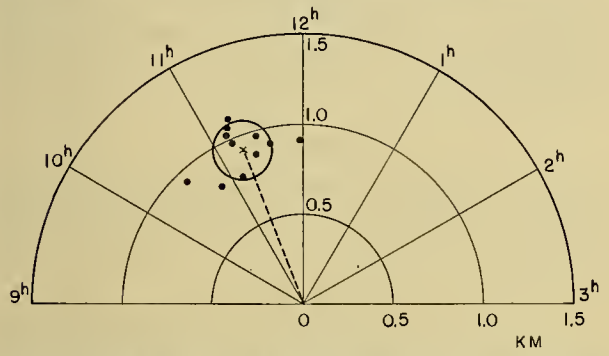

FIG. 14.—Harmonic dial [6] for the lunar tide in the E-region of the ionosphere. The circle shows the probable error for any one of the eleven separate dial points, each determined from 12–14 days' data.

Lunar Tidal Variations of Cosmic Rays. Cosmic ray observations provide, in a surprising and most interesting way, information as to the lunar air tide at a level of eighteen or twenty kilometres above the ground, though a precise interpretation of the data awaits further study. Among the cosmic rays received at the ground are mesons, supposed to be generated (by the primary rays) at this level; being unstable, a proportion of them are transformed on their way to the ground. If the lunar tide raises or lowers the level of the mean air pressure at which the mesons are generated, their path to the ground will be lengthened or shortened, and the number of survivors at ground level will be reduced or increased. Duperier [59] has made a reliable determination of L_2 in his recorded amounts of cosmic ray reception (mainly of mesons) at London, and has inferred therefrom that the lunar tide at about 18 km height is considerably magnified (about tenfold as compared with the equilibrium tide), though much less than in the ionospheric E-layer.

The Geomagnetic Lunar Tide. Nearly a century ago a small lunar daily variation was detected in the records of the components (or "elements") of the earth's magnetic field. This variation is produced (like the corresponding solar daily geomagnetic variation) mainly above the earth's surface, though these varying "primary" magnetic fields of external origin induce electric currents in the conducting body of the earth—mainly deep down, but also, to a lesser degree, near the surface, where they can be measured and recorded. The analysis of these earth-current records reveals solar and lunar daily variations, which form yet another curious by-product, as in the cosmic rays, of the high-level solar and lunar tidal atmospheric oscillations.

The external source of these solar and lunar daily geomagnetic variations consists of systems of electric currents flowing in some layer or layers (not yet clearly identified) in the ionosphere, and these currents are induced by mainly horizontal oscillatory large-scale motions of the ionospheric air. The process is similar to that in a dynamo, as first suggested by Balfour Stewart [42, 49]. The moving air corresponds to the armature, the conducting ionospheric layers to the armature windings, and the earth's main magnetic field to the field of the dynamo pole pieces.

From the determinations of S_n and L_n in the magnetic records of many stations it is possible to determine the distribution and intensity of these solar and lunar daily-varying electric current systems in the ionosphere, and also the *type* of the inducing atmospheric motions at those levels. To infer the *intensity* of these motions requires a knowledge of the electric conductivity of the layers in which the known electric currents flow. Until the precise situation of the currents is ascertained, and their electric conductivity, the intensity of the solar daily and lunar daily oscillations in the ionosphere cannot be precisely inferred from the geomagnetic data. The present indication is that the lunar tidal horizontal movements, like the lunar tidal rise and fall of the E-layer, are very greatly magnified as compared with what the barometric L_2 data would suggest. It is, however, of interest to note that the *ratio* of S_2 to L_2 in the magnetic records is about the same as that in the barometric variations. There is much scope for further investigation, both by observation and theory, of the bearing of the geomagnetic data on the solar and lunar daily atmospheric oscillations.

THE SOLAR SEMIDIURNAL OSCILLATION S_2

The Components S_n of the Solar Daily Barometric Variations. In middle and high latitudes the barometric variations are large, and mainly connected with weather changes. By averaging over many days selected in any way—days of a given season or calendar month, or days of high barometer or of rain—characteristic daily barometric variations can be determined. In the tropics, where large irregular barometric changes are rare, S_2

6. For other lunar ionospheric tidal determinations see [4, 5, 26, 81], and a forthcoming report by D. F. Martyn in the Zürich (1950) Proceedings of the International Union for Scientific Radio (U.R.S.I.). The lunar *diurnal* variation in the thickness of the F_2-layer in Alaska, reported by M. W. and J. G. Jones, in *J. Meteor*, 7: 14–20 (1950), is not real.

can be perceived (as also often at some European stations and others in moderate latitudes) even in the records for individual days.

By harmonic analysis the components S_n of the solar daily variation ($n = 1, 2, \ldots$) can be determined and separately studied.

The diurnal component S_1 [68, 69] differs remarkably from S_2, being (unlike S_2) much affected by local weather (cloud or sunshine) and topography. At the bottom of deep valleys it is greatly magnified. Its amplitude s_1 is much greater in summer than in winter; its phase σ_1 is about 90°, the maximum of S_1 thus occurring near local noon. It is not a world-wide oscillation, but a thermal effect [68, 71] sensitive to local influences. It will not be further considered here.

The components S_3 and S_4, with periods of eight and six hours, are also thermal effects (the sun's tidal action has no appreciable components with these periods). They result from the corresponding components T_3 and T_4 of the daily variation of air *temperature*, which they resemble in their geographical distribution and seasonal changes. For example, S_3 and T_3 have opposite phases in opposite hemispheres, and these phases are reversed from summer to winter. The S_3 barometric variation manifests a world-wide atmospheric oscillation [93], less simple and regular than the S_2 oscillation; the S_4 oscillation is still less regular [87]. These S_3 and S_4 oscillations should be further studied to fill in the framework of the whole subject of atmospheric oscillations [12–16, 18, 55, 102, 111].

The Solar Semidiurnal Oscillation S_2. In modern times Hann [63–67], Angot [3], Schmidt [92, 94], and Simpson [95] have taken a leading part in collecting and discussing the data for S_2. The literature is too vast to be cited here, but further references may be found in the papers quoted, particularly those of Hann.

Simpson's study was based on data from 214 stations. He illustrated the regularity of phase of S_2 in low latitudes by showing that at seventeen stations between latitudes ±10°, the local time of maximum of S_2 lay between 9.5^h and 10^h (A.M. and P.M.) at all but one, at which it was 10.3^h.

In the polar regions this uniformity of *local* time of maximum gives place to a different uniformity, that of *absolute* (*e.g.*, Greenwich) time of maximum [2, 9, 62]. At ten out of fifteen stations north of latitude 70°, this Greenwich time lay between 11.5^h and 12.5^h. As Schmidt [92] indicated, this shows that S_2 is a combination of a regular double wave travelling westward round the earth like the sun, and a semidiurnal oscillation of the air, symmetrical about the earth's axis, between the poles and the equator.

Simpson expressed S_2 at each station (in longitude φ east of Greenwich, expressed in time units, 15° per hour) as the sum of two terms corresponding to two such oscillations:

$$s_2 \sin(2t + \sigma_2) = b \sin(2t + B) + c \sin(2t - 2\varphi + C),$$

wherein t denotes *local* solar time and $t - \varphi$, *Greenwich* time. From 190 stations divided into eight latitude groups, from 10°S to 85°N, he determined b, B, c, C for each group, as given in Table I.

Table I. Constants for the Representation of S_2 at Various Latitudes [95]

Group		Travelling wave		Symmetrical wave	
Mean lat.	No. of stations	b (mm)	$B°$	c (mm)	$C°$
0	17	0.920	156.8	0.068	−4.0
18	15	0.835	155.3	0.082	−23.2
30	12	0.628	149.1	0.059	10.4
40	46	0.387	153.9	0.043	91.1
50	60	0.240	153.0	0.041	104.4
60	18	0.096	158.0	0.062	108.4
70	14	0.022	152.9	0.072	98.6
80	8			0.080	116.4
		Mean	154.1		

The phase B of the travelling wave has a remarkably small range (9° or ±9 minutes of time) in the eight zones. The amplitude b, decreasing steadily polewards from the equator, is well represented by the formula (l = latitude):

$$b = 0.937 \cos^3 l.$$

Up to about 60° latitude the other wave is of minor importance. Wilkes [111] has represented it by the formula:

$$[0.07 - 0.1 |\sin l|] \sin 2(t - \varphi) + 0.075 |\sin l| \cos 2(t - \varphi),$$

where $|\sin l|$ denotes the positive magnitude of $\sin l$.

Figure 15 shows dial vectors for S_2 (in barometric pressure) which relate to the points at their *thick ends* (not their centres, as in Figs. 5 and 7 for L_2). It illustrates

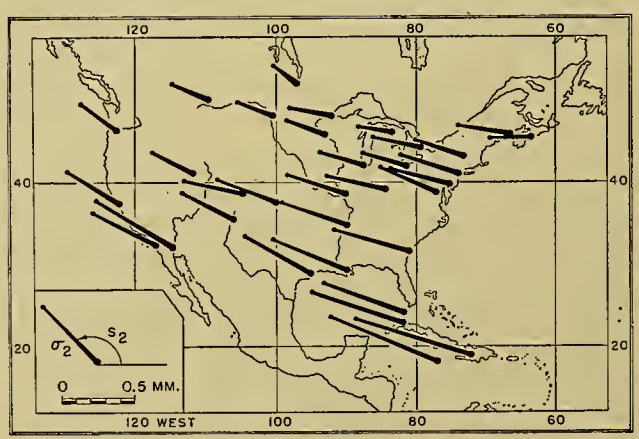

Fig. 15.—The distribution of the annual mean solar semidiurnal barometric variation (S_2) over North America. Each dial vector refers to S_2 at the point at its thick end (*cf.* with the lunar Figs. 5, 7, where each vector refers to L_2 at its centre).

the regularity of S_2 in phase and amplitude (decreasing northward) over North America; but it shows also that S_2 like L_2 (Fig. 7), though to a much less extent,

is reduced near the Pacific Coast [16]. This was noted by Hann, who also found that s_2 is less on the east Adriatic Coast than in Italy, and in the West Indies as compared with the East Indies, where indeed s_2, like l_2, is abnormally large.

The Annual Variation of S_2. The solar semidiurnal barometric variation also shows, as Hann indicated [67], considerable regularity in its change throughout the calendar year. This is illustrated in Fig. 16 by dial diagrams for four widely spaced stations in temperate latitudes (N or S), namely, (*a*) Washington, D. C. [16]; (*b*) Kumamoto (33°N, 131°E) [43]; (*c*) the mean of Coimbra, Lisbon, and San Fernando [57] (as in Fig. 10*f* for L_2); and (*d*) Montevideo, Uruguay [67].

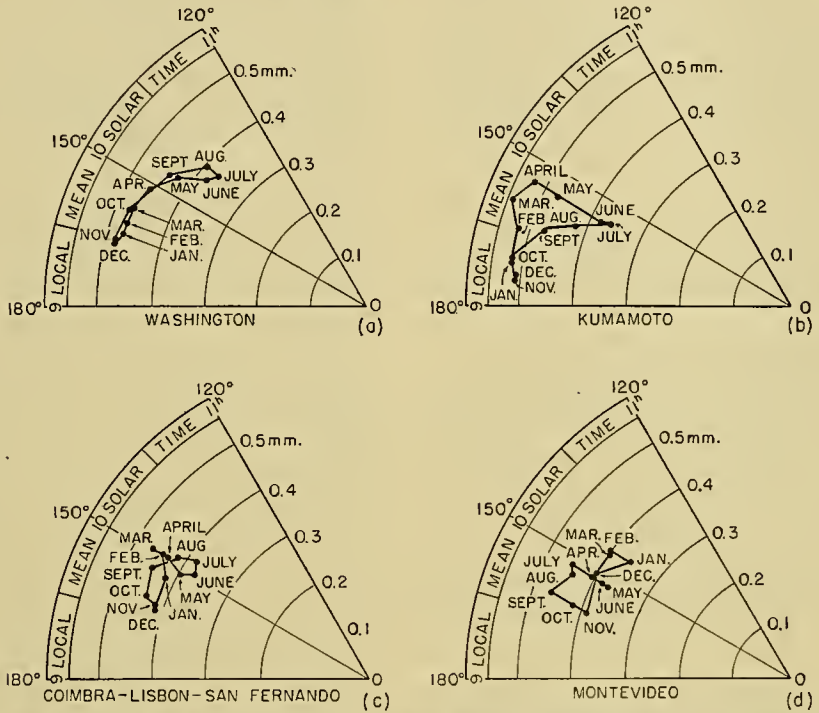

FIG. 16.—Harmonic dials indicating the annual change in the solar semidiurnal barometric variation (S_2) at four widely spaced points in middle latitudes, (*a*) Washington, D. C., (*b*) Kumamoto (33°N, 131°E), (*c*) mean of Coimbra, Lisbon, and San Fernando, (*d*) Montevideo, Uruguay.

The annual paths of the S_2 monthly dial points are much better determined than the L_2 paths in Fig. 10, yet they seem to differ more from one another, suggesting greater regularity of annual variation for L_2 than for S_2, which if established would be very remarkable.

Hann [67] considered separately the annual variations of s_2 and σ_2, though it would certainly be better to treat them together, that is, to discuss the annual movement of the S_2 dial point. He expressed the yearly variation of s_2 as the sum of a twelve-monthly and semiannual term:

$$s_2 = \alpha_0 + \alpha_1 \sin(x + \beta_1) + \alpha_2 \sin(2x + \beta_2),$$

reckoning x from mid-January at the rate 360° per year. He found that α_2 decreases polewards from the equator rather regularly, from 0.075 mm at the equator to 0.035 at 30° and 0.026 at 60° latitude, and that β_2 has a mean value of 311° from 0° to 40°S latitude, and 299° from 0° to 40°N. The corresponding means of α_1 and β_1 are 0.020, 0.078 and 134°, 94°. He discussed in much detail the regional irregularities in the distribution of α_1 and β_1.

As regards σ_2, Hann concluded that from 14°S to 50°N it has its maximum in January, and south of 14°S, in July. Figure 16 does not altogether confirm this. The many other details of Hann's discussion of S_2 cannot be summarized here. The data now available for S_2 and L_2 call for a more comprehensive comparative discussion than has yet been attempted.

THE THEORY OF THE ATMOSPHERIC OSCILLATIONS

Newton to Kelvin. Newton, in his *de Mundi Systemate* (the third part of his *Principia*) remarked that universal gravitation implies a tidal ebb and flow in the atmosphere as well as in the oceans. He rightly considered that it would be inappreciable—though it has been seen (on p. 519) that this flux and reflux *can* be determined by extensive computation from sufficient wind data.

Laplace in his dynamical theory of tides laid the foundation for all subsequent work on the subject. He first determined the tides of a liquid ocean completely covering a spherical rotating earth. In most of his work he took the ocean to be of uniform depth. Later he showed that he could associate the theory for such an ocean with the tidal oscillation of the (compressible) atmosphere, provided that the vertical accelerations are neglected (which we now know is permissible), that the

atmosphere is isothermal and of constant composition, and that the density variations accompanying the tidal motion occur isothermally.

Let p, ρ, T denote the pressure, density, and absolute temperature of the air at height Z above the ground, and let the suffix zero added to these and other symbols distinguish the values for $Z = 0$, that is, the ground values. The equation of static equilibrium of the air is

$$d(\ln p)/dZ = -1/H,$$

where $H = p/g\rho$ and the logarithm is to the natural base e. Clearly H is the height of the column of air of *uniform* density ρ required to give the pressure p (if the variation of g with height is ignored, though g is reduced by 3 per cent at 100 km). Hence H_0 is called the height of the homogeneous atmosphere; H is called the *scale height* of the atmosphere at the height Z, and is in general a function of Z.

In a perfect gas

$$p = knT = k\rho T/m = RT/M,$$

where

k denotes Boltzmann's constant (1.380×10^{-16} ergs per degree C),

n the number of molecules per cubic centimetre,

m the mean molecular mass,

$R = kN$, where N is Loschmidt's (less appropriately, Avogadro's) number (6.023×10^{23}) = 8.313×10^{7}.

M is the mean (chemical) molecular weight of the air (about 29); $M = Nm$. Hence

$$H = kT/mg = RT/Mg.$$

In the atmosphere considered by Laplace, H had the constant value H_0, because T and m are the same at all heights. Hence

$$p/p_0 = \rho/\rho_0 = e^{-z/H}.$$

Laplace showed that the tidal oscillations in such an atmosphere could be inferred from those for a liquid ocean of uniform depth H_0, which is therefore in this case called the (tidally) equivalent depth of the atmosphere. His theory, however, is not applicable to the actual atmosphere, in which T is not the same at all heights. Moreover, his condition that the density changes occur isothermally was doubtful. Newton had made the same assumption in his theory of sound waves, leading to an erroneous value for the speed c of sound, namely, $c^2 = p/\rho = gH$. Laplace had corrected this to $c^2 = \gamma gH$, where γ denotes the ratio of the specific heat at constant pressure to that at constant volume, to allow for the *adiabatic* character of such rapid density changes. It might well seem that for such slow oscillations as S_2 and L_2 the density changes would be isothermal, but calculation [34; 36; 111, p. 36] shows that they too must be adiabatic, because of the long wave length; and this is confirmed by the determination of the lunar tidal variation of air temperature at Batavia (p. 519).

It was to test his tidal theory that Laplace attempted, without success, to compute the lunar atmospheric tide L_2 for Paris. He realised that the magnitude of L_2 was very small, and as S_2 is so much larger he concluded that S_2 is due mainly to the sun's thermal action, the tidal contribution being insignificant. He seems also to have thought that there was little hope of constructing a theory of the oscillations produced in the atmosphere by its daily heating and cooling.

In 1882 Kelvin gave his attention to the subject, and in a presidential address to the Royal Society of Edinburgh [102] he quoted a table showing the 24-, 12-, and 8-hour periodic components (S_1, S_2, and S_3) of the solar daily barometric variation for thirty different stations. He pointed out that the 12-hour component exceeds the 24-hour component, especially in the higher latitudes, although in the daily variation of air temperature the 24-hour component is the larger. He suggested that the cause lies in the existence of an atmospheric free oscillation, of period nearer to 12 than to 24 hours, so that the 12-hourly thermal influence is magnified by *resonance*. His words were as follows:

> The cause of the semi-diurnal variation of barometric pressure cannot be the gravitational tide-generating influence of the sun, because if it were there would be a much larger lunar influence of the same kind, while in reality the lunar barometric tide is insensible, or nearly so. It seems, therefore, certain that the semi-diurnal variation of the barometer is due to temperature. Now, the *diurnal* term, in the harmonic analysis of the variation of *temperature*, is undoubtedly much larger in all, or nearly all, places than the *semi-diurnal*. It is then very remarkable that the *semi-diurnal term of the barometric effect* of the variation of temperature should be greater, and so much greater as it is, than the diurnal. The explanation probably is to be found by considering the oscillations of the atmosphere, as a whole, in the light of the very formulas which Laplace gave in his *Mécanique céleste* for the ocean, and which he showed to be also applicable to the atmosphere. When thermal influence is substituted for gravitational, in the tide-generating force reckoned for, and when the modes of oscillation corresponding respectively to the diurnal and semi-diurnal terms of the thermal influence are investigated, it will probably be found that the period of free oscillation of the former agrees much less nearly with 24 hours than does that of the latter with 12 hours; and that, therefore, with comparatively small magnitude of the tide-generating force, the resulting tide is greater in the semi-diurnal term than in the diurnal.

The Development of the Resonance Theory. The periods of free atmospheric oscillation, on a plane or spherical earth, were investigated by Lord Rayleigh [90], in 1890, with conclusions somewhat in favour of the resonance theory; but they could not be relied upon, partly because he did not take the earth's rotation into account.

Margules [75], with the explicit object of testing the resonance theory, investigated in much detail the free and forced oscillations of the atmosphere on the basis of Laplace's theory, and concluded that Kelvin's expectation was closely fulfilled. But Margules' conclusions cannot be relied upon either, partly because he did not take account of the true distribution of temperature with height in the atmosphere, which, indeed, at the time he wrote, was quite inadequately known. He also attempted to calculate the forced oscillations due to the daily variation of air temperature, on various hypotheses

as to its distribution with height, the most realistic being that its amplitude decreases exponentially upwards, as it would do if the heat were supplied at the ground and transmitted upwards by uniform conductivity; but he did not take into account the linear retardation of phase with height, which in this case should accompany the decrease of amplitude.

In 1910 Lamb [72] made a most important extension of Laplace's theory. His work related to an atmosphere on a plane base, thus abstracting from the problem the sphericity and rotation of the earth; but later [73] he removed these last two restrictions, though only for an atmosphere in convective equilibrium. His main discussion referred to an atmosphere in which H varies uniformly with the height ($H = H_0$ being a special case). He showed that the propagation of long waves in such an atmosphere is similar to that of long waves in a liquid ocean of depth H_0 in two special cases, namely, (1) Laplace's case, in which $H = H_0$ (or $T/m = T_0/m_0$) at all heights, and the density variations occur isothermally; and (2) for an atmosphere in adiabatic equilibrium (so that its height is $\gamma H_0/(\gamma - 1)$, the temperature T decreasing uniformly upwards to zero at the rate $(\gamma - 1)\, T_0/\gamma\, H_0$), and in which the density variations occur adiabatically (Laplace's case can be considered as corresponding to $\gamma = 1$).

The atmosphere is not in adiabatic equilibrium, so that it cannot be supposed, at least without further proof, that the tidally equivalent (liquid ocean) depth for the atmosphere is H_0. Lamb in fact showed that when H varies linearly with height, but not adiabatically, there is an infinite series of speeds for long waves, with the *implication* that there is a similar series of values of the equivalent depth h. However, the impression persisted for over twenty years that for any type of atmosphere there is just *one* value of h.

Lamb briefly discussed the resonance hypothesis of S_2 in his 1910 paper and in subsequent editions of his *Hydrodynamics*. He estimated from the improved form of Laplace's theory given by Hough [70], in terms of spherical harmonic functions, that if the atmosphere is resonant with a free oscillation similar to S_2 in its geographical distribution, h must be about 8 km, whereas for the actual atmosphere H_0 varies from about 7.3 km at the poles to 8.7 km at the equator. He continued:

> Without pressing too far conclusions based on the hypothesis of an atmosphere uniform over the earth, and approximately in convective equilibrium, we may, I think, at least assert the existence of a free oscillation of the earth's atmosphere, of "semi-diurnal" type, with a period not very different from, but probably somewhat less than, 12 mean solar hours.

He continued further:

> At the same time, the reason for rejecting the explanation of the semi-diurnal barometric variation as due to a gravitational solar tide seems to call for a little further examination. The amplitude of this variation at places on the equator is given by Kelvin as 0.032 inch. The amplitude given by the "equilibrium" theory of the tides is about 0.00047 inch. Some numerical results given by Hough in illustration of the kinetic theory of oceanic tides indicate that in order that this amplitude should be increased by dynamical action some seventy-fold, the free period must differ from the imposed period of 12 solar hours by not more than 2 or 3 minutes. Since the difference between the lunar and solar semi-diurnal periods amounts to 26 minutes, it is quite conceivable that the solar influence might in this way be rendered much more effective than the lunar. The real difficulty, so far as this point is concerned, is the *a priori* improbability of so very close an agreement between the two periods. The most decisive evidence, however, appears to be furnished by the *phase* of the observed semi-diurnal inequality, which is accelerated instead of retarded (as it would be by tidal friction) relatively to the sun's transit.

In 1924 Chapman [31] stressed the argument for strong resonance of S_2, based on the regularity of its geographical distribution, as compared with the considerable nonuniformity of the solar semidiurnal variation of air temperature (especially as between land and sea areas), which according to Lamb's last-quoted remark must be at least an important part of the cause of S_2. This argument he strengthened by contrasting the regularity of the geographical distribution of S_2, due partly to an irregular cause, with the degree of irregularity shown by L_2, whose cause is certainly distributed very regularly.

Chapman also extended Margules' calculation of the oscillations produced by the semidiurnal component of the daily variation of air temperature (T_2, see p. 522) taking account of the variation of phase (later discussed, in this connection, by Bjerknes [23*a*]), as well as of amplitude, with height. He concluded that the phase of the part of S_2 which is of thermal origin must be about 135° in advance of the phase of T_2, which he tried to estimate from the temperature data collected by Hann and others, using Taylor's estimate of the thermal conductivity due to eddy motion.

He also compared the magnitudes of the thermal and tidal contributions to S_2, which is possible because (substantially) both are affected by the same resonance magnification. He was able to show that they were of roughly equal order of magnitude (the inadequacy of the data regarding T_2 precludes a more accurate statement as yet), and on this basis he was able to explain the observed phase of S_2 from the phase of the thermal part, inferred from T_2, and on the assumption that the tidal part is in phase with the sun. This further enabled him to estimate the factor of resonance magnification as about 100. He was unable to prove that the atmosphere has a free period of oscillation (of the right geographical distribution) which would give this magnification. As the resonance magnification (when considerable) would be proportional to $1/(t_i - t_f)$, where t_i denotes the imposed period and t_f the free period, he concluded that despite the a priori improbability, $t_i - t_f$ cannot exceed 2 or 3 minutes, and is positive.

Whipple in 1918 [109], and also in 1924 in the discussion on [31], found great difficulty in accepting the resonance theory, on account of the possibility that such accurate "tuning" of the forced to the free oscillation might be upset by the large changes in air pressure and

temperature associated with weather and annual variations, and also on account of the difficulty the S_2 wave would have in twice daily surmounting the heights of Central Asia and the Rocky Mountains without losing a material fraction of its energy. These irregularities, however, are on a relatively small scale. The possibility that the variations of mean temperature from year to year might affect the tuning was examined by Bartels [12], but no such effect was found.

Taylor also was led to doubt the validity of the resonance hypothesis, despite the strength of the general arguments in its favour. Lamb had assumed, on the basis of the work already mentioned, that free oscillations of the atmosphere can exist which are identical, in distribution and period, with those of an ocean of such depth that long waves are propagated in it with the speed that he calculated for plane atmospheric waves. This assumption was used by Taylor [100] to estimate the period of the oscillation of S_2 type to be expected in an atmosphere in which the speed of propagation of long waves was that of the waves produced by the Krakatoa volcanic eruption of 1883. This great atmospheric pulse was propagated more than once round the entire earth, with a speed of 319 m sec^{-1}, which corresponds to an equivalent depth $h = 10.4$ km, a value markedly too great to give a free period (for an oscillation of S_2 type) nearly equal to 12 hours.

Lamb's assumption may be regarded as an extension of Laplace's theory of waves in an isothermal atmosphere. As realised later by Taylor, it involves the possibility that the atmosphere may have many equivalent depths, a contingency not possible in the atmospheres of the special type considered by Laplace and Lamb, for which $h = H_0$. Lamb's assumption is not obviously true, but in 1936 Taylor [101] proved its validity, and further developed Lamb's investigation of oscillations that are distributed in a similar way geographically (that is, as functions of longitude φ and colatitude θ), but have different height distributions of motion. In this work he was the first to take account of the cessation, at the tropopause, of the upward decrease of temperature.

The following year Pekeris [86] applied Taylor's methods to determine the free periods of an atmosphere in which the stratospheric temperature increases upwards above a certain height. This temperature distribution had been inferred from studies of the abnormal propagation of sound to great distances (beyond a zone of silence surrounding the source of sound), as well as from the heights of occurrence of meteors. Pekeris showed that, subject to a certain condition, the atmosphere could oscillate in ways corresponding to two equivalent oceanic depths. One of these was about 10 km, associated with a speed of propagation equal to that of the Krakatoa wave; the other gave a period (for a geographical distribution of S_2 type) of very nearly 12 hours, though the uncertainty of the upper atmospheric data precluded an exact calculation of the free period. The condition referred to was that the atmospheric temperature, after increasing upward above the stratosphere, should reach a maximum and thereafter decrease upwards to a low value. This was in agreement with the temperature distribution proposed by Martyn and Pulley [80] in 1936.

An important conclusion reached by Pekeris on this basis was that at high levels the pressure variation may be reversed in phase and highly magnified. This fitted well with the dynamo theory of the solar and lunar daily geomagnetic variations, the phases of which disagree with those of S_2 and L_2 at the ground, and the amplitudes of which, in the light of present knowledge of the electrical conductivity of the ionosphere, must be much greater than those of S_2 and L_2 at the ground. The magnified amplitude of L_2 there is confirmed by the determination [6] of the lunar tide in the E-layer, though the phase in the E-layer (over England) does not show the predicted reversal.

Pekeris [86] in 1939 re-examined the barometric traces for the Krakatoa waves and found evidence of a minor component wave propagated with the speed of 280 m sec^{-1}, corresponding to an equivalent depth of 7.9 km, accordant with a free oscillation (of S_2 type) with a period nearly equal to 12 hours. He showed that as the explosion occurred at a low level most of the energy of the pulse should go into the faster-travelling wave. (He estimated this energy as about 10^{24} ergs, roughly 1000 times that of the waves set up by the Nagasaki atomic bomb explosion.) The waves set up by the 1908 Siberian meteorite have been similarly examined [110] by Whipple.

The discussion by Pekeris has been extended by Weekes and Wilkes [107, 111], who have shown that according to theory the height distribution of the amplitude and phase of L_2 may differ materially in the ionosphere from that of S_2, if there is an upward rise of temperature in the E-layer followed by an upward decrease above some height in that layer, where the temperature has another maximum (with a further rise of temperature in the F-layer). The observational studies of the tidal motions and tidal changes of electron density in the different ionospheric layers, now being actively pursued [4, 5, 26, 76–81], will throw light on this possibility. Reliable measurements of ionospheric temperatures by rocket-borne instruments naturally provide a valuable additional basis for a detailed theory of the oscillations.

In the free oscillations of a liquid ocean of uniform depth h, the velocity components u, v, and w, and the departure Δp of the pressure from its mean value p (at each depth), have a relative geographical distribution (or variation with θ and φ) that is independent of depth. These dependent variables u, v, w, and Δp are taken to be proportional to (the real part of) $\exp i(s\varphi + \sigma t)$, where $2\pi/\sigma$ is the free period t_f. Laplace obtained a "tidal" equation which, for given values of s and h, determines a series of values of σ, and a corresponding series of functions representing the variation of u, v, w, and Δp with the colatitude θ.

The same equation is applicable to the *forced* oscillations of an atmosphere, whatever its temperature-height distribution (supposed uniform over the globe); in this case σ (as well as s) is known ($2\pi/\sigma$ is the imposed

period t_i), and the equation determines a series of values of h and a corresponding series of functions representing the latitudinal variation.

The height distribution of u, v, w, Δp, and $\Delta\rho$ (the departure of the density at any height from its mean at that height) is determined by a separate equation, conveniently expressed in terms of the pressure at each height, as an independent variable, by taking $x = -\ln(p/p_0)$. If we write

$$\text{div } \mathbf{v} = -D \ln(\rho + \Delta\rho)/Dt = (p_0/p)^{\frac{1}{2}}y,$$

where $\mathbf{v}$ denotes the vector velocity, and D/Dt the "mobile operator" [73], the equation is

$$\frac{d^2y}{dx^2} + \left[-\frac{1}{4} + \frac{1}{h}\left(\frac{\gamma - 1}{\gamma} H + \frac{dH}{dx}\right)\right] y = 0,$$

in which the height-distribution of the atmosphere (depending on the temperature T and the mean molecular mass m), is involved through H. In so far as y can be considered as of fairly constant order of magnitude (and this is a matter for examination by means of this equation), the expression for div $\mathbf{v}$ above indicates an upward increase of div $\mathbf{v}$ inversely proportional to $p^{\frac{1}{2}}$, that is, by 1000-fold at about the height of the E-layer.

Weekes and Wilkes have given an interesting interpretation of this equation by analogy with the propagation of electromagnetic waves in a medium having a variable refractive index. In the atmospheric case the expression for the analogous "equivalent" refractive index is

$$\mu^2 = -\frac{1}{4} + \frac{1}{h}\left(\frac{\gamma - 1}{\gamma} H + \frac{dH}{dx}\right).$$

If the height-distribution of H, for any value of h, makes μ^2 negative at a certain level, upward propagation of the energy, mainly put into the atmosphere by tidal or thermal causes in the lower layers, is effectively blocked. The air at that height acts as a barrier, total or partial, trapping the energy, and building up the amplitude in the whole spherical shell between the ground and the barrier, giving rise to resonance. If μ^2 is negative, not for all heights above the level Z at which it first becomes zero, but only for an interval of height, the barrier is partially transparent, and some of the oscillatory energy passes through it, either to a second (or third) barrier where there is a height interval of negative μ^2, or to the high levels at which thermal conductivity and dissipation of the energy into heat by viscosity become important. At these high levels the condition that $\Delta p/p$ or $\Delta\rho/\rho$ is small, as assumed in the equation, ceases to hold, and the modified differential equations will become nonlinear.

The conditions favouring negative μ^2 are that H should be small and that dH/dx should be either positive and small, or negative, corresponding to an upward *decrease* of temperature, because x increases upwards. The number of barriers to energy flow depends on the number of such regions of upward-decreasing temperature, but they alone are not sufficient to give a barrier, unless the value of h is appropriate, which in turn depends on the mode and period of the oscillation under consideration.

The boundary conditions in the equation for y are that at high levels the energy flow is upwards, and that at the ground ($Z = 0$ and $x = 0$) the vertical velocity is zero—unless the influence of the tidal motions of the under surface of the atmosphere (the tides in the oceans and in the solid earth) is being taken into account [12, 55], in which case at $Z = 0$ the vertical velocity w must have the corresponding distribution of values.

Wulf and Nicholson [112] have made a bold and imaginative attempt to explain the main irregularities of the geographical distribution of L_2, and its remarkable annual changes, stressing in particular the much greater and more widespread surface irregularities over the earth's Northern Hemisphere than over the Southern Hemisphere. Their suggestions need to be formulated and analysed mathematically, and tested also by reference to S_2, with its somewhat different geographical pattern and annual change.

The part of S_2 that is symmetrical about the earth's axis must be due to some inequality in longitude in the distribution of the semidiurnal component of the daily variation of air temperature, but no detailed study of this has yet been made.

SUGGESTIONS FOR FUTURE WORK

There is still great scope for useful extensions of our knowledge of the *facts* of the atmospheric oscillations, both solar daily and lunar daily. The newest and richest field of such observational and computational study is offered by the ionosphere with its several layers, each of which needs separate examination as regards the solar and lunar daily changes in its height, electron density, and other properties. Another new and almost untilled field of study is offered by the continuous records of cosmic radiation, whose components with different penetrative powers likewise deserve independent treatment. An older but far from exhausted field is that of the daily magnetic variations, which are causally due to the atmospheric oscillations in the ionosphere. Meteoric data may also add to our knowledge of the oscillations, though their more sporadic nature renders them less convenient for statistical treatment; this disadvantage may possibly be mitigated in the future if practical methods of radio observation of meteors, continuous throughout the day and night, are developed.

Even as regards the manifestation of the oscillations at ground level, where they have been studied for over a century, there remains much useful work to be done; the daily variations of pressure still need further study, and an improved treatment of the solar daily variation of air temperature is required to elucidate the thermal part of the solar half-daily tide. The lunar tide in air temperature found at Batavia might usefully be confirmed by a similar reduction for some continental station, and a reduction for some station on a small isolated island in mid-ocean would throw light on the systematic heat interchange between the air and the ocean.

The study of the lunar tidal winds has barely been

begun, and there is much scope for study of the periodic winds associated with both the solar and the lunar daily atmospheric oscillations.

In all these fields it is desirable to extend the search to the minor periodic components, such as the lunar diurnal tide, and the components associated with the changing distance of the moon.[7]

On the theoretical side also there is much scope for further work; the existing theory will need to be revised as our knowledge of the temperature-height distribution in the upper atmosphere advances through rocket investigations and in other ways; it will also need to be extended to take account of the nonuniform geographical distribution of temperature and of its height distribution in different regions. Moreover, the regional anomalies in the distribution of the lunar tide, as shown by the barometric variations, require quantitative explanation, including calculations of the effects of land and sea distribution as suggested by Wulf and Nicholson.

APPLICATION OF THE THERMODYNAMICS OF OPEN SYSTEMS TO METEOROLOGY*

By JACQUES M. VAN MIEGHEM

University of Brussels

HOMOGENEOUS SYSTEMS

Introduction. The systems which are generally considered in thermodynamics exchange energy (*e.g.*, heat) with their environment; however, they neither give up nor receive mass. It is for this reason that they are called *closed systems*. An *open system*, on the other hand, is a system which exchanges not only energy but also matter with the surrounding medium [4]. A cloud from which precipitation is falling is thus an open system.

It will be assumed in this first section that the system is homogeneous, that is to say that its physical variables (pressure p and absolute temperature T) are uniform throughout the volume V under consideration. This will always be the case in the atmosphere, provided one takes a volume of air which is not too extensive.

Uniformity of the quantities p and T involves an important consequence: The system cannot be the site of irreversible transformations which bring about the equalization of temperature or pressure between different points of the system. Therefore it is natural to suppose that physical transformations of the system, involving no internal modifications of mass, are reversible; only transformations involving changes of the masses m_j of certain of its constituents j may be irreversible.

At the foundation of any thermodynamic investigation lie two functions of state: the *internal energy* E and the *entropy* S of the system. With these are generally associated the *enthalpy* $H \equiv E + pV$ and the Gibbs *thermodynamic potential* $G \equiv H - TS$. Any one X of these functions depends on p and T, and on the masses $m_1, m_2, \cdots$ of the constituents. According to Gibbs, the functions of state of a system are homogeneous functions of the first degree in variables $m_1, m_2, \cdots$; therefore one has $X = \sum_j m_j x_j$, where the specific functions of state $x_j \left(\text{where } x_j = \frac{\partial X}{\partial m_j}\right)$ of the constituents j are homogeneous functions of zero degree in the variables m_j ($j = 1, 2, 3, \cdots$).

The First Law. The specific internal energy (per unit mass) of the system will be designated by e, its specific enthalpy by h, its specific volume by v, the heat added to the system from time t to time $t + dt$ ($dt > 0$) by dQ, and the heat added to the unit mass during the same time interval by dq. If we let m represent the total mass of the system, the following relations then hold: $H = mh$, $V = m\text{v}$, $dQ = mdq$.

The intensive (or local) form

$$dq = de + pd\text{v} = dh - \text{v}dp \qquad (1)$$

of the first law still applies when the system under consideration is open, provided that we assume the heat dq added to a unit mass includes, in addition to the heat received by radiation and conduction (the case of closed systems), the heat received by convection (an exchange of matter with the surrounding medium). Upon multiplying the two sides of (1) by m, we obtain the extensive form

$$dQ + hdm = dE + pdV = dH - Vdp \qquad (2)$$

of the first law for the case of an open system [7, 9, 14]. *The sum of the quantity dQ of heat received by the open system plus the enthalpy increase hdm of the system, resulting from exchange of matter with the surroundings, is equal to the increase dE in internal energy E of the system plus the term pdV.*

If the masses m_j of the constituents of the system are introduced, it is clear that $m = \sum_j m_j$. It should be noted that the total increase dm_j of mass m_j of constituent j arises from an increase $d_i m_j$ due to *internal* mass modifications and from an *external* contribution $d_e m_j$ ($\gtrless 0$) during the same time interval dt. Therefore $dm_j \equiv d_i m_j + d_e m_j$, with the condition $d_i m \equiv \sum_j d_i m_j = 0$, and as a result $dm = d_e m \equiv \sum_j d_e m_j \neq 0$. Furthermore the differential of any function of state whatever, for example H, assumes the form $dH = d_i H + d_e H$, with

$$d_i H = \frac{\partial H}{\partial T} dT + \frac{\partial H}{\partial p} dp + \sum_j h_j d_i m_j,$$

and

$$d_e H = \sum_j h_j d_e m_j,$$

where h_j is the specific enthalpy of constituent j. It then turns out, as a consequence of (2), that dQ can be written $dQ = d_i Q + d_e Q$, with

$$d_i Q = d_i H - Vdp, \quad d_e Q = \sum_j (h_j - h) d_e m_j, \qquad (3)$$

where the quantity $d_i Q$ of heat received by the system is associated with internal, physico-chemical changes of state which it undergoes during the time interval dt, while the quantity $d_e Q$ of heat received is associated with exchanges of mass with the surroundings during the same lapse of time. However, the separation of dQ into $d_i Q$ and $d_e Q$ was not accomplished as a result of the different mechanisms of heat exchange (radiation, conduction, or convection) between the system and the surroundings, but rather as a result of the effects produced by the added heat on the physico-chemical variables T, p, $m_1, m_2, \cdots$ of the system [14]. We observe

* Translated from the original French.

moreover that $d_eQ \equiv 0$ when the open system contains only a single constituent.

The Second Law. Gibbs' fundamental relation [2, 3, 5]

$$dH = TdS + Vdp + \sum_j \mu_j dm_j, \tag{4}$$

where $\mu_j \equiv \dfrac{\partial G}{\partial m_j} = h_j - Ts_j$ stands for the chemical potential of constituent j, is valid whatever the changes dT, dp, dm_j in state variables T, p, m_j of the system; consequently it is applicable to open systems. By substituting (2) into (4) it follows [7, 9, 14] that

$$dS - sdm = dQ/T + dQ'/T, \tag{5}$$

where the uncompensated heat of Clausius dQ' is defined by $dQ' = d_iQ' + d_eQ'$, in which

$$\begin{aligned} d_iQ' &= -\sum_j \mu_j d_i m_j \geq 0, \\ d_eQ' &= \sum_j (\mu - \mu_j) d_e m_j \gtrless 0, \end{aligned} \tag{6}$$

and $\mu \equiv h - Ts$. The specific entropy of the system is denoted by s, and $S = ms$. The increase dS which the entropy S of an open system undergoes from time t to time $t + dt$ ($dt > 0$) includes [7, 14]:

1. *The entropy change* due to exchange of matter and energy during the time interval dt,

$$dQ/T + d_eQ'/T + sdm \gtrless 0.$$

2. *The entropy production* in the interior of the system during the same time interval,

$$d_iQ'/T \geq 0.$$

The second law states that *the entropy production d_iQ'/T due to the internal mass transformation is real*, that is to say that the irreversibility of this transformation never entails destruction of entropy. By deduction from (3), (6), and (4),

$$d_iQ + d_iQ' = Td_iS. \tag{7}$$

Attention should be drawn to the fact that mass exchanges d_em_j between the system and the surroundings must take place at the temperature T and the pressure p of the system. This condition is usually satisfied in the case of a system which loses mass; when, on the other hand, mass enters the system the condition is no longer necessarily fulfilled. In the latter case it is well to make sure that this restriction is fully satisfied before applying the two laws which we have just formulated.

Fundamental Differences Between Open and Closed Systems. In the case of a *closed* system, the analytical expression $dQ = dE + pdV$ for the first law consists of three terms for each of which there is an exact, well-known physical meaning. We have already seen what meaning is assumed by the term dQ in the case of an *open* system. It should be noted that in this more general case the other two terms no longer have physical meanings. For example, the term pdV is no longer "the mechanical work done by the system during time interval dt," as a hasty generalization might lead one to believe [14]. Indeed, dV can be broken down into two additive terms, one of which d_eV depends essentially on the arbitrary addition of mass from the outside. Furthermore, when the boundary of a system is opened to an exchange of matter with the environment ($dm \neq 0$), the increase dX of any function of state X of the system is deprived of all physical sense. Mathematically, one obviously has $dX = mdx + xdm = \sum_j m_j dx_j + \sum_j x_j dm_j$. However, since the specific state functions x and x_j are determined only up to an arbitrary additive constant [14], the terms xdm and $x_j dm_j$ of dX have indeterminate values. On the other hand the expression $dX - xdm = mdx$ has a perfectly well-defined value, and consequently this is the case with expressions (2) and (5) for the two laws. Moreover, since the arbitrary constant which may be added to functions x and x_j is the same for all these functions [14], the differences $x - x_j$ and $x_j - x_k$, ($j, k = 1, 2, 3$), have well-defined values, and this is the case with expressions (3) and (6) for d_iQ, d_eQ, d_iQ', and d_eQ'.

In the case of a *closed* system, the second law can be written $TdS - dQ = dQ' = -\sum_j \mu_j dm_j \geq 0$, where $dQ' = 0$ corresponds to reversible transformations and $dQ' > 0$ corresponds to irreversible transformations. The physical meaning of the uncompensated heat of Clausius dQ' appears in the simplest fashion when a closed isothermal cycle is considered. During such a change of state, the uncompensated heat of Clausius received by the system is equal to the excess of the heat effectively given up over that effectively received by the system. In the case of an open system, however, dQ' is composed of two terms: the first depends on arbitrary addition or removal of mass and consequently may sometimes be positive and sometimes negative; the second depends on the internal physico-chemical transformation and is always positive. It is this latter term which actually generalizes, in the more realistic case of an open system, the classical concept of the uncompensated heat of Clausius.

In order to make clearly evident the differences in the significances of dQ and dQ', first for a closed and then for an open system, it is enough to set down the two laws for the case of a closed system consisting of two phases (a liquid and its vapor, for example) which undergoes only isobaric and isothermal transformations (vaporization and condensation at constant p and T), then to regard this system as being composed of two open systems (the gaseous phase and the liquid phase) and to see how the relations (2), (3), (5), and (6) reduce in this case [7].

Pseudoadiabatic Transformations. When the heat received by an open system does not alter the internal transformation of which the open system is the site, the system is said to undergo a *pseudoadiabatic* transformation [14]. In this case $d_iQ = 0$, and as a result of (3) and (7),

$$\begin{aligned} d_iH &= dH - \sum_j h_j d_e m_j = Vdp, \\ d_iS &= dS - \sum_j s_j d_e m_j = -\sum_j \frac{\mu_j}{T} d_i m_j. \end{aligned} \tag{8}$$

Let us now consider a system containing mass m_a of dry air, mass m_v of water vapor, and mass m_w of water (aqueous cloud), and further let us suppose that the system receives water or gives it up (rain). In this case

$$dm_a \equiv d_i m_a \equiv d_e m_a \equiv 0, \quad dm_v \equiv d_i m_v, \quad d_e m_v \equiv 0, \quad dm_w \equiv d_i m_w + d_e m_w,$$
$$d_i m_v + d_i m_w = 0, \quad dm = d_e m = d_e m_w \not\equiv 0. \tag{9}$$

The equation for pseudoadiabatic transformations of this system can be deduced at once from (8); it follows that

$$d_i S = dS - s_w d_e m_w = \frac{A_v}{T} dm_v \geq 0, \tag{10}$$

where $A_v \equiv \mu_w - \mu_v$ is the affinity of vaporization [2]. If S in (10) is replaced by its value $S = m_a s_a(T, p_a) + m_v s_v(T, p_v) + m_w s_w(T)$, where p_a and p_v represent the partial pressures of dry air and water vapor, we obtain, after using the relation $T(s_v - s_w) = L_v + A_v$ from [14], the differential equation of pseudoadiabatic transformations of moist air,

$$d\left(m_a s_a + \frac{m_v L_v}{T}\right) + (m_v + m_w) c_w \frac{dT}{T} + m_v d\left(\frac{A_v}{T}\right) = 0. \tag{11}$$

Here L_v stands for the heat of vaporization and c_w for the specific heat of water [14]. We suppose that the water vapor is at saturation value ($A_v = 0$), and we assume that the water that is brought in evaporates as soon as it is introduced or that the water formed in the interior of the system leaves as soon as it is formed ($m_w \equiv 0$, $d_i m_w = -d_e m_w = -d_i m_v$). Under these conditions the pseudoadiabatic transformation of the air is said to be reversible and dry [9, 14]; following (11)

$$d\left(s_a + \frac{r_v L_v}{T}\right) + r_v c_w \frac{dT}{T} = 0, \tag{12}$$

where $r_v \equiv m_v/m_a$ represents the mixing ratio of the water vapor. This equation is immediately integrable; employing the theorem of the mean, we find [9, 14]

$$(c_{pa} + r_v^* c_w) \ln T - R_a \ln p_a + \frac{r_v L_v}{T} = \text{const}, \tag{13}$$

where r_v^* is a mean value of r_v, c_{Pa} is the specific heat of dry air at constant pressure, and R_a is the specific perfect gas constant for dry air.

The finite equation (13) of reversible, pseudoadiabatic transformations of air saturated with water vapor is one of the fundamental equations of atmospheric thermodynamics; we have just derived it rigorously.

Polythermic Systems. A polythermic system is one in which all the phases do not have the same temperature. Since, by hypothesis, the temperature is a quantity which is constant throughout the interior of each phase, we can treat each one of them as an open system whose state is defined by the temperature of the phase, by the pressure p which is assumed the same for all phases, and by the masses of the constituents of the phase. The thermodynamics of polythermic systems, therefore, is only a special case of the thermodynamics of open systems [7, 14].

In order to establish our ideas, let us treat a closed polythermic system consisting of two phases: a gaseous phase (*first* phase) and a liquid phase (*second* phase). The gaseous phase comprises a mass m_a of dry air and a mass m_v of water vapor at temperature T'; the liquid phase, a mass m_w of water at temperature T''; the two phases are assumed to be at atmospheric pressure p. In this case we have $d_i m_a = d_i m_v = d_i m_w = 0$, $d_e m_a = 0$, $d_e m_v + d_e m_w = 0$, $dm_a = 0$, $dm_v \equiv d_e m_v$, $dm_w \equiv d_e m_w$. Application of the first law (2) to each of the two phases [7, 14] leads to the relation

$$[(d'Q)'' + h' dm_v] + [(d''Q)' + h'' dm_w] = 0, \tag{14}$$

which shows that the heat $(d'Q)''$ received by the *first* phase (gas) from the *second* phase (liquid) is not equal and opposite in sign to the heat $(d''Q)'$ given up by the *first* phase to the *second* phase. Furthermore, by a similar application [7, 14] of the second law (5) we obtain

$$dS = \frac{(d'Q)^*}{T'} + \frac{(d''Q)^*}{T''} + \left(\frac{1}{T''} - \frac{1}{T'}\right)(d''Q)' + \left[\frac{\mu_w(T'')}{T''} - \frac{\mu_v(T', p_v)}{T'} - \left(\frac{1}{T''} - \frac{1}{T'}\right) h_w(T'')\right] dm_v, \tag{15}$$

where $(d'Q)^*$ and $(d''Q)^*$ represent the heats added to the *first* and *second* phases by the surroundings of the system. It is clear that $d'Q \equiv (d'Q)^* + (d'Q)''$ and $d''Q \equiv (d''Q)^* + (d''Q)'$, where $d'Q$ and $d''Q$ are the quantities of heat received by each of the two phases. Equation (15) shows that the increase dS in the entropy S of the system consisting of two phases includes:

1. The change of entropy due to influx of heats $(d'Q)^*$ and $(d''Q)^*$ from the surroundings, and
2. The production of entropy resulting from exchanges of heat $(d''Q)'$ and matter dm_v between the phases. The second law states that there definitely is production and never destruction of entropy in the interior of the system.

Finally, the first law applied to the closed system consisting of the two phases provides the relation

$$dQ = dH - V dp, \tag{16}$$

where $dQ \equiv (d'Q)^* + (d''Q)^*$, and where the enthalpy H depends among other things on the temperatures T' and T'' of the *first* (gas) phase and the *second* (liquid) phase, respectively.

The fundamental equations (14), (15), and (16) allow studies to be made of the "horizontal mixing" of two air masses of different temperature and of the evaporation of rain in the free atmosphere [14].

The Temperature of the Wet-Bulb Thermometer and the Equivalent Temperature. Let us consider a closed system consisting of a mass m_a of dry air, a mass

m_v of water vapor at temperature T', and a mass m_w of water at temperature T''. Both phases are presumed to be at atmospheric pressure p. We will assume that the system undergoes only adiabatic ($dQ = 0$) and isobaric ($dp = 0$) transformations; in this case we have, (16),

$$m_a = m_a^*, \qquad m_v + m_w = m_v^* + m_w^*,$$

and

$$H(T', T'', m_a, m_v, m_w) = H(T'_*, T''_*, m_a^*, m_v^*, m_w^*),$$

where (T', T'', m_a, m_v, m_w) and $(T'_*, T''_*, m_a^*, m_v^*, m_w^*)$ represent two states of the system at the same pressure p. It turns out [14] that

$$\begin{aligned}(m_a c_{pa} + m_v c_{pv})(T' - T'_*) &= (m_v^* - m_v)\,[L_v(T'_*) + h_w(T'_*) - h_w(T'')] \\ &\quad + m_w^*\,[h_w(T''_*) - h_w(T'')],\end{aligned} \tag{17}$$

where $L_v(T'_*) = h_v(T'_*) - h_w(T'_*)$ is the heat of vaporization of water and c_{pa} and c_{pv} are the specific heats at constant pressure of dry air and water vapor.

Let us first consider a mass $(m_a + m_v)$ of moist air at temperature $T = T'$. At pressure p, assumed constant, we evaporate into this system a mass of water m_w such that the vapor becomes saturated at temperature T'_*. This temperature, which is represented by T_w, is by definition the temperature of the wet-bulb thermometer if the evaporating water assumes the temperature T_w of the saturated gaseous phase. Thus we are led to put $T' \equiv T$, $T'_* \equiv T'' \equiv T_w$, and $m_w^* \equiv 0$ in (17) from which is obtained the psychrometric formula

$$T_w = T - \frac{[r_v(T_w) - r_v(T)]L_v(T_w)}{c_{pa} + c_{pv} r_v(T)}, \tag{18}$$

where $r_v(T)$ stands for the mixing ratio of water vapor at temperature T.

Now let us consider a mass $m_a^* + m_v^*$ of moist air at temperature $T = T'_*$. We will assume that at constant pressure p one can condense the mass m_v^* of water vapor contained in the mixture. The temperature T' which the system then reaches is the equivalent temperature T_e of the moist air under consideration, provided it is assumed that the vapor can be condensed at temperature T'_* of the gaseous phase. Thus we are led to put $T'_* \equiv T'' \equiv T$, $T' \equiv T_e$, and $m_w^* \equiv m_v \equiv 0$ in (17), from which results von Bezold's formula

$$T_e = T + \frac{r_v(T)L_v(T)}{c_{pa}}. \tag{19}$$

We note that this isobaric condensation is a fictitious transformation, since it can never be realized physically.

NONHOMOGENEOUS SYSTEMS

General Remarks. The open nonhomogeneous system of greatest interest to meteorologists consists of a turbulent fluid. The *physical* state of the fluid is defined by the specific mass ρ and the pressure p, its state of motion by the components (v^1, v^2, v^3) of velocity $\mathbf{v}$ in a system of rectangular Cartesian coordinates (x^1, x^2, x^3), fixed with respect to the earth.[1] Scalars ρ and p and vector $\mathbf{v}$ are functions of x^1, x^2, x^3 and of time t.

By hypothesis, a mass element[2] $\rho\delta x^1\delta x^2\delta x^3$, moving at velocity v^k, exchanges no mass with the surroundings (absence of *molecular* diffusion). Therefore the system satisfies the equation of continuity in ρ and v^k; its movement is governed by gravity, the Coriolis force, and the pressure gradient force. The equations of balance of momentum $\rho\mathbf{v}$ defined by the components ρv^k, and of kinetic energy $k \equiv \frac{1}{2}v^i v^i$, can easily be deduced from the Eulerian equations of motion [11].

We designate by $\bar{X}$ the Reynolds mean of the function X and by $\widehat{X} = \overline{\rho X}/\bar{\rho}$ the corresponding weighted mean. It should be recalled that $\bar{X}' = 0$ and $\overline{\rho X''} = \bar{\rho}\widehat{X''} = 0$, where $X' \equiv X - \bar{X}$ and $X'' \equiv X - \widehat{X}$.

The *mean* state of the fluid is defined by $\bar{\rho}$ and $\bar{p}$, and its mean motion by $\widehat{v^k}$, $(k = 1, 2, 3)$. Since $\overline{\rho v''^k} = 0$ there is no diffusion at the scale of the mean state and of the mean motion, and as a result the mass element $\bar{\rho}\delta x^1\delta x^2\delta x^3$, moving at the mean velocity $\widehat{v^k}$, does not exchange matter with its environment. Therefore the mean system satisfies the equation of continuity in $\bar{\rho}$ and $\widehat{v^k}$. We know that the movement is governed by gravity, the Coriolis force (velocity $\widehat{v^k}$), the force due to the gradient of mean pressure $\bar{p}$, and the resultant force due to the Reynolds stresses $R_j^k \equiv R_k^j \equiv -\overline{\rho v''^k v''^j}$ $(j, k = 1, 2, 3)$. The equations of balance of the momentum components $\bar{\rho}\widehat{v^k}$ and of the corresponding kinetic energy $k_m \equiv \frac{1}{2}\widehat{v^j}\widehat{v^j}$ of the mean motion can easily be deduced from the equations of motion [11]. We observe that the absence of diffusion of mass ($\overline{\rho v''^k} = 0$) at the scale of the mean state does not imply the absence, at this scale, of diffusion of the properties of the fluid. In fact, if f represents the specific magnitude of any property whatever, we have in general $\overline{\rho f v''^j} \neq 0$. For example, by substituting $f \equiv v^k$ we would obtain $\overline{\rho v^k v''^j} = \overline{\rho v''^k v''^j} = -R_j^k$. Thus it appears that the Reynolds stresses R_j^k result from turbulent diffusion of momentum ρv^k. By contrast, a mass element $\rho\delta x^1\delta x^2\delta x^3$ moving with mean velocity $\widehat{v^k}$ diffuses mass and for this reason constitutes an open system, which does not admit an equation of continuity.

Finally, by subtracting the equations of kinetic energies $\widehat{k}$ and k_m, we find the equation of balance of turbulent kinetic energy $k_t \equiv \frac{1}{2}v''^i v''^j$ [1, 11],

$$\frac{\partial}{\partial t}(\bar{\rho}\widehat{k_t}) + \frac{\partial}{\partial x^j}(\bar{\rho}\widehat{k_t}\widehat{v^j} + \overline{\rho k_t v''^j}) = \bar{\rho}(\Delta_t + \Delta_i) \equiv \bar{\rho}\kappa, \tag{20}$$

where

$$\Delta_t \equiv \frac{R_j^k}{\bar{\rho}}\frac{\partial \widehat{v^i}}{\partial x^k} \quad \text{and} \quad \Delta_i \equiv \widehat{\frac{dv^k}{dt}\,v''^k}, \qquad (j, k = 1, 2, 3). \tag{21}$$

1. In order to simplify the discussion we have neglected molecular viscosity. Extension of the results of this section to the case of a viscous fluid does not present any difficulty [11].

2. By hypothesis, $\delta t \equiv 0$.

Here, Δ_t represents the fraction of kinetic energy of mean motion dissipated by turbulence per unit mass and time, and Δ_i the work per unit mass and time done in the course of eddying motion v''^i by the resultant of all the effective forces (excluding Reynolds' apparent force $\partial R_k^i/\partial x^i$) applied to the unit of mass considered. Work Δ_i can be regarded as being energy released by instability, per unit mass and time, in the course of the eddying motion v''^k [11]. When $\Delta_i < 0$, the turbulent motion is stable; when $\Delta_i > 0$, it is unstable [11]. In the first case Δ_i represents the fraction of turbulent kinetic energy transformed into heat per unit mass and per unit time; in the second, it represents the quantity of heat transformed into turbulent kinetic energy [13].

Finally we observe that turbulence can maintain itself only if $\kappa > 0$ (generalization of the criterion of L. F. Richardson). .

The First Law. The unit mass of the fluid (ρ, p, v^k) being a closed system, we can apply to it the principle of conservation of energy, from which we obtain [10]

$$\frac{d}{dt}(e + k + \varphi) = \frac{dq}{dt} - \frac{1}{\rho}\frac{\partial p v^k}{\partial x^k}, \qquad (k = 1, 2, 3). \quad (22)$$

This equation states that, *per unit mass and time, the increase in the sum of internal energy e, kinetic energy k, and potential energy φ, is equal to the quantity of heat received dq/dt, plus the surface work done by the surroundings on the unit of mass under consideration during the same time interval.*

Because of the equation of kinetic energy k and the equation of continuity in ρ and v^k, equation (22) takes the form (1), the enthalpy h being defined by $\rho h = \rho e + p$.

By setting

$$\rho \frac{dq}{dt} \equiv \rho\alpha - \frac{\partial W^k}{\partial x^k}, \quad (23)$$

where α represents the rate of production of heat per unit mass and W^k the components of heat flux (conductivity and radiation), equation (22) assumes (taking account of the equation of continuity) the form of an equation of balance [1, 11]:

$$\frac{\partial}{\partial t}\rho(e + k + \varphi) + \frac{\partial}{\partial x^k}\left[\rho(e + k + \varphi)v^k + pv^k + W^k\right] = \rho\alpha. \quad (24)$$

The existence of an equation of continuity for the system $(\bar\rho, \bar p, \widehat{v^k})$ justifies application of the Reynolds mean operation to the two sides of (24). By simplifying the equation thus obtained, with the help of the equation of kinetic energy k_m and of equation (20), we finally obtain the equation of balance of mean internal energy [11],

$$\frac{\partial}{\partial t}(\bar\rho\widehat{e}) + \frac{\partial}{\partial x^k}[\bar\rho\widehat{e}\widehat{v^k} + \overline{\rho h''v''^k} + W^k] = -\bar p\frac{\partial\widehat{v^k}}{\partial x^k} - \bar\rho\Delta_i + \overline{\rho\alpha}. \quad (25)$$

This equation shows that the apparent diffusion due to turbulence causes a flux of convective heat, described by its components [6, 11]

$$W_t^k \equiv \overline{\rho h''v''^k}. \quad (26)$$

Finally, if the equation of continuity in $\bar\rho$ and $\widehat{v^k}$ is substituted in (25), it follows [11] that

$$\frac{\widehat{d}\widehat{e}}{dt} + \bar p\frac{\widehat{d}}{dt}\left(\frac{1}{\bar\rho}\right) + \Delta_i = \frac{\widehat{d}q_m}{dt}, \quad (27)$$

where $\widehat{d}/dt$ represents the rate of variation of any quantity following the mean motion and where

$$\bar\rho\frac{\widehat{d}q_m}{dt} \equiv \overline{\rho\alpha} - \frac{\partial}{\partial x^k}(W^k + W_t^k) \quad (28)$$

represents the heat received per unit volume and per unit time. This quantity of heat includes the heat produced in a unit volume and the heat added by radiation, conduction, and convection (in the sense of the physicists).

Equation (27) states that *the quantity of heat received, per unit time and per unit mass of fluid, is equal to the sum of the increase in internal energy of the unit mass considered during this time interval, the mechanical work of expansion performed by this unit mass during the same time, and the energy of instability which it releases in this time interval.*

The Second Law. The second law states that the degradation of "noble" energy (in this case, kinetic energy) into internal energy or into heat is always accompanied by an increase in entropy. The evolution of the system is determined in this way.

In the case of a turbulent fluid there occurs simultaneously with this degradation the transformation of a fraction of the kinetic energy of mean motion into kinetic energy of turbulence, and also, more generally, a transformation of the kinetic energy at one scale of turbulence into energy at the scale of turbulence immediately smaller. Thus in a turbulent fluid, kinetic energy of motion is degraded not only into heat (the case of viscous fluid [11]), but also into kinetic energy of "inferior quality." The second law requires that the entropy of the system is always increasing in the course of these transformations of energy.

In order to account for this degradation, let us suppose that the mean physical state of a turbulent fluid has a corresponding mean specific entropy, which is a function of the mean internal energy and of the mean specific mass,

$$s_m = s_m(\widehat{e}, \bar\rho). \quad (29)$$

This satisfies the Gibbs relation (4),

$$\frac{\widehat{d}s_m}{dt} = \frac{1}{T_m}\frac{\widehat{d}\widehat{e}}{dt} - \frac{\bar p}{(\bar\rho)^2 T_m}\frac{\widehat{d}\bar\rho}{dt}, \quad (30)$$

where T_m is the "temperature" which characterizes the mean thermal state of the fluid and where

$$\frac{\widehat{d}}{dt} \equiv \frac{\partial}{\partial t} + \widehat{v^k}\frac{\partial}{\partial x^k},$$

($k = 1, 2, 3$). Upon substituting (27) and (28) into (30) we find, after taking account of the equation of continuity of mean motion [11],

$$\frac{\partial}{\partial t}(\bar{\rho} s_m) + \frac{\partial}{\partial x^k}\left[\bar{\rho} s_m \widehat{v^k} + \frac{W^k + W_t^k}{T_m}\right] = \sigma, \qquad (31)$$

where

$$\sigma \equiv -\frac{W^k + W_t^k}{(T_m)^2}\frac{\partial T_m}{\partial x^k} + \bar{\rho}\frac{(\widehat{\alpha} + \Delta_t - \kappa)}{T_m} > 0 \qquad (32)$$

represents the rate of production of entropy. The second law states that the entropy production is real ($\sigma > 0$). We recall that $\Delta_t - \kappa = -\Delta_i$ from (20).

Equation (31) shows that *the flux of mean entropy includes a convective flux and a thermal flux due to radiation, conduction, and turbulence. The production of entropy results from the nonuniformity of the temperature, from the production of heat, from the dissipation of kinetic energy of mean motion by turbulence, and from the destruction of turbulent kinetic energy* [11].

Finally, it should be noted that in the case of a viscous fluid the expression Δ_i which appears in (25), (27), and (32) must be replaced by $\Delta_i - \Delta_v$ where $\Delta_v (> 0)$ represents Rayleigh's dissipation function, that is, the fraction of kinetic energy of mean motion which is dissipated by viscosity (internal friction on the molecular scale) into heat per unit mass and per unit time.

The Heat Flux Due to Atmospheric Turbulence in the Vertical Direction. If it is assumed that the mean motion of the air is horizontal, the adiabatic eddying motion in the vertical direction is governed by the differential equation [11]

$$\frac{dv_z''}{dt} = -\frac{\Gamma c_{pa}}{\widehat{T}}[(\Gamma - \gamma) r_z - T_*''], \qquad (33)$$

where v_z'' = the eddying velocity in the vertical z direction,
r_z = the mixing length,
$\widehat{T}$ = the mean temperature of the dry air,
γ = the vertical lapse rate $-\partial\widehat{T}/\partial z$,
Γ = the adiabatic lapse rate (g/c_{pa} where g represents gravity),
T_*'' = the excess of the temperature of the parcel above the mean temperature of the level from which it originated.

After multiplying (33) by $\rho v_z''$ we obtain the expression for the energy of instability Δ_i released during the eddying motion, (21),

$$\bar{\rho}\Delta_i = \overline{\rho v_z'' \frac{dv_z''}{dt}} = -\frac{\Gamma c_{pa}}{\widehat{T}}[A(\Gamma - \gamma) - \overline{\rho T_*'' v_z''}], \qquad (34)$$

where $A \equiv \overline{\rho r_z v_z''} > 0$ is the exchange coefficient (Schmidt's austausch) in the vertical direction.

As for the heat flux W_t resulting from the adiabatic eddying motion in the vertical direction, it is given by (26):

$$W_t = c_{pa}\overline{\rho T'' v_z''} = -Ac_{pa}(\Gamma - \gamma) + c_{pa}\overline{\rho T_*'' v_z''}. \qquad (35)$$

The first term of the last member of (35) represents the flux of Schmidt and the second, the thermo-convective flux (Ertel, Priestley, and Swinbank) due to differences between the temperatures of parcels from the same level. These differences are initiated and maintained by sources of heat whose distribution is determined by $\overline{\rho\alpha}$. Because of this fact, parcels which are displaced vertically experience an additional hydrostatic buoyant force per unit mass equal to $gT_*''/\widehat{T}$. According to whether $T_*'' <$ or > 0, that is to say according to whether the particle is more or less dense than its surroundings, we have $v_z'' <$ or > 0 and consequently $T_*'' v_z'' > 0$. This inequality brings out the manner of organization of thermal convection. It turns out that the energy of instability due to the excess T_*'' of the parcel's temperature above the mean temperature of its starting level is always positive and therefore corresponds to a positive production of turbulent kinetic energy. This production can result only from a transformation of heat into kinetic energy, and consequently

$$\overline{\rho\alpha} > \frac{\Gamma c_{pa}}{\widehat{T}}\overline{\rho T_*'' v_z''} > 0. \qquad (36)$$

Moreover we observe that the thermal-convective flux of heat is always upward.

Finally, by returning to equation (32), it can be shown that the intensity of the entropy source associated with heat flux (35) is given by

$$\sigma = \frac{Ac_{pa}(\Gamma - \gamma)^2}{(\widehat{T})^2} + \frac{c_{pa}\gamma}{(\widehat{T})^2}\overline{\rho T_*'' v_z''} + \frac{1}{\widehat{T}}\left[\overline{\rho\alpha} - \frac{c_{pa}\Gamma}{\widehat{T}}\overline{\rho T_*'' v_z''}\right] > 0, \qquad (37)$$

provided that $T_m \equiv \widehat{T}$. From (36) and the inequality $\gamma > 0$, the inequality of (37) is always verified. The flux W_t is therefore compatible with the second law of thermodynamics without the necessity of assuming a priori that it is upward (as Ertel claims). It should be noted[3] that the heat flux of Schmidt involves an effective production of entropy represented by the perfect square in the first term of the expression for σ.

Application to the General Circulation of the Atmosphere. The equations which we have considered above can be of use in the study of the general atmospheric circulation. The "mean motion" is then a zonal current (westerly or easterly), and the "eddying motion" cor-

3. Bibliographical information and further details can be found in [11].

responds to perturbations embedded in this current. In this case it is clearly a question of turbulence on a very large scale (synoptic scale), essentially different from the small-scale turbulence which is usually studied. At the scale of the general circulation it becomes difficult indeed, if not impossible, to admit the conservation of potential temperature and of momentum or angular momentum of the large eddies along their trajectories.

On the other hand nothing allows us to state a priori that a fraction of the kinetic energy of the zonal current is really transformed into kinetic energy of large-scale turbulence (macroturbulence); in this case, the opposite might very well occur and probably does occur. In short, a thermomechanical theory of macroturbulence (*Grossturbulenz* of A. Defant) remains to be worked out.

The equations of balance of momentum and kinetic energy can be used to obtain qualitative indications of the production and transport of these quantities in the atmosphere [8, 12]. Unfortunately, in the case of large-scale turbulence we do not have the exact values of the Reynolds stresses R^k_j, the fraction Δ_t ($>$ or $<$ 0) of the kinetic energy of mean motion dissipated by turbulence, and the energy of instability Δ_i released in the course of the eddying motion. It is therefore impossible to make a quantitative theoretical study of the distribution of sources of zonal momentum, of kinetic energy, of internal energy, and of entropy, as well as of their manner of redistribution in the atmosphere.

Knowledge of the tensor of large-scale turbulence would permit us to achieve a better comprehension of the processes and the evolution of the general circulation of the atmosphere. New investigations, both theoretical and synoptic, into the sources and the flux of momentum, of energy in its various forms [13], and of entropy appear desirable.

Final Remarks. When the system under consideration is homogeneous, the fundamental equations of thermodynamics can be written for the case of arbitrary addition of mass ($dm \gtrless 0$) to the system. These equations have manifold applications not only in meteorology (clouds with precipitation, evaporation of precipitation, mixing of air masses of different temperatures, psychrometry), but also in chemistry, in biology, and in industry.

The situation is not quite the same when the system is nonhomogeneous (gradients of T and p), for in this case the material points of the system are necessarily in motion. Now the notion of movement can be defined and studied only if the moving element retains its identity in the process of its displacement; in other words, a system of dynamical equations can give a true representation of motion only if it includes the equation of continuity of mass, expressing the invariance of the mass of an element along its trajectory. Furthermore, in the case of a nonhomogeneous system, it is necessary to adopt in succession two scales of observation: first the microscopic scale, that is, the scale of the individual elementary eddy (the scale of the molecule, if one envisions diffusion and molecular viscosity), then the macroscopic scale, that is, the scale of the mean motion. It must be observed that the latter scale cannot be adopted arbitrarily, for there must be no diffusion of mass at this scale ($\overline{\rho v''^k} \equiv 0$). If this were not true, there would be no equation of continuity on the macroscopic scale, and it would be impossible to define and study the mean motion. Therefore the extension of the laws of thermodynamics for nonhomogeneous systems, to which mass can be added or removed arbitrarily, encounters difficulty in the very beginning unless it is possible to satisfy the condition $\overline{\rho v''^k} \equiv 0$. We shall assume this condition to be met; then for an observer who is carried along with the mean motion and follows the evolution of the system on a microscopic scale, the flux of the diffusion of mass is expressed by means of $\rho v''^k \neq 0$ and the intensity of diffusion by means of $-\overline{\frac{\partial \rho v''^k}{\partial x^k}} \neq 0$ ($k = 1, 2, 3$). However, as we have said before, the absence of diffusion at the scale of mean conditions ($\overline{\rho v''^k} \equiv \overline{\frac{\partial \rho v''^k}{\partial x^k}} \equiv 0$) does not imply the absence at this scale of diffusion of any arbitrary property f (intensive quantity) of the fluid, within the flow of which the mean flux of f is given by $\overline{\rho f v''^k} \neq 0$. Thus it is possible to carry out a study of the turbulent diffusion (eddy diffusion) in the atmosphere of water vapor ($f \equiv$ the specific humidity ϵ) or of any other substance in suspension in the air, of sensible heat ($f \equiv c_{pa}T$), of latent heat ($f \equiv \epsilon L$), of internal energy ($f \equiv e$), of entropy ($f \equiv s$), of kinetic energy ($f \equiv k$), of momentum ($f \equiv$ v), etc.

One final remark: The necessary condition $\overline{\rho v''^k} \equiv 0$ shows that v''^k is the fluctuation relative to a weighted mean, and consequently the components of the mean flow are necessarily the weighted means $\widehat{v^k}$ of the components v^k of the velocity of the elementary eddies. The weighted mean has the unique property of decomposing, in an additive fashion, the average of the total kinetic energy k into kinetic energy of mean motion and mean kinetic energy of turbulence ($\widehat{k} = k_m + \widehat{k_t}$). No other mean possesses this same property. Therefore, it is impossible to avoid the necessity of introducing the weighted mean into the study of turbulence of fluids.

THE PHYSICAL BASIS FOR THE GENERAL CIRCULATION

By VICTOR P. STARR

Massachusetts Institute of Technology

Since time immemorial man has inescapably observed the atmosphere in which he lives and has his being. It would therefore seem reasonable to expect that at the present date the science of meteorology should be one of the most advanced fields of human endeavor. Yet, if a distinction is made between the mere collection of descriptive facts of observation on the one hand and interpretative work which aims to give a rational intellectual understanding of phenomena on the other, it must be confessed that our knowledge concerning the large-scale motions of the atmosphere is restricted mostly to the former category of information. Thus, for example, no one has as yet given a satisfactory rational explanation for one of the most outstanding features of the general circulation, namely the large belts of westerly winds in the temperate latitudes of each hemisphere. However, it must be recognized that it is only in the last few decades that anything approaching sufficiently complete global observations *for the checking of hypotheses* regarding the general circulation has become available, so that progress at a more accelerated pace should now be forthcoming.

The physiognomy of present-day meteorology bears much of the imprint imparted to it by the (so to speak) accidental way in which synoptic reporting networks developed and grew. In fairly recent times it was quite an achievement for a meteorologist to have at his command a network of reports large enough to depict an entire cyclone. The immediate temptation was then to treat this feature as an independent entity and to separate it artificially from its meteorological environment in seeking a rational explanation for it. The cyclone thus became a phenomenon that existed independently. More extensive observations now available point to the inadequacy of this tacit assumption. The cyclone constitutes a cogwheel in a larger mechanism and probably can be understood only in relation to and not independent of its atmospheric context.

A criticism which is the same in principle can be leveled against many other efforts to explain synoptic structures. Indeed meteorology is replete with attempts to formulate *ad hoc* explanations for individual details of the general circulation without due cognizance of their role as functioning parts of a global scheme.

In the more recent literature there are signs that we are outgrowing this restricted point of view; there are indications which emphasize the essential oneness of the atmosphere which must be studied as an internally integrated and coordinated unit. The general circulation presents a puzzle to be solved. We must learn how the various parts fit together into a whole if we are to understand it. With the hemispherical data now becoming available and the clues already at our disposal the avenue to sound progress is wide open and, at least as far as the writer is concerned, quite inviting.

It is therefore in the spirit of appraising our knowledge from the larger point of view that this commentary is written. Admittedly and intentionally the treatment reflects the writer's viewpoint gained through a number of years of concentration on the subject under consideration. As a candid personal sidelight it should be mentioned, however, that much of the material is in a sense a relatively recent culmination of the writer's striving toward a more unified and coherent conception of the global circulation. Nor is there currently any sign that this process has reached a state of final crystallization. This paper is therefore in the nature of an individualistic progress report designed to portray and to share with others a certain outlook and approach in the hope that really substantial and enduring progress may eventually be attained thereby. Within the space of these pages we cannot hope to give anything approaching an exhaustive exposition of various topics. For this reason only certain basically important highlights will be elaborated, and we shall rely upon the reader's competence to interpolate various items of information which are generally available in the literature. Furthermore, the selection of the subjects touched upon is not one dictated by an aim at logical completeness, but rather is limited to those aspects which in the writer's mind are most likely to be conducive to further results at the present stage of development of the science.

As an outstanding problem of paramount importance for human activities, it is rather astonishing that the global circulation of the atmosphere has not up to the present time received more consideration from physical scientists generally. This situation is probably due in part to the lack of proper observational information so necessary for the successful prosecution of research concerning the subject. The gaps in at least our gross factual information are currently being removed rather rapidly, with the consequence that questions regarding the proper interpretation of the data begin to be the major issues. We might, with benefit in this connection, digress for a moment and compare the development of meteorology with that of another physical science, namely astronomy. No one can dispute the claims that Galileo and Newton created a new and orderly conception of the solar system. This achievement was necessarily preceded not only by the laborious accumulation of observational knowledge by Tycho Brahe and others but also by the proper interpretation of these data by Kepler who, it might be said, defined in precise terms the dynamic puzzle to be resolved. In meteorology we find ourselves in what might be called

the Keplerian era. It behooves us to marshal and correlate our observations into as precise and consistent a scheme as possible in order that we may know in sufficient detail what is to be explained.

From what has been said it might seem to the reader that meteorology must still undergo a rather protracted period of development before results can be expected at the final fruition of this process. Although there is reason to expect this pattern of events in the philosophical aspects of the subject, it should not be forgotten that the main practical use of meteorological knowledge, the preparation of weather forecasts, is at present largely an empirical procedure. As such, every improvement in our empirical information about the atmosphere enhances in some degree the possibility of improved forecasts, even though satisfactory understanding still remains to be achieved. Here only the intellectual aspects of problems are touched upon, leaving any possible practical applications for treatment elsewhere.

Following the general plan implied in what has been said, let us begin by examining how the general circulation, as we observe it, *achieves internal dynamic consistency in several important respects.* As will be seen, this is merely the extraction from data and interpretation of certain information, and does not in any sense constitute an *explanation* of why the facts are as they are found. In order to concentrate attention on the most basic processes, let us first consider the mean state, leaving the temporal fluctuations in the general circulation as a problem of much greater difficulty to be touched upon later.

If an observer equipped with suitable instruments were to measure the motions of the atmosphere from some extraterrestrial vantage point, in the same manner as we measure the motions in the sun, he would probably be impressed by the irregularities of the details, but at the same time he would discern that there is a pronounced general drift of the air from west to east relative to the earth in middle latitudes, extending from the surface to the stratosphere and even beyond. On the other hand, in the more equatorial regions (and at times near the poles, at least the North Pole) he would discern a drift from east to west from the surface to great heights. This situation immediately poses perhaps the most important problem concerning the general circulation. The specific question involved here is how the belts of westerlies can maintain their high rate of rotation in the face of the retarding effect of surface friction, flanked as they are by oppositely directed winds on at least their equatorial sides. No really satisfactory rational theory for this state of affairs has yet been given, although some deductions can easily be made concerning the nature of certain aspects of the mechanism which is necessary to maintain these existing motions.

The retarding effect of the surface frictional forces on the middle-latitude westerlies may be looked upon as a continuous abstraction of absolute angular momentum from the atmosphere in these regions. According to simple principles of Newtonian mechanics, this drain can be compensated only by an equivalent flow of angular momentum into the westerly belts. Likewise the surface frictional effect in the regions of the easterlies may be interpreted as a flow of angular momentum from the earth into the atmosphere. In order that the angular momentum so transferred into the easterly regions should not progressively accumulate and destroy these wind systems, it is necessary that an equivalent flow out of these regions should exist.

The inescapable conclusion is that the accounts are balanced by a flow of angular momentum from the easterlies in the more tropical regions poleward to the westerly belts (the polar easterlies are of relatively small importance in this connection). Such a flow of angular momentum, let us say northward at the northern border of the tropical easterlies, can be measured in terms of an equivalent tangential stress acting across a vertical surface parallel to the latitude circle. A crude estimate of the value of this stress may be made from existing information concerning the surface frictional forces on the easterlies to the south.[1] The result is of the order of 50 to 100 dynes cm^{-2}. Molecular and small-scale eddy viscosity cannot transmit stresses of this magnitude under the existing conditions, so that very large-scale nonzonal components of motion must furnish the necessary eddy-transfer of angular momentum. We thus come to the very pertinent observation due to Jeffreys [5], namely that the large nonzonal components of motion in the atmosphere are necessary for the maintenance of the average zonal components.

Most classical models for the general circulation as well as some more recent ones (see for example Rossby [9]) have followed along lines originally proposed by Hadley [4] in that they assume the existence of large, slow, convectively driven closed circulations in meridional planes. The development of the mean zonal motions is then ascribed to the effect of the earth's rotation on these primary circulations. According to this view the necessary transport of angular momentum could be achieved if, for example, the poleward branches of the meridional circulations carry more angular momentum than the returning ones at other levels.

For several reasons many modern meteorologists have come to view models of the Hadley type with skepticism. In the first place, the warmest regions of the atmosphere are not usually found in the tropics as most schemes of this kind visualize, but rather some distance away from the equator. Also, at best it is difficult to account for the great extent of the westerlies in the atmosphere on any such basis. Finally, there is a suggestion in the climatological distribution of precipitation and in the poleward flow of air in the friction layer for the existence of a slow meridional circulation with an upward branch in middle latitudes and a downward branch toward the subtropics, as originally suggested by Bergeron [2]. Such a "reverse" cell with equatorward flow aloft would, due to the action of Coriolis forces, tend to establish east winds in the

1. It is here assumed that the main transfer of momentum takes place in the troposphere.

region where the strongest westerlies are actually encountered. The writer rather inclines to the view that although very small mean meridional circulations do perhaps exist, their role in the horizontal transport of angular momentum, at least in the middle latitudes, is overshadowed by the characteristics of other horizontal motions. This is not in conflict with the views expressed by Jeffreys [5] and is reinforced by analysis of data to be quoted presently.

If emphasis is placed upon the horizontal circulations in transporting angular momentum poleward, by and large the zonal and meridional components of velocity should be correlated at each level where such transport occurs. Evidences of this correlation are then to be expected in the detailed structure of the instantaneous horizontal streamline patterns observed, as pointed out by the writer elsewhere [10]. Qualitatively these expectations are amply borne out even by casual inspection of weather maps. Except at high latitudes, closed horizontal circulations usually exhibit a northeast-southwest elongation (Northern Hemisphere) and the troughs, ridges, and shear lines show a tendency to tilt in this same sense. All these characteristics are recognized almost instinctively by the meteorologist as typical of atmospheric flow patterns. From our viewpoint they are telltale indications of a poleward flow of angular momentum. One may nevertheless ask whether an objective quantitative evaluation of the transport by this mechanism can be made from actual hemispheric data. For it is not sufficient to advance merely a qualitative substitute for the classical hypothesis without investigating the potency of the new alternative to produce the needed effect. A question involved here is whether the observations we possess are extensive enough and of sufficient accuracy. It is a simple matter to set up an integral expression for this (say) northward flow of absolute angular momentum across the vertical surface at a given latitude after the manner of Jeffreys, or to derive it from the atmospheric equations of motion as has been done by Widger [17]. The latter author proceeded to evaluate this flow of angular momentum by finite difference methods, as follows.

During the last several years sufficient observations of the free atmosphere have been made to allow the construction of daily isobaric charts through most of the troposphere. In addition it is becoming possible to obtain fairly complete direct radiowind observations extending to great heights on a circumpolar basis within restricted latitude belts. The global wind distributions may be approximated from isobaric charts according to the geostrophic wind formula or may be taken directly from actual wind observations. The use of the geostrophic estimates may introduce certain errors for the present purpose. On the other hand this use of the geostrophic winds automatically excludes the contributions to the angular momentum transport due to mean meridional circulations of the Hadley type, so that an advantage is gained if it is desired to study other modes of such transport. Several surveys of the angular momentum balance have been made in the past few years (Widger [17], Mintz,[2] Starr and White [12]) both from isobaric charts making use of the geostrophic approximation, and directly from a circumpolar network of actual wind observations. The survey of the angular momentum balance made by Widger covers the month of January 1946 and the results give the total geostrophic transfer by latitudes for various layers during this period up to the 7.5 km level. In this study estimates were made of the surface frictional torques. The investigation by Mintz covers the month of January 1949 and his results give the geostrophic flux of angular momentum at various levels up to 100 mb. Starr and White made use of a circumpolar network of actual wind observations at a mean latitude of 31°N for a period of six months from February 1949 to August 1949 up to an elevation of 50,000 ft. For various details of these investigations reference must be made to the original papers.

The computations give results which are entirely reasonable, being quite in accord with what would be expected on the basis of the foregoing discussion. Thus the total northward transport increases in magnitude from low latitudes to about 30°N as the surface easterlies are passed, then decreases progressively northward as angular momentum is removed by surface frictional torques acting in the westerly belt. Nearer to the pole the transport is reversed, indicating a flow southward from the polar easterly zone, although the magnitudes involved here are small as is to be expected from the fact that the torque arm associated with the surface frictional forces is small in the polar regions.

The main transfer across 30°N increases in intensity with elevation, reaching a pronounced maximum at about the level of the jet stream. On the basis of estimates of the surface torques during these periods it appears that sufficient angular momentum is transported into the belt of westerlies to maintain them against friction. Let it be noted, however, that the general results appear to be in harmony with the thesis that *practically all the necessary horizontal transfer of angular momentum could be accomplished without recourse to the agency of mean meridional circulations.* On the basis of what has been said, however, we cannot make any statement concerning other possible functions of meridional circulations such as, for example, the vertical transport of angular momentum.

At this point let us pause in order to take stock of what has been described and to see more clearly how it fits into the plan for research advanced in the introductory paragraphs. Have we by this study of angular-momentum considerations provided a theory for or achieved a rational solution for the problem of the distribution of zonal westerlies and easterlies in the atmosphere? Not by a long way. We did not solve the equations of motion[3] nor did we deal with radiative

2. "The Geostrophic Meridional Flux of Angular Momentum for the Month of January 1949." Presented at the 109th national meeting of the American Meteorological Society, Jan. 29–Feb. 1, 1951, New York.

3. Actually only one equation of motion, namely the one for the zonal direction, is needed to treat the balance of absolute

processes, which must ultimately be responsible for all air motions and are a determining factor for the form of the general circulation. What we have done is simply make a systematic analysis of data to portray as clearly as possible one important, but not patently apparent, attribute of the general circulation—namely, the angular-momentum balance. This study attempts to show how the actual atmosphere attains an internal consistency in one important respect.

What purpose can such information as this serve in the future of meteorological theory? The answer to this query is obvious. Once the announcement was made by Kepler that planets move in ellipses, any proposed dynamic theory of mechanics which would require them to move in significantly different paths was immediately pushed into the limbo. Likewise for the atmosphere any proposed rational theory for the general circulation which significantly contradicts the general outlines of the needed angular-momentum balance at once finds itself afflicted with a serious and perhaps even crucial drawback. On the other hand, the uses of such information need not be purely negative. The facts might well serve as one guide (among many others) for the formulation of satisfactory rational schemes.

What has been described is not a very profound concept, but merely a rather simple consequence of Newton's laws of motion applied to the atmosphere. The gist of the idea was presented many years ago, by Jeffreys in 1926. How is it then that it was permitted to lie fallow for so long a time? Aside from the lack of proper data, a contributing factor has doubtless been the preoccupation of research meteorologists with phenomena on a relatively local scale, this in turn being due to the limitation of our mental horizons to a scale commensurate with the daily weather map.

One might well venture the guess that at present we have not attained even a measure of the tasks which confront us. And this statement is in no way intended as a repetition of a common platitude. We have not fathomed the profundity of our subject, let alone solved the fundamental problems. In the years to come, when our knowledge will have increased, we may in retrospect wonder why we were so inappreciative of various gross and essential attributes of the general circulation. It would therefore be wrong and dangerous to post a sign along any plausible path of research which states "Thou shalt not enter here," seeking thereby to channel activity along certain predetermined lines. True science tolerates no prohibitions, and in principle no servile adherence to tradition. Rather we must open up and exploit all possible new channels that appear reasonable in order that we do not miss important facts.[4] It is in this spirit that the writer would recommend the further exploration of the essential properties of the global circulation *as we know it from observations* with regard to such dynamic quantities as angular momentum, vorticity, kinetic energy, heat energy, geopotential energy, and latent heat, so that we may find ourselves in a more advantageous position in formulating rational hypotheses.

For the purpose of exemplifying further the suggestions previously made, let us consider in a general way their application to questions concerning energy in the atmosphere. Much of what has been written concerning this subject has been deficient in two respects. In the first place investigators have been prone to lump together various diverse forms of energy indiscriminately, thereby losing the advantages to be gained from the fact that each form of energy is produced from and converted to other forms in its own characteristic fashion, permitting individual study. Likewise for each form there exist specific modes of transfer and redistribution. Unless these specific characteristics are subject to scrutiny in detail, only very broad generalizations can be reached, which lack a keen enough resolving power to yield much that is new concerning the mechanism of the atmosphere.

In the second place, as will be discussed presently, the modes of energy transfer within the atmosphere are so effective that no feature such as a cyclone can be treated independently without due allowance for exchanges of energy between it and the remaining atmosphere. It is therefore inappropriate to treat such a feature as in any sense a closed system. Modern trends in the literature are beginning to give proper cognizance to this circumstance, although much of the too-restricted point of view is still prevalent. Probably the only system which can be treated as a closed one (mechanically) is the atmosphere as a whole and even then it cannot be treated as closed from a thermodynamic viewpoint because of radiative exchanges of energy with the cosmic environment and otherwise.

Proceeding now to a discussion of the kinetic energy balance of the atmosphere, it is worthy of note in the first place to observe that whereas angular momentum is a quantity which is conserved in the sense that no real sources of it can exist, kinetic energy on the other hand may appear or disappear because of transformation processes involving other forms of energy. In other words, the flow and redistribution processes for kinetic energy are not source-free as is the case with absolute angular momentum. We may therefore say a priori that there is no reason to suppose that there may not exist in the atmosphere preferred source-regions for

angular momentum about the earth's polar axis. In effect this equation takes on the form of a continuity equation for absolute angular momentum.

4. When one compares the general nature of the results of research in meteorology as reported in our journals with the nature of research communications in let us say chemistry, there is a fundamental contrast to be noted. In our field there is a great diversity of views expressed on individual topics. Often these views are in direct conflict. Also one gains the impression that there is less of the orderly progressive accumulation of knowledge. This phenomenon is doubtless due to the fact that meteorology is in a far different stage of development as a science. In the better sense of the word we are alchemists still in the process of groping for a common denominator of unifying principles. We must not relax but rather continue to stumble and grope with more determination. The writer has the immutable belief that a proper foundation *does* exist and *will* be found.

atmospheric kinetic energy as well as preferred regions for its disappearance by conversion into other forms of energy through friction or otherwise.

With the aid of the examination and interpretation of the fundamental dynamical principles relating to kinetic energy given elsewhere in this volume[5] we shall now attempt to discuss this phase of the energy problem. In the reference mentioned there is presented a discussion of the process whereby kinetic energy is produced in the atmosphere. According to the views expressed there, kinetic energy of large-scale motions can be generated only through the work of expansion by pressure forces. Furthermore, kinetic energy associated with *horizontal* motions can be generated only through work done by *horizontal* pressure forces. It is thus pointed out that the rate at which horizontal kinetic energy is generated at a given point in the atmosphere is equal to the product of the pressure into the horizontal divergence of velocity. This carries the implication that regions of horizontal convergence are hydrodynamic sinks for kinetic energy which act independently of friction.

Speaking next of the transport of horizontal kinetic energy, it has been shown that this process is accomplished either through the work done by the pressure forces in virtue of the horizontal velocities across the boundary or by the advection of sensible kinetic energy. Since the latter (meridional) transport is small, it follows that the significant (meridional) transport of kinetic energy is accomplished through the work done by the pressure forces, which in turn is *proportional to the advection of internal heat energy* and occurs in addition to it. Applying these ideas to the transfer of kinetic energy across the vertical boundaries of an equatorial strip between two fixed middle latitudes $+\phi$ and $-\phi$, our general information would lead us to suppose that there exists a net transport of internal heat energy and therefore of kinetic energy poleward across these boundaries. Estimates from data tend to confirm this supposition, and indeed it also appears reasonable from common synoptic experience. We are therefore confronted by the very important conclusion that regardless of the nature of other details of the atmospheric circulations the more tropical regions appear to be preferred regions for kinetic-energy generation in that they not only produce sufficient kinetic energy to overcome frictional losses within these regions, but also provide an excess which is transferred to the polar caps.

Apparently we may also conclude that in the long run the more polar regions must serve as preferred regions for the disappearance of kinetic energy, since here the losses must be sufficiently great not only to offset whatever amounts of kinetic energy are generated locally but also to absorb the kinetic energy which is supplied from the more tropical regions. It is therefore reasonable to suppose that in the normal state of affairs in the atmosphere there are vast amounts of kinetic energy generated in the more tropical regions and vast amounts consumed in the polar caps. The existing kinetic energy is merely a small difference due to the fact that the positive generation process in the more tropical regions is slightly larger than the losses in regions of negative generation in the polar caps.

It is a matter of interest to examine the import of the views expressed above for the nature of the secondary circulations of the middle latitudes. It would thus be suggested that the kinetic energy supply for the main cyclone belt of each hemisphere is perhaps provided by the poleward flow of such energy from more tropical regions. Furthermore this flow is measured by (but exists in addition to) the poleward flow of internal heat energy. Although this flux of energy has some average mean value, there can be no doubt that in its details the process is a sporadic one with irregularities both in time and in longitude. Each cyclone may thus be considered as producing a spurt or poleward surge in this transport locally during its period of development.

According to the classical view, the kinetic energy for a developing cyclone is obtained from the sinking of dense masses of cold air in the immediate vicinity, so that by and large the decrease in potential and internal energy represents a corresponding increase in kinetic energy. From the present viewpoint the kinetic energy increase could equally well be derived from a pronounced local poleward flow from the more tropical regions, since a developing cyclone is accompanied by a marked increase in the net local poleward transfer of internal heat energy.

As a matter of fact it is not too difficult to visualize the general outlines of a certain type of instability associated with a developing cyclone when viewed in this way. For if it is granted that there exists a supply of warm and cold air in the vicinity, it may be that the pronounced local surge of kinetic energy once started serves to increase the intensity of the cyclone which in turn further increases the flow of kinetic energy and the intensity of the cyclone. The intensification finally ceases when complete occlusion takes place and the net heat transport disappears.

In a recent discussion the writer [11] has made an endeavor to elaborate further this picture of the kinetic energy balance of the atmosphere, making use of the assumption that mean meridional circulations do not play a significant role in these processes. The plausibility of this supposition is supported by the study of the angular momentum balance outlined earlier. Under such circumstances, since data show that near the surface poleward-moving individual air masses possess a higher specific volume than the equatorward-moving ones, it follows that there should exist a *mean horizontal velocity divergence* in the more tropical regions and a *mean horizontal velocity convergence* in the polar caps. This situation should thus contribute to a net production of kinetic energy, in view of the normal mean meridional distribution of pressure along horizontal

5. Consult "Applications of Energy Principles to the General Circulation" by Victor P. Starr, pp. 568–574.

surfaces.[6] Such estimates as can be made indicate that this gross average action may be of very great effectiveness.

In view of the fact that the correlation of density with meridional motion is most marked near the surface, it follows that the mean meridional distribution of this divergence and convergence shows greatest contrasts at low levels. This at once suggests that the mean meridional distribution of *net external heating and cooling* of the atmosphere is linked with the process, since the heating of the atmosphere is most intense near the surface and much of the cooling is accomplished through surface effects also. Thus it would be logical to suppose that the net external heating in the more equatorial latitudes causes a net horizontal expansion, while the net cooling in the polar caps brings about a net horizontal contraction, accounts then being balanced, as far as mass continuity is concerned, by differential advection across middle latitudes.

If one agrees to argue on this basis, a far-reaching observation may be made, subject of course to the correctness of the premises involved. Earlier in the discourse it was pointed out that one of the most fundamental questions in meteorology relates to the presence of broad belts of westerlies in the middle latitudes of each hemisphere. Speaking now only of the lower levels we see that the presence of the westerlies coincides with the requirement that the regions of net external heating and divergence should coincide with regions of higher pressure along horizontal surfaces. Unless this situation exists a net production of kinetic energy to overcome friction would be impossible. Thus, if for a moment we were to visualize a hypothetical situation with mean easterlies in middle latitudes, the net heating and consequent divergence would take place at a relatively low pressure in the more tropical regions, while the convergence and cooling in the polar caps would take place at a relatively high pressure. Such a hypothetical situation would then be rapidly destroyed, since more kinetic energy would necessarily disappear in the polar caps through convergence than could be generated in the more tropical regions by heating and divergence.

Although the net heating and cooling of the earth is ultimately caused by radiational exchanges with space, when one isolates the atmosphere and considers the circumstances in the winter season especially, due regard has to be given to the strong heating of the atmosphere by the oceans when cold air masses flow out over relatively warm water surfaces. As has been pointed out by Sverdrup and others [13], the oceans serve in a manner of speaking as a hot-water heating system. It should thus be expected that during winter the regions of net heating for the atmosphere extend much farther into middle latitudes than might otherwise be supposed.

6. Since variations of pressure along horizontal surfaces are necessary for the generation of a net amount of kinetic energy to overcome friction, it is indeed reasonable on general grounds to suppose that the atmosphere behaves in such a way as to take advantage of the large systematic pressure differences between the polar and tropical regions.

Since we have been speaking of the meridional transfer of internal heat energy, it is desirable to mention also the effects of the meridional transfer of latent heat. Crude estimates made by the writer using such data as are available indicate that very considerable amounts of energy are transferred poleward by this means. However, whereas the transport of internal heat energy cannot take place without a proportional transport of kinetic energy, the meridional transfer of latent heat energy is not related to the kinetic energy in the same way. It is thus possible to transfer large amounts of energy in the form of latent heat without a proportional kinetic energy flow being present. Whereas the flow of kinetic energy and therefore of internal heat energy may be regulated by the distribution of pressure and of divergence and convergence, this particular limitation does not enter as far as latent heat is concerned. One could therefore find arguments to support the view that the transport of latent heat furnishes a means for balancing the radiation requirements of the general circulation which bypasses the kinetic energy balance. For if the portion of the total meridional energy flow represented by the transfer of latent heat energy had instead to be transported as additional internal heat energy, a far more intense flow of kinetic energy would also be necessary. Whether this would imply a more "vigorous" general circulation is, however, a question which cannot be readily dealt with.

The meridional transport of geopotential energy is of course immediately ruled out in the average condition discussed here, because of the assumption that mean meridional circulations are not significant.

In the discussion mentioned above [11], an endeavor was made to study the fluctuations in the kinetic energy balance of the Northern Hemisphere with the aid of 5-day mean data such as are used by the U. S. Weather Bureau in extended-period forecasting. Only data for the colder half of each of seven successive years were used, so that essentially winter conditions were studied. By approximate methods a measure was secured of the intensity of differential advection of air with varying density across 45°N. This quantity τ is therefore a measure of the net volume transport northward across 45°N and hence also a measure of the mean convergence in the polar cap and to some degree probably a measure of the mean divergence in the more tropical zones of the Northern Hemisphere. A mean for the layer between sea level and 10,000 ft was used.

It became immediately apparent that the quantity τ undergoes large fluctuations, being high during those periods which are commonly designated as "low-index" periods and low during "high-index" conditions. The practical question involved here concerns itself with the cause of these vagaries in the behavior of the general circulation, for if this were known a better insight into the long-range forecasting problem might result.

In view of the fact that τ is also a rough measure of the rate of kinetic energy transport into the polar cap, it is interesting to note its relationship to the general pressure distribution there. If these pressures are low compared to the pressures farther south, a relatively

large fraction of the kinetic energy so transferred should remain without being destroyed by the mean convergence, while if these pressures are high practically all the kinetic energy fed into the cap should disappear because of the mean convergence. For this purpose it was decided to examine τ with reference to the *area-mean pressure deficit* north of 45°N as compared to the pressure at 45°N. This pressure deficit was denoted by π and was computed from sea-level pressures. It became apparent that abnormally large values of τ are, generally speaking, encountered only when the pressure deficit is small or negative, in other words when the capacity of the polar cap to destroy kinetic energy is abnormally great.

From these general observations it would appear that large meridional transports of internal heat energy and of kinetic energy take place during those periods when the mean meridional pressure distribution at lower levels is relatively flat north of the subtropics with no marked polar low present. How can a situation such as this maintain itself over appreciable intervals of time, as is known to be the case? Is it a quasi-steady state or is it a dislocation which becomes progressively more difficult to maintain? We can only speculate about the answers, but it is rather interesting to do so.

First let us consider the fact that it is during these low-index conditions that very cold air masses are injected into southerly latitudes. This in turn means a very strong heating of the atmosphere in middle latitudes and the subtropics, especially over ocean areas, so that a rapid replenishment of heat and also a rapid generation of kinetic energy would be a normal accompaniment of this state of affairs. This consideration would argue for the possibility of quasi-steady state.

On the other hand in order to maintain a quasi-steady condition, means would have to be present to dispose of large quantities of heat in the polar cap. It is unlikely that the net heat loss through radiation could be stepped up enough to meet this requirement. Progressive melting of ice in the polar regions could absorb large quantities of heat, but probably exactly the opposite is actually the case, since very low temperatures are apt to prevail at low levels in the arctic and subarctic regions under these circumstances.

Observationally there is some qualitative evidence that during prolonged low-index conditions there is apt to be present in polar regions an accumulation of abnormally warm air a little distance above the surface in the troposphere and in the stratosphere. Also there is some evidence that there is actually a progressive depletion of heat energy from middle latitudes (in spite of the strong surface heating) with a consequent progressive southward shift of the latitude of the maximum westerlies at higher levels. What ultimately puts a stop to the trend of developments is not obvious.

Contrasted with the low-index regime, during periods of a strong polar vortex at low levels the heat and kinetic energy transport is weak. Relatively warm air streams across the continents and oceans in a more zonal manner so that no very vigorous heating takes place. So far no difficulties seem to be present as far as the more southerly regions are concerned. It would appear, however, that progressive cooling should now take place in the arctic regions since the abnormally low heat input would appear to be insufficient to maintain the *status quo*.

On the whole there may be good and sufficient physical reasons, such as those mentioned above, why the general circulation does not persist indefinitely in one or the other abnormal conditions but rather tends to shift about a general average state. There is nevertheless the important question why the average state does not persist without such pronounced departures as those just described. The writer's conjecture on the matter is that the average state can too easily be disrupted by the effects of the nonzonal continentality found especially in the Northern Hemisphere. Such effects may be partly due to the fact that the continents provide avenues for the southward penetration of intensely cold air masses which can thus arrive at relatively low latitudes without undue modification. The occasional outpourings of such cold masses over adjacent water areas at fairly low latitudes could easily result in abnormal heating of the atmosphere sufficient to disrupt the average regime.

Also it should not be forgotten that large mountain ranges extending over an appreciable spread of latitude can exert powerful mechanical effects upon the atmosphere, as pointed out by White [16]. By way of example large pressure differences across the Rockies in North America could perhaps disrupt the angular momentum balance in the belt of the prevailing westerlies.

Finally the suggestion made by Willett [18] that the seat of the variation could perhaps be found in the variations in solar output, and hence the heating of the atmosphere, deserves study. For it may be that the final answer is bound up in a combination of effects, especially if long-term aberrations of the general circulation during historic and geological periods are also considered.

From what has been said in the several preceding paragraphs it might appear that too little emphasis has been placed upon the influence of the conditions in the upper troposphere and in the stratosphere. In the final analysis it is obvious that the entire atmosphere must form an integrated system. It would seem, however, that the lower layers furnish the seat of thermodynamic activity and provide the motive force for the general circulation. The writer's colleague, Dr. H. L. Kuo, is currently engaged in a theoretical study of the effects which might result at the level of the jet stream from forced disturbances originating in the lower levels. From his preliminary work it would appear that the generation and maintenance of the jet stream itself are a necessary consequence of such impulses received from below. Likewise the characteristics of the angular momentum balance as outlined previously, including such features as the tilted (and properly curved) trough and ridge lines, as well as the development of regions of sharp shear to the north and to the south of the jet follow as consequences of the analysis.

Having made an excursion into some of the ramifi-

cations involved in the study of the balance of angular momentum and of kinetic energy in the atmosphere, let us now consider the general circulation from the standpoint of a *rational theory* for atmospheric motions. By this term we mean essentially a *solution of the equations of motion* which purports to give a picture of the circulation or some portion of it. This is sharply contrasted with the study of the balance of various quantities, because the latter involves hydrodynamical principles only to the extent of formulating several integral requirements for the atmosphere. The investigation of how the atmosphere actually fulfills these requirements is then necessarily an empirical and observational problem.

Logically, then, the empirical picture obtained from the study of the balance of various quantities and from other observational studies should give us the fundamental physical characterization of the atmosphere which is then to be explained in terms of some rational theory. But, in a larger sense, the proper physical characterization of the general circulation is a subject which up to the present has hardly been entered upon. We need quantitative estimates of the flow of heat, of kinetic energy, of momentum, etc., for the mean state and also when consideration is given to synoptic and seasonal variations. The labor involved in order to supply this information is bound to be tremendous, involving the cooperation of meteorological services over the entire globe. Nevertheless progress is being made and there is reason for optimism.

In view of this state of affairs it is not surprising that the development of a rational theory for the general circulation has not made very much headway up to the present time. Thus the scope of the more successful efforts toward the solution of the hydrodynamic equations has necessarily been severely limited to certain portions of the atmospheric circulation where the introduction of drastic simplifications still leads to results of interest. As an example we might cite the several solutions of the two-dimensional barotropic vorticity equation given by Rossby [8] and recently elaborated by Charney and Eliassen [3] and others. For short-period extrapolation it appears that these results may prove to be of more and more value in forecasting, even though these solutions leave unanswered some of the fundamental questions concerning the energy balance when long-term effects are contemplated.

As a general comment it can be said that really adequate solutions which link the mechanics of the atmospheric circulation to the source of energy from solar radiation are a desideratum for future research, although the situation does not warrant undue pessimism. In this connection reference may be made to a recent publication by Lorenz [6] which is concerned with the solution of the two-dimensional equations of motion for the region near the pole, taking into account friction and external heating and cooling.

Leaving now the discussion of illustrative topics, what are the avenues for future progress which are indicated as of today? This is necessarily a subjective matter in which various investigators must follow their own inclinations and tastes, for there is no shortage of diverse problems which are worth while. The inclinations of the writer, as one of these investigators, are probably quite apparent from what has already been said. The underlying and oft-recurring motif of this essay is the need for a more complete and systematic empirical description of the basic physical processes involved in the general circulation. We are now beginning to have sufficient observational material at least in the Northern Hemisphere.

Before making concrete proposals, let us take a glance at what is being done which may serve as a beginning toward this aim. In the enumeration of activities which follows, any omission of important work is inadvertent and is due simply to the writer's lack of information. At the Massachusetts Institute of Technology Willett [18] has for a period of years gathered statistical information concerning the general circulation in the Northern Hemisphere in the form of 5-day averages. More recently he has begun gathering similar data for the Southern Hemisphere. The writer has found this material invaluable for the study of the general circulation. The Department of Meteorology of the University of California at Los Angeles has undertaken a study of the angular momentum balance of the atmosphere by means of finite difference integration procedures. This project will probably also include a similar study of the energy balance later.

Priestley [7] of Australia has proposed a program for the observational study of the momentum and energy balance of the atmosphere, utilizing radiosonde and radio-wind observations directly. Samples of his analyses already prepared by him have proven to be of great interest, but require elaboration.

Van Mieghem [15] of Belgium has proposed the study of the balance of various forms of energy, entropy, and momentum, emphasizing the importance of such studies for the progress of research concerning the general circulation.

The Extended Forecast Division of the U. S. Weather Bureau has for some years been amassing observational material in the form of 5-day averages for the Northern Hemisphere. The Weather Bureau [14] has recently also been preparing in published form very complete daily Northern Hemisphere maps for the surface and 500 millibars. These charts are most excellent and should prove to be invaluable for research purposes.

Finally mention may again be made of the studies of the angular momentum and energy balance initiated by the writer at the Massachusetts Institute of Technology.

The items listed above do not purport to cover all important research on the general circulation conducted currently, but rather only such activities as are apt to furnish statistical information concerning the gross character of the general circulation. Thus various other synoptic and theoretical activities are not included even though they may in the end furnish indispensable insight as to the interpretation of the empirical picture given by the statistics.

The general trend to be discerned is that the em-

pirical study of the general circulation is becoming a matter involving vast amounts of data properly and purposefully organized in order to be useful for the systematic evaluation of various specific and well-defined processes over long periods of time. It is being undertaken piecemeal by various institutions to an extent determined by their financial resources and facilities. In the initial stages of such exploratory activities it is probably most desirable that there should exist diversified direction of individual small-scale projects of this nature. However, once the best general patterns for such research have become apparent, a number of considerations point to the desirability of more consolidated effort. Thus some central organization could perhaps offer the advantages of a long-term program, more economical operation, better facilities such as high-speed computing equipment and better availability of computed results. Such an institute could even be of an international character under the auspices of the United Nations, since the purpose would indeed be of global importance in a very literal sense.

Beyond the broad recommendations just set forth, the writer wishes to state his belief that periodic reviews of progress such as the ones contained in this volume should be planned by appropriate organizations in an effort to stimulate comparison of differing opinions and to bring forth suggestions. Another matter of somewhat similar nature is the periodic publication of selected reprinted papers, adjudged to be of fundamental importance, in the form of collections similar to those edited by Cleveland Abbé [1] several decades ago. A practical problem here would be the selection of a capable (and so to speak disinterested) editor.

Finally a word about certain philosophical and theoretical aspects. In a science such as meteorology in which the rational explanation of the most gross features is still to be found, much attention must be given to questions regarding the general techniques for *interpretive* research in order to ascertain if possible the ones which are suitable. In any well-developed science, as for instance physics, it is often possible to arrive at new results by purely deductive means. However, it must be granted that the more fundamental scientific achievements of an interpretative nature have usually stemmed from *the deliberate introduction of new physical hypotheses*. Such hypotheses are usually the direct product of creative minds who through sufficient insight are able to recast a given problem into a new form. Although such formulation of novel hypotheses is perhaps the most difficult task confronting a scientist, we cannot afford to dispense with it in any attempt at understanding the motions of the atmosphere at the present time.

Without the use of creative imagination to give it form, our science could easily become a repetitious accumulation of bits of petty dogma, a jargon of catchwords and sophistries, a species of scholasticism lacking a firm basis or unifying principles. We need men with vision and courage who would not be content in occupying themselves with odd bits of research, but would tackle the fundamental problems. Men who have something of the spirit of daring which prompted Newton to propose the theory of universal gravitation and Einstein to suggest anew the quantum character of radiation.

Much of what has been said in the last two paragraphs has a direct bearing upon the use of mathematics in meteorological research. To regard the fundamental problems of meteorology as purely mathematical ones is hardly warranted. It is true that many of the hydrodynamical and physical principles involved are capable of mathematical statement, but it is only through the leaven of some purely physical hypothesis that we are guided to the appropriate mathematical use of these principles.

As stated previously, present-day meteorology may be thought of as being in the Keplerian era. It finds itself, however, side by side with very much more advanced physical sciences in which research is carried on with the aid of very sophisticated mathematical and theoretical tools designed for the purpose through the laborious efforts of past generations. Although much may be gained by borrowing certain of these techniques where proper analogies have been established, still there are certain philosophical pitfalls which arise when this is done merely in slavish effort at imitation without proper caution. Such superficial efforts are sometimes entered upon in order to gloss over the prerequisite of clear physical thinking. We cannot telescope the evolution of a new science by omitting essential phases of its natural development. We cannot hope for a magic carpet which would carry us directly from Kepler to Einstein, eliminating the growing pains of Newtonian mechanics.

OBSERVATIONAL STUDIES OF GENERAL CIRCULATION PATTERNS

By JEROME NAMIAS and PHILIP F. CLAPP

U. S. Weather Bureau, Washington, D. C.

Any reasonably brief treatment of a subject so vast as "Observational Studies of General Circulation Patterns" is bound to be biased in its selection of material. To be sure, any and all real information derived from the atmosphere constitutes an integral part of the material upon which students of the general circulation must draw. Inasmuch as our knowledge of the general circulation is very far from complete, it is difficult at this time to decide what statistically or observationally determined facts are especially pertinent. In selecting these data the authors confess to a bias in the direction of hemispheric or world-wide phenomena and also to those facts which have emerged from a fifteen-year-old experiment in the anatomy and physiology of the general circulation with which the authors have had the pleasure to be affiliated [33].

NORMAL STATE OF THE GENERAL CIRCULATION OVER THE EARTH

Sources of Data—Historical and Current. Ideally, the data upon which studies of general circulation patterns are based should consist of a series of complete and well-analyzed sea-level and upper-level charts covering the globe or at least a hemisphere for a period of decades. At the present writing this ideal state of affairs is far from being realized. For the Northern Hemisphere the longest series of analyzed charts at sea level embrace a period of about fifty years and at upper levels about fifteen years. Such a short period is woefully inadequate for studies of large-scale weather phenomena, particularly when one considers time intervals of a month or more. Furthermore, many of these charts are incomplete or inaccurate, and the upper-air charts are mainly for one level only (either 700 or 500 mb). In the Southern Hemisphere the situation is materially worse, although it will be partly remedied in a few years after several units, including the Department of Meteorology at the Massachusetts Institute of Technology, have completed files of Southern Hemisphere sea-level charts. The M.I.T. series began with January 1949.

Figures 1 and 2 give some idea of the amount and extent of data currently available for the construction of Northern Hemisphere charts at the Central Office of the U. S. Weather Bureau. This represents a vast improvement over conditions existing ten years ago, largely as a result of the increasing need for data during World War II.

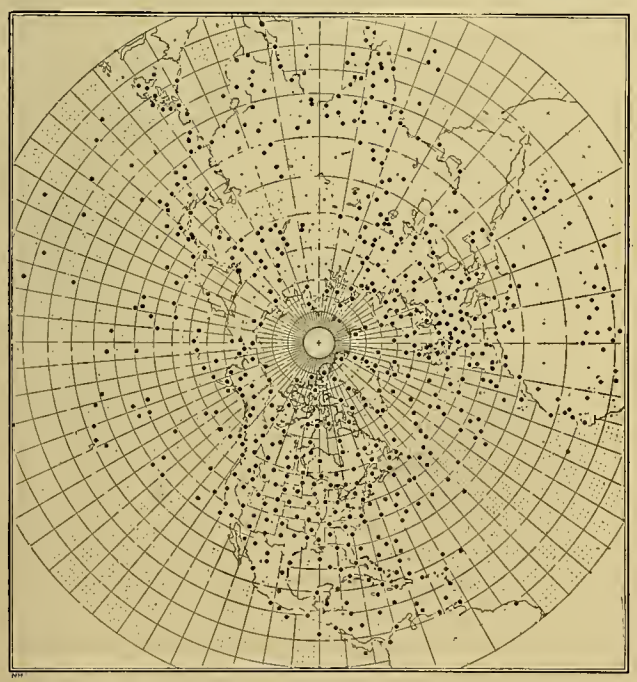

FIG. 1.—Typical data coverage at sea level for the Northern Hemisphere. Solid circles represent data actually received at 1200Z June 25, 1949. Some data have been omitted over the United States and parts of Europe because of space limitations.

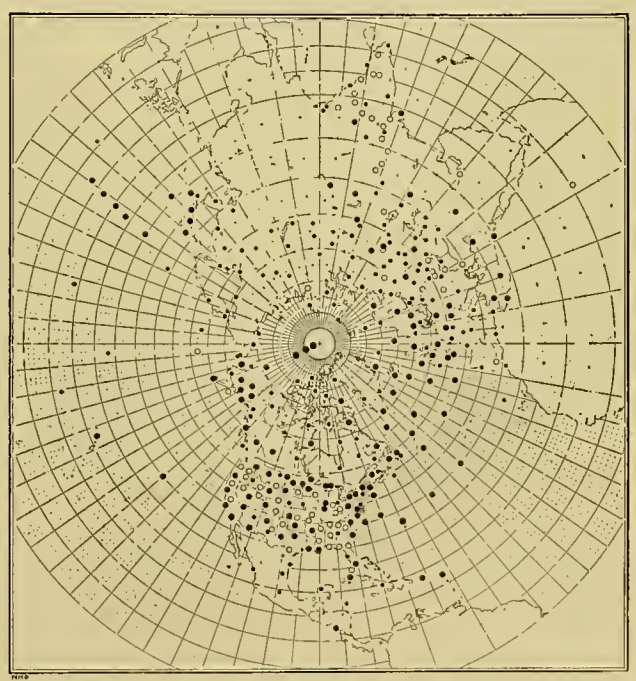

FIG. 2.—Typical data coverage at 500 mb. Small solid circles represent radiosonde data; large open circles, wind data; and large solid circles, both radiosonde and wind data actually received at 0300Z June 24, 1949. Winds are by pilot balloon, radar, or direction finder. The three observations near the pole and the five in the southwest Pacific centered at 20°N, 147°E are aircraft reconnaissance data.

While the coverage shown in these figures is reasonably adequate in heavily populated land areas and in the much-traveled North Atlantic, there are still many important gaps, notably in the southern portions of the North Atlantic and North Pacific Oceans and in many parts of Asia. This situation is due in part to communication difficulties and to the fact that it is more expensive and difficult (or even dangerous) to establish stations in unfrequented and less habitable areas. Nevertheless, political and economic forces are also partly responsible for the tendency of the density of observations to be proportional to the number of inhabitants. Since there is mounting evidence (some of which will be presented in this paper) that weather in any given area of the globe may be importantly influenced by conditions in other areas, no matter how remote, it would appear preferable to reduce the amount of data in populated areas and use the money thus saved to increase the number of reports, particularly upper-air reports, from remote areas. Certainly it is a mistake to reduce the amount of hemispheric data on the grounds that it is no longer necessary for military purposes. For the past two or three years there has been a strong tendency in this direction. The International Meteorological Organization, the International Civil Aviation Organization, the Pacific Science Association, and similar organizations should be commended for and encouraged in their present efforts to improve the data coverage of the world.

A brief list of published hemisphere charts is given in the references [1, 9, 17, 28, 29, 30, 46, 50, 51]. The Air Weather Service and U. S. Weather Bureau Northern Hemisphere sea-level and 500-mb analyses contain, in addition to analyzed charts, a valuable listing of all data received. To date the Air Weather Service charts have been published only from October 1945 to September 1946. The U. S. Weather Bureau commenced analysis and publication of this series beginning with January 1949. Charts for January through November 1949 are currently available. Efforts should be made to close the gap in the historical map series from 1939 to 1945. This includes the years 1944 and 1945 when hemispheric data, particularly in the South Pacific, were more complete than at any other time.

Many of the investigations to be discussed in this article were made using unpublished operational analyses. These include twice-daily sea-level and 10,000-ft (or 700-mb) charts over the Northern Hemisphere from 1940 to date as analyzed at the Extended Forecast Section of the U. S. Weather Bureau. Not until mid-1943 do these charts cover half a hemisphere or more. From them, twice-weekly five-day mean maps and twice-monthly thirty-day charts have been constructed. Five-day mean twice-weekly sea-level and 3-km charts for the cold season October through March 1933 to 1940 have been prepared by the Department of Meteorology at M.I.T. The 40-yr daily historical map series [28] has led to the construction of monthly mean sea-level charts. Corresponding 10,000-ft monthly mean charts have been constructed partly by extrapolation from sea level for the period 1932 to 1939.[1]

Reasons for the Use of Mean Charts. Mean charts, showing the average state of the general circulation for specified periods of time, have been used extensively by many investigators, including the authors, for studying the observed behavior of the general circulation. Here are some of the advantages of mean charts over daily synoptic charts:

Because of the unreliable nature of portions of hemisphere-wide analysis, the use of means leads to a smoothing which tends to eliminate experimental errors. Furthermore, such smoothing also eliminates irregularities in the flow pattern, such as small eddies or minor atmospheric waves. These irregularities, while real enough, tend to confuse the large-scale features of the circulation which are of most importance in long-range forecasting. To a lesser degree this second type of smoothing may be attained by the use of synoptic charts from higher tropospheric layers or by mathematical devices, such as Charney's geostrophic wind approximation [10].

Perhaps the most important justification for the use of means is that they reveal large-scale features having a long period. Indeed the speed with which a given pattern changes appears to vary inversely as the number of days over which the averaging is done. The authors feel that slow evolution of this character holds out the hope for successful long-range weather forecasting.

Granting the correctness of the arguments given above, the question has often been raised as to how mean charts are to be interpreted from a physical point of view. In particular, it has been argued that the equations of motion cannot be applied to a mean flow pattern, for, since these equations are nonlinear, the average value of acceleration will not equal the sum of the corresponding average values of the other terms. The answer to this question cannot yet be given. However, this problem seems to be closely connected with the statistical theory of turbulence [3]. Briefly, this theory states that if a given fluid consists of an average flow upon which are superimposed random eddies, then the equations of motion for laminar flow can be applied, provided certain frictional stress terms are added which express the cross-flow eddy transfer of momentum. There seems to be no obvious reason why it should be necessary to place any arbitrary time limit to the average flow, so that the equations of motion ought to be just as applicable to mean charts of a month's duration as they are to mean charts of a few minutes (synoptic charts)—provided the proper frictional terms are added [20]. This type of reasoning has been used by Defant [16], Lettau [32], and more recently by Elliott and Smith [21] to measure the frictional stress exerted by traveling cyclones and anticyclones. The omission of frictional terms in applying the equations of motion to

1. All of these charts have been microfilmed and copies may be purchased by writing to the Librarian, U. S. Weather Bureau, Washington, D. C.

mean charts may be no more serious than on daily charts. In the following pages it will be seen that mean circulations behave as though they were true physical entities.

Normal Circulation of the Troposphere and Lower Stratosphere. The prevailing motion of the greatest mass of the earth's atmosphere is in general eastward. The most recent normal maps prepared by the U. S. Weather Bureau [30, 50] and by the British Meteorological Office [9] effectively bring to light the existence of a vast circumpolar whirl which, while somewhat obscured at the earth's surface, becomes stronger with elevation until near the base of the stratosphere it assumes the characteristics of a sharp maximum in speed. This narrow band of high speed, called the jet stream, and illustrated by Willett [56] and Hess [24] in north-south mean wintertime sections (not reproduced), seems to be found at most meridians around the Northern Hemisphere. What meager data are available in the Southern Hemisphere (worked up by Flohn [22]) also suggest a jet stream there. A series of unpublished vertical cross sections for each 20° of longitude around the Northern Hemisphere have been prepared at the U. S. Weather Bureau as part of the work in constructing normal monthly maps at various levels up to 19 km [30]. From these cross sections, showing the geostrophic zonal wind component as a function of elevation, the latitude, strength, and horizontal shear across the jet stream have been entered and analyzed around the Northern Hemisphere as shown in Figs. 3 and 4 [38].

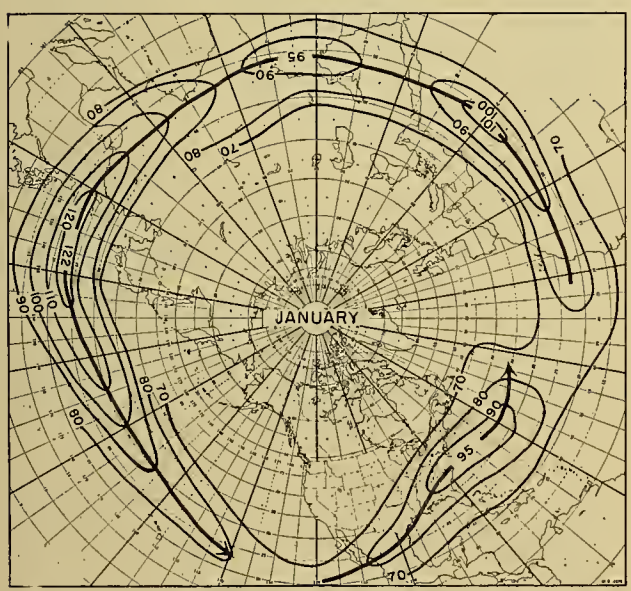

FIG. 3.—Average position and strength of the jet stream for January, prepared from eighteen hemispheric meridional cross sections. Heavy solid lines indicate geostrophic wind speed in miles per hour at the level of maximum speed. Heavy arrows represent axis of the jet. (*After Namias and Clapp* [38].)

The elevation of the jet, not shown on these figures, is everywhere in the range between 11 and 14 km. The material presented in these figures must, of course, be taken with some reservation, and one cannot scale off from them numerical values upon which to draw refined conclusions. Besides, they represent only the zonal component of flow; but this is by far the largest component, and an analysis of the total flow (not shown) gives a quite similar picture of the normal character of the jet stream.

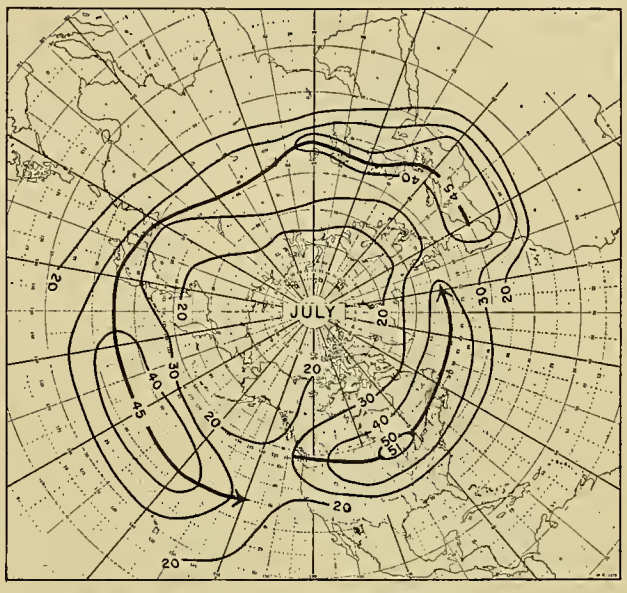

FIG. 4.—Average position and strength of the jet stream for July. (See Fig. 3 for legend.)

The characteristic features of the normal jet stream seem to be:

1. Its nature is essentially circumpolar in both summer and winter.

2. It is considerably farther north and weaker in summer than in winter—from a surprisingly low latitude of about 20°N to 35°N in winter, to perhaps 35°N to 45°N in summer, and with roughly double the speed in winter.

3. The location of the jet stream appears to coincide with the strongest meridional temperature gradient just below it in the mid-troposphere.

4. The jet stream is found where the tropopause has its greatest change in elevation.

5. The ideal circumpolar appearance of the jet stream is marred by appreciable longitudinal differences in strength. Thus in winter (Fig. 3) the jet stream reaches its maximum strength along and just off the east coasts of Asia and North America and decays in the eastern parts of the oceans. Another maximum appears over Africa.

6. The distribution of wind speed across the jet stream shows very strong lateral shear both to the north and to the south; the vertical component of the total absolute vorticity north of the jet stream (not illustrated here) suggests approximate constancy with latitude.

To a considerable extent charts constructed in mid-troposphere (Figs. 5 and 6) bear a striking resemblance to those at the level of the jet stream. This might be

inferred from the classical work of Dines [18] in which was pointed out the good correlations between temperature and pressure in mid-troposphere and at the tropopause. The strength of the circumpolar whirl is diminished with decreasing elevation. Below the level of 700 mb the circumpolar vortex begins to be somewhat obscured by the appearance of a more cellular character of the general circulation, and by the time we reach maps at sea level (Figs. 5 and 6) the "centers of action" take on considerable cellular character. Noteworthy is the emergence of easterly winds north of the subpolar lows and in the subtropics. The easterlies of the polar regions are for the most part shallow phenomena generally below 3 km, but in low latitudes, particularly in summer, easterly winds are very deep and extend well into the stratosphere.

The circumpolar vortex in the upper troposphere and lower stratosphere, while primarily zonal in character, undergoes gentle north-south undulations so that the isobars have a roughly sinusoidal character. The ridges and troughs aloft have their reflections at the surface

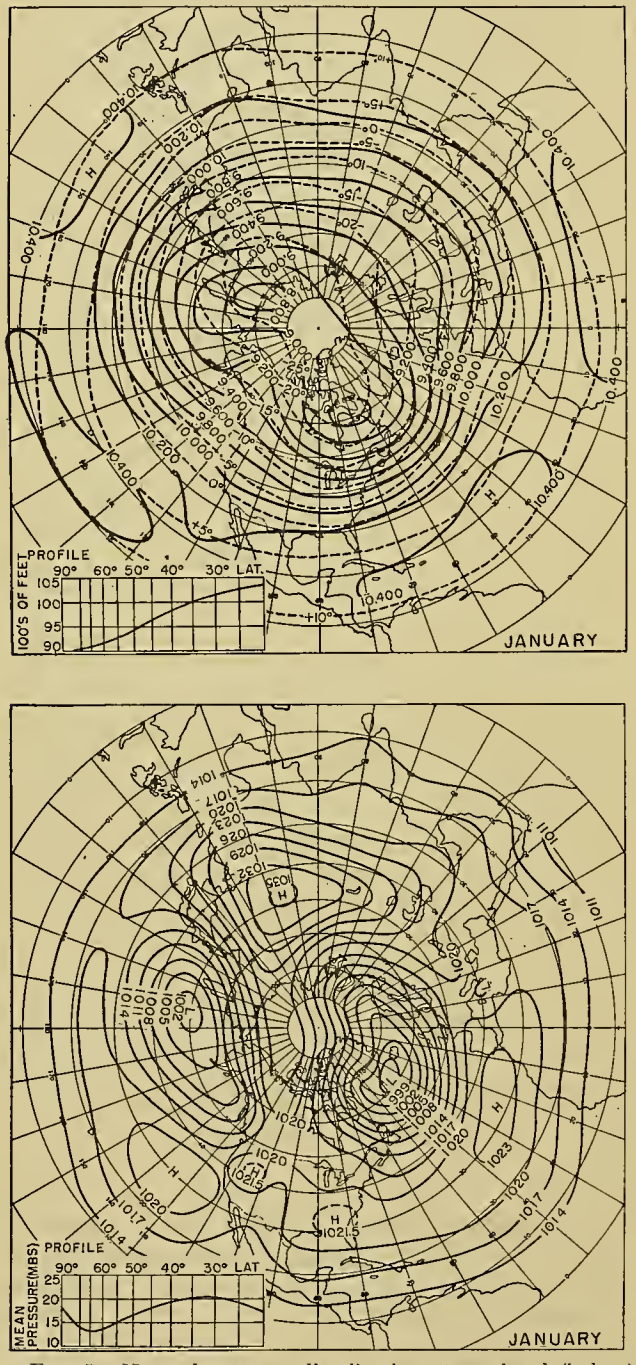

Fig. 5.—Normal pressure distribution at sea level (below) and normal contours at 700 mb (above) for January. Profiles inserted. Dashed lines at 700 mb are isotherms for every five centigrade degrees.

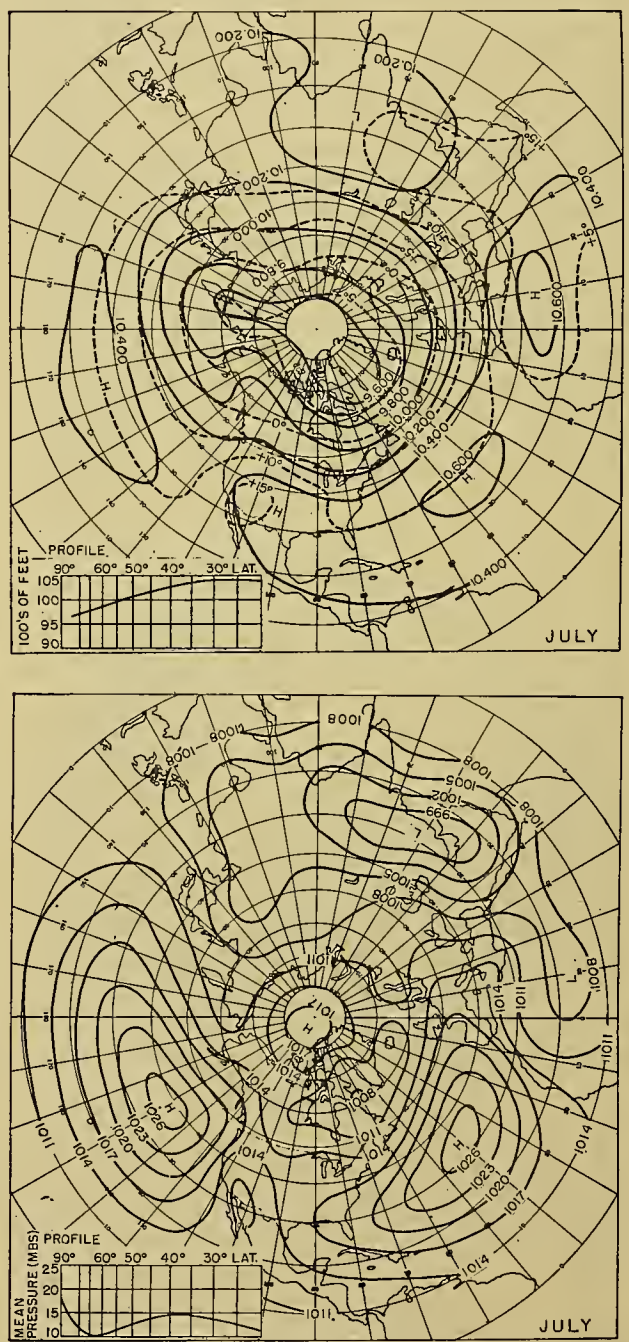

Fig. 6.—Normal pressure distribution at sea level (below) and normal contours at 700 mb (above) for July. Profiles inserted.

in the centers of action. Even at 300 mb the Icelandic and Aleutian lows of winter have not lost their identity although they are displaced considerably northwestward. The Siberian wintertime anticyclone apparently gives way to westerlies aloft.

The contrast between winter and summer shows up chiefly in diminished gradients and northward migration. With the approach of summer the sea-level subpolar lows lose much of their strength, the subtropical oceanic highs become much stronger, and over Eurasia the well-known monsoonal reversal of pressure sets in.

The comparison of circulations between the Northern and Southern Hemispheres is much more difficult in view of the relatively scant supply of data in the Southern Hemisphere—particularly at upper levels.[2] Certain attempts have recently been made to improve on Shaw's Southern Hemisphere charts [47] notably by the British Meteorological Office [9] for upper levels and by Willett [60] for sea level using Serra's world charts [46]. From these data a few seemingly reliable statements appear to be possible:

1. The zonal circulation at sea level appears to be stronger in the Southern Hemisphere than in the Northern Hemisphere. This is strongly indicated in a table of average circumpolar zonal wind speeds computed by Willett [60] who made use of Serra's monthly mean maps [46] for the months of January, April, July, and October from 1879 through 1934. (See Table I.)

Table I. Selected Normal Circulation Indices at Sea Level*

	Maximum zonal westerlies		Maximum subtropical easterlies	
	Wind speed (m sec^{-1})	Lat.	Wind speed (m sec^{-1})	Lat.
Winter				
Northern Hemisphere (Jan.)	2.25	54°N	5.60	20°N
Southern Hemisphere (July)	7.10	50°S	8.15	13°S
Summer				
Northern Hemisphere (July)	1.10	53°N	1.25	25°N
Southern Hemisphere (Jan.)	5.60	50°S	3.10	22°S

* Determined by choosing the 20° latitude band of greatest meridional pressure change, converting to geostrophic speeds, and noting the central latitude of the 20° band.

Clearly, the Southern Hemisphere zonal wind system at sea level is relatively stronger, displaced farther equatorward, and shows a smaller percentual seasonal variation than that of the Northern Hemisphere.

Willett also points out the surprisingly large seasonal fluctuation of the subtropical easterlies and their great strength as compared even to the zonal westerlies. This is indeed a fact which must be of importance in treating the general circulation, for the area covered by this wind system is far greater than that embraced by other branches of the zonal circulation.

A comparable table for upper-level circulations for both hemispheres is impossible to present at this time. From the British upper-level normals [9], however, it appears that the contrast of zonal wind speeds, so evident at sea level, is much less pronounced or perhaps even lacking at mid- and high-tropospheric levels. For example, the geostrophic zonal wind speed computed between latitudes 20° and 40° from the British 300-mb charts for both hemispheres during winter (December–February in the Northern Hemisphere, and June–August in the Southern Hemisphere) gives 29.5 m sec^{-1} for the Northern Hemisphere as compared with 29.7 m sec^{-1} for the Southern Hemisphere.

2. The undulations in the circumpolar vortex of the Southern Hemisphere appear to be much less pronounced (*i.e.*, have much less amplitude) than in the Northern Hemisphere. In fact, according to the British charts at 300 mb, it seems questionable even to talk of troughs and ridges in the Southern Hemisphere.

3. The cellular character at sea level is correspondingly less pronounced in the Southern Hemisphere than in the Northern Hemisphere, although "centers of action" are plainly present.

Various attempts have been made to characterize the state of the general circulation by numerical values. Thus certain circulation indices have come into use. Among the most prominently used are the geostrophic zonal wind speed, the "maximum" index, the meridional index, and zonal wind-speed profile. Definitions follow:

1. The geostrophic zonal wind speed within different latitudinal bands is computed either regionally or for the entire hemisphere. Such quantities as the "zonal index" express numerically the zonal wind speed averaged between two latitudes (generally 35°N and 55°N) and characterize the temperate-latitude westerlies. The polar easterlies (55°N to 70°N) and subtropical easterlies (35°N to 20°N) are similarly computed. These indices may also be evaluated for upper levels of the atmosphere.

2. The "maximum index" expresses the peak strength of some particular branch of the zonal circulation, as well as the latitude at which it appears.

3. Meridional indices express numerically the total north-south flow across a particular latitude circle.

4. In the last few years another effective form of representing important characteristics of the general circulation has come into use. This is the zonal wind-speed profile, on which the mean zonal speed within 5° latitude zones is plotted against latitude.

The seasonal behavior of Northern Hemisphere zonal indices computed for monthly periods is shown in Fig. 7. Recent work [35] with hemisphere-wide upper-air maps suggests that, at least at certain times of the year, normals computed for periods as long as a month contain smoothing sufficient to obscure certain important shorter period variations. Most important of these is the primary decline and subsequent rise of the mid-troposphere zonal westerlies which usually takes place

2. Subsequent to the preparation of this article two papers dealing with conditions at upper levels in the Southern Hemisphere have been published: "A Meridional Aerological Cross Section in the Southwest Pacific" by F. Loewe and U. Radok, *J. Meteor.*, 7:58–65 (1950); and "A Meridional Atmospheric Cross Section for an Oceanic Region" by J. W. Hutchings, *J. Meteor.*, 7:94–100 (1950).—*Ed.*

in February and March, the zonal index reaching a minimum around the beginning of March. Clearly such a minimum could not show up in monthly mean values such as are represented in Fig. 7. But averages com-

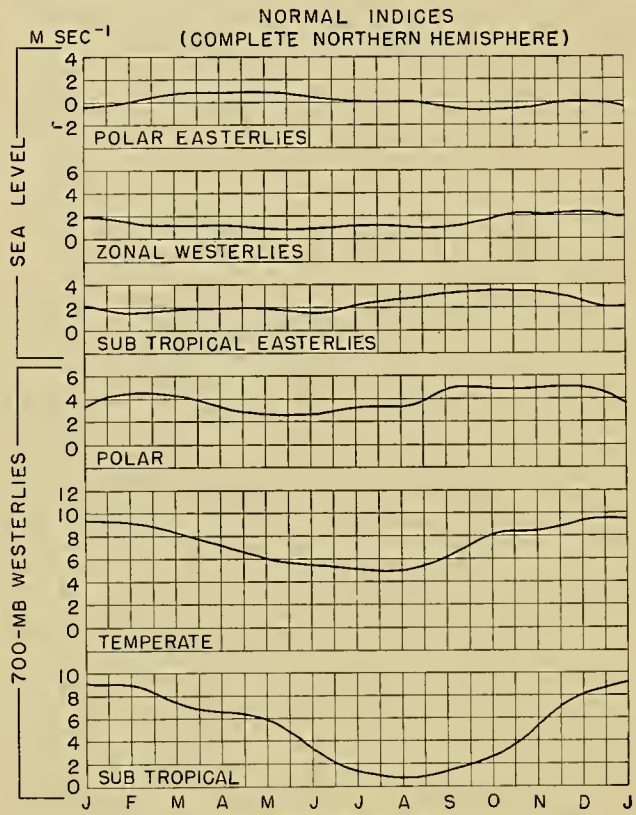

Fig. 7.—Normal Northern Hemisphere monthly indices.

puted from five-day mean charts worked up for ten-day intervals during the six years 1944–49 (when reliable upper-air data were available) strongly suggest the reality of this "global singularity." Another period of similar data (1932–39) worked up in part with the help of extrapolation techniques [59] also suggests the reality of this sharp dip in the normal zonal index. More concerning this topic will be said in a following section.

As pointed out earlier, the state of our knowledge of the observed normal state of the general circulation is still quite inadequate. Our deficiencies lie particularly in the absence of a long period of record of upper-air data over large areas of the Northern Hemisphere and over most of the Southern Hemisphere. Not much can be done for many years to remedy the "long-period" part of this deficiency. But it would appear well worth while to obtain, if only for one year, a reasonably complete series of daily soundings well into the stratosphere covering the entire world. From this material many of our blind spots would be cleared up. It might even be possible to link up interactions between the circulations of the hemispheres. Also, secrets of behavior of atmospheric circulation might conceivably be easier to find in the Southern Hemisphere where topographically produced distortions are comparatively lacking. In terms of modern expenditures for scientific work the cost of such a truly international observation year would not appear to be prohibitive. A more modest though much less effective proposal would be to establish at least one meridional cross section from the Arctic to the Antarctic.

There is also certain additional work which can be accomplished with our present material which could assist in a better definition of the character of the general circulation. It must be remembered that the normal state of the general circulation is not something which can be determined once and for all. It is something toward which successive approximations must be made. In the Northern Hemisphere the rate of increase in aerological data over the past ten years has been large. A stock-taking of our present rate of accumulation of this material indicates that new monthly normal charts for upper levels should again be prepared. This might be especially worth while in polar and subtropical regions. It would appear that the present rate of accumulation of aerological information would make necessary the routine preparation of upper-level normals at least every five years.

Physical Climatology of the General Circulation. The large-scale pressure patterns and other features revealed by a study of the normal or average conditions of the general circulation are generally assumed to have definite physical significance in the sense that they represent a stable stationary state of the circulation rather than a haphazard combination of daily highs and lows. To the extent that this is true it is desirable to find logical physical-mathematical definitions and explanations of these normal features, since they represent relatively simple states of the circulation which up to the present have been easier to depict than individual daily circulations.

A striking feature of the normal charts for the Northern Hemisphere [30] are the very long waves of finite amplitude at upper levels which are superimposed on the circumpolar westerly current. While their amplitude increases with latitude and decreases with altitude in the troposphere, their wave lengths do not change markedly with either of these coordinates.

These waves have dimensions greater than those of any other atmospheric wave systems. The smallest of them has a length of about 4000 mi and an amplitude of about 550 mi, compared to a dimension of about 1000 mi for waves associated with extratropical cyclones. Other interesting features are the consistently larger wave lengths and amplitudes found over Asia as compared to those found over North America, and the marked seasonal variations.

Some of these features appear to be explained at least qualitatively by the simple theory of conservation of vorticity as applied to planetary waves. Thus Rossby in 1939 [44] was the first to explain on a theoretical basis how a system of waves could be superimposed on the circumpolar band of westerlies, with troughs and ridges located in fixed geographical regions. He explained the anchoring of certain waves on the basis of distortions of the westerly flow due to north-south ori-

ented solenoidal fields at coast lines. More recently a similar role has been ascribed to mountain barriers.

By the use of Rossby's now classical formula,[3] plus the normal strength of the westerly flow, theoretical stationary wave lengths may be computed for each season for North America and Asia. The smallest of these has a length of 2500 mi, considerably larger than the dimensions of the average cyclone. Also, the seasonal variation of theoretical and observed stationary wave lengths is similar over North America. However, the observed waves are considerably longer than the theoretical waves. In view of the fact that average zonal wind speeds over the Eastern Hemisphere are somewhat lower than those over the Western, it becomes difficult to explain the larger observed wave lengths over Asia.

Among the many factors responsible for these discrepancies perhaps the most obvious is that the continents, in contrast to the oceans, interpose not merely one narrow obstacle in the path of the westerly flow but a whole series of more or less continuous obstacles of varying importance all the way around the globe. Thus, at best, we must regard the observed flow pattern as a heterogeneous combination of waves set up by each of the numerous obstructions. Precisely this line of attack has been taken by Charney and Eliassen [12].

Perhaps the most important reason for the discrepancies is that the atmosphere is baroclinic so that the westerly winds increase with height. As shown by Bjerknes and Holmboe [4], the only way to maintain a system of free stationary waves of constant wave length in such a current is to have a distribution of divergence such that in the lower layers there is mass convergence east of the trough lines and mass divergence to the west. At high levels they postulate the reverse distribution of divergence. Now the average level of nondivergence has been estimated to be at roughly 16,000 ft. Thus, the assumption of nondivergence at the 10,000-ft level, made in deriving the classical wave formula, is not valid. The distribution of divergence postulated above has the effect of increasing the stationary wave length.

Charney and Eliassen [11, 12] have shown that the effects of topography, surface friction, and baroclinity can all be expressed in terms of divergence at upper levels. It is therefore desirable to obtain an estimate of the normal fields of divergence. An attempt along this line has been made for the 10,000-ft level by the authors [37] and a sample of the results for February is shown in Fig. 8.

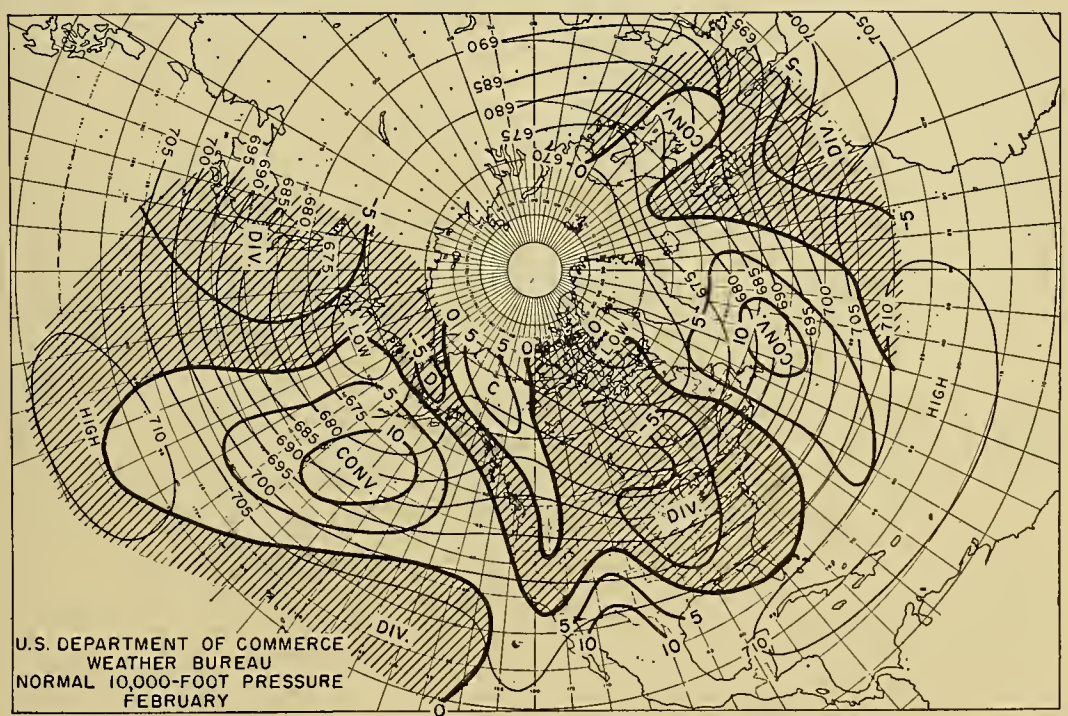

FIG. 8.—Normal field of divergence at 10,000 ft for February. Thin curved lines are isobars for 5-mb intervals; heavy curves, divergence for intervals of 5×10^{-7} sec^{-1}. (*From Namias and Clapp* [37].)

The large-scale features within the belt of strongest westerlies indicated in Fig. 8 show regions of maximum divergence to the west and convergence to the east of the trough lines, in partial confirmation of the Bjerknes-Holmboe theory [4] mentioned above. Another noteworthy finding (not illustrated here) is the increasing strength of the divergence fields from winter to summer accompanying subtropical highs while the fields associated with the circumpolar westerlies are weakening.

The effect of topography is also apparent from Fig. 8. As air is lifted over the Rocky Mountain chain from Alaska to Mexico, it is subjected to vertical shrinking (horizontal divergence), and as it sinks down the eastern

3. $L_s = 2\pi\sqrt{U/\beta}$, where U is the zonal wind speed (index), L_s the stationary wave length, and β the northward rate of change of the Coriolis parameter.

slopes it is subjected to vertical stretching (horizontal convergence). A similar phenomenon is observed in August but is interrupted at lower latitudes by the upper-level anticyclone over the United States. Similar charts, prepared for other levels, might throw considerable light on many problems of the dynamics of the general circulation.

If the normal fields of divergence at 10,000 ft are fairly representative of the average divergence in lower atmospheric levels where there are no mountains, it is possible to obtain some idea of the normal fields of vertical motion. Thus there is probably a region of gradual subsidence over the eastern United States and a region of gradual ascent over most of the Atlantic. Similar regions are indicated over the Pacific. The charts also indicate subsidence in eastern portions of the subtropical highs and ascent in western portions, conclusions which are in good agreement with the Bjerknes subtropical models [5] and with observed precipitation regimes.

It is recognized that in order to obtain a complete explanation of the normal state of the general circulation it is necessary to locate and determine the magnitude of the sources of heat and moisture in the entire world's atmosphere, for it is these sources which supply the necessary energy to drive the atmospheric heat engine. Some of the most recent work on this topic has been done by Wexler [54] and by Jacobs [25, 26].

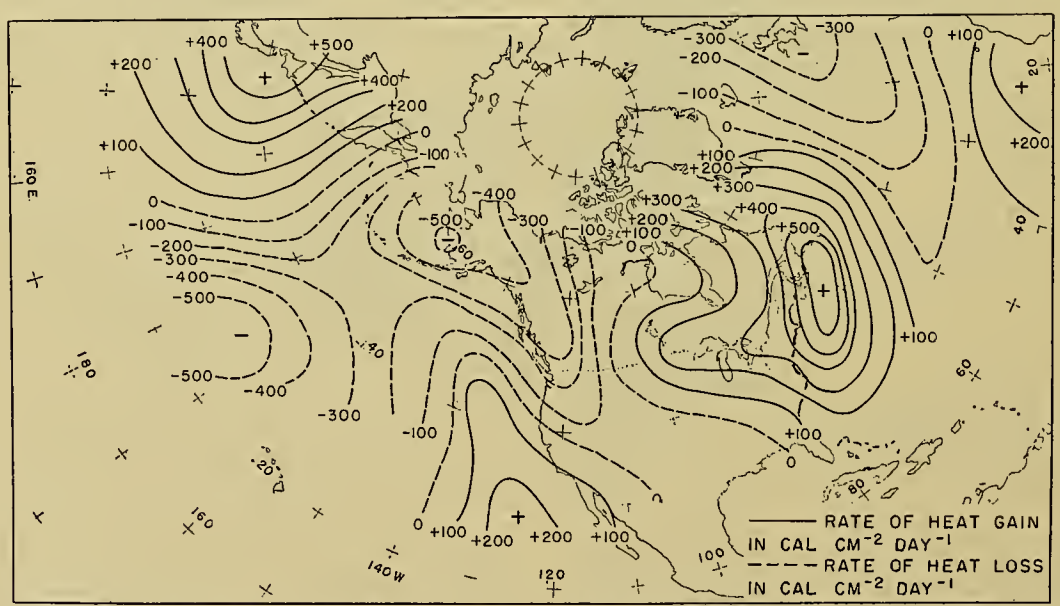

FIG. 9.—Regions of normal heat gain and loss for the layer from sea level to 10,000 ft for February. (*After Wexler* [54].)

Using data for the Northern Hemisphere, Wexler estimated the normal regions of heating and cooling of the air in the layer between sea level and 10,000 ft for the months of February (Fig. 9) and August. As Wexler points out, more exact values of the total heat gain or loss would be possible if the effects of vertical motion were considered. But the quantitative evaluation of this term is difficult. In an attempt to extend Wexler's study, Winston and Aubert,[4] estimating the effects of vertical motion, find that Wexler's method appears to give good estimates of total heating in regions where this heating or cooling is large. Thus, while part of the heat gain shown over eastern North America in Fig. 9 may be attributed to adiabatic warming through subsidence, it is not possible to explain in this manner the centers of strong heating appearing off the coasts of the continents. Apparently these represent heat sources instrumental in driving the circulation of the Northern Hemisphere. Similar reasoning applied to other areas suggests that the regions of cooling over the northeastern parts of oceans are heat sinks, while subsidence accounts for the apparent heat sources over the southeastern Atlantic and Pacific.

The studies discussed above do not consider individual heating processes affecting the circulation, for example, radiation, condensation, sensible heat exchange with the earth's surface, and mixing. Contributions to these aspects of the problem have been made by Jacobs [25, 26] who calculated for the air overlying oceanic regions the normal seasonal heating due to condensation and to sensible heat exchange with the surface. Jacobs found that the air was being heated from below in both the western and the northeastern portions of the oceans. The amounts of heating he found are in general agreement with the total heating as given by Wexler only in the western portions, but in the northeastern portions Wexler's values (showing net cooling) must be accounted for in some other manner, perhaps by radiation or mixing. Indeed the importance of horizontal mixing in cooling northward-moving air

4. Part of the work of this continuing project at the Extended Forecast Section of the U. S. Weather Bureau will be published shortly. A further study is being made of normal and anomalous sources and sinks for other months and other levels.

masses in the northeastern oceans is strongly suggested by the work of Elliott and Smith [21].

In studying the sources and transformations of atmospheric moisture Jacobs showed that the greatest evaporation in winter takes place over western oceans. According to him this latent heat appears to be released to the atmosphere largely in the eastern portions of the oceans where condensation reaches its maximum.

Another method of investigating the availability of moisture for atmospheric processes resulted from the technique of isentropic analysis. By this means Namias and Wexler [55] were able to construct monthly mean isentropic charts for summer over the United States and thereby indicate the normal upper-level sources of moisture. Unfortunately, due more to the discontinuance of the isentropic technique than to the lack of upper-air data, such charts for other areas and seasons have not been constructed.

The transport of various meteorological quantities by methods other than isentropic analysis has received considerable attention in recent years. Thus, Priestley [41] has suggested a systematic study of the transport of heat, moisture, and momentum through the use of radiosonde and radiowind measurements at a large network of individual stations. The importance of the transport and convergence of momentum and heat in producing local wind accelerations has been stressed by Namias and Clapp [38] and by Starr [48]. More study can profitably be made of the significance of thermal convergence in producing local transformations of energy.

NONSEASONAL (IRREGULAR) VARIATIONS IN THE GENERAL CIRCULATION

Qualitative Synoptic Studies. The "normal" state of the general circulation, as shown by normal hemisphere maps, is one which is never strictly encountered in any given daily map nor, for that matter, in any weekly mean or monthly mean. Indeed, the normal map is composed of the averages of circulations which appear remarkably different from week to week and even between corresponding months of different years. In any given region, however, there appears to be a preferred circulation type for a given month or season, so that the normal map computed from a long series of data achieves a certain character.

The variations of the circulation about its normal, considering weekly or monthly mean charts, is far greater than that which one would obtain if the circulation types followed each other in purely random sequence. This fact is reflected in the amazingly large variability of means for a month, year, or decade and probably for still longer periods up to the ice ages, as stressed by Willett [58] and Tannehill [49].

The observed sequence of types in any particular month or season more often than not takes the form of an alternation between two or more mid-tropospheric flow patterns, one of which persistently recurs and dominates the mean over longer periods. It is presumably this persistent recurrence which led the Multanovsky School of long-range forecasting [39] to draw conclusions with regard to "natural synoptic periods," to the opposition of types between natural periods, and to the relative constancy of length of the natural period during one "synoptic season."[5]

Some idea of the weekly variations of the strength of the zonal circulation at sea level may be obtained from Fig. 10. The absolute variations at higher elevations appear to increase up to the level of the jet stream, but the percentage variation of normal strength is probably quite similar at all levels. If the average zonal wind speed for the hemisphere is considered as a whole and for weekly periods, this variation is of the order of 50–150 per cent of the normal speed. Regional and shorter-period variations may, of course, exceed these values, and localized jet streams reaching three times their normal value have been recorded. There is some suggestion in the distribution of zonal indices of mid-troposphere that the frequency curve of index values is skewed in a direction such that high values (relative to normal) are less frequent than low. Perhaps this is suggestive of an atmospheric braking mechanism whereby some form of stability permits very low zonal wind speeds to persist but kills off unusually fast currents.

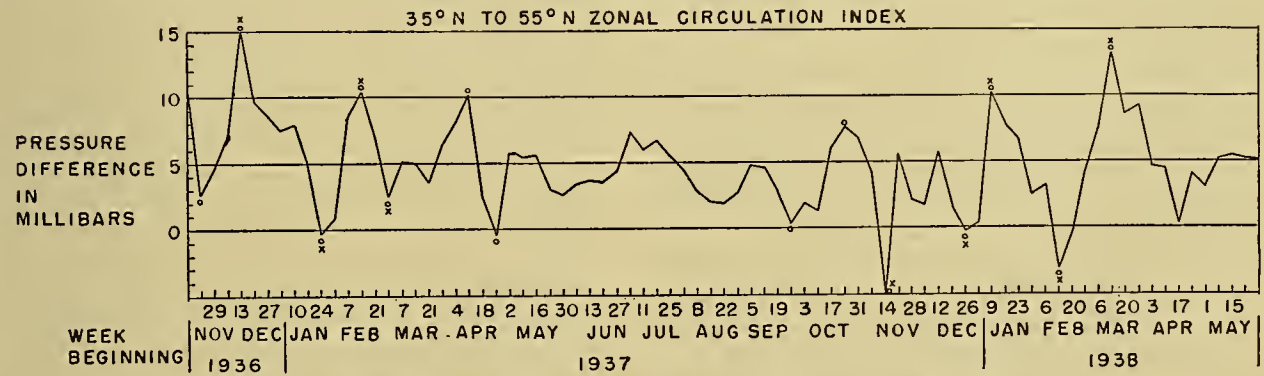

Fig. 10.—Weekly averages of zonal westerlies index, November 1936—May 1938.

5. Consult "General Aspects of Extended-Range Forecasting" by J. Namias, pp. 802–813 in this Compendium.

The variation in speed of the zonal circulation may also be treated from the standpoint of the maximum index, or the values of zonal wind speed taken at whatever latitude the maximum speed is reached. While the nature of the speed variations thus treated is similar to those taken between fixed latitudes, this form of treatment brings out some important additional information indicating that some of the highest speeds are reached when the jet is found at low latitudes. It also brings to light latitudinal variations in the position of the jet stream about the normal which are amazingly large. Even if averaged over the hemisphere for periods as long as a month, this variation can be as large as 20° of latitude during one season. For shorter periods, and particularly for selected regions, the latitudinal variation of the jet stream can be much greater. Regional jet streams have been apparently observed in areas ranging from the pole almost to the equator.

To the extent that we may speak of the maximum high-level zonal current averaged over the hemisphere as a jet stream, we may summarize the foregoing remarks by saying that there are large day-to-day, week-to-week, and month-to-month variations in the strength and latitude of the jet stream. The latitudinal variations may be looked upon fundamentally as an expansion and contraction of the circumpolar vortex toward or away from the pole.

The regional variations in the latitude and perhaps in the strength of the jet stream are associated with the wave patterns in the circumpolar vortex which were, to some extent, treated in a foregoing section. Ideally these long waves are generally looked upon as a simple wave pattern in the upper troposphere and lower stratosphere with from four to six meridionally extensive ridges and troughs around the hemisphere. The observed wave patterns are rarely if ever so ideal, and a more accurate description would be that there are generally two (sometimes more) different families of waves in different latitude bands. These two wave trains may, and usually do, possess different wave lengths (in degrees of longitude) and hence around the hemisphere there may be a different number of waves in higher latitude bands than in lower latitude bands. For this reason, too, the waves in the two bands are frequently out of phase. These remarks pertain equally well to daily, weekly, or monthly mean maps.

When the jet stream of the circumpolar vortex is well to the north of its normal position, the ridges and troughs are generally strongly tilted in a northeast-southwest direction or even fractured as indicated in Fig. 11, Stage 1. When the waves get into phase (*i.e.*, when the troughs and ridges are more or less meridionally extensive) the latitude of the jet stream usually lowers but does not reach its lowest value. This position is reached only after the entire character of the hemispheric upper-tropospheric circulation is radically altered to a cellular rather than a wavelike structure. The explanation of this fundamental change in character, in spite of its enormous importance to meteorology, is not yet known. However, in following the development of such transitions it often appears that the changes go on somewhat as follows: In the initial stage (illustrated schematically in Fig. 11) there are extensive zones of confluence where deep cold polar and warm

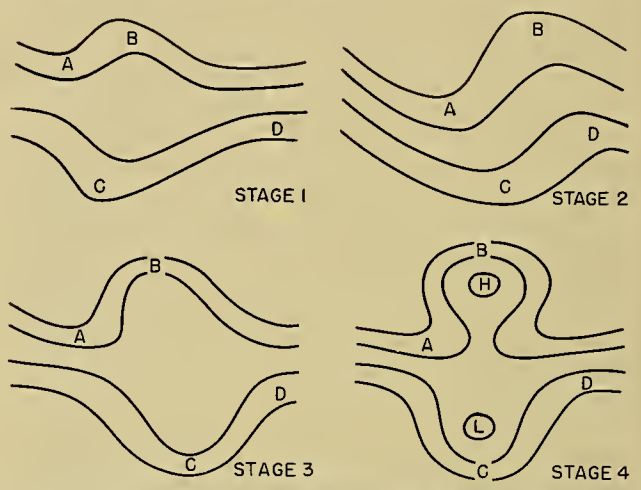

Fig. 11.—Schematic representation of successive circulation patterns of the index cycle. The time interval from Stage 1 to Stage 4 is about two weeks.

tropical air masses are forced to flow side by side, associated with filaments of regional jet streams to the east of the zones of confluence. In Stage 2 the waves, perhaps through some form of relative motion associated with a nonstationary wave length, have combined into deep full latitude troughs and ridges. This combination permits vast meridional transports of deep polar and tropical air. Stage 3 results from a refracture of the troughs at high and low latitudes, again perhaps in an attempt to readjust wave lengths to equilibrium values. The cold polar air masses brought equatorward and the warm currents which were delivered to polar regions by the in-phase troughs and ridges now have no return passage to their source regions—that is, the evolution of the flow patterns is now in the direction of trapping both the equatorial air in the north and polar air in the south. Finally, in Stage 4 the cold pools (*Kaltlufttropfen*) in the subtropics and the warm pools in the subpolar regions take on characteristic cyclonic and anticyclonic cellular circulations. In these schematic models it will be noted that certain asymmetry and tilt of the troughs and ridges are introduced where necessary to bring about the advection of momentum required to maintain the westerlies in the manner postulated. Jeffreys [27] and lately Starr [48] have emphasized the importance of such asymmetry as related to the transfer of momentum.

This idealized sequence of events generally does not take place simultaneously in all parts of the hemisphere. However, when such a development on a large scale takes place in one region, it is often followed by similar reactions in other regions. This transition of the circulation wherein deep cold cyclones are ultimately formed at low latitudes and deep warm anticyclones are formed at high latitudes is referred to as *blocking*. The most commonly observed behavior of blocking action is a progressively westward development of re-

gionally low-index circulation patterns at a variable speed which synoptic experience suggests may be of the order of 60° of longitude per week. At the surface in the area of blocking, pronounced anticyclogenesis (or cyclolysis) is observed in higher latitudes, while wave cyclones are forced to skirt the perimeter of the developing high-latitude anticyclone, either northward west of the developing upper-level ridge at high latitudes, or southeastward into the cold developing vortex of southern latitudes. A good description of the evolution of the day-to-day westerly waves in the mid-troposphere westerlies [2] during blocking is that they appear to become progressively shorter and increase in amplitude as the scene of the blocking action is approached. In this respect they may be likened to waves advancing on to a beach, or to the pleats in an accordion.

Westward progression of characteristic circulation features, while by no means rare, does not appear to be as common as eastward progression. Thus a sudden increase in amplitude of a wave system in North America may be shortly followed by a similar increase over the Atlantic and Europe. The speed at which this readjustment occurs often exceeds that of the zonal speed of the air particles—a fact which of late has received considerable attention from theoreticians [43, 61] following its discovery in synoptic practice [36].

The transition in temperate latitudes from strong to weak zonal circulation and back again has been referred to as the index cycle. On the basis of a careful synoptic and statistical study of seven years of Northern Hemisphere data, Willett [45] has given a description of the index cycle which can hardly be improved upon. His statements follow:

> . . .four principal states of the index cycle are recognized, each of which can be briefly characterized essentially as follows:
>
> (1) Initial high index (strong sea-level zonal westerlies), characterized by (*a*) sea-level westerlies strong and north of their normal position, long wavelength pattern aloft; (*b*) pressure systems oriented east-west, with strong cyclonic activity only in higher latitudes; (*c*) maximum latitudinal temperature gradient in the higher middle latitudes, little air mass exchange; and (*d*) the circumpolar vortex and jet stream expanding and increasing in strength, but still north of the normal seasonal latitude.
>
> (2) Initial lowering of sea-level high-index pattern, characterized by (*a*) diminishing sea-level westerlies moving to lower latitudes, shortening wave-length pattern aloft; (*b*) appearance of cold continental polar anticyclones in high latitudes, strong and frequent cyclonic activity in middle latitudes; (*c*) maximum latitudinal temperature gradient becoming concentrated in the lower middle latitudes, strong air mass exchange in the lower troposphere in middle latitudes; and (*d*) maximum strength of the circumpolar vortex and jet stream reached near or south of the normal seasonal latitude.
>
> (3) Lowest sea-level index pattern, characterized by (*a*) complete breakup of the sea-level zonal westerlies in the low latitudes into closed cellular centers, with corresponding breakdown of the wave pattern aloft; (*b*) maximum dynamic anticyclogenesis of polar anticyclones and deep occlusion of stationary cyclones in middle latitudes, and north-south orientation of pressure cells and frontal systems; (*c*) maximum east-west rather than north-south air mass and temperature contrasts; and (*d*) development of strong troughs and ridges in the circumpolar vortex and jet stream, with cutting off of warm highs in the higher latitudes and cold cyclones in the lower latitudes.
>
> (4) Initial increase of sea-level index pattern, characterized by (*a*) a gradual increase of the sea-level zonal westerlies with an open wave pattern aloft in the higher latitudes; (*b*) a gradual dissipation of the low-latitude cyclones, and a merging of the higher-latitude anticyclones into the subtropical high-pressure belt; (*c*) a gradual cooling in the polar regions and heating of the cold air masses at low latitudes to re-establish a normal poleward temperature gradient in the higher latitudes; and (*d*) dissipation of the high-level cyclonic and anticyclonic cells, with a gradual re-establishment of the circumpolar vortex jet stream in the higher latitudes.

While the index cycle described above appears to be recognized in its essential character during most winters, its precise form of operation, time of onset, and even its length and intensity are subject to appreciable variations. Extensive studies directed along these specific lines appear to be long overdue. A beginning on this problem [35] was made with the help of hemisphere-wide upper-air coverage obtained during the six-year period 1944–49. These data suggested the following conclusions:

1. There is a strong preference for the winter's primary index cycle to occur in February and March, the minimum index occurring around the beginning of March, and the beginning and end points being removed by about three weeks from the minimum.

2. The total momentum of the mid-troposphere westerlies around the hemisphere tends to reach a certain value characteristic of the season, and it is only the distribution of this momentum with latitude that varies. Hence the low index of temperate latitudes really consists of a displacement of the "high-index" strong westerlies (farther southward).

3. Each primary index cycle is usually associated at its onset with a strong wave of Atlantic blocking, with a tendency to form warm anticyclones in high latitudes and cold cyclones in low latitudes. However, the blocking appears to be only a necessary and not a sufficient condition for a primary index cycle.

4. The intensity of long index cycles appears to be largely determined by the reservoir of cold air in polar regions preceding their onset.

These four statements appear to be sufficiently backed by empirical evidence to be considered in any theoretical treatment of the problem of the evolution of the radically different states of the general circulation. A qualitative treatment along these lines has been given [35]. The reader is referred to this paper since the presentation of theories lies outside the scope of this article. Other earlier attempts to explain the index cycle have been given by Rossby and Willett [45].

The index cycle, consuming about six weeks, is naturally not the only important period of evolution of radically different circulation patterns. Indeed for many years the problem of monthly mean, seasonal, and even secular large-scale circulation anomalies has been of paramount concern to meteorologists. While such evolutions undoubtedly lie in the province of "Observed

Studies of General Circulation Patterns," it would appear that the principal treatment of this vast subject belongs elsewhere in this Compendium.[6]

Before we leave the subject, however, a few pertinent remarks are in order. First, it appears from actual studies that the choice of the length of period does not essentially change the character of the problem of fundamental oscillations of circulations from high- to low-index states. In fact, there is evidence to suggest (Willett [57], Tannehill [49]) that the longer the period, the correspondingly greater the interperiod variability compared with what might be expected if the variations were random in character. Secondly, experience with monthly mean charts over the past eight years suggests an evolution which is not entirely chaotic and which indeed appears capable of kinematic and possibly physical rationalization [31, 34]. The kinematic aspects were pointed out as early as 1926 by Brooks [8].

In short, the problem of the index cycle and its evolution would appear to be an integral part of any theory of secular, climatic, and geological (*i.e.*, ice-age) variations of world weather—a fact repeatedly stressed by Willett [58].

Quantitative Empirical Studies. The qualitative behavior of large-scale circulation patterns described above is obviously of sufficient interest to justify more objective quantitative studies. Such studies have two basic purposes: to provide empirical formulas for predicting the motion and development of large-scale circulation features, and to furnish the theoretical meteorologist with quantitative evidence for supporting or extending his theories. Since the forecasting aspects of these studies are treated elsewhere,[5] we shall treat here only the theoretical implications.

One investigation of this sort, involving the motion of long waves at different latitudes, was made by the authors with the aid of two-and-a-half years of five-day mean 700-mb charts [36]. This study was an attempt to verify and make use of the simple theory of planetary wave motion based on the principle of conservation of absolute vorticity [44].

From this material it was found that while there is positive (but far from perfect) correlation between observed and theoretically computed displacements of selected trough systems, observed waves usually travel much faster than the speed given by the vorticity theory, thereby making necessary large empirical corrections. The reason for this discrepancy seems to lie in part in the fields of divergence accompanying observed waves, whereas the theoretical formula is based on the assumption of no divergence. This problem, as it affects the stationary wave length, was discussed in the section of this article dealing with physical climatology.

Of considerable importance is the empirical finding that when wave length and zonal wind speed are considered separately there appears no significant relationship between wind speed and displacement. This was certainly not expected from theory. While no satisfactory explanation for this discrepancy has yet been found, it may be due in part to a possible interdependence of wave length and zonal index [13] or, as Cressman [14] indicates, to the small variability of the zonal index which cannot produce changes in displacement larger than the errors of measurement.

Because of this finding, empirical formulas were derived by considering that displacement is a simple linear function of wave length. This is equivalent to substituting the average or normal value for zonal wind speed in the theoretical displacement formula and then assuming that the range in wave length is small in comparison to its average magnitude.

The latest unpublished studies of this kind show that the stationary wave lengths (the wave lengths observed when trough displacement is zero) for North America are roughly the same as the normal wave lengths obtained from normal upper-level charts. This means that when the wave lengths found on individual five-day mean charts exceed the normal value, the waves will tend to retrograde (move westward) while they will be progressive (move eastward) if the observed wave lengths are smaller.

It was previously suggested that seasonal variations of the normal wave lengths could be accounted for by seasonal changes in the zonal index. But there are also pronounced geographical variations. Thus the stationary wave lengths for the Atlantic are found to be shorter than those for North America, suggesting that for the same wave length, displacements in an easterly direction are slower over the Atlantic. This better agreement with the theoretical wave formula indicates that waves over flat ocean areas more closely approximate free perturbations.

The empirical studies also show a systematic decrease of wave speed with time. This may be a purely statistical result, but a possible physical explanation may lie in the Rossby wave formula in which a decrease in wave speed may result from a systematically increasing wave length. It has been suggested [36] that such an increase in wave length as troughs move eastward may be due to the tendency for certain troughs and ridges to be fixed because of topographical or solenoidal effects. For example, the length between a trough moving eastward over the Mississippi Valley and a ridge fixed to the Rocky Mountain area must continually increase, resulting in a deceleration.

Perhaps a more universal explanation for systematic changes in wave length has been offered by Cressman [15], who has adapted the theory of group velocity to changes in wave length of individual systems. Synoptic evidence, on both daily and five-day mean charts, appears to support his conclusion that if the wave length increases in an upstream direction the easternmost wave will slow down, while the opposite distribution of wave length will lead to acceleration.

In investigating other parameters besides wave length which might be related to displacement, it was found that the shape of the wave was often quite important [13]. Thus, if the wave amplitude to the west of a given

6. See, for example, the discussion in "Solar Energy Variations as a Possible Cause of Anomalous Weather Changes" by R. A. Craig and H. C. Willett, pp. 379–390.

trough is greater than that to the east, the trough will tend to move faster than expected from the empirical wave formula. The opposite result is often obtained if the amplitude to the east is greater.

Studies of trough motion similar to those above have been made with the aid of constant absolute vorticity trajectories [42]. The theory, which gives an estimate of the paths of individual air parcels, is based on the conservation of absolute vorticity just as in the wave theory, but avoids many of the latter's assumptions. For example, local wind speeds are used in place of a fictitious uniform zonal wind, and the assumption of small perturbations is avoided, so that estimates of wave amplitude may be obtained. However, a new assumption that the speeds of individual air parcels remain constant is introduced.

Using this theory, Bortman [6] obtained empirical corrections (for each season and several geographical areas) to the "first characteristic points." These are the first trough or ridge points following the inflection point of the vorticity path at which the computation is made. The results were quite similar to those using the wave formula in that large eastward empirical corrections were found for the theoretical trough points over eastern North America, indicating that the theoretical trough speeds are too low. Also, there is a positive correlation between theoretical and observed wave speeds. Corrections are generally less over ocean than over land areas. Of special interest are the corrections in the western Rocky Mountain area, where both trough and ridge points give evidence of strong divergence as a result of lifting. The study thereby emphasizes the importance of geographical and climatological features on the behavior of long waves.

Another unpublished empirical study of wave motion on five-day mean 700-mb charts [7] over North America attempts to make use both of the theory of planetary waves and that of constant vorticity trajectories. Thus, following a suggestion by Cressman [14], the wave length and wind speed of observed waves were measured along the streamlines (or isobars) rather than along fixed latitude circles. Amplitudes were measured in the same manner. These three parameters were then related by graphical correlation methods to the observed trough displacements at 45°N. Such a procedure is an empirical attempt to take cognizance of the jet stream, which tends to follow the streamline flow. The results show not only the expected relationship between wave length and displacement, but indicate that amplitude and to a certain extent wind speed are also significant parameters. The most interesting result was the significant positive correlations found among all three independent parameters. The relationships among wave length, amplitude, and wind speed for small and intermediate values of wave length were found to be qualitatively the same as those to be expected from the theory of constant vorticity trajectories, while for larger wave lengths the agreement was poor (Fig. 12). The explanation for this discrepancy has not yet been found but when found it should aid in seeking an understanding of the observed behavior of planetary waves. Studies of a similar nature should be made for other levels and areas besides North America, to which the above study applies.

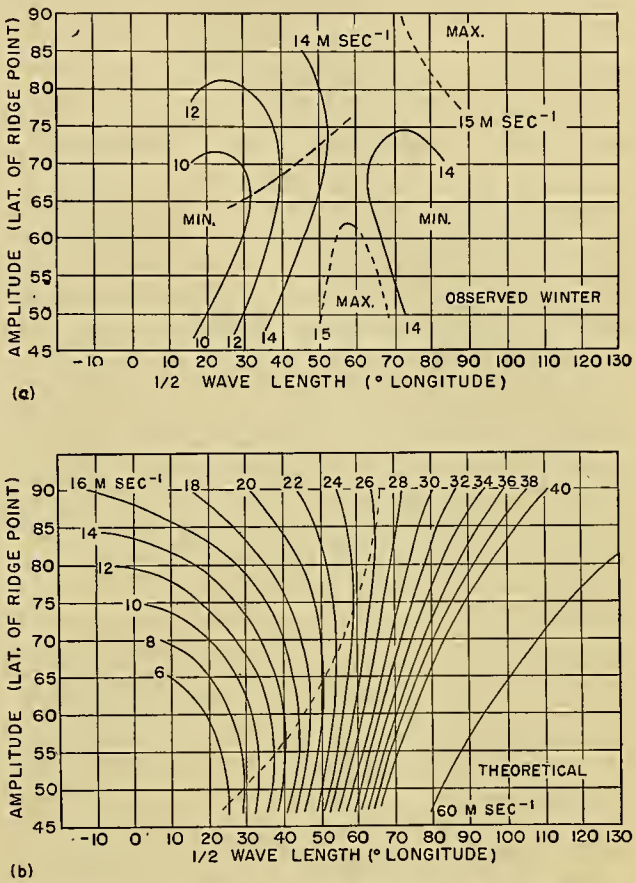

FIG. 12.—(*a*) Observed relationship between wave length, amplitude, and wind speed for waves whose minimum latitude is 45°N, from five-day mean 700-mb charts for the years 1941–47. (*b*) Theoretical relationship between wave length, amplitude, and wind speed for waves whose minimum latitude is 45°N, using the Bellamy vorticity slide rule. (*From Bortman* [7].)

One of the basic difficulties of all studies treated so far is that they require the identification from map to map of various characteristic points or lines (highs, lows, troughs, or ridges). Because of the complexity of atmospheric behavior this is not always easy. This suggests that a more profitable empirical (or theoretical) approach is to study local changes in various meteorological quantities, since this does not involve the troublesome problem of continuity. To a certain extent the vorticity paths are designed to do this, and such use has been made of them by Dorsey and Brier [19] and by Fultz [23].

Dorsey and Brier, using selected trajectories made on daily synoptic 10,000-ft charts, compared the theoretically computed wind speeds and directions with those observed at the same points at intervals of 24 hr up to seven days in advance. Among their interesting results is the finding that trajectories are likely to be more successful when made in a well-defined fast flow. It was also found that if the trajectory verified well for the

first 24 hr it was more likely to be good for subsequent time intervals. In spite of the obvious advantage of avoiding the necessity for determining continuity, it is felt that this method, unlike that used by Bortman [6] places too heavy requirements on the theory, and makes the determination of empirical corrections difficult.

A similar study has been made by Fultz [23] who also used trajectories computed on daily 10,000-ft charts, and in addition estimated the true trajectory of the air parcels. Such a method could obviously lead to quantitative empirical corrections to the vorticity paths in many different geographical areas. However, the number of cases studied by Fultz was small (largely because of the length of time necessary to compute true paths) and the corrections were apparently so complex that the author confined his practical results to a number of valuable qualitative rules.

Among recent studies designed to avoid the problems of determining continuity perhaps the most important is the work of Charney and Eliassen [11, 12] mentioned previously. This represents a considerable refinement of the simple planetary wave formula particularly as it applies to the determination of local pressure (or height) changes. Several empirical studies are currently underway to test and expand this theory.

Before concluding this brief review of quantitative studies of circulation patterns it is necessary to say a few words about the accuracy that has been attained. It must be confessed that in spite of the fact that they seem to fit into a logical pattern which can be explained on physical grounds, these empirical results represent only the average behavior of circulation features. For example, the largest correlation coefficient found between theoretical and observed wave displacement represents a degree of success accounting for perhaps only 50 per cent of the variability of observed motions. These meager results are probably due in part to the great complexity of the atmosphere which makes it impossible for any single factor, such as a wave length, a vorticity path, or a region of confluence to be responsible for more than a small part of the subsequent circulation changes. Only by integrating in some way *all* the many processes taking place throughout the *whole* atmosphere can one hope to approximate a complete solution. Such a desirable goal can be obtained only through continued close collaboration between theoretical and synoptic meteorologists.

Another contributing factor lies in the limits of observational accuracy. Because of instrumental errors, sparseness of upper-air reports, and analytical difficulties it is not generally possible to define a trough or ridge at 45°N any closer than about four degrees of longitude. Because of this one source of error (even supposing that a perfect linear relationship exists between wave length and trough speed), the highest correlation that could be attained is −0.85. This result suggests that in meteorology, as in other sciences, it is highly desirable to include in any quantitative comparison of theoretical and empirical findings a careful analysis of errors.

Statistical Studies of the General Circulation. Meteorology has always been a fertile field for statistics. It contains numbers of observations perhaps equal to or in excess of those in any science. The number of combinations of elements making use of different places and different time intervals is well nigh infinite. Partly for this reason, meteorology has encouraged the use of the correlation technique for discovering significant relationships between meteorological elements or between one and the same element in space or in time. While this statistical procedure has its secure place in meteorological research, it has probably been the cause of more heated controversy among meteorologists than any other research tool. Owing to the amazingly large mass of correlations to be found in the literature and the lack of general agreement as to tests of significance to apply to such statistics, it becomes exceedingly difficult at this time to portray or evaluate the role of statistical studies of the general circulation. Perhaps the most indefatigable worker along these lines has been Sir Gilbert Walker, whose statistical studies of contemporaneous and lag correlations form the basis of many interesting and informative papers [52]. For the most part these papers have been reviewed at length elsewhere [40] and thus the present brief survey will not attempt to treat this work but instead will concentrate on the work of Willett [57, 59] who, perhaps next to Walker, has given the atmosphere its most vigorous statistical workout. Besides, Willett had the distinct advantage of having hemisphere-wide maps at the surface and aloft and could thereby obtain integrated indices of the general circulation which Walker had to estimate by values of elements chosen at selected points. Moreover, Willett's work is of particular interest inasmuch as it ties in with, and indeed, forms some of the basis of, the material discussed in earlier portions of this article.

The principal meteorological material upon which this work was based consists of daily analyzed charts at sea level and at 10,000 ft over the entire Northern Hemisphere for the cold months of the year from October through March for the seven years 1932–39. From these charts, five-day mean maps were prepared twice a week (so that there was one or two days overlap between five-day periods) as well as a host of statistical derivatives. A list of the complete number of these "indices" of the general circulation would in itself occupy considerable space, even without the addition of the vast number of correlations computed between pairs of indices. The principal indices considered on a hemisphere-wide scale can be relegated to three types: zonal, meridional, and solenoidal. The zonal indices have been defined on page 555.

The meridional indices used by Willett express the mean (over space and time) of the north-south component of geostrophic flow averaged for each of the latitudes 30°N, 45°N, and 60°N. This quantity was necessarily obtained from values taken from daily synoptic charts and, as in the case of the zonal indices, was obtained for both sea-level and 10,000 ft.

The solenoidal index measures the poleward gradient of mean virtual temperature between sea level and

10,000 ft in the 20° latitude band of greatest northward rate of change.

With these indices (and many more) Willett proceeded to look for contemporary and lag correlations, after removing the seasonal trend. Ordinary linear (Pearsonian) coefficients of correlation were computed from fifty-two overlapping five-day mean periods for each six-month period (October–March) during each of the seven years and for the seven years as a whole. The terms "significant" and "highly significant" were applied to those correlations which had less than five per cent and less than one per cent probability, respectively, of occurring by chance.

Of the contemporary correlations one of the most significant was the negative one (−0.54) found with fair year-to-year consistency between the average pressure along latitudes 70°N and 35°N. This negative correlation is, on a global scale, the same phenomenon that Sir Gilbert Walker stressed in his North Atlantic and North Pacific oscillations, when he pointed out the opposing reactions of Aleutian and Icelandic lows to North Pacific and Azores subtropical anticyclones, respectively. These results stress the important fact that the polar-cap anticyclone grows at the expense of the subtropical highs, the shifts in mass being associated with an expanded circumpolar vortex of low index described above on page 561.

Largely as a result of this negative correlation the sea-level polar easterlies correlate insignificantly with sea-level zonal westerlies in spite of the fact that these two indices possess the latitude 55°N in common. But the sea-level polar easterlies correlate significantly and consistently from year to year in a positive sense with the zonal westerlies at the 10,000-ft level, indicating that when the sea-level polar easterlies are strong, the poleward temperature gradient in the 10,000-ft layer above the surface is also strong. This is also borne out by significant negative correlation between solenoid index and zonal westerlies and positive correlation between solenoid index and 10,000-ft westerlies. The correlation between the strength of the maximum 3-km westerlies and their latitude, while not significant, is consistently negative from year to year, suggesting the observed fact that the jet stream at times intensifies as it expands equatorward.

The meridional index computed for 45°N shows a tendency (though not quite significant) for strong meridional circulations to be associated with weak zonal components. The meridional exchange at 45°N also appears to be related to the latitude of the maximum 3-km westerlies, since a significant negative correlation exists between these two quantities. Again this reflects the meridional (*e.g.*, cellular) character of the low-index pattern as compared with the high-index pattern.

From these correlations Willett [57] concludes that

> . . .the low index circulation pattern, in contrast to the high index pattern, is characterized by:
>
> 1. A relatively strong poleward temperature gradient, at least between sea-level and the 3-km level.
>
> 2. Relatively weak zonal westerlies at sea-level which increase to relatively strong aloft, with a tendency to be displaced equatorward, that is, an intensified and expanded circumpolar vortex in the upper troposphere.
>
> 3. Strong polar easterlies as a result of a relatively strong sea-level polar anticyclone, which in turn is produced primarily from a weakening of the sub-tropical high pressure belt.
>
> 4. In middle latitudes a relatively strong meridional circulation at sea-level which tends to weaken with height as the zonal westerlies become relatively stronger.

The step from contemporaneous to lag correlations involving features of the general circulation appears to be of a high order of difficulty. In earlier decades, particularly the 1920's, a popular form of research aimed at long-range forecasting consisted of correlating, with different lags, weather or circulation elements at various points over one or both hemispheres. One such ambitious program, undertaken at the U. S. Weather Bureau under Weightman [53], involved correlations between pressure, temperature, and rainfall for lags of three, six, and nine months. It was hoped that these supposedly fact-finding and purely statistical studies would lead to a better understanding of the general circulation and provide a basis for long-range weather forecasting. But the technique was apparently too crude to bring to light any very revealing secrets of the behavior and evolution of atmospheric circulation and concomitant weather. Similarly, in their vast undertaking Willett and his associates, working with data described previously, were unable to detect any reliable predictors of the general circulation in its zonal or meridional branches or in regional divisions, aside from a small degree of persistence. From these negative results Willett [57] concluded that the general circulation possessed no internal mechanism of operation and that there was apparently no one way that a subsequent state could dynamically and thermodynamically evolve from an initial state. From this conclusion it was apparently not a difficult step for Willett to join that group of meteorologists who maintain that controls of nonseasonal variations in the general circulation lie in the sun. One can, of course, question the fundamental premise upon which this latter conclusion was based. Indeed, Willett himself is quite aware of the possibility that the correlation technique, applied as he has applied it, is too crude to unveil the secrets of a highly complex organism like the atmosphere. The restrictions placed upon correlation techniques by fixed time and space intervals, in the opinion of the present authors, are much too severe to fasten upon an evasive atmosphere notoriously resistant to strait jackets.

In this semiphilosophical question seems to lie one of the principal deficiencies of research in the problem of general circulation. Admittedly, all meteorologists aim for objectivity. But in the quest for objectivity it is sometimes forgotten that adequate statistical tools may not yet be developed to treat many complex problems. The problems of time series, so common yet so annoying to meteorology, serve as an example. It thus behooves the meteorologist to encourage the development of statistical tools which are by definition objective

and are at the same time not overly restrictive. Perhaps the way out of this dilemma is offered by new electronic high-speed computing equipment.

CONCLUSIONS

In the brief summary of recent work on the general circulation presented above, three basic aspects have been stressed. The first deals with what is known of the observed fields of atmospheric mass and motion, both in their normal state and in their week-to-week or month-to-month variations. While there is a fair delineation of the pressure field in the Northern Hemisphere and in the lower troposphere for a short period of years, there are considerably less systematic analyses of wind and moisture on a hemispheric scale. The second aspect concerns certain quantities such as divergence, vertical motion, heat sources and sinks, transport of mass and momentum, and other factors which can be derived from the fundamental fields of wind and pressure. Finally, there has been some discussion of the physical interpretation of this great mass of observations. It is this interpretation which provides a basis for long-range forecasting.

Much work remains to be done in all three aspects of the problem, especially in the last. At present there is no completely quantitative utilization of theoretical findings in forecasting. Perhaps the closest approach to this is confined to certain relatively simple applications of the classical hydrodynamical concept of conservation of vorticity. This meager result is due largely to the fact that, just as in other sciences, advances in theoretical meteorology must go hand-in-hand with advances in observation. For example, there appears to be much promise in the application of electronic machines and numerical integration methods to the problem of short- and long-range forecasting. However, even this will be of little avail unless it is accompanied by a better understanding of atmospheric processes through more intensive studies of existing data and improvement in observational techniques.

In various places throughout the text the authors have suggested several ways in which further progress in observational studies can be made. Perhaps the most important of these are the completion of the historical Northern Hemisphere map project for the war years 1939 through 1945. With a complete and improved supply of historical data, further attempts can be made to obtain a more accurate picture than we now have of the normal state of the circulation at many levels, and to study such things as the characteristics of atmospheric waves and circulation indices. Clearly many other projects in addition to those mentioned can be suggested which will lead to better utilization of our existing supply of data.

In addition to utilizing existing data more effectively, meteorologists have the responsibility of seeing that future supplies of hemispheric data are improved. This improvement appears to be more necessary in quality rather than in quantity. Thus, observational networks should be chosen so that there is a more even distribution over the globe. Observations, including winds and moisture, should be taken from high atmospheric levels. The idea of the "polar year" or "aerological days" should be extended so that a global supply of data at all levels will be available for at least one year.

APPLICATIONS OF ENERGY PRINCIPLES TO THE GENERAL CIRCULATION

By VICTOR P. STARR

Massachusetts Institute of Technology

INTRODUCTION

Theoretical hydrodynamics and thermodynamics furnish the basic equations of energy which in the end must describe the energy transformations which take place in the atmosphere. These equations in themselves are not capable of furnishing a sufficient rational explanation of the causes of atmospheric processes, but nevertheless provide a guide to systematic exploration for purposes of finding empirically important facts concerning the behavior of the atmosphere. Thus their utility is much enhanced if consideration is given to observational data.

The most important problem which confronts us in such an effort is therefore not one of merely stating the several pertinent equations in a formally complete manner, but rather one of discussing atmospheric processes as given by observations in terms of these relationships. To this end the principles involved must be moulded and recast in such a form as to permit the desired applications to be made. In this procedure the failure to give proper cognizance to the special circumstances characteristic of the atmospheric processes dealt with can only lead to endless complications and needless confusion.

Much of what has been written concerning this subject has been deficient in two respects. In the first place, investigators have been prone to lump together various diverse forms of energy, thereby losing the advantages to be gained from the fact that each form of energy is produced from and converted to other forms in its own characteristic fashion, permitting individual study. Likewise for each form there exist specific modes of transfer and redistribution. Unless these specific characteristics are subject to scrutiny in detail, only very broad generalizations can be reached. Even here, however, the implications of the balance of total energy for the globe have not yet been studied in sufficient detail as will be discussed later.

In the second place, the modes of energy transfer within the atmosphere are so effective that no feature such as a cyclone can be treated independently without due allowance for exchanges of energy between it and the remaining atmosphere. It is therefore inappropriate to treat such a feature as in any sense a closed system. Modern trends are beginning to give proper cognizance to this circumstance, although much of the too restricted point of view permeates meteorological thought.

In the present discourse only certain phases of the subject are discussed by way of illustrating a general approach. Thus the discussion which follows treats only the global balance of kinetic energy as an example of the study of one individual form of energy. In the last section the total energy balance is re-examined. It is of course true, as has already been stated, that it is also possible to study the global balance of other individual forms of energy such as geopotential and internal heat energy. A beginning in this direction has been made by Van Mieghem [10].

GLOBAL BALANCE OF KINETIC ENERGY

General Considerations. One of the basic problems in the science of meteorology relates to the manner in which thermal energy received by the atmosphere through short-wave solar radiation becomes in part transformed into kinetic energy of motion relative to the rotating earth. Plausible estimates show that the fraction of the total energy so transformed is very small, but must nevertheless be sufficient to account for all air motions, in the absence of any other significant energy sources. Since the kinetic energy of organized motions is continually degraded and ultimately dissipated by turbulence and viscosity, the process of kinetic energy production must be a continuous one with, probably, certain fluctuations about a mean rate when the whole atmosphere is considered. The purpose of this discussion is to examine this production process from a hydrodynamical point of view.

Changes in the kinetic energy of a particle or system of particles can result only from the action of mechanical forces, and hence the rate of kinetic-energy production can be discussed in terms of the joint action of such forces and the kinematics of existing motions. In this light it is not essential to inquire how systems of such forces and such motions in the atmosphere are related to the thermodynamical processes which are ultimately responsible for their existence. In order to demonstrate the particular point in question as simply as possible we shall first consider an example of fluid motion under circumstances which are somewhat artificial, but which still have theoretical interest. In view of the fact that the kinetic energy of vertical motions in the atmosphere is very small compared with the kinetic energy of the large-scale horizontal motions we shall consider only the latter.

The approach used is one suggested by the beautiful classic paper of Osborne Reynolds [6] entitled "On the Dynamical Theory of Incompressible Viscous Fluids and the Determination of the Criterion." Since Reynolds was concerned only with the dissipation of kinetic energy, his treatment must be modified in order to envisage also the process which creates kinetic energy. For this reason his assumption of incompressibility will be abandoned. Also, our restriction to the study of the

kinetic energy of horizontal motions introduces certain changes, although these changes are not actually in the nature of approximations.

Study of a Simple System. Let it be supposed that a mass of gas is confined in a chamber with a plane bottom and vertical walls, under the action of gravity which we assume to be acting vertically downward. If the chamber is of sufficiently great height, it is not necessary that it have a top. Likewise, the gas need not be an ideal one, since for the time being no use will be made of an equation of state. Coriolis forces will, for the present, be omitted. Let it be supposed further that the gas is in some state of motion induced by differential heating and cooling.

If we take x, y, and z to be a Cartesian coordinate system with the positive z-axis vertical, we may write the equations of motion for the horizontal directions in the form

$$\begin{aligned} \frac{du}{dt} &= -\frac{1}{\rho}\frac{\partial p}{\partial x} + F_x, \\ \frac{dv}{dt} &= -\frac{1}{\rho}\frac{\partial p}{\partial y} + F_y. \end{aligned} \tag{1}$$

Here u and v are the velocity components in the directions x and y; ρ is the density; p the pressure; t time; and F_x and F_y are the components of the viscous forces in the x and y directions. Generally speaking, the motions in the chamber might be turbulent. If we wish to regard the dependent variables in equations (1) as representing mean values free of the turbulence components, we shall assume that the only change necessary is to include eddy-stress effects in the quantities F_x, F_y after the manner of Reynolds. More will be said concerning this point later.

The kinetic-energy equation corresponding to the system (1) is

$$\begin{aligned} \rho\frac{\partial}{\partial t}\frac{V_h^2}{2} + \rho u\frac{\partial}{\partial x}\frac{V_h^2}{2} + \rho v\frac{\partial}{\partial y}\frac{V_h^2}{2} \\ + \rho w\frac{\partial}{\partial z}\frac{V_h^2}{2} = -\left(u\frac{\partial p}{\partial x} + v\frac{\partial p}{\partial y}\right) - d. \end{aligned} \tag{2}$$

We use the symbol d to represent the rate at which the turbulence and viscosity are decreasing the kinetic energy per unit volume, and $V_h^2 = u^2 + v^2$. It is possible to rewrite (2) in the following form:

$$\begin{aligned} \frac{\partial E}{\partial t} + \frac{\partial Eu}{\partial x} + \frac{\partial Ev}{\partial y} + \frac{\partial Ew}{\partial z} \\ = -\left(\frac{\partial pu}{\partial x} + \frac{\partial pv}{\partial y}\right) + p\left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y}\right) - d, \end{aligned} \tag{3}$$

where use has been made of the continuity equation

$$\frac{\partial \rho}{\partial t} + \frac{\partial \rho u}{\partial x} + \frac{\partial \rho v}{\partial y} + \frac{\partial \rho w}{\partial z} = 0, \tag{4}$$

which in any case must be true, and where $E = \frac{1}{2}\rho V_h^2$ is the horizontal kinetic energy per unit volume. The quantity represented by the last three terms on the left-hand side of (3) is the divergence of the (three-dimensional) kinetic energy transport vector $E\mathbf{V}$. The quantity in the first parenthesis on the right is the divergence of the horizontal vector $p\mathbf{V}_h$. If equation (3) is integrated over an arbitrary volume, both of these quantities may be represented as surface integrals with the aid of the divergence theorem. Thus, if the limits are fixed, we may write

$$\begin{aligned} \frac{\partial}{\partial t}\iiint E\,dx\,dy\,dz \\ = \int EV_n\,dS - \iint p(v\,dx - u\,dy)\,dz \\ + \iiint p\left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y}\right)dx\,dy\,dz \\ - \iiint d\,dx\,dy\,dz, \end{aligned} \tag{5}$$

where V_n is taken to be the inward component of velocity at the boundary, and dS is a surface element.

Equation (5) may now be given the following interpretation. The total horizontal kinetic energy (T) in a fixed region may be changing in consequence of:

1. An advection of new fluid having kinetic energy across the boundary. This is represented by the term $A = \int EV_n\,dS$. This is then one mode of *redistribution* of kinetic energy.

2. The performance of work by pressure forces at the boundary in virtue of the displacements due to the horizontal velocity components. This is represented by the term $W = -\iint p(v\,dx - u\,dy)\,dz$. This is a second mode of *redistribution* of kinetic energy.

3. A production of kinetic energy within the volume itself. This is represented by the term

$$S = \iiint p\left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y}\right)dx\,dy\,dz,$$

which contains the *primary source* of kinetic energy.

4. The action of frictional forces. This effect would ordinarily consist of a dissipation and is represented by the term $D = \iiint d\,dx\,dy\,dz$.

If the limits of integration include all of the fluid in the fixed chamber, it is clear that the surface integrals must vanish, so that in a *mechanically closed* system (5) reduces to

$$\frac{\partial K}{\partial t} = S - D. \tag{6}$$

Since for such a system the frictional effect would ordinarily lead to dissipation, it follows that S must be positive if the total horizontal kinetic energy K is to remain constant or increase. If a more or less constant amount of kinetic energy is to be present, the dissipation must be balanced by a corresponding positive average rate of production.

The production S may be looked upon as the integral of the contributions from the various horizontal layers of fluid present and written as

$$S = \int \left[\iint p\left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y}\right) dx\, dy \right] dz. \tag{7}$$

In view of the fact that the surface integral

$$\iint \left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y}\right) dx\, dy$$

must vanish if the horizontal velocity is zero across the fixed walls, it follows that a given horizontal stratum of fluid cannot give a positive contribution to S unless larger values of the pressure p are associated with areas of horizontal divergence than are associated with areas of convergence. Thus areas of *horizontal* divergence represent primary kinetic energy sources, while areas of convergence represent sinks for kinetic energy. Furthermore, in a mechanically closed system of the kind here considered it is impossible to have source regions for kinetic energy without at the same time having sinks of a hydrodynamic nature, entirely independent of frictional effects.

Equations for the Atmosphere. Before embarking upon a discussion of the meteorological implications of the material presented above, it is desirable to develop the concepts involved in more general terms, so as to render it possible to perform integrations over the entire mass of the atmosphere.

To a sufficiently close degree of approximation the shape of the geopotential surfaces may be considered as spherical so that we may make use of spherical polar coordinates in which r is the radius, ϕ is latitude, and λ is longitude. By analogy with the Cartesian case we may then write the equations of motion for the horizontal directions (see Brunt [2]) in the form

$$\left.\begin{aligned} \frac{du}{dt} - \frac{uw}{r}\tan\phi + \frac{uw}{r} + 2\Omega(w\cos\phi - v\sin\phi) \\ = -\frac{1}{\rho}\frac{\partial p}{\partial x} + F_x, \\ \frac{dv}{dt} + \frac{u^2}{r}\tan\phi + \frac{vw}{r} + 2\Omega u\sin\phi \\ = -\frac{1}{\rho}\frac{\partial p}{\partial y} + F_y, \end{aligned}\right\} \tag{8}$$

where u, v, and w are the linear velocity components in the eastward, northward, and upward directions, respectively; x and y are measures of linear distance eastward and northward, respectively; and Ω is the angular velocity of the earth. The analogous energy equation in this case may be written as

$$\begin{aligned} \rho\frac{d}{dt}\frac{V_h^2}{2} + \rho\frac{V_h^2}{r}w + 2\rho\Omega uw\cos\phi \\ = -\left(\frac{\partial pu}{\partial x} + \frac{\partial pv}{\partial y} - \frac{pv}{r}\tan\phi\right) \\ + p\left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} - \frac{v}{r}\tan\phi\right) - d. \end{aligned} \tag{9}$$

If we make use of the observational fact that the last two terms on the left-hand side of (9) are of a very small order of magnitude, these terms will be dropped.[1] The manipulation of the remaining term on the left side may now be carried out with the aid of the continuity equation much as before, since this operation is independent of the specific coordinate system used, so that we may write

$$\frac{\partial E}{\partial t} + \operatorname{div}_3 E\mathbf{V} = -\operatorname{div}_2 p\mathbf{V}_h + p\operatorname{div}_2 \mathbf{V}_h - d. \tag{10}$$

A volume integral of (10) may now be taken and written in the form

$$\begin{aligned} \frac{\partial}{\partial t}\int E\, d\tau = \int EV_n\, ds - \iint p(v\, dx - u\, dy)\, dr \\ + \int p\operatorname{div}_2 \mathbf{V}_h\, d\tau - \int d\, d\tau, \end{aligned} \tag{11}$$

where $d\tau$ is a volume and ds a surface element. Equation (11) is physically identical with (5) and has, therefore, the same interpretation. In symbolic form we may write

$$\frac{\partial K}{\partial t} = A + W + S - D, \tag{12}$$

which states that the rate of increase of horizontal kinetic energy for a fixed volume is equal to the net rate of advection of such kinetic energy into the region, plus the rate at which work is being done by the surroundings on the fluid in the region through horizontal motions, plus the production of kinetic energy in the volume, minus the frictional dissipation. For a system which is mechanically closed, A and W again vanish. This is therefore true when the entire atmosphere is considered. In this case the surface integral of the horizontal divergence over each closed geopotential surface must vanish as in the case of the chamber previously considered.

Although it is possible to form other energy integrals for fluid motion, as pointed out in standard texts on hydrodynamics (*e.g.*, [1]), the particular merit of the procedure followed above is that the expression for production of kinetic energy assumes a form which is of interest in meteorological problems. The implications of equation (12) may be stated in brief as follows:

1. The intensity of the primary source of horizontal kinetic energy at a given point in the atmosphere is given by the product of the pressure and the divergence of the horizontal velocity.

2. Positive primary sources must always occur in combination with negative sources or sinks independ-

1. In reality these terms represent a conversion of kinetic energy of horizontal motions into kinetic energy of vertical motions, and as such do not involve a production of kinetic energy. Indeed, by methods similar to those used in this paper one can investigate separately the kinetic energy of motions in each of the three directions, namely, zonal, meridional, and vertical. In that case other conversion terms of a similar nature arise.

ent of frictional effects, when the entire atmosphere is considered.

3. In addition to the action of the sources and frictional effects, the horizontal kinetic energy in a fixed region not embracing the entire atmosphere may change due to advection of kinetic energy across the boundary and due to the redistribution of kinetic energy through the boundary by work done by pressure forces and horizontal velocity components at the boundary.

From the standpoint of the general circulation it would appear that the sources of kinetic energy are to be found in the regions of horizontal divergence. The net contribution from a given level results from the fact that areas of divergence generally occur at a different pressure than do the areas of convergence. Thus at lower levels it is common for horizontal divergence to be present in anticyclonic areas while convergence takes place in cyclonic areas, the net result being positive. We do not as yet have sufficient observational material concerning the distribution of divergence at higher levels, but the fact that the pressure decreases with elevation would seem to indicate that the importance of the higher levels rapidly diminishes. Generally speaking, it would thus appear that the energy sources for the general circulation are to be found principally in the subtropical high-pressure cells, the migratory polar anticyclones, and the subsiding cap of cold air over the polar regions. From these primary centers the kinetic energy is continually transferred to the cyclonic areas with convergence which act as sinks in addition to the action of friction.

One might ask why it is that if the diverging anticyclones act as primary sources of kinetic energy, they are not the scenes of major activity. Actually, however, the generation process cannot be present in such systems without the simultaneous operation of the transfer processes. If divergence exists in an anticyclone, the peripheral outward motion results in a rapid outward flow of kinetic energy through work done by pressure forces and through advection.

It was pointed out that a transfer of kinetic energy of horizontal motions across the boundary of a region which is not mechanically closed may be brought about by advection of existing kinetic energy and through the work done by pressure forces in virtue of the components of horizontal velocity across the boundary. Thus, if one considers a symmetrical polar cap extending from the north pole to some middle latitude ϕ and embracing the entire vertical extent of the atmosphere, the expression for the transfer of kinetic energy across the vertical southern boundary at the latitude ϕ is

$$\int (\tfrac{1}{2}\rho V_h^2 v + pv)\, ds \approx \int pv\, ds = \frac{R}{m} \int \rho T v\, ds, \quad (13)$$

where ds is an element of area, R/m is the gas constant for air, and T is the absolute temperature, while the other symbols have the same significance as previously. The approximate equality of the first two integrals is based upon the fact that the advection of kinetic energy in the atmosphere is of a smaller order of magnitude than the contribution of the term pv except possibly at very high levels. The final form depends also upon the feasibility of applying the ideal equation of state to the atmosphere. If these simplifications are accepted, the following observations may be made.

The last integral is proportional to the advection of internal heat energy northward, and hence is in all probability positive. This would indicate that there is normally a poleward flow of kinetic energy across middle latitudes from the tropics and subtropics which apparently serve as important source regions for such energy. Since this flow must cease as the polar regions are approached, it follows that the cyclone belts in middle and polar latitudes serve as dissipative mechanisms for this kinetic energy through friction and through the horizontal convergence present in them.

It is a matter of common synoptic experience that an extratropical cyclone is more apt to intensify if there is a relatively large contrast in the heat advection on its eastern and western sides. According to the present discussion, it is not essential that the increase of kinetic energy in such cases be produced *in situ* through conversion from other forms of energy. The intensification may be brought about through the increased local poleward transport of kinetic energy from the general source region in lower latitudes, as measured by the large net local heat transport poleward.

We have made the tacit assumption in the development given above that the "frictional" term D leads to a dissipation of kinetic energy. If only molecular viscosity and small-scale turbulent viscosity are included in this term, the assumption is undoubtedly valid. However, if relatively large-scale eddies and other large features of the atmospheric motions are included in the form of a gross turbulence as distinguished from the remaining mean motion, it is apparent that the quantity D may then embrace energy-producing systems and it is possible that it may change sign. Thus, for example, if only the average zonal circulation of the atmosphere be considered as the true mean motion so that the cyclones, anticyclones, and other nonzonal motions appear as turbulence, there is no clear a priori reason for assuming that the term D represents a dissipation.

Finally, it is interesting to compare the results obtained here with those of Margules [5] in his classic paper, "On the Energy of Storms." Very broadly speaking, the two approaches deal with essentially the same process. We have simply enlarged the "chamber" containing the gas used by Margules so as to include the whole atmosphere. Furthermore, whereas Margules considered a discrete process, we have replaced it by a continuous one and restricted our attention to the production, redistribution, and dissipation of kinetic energy of horizontal motions only. Also, we have recognized that under these circumstances the pressure multiplied by the *horizontal* divergence is the measure of the rate at which other forms of energy such as potential and internal energy are being converted into kinetic

energy.[2] When the divergence is negative the sense of this conversion process is reversed. It should be noted that this particular result is independent of the physical nature of the "working substance," which might indeed be partly liquid (or even solid), with the gaseous and liquid components undergoing changes of phase. The result therefore automatically embraces the consequence of all condensation phenomena insofar as they contribute to the horizontal kinetic energy.

GLOBAL BALANCE OF TOTAL ENERGY

Basic Equations. Thus far we have found it convenient to deal with the kinetic energy problem alone, since this quantity can be changed only by mechanical forces, and hence may be studied separately in terms of the systems of such forces considered as given by observational data. However the problems connected with the total global energy balance must in the end be of significance in the further understanding of atmospheric and oceanic circulations. For this reason we shall now attempt to formulate certain relationships involved in this more general subject.

Proceeding along more classical lines, let us consider the statement of the general physical energy equation written in the form

$$\rho \frac{dq}{dt} + \psi = \rho \frac{dU}{dt} + p\rho \frac{d\alpha}{dt} = \rho \frac{dU}{dt} - \frac{p}{\rho} \frac{d\rho}{dt}. \quad (14)$$

Here $\rho\, dq/dt$ is the rate of external heat addition per unit volume, U is the total internal energy per unit mass, $\alpha \equiv 1/\rho$ is the specific volume, ψ is the rate of generation of heat by friction per unit volume, while the other symbols have already been defined. With the aid of the continuity equation

$$\frac{d\rho}{dt} + \rho \nabla \cdot \mathbf{c} = 0, \quad (15)$$

where $\mathbf{c}$ is the total vector particle velocity, we may write that

$$\rho \frac{dq}{dt} + \psi = \rho \frac{dU}{dt} + p \nabla \cdot \mathbf{c}. \quad (16)$$

We next proceed to evaluate the last term in (16) from the dynamical equation of motion written in vectorial form as follows:

$$\rho \frac{d\mathbf{c}}{dt} = -\nabla p - \rho \nabla \Phi - 2\rho \boldsymbol{\Omega} \times \mathbf{c} - \mathbf{F}, \quad (17)$$

where Φ is geopotential energy per unit mass, $\boldsymbol{\Omega}$ is the constant angular velocity of the earth's rotation, and $\mathbf{F}$ is the vectorial retarding force per unit volume due to friction.

The scalar product of (17) with the particle velocity yields the corresponding equation of energy which may be written after slight rearrangement as

$$\rho \frac{d}{dt} \frac{c^2}{2} = p \nabla \cdot \mathbf{c} - \nabla \cdot p\mathbf{c} - \nabla \cdot \rho \Phi \mathbf{c} + \Phi \nabla \cdot \rho \mathbf{c} - d. \quad (18)$$

In (18), c is the magnitude of $\mathbf{c}$, and $d \equiv \mathbf{c} \cdot \mathbf{F}$ is the rate at which work is done by the fluid against frictional forces per unit volume. Assuming that the geopotential Φ is constant with time at a fixed point with respect to the earth (this is true except for such things as the small tide-producing disturbances), we may write, with the aid of the continuity equation in the form

$$\frac{\partial \rho}{\partial t} + \nabla \cdot \rho \mathbf{c} = 0, \quad (19)$$

that

$$\Phi \nabla \cdot \rho \mathbf{c} = -\frac{\partial}{\partial t} (\rho \Phi). \quad (20)$$

Using (18) and (20), we can now rewrite (16) in the form

$$\rho \frac{dq}{dt} + \psi - d = \rho \frac{d}{dt} \left(U + \frac{c^2}{2} \right) + \frac{\partial}{\partial t} (\rho \Phi) + \nabla \cdot (p + \rho \Phi) \mathbf{c}. \quad (21)$$

Since with the aid of (19) it follows that

$$\rho \frac{d}{dt} (\quad) = \frac{\partial \rho (\quad)}{\partial t} + \nabla \cdot \rho (\quad) \mathbf{c},$$

we finally have the equation

$$\rho \frac{dq}{dt} + \psi - d = \frac{\partial}{\partial t} \left(\rho U + \rho \frac{c^2}{2} + \rho \Phi \right) + \nabla \cdot \left(\rho U + \rho \frac{c^2}{2} + \rho \Phi + p \right) \mathbf{c}. \quad (22)$$

The various considerations which have entered into the formulation of equation (22) are true for any fluid medium without significant approximation. We may therefore apply the equation to the entire fluid envelope of the earth or portion of it, making no distinction between the atmosphere and the hydrosphere. We can thus integrate it over an equatorial belt between latitudes $-\phi$ and $+\phi$ and include all bodies of water such as the oceans, rivers, lakes, etc. Considering again the average conditions so that local time variations disappear we have, with the aid of the divergence theorem, that

$$H \equiv \int \left(\rho \frac{dq}{dt} + \psi - d \right) d\tau = \int \left(\rho U + \rho \frac{c^2}{2} + \rho \Phi + p \right) v_n \, ds, \quad (23)$$

where $d\tau$ is a volume element. Equation (23) has of course a very simple interpretation and could have indeed been written directly from general considerations. If we include under friction only the effects of

2. It is worthy of note that the present treatment gives no information as to whether the bulk of the kinetic energy generated in the atmosphere represents a conversion from geopotential energy or whether it represents a conversion directly from internal heat energy.

molecular viscosity or of small-scale disturbances which can produce no significant tangential stresses at the boundaries $-\phi$ and $+\phi$, the contribution of the term d in the integral on the left-hand side may be assumed to represent the mean rate of dissipation of kinetic energy into heat within the equatorial belt and therefore cancels the contribution of the term ψ. It follows therefore that H is the total net rate of heating of the air in the belt. Equation (23) simply states that this net incoming energy is transferred meridionally in the form of (1) internal energy ρU per unit volume, (2) kinetic energy of existing motions $\rho c^2/2$, and (3) potential energy $\rho\Phi$, as well as (4) through work done by pressure forces p. We shall refer to these four items as advective modes of energy transfer.

It is here assumed that there is no advection of energy through the surface of the lithosphere. This is essentially correct except for processes such as volcanism and seismological phenomena, but these are deemed to be too unimportant for the present considerations. Also it is assumed that there is no advection of energy through the top of the atmosphere, which therefore neglects the effect of interchange of molecules with astronomical space and of the mass accretions of meteoric origin. The quantity H, representing the net heat gain within the equatorial belt by processes other than advection, may be very closely identified with the net heat received through exchange of radiation with the extraterrestrial environment. This identification neglects such processes as conduction of heat from the interior of the earth, which is of appreciable importance only locally in connection with volcanism, and it also neglects heat liberated (or consumed) by net progressive chemical changes such as oxidation or photosynthesis processes. Net heat gain through exchange of radiation with other portions of the earth is likewise neglected. All the various corrections mentioned are however in all probability insignificant.

If we take H to be the net gain of heat through exchange of radiation with space, various necessarily crude estimates of this quantity have been prepared. A convenient arrangement of one set of such estimates has been presented by Bjerknes [1]. As is well known, the estimates give positive values of H for all choices of $\pm\phi$ between the equator and the poles with a maximum for about $\phi = \pm 45°$ latitude. It therefore follows that there must be an advective transport of energy poleward by the combination of terms indicated in (23), with a maximum at $\phi = \pm 45°$ latitude in the mean.

It is apparent that the important problem posed by the global energy balance concerns itself with the partition of the poleward energy transport among the several terms in the integrand of the right-hand member of equation (23).

Discussion. Unfortunately our observational information concerning the problem posed by the global energy balance is very sketchy and incomplete. We shall nevertheless endeavor to discuss such aspects of it as are possible with existing knowledge. In the first place, the contribution of the hydrosphere to the transfer integral is probably small (see Sverdrup [9]), but directed toward the poles. A reasonable estimate of this contribution would appear to be about ten per cent of H. Denoting this fraction by h, let us next turn our attention to the state of affairs within the atmosphere.

It has been previously pointed out that the advection of existing kinetic energy $\rho c^2/2$ meridionally is very small, relatively speaking. We are therefore again justified in omitting it. The internal energy U may be considered as being the sum of the internal heat energy and the latent heat of water vapor. Since there is assumed to be practically no net meridional mass transport in the atmosphere, it will suffice to assume that the internal heat energy is given by $c_v T$, c_v being the mean specific heat at constant volume. It thus follows that $U \approx c_v T + \epsilon L$, where ϵ is the specific humidity and L is the latent heat of condensation, assumed to be constant.[3] The term involving the work done by pressure forces may again be transformed according to the ideal equation of state, and finally combined with the internal heat-energy term using the relation between the specific heats of a gas. In the end (23) may be written in the form

$$H = h + \int (c_p T + \epsilon L + \Phi)\rho v_n \, ds, \tag{24}$$

where c_p, the specific heat at constant pressure, is assumed to have a constant mean value.

The contribution of the term involving the latent heat may be estimated from the mean excess of evaporation over precipitation in the equatorial belt. Using data of this kind given by Conrad [3], the writer has estimated that the magnitude of this effect is about one-half of H for an equatorial belt extending to $\pm 40°$ latitude. Let us denote this quantity by l.

The remaining terms may be examined as follows. If we write

$$\rho v_n = \overline{\rho v_n} + \{\rho v_n\}, \tag{25}$$

where $\overline{\rho v_n}$ is the average of ρv_n along the entire length of a closed latitude circle and $\{\rho v_n\}$ is the deviation from this average, it is clear that the identical vanishing of $\overline{\rho v_n}$ implies absence of closed mean meridional circulations, while its presence is required for the existence of such circulations. Here we neglect all topographic inequalities of the earth's surface. In view of the fact that Φ is constant along a latitude circle at any given elevation and that $\{\overline{\rho v_n}\}$ is zero, it follows that (24) may be rewritten in the form

$$H = h + l + \int c_p T\{\rho v_n\} \, ds + \int (c_p T + \Phi)\overline{\rho v_n} \, ds, \tag{26}$$

3. The latent heat as ordinarily discussed is the sum of the change in specific internal energy plus the work done in the expansion during evaporation. Strictly speaking, we are here concerned only with the first quantity, although the difference is not great enough to be of much significance.

where the last integral now represents the contribution of mean meridional circulations of the Hadley type to the poleward energy flux.

It should be remarked that, in a stable atmosphere, a meridional cell of the so-called direct type produces a poleward flow of energy, while one of the indirect type produces a flow in the opposite sense. This can easily be shown from the form of the last integral in (26).

Very preliminary estimates by the writer of the value of the third term on the right-hand side, made from geostrophic wind data for individual Northern Hemisphere maps for various levels seem to suggest that this contribution is somewhere in the vicinity of one-half of H at 40°N latitude. All in all it would thus appear that the contribution of the mean meridional circulations is small or even negative in middle latitudes, although very little reliance can be placed on the figures given or on the value of H obtained from the data given by Bjerknes. Suffice it to say that in all cases reasonable orders of magnitude are obtained, which in itself is somewhat encouraging.

Concluding Remarks. Most classical models for the general circulation of the atmosphere have followed along the lines originally proposed by Hadley [4] in that they assume the existence of large convectively driven closed circulations in meridional planes, at least in the average conditions. The development of the mean zonal motions is then ascribed to the effect of the earth's rotation on these primary circulations. In such a scheme the meridional circulations are a necessary mechanism in the production of kinetic energy. Also, according to this model the necessary meridional transport of angular momentum could be achieved if the poleward branches of the circulations carry more angular momentum than the returning ones at other levels.

For a number of reasons modern meteorologists have come to view models of the Hadley type with skepticism. A discussion of the basis for this current skepticism has been recently given by Rossby [7]. The writer rather inclines to the view that, although some mean meridional circulations in all probability do exist, their role in the energy balance and in the horizontal transport of angular momentum, at least in middle latitudes, may be overshadowed by the characteristics of other types of motion. Thus, following an original suggestion by Jeffreys, the writer has pointed out elsewhere [8] that the transport of angular momentum could be achieved through the observed properties of horizontal motions. This contention has since received a certain amount of corroboration by the observational studies of Widger [11].

The general views expressed in the present paper indicate that atmospheric meridional circulations likewise may not be essential for the global energy balance. Much more could be said if a more satisfactory appraisal were available for the magnitudes of the terms appearing in equation (26), since the values given are useful only for purposes of orientation. Further work in this direction is currently in progress at the Massachusetts Institute of Technology.

EXTRATROPICAL CYCLONES

By J. BJERKNES

University of California, Los Angeles

With the consent of the editor the present article has been written as a summary of the research on extratropical cyclones in which the author himself has been directly involved. References to the work of others are therefore few, and the reader will not get a complete survey of the title subject.

This article is composed of two parts. In the first, extratropical cyclones are treated as simplified models for the sake of clarifying the theoretical principles. In the second, these principles are applied to a real storm over North America whose development may be considered as the prototype of a simple life history of extratropical cyclones. The modifications of that life history, caused by the varying initial conditions and the influence of neighboring systems in the general circulation, are treated by Dr. E. Palmén in his contribution to the Compendium.

DYNAMICS OF SIMPLIFIED CYCLONE MODELS

Theory of Pressure Changes and Thermal Structure of Extratropical Cyclones. The fully developed extratropical cyclone consists of a counterclockwise[1] vortex which extends upward into a wave trough in the upper westerlies. The dynamics of the extratropical cyclone is therefore a composite one, combining the dynamic phenomena of the vortex and the wave. We will here state separately the essential features of the atmospheric vortex and the atmospheric wave and then proceed to describe the composite dynamics of the extratropical cyclone.

In analyzing the displacement, intensification, and weakening of vortices and waves it is useful to consider the accompanying pressure changes, which obey the "tendency equation,"

$$\left(\frac{\partial p}{\partial t}\right)_h = -\int_h^\infty g \operatorname{div}_H (\rho \mathbf{v}) dz + (g\rho v_z)_h. \qquad (1)$$

Expressed in words, the rate of pressure change with time at a fixed point at the level h is determined partly by the net horizontal inflow into the vertical unit air column from h to the top of the atmosphere and partly by the vertical inflow of air through the base of that column.

A circular cyclonic vortex with vertical axis centered at the pole of a planet without mountains represents the simplest case of atmospheric vortex dynamics. In the case of frictionless motion in such a polar vortex the particles could be kept in steady-state zonal motion from west to east. The horizontal divergence is then everywhere zero and no vertical motion occurs, so that the tendency equation must indicate zero local pressure change at all points. With friction against the ground, the flow in the lowest part of the atmosphere would be given a component of indraft towards the vortex center, and this horizontal convergence of mass would make the pressure rise in the central portion of the pressure minimum, thus decreasing the zonal air motion. No steady state would be reached until the flow at the ground and the horizontal pressure gradient at the ground have reached zero. If the central core of the vortex is colder than its environment, there would still be a pressure gradient towards the pole in the free atmosphere, and there the air may continue its west to east circulation without horizontal divergence. This picture corresponds rather well to reality as represented by the time-averaged motion in the arctic region: almost zero meridional pressure gradient and zero zonal motion at the ground, and increasing poleward pressure gradient with height, accompanied by increasing westerlies with height. The initial assumption of a cyclone at the pole, and the additional assumption of friction at the ground, thus lead to the dynamical prediction that the cyclone at the ground should eventually disappear, while in the free atmosphere it should be conserved. This behavior of the circular cyclonic vortex can be generalized to apply also at other latitudes; the simple circular vortex is liable to die out gradually at the ground because of friction.

The circular cyclonic vortex centered in middle latitudes does not represent a steady-state dynamic system even in the absence of friction at the ground. Although the horizontal pressure gradient may everywhere be directed towards the center and its intensity may be a function only of the distance from the center, the motion around the center cannot be a simple circular one, because the Coriolis parameter varies from the northern to the southern part of the vortex. As a result of the variation of the Coriolis parameter the wind will be stronger in the southern than in the northern part of the vortex, and the net air transport across a north-south median wall will be from the western to the eastern half of the vortex. Consequently the pressure will rise in the eastern half because of horizontal convergence and fall in the western half of the low pressure system because of horizontal divergence, so that the pressure minimum and the accompanying vortex will drift westward. Eccentricity of the pressure field of such a sense as to involve a stronger pressure gradient in the southern than in the northern part of the vortex may reduce, neutralize, or even reverse that drift. The dynamic theory for the eccentric vortex has been developed in approximate form

1. All references to the sense of rotation in this article apply to the Northern Hemisphere.

by Holmboe [3]. He defined a "critical eccentricity" which would balance the exchange of air between the two halves of the vortex. Values of the quantity $|v| - |v'| - 2c = 4\Omega a\sigma_p^2 \cos\phi$, evaluated in a narrow isobaric channel of critical eccentricity, are given in Table I (v and v' are the wind velocities at southernmost and northernmost points, respectively, of the isobaric channel, c is the eastward speed of displacement of the vortex, Ω the angular speed of the earth, a the earth's radius, σ_p the angular radius of the isobaric channel, and ϕ the geographical latitude). In the case of the stationary vortex, the exchange of air between the eastern and western halves of the vortex is balanced if the wind velocity in the southernmost point of the isobaric ring exceeds that in the northernmost point by the tabulated amount. Near the center the flow can be almost constant all around the isobaric ring, but the greater the radius the more will the west wind in the south have to exceed the east wind in the north, particularly in low latitudes.

TABLE I. VALUES OF $|v| - |v'| - 2c = 4\Omega a\sigma_p^2 \cos\phi$ FOR CRITICAL ECCENTRICITY (in m sec^{-1})

ϕ	Angular radius of isobaric channel			
	1°	5°	10°	20°
90°	0	0	0	0
80°	0.1	2.5	9.9	—
70°	0.2	4.9	19.4	78
60°	0.3	7.1	28.4	114
50°	0.4	9.1	36.6	146
40°	0.4	10.9	43.6	175
30°	0.5	12.3	49.4	198

In applying the table to a moving vortex, twice the speed of displacement of the vortex must be added to the tabulated speed to give $|v| - |v'|$. For the eastward moving vortex the critical eccentricity is thus stronger than for the stationary one. Even slightly greater eccentricity would be needed to bring about accumulation of air in the western half of the pressure minimum and depletion of air in the eastern half, a condition which would seem necessary to make the system move eastward. A check with measured eccentricities shows, however, only "subcritical" cases; in other words all observed cyclonic vortices accumulate air in their front parts at the expense of the rear parts. The pressure change in such a moving vortex can therefore be explained only if other flow patterns prevail above the vortex. This conclusion is corroborated by the experience of synoptic aerology, and the typical upper flow pattern above moving vortices is that of the atmospheric wave. In the composite extratropical cyclone, the vortex part resists the eastward motion by piling up air in the front half; this resistance increases the faster the vortex is forced to move.

The atmospheric wave[2] superimposes a quasi-horizontal oscillation upon the fundamental current of straight westerlies. This is accompanied by a periodic distribution of horizontal mass divergence, which in first approximation depends on the relative strength of the "curvature and latitude effects" upon the wind speed. The curvature effect makes the air move supergeostrophically while overtaking the wave crest and subgeostrophically while overtaking the wave troughs. The latitude effect upon the wind speed comes from the fact that each flow channel is in a higher latitude at the anticyclonic bend than it is at the cyclonic bend, so that, the horizontal pressure gradients being equal, the geostrophic wind would be stronger at the cyclonic than at the anticyclonic bend. The result of

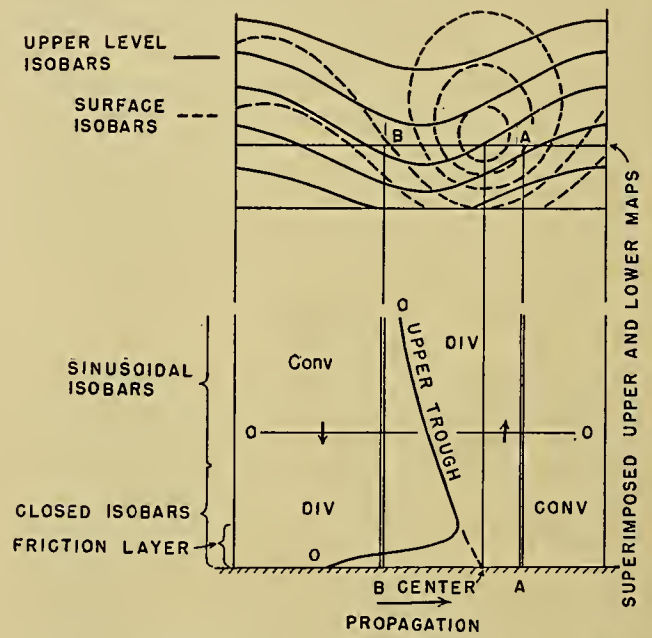

FIG. 1.—Schematic model of cyclone with lower-vortex and upper-wave part. West-to-east vertical profile shows location of horizontal divergence and convergence of mass.

these two opposite effects on horizontal divergence is in favor of the curvature effect when wave lengths are short and the fundamental current is strong. In this case the wave crests are preceded by horizontal convergence and the wave troughs by horizontal divergence. In the case of long waves and/or a weak fundamental current, the opposite distribution of horizontal divergence is established. The same conditions are found in air layers which move eastward more slowly than the wave.

In the usual baroclinic westerly current of middle latitudes a wave extending from the slow-moving lower layers to the fast-moving upper layers would have opposite patterns of horizontal divergence in the upper and lower part (see Fig. 1). At the level of transition between the upper and lower pattern a wave motion with zero horizontal divergence will exist. This "level of nondivergence" will be found at the height where the speed of the undisturbed current, v_x^*, is given by

2. The fundamental properties of the atmospheric waves of synoptic meteorology were first sketched by J. Bjerknes [2] and later developed mathematically by Rossby [26, 27] and Haurwitz [10]. In this article we follow the more recent treatment by J. Bjerknes and Holmboe [3].

$$v_x^* = c + \frac{2\Omega a \cos^3 \phi}{n^2}. \quad (2)$$

In this equation c is the eastward speed of propagation of the wave, Ω is the angular velocity of the earth, a is the earth's radius, ϕ is the geographical latitude, and n is the wave number per circumference of the earth. Numerical values of $(2\Omega a \cos^3 \phi)/n^2$ are given in Table II. This table, in conjunction with equation (2), shows that in short waves, such as are found to accompany the individual traveling cyclone, the level of nondivergence lies at an elevation where the undisturbed current moves only a little faster than the wave. In long waves the air at the level of nondivergence moves eastward much faster than the wave itself, particularly in low latitudes.

TABLE II. VALUES OF $(2\Omega a \cos^3 \phi)/n^2$ (in m sec^{-1})

ϕ	Wave length (deg. long.)				
	180°	120°	60°	36°	18°
70°	9.3	4.1	1.0	0.4	0.1
60°	29.0	12.9	3.2	1.2	0.3
50°	61.6	27.4	6.8	2.5	0.6
40°	104.3	46.3	11.6	4.2	1.0
30°	150.7	67.0	16.8	6.0	1.5

The level of nondivergence may be determined from sets of aerological maps, with the aid of Table II. Its height differs from case to case, but according to Charney [4] and Cressman [5] it averages around 600 mb for both long and short waves. Hence, with a given model of baroclinic westerlies, the speed v_x^* of the undisturbed westerlies at the level of nondivergence is approximately the same parameter for long and short waves. The speed of all such waves, which are superimposed on the same westerly current, therefore varies with wave length according to the formula,

$$c = v_x^* - \frac{2\Omega a \cos^3 \phi}{n^2}. \quad (3)$$

Short waves (large n) move almost with the speed of the air at the level of nondivergence. Long waves move eastward more slowly than short ones, and may also retrograde. Table II, applied to the case $c = 0$, gives us a survey of the wind at the level of nondivergence in stationary waves. At 70° latitude the west wind must be quite light for waves to be stationary, and the 180° wave length seems to be the most likely one for standing waves. Proceeding to lower latitudes, we find that the 180° stationary wave requires stronger westerlies than are ever known to occur. Assuming that v_x^* would never be greater than 30 m sec^{-1}, we see that below 60° latitude the 180° stationary waves would never occur, below 50° the 120° stationary waves also become impossible, and so on. This dependence of the long-wave pattern on geographical latitude usually leads to the establishment of only two or three standing waves per earth's circumference near the pole and stationary patterns with higher wave numbers in lower latitudes. In the latitudes of pattern transitions, complicated cases of wave interference occur.

The waves in the westerlies associated with the moving extratropical cyclones are by necessity of short wave lengths, say thirty degrees longitude. According to (3) and Table II, such waves move with a speed c, only slightly smaller than v_x^*, the speed of the westerlies at the level of nondivergence.

Figure 1 shows the position of the pressure minimum at sea level relative to that of the upper trough. The axis of minimum pressure of the closed low tilts towards the coldest side, which is usually to the west or northwest of the location of the surface center. The tropospheric part of the upper trough is also displaced westward with height, but not as far per unit height as the subjacent center of low pressure.

The friction layer of the closed vortex (up to about 1-km height) has horizontal convergence. Above the influence of surface friction the eastern half of the vortex has horizontal convergence of mass and the western half, horizontal divergence. This holds true also for the upper trough up to the level of nondivergence, beyond which divergence and convergence exchange positions. The tendency equation (1) applied to the schematic cyclone cross section of Fig. 1 gives an answer to the two questions: How can the cyclone move eastward as most middle latitude cyclones do? and, How can it deepen despite the frictional convergence?

The eastward displacement of the cyclone is assured if the vertical integral of horizontal mass divergence in the tendency equation is determined as to sign by the atmosphere above the level of nondivergence. The deepening of the pressure minimum likewise depends on the influence from above the level of nondivergence. Because of the westward tilt of the axis of the cyclone a vertical air column located at the surface center will show horizontal convergence in its lower portion, where it passes through the forward part of the vortex, and horizontal divergence where it traverses the upper wave pattern east of the wave trough. Deepening of the surface center will occur only if this upper-air divergence overcompensates the low-level convergence.

In all parts of the cyclone the surface pressure tendency represents a small change in the weight of the local vertical column, resulting from the difference between accumulation and depletion of air, each of which represents much greater weight changes. The natural adjustment of the pressure tendencies to the observed moderate values can be visualized as follows. In the low-level vortex, the convergence in the front and the divergence in the rear are more strongly developed the faster the vortex is forced to move. We have also seen from Table II that the level of nondivergence in the upper wave rises to a higher elevation, and the divergence values above that level decrease, when the wave speed increases. Therefore, a supposed increase in speed without a change in the structure of the cyclone would lead to a weakening of the high-level contribution and a strengthening of the low-level contribution to the change in weight of air columns. This would be tantamount to a decrease in pressure tendencies. Quite analogously, it can be shown

that a supposed slowing down of the cyclone without change in its structure would lead to increasing surface pressure tendencies. From this it can be concluded that the speed of a given cyclone is stable as long as its total three-dimensional structure remains the same. The pressure tendencies are then also stable although they are made up as small differences of large opposite contributions of horizontal divergence and convergence.

A real increase in the divergence effects of the upper wave would come from a lowering of the level of nondivergence and an inherent increase of that part of the atmosphere in which the air current is supercritical. According to (3), this may take place through one of the following changes of parameters in the upper wave: (1) an increase of the speed v_x of the upper westerlies, (2) a decrease of angular wave length $2\pi/n$, and (3) travel towards higher latitudes. In all these cases the compensating mass-divergence effects from low levels automatically become greater as the speed of the cyclone increases. The occurrence of excessive values of barometric tendencies is thus automatically avoided.

The slowing down which is normally observed in deep and extensive cyclones is associated with the great depth of atmosphere moving in a closed cyclonic flow pattern. If that pattern has a subcritical eccentricity, which is the more frequent case, it will maintain mass convergence in the eastern half and mass divergence in the western half. The influence of an upper wave pattern can then only barely overcompensate the divergence effects below, and the resulting pressure tendencies will be small. A final reversal of tendencies, and a retrograding of the cyclone, will result if the low-level mass-divergence effects overcompensate those from the upper wave pattern.

The distribution of horizontal divergence also determines the vertical motion, which in the "smoothed" cyclone model always goes upward in the front half and downward in the rear (Fig. 1). This model feature agrees with the observed distribution of cloudiness and precipitation in the cyclones. Modern aerological analysis of the field of vertical motion carried on by the Department of Meteorology at New York University has corroborated these findings. A summary of the careful and extensive work in that field was published in 1948 by Miller [20]. From that report we also know that the vertical motion of extensive air masses usually is less than 3 cm sec^{-1} even at the level of nondivergence, where the maximum upward and downward values of momentum occur. Higher values of vertical motion up to 10 cm sec^{-1} should occur over narrow zones near fronts, while the occurrences of updrafts and downdrafts of several meters per second are restricted to small parts of individual convective clouds.

Typical patterns of temperature distribution in the extratropical cyclone can be seen from the sample cyclones described later in this article. The most frequent development of the temperature pattern in the lower tropospheric part of the vortex can be represented schematically by the maps and profiles in Fig. 2. The incipient cyclone (Fig. 2*a*) coincides with the apex of a warm tongue formed on a "front" across

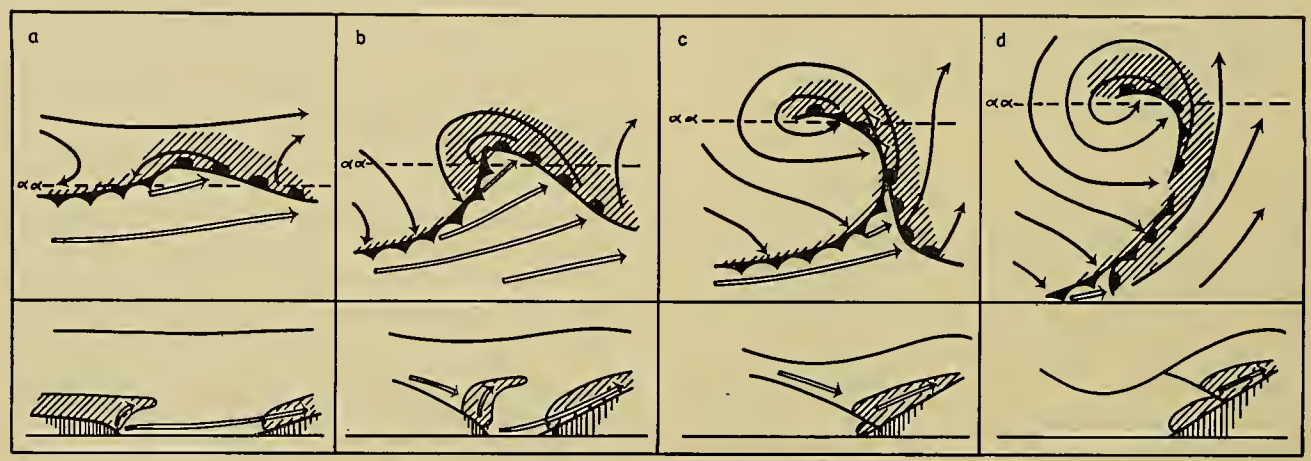

FIG. 2.—Successive stages of development of a frontal wave to an occluded vortex.

which the horizontal temperature gradient reaches a maximum. The frontal surface rises towards the cold side at an angle of inclination averaging around one in a hundred. It conserves its identity from day to day and moves along at a speed determinable from the winds through the kinematic boundary condition. The wave amplitude increases as the cyclone matures (Fig. 2*b*) and the central pressure decreases. Next follows the "occlusion" process (Fig. 2, *c* and *d*) during which the warm tongue is lifted from the ground, first near the center, later also farther out. The occluded front formed at the junction of the two cold wedges tends to wrap around the cyclone center as part of a spiral, and the same shape is found for the warm tongue in all levels of closed cyclonic circulation. In the profile in Fig. 2*c*, which is placed at a short distance south of the cyclone center, the occluded front is a warm-front type, that is, the cold wedge behind the occlusion is less cold than the one in front. This is also true of Fig. 2*d*, but it can usually be assumed that farther south the occlusion is a cold-front type. Where the transition from one occlusion model to another takes place the occluded front on the map must show a little

gap. The lifting of a tongue of warm air relative to a colder environment, illustrated in Fig. 2, can be assumed to furnish a great part of the increase in kinetic energy during the cyclonic development from wave to vortex.

The tropopause is also shown in the profiles. It has a crest over the warm-front surface and a trough over the cold-front surface, and the amplitude of the tropopause oscillation increases with the growth of the cyclone. In Fig. 2*d* the tropopause has a deep depression almost coinciding with the cyclone center, which is at that stage surrounded by air of cold origin up through the whole troposphere. Details of tropopause structure, such as the frequent subdivision into multiple tropopauses, have been left out in Fig. 2.

Hatched areas in Fig. 2 indicate the location of the main precipitation areas of the cyclone. The largest area is covered by the warm-front rain, where the air from the warm tongue climbs the receding wedge of cold air and condenses much of its moisture. A more narrow zone of precipitation accompanies the cold front where some air from the lower part of the warm tongue is lifted by the advancing cold wedge. Higher portions of the warm tongue move faster than the cold-front wedge and are not lifted by it. The described upward motion of the warm air next to the frontal surfaces should be visualized as being superimposed on the general pattern of vertical motion, upward in the front half and downward in the rear half of the cyclone (Fig. 1). This general, upward motion is sometimes sufficient to cause rain where it is not called for as a consequence of upgliding on frontal surfaces. Some extensive warm-sector rains and also the rain in the front half of a cold trough or a cold vortex are probably to be explained by the general upward motion shown in Fig. 1.

To complete the precipitation picture of the cyclone the air-mass precipitation should also be added, that is, the drizzle in the warm moist parts, caused by condensation from low clouds formed by the cooling of the warm air over cold surfaces (mainly ocean surfaces), and the convective showery precipitation formed through the heating from the ground, or through lifting of convectively unstable air at fronts.

While the thermal pattern of the cyclone near the ground is the result mainly of horizontal advection and nonadiabatic gain or loss of heat exchanged with the ground, the pattern in the free atmosphere is also influenced by the slow but systematic vertical displacement of the air shown in Fig. 1 and by the heat transfer of penetrative convection. However, the dominant process for the shaping of the upper-tropospheric temperature field is horizontal advection. The development of the thermal pattern of the waves in the upper westerlies follows roughly the advective scheme shown in Fig. 3. A warm tongue forms in the part of the wave with advection from the south, and a cold tongue in the part with advection from the north. In this early stage of the wave the pressure crests and troughs must tilt westward, as shown for the pressure trough in Fig. 1. In the further development, both warm and cold tongues grow in amplitude and move forward relative to the pressure wave, because the eastward motion of the air exceeds that of the wave. If the wave motion were entirely horizontal, a thermal pattern of permanent structure relative to the moving wave would be reached when the isotherms have adapted to the shape of the relative streamlines. For the idealized case of v_x = constant in each level of the sinusoidal

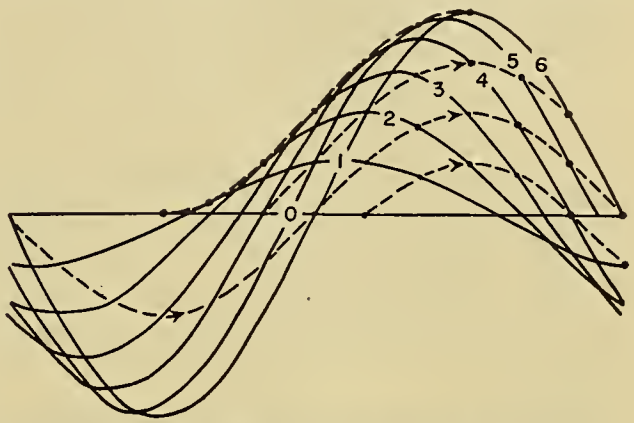

FIG. 3.—Advective formation of the thermal upper wave by the winds blowing relative to the moving pressure wave.

wave pattern, the ratio of the amplitude A_R of the relative streamline to that of the streamline A_S would be

$$\frac{A_R}{A_S} = \frac{v_x}{v_x - c}. \tag{4}$$

Hence, close to the level where v_x is equal to the wave speed c, the relative streamlines, and with them the advectively transported isotherms, would acquire a much greater amplitude than that of the streamline. The ratio A_R/A_S will decrease from that level upward to the tropopause, where v_x has its maximum.

Under the influence of the upward motion ahead of the pressure trough and downward motion behind it, the ratio in (4) would be reduced, as shown by Miller [20]. Synoptic experience shows that A_R/A_S stays positive in all tropospheric levels where $v_x > c$, also under the joint influence of vertical motion and horizontal advection. In other words, after a period of thermal transformation of the type shown in Fig. 3, the waves in the upper troposphere tend to become thermally symmetric, with warm tongues coinciding with pressure crests and cold tongues with pressure troughs.

With the reversal of the meridional temperature gradient from troposphere to stratosphere, the advective effects on temperature in the upper waves are also reversed. Hence the stratospheric pressure crests are cold and the pressure troughs warm. It then follows indirectly that the wave pattern of pressure crests and troughs rapidly loses amplitude with height in the stratosphere. In the stably stratified stratosphere the local warming and cooling through vertical motion are stronger than in the troposphere, and are quite

often stronger than the temperature change by advection.

Vorticity Analysis of the Extratropical Cyclone. An analysis of the vorticity distribution and the history of vorticity change of individual parcels in the vortex and wave will reveal more of the dynamics of the cyclone. The vertical component of the vorticity ζ may be identified on the horizontal streamline maps as a particle rotation about a vertical axis, partly due to curvature, v/r_s, where r_s is the radius of curvature of the streamline, and partly due to shear, $-\partial v/\partial n$:

$$\zeta = \pm \frac{v}{r_s} - \frac{\partial v}{\partial n} = \frac{\partial v_y}{\partial x} - \frac{\partial v_x}{\partial y}. \tag{5}$$

The rules for determining the algebraic sign can always be decided upon by referring to the Cartesian component form of vorticity, added as an alternate expression in (5). The convention used here is to let the positive direction of the coordinate n point to the left of the wind, to consider v and r_s always positive, and to use the positive sign in front of v/r_s for cyclonic and the negative sign for anticyclonic curvature of the streamlines.

The vorticity change of the individual traveling particle [11, 13, 16, 26, 27] is given by the equation,

$$\frac{d\zeta}{dt} = \frac{\partial p}{\partial x}\frac{\partial \alpha}{\partial y} - \frac{\partial p}{\partial y}\frac{\partial \alpha}{\partial x} - (\zeta + 2\Omega \sin\phi)\,\mathrm{div}_H\, \mathbf{v} - \frac{(2\Omega \cos\phi)}{a} v_y + \frac{\partial v_z}{\partial y}\left(2\Omega \cos\phi + \frac{\partial v_x}{\partial z}\right) - \frac{\partial v_z}{\partial x}\frac{\partial v_y}{\partial z}. \tag{6}$$

The first two terms on the right represent in component form the effect of isobaric-isosteric solenoids on the change of vertical vorticity. These terms are always found to be insignificant compared to the following ones. The divergence term shows how horizontal expansion (divergence) creates negative (anticyclonic) vorticity, and horizontal contraction creates positive (cyclonic) vorticity. The next term shows the effect on relative vorticity ζ of the displacement of the air, either towards the polar regions where the vertical component of the earth's vorticity $2\Omega \sin\phi$ is great, or towards the equator where $2\Omega \sin\phi$ is zero. In the absence of the other factors, poleward movement would entail a decrease of relative cyclonic vorticity or an increase of relative anticyclonic vorticity, and movement away from the pole would entail an increase of relative cyclonic vorticity or a decrease of relative anticyclonic vorticity. The last two terms on the right-hand side describe the influence of the vertical motion in changing the vorticity about the vertical. The term involving $\partial v_z/\partial y$ represents, in part, the fact that the infinitesimal disk of air, whose rotation decides the value of ζ, arrives at a horizontal position from earlier positions with meridional tilt. In terms of relative-vorticity change, this is equivalent to a change in latitude in addition to that by horizontal meridional advection, as can be seen from the analogy between the terms $(2\Omega \cos\phi)\partial v_z/\partial y$ and $-(2\Omega \cos\phi)v_y/a$. Furthermore, the term in $\partial v_z/\partial y$ represents the effect of rotating the air in the yz-plane so that the vorticity about the y-axis, $\partial v_x/\partial z$, acquires a vertical component at the rate $(\partial v_z/\partial y)(\partial v_x/\partial z)$ per unit time. Analogously, the last term in (6) represents the rate of change of vorticity about the z-axis resulting from a rotation of the air in the xz-plane. Usually the terms in $\partial v_z/\partial y$ and $\partial v_z/\partial x$ are considered to be insignificant in relation to the divergence term and the meridional advection term, but possible exceptions will be mentioned below.

In the frontal wave of the lower troposphere, the cold air enters the moving cyclone along the warm front (Fig. 4). Near the front it has initial cyclonic shear

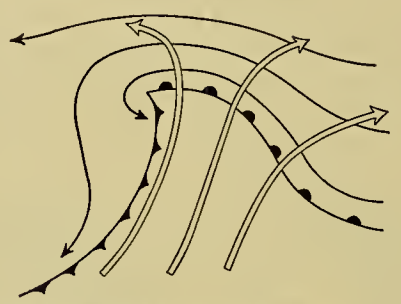

FIG. 4.—Motion of warm and cold air relative to the moving frontal wave.

which had been acquired during the period of frontogenesis (see p. 590). The increase of the cyclonic vorticity in the cold air on its way toward the wave apex is due to the horizontal convergence, which extends all over the front half of the cyclone (see Fig. 1). This creation of relative cyclonic vorticity is somewhat reduced by the effect of the poleward component of air travel. Behind the wave apex the air returns southward and as a result its relative cyclonic vorticity should increase. At the same time, however, the air enters the region of horizontal divergence, which has the opposite effect upon vorticity change. The result is that the air which had acquired maximum cyclonic shear along the warm front maintains cyclonic vorticity after passing the wave apex, but with a simultaneous shift from shear to curvature vorticity. The cold air passing at greater distance from the center changes from moderate cyclonic to anticyclonic vorticity. During the growth of the cyclone more and more of the cold air is able to maintain its cyclonic vorticity after passing the wave apex.

The warm air in the frontal wave enters the cyclone from the southwest. Its speed in lower levels just barely exceeds that of the cyclone in its eastward motion. Upon arrival at the warm front the warm air climbs the receding cold wedge. Again, one branch of anticyclonic and another of cyclonic vorticity may be discerned. Farthest away from the center, where the horizontal convergence is moderate or nonexistent, the warm air gains anticyclonic relative vorticity through the poleward component of movement. Closer to the center, where the horizontal convergence is stronger, the warm air acquires cyclonic relative vorticity despite its dis-

placement polewards. This latter development, which does not start until the cyclone is past the nascent stage, gains in magnitude with the growth of the cyclone.

In the westerly wave of the upper troposphere, as represented in Fig. 1, the air enters the cyclone from the northwest and leaves it toward the east, across the wave crest ahead of the surface cyclone. As long as the upper wave does not degenerate, the relative vorticity changes sign at the longitude of the inflection points, thus changing from anticyclonic to cyclonic relative vorticity in the middle of the upper zone of convergence, and from cyclonic to anticyclonic in the middle of the upper zone of divergence. This vorticity change by divergence is supported by the effect of meridional advection.

The factor $(\zeta + 2\Omega \sin \phi)$ in the divergence term of (6) is equal to the absolute vorticity ζ_a of the air relative to a nonrotating coordinate system. When ζ is positive (cyclonic), ζ_a is large and the individual vorticity change with time becomes quite sensitive to horizontal convergence or divergence. If the air is subject to a sustained process of horizontal convergence, its cyclonic vorticity will increase without any theoretical upper limit. The cyclonic bends of an upper sinusoidal westerly are therefore frequently seen to become strongly curved. On the other hand, when ζ acquires large negative (anticyclonic) values, the absolute vorticity may go to zero or even become negative. This happens almost exclusively in the upper troposphere and lower stratosphere where the wind velocities are very strong. On wave crests where ζ_a reaches values close to zero, the vorticity change is only feebly influenced by horizontal divergence, and obeys mainly the term of meridional advection in (6). This would be equivalent to motion under approximately constant absolute vorticity $\zeta_a \approx 0$ or $\zeta \approx -2\Omega \sin \phi$. If a wave crest in the upper atmosphere has developed to that extreme stage, the particles overtaking the crest would maintain their anticyclonic vorticity (in the form of curvature and/or shear) for a long period thereafter. Figure 5 illustrates that case schematically. From an initial flow pattern of sinusoidal westerlies (streamline 1) a "meandering" westerly current develops through the growth of the wave crest and the deepening of the next downwind wave trough (streamlines 2 and 3). This development towards meandering flow is not dependent on the absolute vorticity's actually having reached zero. With absolute vorticities still positive, but numerically small, the vorticity change begins to react sluggishly to horizontal convergence with the result that the sinusoidal perturbation of the westerlies begins to degenerate. The meandering development may also start from an initially straight current with anticyclonic shear close to the value $-2\Omega \sin \phi$. Any small wave impulse may then develop into meandering wave patterns.

It is obvious that the meandering phenomenon, once started in regions of excessive anticyclonic vorticity in the upper atmosphere, will also have a profound influence on the total cyclone picture down to the ground. The deepening of the upper wave trough is associated with the deepening of the cyclonic vortex underneath, and usually also entails a southward component added to the normal eastward displacement of the cyclone. In all cases of such deepening the initial upper disturbance must start through the build-up of excessive anticyclonic curvature on the wave crest to the west of the cyclone. Above the level of nondivergence, the divergence term and the meridional advection term in (6) are of the same phase, so that the additional terms in $\partial v_z/\partial y$ and $\partial v_z/\partial x$ are not likely to affect the general pattern of $d\zeta/dt$ very much. The two levels where their influence may be expected to count are (1) close to the level of nondivergence, and (2) at the localities where

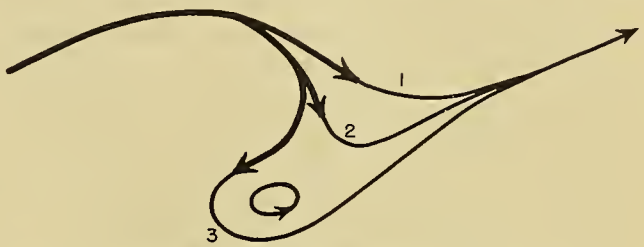

FIG. 5.—Successive (1→3) degeneration of sinusoidal wave-pattern caused by excessive anticyclonic vorticity on wave crest.

$\zeta - 2\Omega \sin \phi$ is near zero. In both cases the competition with the divergence term is almost eliminated. Furthermore, v_z and its horizontal derivatives reach their maximum in the upper troposphere (about two kilometers above the level of nondivergence where $|\rho v_z|$ has its maximum).

The most compelling reason for admitting a perceptible influence of the terms in $\partial v_z/\partial y$ and $\partial v_z/\partial x$ on the variations of ζ lies in the fact that neither the divergence term, nor the meridional advection term, nor their sum, can account through equation (6) for the occurrence of negative absolute vorticity. Analyses of observational data do show areas of negative absolute vorticity on pronounced upper wave crests and/or south of pronounced "jet streams" (see Fig. 7). A vertical motion effect of the right sign to explain the growth of $-\zeta$ beyond $2\Omega \sin \phi$ would be found north of the maximum of upward velocity in the cyclone ($\partial v_z/\partial y < 0$, $\partial v_z/\partial z > 0$). The result in terms of a large anticyclonic vorticity, and occasionally a negative absolute vorticity, can then be expected to accrue on the upper wave crest to the east of the cyclone.

The above reasoning about the vertical motion terms in equation (6) has been developed by L. Sherman and will appear under his authorship.

Inertial Motion in Isentropic Surfaces. In slow-moving long waves of the upper westerlies, the streamlines relative to the waves almost coincide with the streamlines relative to the earth, and the isotherms will be moved advectively so as to coincide more or less with the isobars. Around the inflection points of such long waves we find the best approximation to the relatively simple conditions of straight baroclinic flow. Frontogenesis and frontal cyclogenesis are frequent

under the straight southwesterly currents of long waves, and for a study of these phenomena we will here consider the theory of adiabatic, inertial motion in tilting, stationary isentropic surfaces. Adiabatic (or pseudo-adiabatic) changes of state of particles in the free atmosphere can justifiably be assumed, because non-adiabatic temperature changes are so slow and uniformly distributed that they do not appreciably affect a relatively rapid phenomenon such as cyclogenesis.

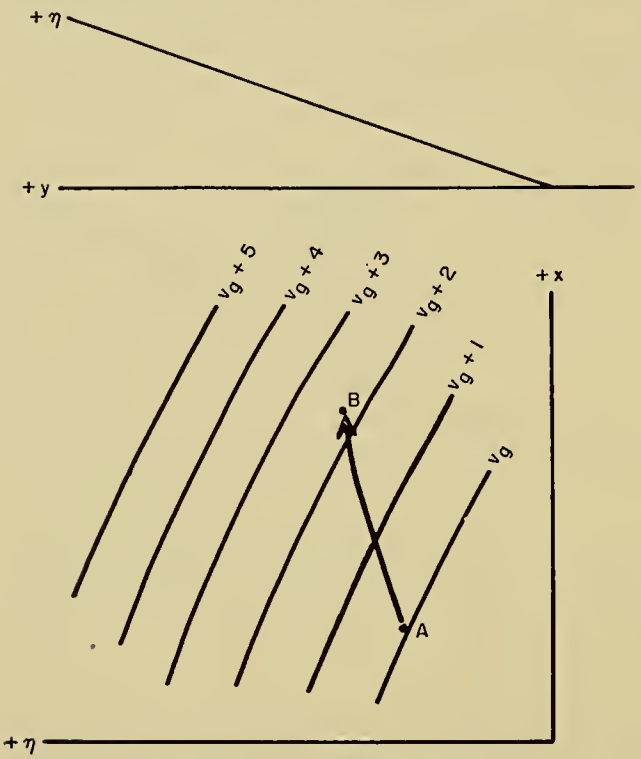

FIG. 6.—Profile of sloping isentropic $x\eta$-plane and sample distribution of the isovels of v_g in $x\eta$-coordinates.

The following simplified analysis has been inspired by the theoretical studies on "dynamic instability," which go back to the classical paper of Helmholtz, "Über atmosphärische Bewegungen," published in 1888 [12]. Several recent contributions by theoretical meteorologists to the same field have been included in the list of literature references [6–9, 14, 15, 17–19, 21, 31, 32]. The synoptic applications of equation (11) in this article to the problems of frontogenesis and cyclogenesis have, to my knowledge, not been attempted before.

The adiabatic movement of a particle parallel to an isentropic surface (sloping or horizontal) is not opposed by buoyancy forces and is left to the stable or unstable control of the horizontal pressure gradient and the Coriolis force. The same is true for particles of entire isentropic sheets moving in unison, when they are far enough from the ground to be independent of boundary effects. For the purpose of this article we shall consider the environmental field of pressure and potential temperature constant while the sample particle (or sample isentropic sheet) moves isentropically through the field. We shall consider part of an isentropic surface of sufficiently small extent to be treated as a sloping plane (Fig. 6), on which the horizontal direction will be called the x-direction (due eastward) and the direction of steepest slope (due northward) will be called the η-direction. The η-axis is supposed to form an angle with the horizontal y-axis of the order of one in a hundred or less. The undisturbed air motion is supposed to be zonal, geostrophic, and horizontal, which allows the isentropic surface to stay fixed in space. Furthermore the fundamental motion is constant along each streamline, $\partial v_x/\partial x = 0$, and represents a steady state, $\partial v_x/\partial t = 0$. Later application to the long wave, where the quasi-straight flow is not exactly zonal, will be done without any strict mathematical treatment. The disturbed motion of the sample particle is supposed to be contained in the isentropic surface and to have an initial upslope component v_η superimposed on the general horizontal motion characteristic of the environment.

The x-component of acceleration of the disturbed particle amounts to

$$\frac{dv_x}{dt} = 2\Omega_z v_y \cong 2\Omega_z v_\eta, \tag{7}$$

and makes the particle speed up in the positive x-direction while it climbs the isentropic slope. The wind of the environment v_g, which is geostrophic and directed along the x-axis in the whole field, changes in value along the path of climb. An observer following the disturbed particle would see the environmental geostrophic wind, relative to the earth, change by

$$\frac{dv_g}{dt} = v_\eta \frac{\partial v_g}{\partial \eta}. \tag{8}$$

The x-component of the speed of the disturbed particle was assumed to be equal to the geostrophic wind v_g at the initial time. Depending on whether $dv_x/dt > dv_g/dt$ or $dv_x/dt < dv_g/dt$, the disturbed particle will move eastwards faster or slower than its new environment after a time differential of climbing. In the first case, the y-component of acceleration of the disturbed particle $dv_y/dt = -2\Omega(v_x - v_g)$ will be directed down the isentropic slope opposite to the initial disturbance. A stable inertia type of oscillation will then result. In the second case, the y-component of acceleration will point in the same direction as the initial disturbance velocity v_η, so that an exponential growth of the disturbance will follow. The instability case is thus $dv_x/dt < dv_g/dt$. In order to make the instability criterion applicable also for the downward directed disturbance, it should be written $\left|\frac{dv_x}{dt}\right| < \left|\frac{dv_g}{dt}\right|$.

Now, provided that the substitution of v_η for v_y in (7) is justified by a sufficiently small inclination of the isentropic surface, the instability criterion derived from (7) and (8) takes the simple form,

$$\frac{\partial v_g}{\partial \eta} > 2\Omega_z. \tag{9}$$

The observed increase of westerly geostrophic wind from the lower to the higher portion of an isentropic

surface sometimes satisfies this instability criterion, as will be shown later.

If we drop the initial conditions of $\partial v_x/\partial x = 0$ and $\partial v_x/\partial t = 0$, no exact treatment can be offered, because then the fundamental current is not a steady-state one. The following reasoning should however be valid, provided that the long-wave deformations of the fundamental current are much slower than the short-wave developments on the isentropic surface. This condition is usually fulfilled.

In Fig. 6 an element of the isentropic surface is shown in $x\eta$-coordinates. Isobars on that surface are parallel to the x-direction, while the distribution of the speed of the geostrophic wind v_g is shown by slanting scalar curves. Thus v_g has a gradient in the x-direction in addition to the much stronger gradient in the η-direction. The disturbed path of a sample particle along the isentropic surface is supposed to go from A to B during the time differential. The x-component of the acceleration (parallel to the isobars) of the sample particle is again, to a first approximation, $dv_x/dt = 2\Omega_z v_\eta$, while the change of geostrophic wind encountered along the path is

$$\frac{dv_g}{dt} = v_\eta \frac{\partial v_g}{\partial \eta} + v_x \frac{\partial v_g}{\partial x} + \frac{\partial v_g}{\partial t}. \tag{10}$$

The acceleration of the particle in the η-direction is supposed to be zero at the initial point of the trajectory A. The acceleration in the η-direction will also be zero at the end of the trajectory B if $dv_x/dt = dv_g/dt$, or

$$2\Omega_z v_\eta = v_\eta \frac{\partial v_g}{\partial \eta} + v_x \frac{\partial v_g}{\partial x} + \frac{\partial v_g}{\partial t},$$

that is,

$$v_\eta = \frac{v_x \dfrac{\partial v_g}{\partial x} + \dfrac{\partial v_g}{\partial t}}{2\Omega_z - \dfrac{\partial v_g}{\partial \eta}}. \tag{11}$$

Specializing now for the condition $2\Omega_z - \partial v_g/\partial \eta > 0$ and for $v_x \partial v_g/\partial x + \partial v_g/\partial t > 0$, we find that the particle given an initial speed component v_η greater than the value found in (11) will have an acceleration component dv_η/dt opposite to v_η. Given a smaller positive initial v_η, or a negative initial v_η, the particle would accelerate towards the value for v_η given in (11). This value of v_η therefore represents the η-component of a stable upgliding motion in which all the particles of the isentropic surface may join. The η-component of the stable upgliding motion approaches infinity when $2\Omega_z - \partial v_g/\partial \eta$ goes to zero. In other words, in the case of inertial indifference any finite initial v_η would increase exponentially.

Quite analogous reasoning in the case $2\Omega_z - \partial v_g/\partial \eta > 0$ and $v_x \partial v_g/\partial x + \partial v_g/\partial t < 0$ reveals the existence of stable downgliding motion in which the η-component is also given by (11).

The difference between the cases $v_x \partial v_g/\partial x + \partial v_g/\partial t = 0$ and $\gtrless 0$ is thus the following: In the former case the departures from the geostrophic wind remain of a stable oscillatory nature until the anticyclonic isentropic shear reaches the critical value of $-2\Omega_z$. In the latter cases there is a sustained stable departure from the geostrophic wind, represented by v_η, which has finite values also when $2\Omega_z - \partial v_g/\partial \eta > 0$. In addition there may be inertial perturbations superimposed on the current representing the vector sum of geostrophic motion v_g and isentropic motion v_η; such perturbations will be stable as long as $2\Omega_z - \partial v_g/\partial \eta > 0$.

The demonstration of the occurrence of anticyclonic shear in the upper atmosphere, which approaches or even surpasses the critical limit of dynamic instability, is due to recent research work at the University of Chicago. The first profile of the westerlies showing such conditions was analyzed by Palmén [23] in 1948. In the same paper it is also shown how we must treat zonal flow as curved flow (radius of curvature $r = a \operatorname{cotan} \phi$) in order to arrive at a satisfactory accuracy of an isovel profile which is to correspond to an observed meridional pressure profile. In the following discussion we shall use the model of straight baroclinic westerlies with a stationary polar front published by Palmén and Newton [24] and reprinted here as the left part of Fig. 7. It represents an isotherm-isovel profile based on an averaging of twelve eastern North American meridional profiles made during December 1946. In the right-hand part of Fig. 7 we have added a diagram of the computed quantity $2\Omega_z - \partial v_g/\partial \eta$, with η interpreted as the curvilinear isentropic coordinate (positive direction northwards). In most of the field $2\Omega_z$ is greater than $\partial v_g/\partial \eta$, indicating inertial stability; but in a narrow zone south of the maximum upper westerlies, $2\Omega_z - \partial v_g/\partial \eta$ is negative, indicating inertial instability. Furthermore, in the frontal zone below 600 mb, where $\partial v_g/\partial \eta$ has been measured along saturation isentropes, the values of $2\Omega_z - \partial v_g/\partial \eta$ indicate only a slight amount of inertial stability. We shall focus our attention first on that part of the profile.

The small positive (or in some individual cases negative) values of $2\Omega_z - \partial v_g/\partial \eta$ are located in a narrow frontal zone, while in the adjacent parts of the warm and cold air masses, $2\Omega_z - \partial v_g/\partial \eta$ is positive and far from zero. Since in (11) the component of stable upgliding or downgliding is inversely proportional to $2\Omega_z - \partial v_g/\partial \eta$, it follows that the air in the narrow frontal zone has a much greater possibility for isentropic up- or down-displacements than the air masses on either side.

The quantity $v_x \partial v_g/\partial x + \partial v_g/\partial t$, representing the numerator in the expression for v_η in (11), cannot be judged from the data of one profile alone. It will be large and positive (1) where the isobars of the horizontal pressure distribution converge, and (2) where the gradient wind increases locally with time. The first condition is fulfilled, for example, along the axis of kinematic dilatation extending eastward from a col of the pressure field. This synoptic situation is known to be frequently associated with frontogenesis and subsequent maintenance of a sharp front. The second condition, local increase of gradient wind parallel to the frontal zone, frequently occurs during frontogenesis,

but the cause of such an increase of gradient wind is not necessarily attributable to the frontal mechanism.

Whenever $v_x \partial v_g/\partial x + \partial v_g/\partial t$ has the same sign in each of the two air masses, v_η will also have the same sign in the whole field; but its maximum numerical value, as far as the lower troposphere is concerned, will be found in the frontal zone where $2\Omega_z - \partial v_g/\partial \eta$ is at a minimum.

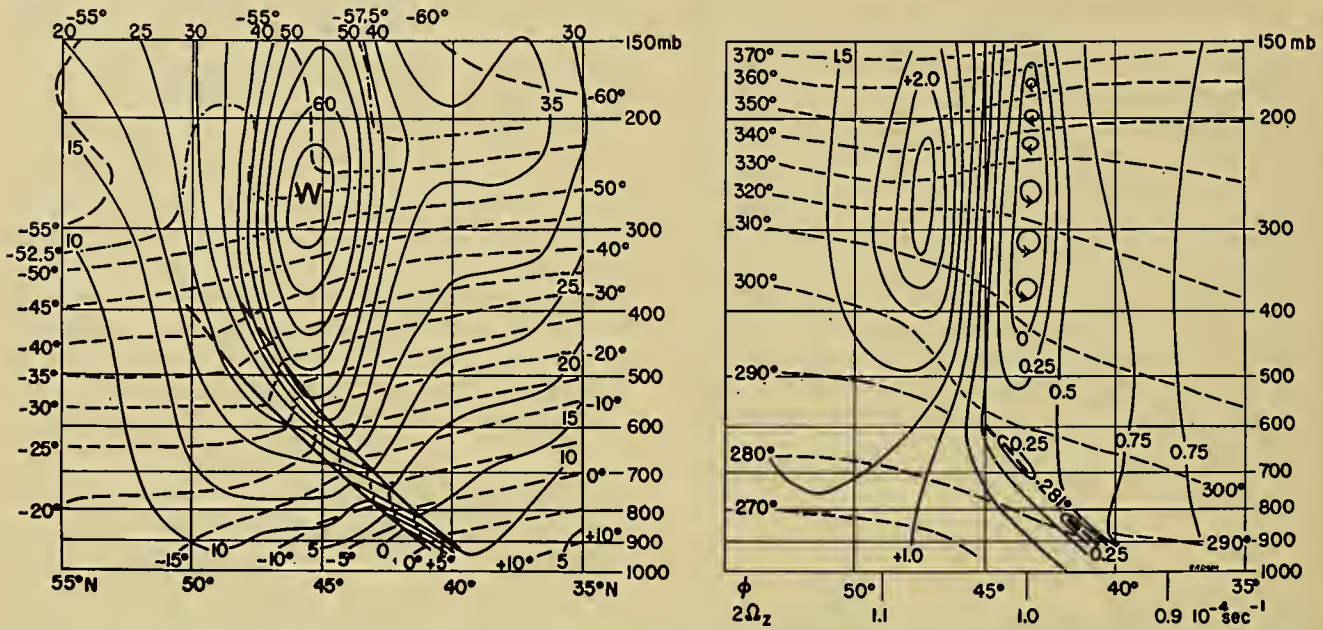

Fig. 7.—Meridional profiles through a model of straight westerlies with quasi-stationary polar front (Palmén and Newton [24]). Left: Dashed lines show isotherms (degrees centigrade), and solid lines isovels (m sec^{-1}) of zonal geostrophic wind. Right: Dashed lines show the field of dry-isentropes (degrees absolute), and the saturation-isentrope of 281° in the frontal zone. Solid lines represent the quantity $2\Omega_z - \partial v_g/\partial \eta$ in units of 10^{-4} sec^{-1}.

As shown in Fig. 7, the warm air over the lower and intermediate portion of the polar-front surface has anticyclonic isentropic shear, increasing to great values in the upper troposphere, whereas the air above the upper part of the frontal surface has cyclonic shear, likewise increasing to high values in the upper troposphere. The dividing line between anticyclonic and cyclonic shear runs almost vertically through the maximum of west-wind velocity, which in the average condition represented by Fig. 7 is located above the place where the frontal surface intersects the 500-mb level. Isentropic upgliding or downgliding as defined by equation (11) will reach larger values south of the velocity maximum than north of it. It is likely that this difference in v_η values north and south of the velocity maximum does give rise to important horizontal divergence effects because the η-component represents a nongeostrophic part of the total wind. The v_η-divergence effect in the jet-stream region should work out as shown schematically in Fig. 8. Where there is "confluence" of the winds into the western beginning of a "jet stream," equation (11) indicates a superimposed isentropic upgliding $v_\eta > 0$ and "isentropic convergence" $\partial v_\eta/\partial \eta < 0$ north of the line of maximum $|v_\eta|$. Where the wind velocity decreases along the streamlines in the "delta" of a jet stream, equation (11) indicates isentropic downgliding $v_\eta < 0$ and isentropic divergence $\partial v_\eta/\partial \eta > 0$, north of the line of maximum $|v_\eta|$. In the stratosphere the terms downgliding and upgliding must be interchanged, because of the opposite tilt of isentropic surfaces, but the statement about the isentropic divergence remains identical for stratosphere and troposphere. At the line of maximum $|v_\eta|$ values the isentropic divergence $\partial v_\eta/\partial \eta$ changes sign, as shown by the hatching in Fig. 8.

In figuring out the effect of the isentropic divergence in changing the pressure field we may think of the distribution of $\partial v_\eta/\partial \eta$ as representing in the first approximation a field of $\partial v_y/\partial y$, where v_y is the nongeostrophic y-component of motion. Assuming that the distribution of $\partial \rho v_y/\partial y$ can also be qualitatively represented by the hatched and unhatched areas in Fig. 8, we have in that diagram an outline of the contribution of isentropic divergence to the total horizontal divergence. The isentropic divergence, acting in the same sense through

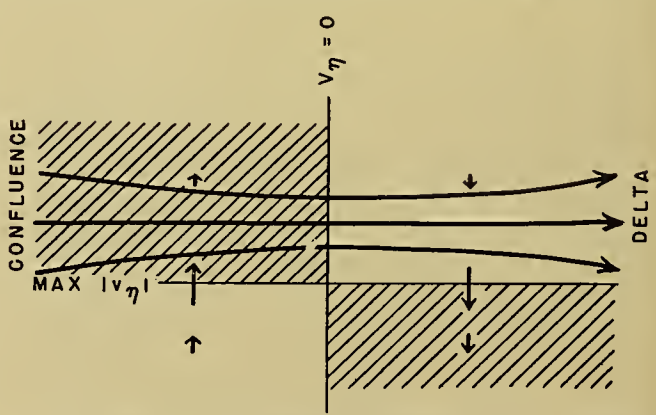

Fig. 8.—Isentropic convergence (hatched) and divergence (unhatched) in the regions of jet-stream coufluence and delta.

the stratosphere and the upper half of the troposphere, may be an important effect to consider together with the divergence effects represented in Fig. 1. A cyclonic storm traveling along the jet-stream zone would come under the influence of superimposed upper mass divergence from the time when it passes the place of greatest constriction of the upper streamlines. A complete theoretical treatment of this case, which calls for a combination of the divergence effects of Fig. 1 and Fig. 8, is not available; but there seems to be considerable empirical evidence for strong cyclonic deepening under the described circumstances. Such synoptic evidence has mainly been gathered by Scherhag [30]. Scherhag points to Ryd [28, 29] as the originator of the idea that mass divergence of importance for cyclone deepening should occur in upper delta patterns. Ryd's theoretical contributions appeared in 1923 and 1927 when there were as yet no upper-air maps.

Returning to Fig. 7, we see that complete inertial instability $\partial v_g/\partial \eta > 2\Omega_z$ may at times extend from 150 mb down towards the 500-mb surface. It may also extend over a thousand kilometers' length of current, but the width of the zone of such unstable shear is hardly more than three hundred kilometers at any one point. Inside that volume of current the geostrophic wind, with its superimposed component of isentropic upgliding or downgliding, does not represent a stable flow. However, with stable neighboring flow on either side, no very large unstable deviations from geostrophic flow will be able to develop. The most likely system of perturbations in the unstable part of the current will be helical cellular circulations, as indicated in Fig. 7. Such circulations would serve the purpose of exchanging momentum across the zone of unstable shear and thus lessen that shear. The height of each cell would have to be small, probably less than one kilometer, so that the solenoid field set up by the cellular circulation should not grow strong enough to reverse the initial circulation. An indirect indication of the existence of the helical cellular circulations is seen in the observed "multiple tropopauses," each one probably representing a cell wall between superjacent circulation rolls. According to Palmén [22], these multiple tropopauses are quasi-isentropic as would be expected if they are formed as circulation-cell boundaries.

SYNOPTIC EXAMPLE OF AN EXTRATROPICAL CYCLONE

The weather situation over North America during November 7–10, 1948, has been selected to illustrate the principles of this article. A large occluded cyclone which was located over the Hudson Bay region during this period can serve as a model of the most frequent structure of old cyclones, while over the central United States the atmosphere displays all the successive stages of frontogenesis and the early life history of a growing frontal wave cyclone. Our description will begin with the evolution of the long-wave background pattern of the upper layers, represented by a set of 300-mb maps, then the advective frontogenesis in the lower troposphere will be illustrated by a sequence of ground-level and 850-mb maps as well as selected profiles, and finally the three-dimensional structure of the frontal wave cyclone will be shown by a synoptic set of maps from the ground to 300 mb.

Synoptic Evolution of the Upper Layers. The six 300-mb maps at 12-hr intervals in Fig. 9 all show the semipermanent Hudson Bay cyclone. Through the whole troposphere this cyclone is a cold-core vortex and therefore shows up as a deep center on the 300-mb maps. Equally permanent is the crest of high pressure extending northwards from a warm anticyclone over the eastern North Pacific. Both the Hudson Bay low and the eastern Pacific high are typical features of the general circulation but they have more than average strength during November 7–10. The westerly current meandering through between them is quite strong over a narrow zone, while the pressure gradients in the high and the low are quite weak. The trough located over the western United States on November 7 moves slowly to the central states and deepens gradually from November 7 to November 9. This upper-air process plays an important role in the formation of the frontal cyclone which takes place under the pre-trough southwesterly current (without producing any separate low-pressure center at 300 mb).

The deepening of the upper trough may be caused in two ways (see equation (1)): either through a sinking component of motion at the 300-mb level, or through horizontal mass divergence in the column above 300 mb. In the former case the temperature in the trough at 300 mb ought to be rising with time. This is not borne out by the observations during November 7–9, so that we are left with the horizontal mass divergence as the probable cause of the deepening of the trough. The mass divergence must be operated through the feeding of air into the trough with such a high velocity that the Coriolis force and centrifugal force overcompensate the initial pressure gradient. The mechanism for producing such a strong jet in the northerly current behind the trough must be sought on the anticyclonic bend to the west.

The maximum curvature of the 28,400-ft contour of the 300-mb surface is represented on the November 7th map by an arc of a circle with radius r_i. At the same place in western Canada the maximum possible curvature of a steady-state anticyclonic current, flowing under the influence of the observed pressure-gradient force, is represented by another arc of a circle with radius $r_{\min}$.[3] The curvature analysis on the 300-mb

3. The value of $r_{\min}$ is obtained from the equation of anticyclonic circular motion

$$-v^2/r = -2\Omega_z v - \partial\Phi/\partial r = -2\Omega_z(v - v_g), \qquad (12)$$

in which Φ stands for the geopotential in the pressure topography, r and v are positive, $-\partial\Phi/\partial r$ is the outward-directed pressure gradient, $-2\Omega_z v$ is the inward-directed Coriolis force, and $-v^2/r$ is the centripetal acceleration. When equation (12) is applied to a selected point on the map, Ω_z and $\partial\Phi/\partial r$ are

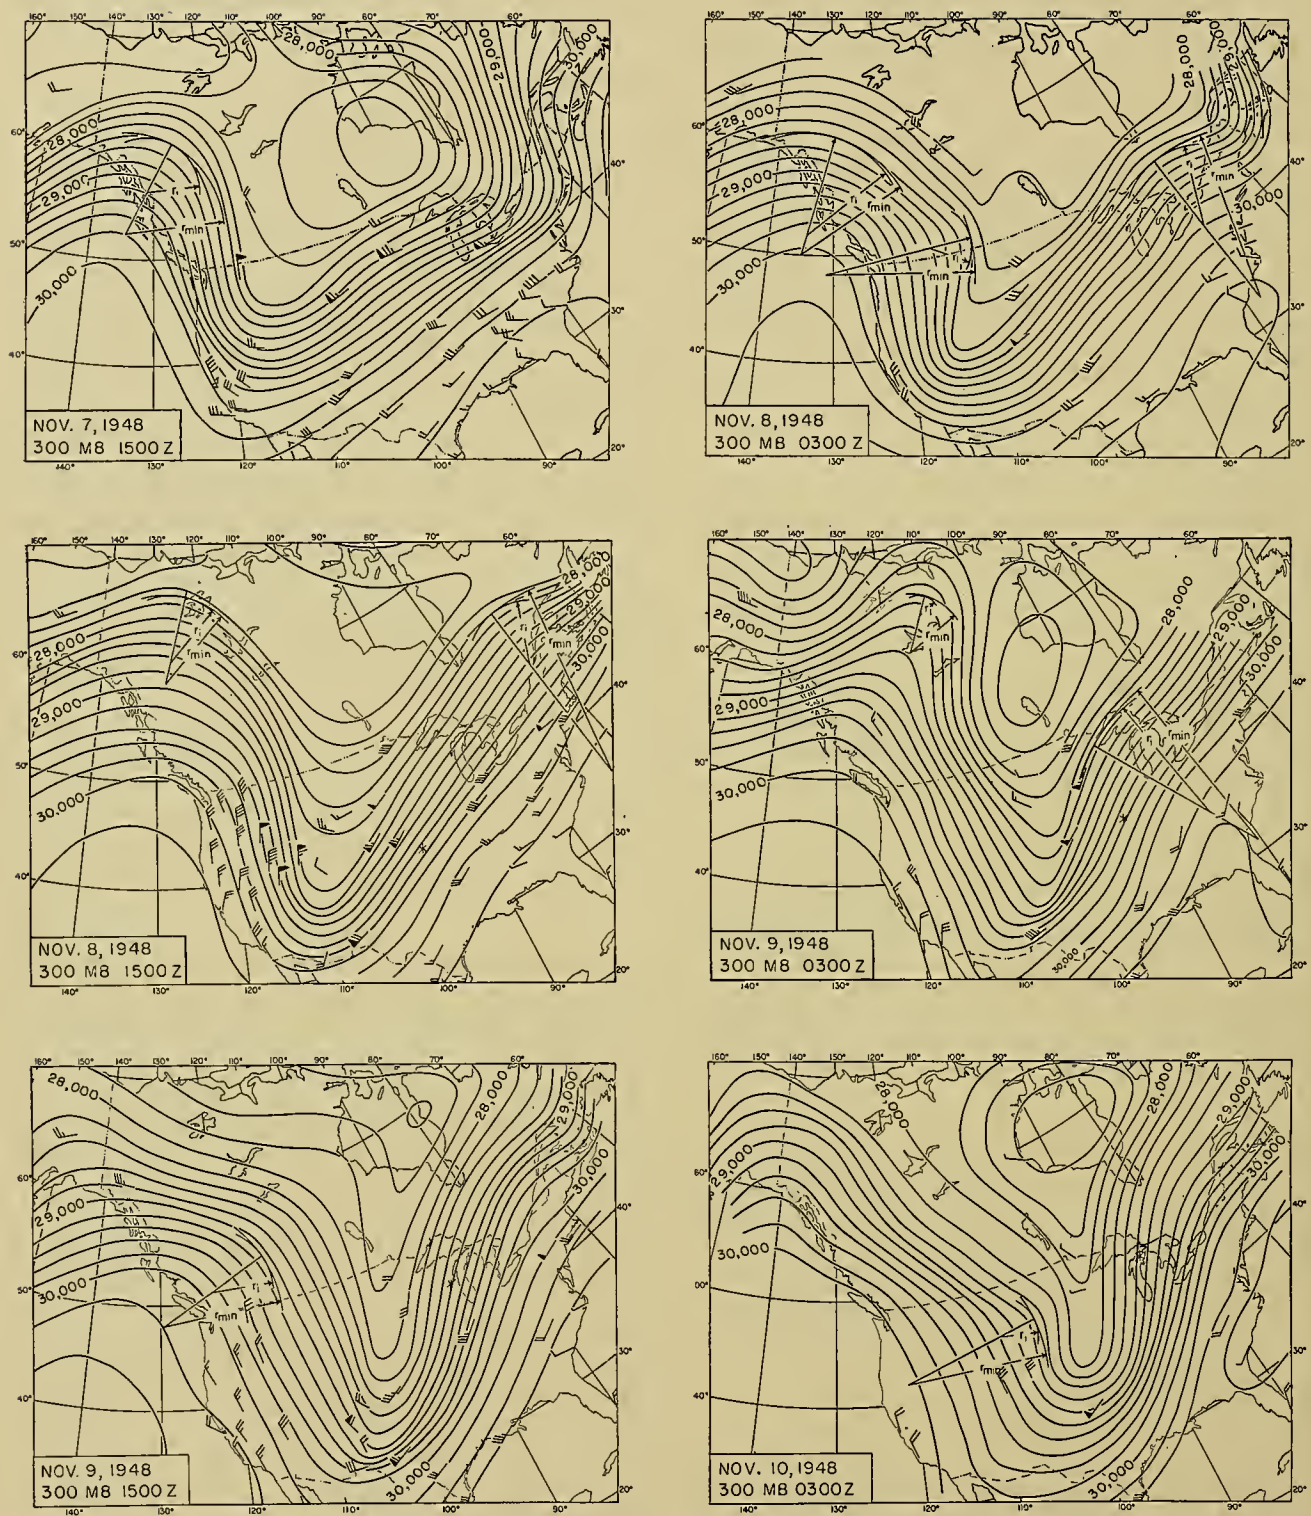

FIG. 9.—Twelve-hourly sequence of 300-mb maps during November 7–10, 1948 (r_i = radius of isobaric curvature, $r_{\min} = -\frac{\partial \Phi}{\partial r}/\Omega_z^2 = 2v_g/\Omega_z$). Asterisk marks position of apex of frontal wave on sea-level map. Half barb 5 m sec^{-1}, full barb 10 m sec^{-1}, triangular barb 50 m sec^{-1}.

anticyclonic bend over western Canada on November 7 and the following days shows that instances of $r_i < r_{min}$ are quite frequent, in other words, that with the given pressure gradient and contour curvature the paths of particles often cannot have as small a radius of curvature as that of the isobaric contours. If that applies to a quasi-stationary pressure ridge like the orographic one over the Canadian Rockies, where the radius r_s of streamline curvature is equal to the radius r of path curvature, the air would have to cross the isobars towards low pressure while making the anticyclonic turn. This must imply a forward acceleration of the particle leading up to maximum speed at the end of the anticyclonic sweep. If such fast-moving air is fed directly into a pressure trough downstream, in which the pressure gradients were adapted to smaller wind speeds, an intensification of the trough should follow. The deepening of the large pressure trough over western and central United States during November 7–9, 1948, should probably be interpreted this way. Measured winds are unfortunately not available for a complete check of these ideas. The only part of the phenomenon that can be well demonstrated is the general occurrence of wind components towards high pressure, resulting from the supergeostrophic velocity of the air that is leaving the anticyclonic bend (see winds over the western United States on the 300-mb map of November 8, 1500Z).

The flow around the quasi-stationary anticyclonic bend over western Canada cannot be a steady-state one, although the major features of that part of the map do remain unchanged. The 300-mb maps show how one moving wave perturbation after the other appears on top of the large stationary crest of high pressure in the west. The first of these traveled about 1500 km during twelve hours (35 m sec^{-1}) and is found on the second map with its wave crest in the northerly current at the Canadian-United States border. The 300-mb contour curvature at that time and place defines an r_i which is much smaller than r_{min} .

The radii of curvature of streamlines, r_s , and of air trajectories, r, in a moving sinusoidal wave, are related to each other by the formula

$$r_s = r\,\frac{v - c}{v}, \tag{16}$$

---

constants. Solving (12) for

$$r = \frac{v^2}{2\Omega_z v + \partial\Phi/\partial r} = \frac{v^2}{2\Omega_z(v - v_g)}, \tag{13}$$

and seeking the value of v for which r is a minimum, we obtain

$$v = \frac{-\dfrac{\partial\Phi}{\partial r}}{\Omega_z} = 2v_g. \tag{14}$$

The corresponding values of r_{min} and v are thus

$$r_{min} = -\frac{\dfrac{\partial\Phi}{\partial r}}{\Omega_z^2} = \frac{2v_g}{\Omega_z}, \qquad v = 2v_g. \tag{15}$$

where c is the speed of the wave. No measured wind velocities are available at 300 mb in western Canada during the days under consideration. Theoretical estimates of v must lie between v_g and $2v_g$, and are most likely closer to the lower than the upper limit, as will be shown later. Assuming tentatively for the moving pressure crest at the Canadian–United States border on November 8, 0300Z, $v = 1.1v_g = 49$ m sec^{-1}, we would have from (13)

$$r = \frac{49^2}{1.08 \times 10^{-4}(49 - 44.5)} = 4900 \text{ km},$$

and would arrive at the following estimate of r_s :

$$r_s = 49 \times 10^5\,\frac{49 - 35}{49}\,\text{m} = 1400 \text{ km},$$

which is much longer than the measured radius of contours $r_i = 440$ km. These estimates and measurements are of course subject to great errors, but even so, the conclusion seems to be that also on the moving pressure crests the streamlines will fail to adapt to the strong curvature of the isobars. It then also follows that the moving pressure crests at the 300-mb level are preceded by a velocity maximum. When the air from that velocity maximum enters the slow-moving low-pressure trough, a pulse of deepening by centrifugal action would result. The rapidly moving upper wave cannot be seen to continue its propagation on the front side of the deep slow-moving trough. Hence all its wave energy must have been absorbed in the large trough.

With the above estimate of $v = 49$ m sec^{-1} and $r_s = 1400$ km, the anticyclonic vorticity due to curvature $-v/r_s$ amounts to -3.5×10^{-5} sec^{-1}. This is numerically much less than $2\Omega \sin 50° = 1.1 \times 10^{-4}$ sec^{-1}, so it does not seem likely that the complete anticyclonic vorticity $-v/r_s - \partial v/\partial n$ reaches the critical value of $-2\Omega_z$ anywhere in the rapid wave at 300 mb. The described manifestation of instability through cross-isobaric flow on the anticyclonic bend thus takes place independently of the fulfillment of the criterion $-v/r_s - \partial v/\partial n + 2\Omega_z < 0$.

On November 8, 1500Z, when the most unstable part of the anticyclonic flow was found far north (again marked by $r_i < r_{min}$), a growing crest and a downwind, deepening trough formed simultaneously. When that perturbation caught up with the slow-moving trough ahead, another deepening occurred (see November 9, 1500Z), this time in the north-central United States while the southern end of the trough was losing depth.

These fast-moving unstable waves on the 300-mb maps are, of course, at times connected with disturbances in the lower atmosphere. The first of the upper waves was formed on November 7, 1500Z, as an occluded front was approaching from the west; it is likely that the excessive anticyclonic curvature resulted from a superposition of the upper wave crest (associated with the occluded cyclone) upon the semipermanent anticyclonic bend produced orographically by the northern Rocky Mountains. Once formed, the unstable

upper wave separates from the frontal disturbance by virtue of its superior speed (35 m sec^{-1}). The second unstable upper wave had no clear connection with any frontal disturbance.

During the selected period, the flow of air east of the big slow-moving trough turned gradually from west-southwest towards south-southwest while increasing a little in strength. On November 8, 1500Z, after the cold trough of the Hudson Bay cyclone had moved off to the northeast, the upper current over the eastern half of the United States and Canada became almost straight. On November 9, 0300Z, when the growing frontal cyclone (marked by an asterisk on the 300-mb maps) began to exert influence high up, the upper current became slightly S-shaped. The newly formed upper wave moved along with the cyclone center below at a speed of only 9 m sec^{-1}. The best estimate of the wind speed on the anticyclonic bend is probably 80 m sec^{-1} (see below) and hence $r_s = r(80 - 9)/80 = 0.9r$. Even with $r = r_{min} = 1950$ km, r_s would be 0.9×1950 km = 1760 km, which is greater than the measured $r_i = 1350$ km. The streamlines will consequently not be able to adapt to pressure contours around the anticyclonic bend.

The tentative assumption of $r = r_{min}$ given above is really predicated on the further assumption that the wind maintains a speed of $2v_g$ around the anticyclonic bend. We can in this case show convincingly that the wind does not reach such a speed and therefore that the air trajectory must have a radius of curvature considerably longer than r_{min}.

The geostrophic wind in the strongest part of the straight southwesterly current on November 8, 1500Z amounted to about 70 m sec^{-1}, and on the chart for November 9, 0300Z a measurement of the geostrophic wind in the Great Lakes region gives nearly the same value. Even at the geostrophic speed of 70 m sec^{-1}, which gives a speed of 70 − 9 = 61 m sec^{-1} relative to the wave, it would take only 4½ hours for each air parcel to cover the 1000-km distance along which there is anticyclonic curvature. Suppose a particle passes the inflection point at 70 m sec^{-1} and from then on experiences a forward tangential acceleration $(dv/dt)_t = 2\Omega_z v_r$ on the anticyclonic bend. If v_r, the wind component directed outward normal to the isobars, reaches the high average value of 10 m sec^{-1} on the anticyclonic bend, the speed of the particles would increase at a rate of 10 m sec^{-1} per three hours, and at most by 15 m sec^{-1} during the whole travel from inflection point to inflection point. This increase in speed would thus go only one-fifth of the way from v_g to $2\,v_g$. This reasoning justifies the earlier assumption of the moderately supergeostrophic wind of 70 + 10 = 80 m sec^{-1} on the middle of the anticyclonic bend.

Another effect of the transisobaric wind component on the anticyclonic bend is also worth considering. A flow component across anticyclonic contours towards low pressure is usually synonymous with horizontal divergence of mass, and offers in that way a contribution to pressure fall (see equation (1)). The basic pattern in Fig. 1 of horizontal divergence in westerly waves would thus, in the levels of strongest westerlies, show the divergence extending forward beyond the ridge of highest pressure. The implications of this divergence on the pressure ridges of the upper atmosphere for the storm development in the lower atmosphere will be considered on p. 597.

Frontogenesis. Figure 10 illustrates three stages of frontogenesis, 24 hours apart, represented by simultaneous sea-level and 850-mb maps. At the first map time the Hudson Bay cyclone is also shown. Its thermal structure is that of an old cyclone with the occluded front beginning to wrap around the center. The upper warm tongue, extending east and north of the Hudson Bay center from the warm-air reservoir over the Atlantic, is shown clearly in the 850-mb isotherms. The pressure trough pointing southwards from the Hudson Bay cyclone is not of frontal nature, as can be seen from the weak temperature gradient at 850 mb in that region. The same nonfrontal trough continues up to the 300-mb level (Fig. 9), where its orientation approaches northwest-southeast, and in those upper layers it actually extends out over the Atlantic, producing a bend in the warm sector current. Such troughs always move more slowly than the air, and it is kinematically impossible for fronts to develop in them.

Historical continuity made it obvious that the cold front from the Hudson Bay cyclone had reached Florida by November 7, 1500Z, but the 850-mb map shows how the cold air, after arriving over the Gulf States, must have subsided and thereby effaced most of the frontal temperature contrast. The bundle of isotherms running along the northern part of the cold front bends westward over the Carolinas and northern Georgia and there marks the intersection of the 850-mb map with the tilting surface of subsidence. The 850-mb winds in that region blow across the isotherm bundle from cold to warm, but fail to produce any local fall in temperature because of the simultaneous sinking. The deviations from geostrophic flow are quite striking in that sinking air mass. While descending from the levels of strong west winds the air particles must be retarded and, in order to do so, they must move with a component towards high pressure, as shown on the 850-mb map of November 7, 1500Z. The same type of geostrophic departure is found on that day over the southeastern United States all the way up to 300 mb (Fig. 9). On the following day (November 8), the geostrophic departures characteristic of the front side of moving anticyclones can be seen on the 850-mb map over New England. In the rear of the moving anticyclone the opposite geostrophic deviation is observed. In that part the air is ascending and accelerating and must have a horizontal component towards low pressure. This phenomenon is actually part of the process of frontogenesis over the central United States which will be considered next.

Frontogenesis by horizontal advection operates when a field of deformation is maintained in a baroclinic air mass. Optimum efficiency in this process is achieved when the axis of dilatation of the field of deformation coincides with the direction of the isotherms. The

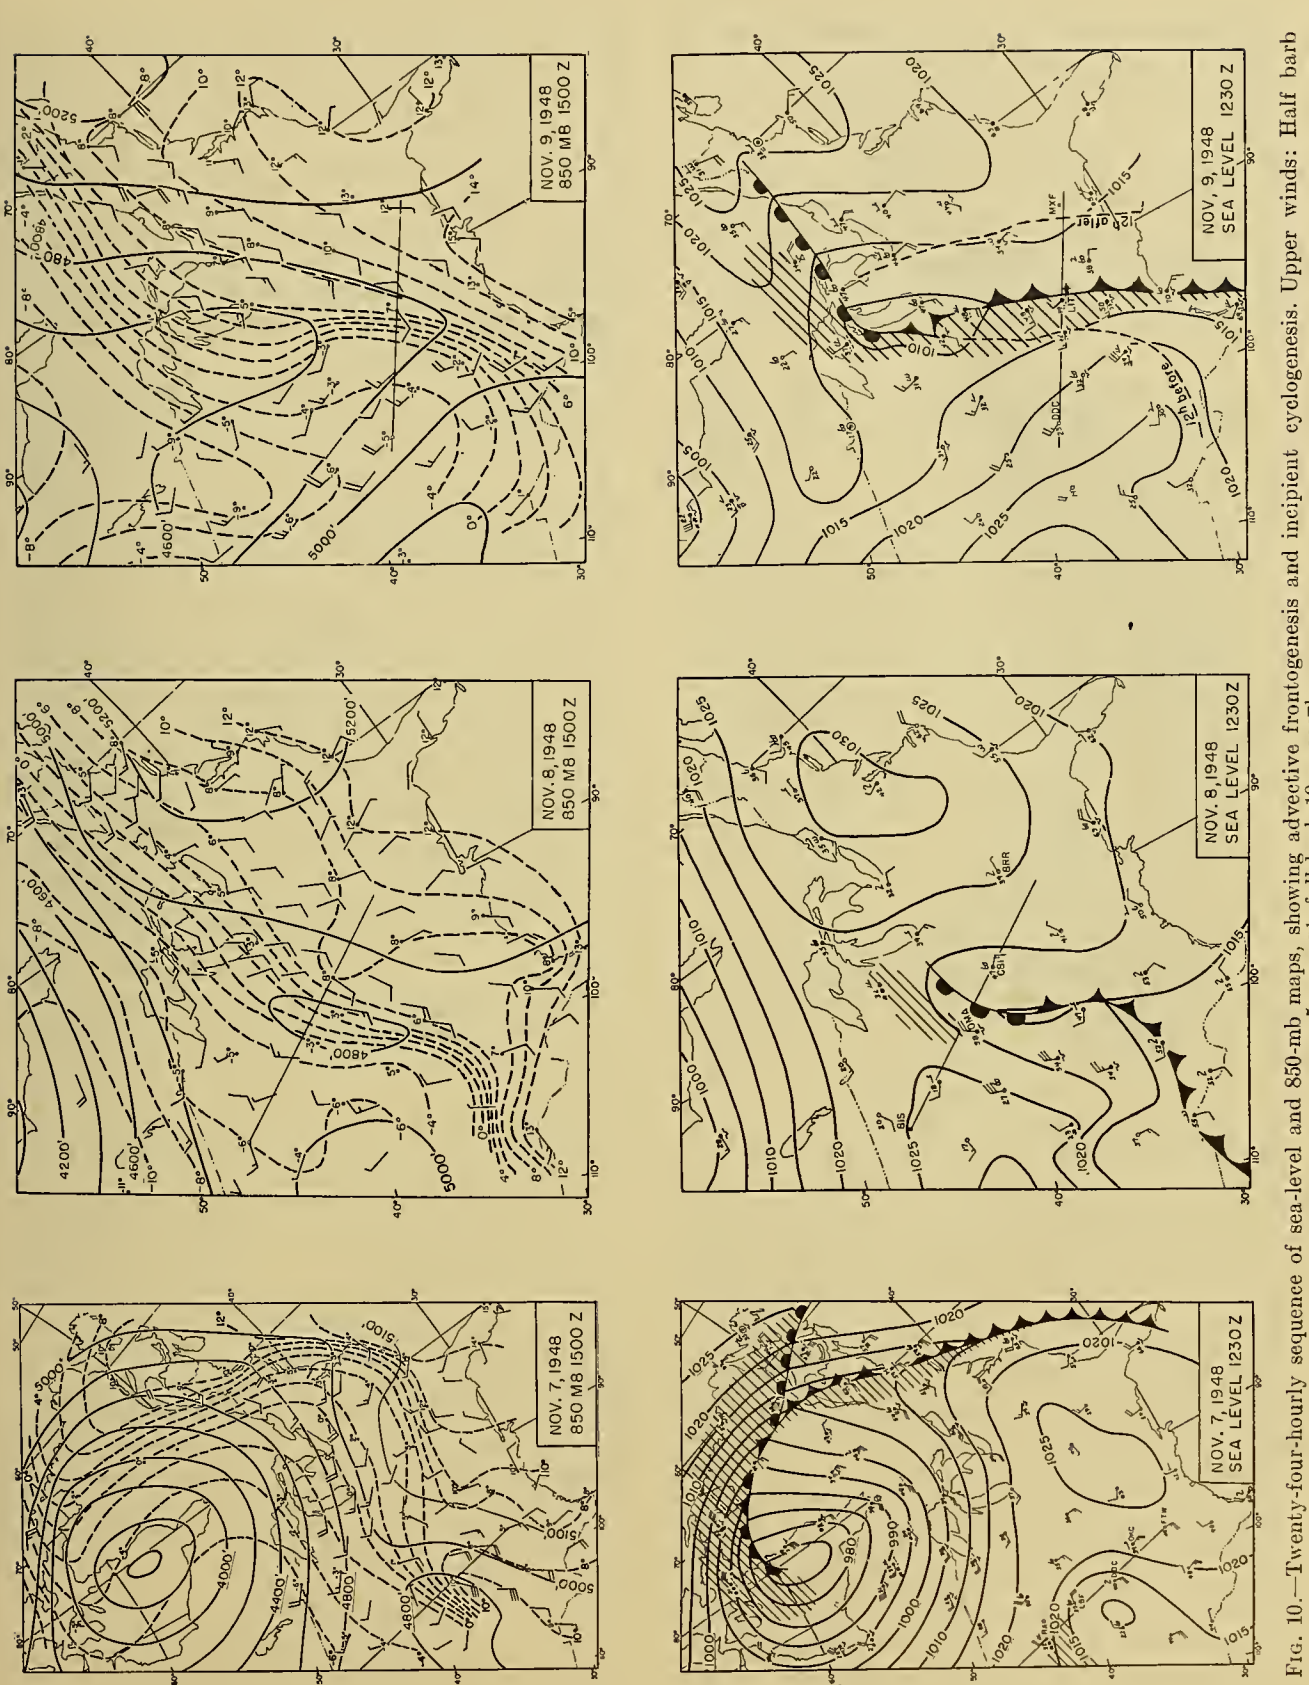

FIG. 10.—Twenty-four-hourly sequence of sea-level and 850-mb maps, showing advective frontogenesis and incipient cyclogenesis. Upper winds: Half barb 5 m sec^{-1}, full barb 10 m sec^{-1}.

streamlines in the col over the central United States on November 7, 1500Z, fulfill that condition fairly well. The mentioned geostrophic departure towards low pressure on the warm side of the col also favors the transportation of the isotherms towards the axis of dilatation. As a result of these processes a surface front has formed on November 8, 1500Z, over the region previously occupied by the col, while frontogenesis is in progress over the Great Lakes region where the col has now arrived. A frontal wave has already formed over the state of Missouri and is represented in the pressure field by a small elongated low. During the following twenty-four hours the new cyclone deepens and moves along the front northeastward. A new field of deformation is active on November 9 along the cold front of that cyclone and helps maintain the frontal temperature contrast.

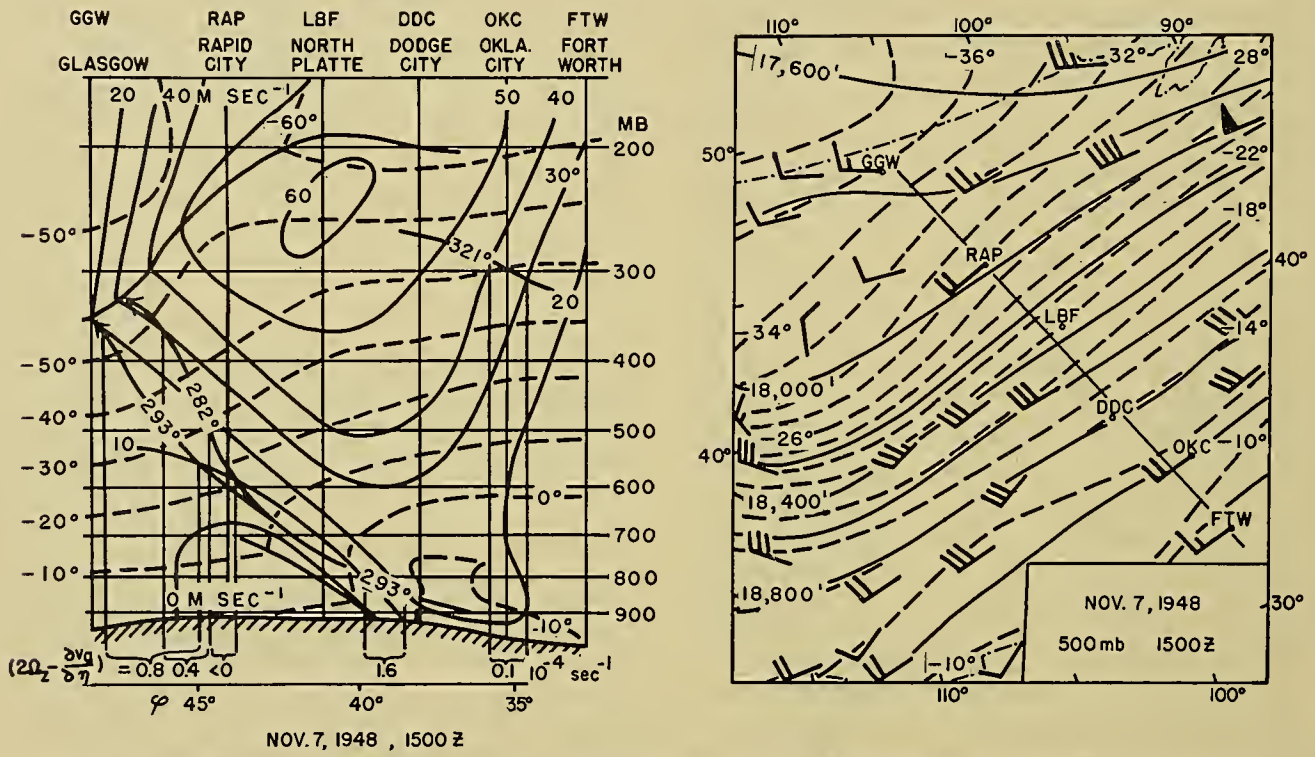

FIG. 11.—Profile of early frontogenesis, November 7, 1948, 1500Z, and part of the 500-mb map for the same time. Sample evaluations of $2\Omega_z - \partial v_g/\partial \eta$ below diagram. Upper winds: Half barb 5 m sec^{-1}, full barb 10 m sec^{-1}, triangular barb 50 m sec^{-1}.

The described frontogenetical development near the ground conforms with the advective rules set forth by Bergeron [1] and Petterssen [25]. We shall here add a study of the dynamical conditions for isentropic upgliding in the free atmosphere, which is an important part of the process of frontogenesis.

The rate of frontogenesis near the ground is increased considerably if the air of the lower part of the frontal zone is removed by upgliding. The dynamical possibilities for that process are considered in Fig. 11, which contains a profile across the zone of frontogenesis during its early stage on November 7, 1500Z. At that time no clear-cut front was yet discernible on the surface map, but on the 850-mb map there is great crowding of isotherms between the cold air over North Platte and the foehn air over Dodge City. The foehn on the warm side of the col gives the frontogenesis a good start in the layers below the level of the continental divide, but the process also takes place higher up, as shown by the isothermalcy between 600 and 560 mb at Rapid City.

The thermodynamics of upgliding in the sloping frontal zone can be tested through an inspection of the 293° dry-isentrope which has been inserted in Fig. 11. It shows that a particle could be brought dry-adiabatically along the profile from near the ground in Oklahoma to the tropopause at 350 mb over Montana without being subject to stabilizing gravity effects. If we take into account that condensation would begin in such a particle at 700 mb, the ascent from there on would follow the saturation isentrope of 282°, which climbs more steeply than the dry-isentrope and likewise reaches the tropopause. Actually no single particle undergoes such far-reaching isentropic displacements inside the profile; but the isentropes can still be used as indicators of the direction of the component of stable upgliding (see p. 585), which the particles may have in addition to their much stronger geostrophic component of motion normal to the profile.

A study of the values of the isentropic upgliding (equation (11)),

$$v_\eta = \frac{v_x \frac{\partial v_g}{\partial x} + \frac{\partial v_g}{\partial t}}{2\Omega_z - \frac{\partial v_g}{\partial \eta}},$$

along the different sections of the inserted isentropes, will reveal the dynamical possibilities for frontogenesis.

The denominator in the expression above can be determined uniquely from the data contained in the profile, whereas the numerator depends on derivatives of the geostrophic wind normal to the profile and derivatives in time. Let us consider the denominator first.

Along the lower part of the 293° isentrope the geostrophic shear $\partial v_g/\partial \eta$ is negative, and hence $2\Omega_z - \partial v_g/\partial \eta$ is large. Between the points of intersection of the 293° isentrope with the isovels of 20 m sec^{-1} and 10 m sec^{-1} the value of $2\Omega_z - \partial v_g/\partial \eta$ can be computed to be 1.6×10^{-4} sec^{-1}, as indicated at the bottom of the profile. Farther up along the 293° isentrope, $\partial v_g/\partial \eta$ changes sign and $2\Omega_z - \partial v_g/\partial \eta$ decreases despite the northward increase of $2\Omega_z$. In the baroclinic field between Rapid City and Glasgow $2\Omega_z - \partial v_g/\partial \eta$ has decreased to 0.8×10^{-4} sec^{-1}. Still smaller values are found along the 282° saturation isentrope, and a negative $2\Omega_z - \partial v_g/\partial \eta$ results in the section near Rapid City. The latter value indicates dynamic instability or, in other words, the condition of upgliding without dynamic brake action. Actually only small volumes of saturated air (altostratus and cirrus) occur in the region under consideration during the early stage of frontogenesis, and friction of such air against the dry environment probably exerts enough of a brake action to preclude violent developments. The dry-adiabatic upgliding thus still applies to the greater part of the baroclinic upper-tropospheric air.

The numerator in the expression for v_η can be judged from an inspection of the 500-mb map (in Fig. 11). If $v_x \partial v_g/\partial x$ is measured on the map just north of Rapid City, it amounts to $20 \times 2.6 \times 10^{-5}$ m sec^{-2} $= 5.2 \times 10^{-4}$ m sec^{-2}. The large value of the term comes from the convergence of the 500-mb contours and that feature, in turn, is inherent in the structure of the large pressure trough to the west with its central area of weak pressure gradient bordering on strong pressure gradients to the south. The large value of $\partial v_g/\partial x$ is, of course, also corroborated by measured wind velocities, which increase from 10 m sec^{-1} to 50 m sec^{-1} along the streamline from northern Wyoming to Green Bay, Wisconsin. In addition, the 300-mb map (Fig. 9) shows the same convergence of contours a little farther north.

An evaluation of v_η at the 500-mb level just north of Rapid City gives

$$v_\eta = \frac{5.2 \times 10^{-4}}{0.8 \times 10^{-4}} = 6.5 \text{ m sec}^{-1}.$$

Here $\partial v_g/\partial t$ has been neglected as insignificant in comparison with $v_x \partial v_g/\partial x$. The corresponding v_z would be about one-hundredth of v_η, hence 6.5 cm sec^{-1}. Corresponding determinations of v_η lower down on the frontal slope result in smaller values, and consequently $\partial v_\eta/\partial \eta$ is positive. With $\partial v_\eta/\partial \eta$ and $\partial v_x/\partial x$ both positive in the frontal zone, there is stretching in both the η-direction and the x-direction, so that frontogenesis progresses under optimum conditions.

In the upper troposphere south of the maximum westerlies $\partial v_g/\partial \eta$ assumes large values approaching those of $2\Omega_z$. In Fig. 11, $2\Omega_z - \partial v_g/\partial \eta$ measured at 300 mb over Oklahoma City is only 0.1×10^{-4} sec^{-1}. However, $v_x \partial v_g/\partial x + \partial v_g/\partial t$ is also small at that place (see Fig. 9) so that no great v_η-component results. Farther east near the Atlantic, where the anticyclonic isentropic shear is equally great and $v_x \partial v_g/\partial x$ has a large negative value, v_η is observed to have a large negative value (directed towards high pressure) at all reporting upper-wind stations. This is an example of the systematic nongeostrophic wind components at the "delta" of an upper jet stream derived in Fig. 8. The horizontal convergence resulting in the southern half of the delta is instrumental in providing the pressure rise ahead of the moving high in the southeastern United States (Fig. 10).

Figure 12 shows a profile through the zone of frontogenesis twenty-four hours later. The frontal slope has become steeper ($\frac{1}{50}$ in the lowest portion) and the frontal shear $-\partial v_x/\partial y$ is now characterized by a sharp 180° wind shift. Negative v_g values (northeast wind) stronger than 10 m sec^{-1} now occur in the lower part of the cold wedge near the front. Applying the v_η-formula to particles in the northeast current, we find conditions set for isentropic downgliding because the numerator $v_x \partial v_g/\partial x + \partial v_g/\partial t$ is now negative. A numerical estimate of the downgliding along the 281° isentrope near the cold edge of the frontal zone at 850 mb follows:

$$v_\eta = \frac{v_x \dfrac{\partial v_g}{\partial x} + \dfrac{\partial v_g}{\partial t}}{2\Omega_z - \dfrac{\partial v_g}{\partial \eta}} = \frac{-10 \times 1.4 \times 10^{-5} - 10^{-4}}{0.96 \times 10^{-4} - 0.1 \times 10^{-4}} = -2.8 \text{ m sec}^{-1}.$$

The resulting dry-isentropic descent traverses the frontal zone with a component from the cold to the warm side. This nongeostrophic component towards the frontal trough, together with the frictional flow component in the same direction, accounts for the subgeostrophic displacement of warm fronts in general. In some cases the nongeostrophic component normal to the front may permit the cold wedge to advance against a moderate geostrophic component from warm to cold.

In the upper part of the frontal zone, isentropic upgliding continues on November 8 just as on November 7, as can be seen from the convergence of contours between Omaha and Bismarck on the 500-mb map (Fig. 12). The same contour convergence is found right over Omaha on the 700-mb map (not reproduced). In the profile the 284° saturation isentrope approximately follows the warm edge of the frontal zone; $\partial v_g/\partial \eta$ measured along that isentrope gives values greater than $2\Omega_z$ from the condensation level up to 700 mb. This lower portion of the frontal zone is thus dynamically unstable; while higher up, where the 284° isentrope turns parallel to the v_g-isovels, finite speeds of upgliding can be determined. An estimate of the upgliding on the saturation isentrope of 284° at the 500-mb level gives

$$v_\eta = \frac{23 \times 1.4 \times 10^{-5}}{(1.0 - 0.1) \times 10^{-4}} = 3.6 \text{ m sec}^{-1}.$$

Exploring the whole frontal zone for nongeostrophic isentropic motion, we find the conditions for downgliding limited upwards by the zero isovel, while upzone is about $\frac{1}{50}$ in the upper portion, and it is quasivertical near the ground, while an intermediate portion around 700–800 mb tilts only by $\frac{1}{130}$. The general

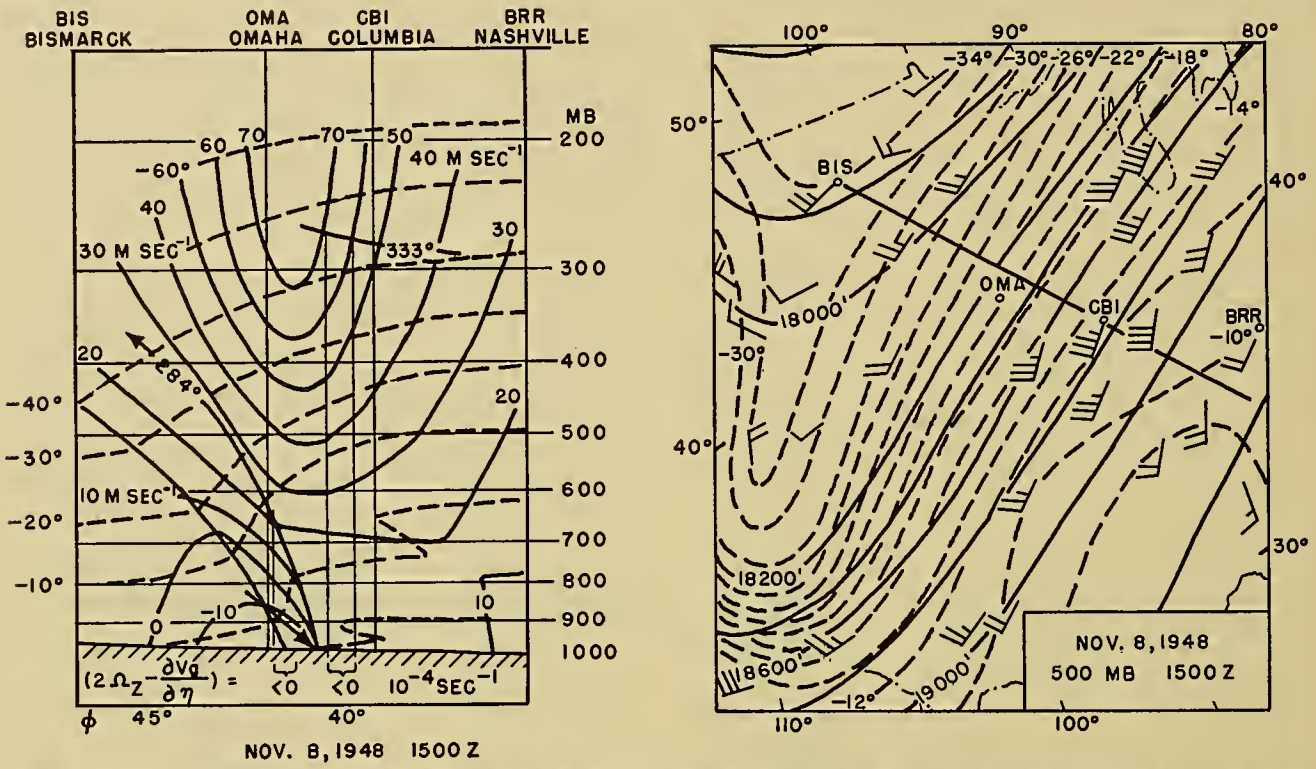

FIG. 12.—Profile of the warm front of the incipient wave on November 8, 1948, 1500Z, and part of the 500-mb map for the same time. Sample evaluations of $2\Omega_z - \partial v_g/\partial \eta$ below diagram. Upper winds: Half barb 5 m sec^{-1}, full barb 10 m sec^{-1}.

gliding begins above that line. Moreover, we find that the dry-isentropes indicate a downgliding with a horizontal component across the front from cold to warm, while the upgliding along saturation isentropes remains almost parallel to the frontal slope. The frontal profile therefore must begin to bulge forward from cold to warm in the lower layers while remaining rather unchanged higher up. That is what happens when the apex of the frontal wave goes by, as will be discussed in connection with the maps in Fig. 14.

The anticyclonic shear south of the westwind maximum has grown to the state of dynamic instability as shown in Fig. 12 by means of the differentiation of v_g along the 333° isentrope. Shears rather close to the instability limit also extend down to the 500-mb level and make possible the rather large and systematic wind component towards low pressure observed on the 500-mb map southeast of the jet stream.

Figure 13 shows a profile across the cold front from Dodge City (Kansas) to Maxwell Field (Alabama) on November 9, 1500Z. The corresponding sea-level and 850-mb maps are to be found in Fig. 10. The profile shows that strong horizontal temperature gradients have formed all the way to the top of the diagram. The frontogenetical process by horizontal advection has actually been operating through the whole troposphere (in Fig. 14 the resulting frontal zone shows up well even at the 300-mb level). The inclination of the frontal shape of the profile can be understood as the result of the bulging forward of the lower portion of the cold wedge after the passage of the frontal wave apex. The

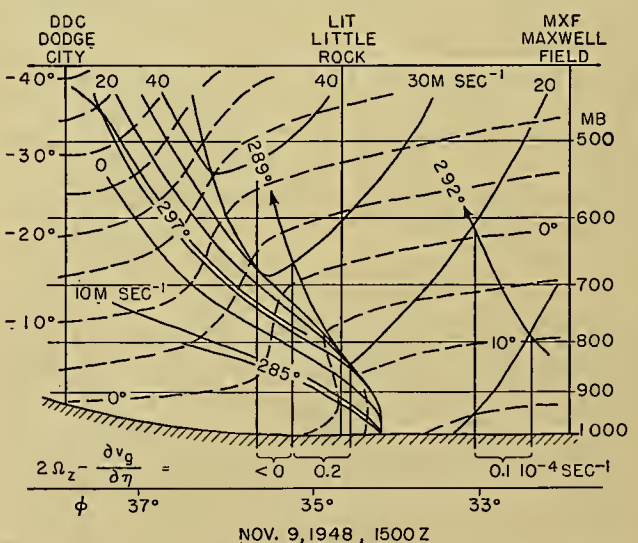

FIG. 13.—Profile of the cold front on November 9, 1948, 1500Z. Sample evaluations of $2\Omega_z - \partial v_g/\partial \eta$ below diagram.

nongeostrophic downgliding responsible for that process was found to be dynamically justified from the study of the frontal profile 24 hours earlier, $v_x \partial v_g/\partial x$ +

$\partial v_g/\partial t$ being negative in the lower portion of the cold wedge. The sea-level map for November 9, 1500Z (Fig. 10) shows a positive $\partial v_g/\partial x$ along the whole cold front (the geostrophic wind component parallel to the front in the cold air is increasingly negative as we pass towards the negative x-direction), but the actual wind component v_x, parallel to the front, is about zero in the forward part of the cold wedge; $\partial v_g/\partial t$ also is small. Hence it follows that the isentropic downgliding v_η should be insignificant except where $2\Omega_z - \partial v_g/\partial \eta$ is zero or negative. The profile in Fig. 13 shows an almost perfect parallelism of v_g-isovels and dry-isentropes in the cold wedge, so that $\partial v_g/\partial \eta = 0$. Therefore, no dynamic instability occurs inside the cold air, not even in the upper part where the frontal zone is quite steep. The only place for dynamic instability to occur inside the cold air is right at the quasi-vertical part of the frontal surface near the ground, where a real temperature discontinuity exists. However, the air volume involved is too small to appear on a profile of the scale used in Fig. 13. The release of the dynamic instability at the cold front is responsible for maintaining the downdraft, which is always observed in a strip of a few kilometers' width following the frontal passage. This cold-air downdraft is instrumental in giving the cold front a greater speed of displacement than would have been indicated by the geostrophic wind determined from the sea-level pressure distribution. In Fig. 10 the computed twelve-hour geostrophic displacement of the cold front is represented by a short arrow of 80-km length, while at the same place the preceding twelve-hour displacement was 210 km and the subsequent one 460 km. The geostrophic wind component normal to the front computed from the 850-mb map is large enough to account for the frontal displacement, and we must assume that air from this level enters the frontal downdraft and carries westerly momentum to the surface layer. In the layers above 850 mb the cold-air current is cyclonically curved and hence subgeostrophic. With increasing height, the wind in the frontal zone also becomes more and more parallel to the frontal boundary, so that the frontal displacement is less there than at the ground.

The prefrontal air in the profile in Fig. 13 has a lapse rate slightly less than the saturation adiabatic, but with the existing horizontal temperature gradient a saturation-adiabatic ascent is possible at the rather steep angle of $\frac{1}{50}$, as shown by the sample saturation isentropes of 289° and 292°. The measured values of $2\Omega_z - \partial v_g/\partial \eta$ show a close approach to dynamic indifference and even some dynamic instability. A saturation-isentropic upgliding is in order at 850 mb, as can be seen from the convergence of contours ($v_x \partial v_g/\partial x > 0$) in the warm current intersected by the profile (Fig. 10). The same is true for the 700-mb map (not reproduced) but not for the 500-mb and 300-mb maps (Fig. 9). The frontal upgliding should therefore be confined to the layers under 500 mb. This is also verified by the Little Rock sounding, which goes up through the cold-front rain but shows a 35 per cent relative humidity at 500 mb. Thunderheads growing up from the cloud mass of the cold front would, of course, go well beyond 500 mb, but such phenomena of "vertical instability" were not reported in the case under consideration. Intermittent, light prefrontal rain, which was reported as far as 300 km ahead of the cold front, can be accounted for quite well by the saturation-isentropic upgliding. In the warm season such upgliding in the tropical air current may be sufficient to trigger thunderstorm formation, which in turn may develop prefrontal squall lines.

Structure of the Maturing Frontal Cyclone. Figure 14 presents the sea-level, 700-mb, 500-mb, and 300-mb maps for November 10, 0300Z, depicting the structure of the maturing frontal cyclone. The amplitude of the frontal wave on the surface map has now increased considerably, and the cold air from the rear begins to encircle the cyclone center. It is clearly seen how this occlusion process has had its inception only at the ground, while the isotherm patterns of the upper maps still indicate an open wave of small amplitude. This shows that while the wave travels along the front the frontal slope increases to a maximum at the wave apex. At that point the smooth wave "breaks" and a relatively shallow cold outbreak fans out along the ground. The mechanism of this breaking of the smooth wave probably lies in the dynamic instability of the lower part of the frontal zone, described in its stage of inception in Fig. 12 and continuing in the form of the frontal downdraft in Fig. 13. During the process, the cold front part near the cyclone center undergoes frontolysis through cold-air downgliding. This is always noticeable in the surface-map analysis, and, on November 10, 0300Z, it also shows up in a weakening of the frontal temperature gradient on the 700-mb map. Farther south, where the cold front passes through the frontogenetical field of deformation, the frontal temperature gradient remains rather strong. The strongest frontal temperature gradient, however, is found at the 500-mb level where the breaking of the frontal wave has not yet started. The 300-mb map also shows fairly strong temperature gradients across the pressure trough, which may justify the use of the term "front" even at that level. Particularly striking is the crowding of isotherms in the southwestern corner of the map, probably an effect of frontogenesis in a 300-mb col in the unmapped area west of Mexico. The 300-mb map under consideration is just tangent to a tropopause depression over the cold tongue of tropospheric air in the west. The map intersects the tropopause along the zone of lowest temperature across Labrador and northern Ontario. The temperature maximum east of the Hudson Bay cyclone is stratospheric. The cold air to its north is tropospheric and has been brought from lower latitudes as part of the warm sector shown in Fig. 9. On the 500-mb map, which is entirely tropospheric, the Hudson Bay center has a cold core with warmer surroundings both to the north and to the south.

The pressure minimum of the frontal wave at the Great Lakes continues up to 700 mb with some westward tilt, but at that level it has already shrunk so as to be a minor feature in the pressure field compared to

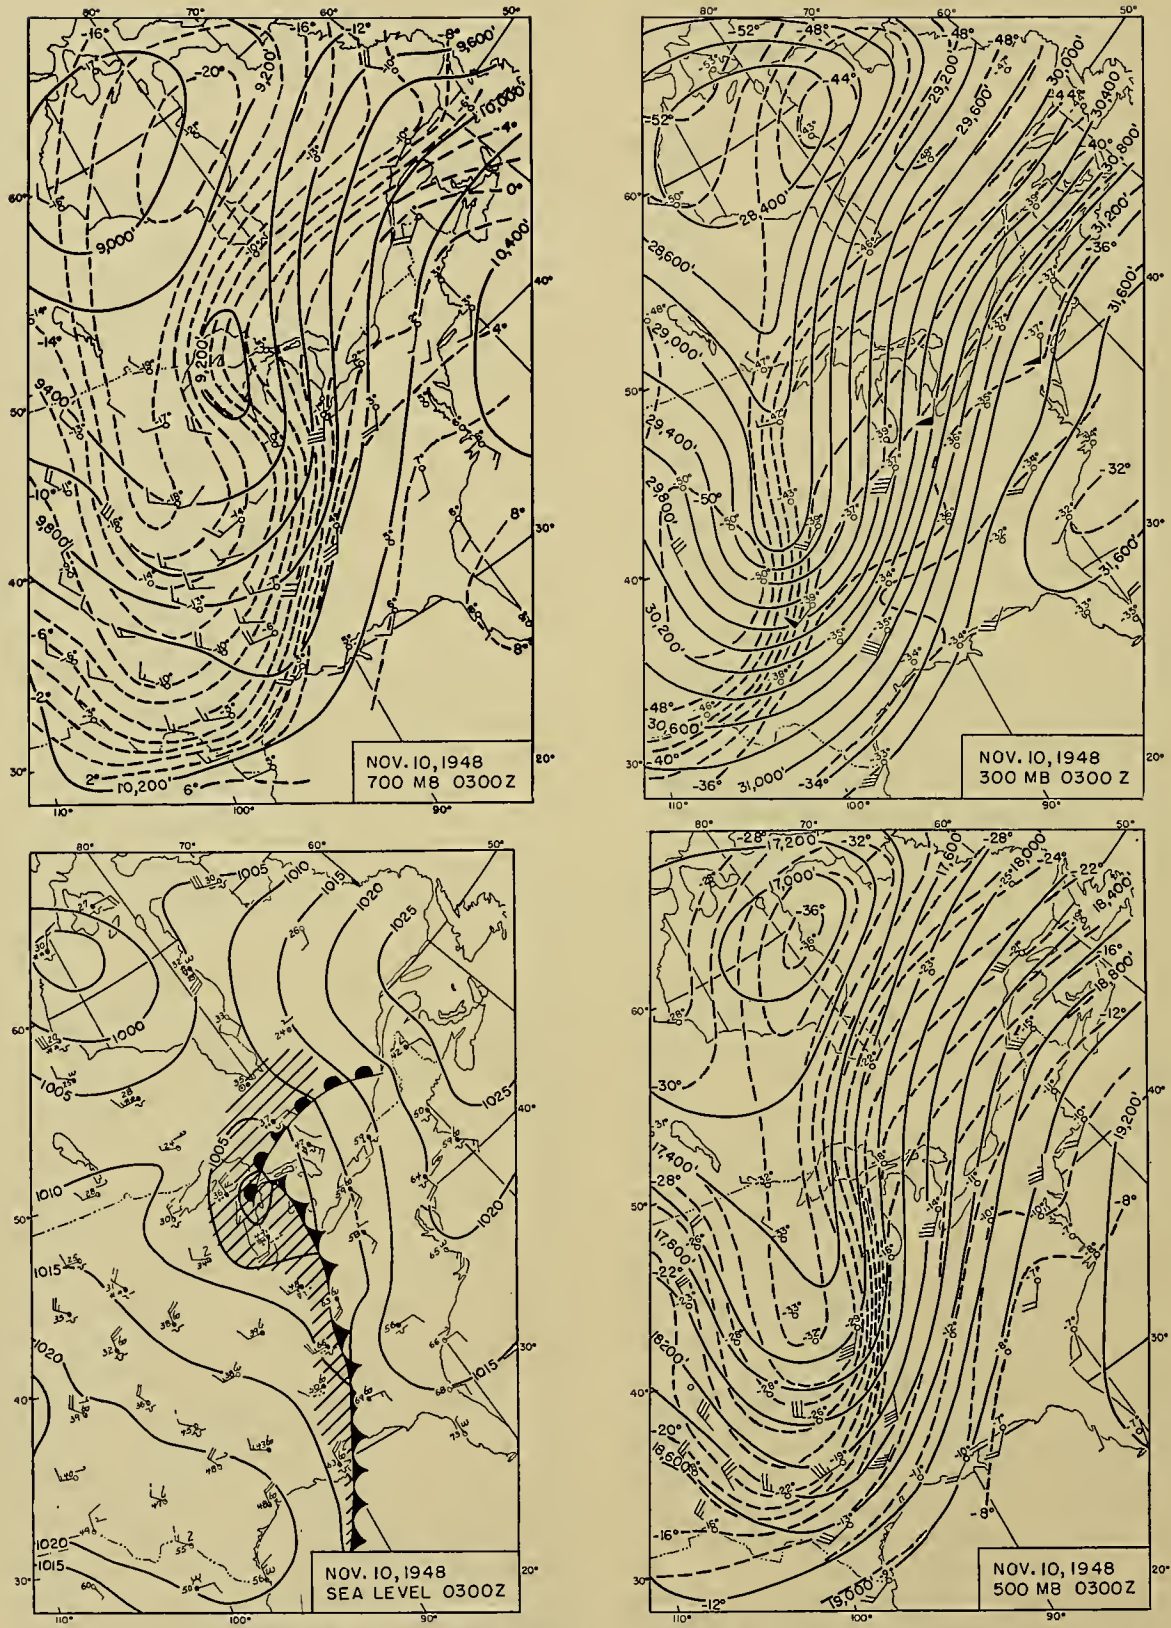

FIG. 14.—Structure of maturing frontal cyclone at sea level, 700 mb, 500 mb, and 300 mb, on November 10, 1948, 0300Z. Upper winds: Half barb 5 m sec^{-1}, full barb 10 m sec^{-1}, triangular barb 50 m sec^{-1}.

the old stationary Hudson Bay minimum. But the young cyclone over the Great Lakes has all the potentialities of development inherent in the solenoid field concentrated along the frontal wave all through the troposphere. As a hydrostatic consequence of the wave-shaped pattern of isotherms, the upper current above the closed center is likewise wave-shaped with an anticyclonic bend over the warm-front area of upgliding.

The frontal cyclone deepened at the rapid rate of 14 mb per twelve hours during November 10, and ended up as a storm center of 975 mb over northern Labrador on November 12. We shall briefly consider the application of the various theories of upper-air divergence which may claim to explain the deepening. Considering first the formation of the upper pressure crest which precedes the surface cyclone, we shall see the nature of the interplay between lower and upper layers. The fact that the upper pressure crest moves at a speed of only 9 m sec^{-1} in a current of 70–80 m sec^{-1} shows that the upper wave cannot be a free one. The time and place of the first appearance of the pressure crest on the 300-mb map (November 9, 0300Z) make it likely that the upper crest was formed by the upward motion connected with the beginning frontal upgliding in the nascent frontal wave. Once the upper wave is established, upper divergence will be located in the area between the pre-existing upper pressure trough and the new upper pressure crest ahead of it. With the trough in north-northeast–south-southwest orientation and the pressure crest in northwest–southeast orientation, the half wave length between them shortens northward and makes the upper divergence particularly strong in that region. This is also the region where the rapid deepening of the frontal cyclone takes place. So far, the dynamics involved in the deepening process conform with the principles of Fig. 1. With that basic pattern accepted, we must also admit the existence of the following modifying processes.

The upper pressure crest is continually being fed from below by the rising motion in the front half of the cyclone and therefore is forced to maintain the same slow speed of propagation as the surface vortex. When the curvature of the anticyclonic bend of upper isobars becomes sufficiently strong, the fast upper current is unable to follow the isobars in gradient wind fashion, and horizontal divergence must result on both sides of the upper crest line (see p. 590). This component of upper divergence modifies the model in Fig. 1 in the sense of extending the pressure fall farther ahead of the surface center.

The upper-air divergence of the Ryd-Scherhag theories (p. 586) is also superimposed on the divergence and convergence inherent in the wave pattern. It can best be judged by comparing the geostrophic wind at two successive inflection points. The average geostrophic wind between the 30,000-ft and 29,000-ft contours at the inflection point southwest of the Great Lakes was 60 m sec^{-1}, and between the same contours at the inflection point over Labrador it was 42 m sec^{-1}. Therefore it can be concluded that the Great Lakes cyclone was situated under a "delta" of the upper current, and that an upper divergence pattern in the style of Fig. 8 would be superimposed. This upper pattern would tend to produce pressure falls in the northern half and pressure rises in the southern half of the delta. It may be counted in favor of this reasoning that the Great Lakes cyclone proceeded northeastward to northern Labrador and not along the 300-mb contours ahead of the storm which would have meant east-northeastward propagation.

The sample cyclone described above had its early development near the ground, where the frontal upgliding of the warm air and the downgliding of the cold were a direct consequence of the preceding frontogenesis. Such wave cyclogenesis is typical for all the frontogenetical areas of the middle and high latitudes. Another type of cyclogenesis occurs at times independently of any pre-existing low-level front. The cyclogenetic mechanism in that case seems to lie in the dynamic instability of the upper tropospheric westerlies, which leads to the meandering of the current and the subsequent formation of an upper cold low. Cyclogenesis of this kind is described by means of two synoptic examples in the following article by E. Palmén. In one example, that of November 4, 1946, the upper low did not reach a frontogenetical area, and did not extend down to the surface. In the other case, that of November 17–18, 1948, a frontal wave action can be discerned but, in contrast to the case of November 7–10, 1948, the wave motion started first in the upper troposphere and later extended to low levels.

CONCLUSION

Summing up our state of knowledge of extratropical cyclones, we may classify their formation as being due either to unstable frontal wave action or to unstable growth of an upper wave trough. A subsequent combination of both processes is quite frequent, and all the strongest cyclones on record seem to have that double origin. This article has dealt mainly with the unstable frontal wave action, which is in itself a large subject. The descriptive study of cyclogenesis and cyclone growth is carried out daily by all the weather forecasters of middle latitudes, and an adequate report on their experiences would have exceeded by far the scope of this article. The theoretical study of the model of frontal cyclogenesis has been the work of a small number of scholars of dynamical meteorology. Viewed in retrospect, the contribution of H. von Helmholtz to this field of research appears to be of outstanding importance and to represent the foundation upon which contemporary and future theories should build. The Helmholtzian concept of dynamic instability of the inertial motion in isentropic surfaces points out which properties of the atmospheric fields of mass and motion on a rotating earth are conducive to the growth of perturbations from infinitesimal to finite amplitudes; and it seems obvious that such a fundamental theoretical principle must have its applications to the early phases of the life cycle of cyclones. However, there is still a wide gap to be bridged between the existing theory of dynamic instability and the applications called

for in daily synoptic practice. Helmholtz considered only the background pattern of an atmosphere moving zonally at all longitudes. What synopticians need are the criteria of dynamic instability for large-scale atmospheric currents which are nonzonal and nonpermanent, because they are part of a slowly moving, long-wave pattern, but still offer the propitious environment for the quick growth of perturbations of cyclone size.

Once the frontal wave has occluded, dynamic instability in the Helmholtz sense is eliminated, because of the accomplished spread of cyclonic vorticity to the whole cyclonic area. Indirect effects of dynamic instability may, however, be brought to the cyclone from the neighboring upwind anticyclonic part of the upper-tropospheric westerlies. In the absence of such a rejuvenating influence, the cyclone is left to decay by frictional inflow at the surface unopposed by deepening effects in the upper troposphere. This sketch of the last part of the life cycle of cyclones is even less intimately related to exact dynamic theories than is the existing theory of frontal cyclogenesis. The most hopeful approach to a solution of the problems of the old cyclone is most likely to be through the study of the energy transformations in the cyclone and its farther environment. The major old cyclones occupy such big fractions of the volume and weight of the atmosphere that the "farther environment" must be taken to mean the whole hemispherical circulation.

THE AEROLOGY OF EXTRATROPICAL DISTURBANCES

By E. PALMÉN

Academy of Finland

The present article deals mainly with the role of extratropical disturbances as links in the general atmospheric circulation and as cells for meridional exchange of air masses. Because of limited space we cannot discuss the subject in detail. Since there already exists a large amount of literature on the structure and behavior of cyclones in the surface layers, most emphasis has been placed in this article on the structure of disturbances in the free atmosphere. Most of the ideas and viewpoints expressed here can be found in the extensive writings dealing with extratropical cyclones. However, it has not been possible to refer directly to more than a portion of this material.

This article was prepared in final form while the writer was under appointment as visiting professor at the University of Chicago. The writer is indebted to Mr. C. W. Newton for his valuable help in preparing many of the figures in the article and especially for his analysis of the cyclone of November 17–19, 1948.

CHARACTERISTIC TEMPERATURE AND WIND DISTRIBUTION IN THE WEST-WIND ZONE

The formation of extratropical cyclones is connected with fronts separating air masses of different origin.[1] The most important front is that which separates air masses of polar origin from those of tropical origin. This "polar front" can, at least during the colder season, be followed relatively easily around half or more of the Northern Hemisphere on daily synoptic surface maps. The breaks in the polar front are of great importance. In their classical paper on the polar-front theory, J. Bjerknes and H. Solberg [7] pointed out that these breaks in the polar front are necessary in order to permit an exchange of air masses between the polar and tropical source regions.

From studies of synoptic charts for different levels one can conclude that the outflow of polar air from the polar source region occurs particularly in the regions between two polar fronts separated by a cold anticyclone. The polar outflow here appears in the southern parts as a relatively shallow layer of subsiding air masses. On the other hand, the inflow of tropical air into the polar region at higher latitudes usually appears as currents of warm air in the upper atmosphere. This can be seen from statistical studies of the frequency of the two principal air masses at different levels [35]. Frontal analyses of upper-air charts indicate that the area occupied by tropical air increases with height at all latitudes. Since the characteristic difference between polar and tropical air at a given latitude could not be maintained for a long time without advection, the only possible explanation for the above-mentioned fact seems to be the existence of a systematic meridional circulation of the type outlined here.

It is necessary to emphasize that the meridional circulation appears as a statistical fact. The average meridional circulation is naturally not the same at all longitudes nor at all times during a certain season. The circulation has a tendency to break up into several cells with quasi-vertical axes, depending upon the geographical distribution of continents and oceans and the formation of disturbances [11]. Thus the paths of individual air parcels are extremely complicated and the different air parcels carry out various kinds of complicated oscillating movements before they have performed a complete meridional circulation.

If there is a statistically opposite meridional movement in the lower and upper troposphere, obviously there must also be a surface of zero average meridional movement, separating the northward flow in the upper troposphere from the southward flow in the lower troposphere. This surface has a tendency to become a frontogenetical surface. Since the meridional movements discussed here are average displacements for longer periods, the separating surface naturally cannot have the character of a real front. However, synoptic experience shows that in nature there is a strong tendency to concentrate the contrasts between the air masses of tropical origin and those of polar origin in a relatively thin layer of transition. This transitional layer must have a certain inclination toward the horizontal surfaces because of the earth's rotation. On a nonrotating earth, frontal surfaces of the type observed in the atmosphere, with an inclination of the order of $\frac{1}{50}$–$\frac{1}{200}$, could never form.

It is obvious that there must be a transformation of polar air into tropical air at low latitudes and that the opposite must be true at high latitudes. The outflow of polar air into the subtropics takes place in the lower troposphere and the inflow of tropical air into the polar regions takes place in the middle and upper troposphere, and perhaps partly in the lower stratosphere. Therefore there cannot be any continuous frontal surface around the whole hemisphere in the vicinity of the earth's surface or in the upper atmosphere. However, in other parts of the troposphere there is nothing in principle against the idea of having a continuous polar front around the entire hemisphere.[2]

1. If taken in the broadest meaning of the word, cyclones or depressions of different types can form without any preexisting fronts or frontal zones. These types of irregular, generally weak depressions will not be discussed here.

2. The concept of a front is here used in the broad sense; it is obvious that a distinct upper polar front can be expected only in special situations favoring an extreme concentration of the air-mass distinctions.

Another point of importance should be noted here. The source region of polar air is smaller in area than the source region of tropical air. Therefore any outflow of polar air into lower latitudes must have a tendency to break up into "streams" embedded in tropical air. These streams of polar air often select "preferred regions" determined by geographical factors. Several such preferred regions for polar outflow can be found in the Northern Hemisphere. It is through these regions of preferred polar-air outflow that the principal frontogenetical regions on the earth's surface are determined, as Bergeron pointed out in his outline of dynamic climatology [3].

Analyses of synoptic charts for different levels indicate that in the region between two cyclone families, where no surface polar front exists, pronounced frontal zones appear on the charts for the middle troposphere (*e.g.*, at the 700- and 500-mb surfaces). In such cases the polar front appears to be interrupted only in the surface layers and not at higher levels in the atmosphere (compare Figs. 5 and 6). Since this difference between the polar front on the surface and in the free atmosphere is essential for an understanding of the three-dimensional air movement in cyclones, it is necessary to discuss the problem of meridional movement of air masses before we go further in our description of the characteristic structure of the atmosphere.

If ζ denotes the vertical component of the relative vorticity, ϕ the latitude, Ω the angular velocity of the earth's rotation, and D the depth of a given air mass (here regarded as incompressible), the principle of conservation of potential vorticity, according to Rossby [52], can be expressed by the equation

$$\frac{d}{dt}\left(\frac{\zeta + 2\Omega \sin \phi}{D}\right) = 0. \tag{1}$$

From (1) it follows that the individual change of vorticity is

$$\frac{d\zeta}{dt} = -\frac{2\Omega \cos \phi}{a} v + \frac{1}{D}\frac{dD}{dt}(\zeta + 2\Omega \sin \phi), \tag{2}$$

where v is the meridional wind component and a the radius of the earth.

The first term on the right in (2) gives the change of vorticity due to the meridional motion; the second term, the effect resulting from the change in depth of the air column. If we assume that the air moves without change in depth, the vorticity increases for movement toward the south. If, in order to simplify the discussion, we assume that the increase in vorticity appears as increasing curvature, the air parcel continuously curves to the left if v is negative (north wind). It is then easy to show that any air column moving without shrinking must ultimately bend back after reaching a lowest latitude. According to equation (1), this latitude is determined by the initial latitude, meridional wind component, and vorticity of the air parcel.

The change in depth of an air column moving southward can be computed from equation (2) if the vorticity along the trajectory is known. In the special case of a straight flow without horizontal shear (relative vorticity $\zeta = 0$) we obtain

$$\frac{1}{D}\frac{dD}{dt} = \frac{v}{a} \operatorname{ctn} \phi. \tag{3}$$

This equation determines the shrinking of a polar air column moving with the north-south velocity v along a trajectory of zero relative vorticity.

If we use either equation (1) or (3) for $\zeta = 0$, it is possible to compute the depth of a polar air mass at different latitudes as a function of its original depth at a given latitude. If we assume a depth of 8 km at latitude 60°N, we obtain the following values for D at lower latitudes:

Latitude N (deg)	60	50	40	30	20	10
Depth (km)	8.0	7.1	5.9	4.6	3.1	1.6

The foregoing values are very approximate. If we permit an increase in relative vorticity, higher values of the final depth of the polar air result. On the other hand, however, air which descends from the level of 8 km to, for example, 5 km will undergo a temperature increase of about 30C. In other words, the air will no longer be very cold at that lower level. Thus there must be some limit, determined by the original temperature, for the sinking of the polar air.

From the very simplified reasoning above, it follows that there must be some southern limit for the extension of characteristic polar air in the upper-air charts. This southern limit for the 500-mb level is somewhere around latitude 30°N. Systematic analyses of circumpolar 500-mb charts indicate that air masses with the characteristic polar air temperature very seldom reach latitude 30°N, and that 20°–25°N represents the southernmost limit for real polar air at the 700-mb level.[3]

It is now easier to understand the structure of the atmosphere in the area between two cyclone families or surface polar fronts. The breaks in the surface polar front which permit outflow of polar air into the tropics are not necessary at upper levels where the polar air flows southward as a subsiding current. At the 500-mb level, for example, a southern boundary for the polar air can be maintained around the hemisphere, at least in principle.

Many meteorologists who regularly use fronts on surface maps are inclined to reject the idea of upper fronts existing around the hemisphere. Their opinion is founded on the idea that surface friction is necessary for the formation of distinct fronts. It is obvious that surface friction contributes to the sharpening of fronts. In the free atmosphere, however, other frontogenetical factors can be as effective as those in the surface layer, or sometimes even more effective (*cf.* Bergeron [2] and Petterssen [46]). On the other hand it is evident that the great dynamic significance of fronts, confirmed in

3. In this reasoning the nonadiabatic processes have been completely disregarded. A southward-moving polar air mass naturally undergoes a gradual change and eventually completely loses its polar character because of the heat transfer from below.

daily synoptic work, could hardly be explained if fronts were phenomena restricted to the surface layer. Systematic use of the frontal method of analysis of upper-air charts, at least up to 500 mb, has shown that fronts are not only surface phenomena.[4]

The very valuable daily synoptic weather maps published by the United States Weather Bureau in cooperation with the Army, Navy, and Air Force confirm the existence of a band of strong isotherm concentration at the 500-mb level. Over large parts of the Northern Hemisphere this band shows all the characteristics of a real frontal zone; in other parts, however, it is more diffuse. Since this band of crowded isotherms undergoes strong meridional displacements from day to day, it

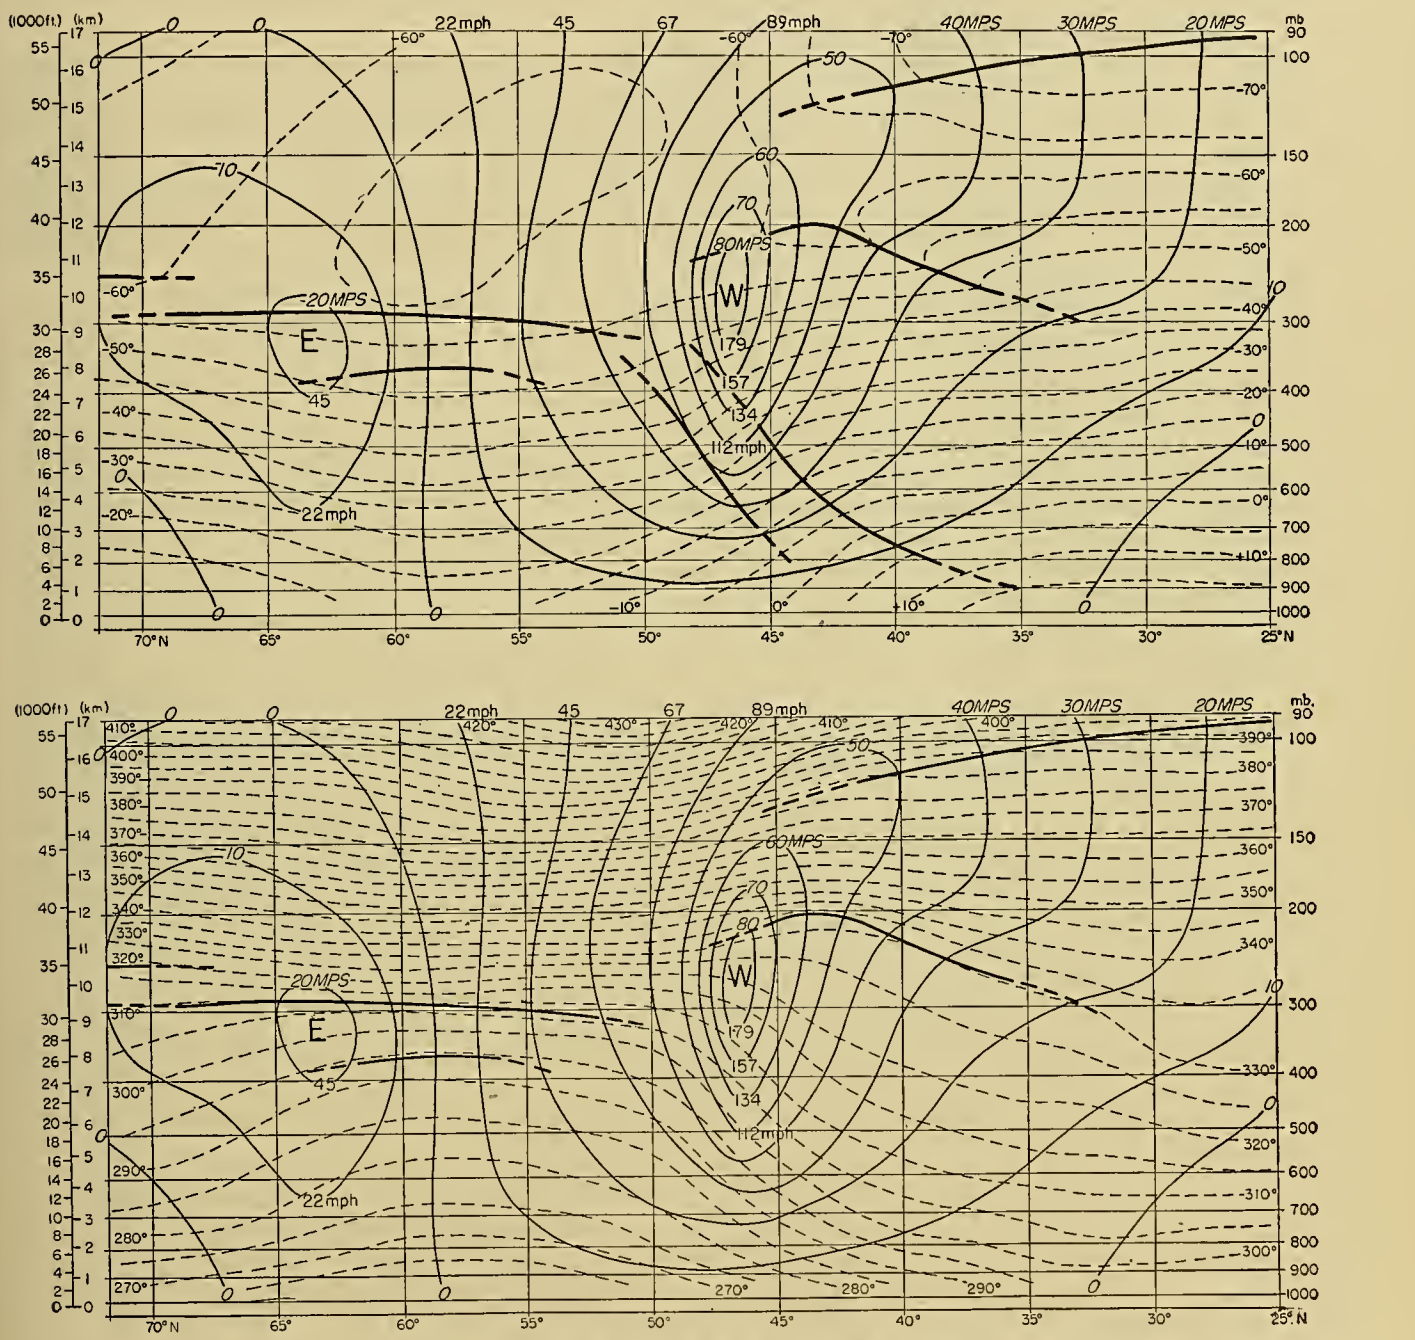

FIG. 1.—Mean cross section for 0300 GMT, November 30, 1946, showing average distribution of geostrophic westerly wind and of temperature over North America from latitude 25° to 75°N in a case of approximately straight westerly flow. Heavy lines indicate boundaries of the principal frontal layer (polar front) and tropopauses. Thin solid lines indicate velocity of westerly wind component (meters per second and miles per hour), and dashed lines temperature (degrees centigrade) in top picture and potential temperature (degrees absolute) in lower picture.

4. The method of drawing frontal contour charts, first used in the analysis of selected European cyclones [9, 10] and later extended to daily weather charts in Canada [18], is very useful for a simple description of actual atmospheric conditions.

cannot show up very clearly in mean cross sections and charts.

Numerous vertical cross sections normal to the average air flow in the free atmosphere have provided detailed information concerning the structure of temperature and wind fields in different synoptic situations. Figure 1 presents a situation with almost zonal flow over North America. The geostrophic wind computed from the height of the standard isobaric surfaces shows the strong concentration in a wind maximum over 80 m sec^{-1} between the 300- and 200-mb levels. The maximum wind (center of the "jet stream") seems to be associated with a typical break in the tropopause as can be seen in Fig. 1. In this special case there seem to be three different tropopauses: a tropical one around 100 mb, a subtropical one between 200 and 250 mb, and a polar one (with multiple structure) over the northern part of the section.

In Fig. 2 one other situation is represented. In this case the vertical cross section is computed along a line from southwest to northeast in Europe. The principal air flow here is from the northwest and the polar front extends from northwest to southeast. In this special case the geostrophic northwest wind shows an even stronger concentration into a jet than in Fig. 1. Isotherms, isentropes, frontal boundaries, and tropopause discontinuities show almost the same characteristics as in the previous figure.

If the polar front zone at the 500-mb surface is used as a reference for coordinates upon which the mean data are computed, it is possible to maintain some of the essential features of the meridional temperature and wind field found in individual situations. Such a computation has been made by Palmén and Newton [43] for the meridian 80°W. The average temperature and wind were correlated with the polar front at the 500-mb surface. The cross section can be regarded as representative of cases with predominant zonal air flow.[5] However, if the cross section is to be used on a hemispherical basis, it must be noted that the average concentration of both meridional temperature gradient and west wind is generally more pronounced in the meridian used for this cross section than along most other meridians.

Characteristic of the temperature distribution in the vicinity of the polar front is the sloping layer of maximum horizontal temperature gradient and pronounced vertical stability, and also the rather strong slope of the isotherms (strong baroclinity) both above and below the frontal surface. This pronounced concentration of the meridional temperature gradient in the polar front itself and in the layers above and below the sloping frontal surface must be associated with a strong concentration of the zonal wind in the upper troposphere and the lower stratosphere as can be seen from Fig. 1.

The equation for the vertical increase of the west wind u (approximately equal to the gradient wind) can be written

$$\frac{\partial u}{\partial z} = -\frac{g}{2\left(\Omega \sin \phi + \frac{u}{a} \tan \phi\right)} \frac{1}{T}\left(\frac{\partial T}{\partial y}\right)_p. \quad (4)$$

Here g is the acceleration of gravity, T the absolute temperature at the level z, and $(\partial T/\partial y)_p$ the meridional temperature gradient measured in an isobaric surface p at the same level. The west wind increases up to the level where the meridional temperature gradient changes its sign (generally at the tropopause level). If u_{max} denotes the zonal wind at that level, one can write

$$u_{max} = u_0 - \frac{g}{2} \int_0^{z_t} \frac{\left(\frac{\partial T}{\partial y}\right)_p}{T\left(\Omega \sin \phi + \frac{u}{a} \tan \phi\right)} dz, \quad (5)$$

where u_0 is the surface wind and z_t the height of the tropopause. Since in most cases the gradient wind at the surface is relatively weak, the wind at the tropopause must be especially strong over the frontal zone and relatively weak outside this zone. Thus any pronounced front with an inclination not too small must be accompanied by a strong upper-level wind concentrated into a relatively narrow band.

The foregoing equations, which are an expression for the assumed balance between gravity, pressure force, and the resultant of Coriolis and centrifugal forces, do not explain the formation of the strong west-wind belt at upper levels, but only establish the fact that the phenomena appear to be parallel. In cases of strong concentration of the meridional temperature gradient in the frontal zone, the wind concentration in the upper troposphere and lower stratosphere is also strong. In such cases it is justifiable to use the name "jet" or "jet stream" for the phenomenon.

The concentration of the pre-existing meridional temperature contrasts into a real frontal zone or layer (frontogenesis) and the concentration of the zonal wind in a jet stream run parallel. Thus any theory for frontogenesis should also be a theory for the formation of an upper jet stream.

The frontal layer in Fig. 2 is separated from the two principal air masses by surfaces of discontinuity for temperature gradient and wind shear, not for temperature and wind as in the classical case treated by Margules [34]. If the angle of inclination of the surface separating the warm air from the air in the frontal layer is denoted by ψ, the change in horizontal wind shear $\partial u/\partial y$ is given [41] by

$$\frac{\partial u}{\partial y} = \frac{\partial u'}{\partial y} - \frac{g \tan \psi}{2\Omega T \sin \phi}\left[\left(\frac{\partial T'}{\partial y}\right)_p - \left(\frac{\partial T}{\partial y}\right)_p\right]. \quad (6)$$

In this equation $\partial u'/\partial y$ and $(\partial T'/\partial y)_p$ represent the wind shear and temperature gradient in the warm air, respectively, and $\partial u/\partial y$ and $(\partial T/\partial y)_p$ represent the same quantities in the frontal zone.

The horizontal wind shear in the frontal zone becomes positive (anticyclonic) if the expression on the right

5. This average cross section is reproduced in Fig. 7 in "Extratropical Cyclones" by J. Bjerknes in this Compendium (see p. 586).

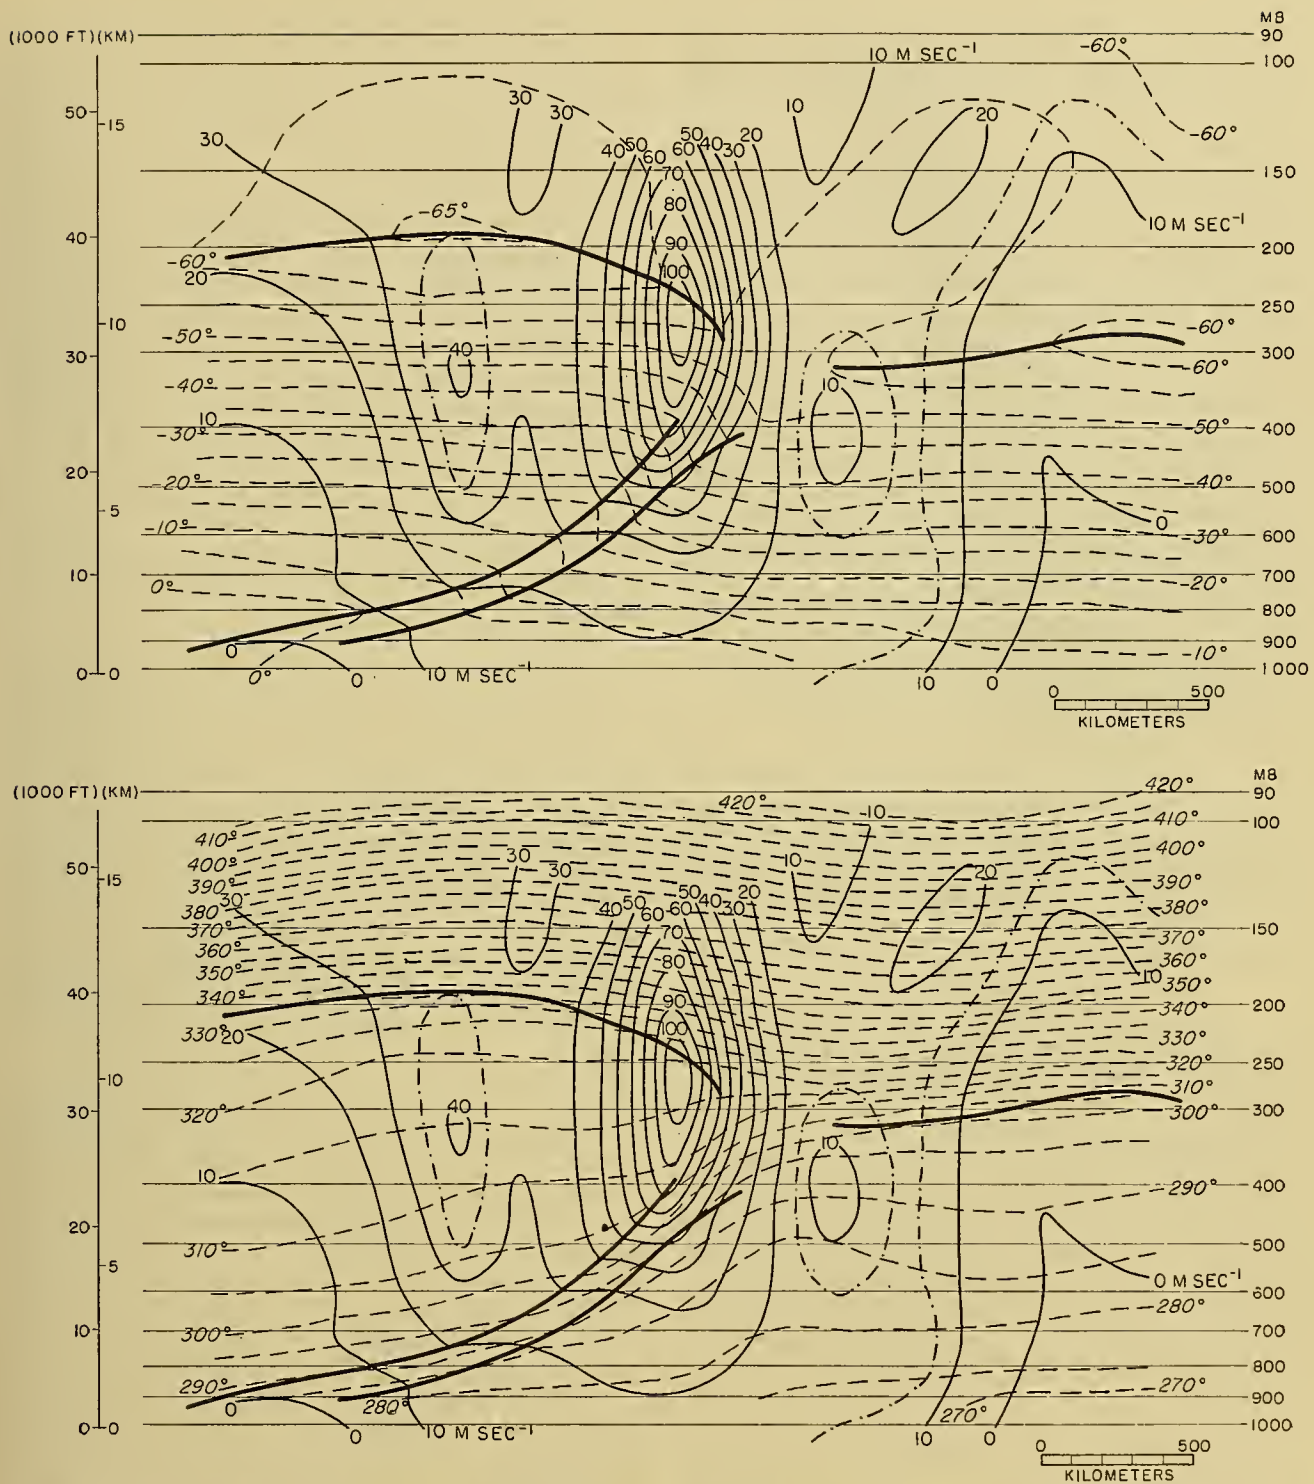

FIG. 2.—Mean cross section through northwesterly flow over Europe. Constructed from all European observations on morning of November 29, 1942 (observations from *Wetterber. Dtsch. Seewarte*). Legend as in Fig. 1 (winds in meters per second). Dash-dotted lines indicate intermediate isovels.

side of equation (6) is greater than zero. Thus, the inequalities

$$\frac{g \tan \psi}{2\Omega T \sin \phi}\left[\left(\frac{\partial T'}{\partial y}\right)_p - \left(\frac{\partial T}{\partial y}\right)_p\right] \gtrless \frac{\partial u'}{\partial y} \begin{matrix}\text{(cyclonic)} \\ \text{(anticyclonic)}\end{matrix} \qquad (7)$$

express the condition for cyclonic or anticyclonic shear in a frontal zone. Hence, the result above can be expressed in the following way: If there is strong anticyclonic shear in the upper warm air, and this anticyclonic shear is greater than the negative value of the second term on the right in (6), the west wind increases toward the north in the frontal zone.

This result concerning the horizontal wind shear in a frontal zone is of considerable importance for the cy-

clone theory. As long as fronts were regarded as surfaces of discontinuity of the order zero (Margules' type) every front was characterized by cyclonic shear. Since real fronts always have a certain width, the principle of cyclonic shear can no longer be sustained in its original form. Analyses of charts for different levels show that although most fronts are characterized by cyclonic shear, fronts with anticyclonic wind shear are not uncommon at the level around 700 mb, whereas practically all fronts in the vicinity of the earth's surface and in the middle and upper troposphere (above 600–500 mb) are characterized by cyclonic shear.

Another characteristic of the westerlies is that there seems to be *an upper limit for the anticyclonic shear of the west wind.* This limit is determined by the rule that the absolute angular momentum about the earth's axis should not increase northward along a horizontal surface. This rule of "dynamic stability," first formulated by Helmholtz [26], has been further developed and used by Solberg [58], Høiland [28], Kleinschmidt [31], Van Mieghem [61, 62], and others, and has been combined with the hydrostatic stability.

The upper limit for the meridional shear in the case of a dynamically stable zonal motion is given by

$$\frac{\partial u}{\partial y} = 2\Omega \sin \phi + \frac{u}{a} \tan \phi. \tag{8}$$

The second term on the right depends upon the horizontal component of the radius of curvature for zonal flow. Since the absolute vorticity ζ_a about a vertical axis is expressed by

$$\zeta_a = 2\Omega \sin \phi + \frac{u}{a} \tan \phi, \tag{9}$$

equation (8) also expresses the rule that the absolute vorticity is negative for a dynamically unstable zonal motion.

In the use of upper-air charts the real wind is commonly identified as the geostrophic wind. In many cases the geostrophic wind gives a sufficiently good approximation to the real wind. However, one must be careful in using the geostrophic approximation in determining the upper limit for the anticyclonic wind shear. If equation (8) is expressed by the geostrophic wind u_g, the following equation for the upper limit of the shear of the geostrophic wind [41] should be used:

$$\frac{\partial u_g}{\partial y} = 2\Omega \sin \phi + \frac{3u_g}{a} \tan \phi. \tag{10}$$

The difference is considerable. If, for example, at latitude 45°N the geostrophic wind at the tropopause level is 80 m sec^{-1} (not an unusually large value), the critical shear for the geostrophic wind is 1.41×10^{-4} sec^{-1}. The corresponding gradient wind (radius of curvature of the trajectory equals $a/\tan \phi$) is only 73 m sec^{-1} and the critical shear for the gradient wind is 1.14×10^{-4} sec^{-1}.

The foregoing results are valid only if the isentropic surfaces are horizontal. In other cases the shear should be determined along a corresponding isentropic surface or, in cases of condensation, along a surface of constant wet-bulb potential temperature. In cases where the slope of these surfaces is not too great the formulas for the critical shear given above can be used; in cases where the slope is greater there should be a corresponding correction. If the shear exceeds the critical value, the air flow is dynamically unstable because in such a case the stabilizing influence of the inertial force vanishes. The importance of this type of instability will not be discussed further here since the problem is treated by J. Bjerknes in his contribution to the Compendium. It might, however, be pointed out that the critical shear represents an interesting analogy to the adiabatic lapse rate of temperature as the upper limit for the vertical temperature gradient in the atmosphere.

The foregoing rule concerning the upper limit for the anticyclonic shear south of the zone of maximum wind should be modified if applied to disturbances, since the curvature of the air flow then becomes of major importance.

Since the existence of a well-marked jet stream in the upper troposphere is associated with the existence of a strong concentration of the meridional solenoid field, a real jet appears on hemispheric upper-tropospheric charts only in regions where the polar front in the middle troposphere is relatively well marked. This means that the jet in actual cases should not be considered as a hemispheric phenomenon without interruptions. A distinct jet stream, as well as a distinct polar front, must be the result of a certain type of disturbance acting frontogenetically. If we use the concept of a hemispheric polar front or hemispheric jet, we do not intend to emphasize that both phenomena should necessarily be fully established around the whole hemisphere.

In mean upper charts and meridional cross sections a relatively well-marked jet stream appears, especially in winter, at latitudes around 20°–40°N according to Namias and Clapp [39]. Also, in mean meridional cross sections studied by Willett [63], Hess [27], and Chaudhury [15], and for the Southern Hemisphere by Loewe and Radok [32], a similarly low latitude for the maximum westerlies was found. Since the average position of the polar front at the 500-mb level appears to be around latitude 45°–50°N, one should expect to find the maximum west wind near this higher latitude. The belt of maximum west wind associated with the upper polar front, however, undergoes such strong meridional displacements and other changes that it could barely be recognized in mean cross sections. Therefore the southern jet on mean cross sections or charts is in some measure another phenomenon probably associated with the northern boundary of the subtropical cell of meridional circulation. Only in cases of very strong southward displacement of the polar-front jet stream are both phenomena combined in one very pronounced belt of maximum west wind. This combination of two upper west-wind maxima appears to be rather common at some longitudes, especially in the vicinity of the meridians 80°W and 120°E.

UPPER LONG WAVES AND CYCLONES

As has been pointed out, the idealized picture of a zonal flow is strongly disturbed in all actual situations. Therefore the real pattern of air flow can be regarded as the superposition of different wind disturbances upon the zonal flow pattern.

There is still no satisfactory theory for the formation of the disturbances of the upper westerlies. However, three general sources for large disturbances must be considered. The first depends upon the topography of the earth's surface, the second is thermodynamical and depends upon the distribution of secondary heat and cold sources connected with the geographical distribution of continents and oceans, and the third is connected with a possible instability of the zonal baroclinic current.

The orographic disturbances are not limited to the regions of mountains. Once formed in such a region, a disturbance has a tendency to influence other regions around the entire hemisphere, as has been pointed out by Rossby [53], Yeh [64], and Charney and Eliassen [14]. The thermodynamical disturbances depend upon the fact that the continents act as secondary cold sources in the winter season and as secondary heat sources in the summer season. The opposite can be said about the oceans. In the cold season the continents are regions of surface outflow or divergence and the oceans are regions of surface inflow or convergence. Correspondingly, there must be upper convergence over continents and upper divergence over oceans. Because of the westerly flow in the middle and upper atmosphere there must be a tendency for the formation of upper troughs over the eastern part of continents, and ridges over the eastern part of oceans. During the summer season the opposite must be true.[6]

The combined effect of the "orographic" and "thermodynamic" disturbances presents a very complicated problem. The location of the hemispheric disturbances dependent on both of these effects is also influenced by the strength of the west wind and the location of the belt of the wind maximum. And because an "orographic" or "thermodynamic" disturbance, once formed, must influence other regions outside its source region, there are a great number of possible combinations for perturbations around the entire hemisphere. Since the influence of these geographical factors can never be eliminated, it is difficult to get any idea of what kind of atmospheric disturbances would form in an atmosphere without any geographical factors influencing the atmospheric processes.

A comparison with the Southern Hemisphere could give some clues for the solution of this problem. However, the upper-air data from the Southern Hemisphere are still so sparse that no satisfactory hemispheric upper-level analyses can be made. Although the influence of mountain barriers and other orographic effects is not as great in the Southern Hemisphere, the continents of Africa, Australia, and especially South America, and in addition the whole Antarctic, have a considerable disturbing influence upon the zonal air flow.

The third type of disturbance, that caused by the supposed instability of the zonal current, has been the subject of a large number of theoretical studies in the last twenty-five years. The instability of "infinitely small" disturbances superimposed upon the westerly current has been the usual starting point in these investigations. A study of these attempts to solve the cyclone problem, however, gives the impression that there still does not exist any theoretical solution fully applicable to the cyclone problem. Therefore the question arises whether it is, in principle, permissible to start from infinitely small perturbations in discussing the cyclone problem. If such an infinitely small perturbation could cause the development of strong cyclones, it would indicate that the atmosphere is extremely unstable. How such an instability associated with storing of useful potential energy could develop in an atmosphere where rather strong perturbations of all kinds are always present seems difficult to understand.

If we consider this, it seems more likely that extratropical cyclones are induced by rather large migrating disturbances which were already in existence. These large disturbances must always be present. Since cyclones and anticyclones are probably cells for transforming potential energy into kinetic energy, the preexistence of a large amount of useful potential energy is necessary for a strong cyclonic development. However, the pre-existing situation must correspond to some kind of *potential instability* that can be released only by the influence of finite perturbations.[7]

The available potential energy of the atmosphere is concentrated primarily in the solenoid field of the polar front. It is also a well-known fact that the polar-front region is the principal birthplace of extratropical cyclones. The question then arises whether a migrating disturbance would induce an irreversible process of the type observed in the development of cyclonic disturbances. The cyclone problem then would become more of a problem of the instability of certain large disturbances always observed on synoptic charts, whereas the ultimate cause of these large perturbations could be neglected. Similar ideas have been expressed earlier by many meteorologists (see, for example, von Ficker [23]).

The 500-mb level has certain advantages for a study of such large disturbances because at that level the upper zonal wind is well developed and the polar-front zone is still not too diffuse.

On circumpolar charts for the 500-mb surface, the belt of the strongest westerlies has the appearance of a "meandering river" situated, on the average, just to the south of, or in the zone of, the strongest horizontal temperature gradient. This zone has already been de-

6. The northeastern part of the North American continent (the Hudson Bay region) acts as a cold source in summer also; in this respect there is a remarkable difference between this region and eastern Siberia.

7. In his contribution to the Compendium, J. Bjerknes discusses in some detail the interaction between migrating upper disturbances and polar-front cyclones.

fined as the intersection between the sloping polar-front layer (surface) and the 500-mb surface. The polar front at the 500-mb level thus shows latitudinal displacements of the same extent as the belt of strongest west wind.

These considerations lead to the assumption that there must be a very close connection between the formation and further development of the long waves and the latitudinal displacement of the tropical and polar air masses in the free atmosphere. The upper troughs are regions for the maximum southward displacement of polar air, and the upper ridges are regions for the maximum northward displacement of tropical air. The existence of a really well-marked polar-front surface in cross sections drawn through formations of this type has been shown by a large number of detailed studies of characteristic situations.

The horizontal dimensions of upper long waves are usually considerably larger than the dimensions of polar-front cyclones on surface maps. Upper long waves, as defined by Rossby [55], correspond more to the individual cyclone families first described by J. Bjerknes and H. Solberg [7] in their original paper on the polar-front theory. The individual members of a cyclone family appear at the 500-mb level as "minor" wavelike perturbations superposed upon the pattern of the long waves. The scheme is presented in Fig. 3, which contains four similar upper long waves at the 500-mb surface, the 500-mb polar front (here considered as a continuous line around the hemisphere), and the four polar fronts at the ground, with their minor cyclonic disturbances. The minor irregularities in the upper polar front and in the contour lines at the 500-mb surface correspond to cyclonic disturbances at the surface. The surface fronts are placed approximately in the same regions as in Fig. 124 in Petterssen's textbook [47, p. 269].

Figure 3 represents a combination of the original polar-front scheme of Bjerknes and Solberg with the scheme for the long waves in the upper westerlies. Both the long waves and the polar fronts on the surface move, on the average, slowly in a west-east direction. The motion of the air at the 500-mb level is faster than the movement of the individual cyclone waves, and the movement of the latter is faster than the eastward displacement of the long waves.

It might be pointed out that the number of four long waves in Fig. 3 is an arbitrary one. Actually the wave number varies from time to time. Also the eastward speed of the waves varies considerably; statistical studies by Cressman [16] indicate that on the average the speed is in fair agreement with Rossby's formula,

$$c = U - \frac{2\Omega a \cos^3 \phi}{n^2}, \qquad (11)$$

for long waves in a barotropic atmosphere (n is the number of hemispheric waves), if U is determined as the mean velocity of the west wind at the level of 600 mb (average level of nondivergence). From equation (11) it can also be concluded that there must be a tendency for a larger wave number n at lower latitudes than at higher latitudes. Thus the scheme in Fig. 3, with four long waves at all latitudes, cannot be maintained; at lower latitudes the waves must show a tendency to be split into a greater number.

The air movement is not strictly horizontal. A complicated vertical movement is superposed upon the horizontal movement expressed approximately by the contour lines in Fig. 3. This vertical movement determines a vertical circulation pattern which is essential for the understanding of the process of development. As a consequence the polar front at the 500-mb surface undergoes continuous changes. These processes will be discussed more in detail in a later section.

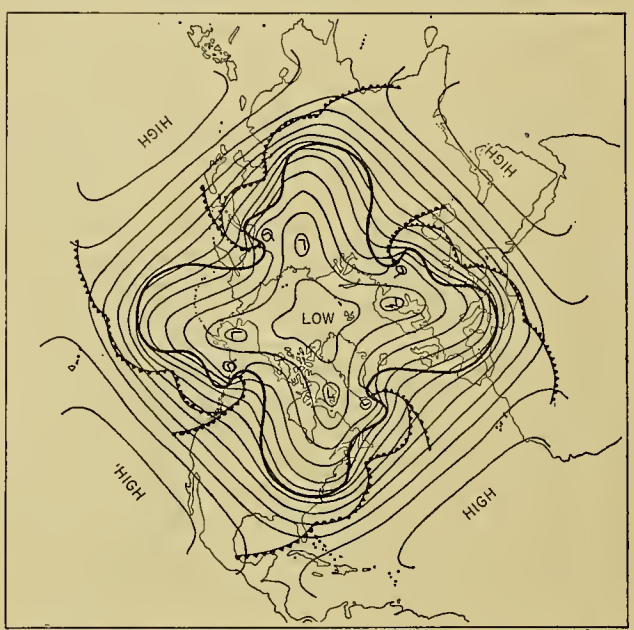

FIG. 3.—Schematic circumpolar chart for the 500-mb level showing four long waves. Heavy line is the polar front at 500 mb and thin lines are contours of 500-mb surface. Fronts at the earth's surface are indicated by the usual symbols.

The changes of the upper polar front and the upper flow pattern can be attributed to some kind of instability of the perturbations in the westerlies. The instability appears, for example, in a rapid increase of the amplitude of the polar-front contour and of the streamlines. At the 500-mb surface, the band of strongest isotherm concentration, which during the coldest season is normally situated in the vicinity of latitude 50°N, may be pushed southward to latitudes 40°–30°N. In the lower troposphere (between about 1000 and 800 mb) this process is connected with a pronounced anticyclonic outflow of polar air masses. The surface polar air thus forms a cold anticyclone, whereas the upper polar air forms an intensified upper trough or, in extreme cases, a closed upper cyclone. The process can be regarded as a combined consequence of increase of cyclonic vorticity due to latitudinal displacement and to convergence in the upper parts of the subsiding cold air.

An opposite process takes place during the formation and strengthening of upper ridges. These ridges are

characterized by cyclonic inflow of tropical air in the surface layers; the upper tropical air forms an intensified upper ridge or, in extreme cases, a closed upper anticyclone, as a result of the latitudinal effect and the divergence in the northward ascending air.

On daily 500-mb charts the formation, intensification, and final degeneration of the upper troughs and ridges can be studied. The disturbances, superficially studied, give the impression of being large waves, and the air flow gives the impression of being a horizontal movement along sinusoidal trajectories. A careful analysis of the real movement of selected air parcels, however, emphasizes the importance of the vertical components of the three-dimensional air flow and the irreversibility of the processes. In the most extreme form the irreversibility of the process appears in cases in which an upper trough develops into a closed "high-level" cyclone to the south of the strongest westerlies, or in which an upper ridge ends up in a closed "high-level" anticyclone to the north of the strongest westerlies. Thus the life history of the upper disturbances shows an irreversibility similar to that which is characteristic of the polar-front cyclones.

Figure 4 presents some of the principal types of upper-air disturbances associated with the deformations of the polar front at the 500-mb level. This figure is a further development of Fig. 3. The polar-front disturbances on the corresponding surface map are indicated by the common symbols for warm, cold, and occluded fronts. Because of technical difficulties in presenting the smaller upper disturbances corresponding to the polar-front waves and cyclones, they have been omitted in drawing the boundary of the polar air and the 500-mb contour lines. The shaded regions indicate the area occupied by polar air at the 500-mb surface.

The scheme presented here consists essentially of four irregular long upper waves as in Fig. 3. The wave troughs are situated on the east coast of Asia, over the Gulf of Alaska, on the east coast of North America, and over eastern and southern Europe. The schematic chart does not intend to present any climatological distribution of the disturbances in question. However, the different types of disturbances are to some extent placed in regions of the Northern Hemisphere where they can frequently be observed on daily synoptic charts. It might, however, be pointed out that not all of the disturbances in Fig. 4 would necessarily appear at the same time over the Northern Hemisphere. The chart corresponds to typical winter situations. For other seasons the intensity of the disturbances is usually weaker, but in principle of the same type.

In addition to the four large upper troughs of different shape, the chart also contains three cold cyclones on the south side of the polar front. These cyclonic disturbances are formed from previous cold troughs of the same type as the four large troughs in Fig. 3. The formation is associated with a gradual "cutting-off" of the polar air from its original source region in the north and will be described later.

The average latitude of the polar front at the 500-mb surface is about 48°N in Fig. 4. The strongest wind at the 500-mb surface, corresponding to the smallest distance between the contour lines, can be observed chiefly in the vicinity of the upper polar front or just to the south of it. Exceptions to this rule, however, can be seen in connection with the strong northward displacement of the polar front from its average position.

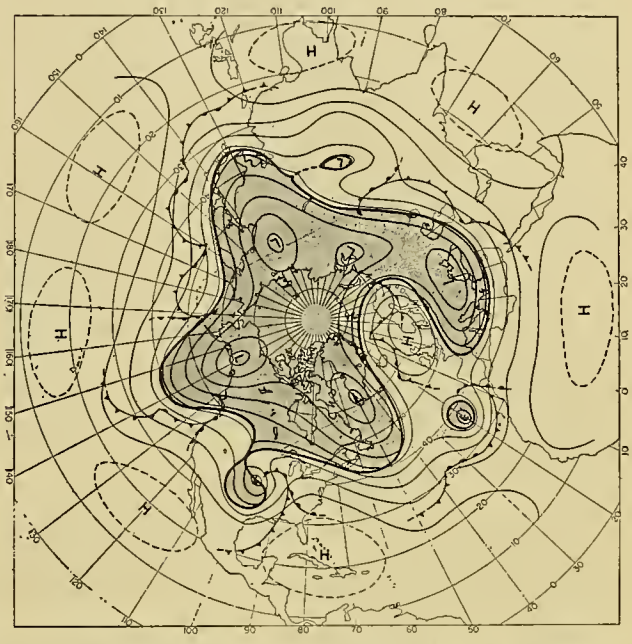

FIG. 4.—Schematic circumpolar chart for the 500-mb level showing several types of disturbances. Heavy line is polar front at 500 mb; thin lines are contours of 500-mb surface. Fronts at earth's surface indicated by usual symbols. Area covered by polar air at 500-mb level is indicated by stippling.

Our schematic figure does not intend to give more than a rather general idea of the development and structure of different types of disturbances. A more detailed description of some of them will be presented in the subsequent sections. There the following special types will be discussed: (1) the cyclone families of the regular type (Fig. 3, or over the Pacific Ocean in Fig. 4); (2) the occluded surface cyclone (represented, for example, by the cyclone over the central parts of the United States); (3) the practically symmetric upper low (east of the Azores); and (4) the warm upper anticyclone (over northwestern Europe) with its series of cyclonic perturbations.

In the schemes presented in Figs. 3 and 4 there is a general difference in scale between the polar-front disturbances connected with individual surface cyclones and those associated with the long upper waves. However there are also cases where one upper long wave is connected with only one large surface cyclone. This type is illustrated in Fig. 4 by the cyclone over the United States.

It seems difficult to maintain the idea of a complete difference in nature between the "long upper waves" and the cyclonic perturbations. Every cyclone naturally influences the upper-air flow and appears as a disturbance on the upper polar front. During the development and deepening of a surface cyclone there is also a

development and intensification of the upper disturbance. However, it is not possible to conclude anything about the causal connection between these phenomena without a detailed analysis.

In a recent paper by Berggren, Bolin, and Rossby [4], the conclusion was drawn that extratropical cyclones comprise a heterogeneous collection of different types of disturbances, including typical frontal waves as well as dynamically quite dissimilar major storms associated with the deepening of planetary wave-troughs in the upper west-wind belt. Our schematic picture is intended to include some of these types.

The surface polar front and the associated perturbations are, in our schematic figures, marked only on the southeastern sides of the large, upper, cold troughs. However, synoptic experience both in North America and in Europe indicates that cyclonic disturbances can often develop also along the southwestern sides of a cold trough. Especially over western Europe during the cold season such disturbances can develop into strong cyclones, though they are usually weaker than the cyclones formed on the southeastern side of a trough. It was not possible to include that type of disturbance in our scheme.

It is not quite clear why there is a preference for the southeastern side for the development of large cyclones. The preference could be associated with the availability of moisture and also with the meridional variation of the Coriolis parameter.

Through the "cutting-off" process associated with the formation of "high-level" cyclones on the south side of the strongest westerlies, a previous large upper trough is gradually eliminated and must ultimately disappear. The number of large upper waves then decreases. Because this process of deformation and ultimate elimination of upper troughs always goes on there must also be an opposite process, namely, the formation of new major troughs. Sometimes this process is a rapid one, an intensifying smaller disturbance developing into a major disturbance. In other cases the process is more gradual, and the new large wave is formed in a region where there is always a general tendency for such a formation, for example, on the east coasts of North America and Asia.

CYCLONE FAMILIES AND THE DEVELOPMENT OF INDIVIDUAL CYCLONES

The general scheme presented in Fig. 3 can be considered the "normal" pattern for the relationship between the surface polar fronts and the long upper waves. Some phenomena associated with this normal pattern for disturbances in the westerlies will be discussed in the following paragraphs. For that purpose a part of the scheme containing two surface fronts with their cyclonic perturbations and the cold anticyclone separating them is reproduced on a larger scale in Fig. 5. In this figure the distance between the two large troughs has been somewhat increased and other small changes have been made.

In Fig. 5 the surface fronts, one over the Atlantic and the other over the Pacific Ocean, with the separating anticyclone over the North American continent, together represent a synoptic situation very common to this part of the Northern Hemisphere. Three frontal perturbations representing different stages of development are marked on both surface fronts. In Fig. 6 the corresponding 500-mb chart with schematic fronts and contour lines is presented. In order to emphasize the connection between both figures, the positions of the surface fronts as well as the contours of the fronts at 700 mb and 500 mb are marked on both the surface chart and the 500-mb chart.

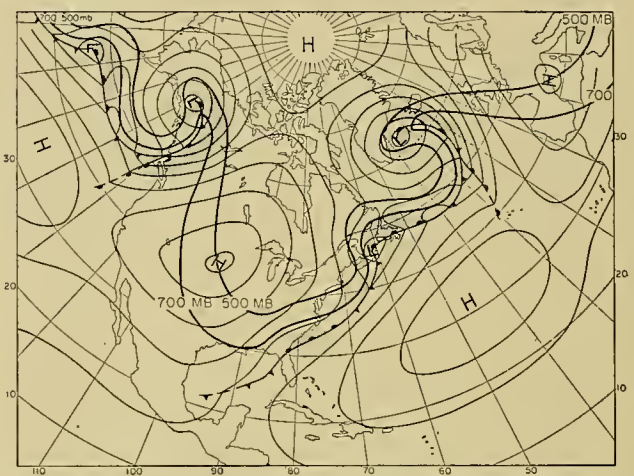

Fig. 5.—Schematic surface map showing cyclone families commonly observed with fairly symmetrical long waves. Heavy lines are 500- and 700-mb contours of polar front, and surface fronts; thin lines, isobars. Precipitation shown by stippled areas.

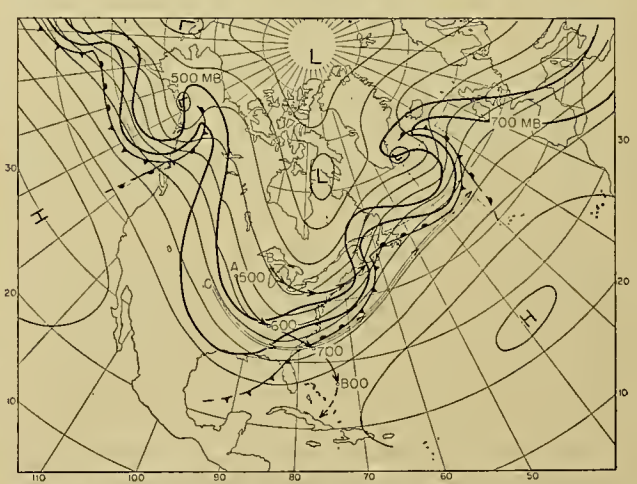

Fig. 6.—Schematic 500-mb map corresponding to Fig. 5. Frontal contours as in Fig. 5; thin lines are contours of 500-mb surface. Arrows starting at *A*, *B*, and *C* indicate approximate 48-hour trajectories of air particles in polar air and in tropical air, respectively. On trajectory *A* are indicated pressure levels reached by particle in frontal layer at approximate 12-hourly intervals.

Analyses of a great number of upper-air charts indicate, as has already been mentioned, that the polar-front zone, interrupted in the surface layers, appears as a rather well-marked zone of transition between the

polar and tropical air higher up in the troposphere. Many times the front is especially well marked only on the southwestern side of the large upper trough. The slope of the front over the western parts of an upper trough is smaller than over the eastern parts. Especially weak is the slope in the region above southwestern parts of the cold surface high, where the cold air appears as a shallow mass. A typical case has been studied in detail by Palmén and Nagler [44].

It might be pointed out that in the region of the surface anticyclone there is often a tendency toward the formation of a new surface front between the colder polar air (continental air or "arctic air") in the northeast and the somewhat warmer polar air (maritime air) in the southwest. This phenomenon is especially common over the United States, where the mountains prevent the cold surface air from penetrating to the western coastal regions. Thus the continental anticyclone is ordinarily not as symmetrical as it has been drawn in Fig. 5; on the contrary, the anticyclone is very often split into two parts separated by a secondary front, making possible the formation of disturbances similar in character, but weaker than those on the polar front. This secondary front has been disregarded in our schematic figures in order to avoid complications.[8]

The general flow pattern at the surface and at 500 mb presented in Figs. 5 and 6 cannot be fully understood if the vertical components of the air motion are not introduced into the picture. In Fig. 6 the upper warm and cold air masses have an almost parallel geostrophic flow. Upon this geostrophic flow is superposed a complicated pattern of nongeostrophic motions. The pattern of vertical movement in upper troughs and associated cyclones has been subjected to a careful study at New York University by Miller [36, 37] and Fleagle [24]. According to their results, there is, on the average, descending motion on the west side of the upper trough and ascending motion on the east side. This vertical motion is accompanied by low-level divergence and upper-level convergence on the west side, and low-level convergence and upper-level divergence on the east side. On the average, the vertical components reach their maximum values at the level of nondivergence (which is not necessarily horizontal). In the divergence field the vorticity of the air parcels moving from west to east undergoes systematic changes; the absolute vorticity has its highest value at the trough line and its lowest value at the ridge line.

This relatively simple pattern for vertical motion and divergence, however, does not describe very well the real movement in a disturbance which necessarily must contain a component of an *irreversible process*, as has been pointed out earlier. Studies of synoptic charts indicate that there is on the average an outflow of cold air from the surface anticyclone and consequently also a general subsidence in the cold air, extending very far up into the upper cold trough. The cold surface anticyclone and the cold part of the upper trough represent regions where cold polar air flows to lower latitudes. In order to maintain continuity the same amount of warmer air must flow into the polar regions. The outflow of cold air on the average must represent a descending current; the inflow of warm air, an ascending current. A vertical circulation therefore is superposed upon the general picture of the horizontal air movement. This circulation is energy producing and serves to maintain the kinetic energy of the westerlies.

In order to obtain a general picture of the three-dimensional movement in synoptic situations of the type discussed here, it would be necessary to follow the three-dimensional air trajectories for air parcels in different parts of our picture. That could to some extent be done by methods developed in the above-mentioned investigation at New York University. However, in order to give results applicable to a general cyclone theory, the method should be combined with a careful three-dimensional frontal analysis and applied to synoptic situations of well-defined types.

Since no such investigations have yet been made, we must restrict the discussion to some rather general qualitative results concerning the three-dimensional trajectories of air parcels in selected parts of our schematic Figs. 5 and 6.

An air parcel initially situated at point A in Fig. 6 is a polar air parcel. It moves with a descending component relative to a warm air parcel at point C of the same 500-mb chart. Both parcels are descending as long as they are on the west side of the trough line. The cold air moves along a path of the type marked in Fig. 6, where the successive positions and pressures are indicated by small circles. The trajectory starts out with a slight cyclonic curvature, corresponding to the cyclonic curvature observed in the upper trough, but the curvature changes gradually to an anticyclonic one when the air parcel reaches levels where $\partial w/\partial z < 0$. At the end of the trajectory the polar air moves anticyclonically as a shallow layer of air which rapidly loses the properties of a cold air mass because of heating from below and adiabatic heating due to subsidence.

The warm air parcel at point C at first descends on the west side of the trough, but gradually overtakes the trough line and then starts ascending. At the time when the cold air flows out in the subtropics as an anticyclonic surface current the warm air parcel has moved very far to the northeast and has eventually left the upper trough in which it started. There is no possibility of giving the exact position of the air, but it follows the general geostrophic flow in the upper troposphere with an average tendency to deviate a little to the left, because of the average southward displacement of the polar air underneath.

If we assume that after thirty-six hours the cold air parcel is at the point marked by 800 mb in Fig. 6, the mean velocity since it started from point A is about

8. This secondary front is usually called the "arctic front" in the United States because the cold Canadian continent is regarded as belonging to the arctic source region in winter. In Europe a similar front often separates the maritime polar air masses from the continental polar air masses over the eastern parts of the continent. Since the source region of the latter air masses in Europe is in the east, not in the north, the corresponding front is not identified with the arctic front.

21 m sec^{-1}. The corresponding vertical velocity is then about -2.8 cm sec^{-1}. This is the order of magnitude of the vertical wind components in the vicinity of the polar front.

Air particles (B in Fig. 6) situated at greater distances from the principal front probably move almost horizontally and thus follow approximately the contour lines on the corresponding chart. Since the air at the 500-mb level usually moves faster than the upper disturbances, a given particle leaves one trough and moves into the next trough. Thus the idea of a quasi-horizontal large-scale wave motion is much more applicable to the air masses far away from the polar front.

The three-dimensional movement outlined here has some resemblance to the helical circulation proposed by Mintz [38]. In our scheme, however, there is no complete left-handed helix, since the transformation of polar air into tropical air, and vice versa, is a much more complicated process than that assumed in the simple model for helical motion.

The movement of a tropical air parcel can be studied in the same way. In this case it is more practical to start from the surface map and discuss the three-dimensional trajectory of a tropical air parcel situated at the beginning in the vicinity of the polar front. A study of the large areas of condensation and precipitation around the principal front shows that the warm air in that vicinity must be subjected to vertical movements of an order of magnitude varying between 1 and 20 cm sec^{-1}. Thus the ascending warm air can rise from the surface layers to the level around 600–500 mb in one day or less. In many cases this rapid ascending motion stops before the air reaches this level, but a careful study of 500-mb charts indicates that moist, almost saturated air, with a potential wet-bulb temperature characteristic of the surface tropical air farther to the south, can be observed in the region above the polar-front surface. The principal area of extended precipitation on the eastern side of the upper trough and in the region of the upper ridge indicates where the principal ascent of the tropical air takes place.

Synoptic experience thus gives some clues concerning the nature of the vertical circulation necessary to maintain the kinetic energy of the atmosphere. The vertical circulation is mainly associated with cyclones and anticyclones. The principal regions of descending polar air are the cold anticyclones separating cyclone families (or individual cyclones) and their counterparts in the free atmosphere, the cold troughs. The tropical air ascends in the regions where condensation and precipitation are observed.

The scheme presented in Figs. 5 and 6 is not a steady-state situation. It represents a certain stage in the development which gradually leads to a degeneration and ultimate elimination of the upper trough. Before we go on to a discussion of that process, however, we must study the development of the typical frontal cyclones.

According to the generally accepted theory for the development of individual cyclones, kinetic energy is produced by a solenoidal circulation connected with sinking of cold air and the ascent of warm air during the occlusion process. The occlusion process in lower layers is associated with convergence and an increase of cyclonic circulation (vorticity). The ascending warm air must form a diverging current in the upper troposphere. The convergence at lower levels and the divergence at upper levels associated with a general ascending movement represent one branch of the solenoidal circulation, the other branch being the combined lower divergence and upper convergence associated with descending movement in the surrounding cold anticyclonic areas.

It is a well-known fact that during the occlusion process the cyclonic circulation gradually spreads to deeper layers of the atmosphere. In a fully developed occluded cyclone, which in the lower troposphere is cold compared with the surrounding air, a strong cyclonic circulation occupies the whole troposphere and the lower stratosphere. However, increasing cyclonic circulation presupposes convergence, according to V. Bjerknes' circulation theorem, and the ascending warm air in an occluding system must be subjected to upper divergence.

This dilemma has been discussed by Brunt [12] in an article on cyclones. In his article, Brunt points out that the upper-level divergence necessary to produce the pressure fall in the central parts of a deepening cyclone must result in increasing anticyclonic circulation in the upper troposphere. The dilemma can be solved, according to Brunt, only if the three-dimensional structure of the cyclone is such that the upper current can remove the air accumulating in the region of lower convergence. This removal is not possible if the extratropical cyclones are symmetrical and, at the same time, the cyclonic circulation is increasing in depth. Here we find one of the principal differences between extratropical and tropical cyclones.[9] In order to find a model which combines the increase in cyclonic circulation with the divergence necessary for removal of the air from the deepening cyclone, we apply J. Bjerknes' tendency equation [6] to a vertical air column situated over the momentary surface center of the cyclone. The pressure change at a level h is then given by

$$\left(\frac{\partial p}{\partial t}\right)_h = -g\int_h^\infty \mathrm{div}_H\,(\rho \mathbf{v})\,dz + (g\rho w)_h. \qquad (12)$$

At the surface, where the vertical component w is zero, the pressure tendency is given by the integrated mass divergence over the whole air column. Since the pressure in a deepening cyclone is falling, the integral of the mass divergence must be positive; since there is low-level convergence during the occlusion process, the upper-level mass divergence must be somewhat stronger than the low-level convergence.

9. The central parts of tropical cyclones are warm compared with the outer parts [51]. The cyclonic circulation therefore decreases upward in tropical cyclones whereas it increases upward in fully developed occluded extratropical cyclones.

Equation (12) can be written

$$\left(\frac{\partial p}{\partial t}\right)_h = -g\int_h^\infty \rho \,\mathrm{div}_H\, \mathbf{v}\, dz - g\int_h^\infty \left(u\frac{\partial \rho}{\partial x} + v\frac{\partial \rho}{\partial y}\right) dz + (g\rho w)_h. \tag{13}$$

In the first approximation we can neglect the second term on the right which represents the contribution of advection to the pressure change. A pressure tendency at the surface of -1 mb hr^{-1} corresponds to an average divergence of -0.3×10^{-6} sec^{-1}. Direct measurements from wind observation by Houghton and Austin [29] and further by Sheppard [1] give values for the divergence of the order of magnitude of 10^{-5} sec^{-1} or even more for specific levels. The disagreement between the average divergence in a whole vertical air column determined from pressure changes and the values for the divergence in different levels computed from actual wind observations shows that vertical circulations are essential for an understanding of the atmospheric processes. Therefore we can state that the surface pressure change is the relatively small sum of two large terms with different signs and that the influence of the upper divergence must be somewhat greater than the influence of the lower convergence if $(\partial p/\partial t)_0 < 0$. Furthermore, we can conclude that there must be a certain level of nondivergence approximately coinciding with the level of maximum vertical wind velocity $|w|$.

We can now use the vorticity equation

$$\frac{d\zeta_a}{dt} = -(\zeta + 2\Omega \sin\phi)\,\mathrm{div}_H\, \mathbf{v} \tag{14}$$

in order to investigate the influence of the divergence field on the upper-air flow above the center of the cyclone. The individual absolute vorticity of the air parcels moving above the cyclonic center decreases under the influence of the field of divergence. If we expand the expression in equation (14), we obtain

$$\frac{d\zeta_a}{dt} = \frac{\partial \zeta_a}{\partial t} + v_s\frac{\partial \zeta_a}{\partial s} + w\frac{\partial \zeta_a}{\partial z}, \tag{15}$$

where v_s is the horizontal velocity component along the momentary streamline. The local change $\partial\zeta_a/\partial t$ is, on the average, positive above the surface center of the cyclone, since the upper trough is approaching. The term $w\partial\zeta_a/\partial z$ is small in the upper troposphere where $|w|$ is small. Since the cyclone and the upper trough west of the surface center are moving slowly compared with the upper wind one can put

$$\frac{\partial \zeta_a}{\partial s} \approx -\frac{\zeta_a}{v_s}\,\mathrm{div}_H\, \mathbf{v}. \tag{16}$$

Thus the absolute vorticity must decrease along streamlines of the upper flow.

The absolute vorticity can be written in the form

$$\zeta_a = 2\Omega \sin\phi + \frac{v_s}{r} + \frac{\partial v_s}{\partial r}, \tag{17}$$

where r is the radius of curvature of a streamline. If we neglect the shear, the cyclonic curvature must decrease in the direction of a streamline. If the air flow has a southerly component, the effect of latitude is negative and the decrease of curvature is greater than in cases with a northerly component.

If we could follow the development over an individua cyclone, the decrease of vorticity along upper streamlines should intensify when the upper divergence field intensifies. Since the latitude effect, which is proportional to the meridional wind component v and to the change of the Coriolis parameter with latitude, $2\Omega \cos\phi$, can easily be computed, the shape of the upper contour lines over a deepening cyclone can be used for an estimate of the upper divergence. Scherhag [56] has strongly emphasized the connection between the movement and the deepening of cyclones and the shape of the isobars or contour lines in the upper troposphere.[10]

Figure 7 shows the characteristic pressure distribution in the lower and upper troposphere for a wave cyclone and for a mature cyclone. The increased number of closed isobars in the surface layer is an expression of the increased cyclonic circulation due to low-level convergence. The deformation of the upper isobars indicates the influence of the upper-level divergence field upon the air moving through the system. In the surface layer the convergence field has a much longer time to influence the air flow than is the case in the upper troposphere where the air moves relatively quickly through the system. The warm-sector air, subjected to strong convergence in the lower and inner parts of a cyclone, leaves this region as a current with decreasing vorticity because of the upper-level divergence field. The principal ascent of the warm air masses takes place in the precipitation region marked in Fig. 7; the extension of the area of precipitation to the west along the occluded front is therefore not primarily the result of the ascent of less cold air moving in from the west or southwest.

In the final stage of occlusion the low at the upper level nearly coincides with the surface low, whereas in the beginning the axis of lowest pressure slopes to the west. Single-station analysis gives a phase displacement with height which gradually diminishes during the occlusion process. The importance of this vertical structure of cyclones was originally emphasized by von Ficker [21, 22]. The deepening of a cyclone due to the occlusion process can formally be considered as the result of an interaction between two pressure waves, an upper and a lower one, according to Defant [19]; if the upper wave moves at a higher speed, it reaches the lower wave at the time of maximum depth.

The divergent flow of the upper air above the frontal system has been verified by numerous studies of European cyclones [8, 9, 10, 40]. The characteristic upper-air flow outlined here is also in agreement with well-known

10. We refer to the very extensive list of references concerning this problem in Scherhag's textbook [56].

facts concerning the movement of cirrus clouds as, for example, shown by Pick and Bowering [49] in 1929.

Sawyer [1] has shown in an interesting study that the change of the vorticity field at different levels during the deepening of a cyclone can be used for computation of the vertical movement of the air. Instead of the real vorticity field, which is difficult to determine, Sawyer used the vorticity field computed from the pressure

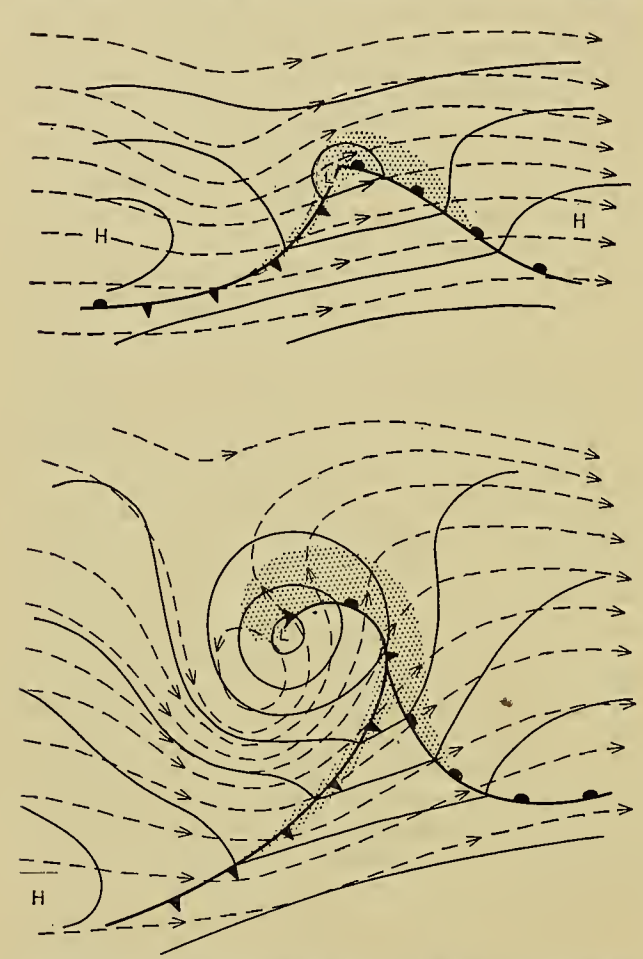

Fig. 7.—Schematic diagrams of young wave cyclone and mature occluded cyclone. Solid thin lines are sea-level isobars, dashed lines are 500-mb streamlines. Precipitation indicated by stippling.

field. Since the pressure field gives an approximate value of the wind field, the change of vorticity can be computed from the pressure changes on consecutive maps. The method is essentially the same as that used here in order to describe the formation of the characteristic upper contour lines in an occluded cyclone.

FORMATION OF HIGH-LEVEL CYCLONES AND ANTICYCLONES

It was pointed out earlier that the cold upper troughs undergo continuous changes and that they have a life history of growth and ultimate degeneration as have the surface cyclones. In some cases the upper troughs seem to be disturbances of larger scale than cyclones; in other cases, however, the dominating upper-air flow is from the west and every individual migrating upper disturbance is associated with a surface cyclone.

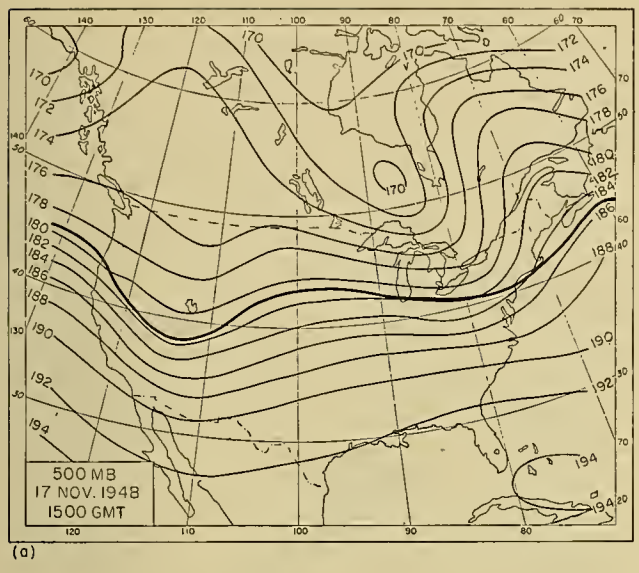
In the following paragraphs some typical cases described in the schematic chart in Fig. 4 will be discussed in more detail. As an example of the development of a strong upper-level low from a pre-existing trough we select the case of November 17–19, 1948 over North America. This situation also illustrates the characteristic structure of an occluded cyclone previously discussed. The sequence of weather maps shows that the structure characteristic of the occluded frontal cyclone can be the result of processes other than the occlusion of wave-shaped frontal perturbations of the type shown in Fig. 7.

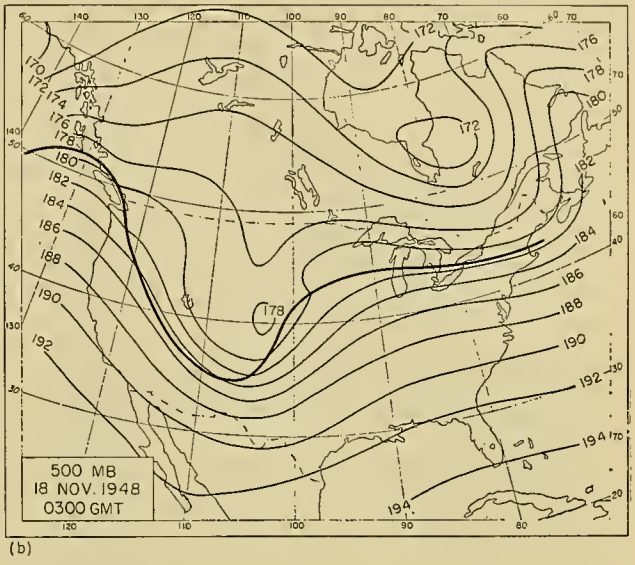
Figure 8 presents five charts for the 500-mb surface. The contour lines and the schematic front show the rapid development of a deep upper cyclone from a relatively weak trough. On the chart for November 17, 1945 the upper flow is predominantly westerly with a cold trough aloft over the western part of the United States. The cold air mass grows gradually out to the south and at the same time a closed upper circulation develops. During the process, which can be followed on the five charts with a time interval of 12 hours, the cold air mass at the 500-mb level is gradually cut off from its polar source region, and on the chart for November 19, 1500 GMT there is left a cold "drop" separated from the cold masses in the north.

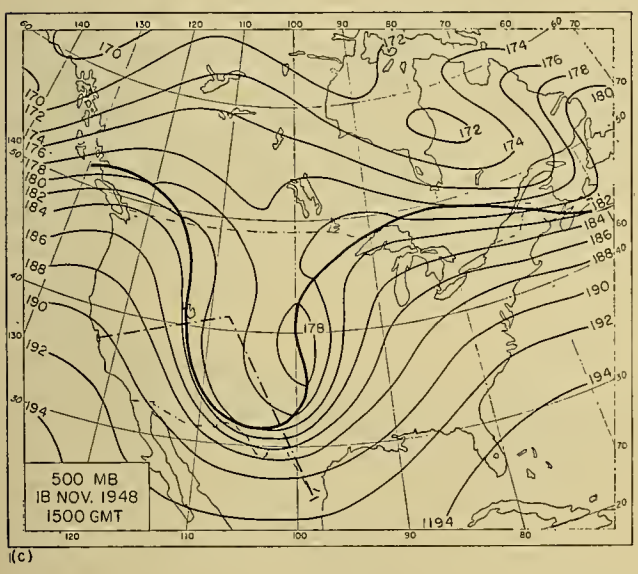
The thermal structure of the air masses can be studied in the vertical cross section (Fig. 9) along the broken line marked on the chart for November 18, 1500 GMT. Especially along the west side of the upper trough, the sloping front is very well marked. The wind component normal to the cross sections shows the characteristic concentration of the maximum wind velocity in a pronounced jet. Figure 9 thus shows that the upper trough consists of a central part filled with cold air masses of polar origin surrounded by warmer air masses. The low tropopause and high stratospheric temperature and the multiple tropopause are very characteristic of all similar situations. The fast-moving upper air in the region of the lower stratosphere is subjected to a strong subsidence on the west side of the trough and to a strong ascent on the east side (see, for example, [24]).

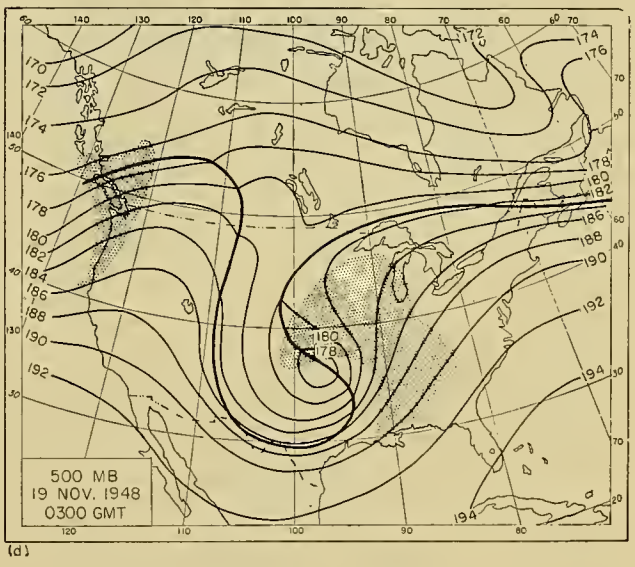
In Fig. 10 the contours of the principal front at the surface and on the 850-, 700-, and 500-mb surfaces are presented for November 18 and 19, 0300 and 1500 GMT. At the beginning of the period there are two surface fronts, one western front connected with the developing disturbance and one eastern front corresponding to the northern boundary of the moist warm Gulf air. On the chart for November 18, 1500 GMT the surface fronts have already been brought so near each other that a separation is impossible. At that time a structure corresponding to the classical picture of an occluded cyclone has already started to develop. On the next day the structure of a regularly occluded cyclone is complete, as can be seen from the surface map in Fig. 11.

In Fig. 8*d* the principal precipitation areas are marked. From the figure it can be seen that the areas of









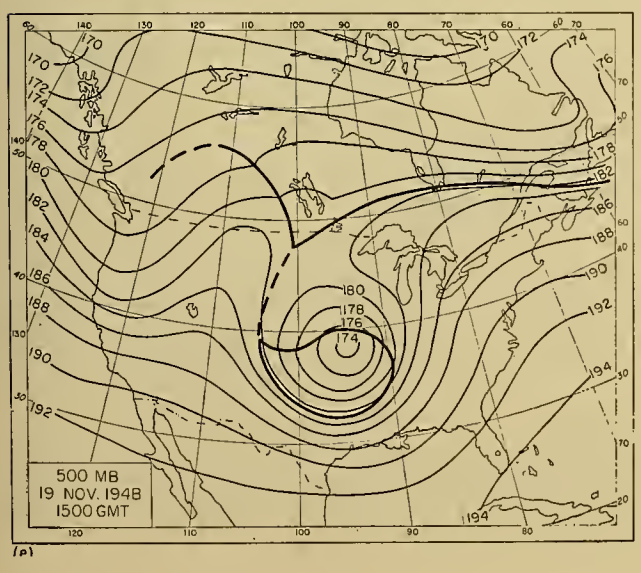


FIG. 8.—Idealized 500-mb charts at 12-hourly intervals from 1500 GMT November 17, 1948 to 1500 GMT November 19, 1948. Heavy lines, 500-mb fronts; thin lines, contours of 500-mb surface (labelled in hundreds of feet). Precipitation areas indicated by stippling in Fig. 8*d*.

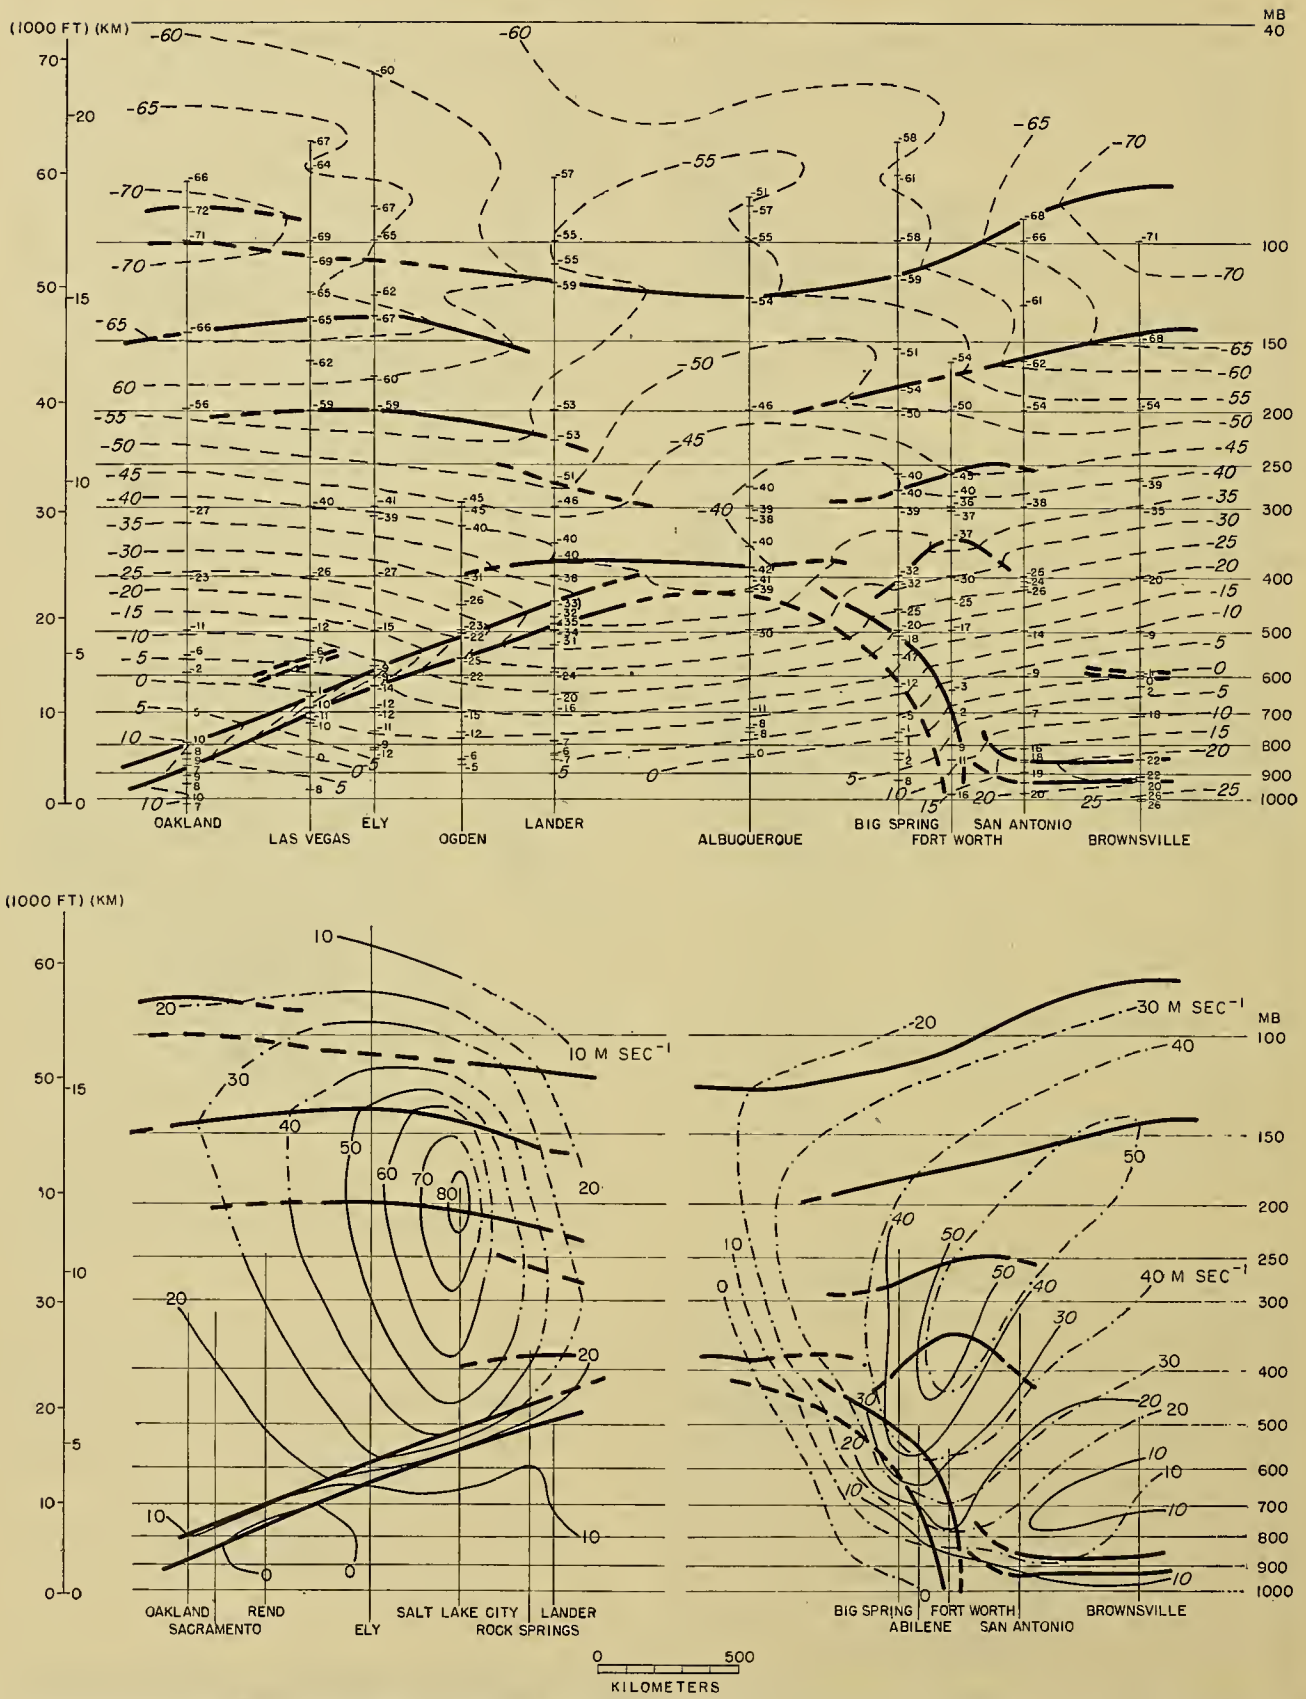

FIG. 9.—Vertical cross section through cold dome at 1500 GMT November 18, 1948, along dash-dotted line in Fig. 8c. In top figure, heavy lines are frontal boundaries and tropopauses, thin lines isotherms (degrees centigrade). Lower figures show isovels of actual wind velocity (solid thin lines, meters per second) supplemented by computed gradient wind velocities (dash-dotted lines).

precipitation approximately coincide with the areas where $\partial\zeta_a/\partial s < 0$. These areas can, according to equation (16), be found where the ascending warm air is diverging. In Fig. 10*c* the arrows indicate the flow of warm air along the frontal surface in some parts of the disturbance. Since the frontal contours also move, one cannot immediately determine the vertical component of the air flow from the map; however, the relatively slow movement of the system and the large component of the warm air flow normal to the frontal contours in the inner parts of the cyclone indicate that here the ascending component w must be large.

The charts for November 19, 1500 GMT present the fully developed upper cyclone which at that time very nearly coincides with the surface center of the "occluded" cyclone. The charts also present a situation in which the cold air at the 500-mb surface is completely cut off from the cold air in the north. This cutting-off process starts in the upper troposphere and gradually penetrates downward. The process of cutting off is not completely finished at the level of the 700-mb surface, as can be seen from Fig. 10.

The case history of November 17–19 represents a common development in the United States, as was pointed out in the previous discussion of the schematic chart in Fig. 4. The fully developed surface cyclone of November 19 has all the characteristics of an occluded polar-front cyclone in spite of the fact that it did not develop from a wave cyclone. The three-dimensional fields of temperature, pressure, and wind presented in Figs. 8–10 are, however, characteristic of every "occluded" cyclone whether it has passed through a regular process of occlusion or not. Essential for the whole development of a mature cyclone is the formation of the

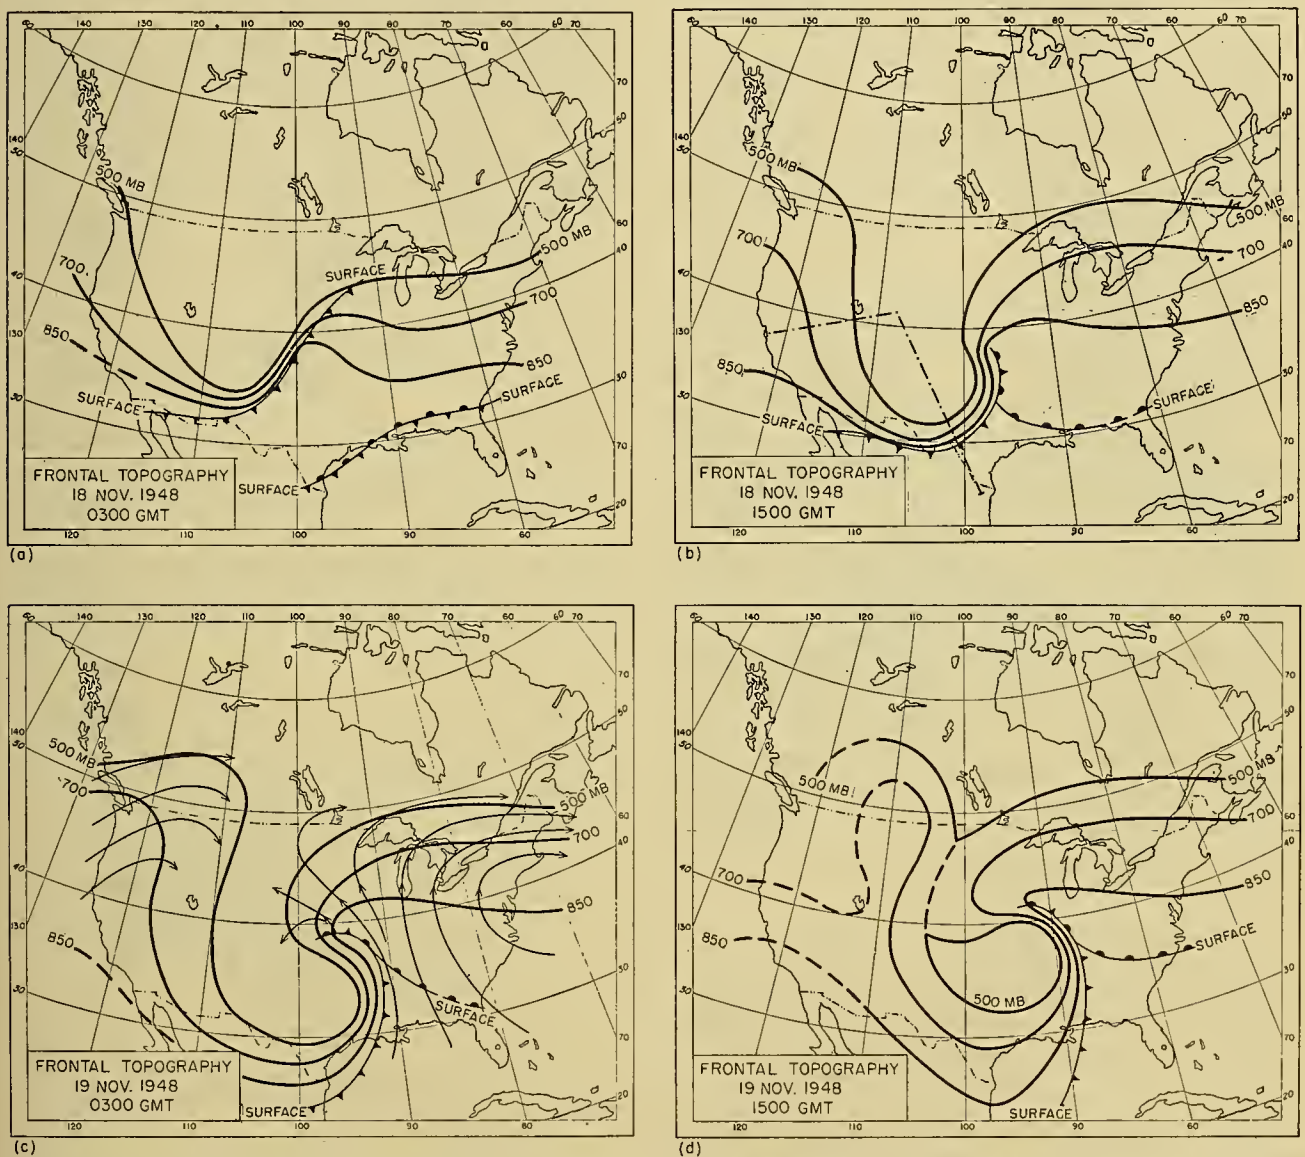

FIG. 10.—Idealized frontal contour charts, November 18–19, 1948, corresponding to charts of Fig. 8*b–e*. On Fig. 10*c*, corresponding to Fig. 8*d*, thin arrows indicate instantaneous streamlines at warm-air boundary of frontal surfaces. On Fig. 10*d* frontal contours are dashed where front is indistinct.

upper disturbance associated with the deformation of the upper front which can be followed on the charts in Fig. 8. This deformation of the upper front is associated with the formation of an upper cyclone or a very deep trough. During the process a large part of the cold air is separated from its original source region and flows as a diverging lower current very far to the south. This diverging lower cold current can be seen on the surface map for November 19 (Fig. 11) in the regions west of the surface cold front.

There is no doubt that many "occluded" cyclones on surface maps have never gone through a real process of occlusion although they show the same characteristic structure as really occluded polar-front perturbations. Obviously a well-marked surface front is not so essential for the development as was generally assumed formerly.

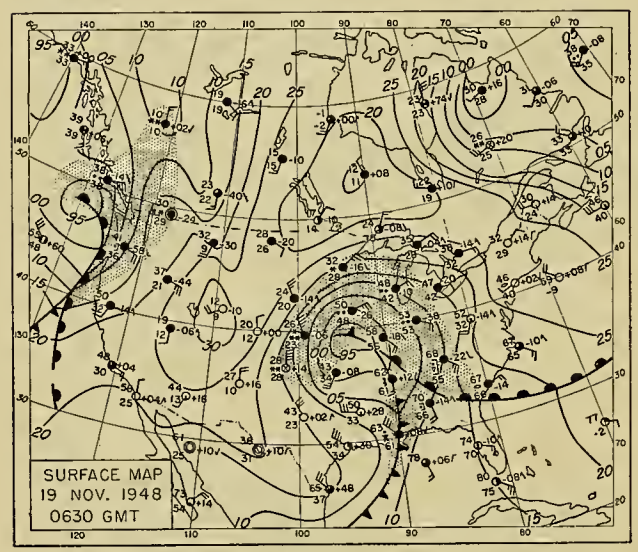

Fig. 11.—Surface map, 0630 GMT November 19, 1948, three hours later than charts of Figs. 8*d* and 10*c*.

One more point should be emphasized. By comparison of the consecutive 500-mb charts in Fig. 8 it can be seen that the area of polar air at that level decreases during the process of cyclogenesis and the development of the deep "occluded" surface cyclone. *The process of seclusion of the polar air at the 500-mb level thus corresponds to the occlusion process in lower layers.* In the upper atmosphere the warm air gains area, in the lower atmosphere the cold air gains area. This process corresponds to the scheme for release of energy of storms proposed by Margules [33] in his classical studies.[11]

As a result of the process described here, the upper cold air (for example, at the level of 500 mb) has been isolated from the main body of cold air in the north. Since the boundary layer separating the warmer air masses in the south from the polar air masses in the north also marks the zone of strongest west wind, the whole process of forming upper cyclones is associated with a meandering of the "jet stream." This meandering very often goes so far that it results in the formation of an almost symmetrical upper cold low at very low latitudes, whereas the strong west wind becomes re-established to the north of the newly formed upper cyclone. Figure 12 shows, according to Hsieh [30], the

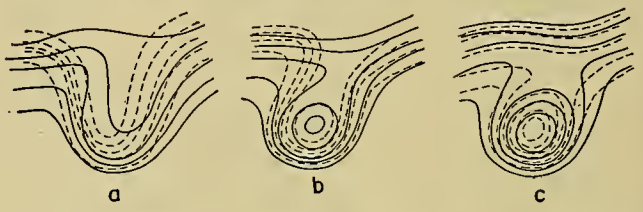

Fig. 12.—Schematic diagrams showing various stages in formation of cut-off cyclone. Solid lines are contours of 500-mb surface, dashed lines are isotherms. (*After Hsieh* [30].)

characteristic change of the pattern of isotherms and air flow in the middle troposphere during the development of a closed cold cyclonic vortex. This formation of "drops of cold air" (*Kaltlufttropfen*) has been well known since aerological observations have been extended over large areas.[12] Figure 13 shows a schematic picture of the frontal contours in such a cut-off low.

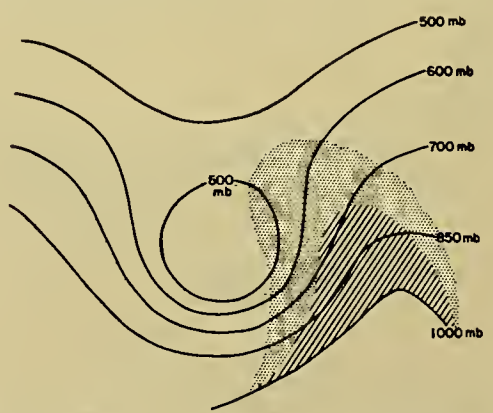

Fig. 13.—Schematic diagram showing frontal contours in cut-off low. Hatching indicates area of heavier precipitation, stippling area of lighter precipitation. (*After Hsieh* [30].)

A beautiful example of this type of high-level cyclone is the case of November 1–7, 1946 over the southwestern part of the United States. This case has been studied in some detail by Crocker [17] and Palmén [42]. Figures 14, 15, and 16 are reproduced from the latter study. Figure 16, in particular, represents an almost ideal picture of a cold symmetrical upper cyclone with its warm, low stratosphere. It should perhaps be mentioned that the tropopause marked as a continuous surface in Figs.

11. The energetics of a similar process of cyclogenesis has recently been studied by Phillips [48]. The main difficulty in applying Margules' ideas on the development of real cyclones depends upon the well-known fact, already emphasized by Schröder [57], that cyclones cannot be regarded as closed systems. Because of this and other difficulties many meteorologists are critical of Margules' theory (see for example [59]). It seems to the author, however, that the theory is essentially sound if applied correctly and with consideration for all complications.

12. See Scherhag's textbook on weather analysis and forecasting [56] for a detailed discussion of the structure and formation of such drops of cold air in Europe. Among other references Nyberg [40], and Raethjen [50] might be mentioned.

15 and 16 could probably be split into several surfaces, as in Fig. 9, by a more detailed analysis.

Raethjen [50] has recently tried to explain the formation of the high-level cyclones associated with drops

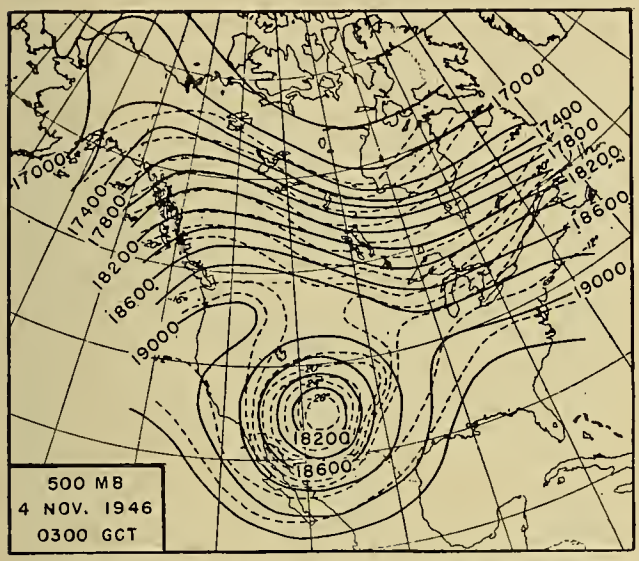

FIG. 14.—500-mb chart over North America, 0300 GMT, November 4, 1946. Solid lines are contours of 500-mb surface, dashed lines are isotherms (degrees centigrade).

of cold air as a result of isentropic exchange of air parcels conserving their absolute angular momentum. This process would obviously result in a change in circulation (increasing cyclonic vorticity in the central upper parts of the cold drop) similar to the vertical circulation outlined here. Quite different points of view have been expressed by Rossby [54] in his paper on the meridional movement of sinking cold domes. It seems obvious that the problem of the extreme meandering of the west-wind belt resulting in the formation of cold upper lows must be subjected to further investigations before the nature of the process can be regarded as completely clarified.

The meandering of the belt of upper westerlies and the deformation of the upper polar front also result in an increase of the amplitude of the warm upper ridges. In extreme cases a warm ridge can be completely separated from its warm source region in the south. The meandering then results in the formation of closed warm upper anticyclones and the belt of strong westerlies can be re-established south of it. These types of warm upper anticyclones consist mostly of cold polar air masses in the lower layers and therefore appear, in a superficial analysis, as cold polar anticyclones. The true nature of these anticyclones has been elucidated through a number of synoptic investigations. The structure of such a warm upper anticyclone has been subjected to a detailed analysis by Berggren, Bolin, and Rossby [4]. The case they studied has been used as a model for the upper anticyclone over northern Europe shown in Fig. 4. The pronounced anticyclonic vorticity in these warm upper highs can partly be explained as a result of advective transport of low absolute vorticity

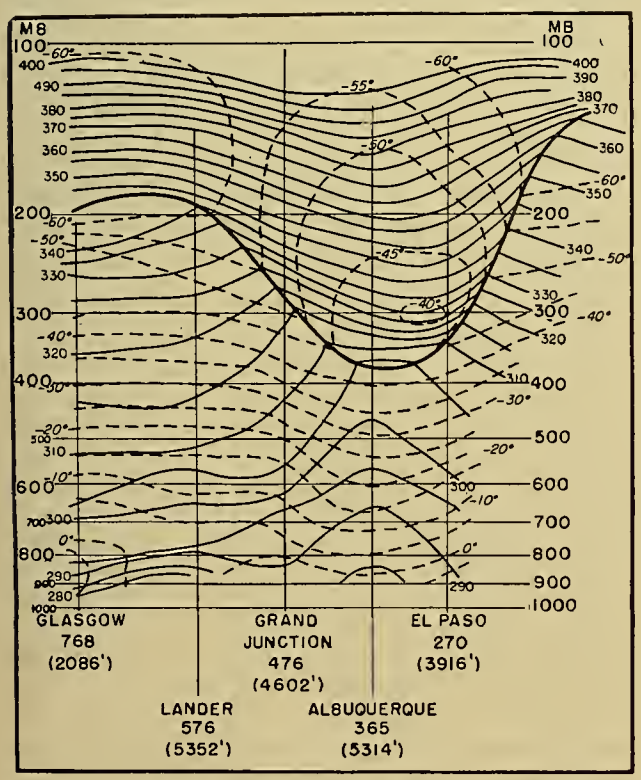

FIG. 15.—Vertical north-south cross section through center of high-level cyclone of Fig. 14. Heavy line indicates tropopause, solid thin lines isentropes (degrees absolute) and dashed lines isotherms (degrees centigrade).

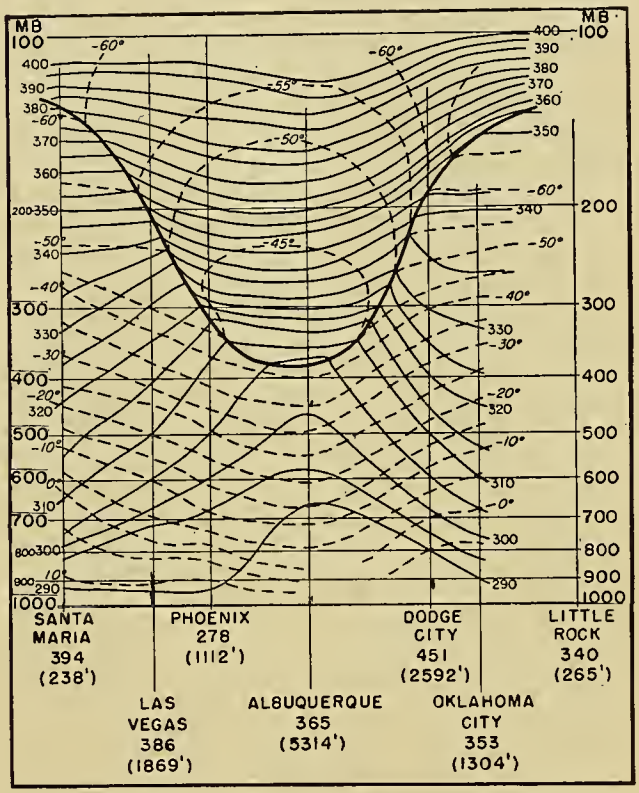

FIG. 16.—Vertical west-east cross section through center of high-level cyclone of Fig. 14. Legend as in Fig. 15.

from the south. However, the influence of the upper divergence field on the development of the relative anticyclonic vorticity should also be considered.

Both the cold upper lows and the warm upper highs can be considered a further development of the upper trough and ridge described here earlier. The cold air in the upper cyclones represents the uppermost part of a sinking cold dome. The warm high-level anticyclones consist essentially of a body of lifted tropical air. These processes are closely related to the processes connected with the formation of cyclones of different types.

SOME GENERAL REMARKS ON THE CYCLONE PROBLEM

There is no question that our knowledge of the structure and life history of extratropical cyclones has greatly improved as a result of the increased network of aerological stations which has been established during the last 10–15 years and especially as a result of the general introduction of radiosonde observations into the daily weather service. The extension of upper-air observations on a hemispheric scale has undoubtedly shown that there exists, not only in the surface layers but also in the middle troposphere, a more or less distinct boundary layer separating air masses of polar origin from those of tropical or subtropical origin. This boundary has the character of a true front only over limited regions; in other regions it appears as a belt of strong meridional solenoid field. Careful analyses of different types of synoptic situations also indicate that this boundary layer of the free atmosphere can be considered a direct continuation of the surface polar fronts. The polar front thus appears as a sloping boundary layer which extends from the surface to the upper part of the troposphere. This is in agreement with the ideas introduced for the first time in clear form by the Norwegian school of meteorologists.

Although the existence of a more or less distinct polar-front surface is thus an empirical fact, the explanation of the formation of this boundary layer is not quite clear. It is obvious that the formation and maintenance of a polar front must be connected with the general atmospheric circulation. However, there still is no complete theory of frontogenesis which considers the entire dynamics of the general circulation. On the other hand, it is undeniable that extratropical cyclones frequently and predominantly form at the polar front although there are other birthplaces for cyclonic depressions. The question of the role of extratropical cyclones in the complex problem of the general circulation is therefore of primary importance not only in the cyclone theory but also for a deeper understanding of the problem of the general atmospheric circulation.

In an earlier section it was pointed out that the polar-front zone in the middle latitudes is not only the zone of strongest solenoid concentration but also the zone of strongest concentration of kinetic energy. Thus the frontogenetic processes operating in the atmosphere on a hemispheric scale form not only the fronts or frontal layers but also the characteristic, strong concentration of the west-wind belt into an upper wind maximum, the jet stream. Frontogenesis hence means at the same time an increase of both solenoidal and kinetic energy in the polar-front zone.

On the other hand, the vertical circulation characteristic of cyclone development also seems to be a "direct" one resulting in an increase of kinetic energy. According to Starr [60], a system is able to produce horizontal kinetic energy if horizontal divergence is associated with relatively high pressure and convergence with relatively low pressure. In the previous discussion of the life history of a cyclone, it was pointed out that the development of a cyclone is characterized by low-level convergence and upper-level divergence. But if we consider not only the cyclone but the total region of an atmospheric disturbance—cyclone + anticyclone—the horizontal divergence (in the lower parts of the anticyclone and the upper parts of the cyclone) actually occurs with higher pressure than does the convergence (in the lower parts of a surface cyclone and the upper parts of a surface anticyclone). This circulation therefore means a transformation of pre-existing potential energy into kinetic energy.

The combined process of frontogenesis and cyclogenesis can probably be described in the following manner. During the time of *frontogenesis* the "available" potential energy[13] of the atmosphere is gradually increased by nonadiabatic processes, primarily radiation, and through a process of concentration of the horizontal temperature contrasts into a relatively narrow zone. During this process, however, the kinetic energy also increases (the surface wind speed remaining relatively constant). The stage of frontogenesis is therefore also a stage with increase of zonal index, especially at upper levels. During the time of *cyclogenesis* the strong zonal flow has a tendency to break down; "available" potential energy is now transformed into kinetic energy. The mechanism of the breakdown of the zonal current into a more irregular form of movement could be attributed to some kind of instability of the zonal movement which is not known in detail.[14] The fundamental cyclone problem would be solved in principle if one could find the causes and mechanism of this instability.

Any theoretical solution of the cyclone problem is still very far from a solution of the cyclone problem presented by nature. Meteorologists are still in disagreement about many fundamental aspects of the cyclone problem. While some meteorologists assume that the kinetic energy of extratropical disturbances represents only a concentration of the pre-existing kinetic energy of the west-wind belt, others regard the disturbances as active cells in the production of kinetic energy. The vertical circulation associated with the growth of the disturbances in the westerlies and particularly with the occlusion process indicates, as already pointed out, that the latter viewpoint is in better agreement with

13. The "available" potential energy is meant to include only the energy available from a redistribution of the mass of the system such that the center of gravity is lowered.

14. Compare, for example, Charney [13], Eady [20], and Godske [25].

our experience. On the other hand, there is probably no doubt that the period of cyclogenesis must be preceded by a building-up of the kinetic energy of the upper west-wind belt and that thus certain types of disturbances also appear as concentrations of already existing kinetic energy.

The principle of dynamic instability may perhaps result in new efforts to solve the problem of the instability of the west-wind belt. A considerable amount of literature on that problem already exists [62]. The aerological analyses of weather situations with distinct fronts has revealed the existence in the atmosphere of zones with a width of 100–500 km (or sometimes even more) in which the criterion of dynamic or inertial instability is fulfilled. The fact that these zones actually exist suggests the need for further investigation of this type of instability. Another approach to a solution of the problem of instability has been proposed by Rossby [54] in his discussion of the meridional displacement of cold air masses.

If the complexity of the cyclone problem is considered, it does not seem likely that any satisfactory theoretical solution can be achieved in the near future. One is also forced to this conclusion by the fact that "extratropical cyclones" obviously do not represent any well-defined single atmospheric phenomenon but more likely a whole group of phenomena. Therefore perhaps no single explanation is sufficient.

The complexity of the atmospheric phenomena associated with extratropical cyclones does not mean, however, that no general features characterize disturbances in the westerlies. Some of the most characteristic ones have been presented in this article. Further detailed synoptic investigations of selected types of disturbances will certainly improve our knowledge and gradually result in a better understanding of the dynamics of the atmosphere. In the opinion of the writer, a detailed and careful synoptic investigation of typical weather situations on a very large scale—approaching hemispheric dimensions—is the only method which can furnish us with the facts which are necessary both for a better understanding and for further theoretical study.

One of the greatest difficulties in synoptic meteorology is that the concept of causality is extremely difficult to explore. To give some examples: Horizontal acceleration appears as the small difference between two large terms, acceleration due to the horizontal pressure field and acceleration due to the earth's rotation. Similarly, the vertical acceleration is the small difference between the opposing accelerations due to the vertical pressure field and to gravity. Again, all pressure changes are small differences between two or three large terms, as can be seen from the tendency equation. Finally, the thermal wind equation represents a balanced condition between a circulation due to the vertical solenoid field and one due to the earth's rotation. Because of inevitable errors in all meteorological observations it is extremely difficult to get a sufficiently exact determination of quantities needed for computing the nonbalanced conditions in an atmospheric situation. Through comparison of successive situations some clues concerning the nonbalanced parts of the movement can be achieved. The time difference between consecutive upper-air observations, especially between radiosonde observations (now twelve hours in most regions), is too large to permit a satisfactory determination of the time derivatives. Special synoptic investigations with several stations operating on time intervals of 2–3 hours would therefore be extremely valuable.

ANTICYCLONES

By H. WEXLER

U. S. Weather Bureau, Washington, D. C.

It is the purpose of this article to summarize briefly what is known of the origin, structure, and transformation of anticyclones and to describe their role in the general circulation and some aspects of their control of weather and climate.

It is natural for the division of subject matter for this Compendium to be made in terms of cyclones, anticyclones, general circulation, and so on. However, this breakdown, while very convenient for the editor and the reader, imposes certain difficulties on the author since it is quite impossible to discuss the anticyclone as a separate entity, with respect to either its origin or its role in the general circulation. For that reason, although much of the discussion here will deal directly with anticyclones, there will be occasional and unavoidable digressions into broader problems.

The writing of this article was made much easier by reference to the excellent review of anticyclones by C. E. P. Brooks [4] in *Some Problems of Modern Meteorology*, the famous British progenitor of this Compendium.

DEFINITION AND THERMAL STRUCTURE OF ANTICYCLONES

An anticyclone is a large atmospheric eddy which rotates clockwise in the Northern Hemisphere about a center at which barometric pressure is higher than that of the surrounding air. Since barometric pressure is a very close measure of the mass of overlying air, an anticyclone is characterized by an excess of air aloft. Thus, over an anticyclone either the effective height of the atmosphere is greater or the air is on the average denser over the same height. Since there exists no evidence to indicate a greater height of the atmosphere, it was once thought that the air over an anticyclone must be colder and denser at all levels than the air over a cyclone. However, from a study of mountain observations in Europe and western United States, Hann in 1876 [14] showed that up to the height of the mountains (3 to 4 km) anticyclones averaged warmer than cyclones except in a shallow surface layer. Furthermore, Hann stated the abnormal warmth and dryness was caused by subsidence. From recent aerological data more has been learned of the general thermal structure of anticyclones as distinguished from that of cyclones. For example, values compiled by W. H. Dines [7] and Palmén [22], based on soundings in England, showed that cyclones are characterized by a cold troposphere, a low (8.5 km),[1] warm (−50C) tropopause, and a warm stratosphere, while anticyclones have a warm troposphere (over a cold, shallow surface layer), a high (11.5 km), cold (−65C) tropopause, and a cold stratosphere.

In 1908, Hanzlík [15] demonstrated the existence of two types of European anticyclones, the shallow cold (polar) anticyclone moving rapidly, usually in the rear of a cyclone, and the deep warm anticyclone moving very slowly or not at all. Quite often the shallow cold anticyclone changes into a deep warm anticyclone, and in so doing slows down and sometimes becomes stationary.

So far as is known there is no statistical study available on the vertical temperature structure of the polar and warm type of anticyclones although it is likely that Palmén's statistics on anticyclones refer mostly to the warm type of anticyclone, since the true polar anticyclone is rare in England. As a rough generalization it may be said that in North America the polar anticyclone is characterized by a troposphere colder than its environment, especially in the lower portion, and a low (5 to 8 km), warm (−50C to −65C) tropopause and warm, lower stratosphere, while the warm anticyclone may have a thin, cold layer at the surface, a warm troposphere, a high (12 to 17 km), cold (−65C to −80C) tropopause, and a cold, lower stratosphere. Quite often, however, anticyclones exist which have the deep surface layer of cold air characteristic of polar anticyclones and the high cold tropopause of warm anticyclones. Such anticyclones, combining the high-pressure producing qualities of both anticyclonic types, are usually extremely intense and would probably never be observed at low latitudes because of absence of cold tropospheric air. For example, in the nineteen unusually intense anticyclones in the North Atlantic and Eurasian regions listed by Scherhag [30], where central pressures ranged from 1047 to 1079 mb, the lowest latitude of location was 50°N.

ORIGIN OF ANTICYCLONES AND THEIR ROLE IN THE GENERAL CIRCULATION

Polar Anticyclone. The polar anticyclone is created by cooling of the surface layer of air, which loses its heat to an underlying cold surface by radiation [35] or by eddy conductivity. The lower temperature of the surface itself is caused by the nocturnal radiational cooling of snow and ice fields, such as those in polar regions, or by bodies of large thermal inertia (heat capacity), such as oceans and large lakes. The cooling and vertical shrinking of the surface layer of air depresses the isobaric surfaces aloft, creating an intensifying "polar cyclone" which causes an inflow of air across the isobars, thus creating a larger barometric pressure at the surface. This process was studied by

1. Values are taken from Palmén.

Wexler [36], using the Brunt-Douglas isallobaric concept, and later by Schmidt [31].

Warm Anticyclone. A satisfactory explanation of the warm, deep anticyclone has not yet been given. The attempted explanations are usually along three lines: radiative, advective, and dynamic. The reasoning based on radiation goes something like this: Since the troposphere over the warm-type anticyclone is warmer than the surroundings, the increased pressure must be caused by colder, denser air in the upper troposphere and lower stratosphere. The argument is then made that this cooling is caused by favorable radiative conditions over a restricted area. Those arguing advectively believe that the cold air results from northward advection of the cold equatorial upper troposphere and lower stratosphere. Various dynamic reasons for warm anticyclogenesis have been proposed, based on wave mechanics of the westerlies, lateral frictional drag, motion of polar domes, etc. Each of these proposed explanations will be discussed in turn.

Radiative Theory. The explanation of anticyclogenesis based on radiative cooling of the stratospheric air [18] appears to be the least convincing. Gowan [13] in his investigation of nocturnal cooling of the ozonosphere (where water vapor, ozone, and carbon dioxide are assumed to be the principal emitting and absorbing gases) finds the temperature decrease in eight hours from sunset varies from less than 0.1C at 15 km to 1C at 30 km, and thus concludes, "It seems certain that the cooling of the lower stratosphere, perhaps up to 30 km, is not governed by radiation." If one looks above 30 km (30-mb pressure), it is difficult to ascribe any significant anticyclogenetic effects to possible horizontal differences in the rates of radiative cooling of air in a layer whose contribution to sea-level pressure is so small.

Advective Theory. The advective theory of stratospheric cooling and anticyclogenesis appears superficially to be very attractive. As Brunt [5] states, the close apparent analogy between the polar and cyclonic stratospheres on the one hand and the equatorial and warm anticyclonic stratospheres on the other, tempts one to explain the anticyclogenesis as a consequence of solid currents moving from south to north. But if the entire atmospheric column at 50° latitude should be replaced by that at 10° latitude, then it can be shown from Wagner's aerological averages [34] that the net change of sea-level pressure would be practically zero. If, however, differential advection were established such that the mass of the column at 50°N between the surface and 8 km remained unchanged, say by the presence of westerly winds, while the air above 9 km came from 10° latitude with southerly winds, then the sea-level pressure would increase by 25 mb, an amount more than sufficient to account for most cases of anticyclogenesis. Thus it is theoretically possible for anticyclogenesis to be explained by high-level advection over a long trajectory from the south. But the problem is more complicated than the simple arithmetic exercise would indicate. Aerological experience indicates that the extreme type of vertical shear in the flow pattern postulated seldom if ever occurs, but that the full depth of the westerlies usually partakes in its meanderings (as would be expected in a barotropic atmosphere). Thus, for example, if the southerly advection from 10°N to 50°N took place above the top of a shallow (2-km) inert layer of surface air, the increase in pressure would only be 5 mb in summer and 11 mb in winter, amounts which are not sufficient to account for many cases of anticyclogenesis.

The advective transport of warm and cold air is intimately connected with the dynamics of the westerly flow pattern. If the westerlies are zonal in character, there would be no north-south advection across the belt of westerlies. True enough, there may be advective transport of a shallow (2-km) surface layer of polar air southward underneath the westerlies; this is associated with a certain type of dynamic anticyclogenesis discussed by Simmers [33] and Wexler [37]. But it is when the zonal westerlies break down into large-scale waves of great amplitude (meandering) that the most pronounced cases of warm anticyclones are found. The amplitude of these waves may become so large that the ridges break down into large-scale anticyclonic vortices to the north and the troughs change into cyclonic vortices to the south. Southerly advection accompanies this process, bringing northward over a shallow surface layer of polar air the warm, lower tropospheric air, and the cold upper tropospheric and lower stratospheric air characteristic of tropical latitudes. *However, advection is not the primary cause of the anticyclogenetic process, but rather both it and the initiation of the anticyclogenesis are the result of a major change in the character of the flow pattern in the westerlies.* It follows that the primary problem becomes one of dynamics although it is acknowledged that once initiated, the secondary advective effects may contribute materially to the anticyclogenesis.

Dynamic Theory. The dynamical explanations of warm anticyclones may be divided into two main types: First, an explanation based on the large-scale changes in the westerly flow pattern, as discussed briefly above; and second, once the "background" flow pattern has become established, an explanation based on cross-isobaric flow of air resulting from nongradient winds. Let us discuss briefly each of the proposed explanations.

In the past two decades intensive research has been performed on what might be called the "wave mechanics" of the westerlies. The pioneering work of V. Bjerknes and collaborators [3] and J. Bjerknes [2], was given further impetus by Rossby and collaborators [28] and was aided by greatly improved aerological coverage over most of the Northern Hemisphere. At the present time the recognition and explanation of the complex behavior of the westerlies have come to be accepted as the central problem of meteorology. Numerous articles in this Compendium deal with various phases of this problem in a much broader manner than can be given here. But in any discussion of anticyclonic origin, development, movement, dissipation, etc., it is necessary at first to depart from the narrow confines of the area usually covered by an anticyclone and obtain a broader

view of the behavior of the westerlies and their influence on anticyclones both of the polar and warm types.

Most of this paragraph is based on Rossby and Willett's discussion of the circulation changes accompanying a complete index cycle [29]. If the westerlies are zonal over the hemisphere, corresponding to "high index," then the anticyclones are located to the south and are large in area, but not abnormally intense, with axes oriented west-east. As the index decreases, the westerlies move southward and become less zonal, permitting the formation of stronger polar anticyclones to the north. With further decrease of the zonal index to its minimum value, the westerlies develop strong ridges and troughs, with cutting-off of warm anticyclones in the higher latitudes and cold cyclones in the lower latitudes. This is the period of maximum dynamic anticyclogenesis of polar anticyclones to the north. When the index begins to increase again, the westerly waves decrease their amplitude and become longer, the higher-latitude anticyclones dissipate, and the "cycle" is ready to begin over again.

This simplified account of the relationship of the westerlies and anticyclones is one of *association* only, and does not pretend to isolate causes and effects. What is quite clear and outstanding, however, is that the phenomena must be considered on a hemisphere-wide scale and not as a local development closed off from the rest of the atmosphere. It is true that there are important local influences pertaining primarily to the character of the earth's surface, some of which will be discussed later, but these must be considered as secondary effects superimposed on the primary pattern of the general circulation.

There is definite evidence that the beginning of the mechanism that transforms a high-index, essentially zonal flow pattern into a low-index, essentially meridional flow pattern is the appearance of a "blocking action" in some portion of the westerlies which effectively obstructs the normally eastward motion of waves in the upper westerlies, or their sea-level counterpart in the form of anticyclones and cyclones. In the excellent aerological study of a case of the breakdown of zonal westerlies, Berggren, Bolin, and Rossby [1] showed how a nearly zonal flow pattern in the 500-mb westerlies, in which were imbedded wave cyclones, moving with uniform speed across the North Atlantic, encountered "blocking" in the eastern Atlantic which caused the westerly waves to fold up like an accordion as their wave length decreased and amplitudes increased. The increase in amplitudes finally resulted in the appearance of "cut-off" cold lows in the south and warm highs in the north. The authors showed that the appearance of blocking is somewhat similar to the "hydraulic jump" which develops in open-channel flow when the depth of the water current drops below a critical depth, and where a certain amount of the initial energy of flow is transformed into turbulent or eddy energy. If the analogy with atmospheric "blocking" is accepted, then perhaps a certain supercritical speed of the westerly jet results in the sudden breakdown of a zonal flow into the large-scale anticyclonic and cyclonic eddies. The exact manner under which this remarkable change in flow pattern occurs is unknown, nor is the process known whereby the blocking, once formed, proceeds upstream for considerable distances—in many cases as a recognizable pressure rise at high latitudes capable of being followed westward for more than 180° of longitude. The importance of blocking in forecasting was first pointed out by Garriott [12] and has received further attention recently by long-range forecasters [9, 21].

The immediate origin of kinetic energy of atmospheric large-scale motions is a knotty problem that has not been fully solved. Rossby and Willett, in their description of the index cycle cited above, explain that the return of the high index, or speed-up of the westerlies, is caused by the re-establishment of the normal, north-south thermal gradient caused by radiative cooling in higher latitudes and radiative heating in lower latitudes. But it is not clear how the new sources of atmospheric energy, in the form of internal heat energy or potential energy, are "tapped" to provide the increased kinetic energy.

Let us turn now to the second type of dynamical explanation of warm anticyclones, based on horizontal mass convergence arising from cross-isobaric flow associated with supergradient winds. Many ingenious solutions have been proposed to explain supergradient winds. One popular explanation is that based on the removal of an air parcel from its high momentum environment to an environment of lower momentum where the winds are gradient. The foreign parcel, maintaining its higher momentum at least momentarily, will, by virtue of the greater Coriolis force acting on it, be flung across isobars towards higher pressure. This explanation was first proposed by Helmholtz [16] in studying the stability of the circular vortex.

Recently many investigators, while agreeing in their use of this basic reasoning in explaining pressure changes, have differed widely in their explanations as to *how* the air parcels are removed from an environment of high momentum to one of low momentum. Rossby [26] proposed that current systems possessing curved lateral velocity profiles would create frictionally driven eddies in isentropic surfaces, and that these eddies would transport momentum laterally thus producing unbalanced flow. In the free atmosphere the lateral frictional stresses within isentropic surfaces would be of greater importance than the vertical frictional stresses arising as a result of vertical wind shear since, in the latter case, the normal thermal stability of the atmosphere would resist vertical motions. Rossby found from a simplified model that the percentual increase in total pressure drop across the current, resulting from the diffusion of momentum, would amount to 8 per cent. The significance of reasoning of this type is enhanced by the recent discovery of the narrow, fast, westerly "jet-stream" flanked by exceedingly strong shears and curvatures of the lateral velocity profile (*e.g.*, see Palmén and Nagler [23]).

Another explanation based on changes in environ-

ment has been proposed by Priestley [24] as an outgrowth of earlier work by Durst and Sutcliffe [8] on the role of vertical currents in producing nongradient winds. Given an increase of wind with height, an upward current will create subgradient winds and a downward current, supergradient winds. Priestley used this rule to explain anticyclogenesis where the downward vertical motions were initiated by (1) frictional outflow from the surface anticyclone or (2) radiative cooling of the tropospheric air over a large area. But, as Priestley showed, neither (1) because of lack of sufficiently large vertical wind shear in warm anticyclones, nor (2) because of lack of strong enough radiative cooling over a sufficiently large area, are by themselves adequate to explain anticyclogenesis as observed. Priestley believes that the two processes must operate simultaneously to produce the observed pressure rises. However, a severe restriction on Priestley's model is that an anticyclone with surface frictional outflow must already be in existence before the nonradiatively caused descent can occur. According to Priestley's reasoning, then, it follows that surface features, such as topography or thermal stability of the air, which diminish the surface frictional outflow of the anticyclone, weaken the downward currents, thus causing a lack of supergradient winds and retarding anticyclogenesis. This result is not in agreement with the high frequency of anticyclones observed over physiographic depressions, such as the Great Basin in the western United States or over cold water, such as the Great Lakes area in summer [32, p. 172]. Regarding the radiatively caused descent, Priestley showed that for a reasonable model, a cooling of the free air of 2C per day over an area 2500 km in diameter is necessary to maintain the anticyclone against normal surface frictional outflow. This cooling value seems too high since Priestley quoted Elsasser [10] with respect only to the emissive cooling of the free atmosphere by long-wave radiation, and did not mention the heating by absorption of solar radiation, which amounts to ½C per day. Also, according to Elsasser [10, p. 95], since water vapor is the principal emitter, the emissive cooling itself decreases very rapidly with moisture content, and this would mean that the dry air above an anticyclone would cool even less than Priestley's assumed value.

In a search for the presence of available energy in the atmosphere which might be used to create unbalanced currents, a sudden cyclogenesis upstream and the resulting acceleration and "banking" of the westerlies to the south has been suggested [21, p. 63]; but this explanation is merely substituting the unknown solution of the cyclogenetic problem for that of the anticyclogenetic problem. A more promising and not unrelated lead is that of the propagation of energy with the group velocity of a train of waves in the westerlies where air parcels move with constant absolute vorticity. This concept, removed from the restraints of sinusoidal wave motion first assumed by Rossby, forms the basis of the Charney-Eliassen numerical prediction technique of westerly waves [6].

The following is a summary of the dynamic causes of anticyclones which appeals most to the writer. It is based on the combined effects of wave mechanics of the westerlies, lateral mixing, radiative cooling of the free atmosphere, thermal stability of the atmosphere (especially that of the surface layer), and the character of the underlying earth's surface. Lateral frictional stresses will cause supergradient winds south of the axis of the westerlies. This will create a northerly component of flow which will vanish far to the south. The convergence of air to the south of the zonal westerlies will result in the formation of an anticyclonic *ridge*. Waves in the westerlies will fracture the ridge into anticyclonic *cells*. Lateral frictional stresses which continue to operate on the sinusoidal westerlies will further increase the convergence into the anticyclonic cells. Factors which block the downward flow of the converging air in the cells and its return to the westerlies in the surface frictional layer will favor anticyclogenesis. These optimum factors are (1) greater thermal stability of the free air combined with low rates of radiative cooling of the air (as in dry air) to hinder the nonadiabatic descent of the air, (2) presence of a very stable surface layer of air, or "shielding layer," which will prevent the descending air from coming under influence of the surface frictional stresses, and thus inhibit air transport north and south across isobars, and (3) presence of a large physiographic depression such as the Great Basin of the western mountains in the United States which "traps" the descending air and interferes with its motion away from the area. Of all these auxiliary conditions, the presence of a shielding layer seems to be most significant. The formation of such a shielding layer is favored by local cooling of air over large areas such as cold water surfaces, the undercutting of the atmosphere by a subsiding and increasingly stable wedge of polar continental air, and by radiative cooling and air drainage in large physiographic depressions.

An important dynamic consequence of the horizontal convergence of the air responsible for anticyclogenesis would be an increasing cyclonic circulation if one applied the conservation of absolute angular momentum to the contraction of rings of air in the absence of external forces. Thus, if convergence is an important factor, one might expect to observe a cyclonic core embedded in the center of an anticyclone aloft. This has actually been observed by Simmers [33, p. 88], but appears to be observed rarely both because of lack of a sufficient density of upper-wind observations and the tendency of the peripheral anticyclonic circulation to obliterate by friction the weak cyclonic circulation at the core.

It should be emphasized that, given the proper conditions, the lateral frictional stresses south of the axis of the westerlies are exerted on all the air flowing through the region in question. The supergradient winds thus created cause a northerly component of flow, probably too small to be observed directly. The resulting horizontal convergence will be relieved by vertical motions downward in lower levels and upward in the upper troposphere. These latter motions will create a

higher, colder upper troposphere and tropopause. The presence of this "cold cap" above surface anticyclones was pointed out by Mügge [18], who showed that advection from the south was not the sole cause. An excellent analysis of a case of anticyclogenesis, showing the vertical structure, vertical motions, and the cold cap, has been given by Fleagle [11]. Fleagle stresses the fact that as one follows the motion of the anticyclone, the upper cold cap is not composed of the same air particles, which is a further indication of the existence of dynamic processes in anticyclogenesis.

MOTION AND TRANSFORMATION OF ANTICYCLONES

The polar anticyclone in its source region is characterized by a large surface inversion and a nearly isothermal layer above, extending usually to no more than 3 km above the surface which marks the top of the true polar continental air [35]. When the anticyclone moves away from its source region and travels over a warm surface, both the heating from below and the onset of mechanically induced turbulence wipe out the surface inversion, and may, in fact, create a steep and even superadiabatic lapse rate in the surface layer. Above this layer of steep lapse rate is usually found an inversion which increases in thickness and magnitude as the air in the isothermal layer subsides. The top of the inversion marks the top of the true polar continental air, while the air above, despite its subsidence, maintains a greater lapse rate. The spectacular nature of the "subsidence inversion," separating as it does the cool, moist, cloudy air below from the warm, clear, dry air aloft, has been studied intensively by Namias [19] and Hewson [17]. The more pronounced cases of subsidence are believed to accompany the transformation of the polar anticyclone into the warm or dynamic anticyclone, and may indeed be considered as one of the by-products of such a transformation.

Forecasting the motion of polar anticyclones away from their source regions is a problem of considerable interest to meteorologists. Often one polar anticyclone follows another in a regular procession from the source region and at other times intense large anticyclones remain stationary for many days. From observations it has been noted that a strong belt of zonal westerlies equatorward of the source region tends to act as a "barrier" preventing appreciable motion southward of polar anticyclonic offshoots. But if waves develop in the westerlies, the troughs act as "spillways" for the release of polar anticyclones.

Another approach to the problem was recently presented by Rossby [27] who studied the conditions necessary for the motion, away from the geographical pole, of barotropic vortices embedded in a motionless barotropic atmosphere of great depth. Taking into account the variation of the Coriolis force with latitude, he found that if vortices are located, or are displaced, away from the geographic pole, the cyclonic vortices will move poleward while the anticyclonic vortices will move equatorward with increasing speed (friction neglected). The motion of the polar anticyclonic vortex will be accompanied by a flattening of the dome and a conversion of the loss in potential and in rotational kinetic energy into kinetic energy of translation of the dome. Some of this translational energy is imparted to the environment which thus acquires motion. Rossby showed that, as the anticyclonic vortex moves southward (in the Northern Hemisphere) and sets the environment into motion, the anticyclonic center (center of the streamlines) is displaced westward and increasingly so with increased speed southward of the vortex. This process represents a dynamic movement of the center of the original polar anticyclone westward from its original position under the highest point of the polar dome. This conclusion is in excellent agreement with the fact long noted by synoptic meteorologists that the top of a southward moving polar dome is found about midway between the surface cyclone center and the anticyc one center to the west. It is not known whether this type of "dynamic anticyclone" leads to higher pressure than that originally found in the center of the polar anticyclone. At the time the center of the anticyclone is shifted westward, a crescent "moon-shaped" cyclonic center appears on the eastern edge of the polar dome. Considering the circular boundary of the original polar dome as the "front," Rossby showed that the southward displacement of the dome is accompanied by frontolysis and a spreading out of the cold air along the western edge, and frontogenesis and steepening of the front along the eastern edge of the cold dome. Both of these latter conclusions are in excellent agreement with observations.

In applying Rossby's results to the problem of release of polar anticyclones initially located away from the geographical pole, it must be remembered that the thermally produced anticyclone should theoretically be accompanied by a polar cyclone aloft at the source region [36], thus indicating the baroclinicity of the polar atmosphere. But if one assumes that Rossby's results, derived for a barotropic atmosphere, hold for this case, there would be a tendency for the surface anticyclone to move equatorward and the upper cyclone to move poleward. This "splitting-off" of the surface anticyclone from its upper cyclone is again quite reasonable in the light of aerological experience. However, as Rossby points out, if the concomitant sinking of the polar dome occurs in an actual atmosphere of normal stability, the resulting convergence aloft should create a cyclonic vortex at upper levels. This dynamically created cyclonic vortex may accompany the cold air dome equatorward, but sooner or later it will have to turn poleward in accordance with the increased poleward force acting on it. Thus, it is likely that, both at the source region and later on in the trajectory of the polar anticyclone, forces operate in such a way as to remove cyclones aloft, and pave the way for upper-level anticyclogenesis.

The likelihood of transformation of a polar anticyclone into a dynamic anticyclone appears to be a function primarily of its position relative to the wave pattern of the westerlies. If the polar anticyclone is associated closely with the motion of a pronounced

trough aloft, it will probably not change into a dynamic anticyclone until the trough fills in response to a change in the wave pattern; this may involve consideration of forces acting over the entire belt of westerlies. When the upper trough fills, leaving the polar anticyclone well to the south of the westerlies, surface conditions become important insofar as they maintain or strengthen the shielding layer which, as explained previously, will permit the accumulation of the subsiding air aloft, leading to anticyclogenesis.

There remain problems not explained by Rossby's theory. For example, a deep combined polar and dynamic anticyclone at the source region might be expected to move more rapidly equatorward than a shallow polar anticyclone possessing its "thermal" cyclone aloft. This is not in accord with synoptic experience and, in fact, the deep anticyclone may remain stationary for such long periods that it appears on a mean monthly map. Such a situation occurred in February 1947 over northern Greenland, as described in the mean by Namias [20]. In this case the deep anticyclonic vortex appeared to be bounded on the south by cyclonic vortices. Applying Rossby's theory we might interpret the stagnancy of the vortex pattern as an equilibrium between forces tending to drive the anticyclone vortex southward and the cyclonic vortices northward.

The ultimate fate of anticyclones which survive as individual entities in their progress to south and east seems to be absorption in and strengthening of the subtropic anticyclones. The subtropic anticyclones themselves are examples of dynamically caused anticyclones located south of the westerlies over areas where both shielding layers (trade inversion) and low, surface frictional outflow favor location of the anticyclones [37].

ANTICYCLONES AND WEATHER

Too often, in the minds of the meteorologist interested in weather forecasting, the anticyclone is considered merely as something that occupies the space on the weather maps between one front and the next. To be sure there is always the problem of forecasting the minimum temperature and the formation and dissipation of stratus and fog, but on the whole, anticyclonic weather is a period of relaxation for the forecaster. This apparent lack of association of spectacular weather with anticyclones probably accounts for the far greater emphasis on study of cyclones. However, under certain conditions the anticyclone does exert a strong, though perhaps subtle, control on weather phenomena, and it is the purpose of this section to describe a few examples.

Summer Showers in the United States. The anticyclonic control of summer shower distribution in the United States has been demonstrated by Reed [25] and Wexler and Namias [38]. In the warm season the westerlies are displaced northward near the United States-Canadian border thus allowing frictionally driven anticyclonic eddies to cover much of the United States. These eddies have preferential average positions —one center located over the central Great Plains and the other off the southeastern Atlantic Coast [37]. These preferential locations indicate that something more than purely dynamic effects of the westerlies are involved in the maintenance of these eddies. The "anchoring" of the summer anticyclonic eddies in the United States is believed to be the result of the very strong horizontal solenoidal field created by the cold air above the eastern Pacific Ocean and the heated air above the elevated plateau region of the western United States, acting in such a manner as to form a pronounced trough in the westerlies located in a mean position off the West Coast. This thermally produced trough creates a "resonance" trough in the Mississippi Valley, the exact position changing according to the varying strength of the westerlies and the position of the West Coast trough. Other troughs are found farther downstream, but in the absence of a long series of aerological observations their average locations must be deduced from other evidence. Between the troughs of the westerlies are the anticyclonic cells composed of two main currents spiraling clockwise—one a dry current from the north and the other a moist current from the south. Summer showers occur more frequently under the deep moist tongues. The preferential average locations of the positions of the anticyclonic eddies and their moist and dry tongues have profound effects on the summer climate in the United States. For example, the dry tongue curving around the West Coast trough accounts for the dry summers in southern California and western Arizona, the moist tongue curving anticyclonically from the Gulf of Mexico around the western anticyclone accounts for the summer maximum in shower activity in eastern Arizona, New Mexico, and portions of Colorado. The dry tongue of this same eddy curving anticyclonically down the Mississippi Valley into the West Gulf and eastern Texas accounts for the fact that this region has less than 50 per cent of the summer precipitation enjoyed by the eastern Gulf states which are under the influence of the moist tongue of the eastern anticyclone. Similar anticyclonic control of summer shower activity must exist in other regions south of the westerlies, and perhaps enough data now exist to permit location of the mean position of the centers of the eddies for the rest of the Northern Hemisphere. The eddy positions and sizes vary from year to year; this has a pronounced effect on the summer rainfall distribution.

The "Indian Summer" Anticyclones in the Eastern United States. During the autumn, and especially in October, stagnant anticyclones appear frequently over the eastern United States and account for calm, mild, hazy days and cool nights. The haze results from the inability of the atmosphere to disperse combustion products and other surface material. The large thermal stability of the atmosphere and the strong solar heating result in large ranges of diurnal temperature; insolation, however, in many cases does not succeed in "burning-off" entirely the inversion created by subsidence within the anticyclone. In some extreme cases where pockets of cold air form in hilly country or river valleys, not even the shallow nocturnal inversion may be completely destroyed by solar heating. This is par-

ticularly true if a thick fog reflects much of the incident solar radiation. In industrial areas located in river or valley locations, pollution products help to create dense, peristent fogs which not only protect the inversion from "burning-off" but serve as a carrier for pollution products confined to the surface layer by the inversion. This in essence is the meteorological background of the disastrous Donora, Pennsylvania, "smog" of October 25–31, 1948 [32] and the similar case in Liège, Belgium, in 1930. Two earlier cases of Donora smog occurred in 1923 and 1938, each time in October. A suspected case occurred in April 1945. Wexler [32] analyzed the necessary conditions for a deep persistent anticyclone to occur over the eastern United States, and found that autumn (in particular October) fulfilled these conditions best, with winter next.

"Back-Door" Cold Fronts. In late spring and summer along the North Atlantic Coast of the United States some of the most outstanding forecast failures occur when a seemingly persistent heat wave is broken unexpectedly by a sudden push of a shallow layer of polar Atlantic air southwestward along the coast. It is no exaggeration to say that this type of weather process brings the greatest relief to the heat-harassed populace and the bitterest self-recrimination to the forecasters involved. Overnight drops in temperature from 98F to 65F and in dew-point temperature from 82F to 62F are by no means uncommon in Washington, D. C.; it would seem offhand that such spectacular weather changes must be accompanied by equally spectacular and well-marked patterns on the weather map, but such unfortunately is not the case. The preceding conditions are usually those in which a cold front has pushed into northeastern United States from Canada, stalled in the vicinity of Boston or New York and then, showing every sign of retreating northeastward as a warm front, gathers sufficient energy to push southward along the coast in a narrow tongue. The cause is usually a sudden but slight anticyclogenesis in the cold air north of the front, which "energizes" the surface cold air into motion. The anticyclogenesis itself seems to have its origin in the warm air above the front and not in any sudden accumulation of cold air below. This tantalizing and important problem has not had the study it deserves.

EXAMPLE OF AN UNUSUAL ANTICYCLONIC THERMAL STRUCTURE

In the first section some "typical" values of the principal upper-air thermal features of anticyclones were presented. It is altogether probable, however, that other more bizarre combinations of upper-air structure may contribute to the excess of pressure at the surface, known as the anticyclone. For example, the writer, in attempting to find illustrations of "typical" soundings of polar and warm anticyclones, studied the anticyclone of December 23–26, 1949, which established some record high pressures in New England. In this case a polar anticyclone left its source region in the Canadian Northwest on December 23 with a sea-level pressure of 1033 mb and typically cold air in the troposphere; at the same time, an older polar anticyclone, which had previously pushed southward to the southwestern United States, proceeded to move northeastward with an initial sea-level pressure of 1028 mb. The anticyclones were steered by their respective currents at 500 mb and approached each other on a collision course, intensifying slightly as they did so, and finally amalgamating with an explosively sudden increase of pressure of 17 mb in 24 hours from the 24th to the 25th, the maximum pressure of 1054 mb being reached in northern Maine. In Fig. 1 it is seen that the sounding at Fort Smith, N.W.T., (665 ft elevation), taken at 0300Z on December 23 when the polar anticyclone of 1033 mb was nearly centered at the station, exhibits the strong surface inversion and isothermal layer above, characteristic of polar continental air, but possesses a high (8.7 km), moderately cold (−60C) tropopause; above the tropopause inversion a steep lapse rate is found to the top of the sounding, apparently indicating the probable presence of another higher, and perhaps colder, tropopause above. In Fig. 1 is also shown a sounding taken sixty hours later at Caribou, Maine (628 ft elevation), when the center of the amalgamated anticyclone of central pressure of 1054 mb was close to the station. This sounding shows a typically modified polar continental air mass in low levels; that is, a steep lapse rate in a thin surface layer and above this, to 2.5 km, marked stability and dryness characteristic of subsidence. Above, a steep

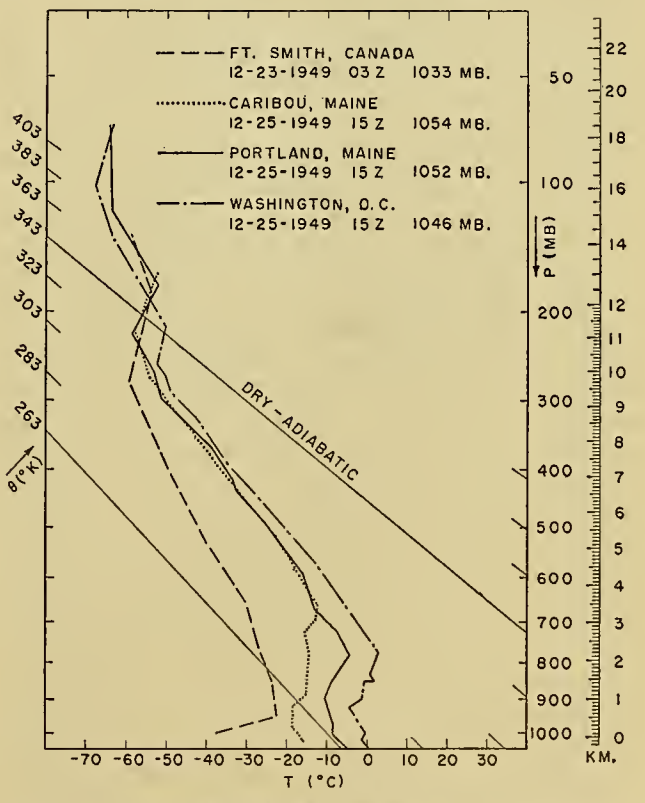

Fig. 1.—Soundings taken near the center of the anticyclone of December 23–26, 1949. Tabulated pressures are reduced to sea level.

lapse rate is found which terminates at a tropopause at 11.2 km, and, in view of the high surface pressure, a surprisingly warm tropopause (−58C). This sounding unfortunately ends at 13.0 km (−52C). In order to obtain an indication of temperatures above the top of the Caribou sounding, recourse was made to the closest sounding which penetrated significantly above 13 km, and was still under the anticyclonic influence. This turned out to be the sounding for Portland, Maine (225 miles south-southwest of Caribou), taken at 1500 Z, December 25; this station has a sea-level pressure of 1052 mb. The Portland sounding shows the presence of two well-marked tropopauses, the lower at 11.1 km, temperature −59C; this is undoubtedly the same tropopause as found over Caribou since the potential temperatures at the bases of the inversions are nearly the same, 330K and 332K, respectively. The base of the upper tropopause at Portland is found at 15.1 km, −64C, and 387K potential temperature. It therefore appears reasonable that the Caribou sounding taken near the center of the 1054-mb anticyclone would also have possessed an upper, high (15 km), cold (−65C) tropopause characteristic of warm anticyclones.

The presence of the relatively high, cold tropopause of the polar anticyclone at its source region, although unusual, is not so surprising, but the presence of a double tropopause in the warm anticyclone was unexpected.

The high potential temperature (387K) of the upper tropopause is worthy of special note since it is even higher than the potential temperature of the equatorial tropopause, 380K, as given in *Physikalische Hydrodynamik*, [3, p. 671]. The Swan Island (17.4°N, 83.9°W) sounding for 1500Z, December 25, has a well-marked tropopause inversion at 17 km, a temperature of −78.2C, and a potential temperature of 388K. In the Washington, D. C., soundings made at twelve hours before and twelve hours after 1500Z of December 25, the potential temperatures at the bases of the exceedingly well-marked upper tropopause inversions are even higher, 395K, 403K, and 408K, respectively. The Washington sounding for 1500Z, December 25, is also shown in Fig. 1. The remarkably high value of the tropopause potential temperatures observed at Washington, D. C., and Portland, Maine, could not have been achieved by adiabatic lifting of the prevailing tropopause at middle latitudes whose potential temperatures of 320K to 360K [3] are so much lower than those observed in the case under discussion. Nor does there appear to be present any radiative process which would cause the formation of an upper inversion over such a large area. It appears certain that in this situation there must have been advection northward of the tropopause from equatorial latitudes to at least the latitude of Portland, Maine, (43.7°N). The complete aerological discussion of this interesting case of anticyclogenesis is outside the scope of this article, but it should certainly be studied in detail to see how each of the large-scale factors—mechanics of the westerly waves and advection from equatorial latitudes—contributed to the anticyclogenesis.

SOME UNSOLVED PROBLEMS

The central problem concerning anticyclones is the explanation of the warm, deep "dynamic" anticyclone. The "piling-up" of air which is associated with this type of anticyclone is of course the counterpart to the removal of air which characterizes the cyclone. Complete explanations of both of these fundamental phenomena are still lacking. The deep anticyclone may be created out of transformation of a shallow polar anticyclone, or it may arise in its own right. Although some promising clues have been uncovered involving configuration of the westerlies and surface conditions, their influence on the cause and location of deep anticyclones is not fully known. That dynamic factors are important is indicated by semipermanent anticyclones located in the subtropics. That surface conditions are important is indicated by certain preferential locations of deep anticyclones. The role of advection in the upper troposphere in instituting or strengthening anticyclogenesis requires clarification. Whether changes in the height and temperature of the tropopause precede, accompany, or follow anticyclogenesis deserves further study. The existence and location of the high-level anticyclones south of the westerlies should be examined, especially in relation to tropical rainfall patterns.

MECHANISM OF PRESSURE CHANGE

By JAMES M. AUSTIN

Massachusetts Institute of Technology

The problem of weather forecasting has been intimately related to the problem of the prediction of the pressure field and, therefore, to the mechanism of pressure change. For this reason meteorologists have sought an explanation of pressure change. However, despite the efforts of research workers during the past century it appears that there is not yet a completely satisfactory explanation of this phenomenon. In view of the uncertain state of knowledge it is the intention of the author to review briefly the more prominent theories of the pressure-change mechanism.

It is important to note that this discussion refers to pressure changes and not to pressure systems. A pressure system and its associated wind and temperature fields may be considered to be the result of a complex series of events following pressure changes. It is difficult, therefore, to investigate pressure changes through a study of the characteristics of pressure centers. For example, a center of a migratory pressure system is intermediate between a pressure rise and fall. This distinction between pressure change and pressure distribution is emphasized because it is believed that too much attention has been focused on meteorological data above the centers of pressure systems.

Historical Note

During the latter part of the nineteenth century Ferrel [8] developed a comprehensive theory of atmospheric processes based upon his own conclusions and the ideas of the earlier meteorologists. Ferrel explained the development of a cyclone as a consequence of localized heating which causes an outflow at high levels and, therefore, a surface pressure fall. The importance of low-level convergence, high-level divergence, and the earth's rotation in the development of the wind field around the pressure fall was well recognized. The heating was attributed principally to the release of latent heat with the condensation of water vapor in conditionally unstable air.

Several objections against this thermal theory were raised by Hann [14] and others. One group of objections which was directed against the latent heat as the cause of the warming could be met by allowing for other processes which would produce localized heating. However, the more serious objections were based upon temperature observations at mountain stations which frequently showed high temperatures over surface anticyclones and low temperatures over surface cyclones. These observations were considered to contradict a heating or cooling hypothesis and, therefore, there was a search for a more acceptable explanation of pressure change. The group of theories which attempt to explain pressure changes without localized heating or cooling as a primary cause are frequently referred to as *dynamic* explanations. An early example is given by Hann [14] who postulated that cyclones originate as a consequence of the damming and acceleration of the high-level air currents. A defect of many such *dynamic* theories is the failure of the authors to give specific details of the mechanism.

Before proceeding further with other theories it is important to investigate to what extent the empirical evidence on pressures and temperatures violates the thermal theory. The temperature data which were used to discredit Ferrel's hypothesis were obtained in the vicinity of the centers of mature slow-moving pressure systems. With such systems the temperature field has been greatly modified by vertical motion. Consequently these data on the temperature distribution in one layer of the atmosphere do not invalidate an argument that pressure falls and rises as a result of localized warming and cooling, respectively.

A survey of the early literature then suggests the following conclusions:

1. A thermal explanation of pressure change was unjustly criticized by reference to temperature observations taken above the centers of mature pressure systems.
2. If the thermal theory is valid there must be a more adequate explanation of the localized heating.
3. The observations which were believed to contradict a thermal theory greatly stimulated research on the so-called "dynamic" theories.

Pressure-Change Theories

Insofar as the pressure at a point is the weight of the air column above that point, it is convenient to discuss pressure changes by means of the hydrostatic equation

$$p_h = \int_h^\infty \rho g \, dz. \tag{1}$$

It follows from this equation that, if the variations of gravity g with height are ignored, the pressure p_h changes whenever there is a net change in the mass of air above h. This change of mass may be accomplished by the heating or cooling of the air without a change in the height of the free surface or by a change in the height of the free surface without the heating or cooling. Consider the simple analogy of a tank of water. If the water is cooled everywhere to the same extent there is a drop in the height of every pressure surface above the base of the tank. Now consider the case where one-half of the tank is cooled. Water flows into the cooled region in response to the horizontal pressure gradients created between the two sections by the cool-

ing and it follows that the pressure at the base of the cooled region rises, in view of the additional mass, while the pressure at the base of the other section falls, as a result of a lowering of the free surface. In a similar manner, it is necessary to heat or cool the atmosphere in one region relative to the remainder of the atmosphere in order to produce pressure changes. The pressure change depends upon the space variation of the heating or cooling and not on the magnitude and sign of the local temperature change. For example, pressure can fall in a region of cooling provided that the cooling is stronger elsewhere. This mechanism of pressure change may be referred to as a *thermal* theory. Various explanations have been offered for the source of local heating and cooling, such as the release of latent heat, the advection of warm or cold air, and the nonadiabatic processes. More information on the thermal theory will be presented in a later section.

An alternate method of producing a change in pressure, which involves no consideration of thermal processes, requires some outside agency to exert a force on the air. For example, a pressure drop may be produced in the center of a container of water by causing the container to rotate so that the drag at the walls sets the fluid in motion. Another illustration of this process is the pressure rise created at the bank of a stream where the water piles up at a bend. The question now arises as to whether pressure changes can occur in the atmosphere by an analogous mechanical process. The formation of high pressure on the windward side and of low pressure on the leeward side of a mountain range may be considered a mechanical process. However, there appear to be no other agencies which can produce significant pressure changes in the atmosphere by mechanical means.

The role of lateral mixing processes in the development of pressure changes has been the object of various studies. Rossby [26] analyzed the pressure changes which accompany the lateral diffusion of momentum in a straight current. It was concluded that the diffusion process could give rise to the formation of a low-pressure trough to the left and a high-pressure ridge to the right of the current. The pressure changes arise from a change in the height of the free surface. This study of the mutual adjustment of pressure and velocity distributions evidently was undertaken in connection with the interpretation of the so-called *dynamic* pressure systems, that is, the warm highs and cold lows. Such an explanation of pressure changes is open to criticism insofar as it leaves unexplained the manner in which the strong current was created in view of the continual operation of diffusion processes. Lateral mixing may be an adequate explanation of some pressure changes but to complete the picture it is necessary to explain the development of the situation which precedes the operation of the lateral mixing process. In his discussion of Jeffreys' theory [19] of atmospheric circulation, Whipple [30] offers a somewhat similar argument to explain the pressure distribution. The suggestion is made that the strong west winds aloft induce strong west winds below through turbulence and that air is flung outwards and creates anticyclonic belts. Whipple points out that the details of the mechanism are not clear.

There have also been a number of explanations of pressure changes which have been based upon the principle that the wind field changes and, therefore, the pressure field changes as a consequence of the mutual adjustment of pressure and wind distributions. The use of constant absolute vorticity trajectories [12] to predict a 10,000-ft pressure pattern is an example of this principle. In this case the question may be raised as to the applicability of the simplified vorticity equation. The final wind field is deduced on the basis of many assumptions concerning the behavior of individual air particles. There appears to be no sound reason why the pressure distribution should change so that the air particles can follow the assumed trajectories. Other explanations of pressure changes as a consequence of wind changes are to be found in meteorological literature. The statements are frequently vague without an explanation of how the pressure changes so that it is difficult to discuss the arguments. However, these explanations usually suffer from a defect like the assumption of a simplified air trajectory or an unexplained change in wind speed. This group of pressure-change theories is often referred to as a dynamic explanation of pressure changes.

A comprehensive discussion of dynamic and other theories of cyclogenesis has been presented by Raethjen [24]. The discussion is pertinent to the problem of the mechanism of pressure change since it considers the formation of a pressure minimum. Raethjen emphasizes the problem of the development of cyclonic and anticyclonic vorticity and includes an analysis of such dynamic theories of pressure change as the concept that the pressure field of a cyclone forms from its wind field. The significance of lateral mixing and friction as processes which influence the vorticity distribution is discussed in some detail by Raethjen.

The various approaches to the pressure-change mechanism may now be reviewed. The *thermal* theory appeals in view of its simple physical picture but presents the problem of how the local temperature changes are produced. The *dynamic* theories which consider that the pressure-change field is a result of a changed wind field are not altogether consistent with the fact that wind changes arise from the accelerations which accompany local pressure changes. Of course, it is possible to determine the average pressure force acting on a particle if the velocity of the particle is known at two different times. However, it does not follow that the change in wind velocity can be considered the cause of pressure changes. Rather it appears more logical to view the changes in the wind field as a consequence of pressure changes. Nevertheless the wind field, in particular the vorticity distribution, is a vital feature of a pressure system. Consequently any theory of pressure change, such as a thermal theory, must include an explanation of the observed changes in the wind field.

Pressure Tendency Equations

In recent years the problem of pressure changes has often been approached from the standpoint of analyzing the components of various equations for the pressure variation $\partial p/\partial t$. Bjerknes [2] discussed the development of pressure changes by use of the following equation for the pressure change at a level h.

$$\left(\frac{\partial p}{\partial t}\right)_h = -\int_h^\infty g\left(u\frac{\partial \rho}{\partial x} + v\frac{\partial \rho}{\partial y}\right)dz - \int_h^\infty g\rho\left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y}\right)dz + g(\rho w)_h, \tag{2}$$

where u, v, and w are the x-, y-, and z-components of the wind. Equation (2) states that the pressure change is determined by the horizontal advection and divergence above the level h and by the vertical advection at h. Sufficient evidence has been accumulated with the advective integral [15] to show that it is of the same order of magnitude as the pressure tendency. On the other hand the divergence integral and the vertical motion term are usually one order of magnitude greater than the pressure tendency. It follows then that the contribution of the last two terms of equation (2) is the small difference between two large quantities. This difference is expressed analytically when the tendency equation is written in the form given by Houghton and Austin [18]:

$$\left(\frac{\partial p}{\partial t}\right)_h = -\int_h^\infty g\left(u\frac{\partial \rho}{\partial x} + v\frac{\partial \rho}{\partial y}\right)dz + \int_h^\infty gw\left(\frac{d\rho}{dz} - \frac{\partial \rho}{\partial z}\right)dz. \tag{3}$$

This tendency equation shows that the field of horizontal divergence and vertical motion gives rise to a pressure change depending upon the manner in which the motion changes the density distribution above the level h.

Alternate forms of the tendency equation have been derived in various ways. The reader is referred to a review given by Godson [13]. Another example of a tendency equation which does not involve the integration to infinity is given by Matthewman [20]. In recent years, with the availability of upper-air data, there have been attempts to compute the values of the factors which give rise to pressure changes. For example, Fleagle [11] has given values of the components of equation (4) at various levels in the atmosphere.

$$\frac{1}{\rho}\frac{\partial \rho}{\partial t} = \frac{1-K}{p}\frac{\partial p}{\partial t} + \frac{1}{\theta}\mathbf{V}_h\cdot\nabla_h\theta + \frac{w}{\theta}\frac{\partial \theta}{\partial z} - \frac{1}{\theta}\frac{d\theta}{dt}. \tag{4}$$

$K = R/c_p$, R is the gas constant for dry air, c_p is the specific heat at constant pressure, θ is the potential temperature, $\mathbf{V}_h$ is the horizontal velocity vector, and $\nabla_h\theta$ is the horizontal gradient of potential temperature. The significance of these terms is apparent when it is noted that

$$\left(\frac{\partial p}{\partial t}\right)_0 = -\int_0^\infty \frac{1}{\rho}\frac{\partial \rho}{\partial t}\,dp. \tag{5}$$

Fleagle has also presented values of the horizontal mass divergence.

The observational evidence of Fleagle and others indicates that all the components of the tendency equation are important, that all layers of the atmosphere contribute to the various integrals, and that the net value of an integral is often the small difference between large values of opposite signs. For this reason it is not possible to compute the pressure tendency accurately from the components of a tendency equation.

The utility of these tendency equations will now be considered. A relationship as expressed by equations (2)–(5) gives an insight into the mechanism of pressure changes only as long as there is a clear understanding of how the components of the equations change. All the tendency equations involve the three-dimensional field of motion and it can readily be shown that, for the computation of the pressure variation, the velocity must be known to an accuracy of the order of 1 cm sec^{-1}. Consequently a tendency equation is helpful in understanding pressure changes provided that the mechanism of wind change is known. This involves a knowledge of the manner in which accelerational fields develop in the atmosphere, and undoubtedly the local pressure changes themselves are of major importance in producing accelerations. From such considerations as the above it would appear that the tendency equations do not contribute significantly to an understanding of the mechanism of pressure changes. Computations of the magnitudes of the various terms do indicate, however, the importance of the various processes which accompany pressure changes. These computations show what is happening in the atmosphere while the pressure changes. For this reason it is necessary that the empirical work be extended as it is probable that the vertical distribution of such quantities as the horizontal divergence differs from one part of an isallobaric system to another. Finally it might be noted that these tendency equations have no prognostic value insofar as it is not possible to predict the values of the various integrals of the tendency equations.

A number of theoretical attempts have been made to analyze the pressure-change mechanism by means of a tendency equation and an assumed wind field. For example, Bjerknes and Holmboe [3] discuss the distribution of horizontal convergence and divergence at various levels in the atmosphere when it is assumed that the wind is gradient at trough lines and wedge lines. Priestley [22] also analyzes pressure changes on the assumption of gradient flow and stresses the importance of the path curvature on the control of atmospheric pressure. Schmidt [27] discusses the components of a tendency equation through the introduction of an approximation concerning the acceleration of the wind. These approaches are subject to criticism on account of the assumptions concerning the wind field. Houghton and Austin [18] and Priestley [23] discuss aspects of the

effect of the deviations from the gradient wind upon the surface pressure field. It seems evident that only limited conclusions concerning the pressure-change process can be drawn from an analysis which specifies a particular type of wind field. Nevertheless this type of approach gives valuable information on the importance of the various parts of the wind field and, therefore, aids in establishing an internally consistent picture of the field of motion with a field of pressure change.

Vorticity Studies

The density changes which lead to a change in mass in an atmospheric column invariably involve the wind field as illustrated by equation (2). A transformation of the horizontal equations of motion leads, with a few simplifying assumptions, to a vorticity equation

$$\mathrm{div}_2 \mathbf{V} = -\frac{1}{\zeta + \lambda}\frac{d}{dt}(\zeta + \lambda), \qquad (6)$$

where $\mathbf{V}$, ζ, and λ are the horizontal velocity vector, the vertical component of vorticity, and the Coriolis parameter, respectively. Although equation (6) does not directly refer to pressure change, it plays an important role in pressure-change research because it expresses certain relationships which must be satisfied by the wind field. For example, if a hypothesis specifies horizontal divergence in the upper troposphere, then vorticity changes consistent with equation (6) should occur in this region.

Consequently, such a vorticity equation and the pressure tendency equations together provide a means for testing the validity of a theory of pressure change. However, like the pressure tendency equations, equation (6) does not lead directly to an explanation of the mechanism of pressure change.

An ever-present difficulty in all wind studies is the lack of a dense network of reliable wind observations, particularly above 10,000 ft. Consequently, most studies of vorticity change have been based upon some assumed wind field such as a geostrophic wind field [28]. In all likelihood, the vorticity of the geostrophic wind differs from the vorticity of the actual wind and this difference may well be large in a region of active pressure change. Since equation (6) is a powerful tool for testing pressure change theories it seems desirable that additional research be conducted on the vorticity field and its changes.

Thermal Theory of Pressure Change

Several aspects of a thermal explanation of pressure change will now be considered. This elaboration of a thermal approach is undertaken because the theory has the advantage of a simple physical picture and because it appears to be as well developed as other theories of pressure change.

Nonadiabatic Temperature Changes. The significant aspects of the thermal theory of pressure change may be demonstrated by means of a simple model. Consider a mass of air above the earth's surface, *BCNM* in Fig. 1*a*, and let the air be heated uniformly from 1000 mb to 600 mb. As a consequence of the heating all the pressure surfaces above *BC* are raised. This expansion is not accompanied by adiabatic temperature changes insofar as there is no change in pressure on individual air particles. The heating then creates a pressure gradient to accelerate air out of the column above *BC*. The vertical displacement of each pressure surface is given by

$$\frac{\delta Z}{Z} = \frac{\delta T}{T}, \qquad (7)$$

where Z is height of the surface and T is the mean temperature from the earth's surface to the level Z. It follows that δZ increases from 0 for the 1000-mb surface to a maximum at 600 mb and that all pressure surfaces above 600 mb are raised by the same amount as the 600-mb surface. The new horizontal pressure field then creates a maximum mass outflow about 600 mb. In response to this outflow the pressure falls near the base of the column *BC* and upward accelerations are created

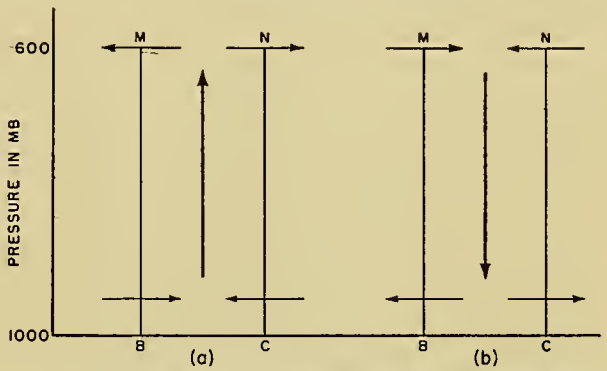

FIG. 1.—Two atmospheric models with (*a*) heating and (*b*) cooling in the region *BCMN*. The arrows indicate the fields of horizontal divergence and vertical motion.

within *BCNM*. As a consequence of these pressure falls there are inward horizontal accelerations near the base of the column. Even though this analysis has treated the problem in a stepwise manner, it is recognized that the process is a continuous one.

The heating then produces a pressure fall at *BC* and a pressure rise in the environment. One modifying influence is the adiabatic temperature changes which accompany the vertical displacements after the establishment of the accelerational field. These adiabatic changes modify the original temperature difference between the heated column and its environment, and the pressure difference at any given time depends upon the net contribution of the heating and cooling processes to the establishment of a temperature difference between the column *BC* and its environment. The wind field at the same time may be determined from the accelerational field created by the heating, from the Coriolis acceleration, and from the effect of friction. The well-known low-level convergence and high-level divergence in the vicinity of centers of pressure fall are readily deduced.

Similar reasoning could be applied to the converse problem of the effect of local cooling. It is apparent from the previous discussion that cooling gives a pressure rise at *BC*, a pressure fall in the environment, and a divergence field like that of Fig. 1*b*.

It is now necessary to investigate the magnitudes of the changes produced by heating and cooling. If the air column *BCNM* were heated 5C relative to the environment, the magnitude of the sea-level pressure change would be somewhat less than the change which would arise if the height of the 600-mb surface should remain invariant and the air column below 600 mb were replaced by a 5C-warmer column, that is, less than 9 mb. The reasons for the smaller change are the raising of the 600-mb surface and the distribution of the outflowing air over a finite region. The extent of the surroundings also determines the sea-level pressure rise in the surroundings. It does appear, therefore, that heating and cooling can produce significant pressure changes and that nonadiabatic processes may be important for the development of pressure fields.

A brief survey of various types of nonadiabatic processes will now be presented. The atmosphere is continually gaining and losing heat by radiation. However, radiation studies indicate that the net loss of heat by the tropospheric air is small and that the space variation of this loss is slight. It appears that the cooling is greater in regions of high specific humidity and consequently direct radiative processes in the troposphere may produce weak pressure fields. The space variation of radiation absorption in the stratosphere, such as in the ozone region, should give rise to high-level accelerational and pressure-change fields (see Haurwitz [16]) However, it is not obvious that these fields have a pronounced effect on the sea-level circulation. A significant difference between low- and high-level heating is the absence of a fixed boundary at the base of the heated layer in the case of the high-level heating. Before it may be concluded that such heating can produce substantial sea-level changes it is necessary to investigate the possible significance of adiabatic processes in the troposphere below the level of heating. Adiabatic cooling can account for a definite pressure fall at high levels and an insignificant sea-level change. Hence the answer to the question of the effect of radiation absorption in the stratosphere upon low-level changes must await the results of further theoretical and empirical studies.

Nonadiabatic temperature changes also arise from the flux of heat between the atmosphere and the earth's surface. Because this heating or cooling is not uniform over the entire globe it should be expected that this thermal process would be accompanied by accelerational fields and pressure changes. The significance of this factor may be illustrated by a few simple examples.

1. The development of low pressure in a region of strong heating is often observed on weather charts. These cyclones are usually referred to as thermal lows.

2. The sea- and land-breeze circulations are good examples of the creation of a small-scale pressure-change field through surface heating and cooling.

3. The mean pressure maps of the Northern Hemisphere demonstrate that the average sea-level pressure over the hemisphere is approximately 4 mb lower in July than in January. This appreciable pressure change between summer and winter is consistent with the heating of one hemisphere relative to the other.

4. Perhaps the most striking pressure changes are those which occur in middle latitudes between land and water areas from summer to winter. In winter, air is being cooled over the land and air from the land is being heated over the water. The converse holds during the summer season. This distribution of heating and cooling requires a pressure rise over the land from summer to winter and a pressure fall over the ocean. From mean pressure and temperature charts it has been possible to determine approximately the pressure and temperature differences. The data in Table I clearly indicate that substantial pressure changes accompany the heating and cooling.

Table I. Seasonal Variation in Average Surface-Air Temperature and Average Sea-Level Pressure

	Lat. 40°N		Lat. 50°N	
	Land	Ocean	Land	Ocean
January				
Pressure (mb)	1023	1015	1022	1006
Temperature (°F)	36	48	10	37
July				
Pressure (mb)	1011	1020	1011	1016
Temperature (°F)	82	67	69	55

5. Wexler [29] has explained the development of a polar anticyclone through cooling and its associated isallobaric convergence. The analysis of the pressure change which accompanies the heating or cooling has been extended by Schmidt [27]. Schmidt assumes a certain distribution of the heating and computes the pressure changes from a consideration of radiative density variations, isallobaric divergence, and the vertical motion of the air. The theoretical formula is tested by a study of the seasonal pressure variations over the vast continents. The theoretical estimates are in good agreement with the observed pressure changes from summer to winter.

6. Estimates [4] have been made of the rate of addition of heat to cold polar air as it leaves the mid-Atlantic coast and moves out over the ocean. This heating can be very pronounced and it would appear that this process alone could produce substantial pressure changes since there is a space variation in the heating. It should be noted, however, that it is difficult to check the importance of the heating directly since a strong advection of cold air is usually associated with a pressure rise (see below). This type of strong heating occurs near the Atlantic coast of North America and the Pacific coast of Asia.

The survey suggests that nonadiabatic heating or cooling of air, through contact with the earth's surface, may produce significant pressure changes. The horizontal mixing of different air masses and the cooling or heating of air by falling precipitation are other examples of nonadiabatic processes which could give rise to pressure changes.

The conclusion which is drawn from this review of the effect of nonadiabatic processes is that they are of a sufficient magnitude to influence the daily pressure

patterns and to be detected in the field of pressure changes. For the day-to-day pressure variations, except for the diurnal change, it would appear that the space variation of the transport of air over colder and warmer surfaces is the most important of the nonadiabatic processes. A satisfactory explanation of the development, intensification, and motion of the fields of acceleration and pressure change must be based, in part, upon the effect of nonadiabatic temperature changes.

Horizontal Advection. Local changes in temperature in one region relative to another may arise through the horizontal advection of warm or cold air. The concept of thermal advection as a cause of pressure changes has been discussed by many meteorologists since Ferrel [8] advanced a thermal theory of pressure changes. For example, Exner [7], Henry [17], Defant [5], and McDonald [21] have illustrated relationships between temperature advection at the surface and the simultaneous pressure change. Austin [1] has shown that regions of maximum advection of warm air near the earth's surface are accompanied by pressure falls at sea level while pressure rises occur in regions of maximum advection of cold air. It was further demonstrated that advection at high levels did not appear to be associated with significant pressure changes at sea level.

Even though prominent relationships have been established between the advection of cold and warm air in the lower troposphere and the occurrence of pressure rises and falls, it is still necessary to explain the mechanism of the pressure change. Perhaps the process may be visualized as the horizontal motion of warm air into a region of cold air giving an outflow at high levels and, therefore, a pressure fall just as the direct heating in Fig. 1 gives rise to a pressure fall. The converse is the transport of cold air into a warm region with high-level inflow and a pressure rise at sea level. Such an explanation replaces the direct heating or cooling of the thermal model in Fig. 1 with the localized heating and cooling which arises from horizontal transport. The process has been described by Douglas [6] as "a convectional overturning between adjacent cold and warm masses." The similarities between the nonadiabatic and advection hypotheses may be summarized as follows:

1. Both types of heating and cooling give rise to sea-level pressure changes when the temperature change extends upward from the earth's surface.

2. High-level temperature changes produced by nonadiabatic processes or indicated by geostrophic advection are not necessarily associated with prominent sea-level pressure changes.

3. The accelerational fields which arise from nonadiabatic processes appear to be similar to those which accompany the differential advection of warm or cold air.

4. Both types of heating or cooling give rise to pressure-change fields only as long as there is a space variation in the heating and cooling.

Two important differences may be stated briefly as follows:

1. The nonadiabatic process gives rise to the pressure change and accelerational field from an initially barotropic state. The advective process requires a particular field of motion relative to the temperature field.

2. The nonadiabatic heat source is stationary whereas the advective heating is a moving source. This distinction is important in problems concerning the pattern of horizontal divergence and vertical motion with moving pressure-change systems.

At this stage it is desirable to consider those aspects of atmospheric pressure change which can be attributed to the differential advection of temperature at low levels.

The major part of a pressure fall or rise in a concentrated region of large pressure changes at sea level can be explained by the advection of warm or cold air in the lower atmosphere. Also many features of the propagation of pressure-change centers may be attributed to this advection process. For example, consider a simple model, as in Fig. 2. It will be assumed that the essential

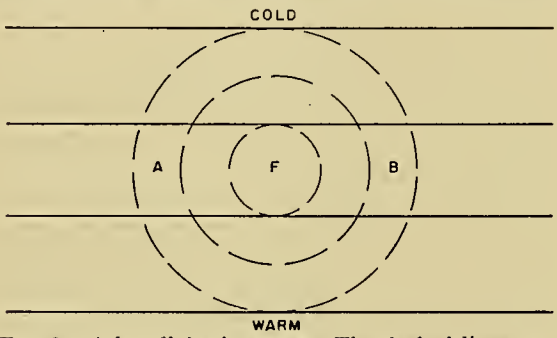

FIG. 2.—A katallobaric system. The dashed lines are katallobars and the solid lines are isotherms.

features of the horizontal advection can be judged from the geostrophic flow even though it is recognized that the motion cannot be geostrophic. The katallobaric system is associated with a strong advection of warm air and consequently it should be expected to move in the direction of the flow, that is, in the direction of the geostrophic wind. However, the isallobars show that the geostrophic field is changing so as to intensify the warm-air advection at B and to produce cold-air advection at A. This changing field of horizontal motion itself gives rise to a motion of the katallobaric center in the direction AB. Hence it should follow that the actual motion of the pressure-change center is in a direction somewhere between the direction AB and the existing geostrophic direction at F. Synoptic studies appear to confirm this conclusion. On the other hand this differential advection, as judged by geostrophic flow, cannot account for the development of new isallobaric systems or for the intensification or weakening of existing isallobaric centers.

One aspect of the motion which requires further investigation in connection with the development of pressure changes at sea level is the role played by ground friction. It seems probable that the retarding effect of friction influences the low-level inflow and outflow which follow the creation of isallobaric fields. This retarding force may affect the ultimate pressure change, and consequently surface friction requires further consideration.

High-Level Processes

A European school of meteorologists proposed a modified thermal theory [9] of pressure change in which the primary cause is thought to be temperature advection in the stratosphere with secondary thermal effects in the troposphere. There is no doubt that there are strong advective fields about the tropopause and, therefore, it seems logical to pay attention to the influence of stratospheric advection on pressure changes. A comprehensive analysis of the large changes which take place near the tropopause has been presented by Fleagle [10]. However, as Fleagle mentions, these changes are not sufficient evidence to conclude that the "seat" of the pressure change resides in the stratosphere. The evidence which has been presented on the relationships between sea-level pressure change and high-level advection do not support a conclusion that the cause of the sea-level change is to be found in advection in the stratosphere.

The strong changes which occur in the upper atmosphere may be considered as arising from vertical motion fields which accompany the sea-level pressure changes and which arise from such low-level processes as heating or cooling. A nonuniform field of vertical motion creates strong advective fields in the lower stratosphere as a result of the abrupt change in the vertical temperature gradient near the tropopause. Hence it may be argued that the high-level advective fields are the result rather than the cause of sea-level pressure changes. Similar explanations have been presented by many meteorologists such as the discussion given by Douglas [6] on "Some Facts and Theories about the Upper Atmosphere." It should also be noted in connection with the high-level processes that Reed [25] has been successful in relating the prominent ozone variations to the fields of vertical motion which are known to accompany the sea-level pressure system.

It would appear then that there is no definite evidence to support a hypothesis that stratospheric advection may be considered a cause of sea-level pressure change. However the evidence does not contradict hypotheses that other high-level processes may produce low-level pressure changes. For example, the observed variations of the temperature field across the tropopause may lead one to suspect that instability in this general region may give rise to significant low-level changes. It would then appear desirable to investigate, analytically and empirically, processes other than advection which might take place in the vicinity of the tropopause and contribute to sea-level changes. As in the case of the high-level heating discussed previously, it will be necessary to consider the effect of tropospheric processes upon the net sea-level change which arises from some high-level process.

High-Level Pressure Changes

The motion and changes in intensity of the weather systems are accompanied by pressure changes at all levels in the atmosphere. The various constant-level charts present a series of horizontal slices through the atmosphere whose over-all behavior is reflected by the sea-level chart.

So far the discussion has concentrated mainly upon the problem of the pressure change at sea level. This approach is justified on the basis of the presence of a fixed boundary which should simplify the problem. When high-level pressure changes are considered it has to be recognized that air can move vertically through the level at which the pressure variation is being analyzed. One method of viewing a high-level pressure change is to explain the change on the basis of the pressure variation at the earth's surface and the change in the temperature or density of the air column from the surface to the level in question. This type of approach is adequate in view of the status of pressure-change theories.

Empirical Evidence

Because of the questionable status of the theories of pressure change it is desirable to investigate those empirical facts which have to be explained by a pressure-change theory. Figure 3 presents a schematic cross section through an area of pressure rise and fall and includes some pertinent information on the changes in the temperature field, the vertical velocities, and the vertical accelerations which accompany the pressure changes. The idealized picture is based upon observational evidence obtained by the pressure-change project at the Massachusetts Institute of Technology and upon the empirical data presented by Fleagle [10, 11]. Whether Fig. 3 is a good approximation to a cross section through an actual weather system is open to question. Since upper-air observations are usually taken at twelve-hour intervals, much of the empirical information on the instantaneous field of vertical velocities has to be deduced from twelve-hour changes. For this reason it is to be expected that a computed field may give a somewhat erroneous impression of the magnitude and space variation of the true field of vertical velocities.

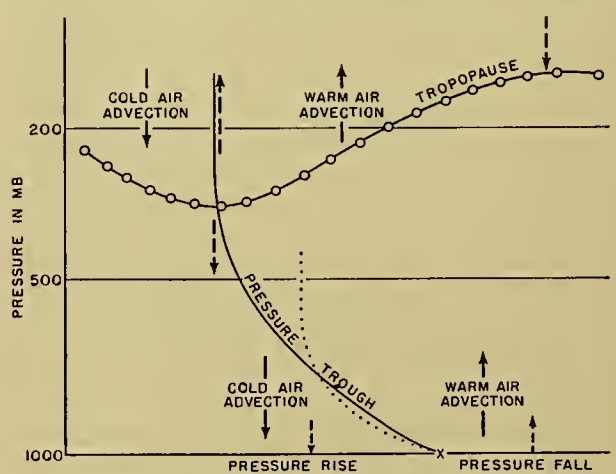

Fig. 3.—A vertical cross section through an idealized pressure trough. The solid and broken lines indicate the directions of the vertical velocities and vertical accelerations, respectively. The dotted line indicates the region of strong horizontal temperature gradient.

The vertical accelerations are the most questionable of the observational data. However, it is believed that the comparatively slow displacement of the high-level field of vertical velocities as compared with the large horizontal velocities makes it possible to estimate the magnitude of the vertical accelerations in the upper atmosphere. The vertical accelerations in Fig. 3 were estimated from such considerations. This idealized model serves to illustrate those features of pressure changes which have been discussed earlier. Two other features of this diagram deserve attention.

1. The pressure trough and the zone of maximum temperature contrast are approximately coincident in the lower atmosphere, consistent with the general concept of a frontal surface. However, above the middle troposphere this coincidence is no longer present. The pressure troughs and ridges in the higher atmosphere are near regions of maxima and minima in the temperature field. The pressure systems move along with the low-level temperature field at a speed which is not vastly different from the horizontal wind speeds. Above the lower troposphere, however, the prominent features of the temperature and pressure field move much slower than the horizontal wind speeds at the respective levels. This behavior of the higher atmosphere may suggest that the primary cause of pressure changes is to be found in the lower troposphere. However, before such a conclusion can be reached it is necessary to explain the origin of the vertical accelerations at high levels.

2. A developing pressure system is usually associated with an intensification of the high-level pressure trough and the associated temperature maximum in the stratosphere. Figure 3 shows that this maximum arises from descending motion upstream from the point of maximum temperature. Consequently a developing pressure system must be accompanied by downward accelerations many hundreds of miles upstream from the stratospheric temperature maximum. This evidence on the high-level accelerational field indicates that the development of a pressure system is accompanied by significant changes over a wide area.

Hence it appears that the problem of pressure changes cannot be localized to processes within the immediate vicinity of an isallobaric system.

Conclusions

It has been shown that there have been various approaches to the problem of the mechanism of pressure change. At present the physical picture is incomplete and, therefore, no definite conclusion can be reached as to the most desirable line of approach. It is evident that a theory must explain an increase or decrease of mass in an air column. In this review the emphasis has been placed upon the thermal explanation of pressure changes since it appears to satisfy many of the observed facts concerning the temperature field. Moreover, a thermal approach is in accord with the general concept that heating and cooling are the primary causes of atmospheric motion. However, it is apparent that the thermal theory has not been fully developed. Many problems remain:

1. Theoretical analyses of the development of divergence and vertical-motion fields with pressure changes appear to be inadequate.

2. The empirical picture of divergence and vertical motion is well established for stationary heat sources; however, it is evident that there are gaps in our knowledge concerning the manner in which divergence and vertical-motion fields develop and move with migratory pressure systems. Much of the empirical information is based upon twelve-hour changes and it is possible that such data give an incorrect impression of the motion in areas of pressure change.

3. The direct influence of nonadiabatic temperature changes on pressure changes requires further consideration.

4. The details of horizontal advection require more investigation in order to ascertain whether advection should be considered a cause or an effect of pressure change.

5. The complexity of the temperature field in the vicinity of the tropopause warrants further consideration of the stability of this field.

6. The influence of surface friction must be further investigated.

7. It is necessary to develop a thermal model which gives a pressure change in a quiescent region, followed by a moving pressure-change field with its associated changes at various levels, and then the end stage of a cold cyclone or warm anticyclone.

Finally, it is important to note that the empirical data indicate that the explanation of pressure changes cannot be localized to processes taking place over a small area. This concept of the extent of the field of influence applies to all analyses of the problem of pressure change. For this reason there is some advantage in specifying a certain unbalanced condition as an initial state in a region where the pressure is changing and later investigating how such a particular initial state might have originated. Such a procedure, which has been followed in some dynamic approaches, might well be adopted in a thermal or convectional approach.

Even though the pressure-tendency equations do not appear to lead to fundamental explanations, they play an important role in research on pressure change. A preliminary step toward an explanation of pressure change is an accurate description of all features of the wind, pressure, and temperature fields in the vicinity of pressure changes. The pressure tendency equations make it possible to check the internal consistency of such pictures. In connection with this important aspect of pressure-change research the author would like to suggest the desirability of utilizing to a greater degree other relationships which may be derived from the equations of motion. For example, vorticity-divergence relationships should also be helpful in determining the reality of an empirical model of a stationary or moving pressure-change system.

This breakdown of approaches to the pressure-change mechanism into the two categories of *thermal* and *dynamic* is perhaps artificial. The classification is consistent with the conventional use of the adjectives thermal and

dynamic. However, it is apparent that *thermal* hypotheses are concerned with the laws governing the air in motion and that a thermal approach must not overlook the necessity of explaining the particular changes in the wind field which accompany pressure changes. Likewise *dynamic* hypotheses recognize the thermal origin of atmospheric motion and a dynamic approach cannot disregard the observed temperature field. The ultimate goal of a complete explanation of pressure change involves the description of processes which satisfy all the laws governing the behavior of the atmosphere. In an attempt to advance toward this goal it may be convenient to reason from one or more of the fundamental laws. Hence all approaches which have physical bases, whether they be called dynamic or thermal, supplement rather than compete with one another. The verified conclusions of one approach should aid the extension of a different line of attack.

LARGE-SCALE VERTICAL VELOCITY AND DIVERGENCE

By H. A. PANOFSKY

New York University

Influence of Scale on Divergence and Vertical Velocity

The vertical velocity is the only component of the air velocity vector not generally recorded. Yet it produces important effects of turbulence and is basic to the formation of precipitation. On a small horizontal scale it has been measured directly in thunderstorm and turbulence research, but the average vertical velocity over large areas (10^{14} cm^2 or more) must be estimated indirectly.

The horizontal velocity divergence, div V (called simply *divergence* in this article), is related to the vertical velocity by the equation of continuity. According to this equation, vertical divergence $\partial w/\partial z$ is almost exactly equal in magnitude and opposite in sign to horizontal divergence, provided that the fractional change of density is small. The distribution of horizontal divergence therefore prescribes the distribution of $\partial w/\partial z$. If the vertical velocity w is known at any one level, the distribution of horizontal divergence determines the distribution of the vertical velocity itself. Generally, the vertical velocity can be assumed to be known at the ground. Because of this close relationship between vertical velocity and horizontal divergence, the two quantities are treated together in this article.

The magnitudes of divergence and vertical velocities are influenced to an extreme degree by the size of the areas over which they are averaged. This can be seen most easily for the divergence. Let x and y be two horizontal Cartesian coordinates and u and v the velocity components in the x and y directions, respectively. Then the divergence is given by

$$\text{div V} = \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y}. \tag{1}$$

If this quantity is averaged over a square of length L, the result is

$$\overline{\text{div V}} = \frac{(\bar{u}_3 - \bar{u}_1) + (\bar{v}_4 - \bar{v}_2)}{L}, \tag{2}$$

where $\bar{u}_3$ is the mean value of u on side 3 of the square, and the other velocity terms have corresponding interpretations (see Fig. 1).

The magnitudes of $\bar{u}$ and $\bar{v}$ are almost independent of scale, and are of the order of 10 m sec^{-1}. Even differences of the horizontal velocities depend relatively little on scale; horizontal velocity differences of the order of 10 m sec^{-1} appear over 100 m as well as over 1000 km.

On all scales there is a tendency for $\bar{u}_3 - \bar{u}_1$ to be opposite in sign and almost equal in magnitude to $\bar{v}_4 - \bar{v}_2$ (*cf.* [5]). It turns out that the numerator of equation (2) is of the order of 1 m sec^{-1}, regardless of scale. Thus the order of magnitude of the divergence is $1/L$ sec^{-1} if L is measured in meters.

On the scale involved in the thunderstorm studies[1] L is of the order of 3000 m, so that actually div V should be near 3×10^{-4} sec^{-1}. The observed values are usually somewhat higher because thunderstorms occur at times of unusual vertical motion. On this scale, 3×10^{-4} sec^{-1} might be regarded as a "normal" order of magnitude of divergence.

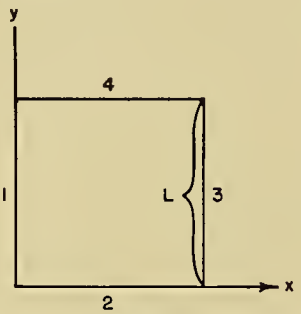

FIG. 1.—Illustration for definition of mean divergence in square area.

On the "weather-map scale" (10^5 m $< L < 10^6$ m) the divergence is between 10^{-5} sec^{-1} and 10^{-6} sec^{-1}. The remainder of this article will be particularly concerned with divergence of this order of magnitude.

On this weather-map scale we may express the equation of continuity in the form (assuming the surface horizontal):

$$w_h = -\frac{\bar{\rho}}{\rho_h} h \overline{\text{div V}}, \tag{3}$$

where w is vertical velocity, h is an arbitrary level, and $\bar{\rho}$ and $\overline{\text{div V}}$ represent density and divergence, respectively, averaged over height. If h is 3000 m and if there is no noticeable difference between the magnitudes of div V and $\overline{\text{div V}}$, the vertical velocity at weather-map scale should be between 0.3 cm sec^{-1} and 3 cm sec^{-1}. Again, vertical velocities much larger than these values appear with smaller scales. Byers finds vertical velocities averaging about 10 m sec^{-1} in thunderstorms.

Direct Measurement of Divergence

Since the divergence is defined in terms of horizontal winds, and since winds can be measured with reasonable accuracy, it is possible in principle to determine the divergence directly from equation (2). Generally, the pseudo-Cartesian coordinates of meteorology are employed in this procedure with x toward the east and y

1. Consult "Thunderstorms" by H. R. Byers, pp. 681–693 in this Compendium.

toward the north. In that case equation (1) has to be modified to

$$\text{div } \mathbf{V} = \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} - \frac{v}{R} \tan \phi, \qquad (4)$$

where R is the radius of the earth and ϕ is the latitude.

Usually, separate maps of u and v are constructed and analyzed, and the partial derivatives are approximated by ratios of finite differences. The differences of velocity components are taken over distances of the order of 100 miles. This method frequently leads to small, irregular patterns [13], the reality of which is doubtful.

A superior technique is based on equation (2). Here it is necessary to find averaged wind components along each side of a square. If the square is so small that only about one wind observation falls along each side of the square, the average wind along each side will be but poorly determined, particularly since the winds are strongly affected by local eddies. In practice, values of divergence can be trusted only if they have been determined from squares with sides 500 km long or longer. Even then, the measurements lead to doubtful results unless the wind coverage is complete in an area somewhat larger than the square.

Another technique of measuring horizontal divergence is based on the expression of mean divergence in "natural" coordinates instead of in Cartesian coordinates:

$$\overline{\text{div } \mathbf{V}} = \frac{\bar{V}_2 S_2 - \bar{V}_1 S_1}{A},$$

where S_1 and S_2 are the distances between two streamlines, measured along orthogonals to the streamlines; $\bar{V}_2$ and $\bar{V}_1$ are the average velocities of outflow and inflow across S_1 and S_2; and A is the area enclosed by the two bounding streamlines, S_1 and S_2 (Fig. 2).

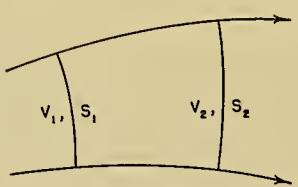

FIG. 2.—Illustration for definition of mean divergence in natural coordinates.

Mantis (see [16]) showed that both the "component technique" (Cartesian coordinates) and the streamline technique (natural coordinates) are about equally inaccurate; even for large areas and good wind coverage the sign of the divergence can be trusted only for relatively large observed magnitudes, for example, greater than 5×10^{-6} sec^{-1}. Recently, an objective method proposed by Bellamy [2] has been used extensively. This procedure is based on a determination of divergence from observations at the corners of a triangle. (For another, much more tedious, objective method see [21].)

Determination of Vertical Velocities

Direct Measurements of Vertical Velocities. Vertical velocities can be measured directly when they are larger than 10 cm sec^{-1}. Some of these methods of measurement are described in Byers' article on thunderstorms.[1] In addition, instantaneous vertical velocities near the ground have been measured by many investigators of turbulence.

Large-scale vertical velocities (horizontal area $> 10^{14}$ cm^2) must be determined indirectly. The two principal methods which have been suggested for estimating these small vertical velocities involve computations (1) from horizontal velocities and the equation of continuity (kinematic method), and (2) from the effect of vertical velocities on temperature, potential temperature, or wet-bulb potential temperature (adiabatic method).

The Kinematic Method of Determining Vertical Velocities. On the scale under discussion here, the vertical velocity at level h can be found from the equation of continuity in the form

$$w_h = -\frac{1}{\rho_h} \int_s^h \rho \text{ div } \mathbf{V} \, dz + w_s \frac{\rho_s}{\rho_h}. \qquad (5)^2$$

Here s stands for surface. The integral can be approximated by a sum, and w_s can be estimated from the horizontal wind field and the slope of the terrain.

A more elegant form of this method is obtained if equation (5) is transformed to

$$w_h = -\frac{\bar{\rho}}{\rho_h} \text{ div} \int_s^h \mathbf{V} \, dz. \qquad (6)$$

The vector $\int_s^h \mathbf{V} \, dz$ is the "resultant vector" which is equal to the horizontal distance from the observer to the position of the pilot balloon at level h, multiplied by the speed of ascent of the balloon. This distance is available directly from the original pilot-balloon runs. The divergence of the resultant vector is computed by one of the techniques described above. The kinematic method yields instantaneous values of vertical velocities, usually averaged over considerable areas. A dense network of actual wind observations is needed, so vertical velocities have been computed by this method only up to 10,000 ft and in regions of good weather. Radar and radio direction-finder pilot balloons should increase the range and applicability of the method.

The Adiabatic Method of Computing Vertical Velocities. The adiabatic method, which is completely independent of the kinematic method, is based on the assumption that rising and sinking air will cool or warm at a known rate. Then a measured temperature change will permit computation of the vertical velocity.

We start from the mathematical identity

$$\frac{dT}{dt} = \frac{\partial T}{\partial t} + \mathbf{V} \cdot \nabla_H T + w \frac{\partial T}{\partial z},$$

where T is temperature and ∇_H is the vector differential

2. Equation (3) is essentially the same as equation (5), but applies only for horizontal ground.

operator applied in the horizontal direction. If temperature changes are adiabatic, dT/dt is given by $-w\gamma_{ad}$ where γ_{ad} is the adiabatic lapse rate. Then

$$w = -\frac{\frac{\partial T}{\partial t} + \mathbf{V}\cdot\nabla_H T}{\gamma_{ad} - \gamma} = -\frac{\frac{\delta T}{\delta t}}{\gamma_{ad} - \gamma}, \qquad (7)$$

where $\delta T/\delta t$ is the change of temperature along a horizontal trajectory and γ is the existing lapse rate.

Air trajectories constructed from observations of either geostrophic or observed winds are not very accurate due to the large time lapse between observations, and the eddy fluctuations of the wind. The inaccuracy of the air trajectories presumably causes errors in the vertical velocities determined by the adiabatic method. Therefore the results could be greatly improved if constant-level balloons [26] were in regular use. Other errors arise from nonadiabatic temperature changes which cannot readily be evaluated. The adiabatic method can be applied in many different forms [10, 11, 14, 20, 23]. Basically, however, all these procedures are subject to similar assumptions and similar errors.

Vertical velocities computed by the adiabatic method are average values over a considerable length of time (usually twelve hours) and over a considerable distance (the length of the trajectory). They are relatively inaccurate at low levels due to nonadiabatic temperature changes there. Furthermore, when the atmospheric stability is nearly neutral, the method does not lead to dependable results.

Unlike the kinematic method, the adiabatic method is not restricted to observed winds; geostrophic winds may be used instead. Since geostrophic winds can be computed even in areas of bad weather, and at high levels, the adiabatic method is useful for drawing daily charts of vertical velocities covering a given region. Moreover, the method has been applied successfully to levels as high as 16 km.

Figure 3, taken from the paper by Panofsky [20] shows a comparison between vertical velocities obtained by the two methods. Both methods yield values of the order of 1 cm sec^{-1}. The figure shows considerable scattering which might be ascribed to inaccuracy of trajectories, small eddies in the wind field, nonadiabatic temperature changes, etc.

Several other methods have been suggested for the determination of vertical velocities. For example, the rainfall intensity is proportional to the mean vertical velocity in a saturated layer [1, 12, 17]. Hence rainfall intensities could be converted into average vertical velocities. Such vertical velocities, however, have some essentially different properties from those computed by the other two methods. For example, if convection produces equal amounts of upward and downward motion, considerable precipitation may fall. Yet the kinematic method would yield a value of zero for the mean vertical motion. This example is important, since occurrence of moderate rainfall without considerable convective activity is not common. Bannon [1] applied this technique and obtained vertical velocities greater than 10 cm sec^{-1}. This large order of magnitude is probably due to the effect of turbulence, or possibly to a somewhat smaller horizontal scale.

Another method of computing vertical velocities is based on determination of divergence from the vorticity equation and integration of the divergence. This technique has been applied by Sawyer [25] to a limited degree. His results agree qualitatively with those obtained by the other methods.

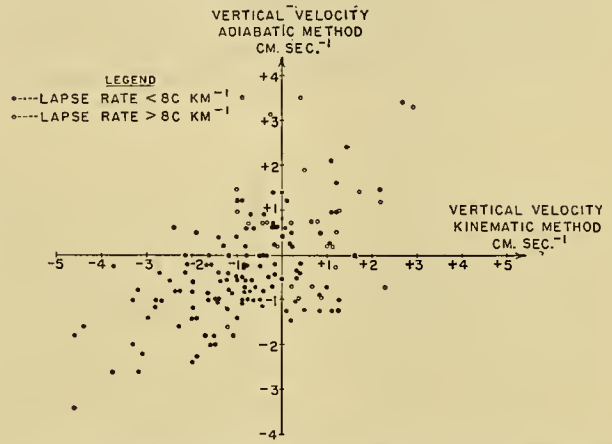

Fig. 3.—Vertical velocity by adiabatic method plotted as function of vertical velocity by kinematic method.

Distribution of Large-Scale Vertical Motion and Divergence

Considerable information is available regarding the distribution of vertical motion in the United States east of the Rocky Mountains at 10,000 ft (700 mb) and to a somewhat smaller extent at 5000 ft [15, 16, 17]. In three selected weather situations, computations were carried out up to 16 km [7]. Similar studies of more limited vertical extent were made in Europe by Hewson [11] and Petterssen [23].

Figure 4 shows a schematic picture of the distribution of divergence and vertical velocity in relation to the pressure distribution. Generally, above 5000 ft the wedge and trough lines coincide with the lines of zero vertical motion, with downward motion east of the wedge line and upward motion east of the trough lines. In other words, above 5000 ft upward vertical motion is associated with geostrophic winds (and observed winds) which have components from the south, and downward vertical motions with winds which have components from the north. Moreover, since pressure systems normally move from west to east, local pressure changes are negatively correlated with vertical velocities. The degree of correlation between vertical velocity on the one hand and meridional velocity and pressure tendency on the other varies from level to level. From 10,000 ft to the tropopause the correlation coefficients vary in magnitude in the range from 0.58 to 0.72.

In the stratosphere, the vertical velocities are generally smaller than they are in the troposphere and are of the same sign, resulting in strong vertical convergence (horizontal divergence) near the tropopause in regions of upward motion. Also, in regions of upward

motion, the equation of continuity requires horizontal convergence at the surface (Fig. 4). Quantitative computations [8] show that divergence in and above the tropopause almost exactly compensates the surface convergence. The same is true for surface divergence and stratospheric convergence. The observations are too crude to permit the exact location of a level of "nondivergence" in the upper troposphere.

For several months, synoptic vertical velocity charts were constructed at New York University at 10,000 ft or 700 mb along with the regular analysis of standard maps. Aside from the correlation between vertical velocities and meridional flow at the same levels, the following qualitative relations between the features of the surface charts and the vertical velocity charts were noted:

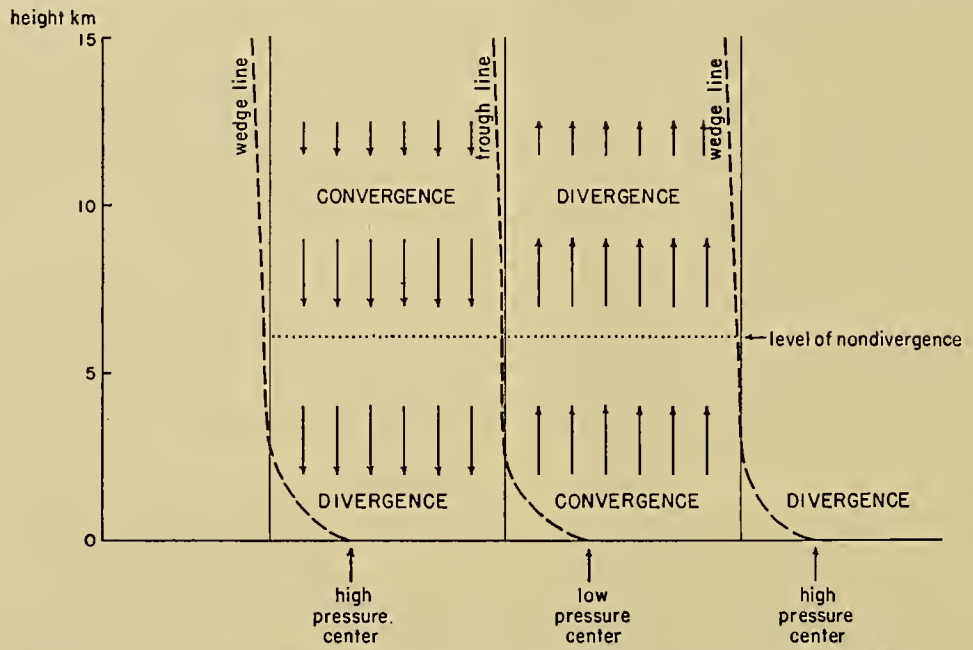

Fig. 4.—Schematic distribution of divergence and vertical velocity in an east-west cross section. Full drawn vertical lines are lines of zero vertical velocity and divergence.

1. Upward motion in cloud and precipitation areas.
2. Upward motion above low-pressure centers and fronts.
3. Downward motion above polar high-pressure regions.
4. Upward motion to the west of wedge lines in strong southerly flow.

In agreement with these results, Petterssen [23] found anticyclonic curvature of surface isobars generally associated with subsidence.

Theoretical Explanations of the Distribution of Vertical Velocity and Divergence

Bjerknes and Holmboe [3] arrived at a distribution of divergence for finite motions under the assumption of the gradient-wind equation. Essentially, there are two contributions to the divergence of the gradient wind: (1) the variation of the Coriolis parameter produces convergence in the northward flow, and (2) the curvature term in the gradient wind equation produces faster motions at the wedge than at the trough lines, hence, for sinusoidal isobars, there is convergence with flow from the north. The curvature term depends on the square of the wind speed, the latitude term on the first power. Thus the curvature term is relatively more important at high than at low levels. Quantitative computations show that near the surface the latitude term determines the distribution of divergence, and that above a critical level the curvature term takes the upper hand. This theory, again, leads to qualitative agreement with Fig. 4. Quantitatively, however, the Bjerknes-Holmboe theory predicts smaller divergence and vertical motion than are actually observed. Part of the discrepancy may be due to the fact that the Bjerknes-Holmboe theory applies to a slightly larger scale than the observations.

Charney [4] arrived at a similar distribution of vertical velocity and divergence from the complete meteorological equations; his work, however, was done by the perturbation method, so it does not permit a quantitative comparison between theoretical and observed vertical velocity and divergence.

Surface friction, which is neglected in these studies, may account for the discrepancy between theory and observations. A simplified treatment based on constant eddy viscosity [16] shows a relationship between $\nabla^2 p$, surface divergence, and vertical velocity above the friction layer; pressure minima are associated with convergence and upward vertical motion.

A simple derivation with no assumption regarding the distribution of eddy viscosity with height shows

that w_H, the vertical velocity at the top of the friction layer, is given by

$$w_H = \frac{1}{\rho f} \operatorname{curl}_v \tau_0,$$

where τ_0 is the surface stress acting on the boundary between air and ground in the direction of the wind, ρ the density, subscript v denotes the vertical component, and f is the Coriolis parameter. It is difficult to evaluate the surface stress quantitatively over land; but since the surface stress is in the direction of the wind and the wind blows counterclockwise about low-pressure centers, this formula also indicates upward motion above pressure minima. Since nonfrictional theories predict upward motion in the southerly flow above low-pressure centers, friction has the effect of increasing the absolute magnitudes predicted by these theories. Possibly a combination of the Bjerknes-Holmboe theory and the theory of friction would account for the observed distribution of divergence and vertical velocity in the troposphere.

The relation between meridional and vertical motion has been observed so far only in the United States and England, where the isotherms run essentially from east to west. It may be asked whether a similar relationship would hold when the isotherms run in some other direction.

Charney's theory is based on the assumption that the isotherms run from east to west. According to the Bjerknes-Holmboe theory the distribution of divergence depends on sinusoidal air motion superimposed on an east-west channel; upper-level streamlines behave in this way only when the isotherms run from east to west. Consequently both these theories show a relation between vertical and meridional velocities only if the isotherms are parallel to the latitude circles. In general, both theories would predict a relation between vertical motion and the horizontal wind component at right angles to the isotherms, or between vertical motion and horizontal temperature advection. Only when the isotherms run from east to west is a relation expected between vertical and meridional motion.

Effects of Divergence

Divergence and Pressure Change. One of the reasons why meteorologists have been interested in divergence is that it is related to pressure change through the Bjerknes pressure-tendency equation:

$$\left(\frac{\partial p}{\partial t}\right)_h = (g\rho w)_h - g\int_h^\infty \operatorname{div} \mathbf{V}\rho \, dz - g\int_h^\infty \mathbf{V}\cdot\nabla_H \rho \, dz, \quad (8)$$

or

$$\left(\frac{\partial p}{\partial t}\right)_s = -g\int_s^\infty \operatorname{div} \mathbf{V}\rho \, dz - g\int_s^\infty \mathbf{V}\cdot\nabla_H \rho \, dz, \quad (9)$$

where s stands for the surface which is assumed horizontal. Fleagle [8] showed that the vertical velocity term in equation (8) almost exactly compensates the divergence term, and in (9) the low-level divergence almost exactly compensates high-level divergence. Therefore neither equation can be applied to determine pressure changes from measured divergence. Moreover, most theories of divergence are not sufficiently accurate to permit estimates of pressure changes from these equations.

Divergence and Change of Vorticity. Another reason for interest in divergence is the effect it has on the individual change of absolute vorticity. The vorticity equation may be written (if we neglect solenoidal fields, friction, and terms depending on the horizontal variation of vertical velocity)

$$\frac{1}{\zeta + f}\frac{d\zeta}{dt} = -\frac{v}{R(\zeta + f)}\frac{\partial f}{\partial \phi} - \operatorname{div} \mathbf{V}, \quad (10)$$

where ζ is the vertical component of vorticity and v is the meridional velocity component.

Rossby's trajectory method was derived from the vorticity equation on the basis of negligible divergence. Some investigators attribute the systematic errors of the method in certain regions to the omission of divergence [18]. Studies at New York University seem to indicate that the divergence term is at least of the same order of magnitude as the term containing the variation of the Coriolis parameter with latitude, even for very large scales (areas of the order of 10^{16} cm^2). The omission of the divergence term is justified only near the level of nondivergence or when equation (10) is integrated vertically through the whole atmosphere.

Divergence and Change of Stability. Local changes of stability can be brought about by three factors [6]: (1) vertical divergence, (2) different horizontal temperature advection at different levels, and (3) vertical advection of lapse rate. Since vertical divergence almost equals the negative horizontal divergence, the latter may be considered as a factor producing stability changes. Fleagle [6] found that the effect of horizontal divergence on stability changes is of the same order of magnitude as that of differential advection; he also noted that accurate forecasts of local stability changes based on measured divergence and differential advection are inaccurate, probably due to the large errors in measurements of divergence.

Effects of Vertical Velocity

Vertical Advection of Velocity. Many of the meteorological equations contain vertical advection terms which have frequently been neglected. For example, the acceleration of the horizontal wind vector may be written

$$\frac{d\mathbf{V}}{dt} = \frac{\partial \mathbf{V}}{\partial t} + \mathbf{V}\cdot\nabla_H \mathbf{V} + w\frac{\partial \mathbf{V}}{\partial z}.$$

Charney [5] indicated that the term containing w should be one order of magnitude smaller than the other terms in the expression. This conclusion, based on a dimensional argument, is at variance with results obtained at New York University. Vertical velocities average about 1 cm sec^{-1}; the vertical shear of horizontal wind

is near 5×10^{-3} sec^{-1}. Hence, the term averages around 5×10^{-3} cm sec^{-2} in magnitude, about half as large as the other acceleration terms. Neglecting the vertical advection terms may lead to considerable errors.

Vertical Advection of Temperature and Potential Temperature. Vertical advection of temperature and potential temperature is also important, as was shown by the fact that reasonable values of w have been obtained by the effect of vertical motion on the temperature field. Again, the effect of vertical motion on local temperature changes averages about half the effect of horizontal advection [7, 19].

Vertical Motion and Pressure Changes. Since the vertical velocity has an important effect on the temperature field, and since changes in the temperature field are associated with pressure changes, Raethjen [24] first suggested a pressure-tendency equation in which the pressure tendency is expressed in terms of an integral with respect to height of local density changes. The density changes in turn are computed from horizontal advection and the effect of vertical motion. The equation can be written

$$\left(\frac{\partial p}{\partial t}\right)_{h_1} = \left(\frac{\partial p}{\partial t}\right)_{h_2} - g\int_{h_1}^{h_2} \mathbf{V}\cdot\nabla_H \rho\, dz + g\int_{h_1}^{h_2} w\rho E\, dz + g\int_{h_1}^{h_2} (1-k)\,\frac{\rho}{p}\,\frac{\partial p}{\partial t}\, dz, \tag{11}$$

where g is the acceleration of gravity, h_1 and h_2 are arbitrary levels, k is the ratio of the gas constant to the specific heat at constant pressure, and E is the stability $(\gamma_{ad} - \gamma)/T$. This equation avoids the low-level, high-level compensation of the Margules-Bjerknes tendency equation. However, the vertical velocity is not known sufficiently well to permit forecasts of pressure tendencies from (11) or a modification of it; on the contrary, Panofsky [19] used this equation to compute the vertical velocity from the pressure tendency. Later Fleagle [8] discussed the relative importance of vertical and horizontal motion on pressure changes in selected situations, and Godson [9] considered the conditions favorable for cyclogenesis, on the basis of a similar equation. These studies indicated that vertical motion has effects on local pressure changes of the same order of magnitude as horizontal motion.

Vertical Velocities and Changes in Cloudiness. Large-scale vertical velocities have their most conspicuous effect in the production of cloudiness. Since air cools when it rises, increasing cloudiness should be associated with positive vertical velocities. Panofsky and Dickey [22] and Miller and others [17] showed that middle cloudiness tends to increase along the trajectories of rising air and decrease along the trajectories of sinking air. However, vertical velocities do not seem to discriminate between overcast with or without precipitation. Figure 5, taken from Miller [15], shows this effect

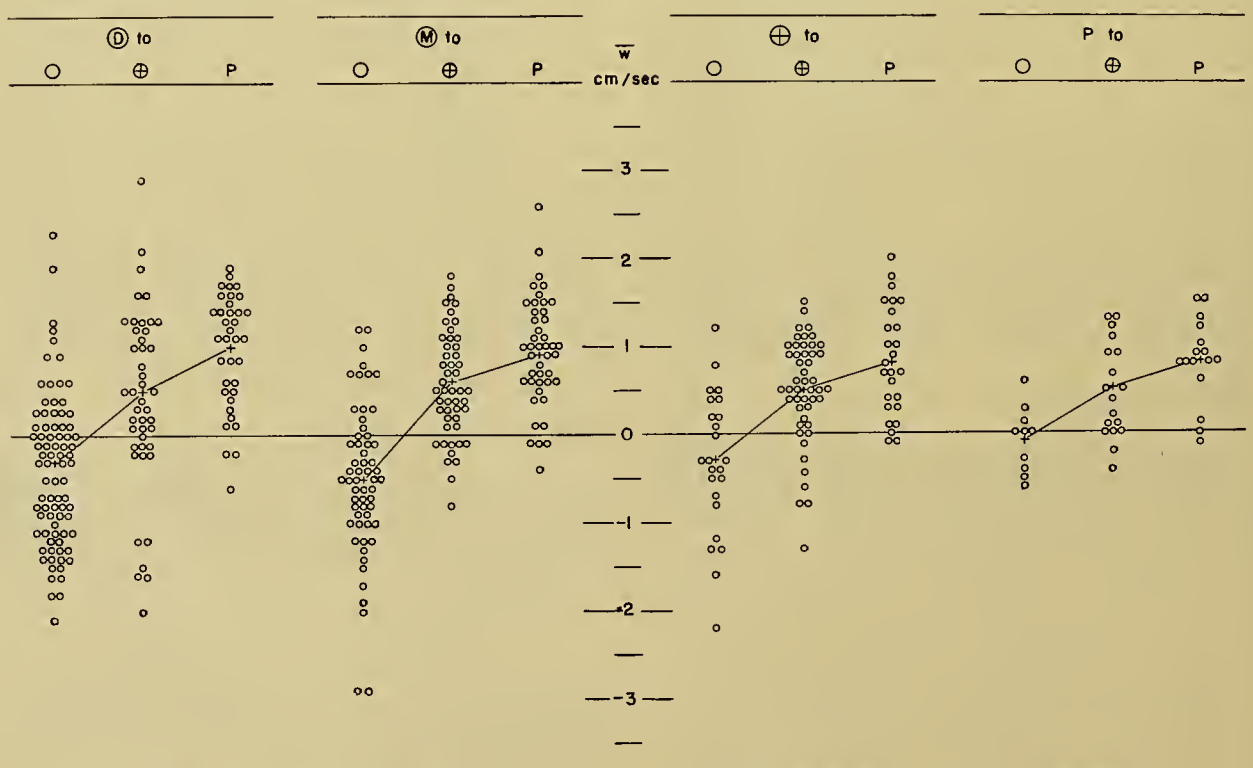

FIG. 5.—Changes of weather following 24-hr isobaric trajectory at 700 mb as function of vertical velocity. The circled D means clear with relative humidity 30 per cent or less, the circled M clear with relative humidity greater than 30 per cent, ○ clear irrespective of relative humidity, ⊕ overcast, and P precipitation. The slanting lines connect mean vertical velocities corresponding to the weather changes indicated at the heads of the columns.

graphically. According to this figure, clear weather at the end of the trajectory was usually preceded by slightly negative vertical velocities, and cloudy weather or precipitation by vertical velocities averaging about $+1$ cm sec^{-1}. These values reflect average conditions only; the figure shows instances where the final weather was clear with upward vertical velocities between 1 and 2 cm sec^{-1}, and a few cases of final precipitation with slightly negative vertical velocities. Apparently, the relation is not perfect, largely due to errors in constructing trajectories, and errors in the vertical velocities.

Vertical Velocities as a Forecast Tool

The relation between vertical velocities and changes in cloudiness suggests the possibility of applying measured vertical velocities to forecasting weather changes objectively. If the air has an upward component of motion, we might expect bad weather soon. One difficulty suggests itself immediately. If vertical velocities are computed by the adiabatic method, observations at the end of a 12-hr period are needed in order to compute average vertical velocities for that period. These vertical velocities are centered in the middle of the period and are therefore already 6 hr old at the time the analysis is started. A further lag is caused by transmission time, analysis and computation, so that the vertical velocities are at least 8 hr late when they are ready for application to "forecasting."

As Fig. 5 indicates, cloud changes are related to the average vertical motion along the air trajectory. If a 24-hr forecast is desired, a 24-hr air trajectory must be forecast and the average vertical velocity along the trajectory must be estimated from quantities at the beginning of the trajectory.

Since the forecasting method was to be objective, it was necessary to devise a method of forecasting trajectories objectively. It would require too much space here to describe the method finally applied; but it is clear that errors in the forecast trajectory will lead to inaccurate future positions of the air and hence to additional errors in the forecast.

Experiments with different variables indicated that an estimate of the mean vertical velocity along the trajectory could be made from the initial vertical velocity and the initial meridional velocity. The multiple correlation coefficient of mean vertical velocity on initial vertical velocity and meridional wind components was 0.64 [15]. Clearly, an estimate of the mean vertical velocity based on these two variables is subject to considerable error.

In practice it was possible to side-step the computation of the average vertical velocity along the trajectory. Since the average vertical velocity is a function of initial vertical and meridional velocity components, and the change of weather is a function of the average vertical velocity along the trajectory, weather changes should be directly related to the initial meridional and vertical velocity components. Charts were constructed for the first half of December 1945, which showed the final weather and cloudiness as a function of initial weather and of the vertical and meridional components of velocity. In certain regions of these charts clear sky (cloudiness 0.4 or less) was predominant; in other regions overcast and precipitation predominated. A line was drawn which separated the sections of predominantly clear sky from sections of sky mainly overcast. It was quite difficult to find dividing lines between overcast and precipitation on these charts. Such lines were drawn, however, under the assumption that precipitation should occur with large upward vertical velocities along the trajectories.

Forecasts were made from these charts for the last half of December 1945. The total percentage of correct forecasts was 69.9 per cent. The chance score was 57.3 per cent.

A more severe test is the comparison of the percentage of successful forecasts with those obtained from "low skill" forecasts. For example, if "clear" had been forecast all the time, the score would have been 69.2 per cent; if no change of local weather had been forecast, the percentage of hits would have been 59.7 per cent. The same forecasts were repeated by two graduate students who had considerable forecasting experience. These forecasters had no knowledge of the vertical velocities at the time. The two forecasters scored 63.4 per cent and 69.8 per cent correct, respectively.

Altogether, the objective method of forecasting vertical velocity did not perform badly, in spite of the many sources of error. Later studies [16] showed the method considerably less successful. Moreover, Miller showed that equally good forecasts could be made by a very similar method, if the initial vertical velocities were not known at all, but the forecasts were based solely on the initial weather and meridional velocity component. Therefore the laborious computation of vertical velocities for forecasting purposes is possibly unnecessary. Apparently, the meridional velocity component is a sufficiently good indicator of the direction of the vertical air motion. The relation between meridional motion aloft and weather is known to many meteorologists, and has been incorporated, indirectly, into other objective forecasting methods.

Some attempts were made to use vertical velocity patterns qualitatively. On daily vertical velocity charts the "unusual" features that did not conform to the simultaneous weather were noted. For example, an area of upward motion over an east coast wedge was judged significant. Such unusual features were followed sometimes, but not always, by unusual developments; for example, unusual centers of upward motion were associated with cyclogenesis. Several forecast rules based on unusual vertical velocity patterns were suggested, but none of them proved reliable. Whether this was due to errors of the vertical velocities cannot yet be decided.

Suggestions for Future Research

Since most of the studies of vertical velocity were completed the network of radio and radar wind observations has been greatly extended. As a result, de-

termination of divergence and vertical velocity by the kinematic method would seem possible in forecasting techniques. The advantage of the kinematic method is the possibility of computing vertical velocities within only a few hours after the time to which they apply. This and the rather indecisive results of the earlier forecast studies might make it desirable in the future to study forecasting techniques based on vertical velocities.

Another possibility, which has been only partially tested thus far, is the application of the vorticity equation (10) to the forecast of changes of vorticity from observed divergence.

So far, systematic work on vertical velocities has been restricted to middle latitudes in the Northern Hemisphere. It is quite possible that the observed relation between vertical and meridional velocities, for example, is not valid everywhere. Studies in other parts of the world are desirable in order to determine whether there exists a general relation between vertical and meridional motion or vertical velocity and advection. Moreover, a study of the relation between vertical velocities, divergence, and weather is desirable in other sections of the globe.

In general, a better understanding of vertical motion will presumably arise out of the work which Dr. Jule Charney and his collaborators are doing at The Institute for Advanced Study on numerical forecasting based on the physical equations.

THE INSTABILITY LINE

By J. R. FULKS

U. S. Weather Bureau, Washington, D. C.

Introduction and General Features

The synoptic meteorologist frequently encounters nonfrontal squall lines, particularly in the warm sectors of certain types of extratropical cyclones. These nonfrontal squall lines, now designated by the International Meteorological Organization as *instability lines*, are relatively frequent in the United States east of the Rockies and may be severe in character. Some are accompanied by tornadoes and presumably extreme vertical instability through a relatively deep layer of the atmosphere.

A well-developed instability line is marked by squalls or thunderstorms along a line that is usually several hundred miles in length, and in the typical case fifty to three hundred miles ahead of a surface cold front. Or, where scattered showers or general rains are already occurring, the instability line represents a sharp intensification of squall conditions and rainfall, lasting usually for about an hour at any one location. Since these conditions may occur, for the most part, between regular synoptic reports, the best evidence is often in the reported time, character, and amount of rainfall, or in frequent intermediate reports. The pattern of reported thunderstorms is usually also an indication of the existence and location of an instability line, but in some situations scattered thunderstorms occur before and after its passage. By convention the line is taken to be the leading edge of the band, usually thirty to fifty miles in width, of greatest convective activity. In more complicated cases, there may be several bands of squalls. Aircraft encounter marked and sometimes dangerous turbulence in flying through an instability line.

The term *instability line* is also applied to the incipient condition, when synoptic factors indicate that a nonfrontal squall line is forming, and may be applied to the line of instability in the dissipating stage when squalls have ceased.

Alternately, the term *instability line* is defined as a pseudo-cold front for which the cold air is presumably produced by precipitation falling from a line of accompanying showers. While the pseudo-cold front marking the leading edge of the outflowing rain-cooled air from instability showers is observed in most nonfrontal squall lines, it appears to be normally a secondary effect, other factors probably being more important in forming and maintaining the line of squalls. However, there are some cases where thundershowers develop over a localized region of, say, 10,000 or 20,000 square miles forming a surface layer of cool air which flows outward in all directions, new thundershowers then tending to develop along the resulting pseudo-cold front where the wind direction in the warm air is favorable to lifting over the cooler surface air.

Unlike a true front, the instability line is transitory in character, usually developing to maximum intensity within a period of twelve hours or less and then dissipating within about the same period of time. Although by definition it is nonfrontal in character, it may cross a front. Often the line extends from the warm sector of a low northward across the warm front and is associated with a line of squalls in the northeastern quadrant of the low.

Harrison and Orendorff [5] in 1941 studied the "precoldfrontal squall line," especially from the standpoint of airline operations. In addition to describing the squall line and associated conditions, they examined physical factors possibly contributing toward its development. Without attempting to reach definite conclusions they presented data which suggested a pseudo-cold front of rain-cooled air moving against a rainless zone in the same air mass, and convergence within a potentially unstable air mass, as being at least possible causative factors in most of the cases studied. One of the significant facts they reported was that activity along the cold front decreases during the active stage of the squall line but regenerates as the squall line dissipates. Their study was confined to the Cheyenne–New York airway (between April 1939 and May 1940) and probably was not fully representative of squall-line conditions elsewhere; for example, they reported no sustained temperature change through the squall line aloft. The heights of upper levels considered were not fully specified; presumably they were flight levels and thus often below heights at which cooling is frequently observed in the general region of the instability line.

Lloyd [6], in his studies of tornadoes, attributed at least the tornado-producing squall-line condition to an upper cold front. Advection of colder air aloft and the resulting decrease of temperature, as would be required by existence of an upper cold front, is observed in many cases. But cooling aloft also takes place, in some instances, ahead of the squall condition, indicating that the degree of instability near the leading edge of the cooling aloft is not always sufficient for convective activity. Back from the leading edge, temperatures aloft may be lower, and surface temperatures higher, so that at some point the critical lapse rate necessary for convection may be realized. The exact distance between the squall condition and the leading edge of the colder air aloft is difficult to determine by observation, but appears to vary from a few miles (possibly less) to hundreds of miles. Where the leading edge of advection of colder air aloft is very close to the squall condition, and there is evidence of a discontinuity in density as required for a front aloft, the condition is not properly classified as "nonfrontal." In many instances, however, the existence of a discontinuity aloft along or near the

squall condition is difficult or impossible to determine from synoptic data and the only practical recourse for the synoptic meteorologist is to follow the instability line.

Synoptic Aspects and Some Associated Physical Factors

Figure 1 represents diagrammatically a typical well-marked instability line in the warm sector of an extra-

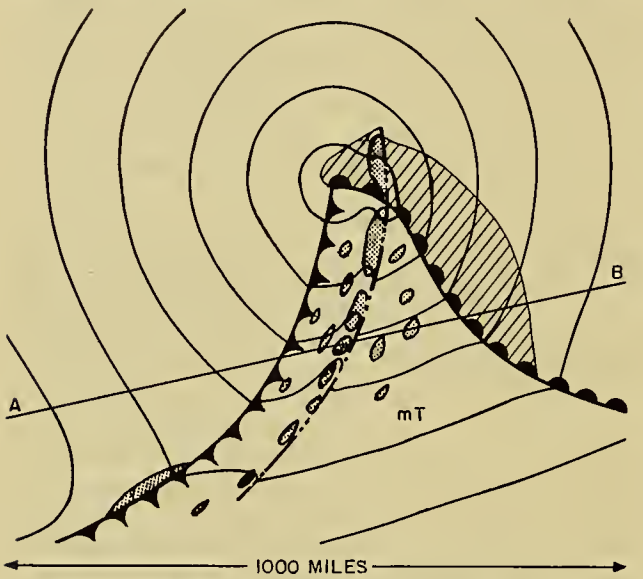

FIG. 1.—Model of cyclone with instability line in warm sector. Shading indicates areas of active squalls, and hatching shows warm-front precipitation.

tropical cyclone. Squalls and thunderstorms (shaded area) are shown as a nearly solid band along the instability line and at scattered points elsewhere in the warm sector and within the area of warm-front precipitation (hatched). In this type of low, and at this stage of development, precipitation is rarely observed behind the portion of the cold front following the instability line.

Figure 2 is a vertical cross section through the line *AB* of Fig. 1. Thin solid lines represent isotherms of

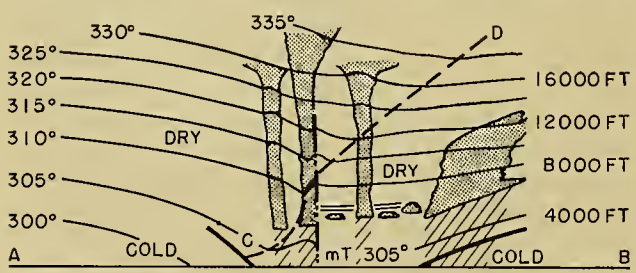

FIG. 2.—Vertical cross section through cyclone with warm sector instability line. The section is taken along the line *AB* of Fig. 1 and is on the same horizontal scale; the vertical scale is indicated roughly in feet on the right-hand side. Thin quasi-horizontal lines are potential temperature, labeled in °K on the left. The dashed line *CD* is the axis of warm air, temperatures decreasing or changing but little horizontally to the right, and decreasing to the left of *CD* (except near the ground where temperature decreases sharply with onset of instability line squalls). Shading indicates cloud masses, and hatched lines show active precipitation; the double horizontal line indicates a stable layer.

potential temperature. The line *CD* is the center of a warm tongue which extends roughly at right angles to the given vertical section. Thus, any constant level or constant pressure surface cutting the vertical section will have a warm tongue, the axis of which intersects the line *CD*. Generally the horizontal temperature gradient to the right of *CD* is less than to the left of *CD*. As the system moves from left to right (normally eastward) cooling aloft over any fixed point will begin as the line *CD* passes, and since the cooling takes place first at the higher levels, there will be a progressive decrease in vertical stability until the arrival of the instability line. Often, at least in the central and eastern United States, there is a stable layer or inversion at approximately 1½ km above the surface and to the east of the instability line; this inversion disappears with the arrival of the instability line. It is probable that this stable layer, when it exists, plays an important part in the mechanism of the instability line, because it provides a "cap" under which the temperature and moisture content may increase until, combined with any cooling aloft, the vertical instability is sufficient for vertical convection. This effect is made possible by slower eastward movement of the surface air as compared to the system as a whole, and is enhanced by conditions usually favorable for low-level advection northward of moisture and warmer air, as pointed out by Means [7]. Apparent warm advection is in some cases, however, indicative of lifting rather than low-level warming.

The cooling aloft, as illustrated in Fig. 2, is in part the result of horizontal advection, as may readily be verified by inspection of constant-level or constant-pressure charts. The typical condition is one of cooling by advection aloft over a region where there is warming by advection at lower levels. The warming by advection at low levels is generally greater in magnitude than the cooling aloft, but cooling aloft is significant in that it permits vertical convection to extend to higher levels than would otherwise be possible, thus becoming an important factor in the intensity of resulting convective activity. It seems certain, however, that factors other than advection are also important in the cooling which takes place aloft over the warm sectors of many lows. An early example of cooling aloft ahead of a surface cold front, accompanied by warm-sector precipitation was presented by J. Bjerknes [1] in 1930. This study was based on a detailed examination of frequent soundings at Uccle, Belgium, during the period December 26–28, 1928.

The cold front as shown in Fig. 2 does not extend far above the surface. When the instability line is well developed, there is usually little or no evidence of the existence of the associated cold front at more than two or three thousand feet above the ground. The position of the cold front at the ground is usually quite well marked by a wind shift, pressure trough, and change of moisture content (dryer on the cold air side). Usually there is little, if any, temperature change immediately across the front, but there is a horizontal temperature gradient toward colder air to the rear, suggesting that,

in many cases at least, there is no true discontinuity of density but rather a discontinuity in the gradient of density. In synoptic practice it is customary, however, to continue to carry and designate this line as a cold front, because at a later stage in the history of the low the instability line tends to dissipate and the "front" again takes on the characteristics of a true cold front.

Along the instability line, when it is well developed, there is marked cyclonic wind shear at low levels, associated with a pressure trough. At higher levels, as in extratropical cyclones generally, there is a pressure trough which roughly parallels the surface cold front. In many cases of well-marked instability lines, the pressure trough aloft coincides with the instability line. In some cases it is back of the surface cold front, as is normal in lows which do not have an instability line.

As with shower conditions generally, surface temperatures usually fall with the arrival of the instability line, and this fact, combined with the cyclonic wind shear, suggests a surface frontal structure. However, the temperature often rises after passage of the instability line and remains high until after passage of the cold front; moisture content also remains high until after passage of the cold front.

The fact that cyclonic wind shear is observed at the surface along a well-developed instability line provides one clue to its location on the surface synoptic chart. Or, when a line of squalls is not yet in existence, the appearance of a line of cyclonic wind shear within a warm moist air mass, particularly in the warm sector of a low, may indicate the existence of an incipient instability line. The instability line is either in a pressure trough, or if parallel to the isobars, is along a discontinuity in pressure gradient. The wind shear in the horizontal is similar to that along a front, but unlike a front, the wind discontinuity is more nearly vertical except along the outrush of cooler air at very low levels ahead of individual squalls.

With the density of reporting stations in the United States, the position of the line of shear can ordinarily be located on the synoptic chart only within a range of fifty or one hundred miles, using only reported pressures and winds. A more exact location of the instability line requires detailed examination of individual reports, particularly for the time of onset of squalls associated with the line and for the time of the wind shift.

Since the instability line is associated with a horizontal discontinuity in pressure gradient moving with the line, it might be expected to exhibit a tendency field similar to any pressure trough, that is, falling pressure ahead and rising pressure behind, or falling ahead and falling less rapidly behind, etc. When there is a sharp pressure trough, a tendency field of this type can be detected, but in general the three-hour tendencies represent a confused pattern that may be misleading if not considered with caution. When the line is accompanied by severe squalls, there may be rapidly falling pressure ahead of the line, a sharp rise with the onset of squalls, then a rapid fall within an hour or so, all of which may take place within the three-hour period for which the tendencies are reported. Also, the severity of the weather along the line tends to vary from station to station, and there are corresponding irregularities in the reported tendencies. The tendencies are, however, a useful guide if viewed with caution and if allowances are made for known squall activity at individual stations. Their use as a guide to location of the instability line should be looked upon as subordinate to the more direct location of the pressure trough or line of wind shear, or the observed onset of squalls at individual stations.

Upper winds, when available, are useful in locating the line of wind shear at the gradient level if reports are not too far apart. Surface winds are similarly helpful if allowance is made for local topographical effects and for the fact that isolated squalls may occur ahead of or behind the instability line.

There is no clear guide to the speed of movement of the instability line other than its past history and the known speed of movement of a low with which it may be associated. The pre-coldfrontal squall line moves slightly faster than the cold front which it precedes. The movement of the instability line is at about the same speed as the axis of the warm tongue aloft, which is normally along or ahead of the instability line and moves with a speed somewhat less than that of the wind speed aloft normal to the axis. The movement of the axis of warm air aloft is not particularly useful for forecasting the movement of the instability line once the line is in existence, but for longer-period forecasting its movement is some guide to the time and location of possible future squall-line developments.

Over the western Great Plains and the Mississippi Valley, a cold front aloft or the advection of colder air aloft often has its inception as a surface cold front over the western mountain region. The surface front, marking the arrival of fresh maritime polar (mP) air from the Pacific, moves across the Plateau region. The shallower portion of the cold air, near the leading edge, becomes heated by the warmer ground over which it moves, and also by compression as it flows downward along the east slope. The heating effect is less within the deeper portion of the cold air so that a horizontal temperature gradient is established within the cold air. The leading edge of the cold air while over the Plateau region remains colder than the surface air ahead of the front, but as the front moves down the east slope of the Plateau it encounters maritime tropical (mT) air which overlies the western plains region and which may intersect the east slope at an elevation of from three to five thousand feet above sea level. Typically, under these conditions, there is a stable layer near the top of the mT air, and the mT air below this stable layer has a potential temperature lower than that of the leading edge of the cold air, so that the leading edge of the cold air seeks out a level within the moist mT air or above it where the potential density is the same as at the base of the cold air. Thus the leading edge of the mP air overrides the surface mT air. Occasionally there is sufficient instability and moisture in the overriding mP air for the development of high-

level showers or thunderstorms entirely within the polar air aloft.

Somewhere within the *mP* air mass, usually between fifty and three hundred miles from its leading edge aloft, the potential density is equal to the potential density of the *mT* air at the ground over the Great Plains region. The *mP* air at that point begins to displace the *mT* air at the ground. The line thus formed between surface *mP* and surface *mT* air has in general the characteristics of an occlusion of the warm-front type, though temperatures at the ground are usually the same immediately on either side of the line. There is usually a marked temperature gradient toward colder air on the *mP* side, and a sharp difference in moisture content between the moist *mT* and the dryer *mP* air. This "front" is not accompanied by precipitation but may mark the end of showers in the *mT* air mass. As the system moves eastward or northeastward across the western Plains and Mississippi Valley a more important surface cold front normally becomes evident in the system between the *mP* air and a colder *cP* air mass to the north.

The conditions thus produced as a result of the eastward flow of cold air off the Plateau become somewhat similar to those pictured in Figs. 1 and 2, and a well-marked instability line tends to develop. The height at which the cold air aloft advances farthest ahead is, however, considerably lower than is shown in Fig. 2. Above that level the boundary of cold air slopes upward to the left as with a conventional cold front.

The existence in the United States of an extensive area of low elevation open on the south to a plentiful supply of warm moist air and bounded on the west by a plateau, combine to make the United States east of the Rockies a favorable region for the production of well-marked instability lines. This is not only because of the tendency for cold air off the Plateau to override *mT* air, but apparently also because the Rockies provide a north-south barrier to lower-level air masses, favoring southward flow of cold air and northward flow of warm air, the zone of interaction between the pure *mT* air and the cold air being most often within the latitude of the United States.

Unique geographical and topographical conditions are, however, by no means necessary to the formation of the instability line. It may be found anywhere in middle or subtropical latitudes and perhaps in other regions. But tornadoes in the United States appear to develop most often with the type of instability line that results when cold air from the Plateau overrides *mT* air over the Great Plains.

Further Discussion of Physical Processes

The pseudo-cold front, suggested by Harrison and Orendorff [5] as important in formation of the pre-coldfrontal squall line, is observed in nearly all cases. Unquestionably its relation to other factors involved must be considered in any complete explanation of the mechanism. However, it seems equally certain that this factor must be secondary to other initial causative factors, because the existence of the shallow layer of rain-cooled air in the proper location appears to be the result of showers already occurring. The same authors suggested that convergence within a potentially unstable air mass might act together with the formation of the pseudo-cold front as a pair of factors to produce the squall line. This might be taken as a suggestion that convergence first produces the line of squalls and that the resulting pseudo-cold front then assists in maintaining the squalls and perhaps in keeping them along a line rather than allowing them to disperse in a disorganized manner. Low-level convergence is of course a necessity along the instability line and needs, itself, to be explained in terms of other factors. Are there other factors which first act to produce low-level horizontal convergence and upper-level divergence, or is vertical motion merely the result of vertical instability and thus the full cause of the convergence-divergence pattern?

The Olivers [9], in discussing forecasting of frontal weather from winds aloft, stated that if the wind component perpendicular to a cold front increases with height through the frontal surface, no weather is produced by the front, but that convergence in the frontal trough may produce weather in the warm sector which ceases abruptly on passage of the surface cold front. They extended this argument further as an explanation of the pre-coldfrontal squall line, that is, the air flowing downslope over the frontal surface may extend to near the ground for some distance ahead of the front and, being dry as a result of subsidence, would prevent shower conditions from forming along or immediately ahead of the cold front, while convergence in the trough would continue to produce showers in the *mT* air. This explanation, as far as it goes, seems to agree well with observation, and if some of the rain falls through the dry subsiding air the condition would be favorable for formation of a pseudo-cold front in the warm sector as envisioned by Harrison and Orendorff. A difficulty is that air at the ground back of the squall line is indistinguishable from the *mT* air at the ground ahead of the line, except for cooling which can be accounted for by rain. However, this difficulty is not serious if the dry air does not extend all the way to the ground, or if its moisture content is increased sufficiently by the rain falling through it.

It has also been suggested by various persons that, from vorticity considerations, the stronger flow of air above the frontal surface will tend to form a pressure trough as it flows into the warm sector, the argument being that subsidence will be greater at low than at high levels, resulting in vertical stretching and therefore increased cyclonic vorticity along and immediately ahead of the surface cold front. This argument is strengthened by its analogy to the explanation of the pressure trough which normally forms in the lee of extensive mountain ranges.

H. B. Wobus (U. S. Weather Bureau, Washington, D. C.) suggested to the author some years ago that the existence of a warm tongue in the mean temperature through a deep layer is favorable for the production of instability along a line near the axis of the tongue, if

it is assumed that the wind at all levels is instantaneously adjusted to the gradient value. Instability lines normally occur near the axis of a warm tongue as represented in the horizontal distribution of mean virtual temperature through a layer, say, 20,000 ft in depth. The curvature of the component of gradient wind flow perpendicular to the axis of the warm tongue must, because of this temperature distribution, become more anticyclonic (or less cyclonic) with height. The component of *gradient* flow across the axis must therefore tend to increase with elevation, and to carry the upper colder air over the lower-level position of the axis of warm air, thus decreasing the vertical stability. Also, in a manner pointed out by Rossby [10], a decrease of mean virtual temperature northward along the axis, as is generally observed, must cause an increase of geostrophic wind from the west and thus normally act in the same direction as the effect of curvature to produce greater eastward advection of colder air aloft as compared to lower levels. These considerations do not, of course, take account of important nongradient components of flow that must exist.

Conditions near the center of a warm tongue are also favorable for upward vertical motion if the energy of the solenoidal field can be realized, and these same conditions provide a means for eviction of air aloft because of nongeostrophic components of flow as pointed out by Durst and Sutcliffe [2]. Release of latent heat of condensation tends to maintain the solenoidal field. Some low-level convergence into the warm axis can be accounted for by frictional effect in the pressure trough. Further low-level convergence is a possibility in the layer above surface frictional effects in the presence of dynamic instability as pointed out by Solberg [12]. However, it is not known from observation that the horizontal component of dynamic instability (as first discussed in this country by Fulks [4]) is of general importance in the case of instability lines, the requirement being that there is appreciable anticyclonic vorticity in the horizontal wind field. Probably this factor is important in the immediate vicinity of the squalls but, in general, instability in the vertical appears to be predominant.

Some Remarks on Tornadoes

Tornadoes occur normally along instability lines and must therefore involve some of the same dynamic factors, though not all instability lines are accompanied by tornadoes. Studies or discussions of the mechanics of tornadoes by Bigelow, Humphreys, Jakl, Showalter, and others in this country, Wegener in Germany, some Russian investigators, and others have given some hint of the factors involved, but much more work remains to be done. Basically, there are two main factors to be explained:

1. *Source of energy.* This has usually been assumed to be vertical instability, such as is known to exist in the vicinity of instability lines. This explanation is, however, not sufficient unless it can be shown that the difference between instability lines which produce tornadoes and those which do not is a matter of degree of vertical instability, or that other factors are absent in one case and not the other. Showalter [11] suggested that precipitation carried aloft and falling ahead of the squalls, cooling the air at higher levels, might be a means of producing a high degree of instability more or less spontaneously. In any case some nearly spontaneous local release of energy seems necessary. Another possible means of creating a vertically unstable lapse rate is for the convectively unstable air mass ahead of the squall line to be lifted bodily. This would itself require some source of energy and seems less likely than the cooling by precipitation aloft for which convective instability is also important in producing a steep vertical lapse rate. An important possible source of energy other than vertical instability, which cannot be ruled out without further study, is that of the already existing wind circulation in the vicinity of tornado formation. Existing kinetic energy fed into the whirl would appear to be at least a contributing factor once the tornado is formed.

2. *Source of rotation.* It seems necessary that the rotation of the tornado results from low-level horizontal convergence within an already existing field of cyclonic (or occasionally anticyclonic) vorticity. The convergence appears to take place first in the upper portion of the warm moist air, roughly 2000–5000 ft above the ground (above surface frictional effects), and the whirl appears to extend rapidly upward and to bore downward to the ground. Tornadoes normally occur along or near a line of cyclonic shear, but this shear line is usually between the warm air moving rapidly northward and the wedge of rain-cooled air moving eastward. Since the required vorticity, to be effective, must be entirely within the warm air because any injection of cooler air at lower levels would tend to damp out convection, it is unlikely that the line of cyclonic shear is a direct source of the vorticity. A more likely source of vorticity is in the interaction between the warm and cool air, especially in warm tongues that must break off from the northward-moving warm air mass and flow into individual convective cells. This turning from northward to westward would produce cyclonic curvature in the warm air as well as some shear, cyclonic on the southern side of the tongue and anticyclonic on the northern side, the latter being a possible factor in producing the rarely observed anticyclonic rotation. In this connection it is also necessary to consider the irregular nature of outflowing tongues of cold air as described by Williams [15] and their possible effect on warm air flow. Another source of rotation that has long been considered is that of the roll cloud of the thunderstorm, the roll being presumed to extend down to the ground, resulting in a cyclonic whirl on one end, or an anticyclonic whirl if the other end should reach the ground; this theory has not been fully refuted or confirmed, but appears unlikely in the light of descriptive reports.

Some Recent Studies

Tepper [13] recently proposed that a "pressure-jump line" is an important part of the mechanism of squall

lines. A sudden rise of pressure is normally observed upon arrival of the wedge of rain-cooled air. However, Tepper further theorizes that the "pressure jump" is associated with a gravitational wave aloft (following a suggestion by Freeman [3]), and he suggests that the wave originates from an acceleration of the cold front. No convincing evidence has been presented in support of this theory. It seems extremely unlikely that there can be any close association between the leading edge of outflowing cold air at low levels and a gravitational wave aloft, as would be required.

The most substantial work to date is that based on observations of the recent Thunderstorm Project. Williams [15] made a microanalysis of selected squall lines passing through the Wilmington net. The official report of the Thunderstorm Project [14] further discusses some of the factors observed in connection with squall lines, and a still more recent paper by Newton [8] attempts to give a more detailed picture of their physical structure and mechanics, based on Thunderstorm Project data. The latter two studies are too recent to have been taken into account in the preceding discussion. Newton's examples probably do not embody the salient characteristics of all types of squall lines but shed light on the type included in his studies. He suggests that squall lines in some cases appear to form first over the cold-front surface and subsequently to move into the warm sector, and he confirms by observation the existence of a pseudo-cold front along the warm-sector squalls. He further suggests that squall-line activity can be accounted for partly as a result of this "front" and partly by the continuous generation of new thunderstorms as a result of convergence-divergence patterns produced by the vertical transfer of horizontal momentum in pre-existent thunderstorms and augmented by solenoidal circulations. He suggests that kinetic energy brought down from higher levels is an essential source of energy for maintaining squall-line activity.

Future Research

Future progress toward a better understanding of the physical structure and mechanics of the instability line will require both the collection of more adequate detailed observational data and the analysis of existing and future data. Undoubtedly there is much to be gained by further analysis of the Thunderstorm Project data, though this project was not aimed so much at the specific problems of the instability line as of the thunderstorm. More observational data for upper levels in the immediate vicinity of tornadoes is especially needed; this is difficult to obtain but will be very important because of the frequent association of tornado conditions with the instability line. A more adequate theory of the mechanics of the tornado would be an important step toward understanding the instability line.

From the practical standpoint of the synoptic meteorologist, whose primary problem is to forecast development of the instability line before it occurs, much remains to be done. His problem is somewhat different from that of basic research in that he must develop better forecasting methods based only on the use of data which are available synoptically. Synoptic data are at best very incomplete, so that he must interpolate to a great extent; better basic knowledge of the phenomenon would aid in this interpolation. There is a large and relatively untouched field for synoptic studies, particularly from a statistical standpoint, in which only synoptically available data are used. There are important geographical differences involved so that similar types of studies need to be made for different geographical areas. While forecasting development of the line is the main synoptic problem, it is also important to develop criteria for determining the individual characteristics of each instability line (turbulence, intensity of rainfall, surface winds, icing, likelihood of tornadoes, etc.) and means of forecasting the dissipation of the line.

INTRODUCTION AND DEFINITION

The terms of the complete equation of atmospheric motion are determined by a number of forces which, through their interplay, cause the movements of the atmosphere. These effective forces are gravity, hydrostatic pressure, friction, and the Coriolis force.

If the Coriolis and friction terms are negligibly small, we deal with *Eulerian wind* equations in which the acceleration can be measured by the pressure gradient. However, if the Coriolis term is large as compared to the acceleration and friction terms, so that the pressure gradient is balanced only by the deflective force of the earth's rotation, we speak of *geostrophic winds.* As a third possibility, the friction terms may be so large that they are of the same order of magnitude as the pressure gradient term, and the Coriolis and acceleration terms may be neglected. In that case the wind blows approximately in the direction of the pressure gradient and it is called an *antitriptic wind* [42].

The antitriptic wind introduces the field of winds restricted to relatively small areas. Their range is of the order of 100 km or less. In this category belong the land and sea breezes, the mountain and valley winds, the jet-effect (*Düseneffekt*) winds, and, at least in so far as their characteristics are determined by the orography of the ground, the foehn and bora winds. These winds of locally restricted influence are classed under the general name *local winds.* They are an elementary yet meteorologically very interesting part of the movement of the atmosphere and a phenomenon which always attracts the attention of the layman.

In the following sections the basic principles of these local winds will be discussed. These winds very closely fulfill almost all conditions of the antitriptic wind since they blow roughly at right angles to the isotherms and isobars and are limited in the vertical to a relatively low altitude.

LAND AND SEA BREEZES

Description of the Phenomenon. In coastal areas, especially on tropical coasts and on the shores of relatively large lakes, we can observe in the course of a day the reversal of onshore and offshore winds, called land and sea breezes. The phenomenon takes the following course:

A few hours after sunrise, depending on location and season, a sea breeze develops, particularly on calm summer days. This sea breeze usually has a noticeable cooling effect, particularly in the tropics; it continues throughout the daylight hours and dies down around sunset. After that the seaward-blowing land breeze appears. This phenomenon, which is restricted to the coastal area proper and which extends only in tropical regions over a 100-km range, must be attributed to the difference in heat response between land and water. On warm, clear, summer days, the horizontal temperature difference between land and water provides the energy that leads to the development of vertical and horizontal air currents of strictly circulatory character. To the ground observer, only the horizontal parts of the circulation are noticeable; the vertical branches can be observed only indirectly, for example, through the formation of clouds over the land. The daytime sea breeze considerably surpasses in intensity the nocturnal land breeze. This is understandable because of the greater daytime arc of the sun during summer and the increased instability and consequently increased vertical austausch in daytime. The nocturnal cooling, on the other hand, produces an immediate stabilization of the air layers near the ground.

It is noteworthy that the direction of the sea breeze does not remain constant in the course of the day, and that this breeze often sets in with considerable gustiness, sometimes in the form of a protrusion similar to a cold front.

It is logical that the gradient wind, as determined by the over-all weather situation, should be superimposed on this local wind system and should at times obscure or even conceal it completely.

As an example of a typical day with land and sea breezes, the wind, temperature, and humidity recordings of the Danzig airfield, 3.35 km inland from the Baltic Sea coast, from June 3 to June 5, 1932, are reproduced in Fig. 1. This diagram clearly shows the onset of the sea breeze from the northeast and north-northeast, respectively, at 1420 on June 3, and at 1430 on June 5, while on June 4 a gradient wind from west-southwest–west-northwest completely conceals the sea breeze. After a calm from 1930 to 2245 on June 3, and from 2100 to 2220 on June 5, the land breeze sets in from southwest and west, respectively, and continues as a mild breeze until 0600 the following day. During the night of June 4–5, a calm from 0030 to 0130 and a shift in wind direction to the southeast are the only indications of the onset of the land breeze, but here also a gradient wind that subsequently appears hinders its development until 0600 in the morning. The temperature and humidity curves of Fig. 1 show characteristic irregularities in their normal trend at the onset and cessation of the sea breeze.

Figure 2 gives an example of the above-mentioned change in velocity of land and sea breezes in the course of the day, as observed at Hock van Holland on July 31, 1938. We can see from this figure the increase in the speed of the sea breeze up to the daily maximum between 1300 and 1400 and a concurrent steady shift

* Translated from the original German.

to the right, which will be explained later. The dying down and continued shifting to the right takes place in similar fashion.

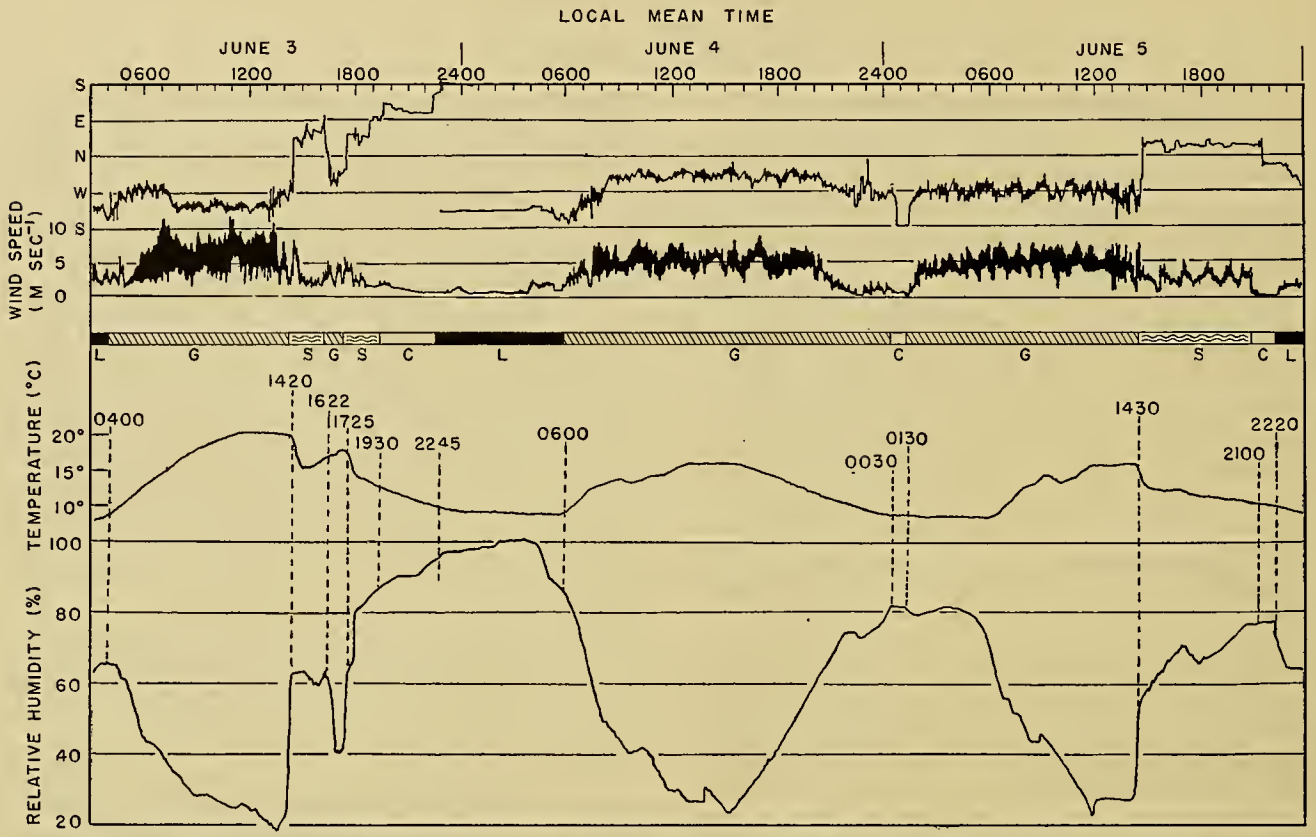

FIG. 1.—Registrations of wind speed and direction, temperature, and relative humidity during the characteristic land- and sea-breeze days from June 3 to June 5, 1932, at Danzig (L = land breeze, S = sea breeze, G = gradient wind, C = calm). (*After Koschmieder* [54].)

As an example of the tropical form of the land and sea breezes the diagram of velocity isopleths by van Bemmelen of the land and sea breezes at Batavia is reproduced in Fig. 3. It is also an example of the vertical velocity distribution during the course of a day.

Explanation of the Land and Sea Breezes. The cause of the land and sea breezes must undoubtedly be sought in the different behavior of land and water under the influence of an equal external heat supply. Water, as compared to soil, has a larger thermal capacity and its specific heat per unit volume reaches a value 40 per cent larger than that of soil. Although water should have a smaller temperature variation for the first reason, the amplitude of these periodic variations would be 1.414 that of the land for the second reason. This difference is equalized through the much smaller heat conductivity of water, and measurements reveal that the surfaces of water and sandy or rocky ground have temperature variations of comparable order. The depth to which radiation penetrates can also not be considered responsible for large temperature differences since the infrared radiation is immediately absorbed in the upper water layers.

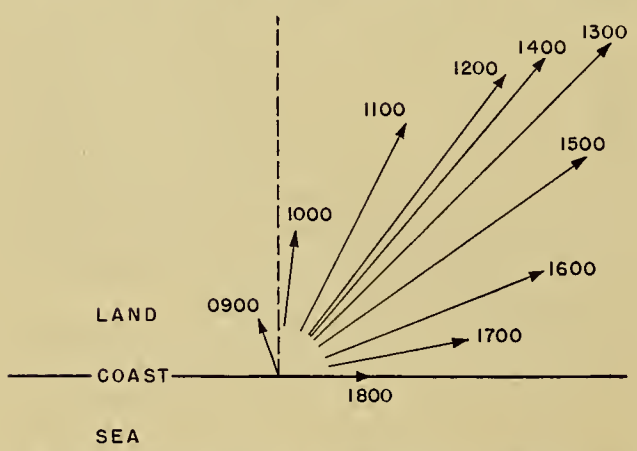

FIG. 2.—Hourly variation of relative wind velocity on a land- and sea-breeze day at Hoek van Holland as recorded on July 31, 1938. (*After Bleeker and Schmidt* [67].)

However, if we direct our attention to the turbulent mixing of the water by wind and waves, which effects a continuous downward transport of surface heat through large masses of water, we recognize that this mixing is the cause of the relatively small temperature variations. It is now clear that the complete absorption of radiant heat in the surface layers of the ground and the weaker influence of this form of energy on the deeper layers result in an entirely different thermal behavior of land and of water. Thus the temperature conditions of the ground are determined almost exclusively by its physical properties, whereas those of

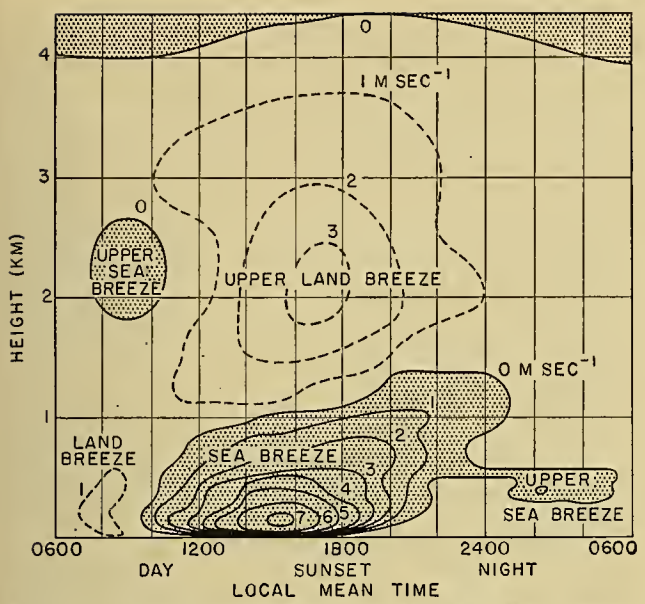

FIG. 3.—Velocity isopleths for the land and sea breeze in Batavia. (*After van Bemmelen* [70].)

the water are governed also by apparent conduction or turbulent mixing. In contrast with the strong heating of the air over the coastal region, the air over the strip of water offshore is only mildly warmed, and, as a result, a temperature difference between land and water develops. This difference diminishes toward sunset and reverses during the night.

Temperature Differences, Pressure Differences, and Pressure Distribution during Land and Sea Breezes. The maximum temperature differences (Δt) are given in the literature as follows: Kaiser [46] gives a range of Δt from 1.6C to 10.9C over a distance of 130 km between Wüstrow and Adlergrund Lightship (anchored in the middle of the Baltic Sea, about 100 km out of Swinemünde) as averages of a period of twenty summer days. Grenander [31] found differences in temperature between 3.6C and 7.6C at 1400, and between 1.4C and 3.1C at 0700 and 2100. These measurements, taken on the Swedish east coast, involved a distance between land and sea stations of 115 km. However, maximum values were as high as 10C or more; on the other hand, very small temperature differences occurred on some sea-breeze days. Measurements of Δt at lakes, as for instance at the Lake of Constance, likewise show a large range of temperature differences, namely values between 0.9C and 4C at 1400. We may conclude from these few measurements that Δt covers a wide range of values, and it is certain that a temperature gradient from sea to land exists in the morning hours. During forenoon a reversal takes place, and in the afternoon an increasing land-sea temperature gradient develops which is the driving force in the formation of the sea breeze. Over inland lakes, where opposite shores show this same behavior, the center of the lake must be a neutral zone. In general it may be assumed that the heating over land during daytime can reach a value five times that over water. Such temperature differences force the development of a pressure gradient and circulation system.

At the beginning of the day, the air pressure at higher altitudes over the land rises, while there is only a negligible increase over the water. As a consequence a drainage of the upper air from the land toward the sea takes place, and during forenoon the pressure close to the surface of the sea begins to rise, while it starts to fall over the land. This developing sea-land pressure gradient is accompanied by an air current in the same direction, that is, the sea breeze. A countercurrent, blowing toward land, is established at upper levels above the surface sea breeze. The circulation in daytime is completed by cumulus-forming convection over land and cloud-dissolving subsidence over water. In the evening the land and the overlying air cool faster than the sea and its overlying air, and a reverse nocturnal circulation develops. This circulation must be of smaller intensity and vertical extent because of the lack of instability and convection.

The land-sea pressure gradient near the surface at night and toward morning, as compared to a sea-land gradient during the day, is clearly discernible in Fig. 4.

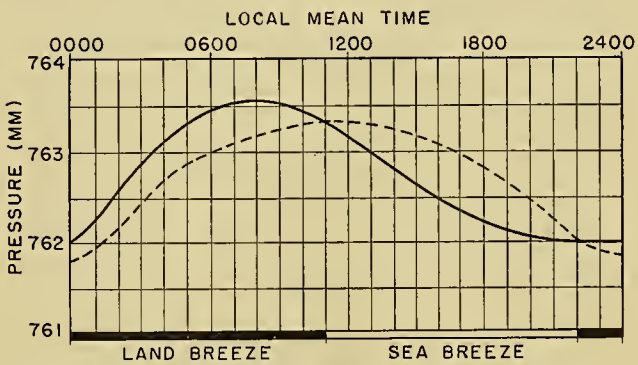

FIG. 4.—Average daily period of the air pressure on twenty sea-breeze days at the Baltic Sea. The solid line refers to Swinemünde; the dashed line, to Adlergrund Lightship. (*After Kaiser* [46].)

It is to be expected that the air current, according to the pressure distribution, is, at first, nearly at right angles to the coast line; only later, during the afternoon, a gradual change in the direction of the sea breeze appears because of the effect of the Coriolis force. However, the influence of the Coriolis force remains slight because of the short distances that these winds travel.

Conditions are somewhat complicated by the addition of a gradient wind associated with the over-all weather situation. A gradient wind blowing parallel to the coast line has no particular influence, since the pressure gradient causing it also acts normal to the coast line and thus only weakens or strengthens the pressure gradient associated with the land or sea breeze. However, a pressure gradient parallel to the coast line with, for example, an offshore gradient wind causes a mass transfer of air seaward. In that case a kink appears in the isobars where they protrude over the sea. Then the condition of gradient force plus Coriolis force equal to zero, which was valid in the previously discussed case, is no longer fulfilled, and unbalanced shoreward components of the gradient wind create a possibility for the development of a strengthened sea breeze. In simple schematic cases these conditions can also be

demonstrated numerically by superimposing the pressure fields of land and sea breezes and gradient wind [54].

Development of Land and Sea Breezes as a Function of Geographical Location, Season, and Time of Day. On tropical coasts, the land and sea breezes appear with great regularity [9, 11, 53, 70], because the clear sky there causes large variations in temperature over the land in the course of the day. Also the usually weak general air motion does not interfere with the development of local winds. It is only in India that the land breeze is completely obscured from May to September by the strong monsoon, which acts as a steady sea breeze during that season. Partial superimposition of mountain and valley winds on land and sea breezes may also cause peculiar wind conditions, as for instance on the coast of Samoa. In higher latitudes these local winds appear almost exclusively, or at least preferably, during the warmer seasons, since only then can sufficiently large temperature or pressure differences develop. In the cooler climates of higher latitudes, as for instance at the shores of the Baltic Sea [46], we can expect land and sea breezes, even in summer, on not more than about 20 per cent of the days. The role of solar radiation becomes apparent in a brief summary (Table I) of the probability of a sea-breeze day for different

Table I. Relationship between Cloudiness and Sea-Breeze Probability

Cloudiness (per cent)	0–50	60–80	90–100
Probability of a sea-breeze day (per cent)	90	39	27

amounts of cloudiness at the Black Sea. Little cloudiness and strong sunshine are decisive in promoting the occurrence of land and sea breezes. In polar regions the phenomenon disappears almost completely and occurs only once in a while on particularly clear summer days.

In the tropics (Batavia) [70] we find about 40–50 per cent of land-breeze occurrences and 70–80 per cent of sea-breeze occurrences to be fairly reliable values for the dry season. During the rainy season both frequencies increase; the land-breeze probability rises to between 60 and 80 per cent, that of the sea breeze to more than 80 per cent. Ramdas [63] gives frequencies for extratropical land and sea breezes in Karachi, India, (25°N) for every month of the year (Table II). We can

Table II. Annual Variation of Land- and Sea-Breeze Frequency at Karachi, India
(*After Ramdas* [63])

Month	J	F	M	A	M	J	J	A	S	O	N	D
Per cent	29	39	31	27	100	100	100	100	100	26	30	42

see from this table a 100 per cent occurrence during the summer months in contrast with the low percentage in the winter. Similarly, in etesian climates (as for instance the Mediterranean climate) spring has land and sea breezes on 31 per cent of the total number of days, the first half of June on 82 per cent, July on 91 per cent, and autumn on only 35 per cent of the days.

Finally, the phenomenon is in almost all regions a function of the time of day, since its periodic course is a consequence of the diurnal temperature variation. Usually, the sea breeze starts between 1000 and 1100, reaches its maximum velocity around 1300 to 1400, and subsides toward 1400 to 2000, whence it is replaced by the nocturnal land breeze. These approximate times naturally vary with the season and with climatic and local differences.

Intensity, Vertical Extent, and Range of Land and Sea Breezes. The height of the sea-breeze layer varies with climatic and local conditions. Its altitude ranges from 150 m at medium-sized lakes to 200–500 m at large lakes and the seacoast. Extending to 1000 m in moderately warm climates, the sea breeze reaches altitudes of 1300–1400 m in tropical coastal regions, as can be clearly seen in Fig. 3. In India, maximum altitudes of 2 km have been observed. In these areas, the nocturnal land-breeze layer is rather shallow by comparison. In Batavia, for instance, it reaches only to about 200–300 m. The difference in height between land and sea breezes is smaller in the temperate zones.

The intensities of the sea breeze cover the entire Beaufort scale. This breeze is of small force at lake and sea shores in the temperate zone (0 to 3 Beaufort); only at the seacoast do some peak values reach 4 to 5 Beaufort at noon. In the tropics, however, the wind may rise to storm intensity with the onset of the sea breeze. A particularly strong increase occurs on coasts with cold ocean currents offshore. While the horizontal speeds are of the order of meters per second, the vertical components are only of the order of centimeters per second.

The landward range of the sea breeze is estimated by many observers at 15–50 km in the temperate zones. Some values, for instance, are 16–32 km in New England, 20–30 km at the Baltic Sea, 30–40 km in Holland, up to 50 km in Jutland, 15 km on the Flemish coast, 40 km in Albania, more than 50 km on the northern coast of Java, and 40–50 km in Sweden. However, land and sea breezes are often augmented by mountain- and valley-wind effects which are difficult to separate from them. In tropical countries the sea breeze reaches 50–65 km, sometimes even 124–145 km into the interior. The seaward range of the much weaker land breeze appears to be everywhere much smaller. At the Baltic Sea, for instance, it extends only to 9 km.

Regarding the vertical temperature distribution in the temperate zone where condensation is relatively rare, nearly adiabatic or slightly superadiabatic gradients are to be expected. In the tropics, however, superadiabatic gradients are the rule, but probably reach only to the upper boundary of the sea breeze and decrease rapidly above it.

Conrad's Minor Sea Breeze, or Sea Breeze of the First Kind. The wind designated by Conrad [13] as "minor sea breeze" does not progress from the sea

toward the coast, but is formed on the boundary line between sea and land and progresses seaward. It is caused by the different heating processes on the flat, sandy beach. This minor sea breeze precedes the major sea breeze, the beginning of which is somewhat retarded by it until the air over the land has become considerably warmer than that over the water. The border line between warm land air and cool sea air, which has been displaced seaward by the minor sea breeze, is eventually overrun, and the cool sea air reaches the coast with an impact. This minor sea breeze, designated as a sea breeze of the first kind, will occur wherever strong pressure gradients connected with the large-scale weather situation do not hinder its development.

The Cold Front-Like Sea Breeze, or Sea Breeze of the Second Kind. The character of the sea breeze having a normal, front-free, and steady development is modified if a wind determined by the general weather situation hinders its regular course. This sea breeze, which develops in opposition to the gradient wind, is characterized by its retarded beginning (usually as late as 1500 to 1600), by its formation at sea and its slow progress toward the coast, and finally by a pronounced break-through of a cold front-like character (distinct gust with wind shift of 180 degrees). The development of this cold-air invasion can be considered to take place in the following way:

In the morning, the offshore gradient wind carries warmed air from the land out to sea and thus displaces seaward and weakens the pressure gradient between land and sea. An air-mass boundary is thus formed at sea against the cool sea air. The warmed land air, which accumulates in a nearly adiabatic layer, is highly turbulent and is able to carry along some of the stably stratified, cold sea air and is forced to rise with it. For a while, a stationary equilibrium between the two air masses may be maintained by an increasingly steepening frontal surface as is depicted in Fig. 5. However,

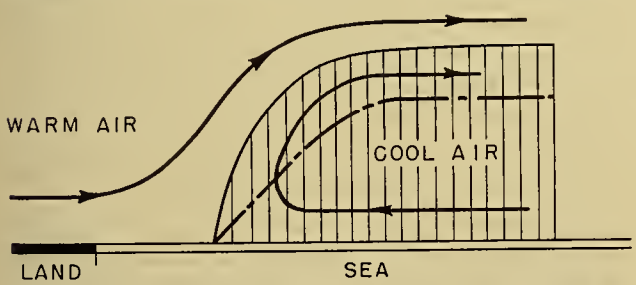

Fig. 5.—Stationary condition before outbreak of the sea breeze. The dash-dotted line is the boundary layer between currents of opposite direction in the cool air mass. (*After Koschmieder* [54].)

with further heating this equilibrium breaks down, the system becomes unstable, and the sea air now breaks through toward the land in the form of a front. This sufficiently explains the gusty onset and the cold-air character. If we consider that the largest vertical temperature gradients are not reached until 1200 to 1400, the retarded onset of the sea breeze is also understandable.

Theory of Land and Sea Breezes. A complete theory of the land and sea breezes must necessarily consider (in addition to the gradient force caused by land-water temperature difference) (1) the influence of the vertical turbulent heat exchange, (2) the turbulent friction of the air motion, and (3) the influence of the earth's rotation. In all existing theories these contributory factors receive only partially satisfactory consideration. Usually, the land and sea breezes are treated as simple, antitriptic currents caused by the unequal heating of land and water.

An older treatment of a stationary circulation is that by Jeffreys [42], who applied it primarily to the sea breeze and to monsoon winds. He considers friction, pressure, and Coriolis force and reaches a solution in which the daily wind change is in phase with the daily temperature oscillation. This result does not conform to reality. The application of this theory to the extended monsoon currents allows the calculation of the height of the monsoon reversal as well as of the amplitude of the surface pressure variations connected with the circulation. The agreement of these calculations with observation proves to be satisfactory.

V. Bjerknes and his collaborators [8] consider the land- and sea-breeze circulation a periodic current around isobaric-isosteric solenoids in which the wind is ninety degrees out of phase with the change in density. Accordingly, the sea breeze would start at the time of the greatest heating and would reach its greatest intensity at the time of the smallest temperature difference between land and sea in the evening. This is not in accordance with observation.

Kobayasi and Sasaki [52] as well as Arakawa and Utsugi [2] base their theories on Lord Rayleigh's convection theory [64]. They consider vertical and horizontal heat transfer in addition to turbulent friction of the air motion, whereby their basis for calculation becomes more complete than that of Jeffreys. Their solutions of the problem allow a comparison between theory and observation, although in order to reach complete agreement a heat conductivity one hundred times greater than that derived by Taylor from observations must be assumed. A further shortcoming of the theory is that the height to which the circulation (including the countercurrent) extends must be known, whereas it actually should result from the boundary conditions of the theory. This theory still neglects friction, which, as had already been pointed out by Godske [30], is responsible for the phase shift between density and wind-velocity variations.

A simple elementary theory of land and sea breezes is due to F. H. Schmidt [67]. In this theory he is less concerned with giving a complete explanation of the circulatory movement than with clarifying characteristic phenomena of the land and sea breezes, such as the phase shift between wind and temperature or the influence of the earth's rotation. A definite temperature distribution in accordance with observations is assumed, and the entire system of currents is calculated, taking the compressibility of the air into account. The Coriolis force is also introduced into the calculations, and thus

Schmidt succeeds in explaining quantitatively all facts of this atmospheric phenomenon in a satisfactory manner. Most certainly, his theory has greatly contributed to a better understanding of local winds.

Schmidt's assumption concerning temperature is characterized by the fact that the entire horizontal and vertical temperature distribution is given. He superimposes on the normal vertical temperature decrease the daily radiation temperature wave which is assumed to reach its maximum amplitude near the coast at a distance inland amounting to half the wave length of the temperature oscillation. This amplitude is supposed to decrease exponentially with altitude. However, for reasons of simplicity, he neglects the fact that the maximum amplitude is a function of time which, after all, should be of some importance to the theory. The variation in air density caused by the radiation temperature wave can be calculated; its amplitude also decreases exponentially with altitude. Part of the pressure variation is ascribed to the resulting density variation, and the remainder is caused by divergence and convergence of the compressible air. This influence of divergence is also assumed by Schmidt to decrease exponentially with altitude. If the pressure gradient is known, the horizontal velocity component can be calculated by application of the Guldberg-Mohn friction formula. Finally, the friction constant is assumed to be a quantity that decreases with altitude according to the expression e^{-rz}, where r is a constant representing the decrease of friction with height and z is the height. This is necessary in order to obtain sufficient variation with altitude of the sea breeze's starting time. We shall not discuss here how far such assumptions are justified; moreover, it would be preferable if the theory itself would yield the variations with altitude of all these quantities. Nevertheless, the theoretical determination of the deviation of the wind direction from the perpendicular to the coast and of the shift of the wind in the course of a day gives a satisfactory result.

The most recent work on the theory and observation of land and sea breezes has been published by Pierson [61]. In this work the theoretical considerations of F. H. Schmidt are considerably improved. Pierson makes assumptions regarding the temperature contrast between land and water that closely approximate reality and he takes into consideration not only the Coriolis force but also that type of friction which is used in the derivation of the Ekman spiral. A solution is given of the Navier-Stokes equations for laminar flow with consideration of the apparent eddy viscosity. Theoretical hodographs illustrate the variations of land and sea breezes under the influence of this type of friction, the Coriolis force, and the variable pressure-gradient force at all altitudes. The temperature contrast between land and water and its periodic variation during the course of a day as well as its variation with altitude are assumed, with due consideration for eddy diffusion (W. Schmidt, see [61, p. 9]), in a manner similar to that employed by F. H. Schmidt. From this the density and pressure distribution can be computed, and the wind field can be obtained from the equations of motion; the equation of continuity is unnecessary here. A comparison of the theoretical results with observations made at Boston (42°N), Madras (13.4°N), and Batavia (6°S) shows good agreement.

Recently, Haurwitz [37] made an interesting and important contribution to the theory of the land- and sea-breeze circulation. In contrast to previous investigators, he chooses Bjerknes' circulation theorem as his point of departure. With it he proves that the intensity increases, not only as long as the land-water temperature difference increases, but that it keeps growing until this difference disappears. Thus, the phase shift between temperature difference and wind maximum would be a quarter of the period, that is, six hours. Haurwitz shows that the introduction of frictional influences causes a considerable decrease of this phase shift which leads to a better agreement with observation. The daily shifting of the sea breeze, which was clearly observed in several locations, can be explained without difficulty as an effect of the Coriolis force. Haurwitz' work excels in its logical, all-inclusive consideration of all factors that are of importance for the development of land and sea breezes. However, as in the work by F. H. Schmidt, the theory of the land- and sea-breeze circulation is incomplete. In all these investigations the temperature contrast between land and water at the surface and at all levels above it is assumed. A complete theory should furnish the temperature distribution with altitude as well as the circulation from a given temperature contrast *at the surface.* The temperature distribution with altitude depends not only on the vertical turbulent heat exchange, but also on the circulation itself. For this reason, with a given boundary condition of temperature at the surface, the equation of heat conduction (as in the theory of the slope winds, see p. 666) must be incorporated in the theory.

If we approach the land and sea breeze as a single circulation cell in the sense of Lord Rayleigh's convection theory [64], we come considerably closer to the problem of these local winds. Furthermore, with this method we can take vertical as well as horizontal heat transfer and turbulent friction into account. The solution must yield not only the entire temporal development of the periodic current system, but also its dimensions as a function of heat supply or of the land-water temperature difference, respectively. I have recently attempted such a solution [18], which actually furnishes the required results in full conformity with observations. For the land-water temperature difference near the surface, which we have assumed as given, I used the simple harmonic function $\vartheta = Me^{i\Omega t} \sin lx$, where x is the normal to the coast, ϑ the potential temperature, M the amplitude of the temperature variation, $\Omega = 2\pi/(\text{sidereal day}) = 7.292 \times 10^{-5}$ sec^{-1}, and the length of the circulation cell is fixed as $L/2 = \pi/l$. This solution permits the utilization of any desired form of the land-water temperature difference, provided it is expressed by a Fourier series; the solution given above then holds for every one of its terms.

This solution, based on the assumption that ϑ is

proportional to sin lx, naturally yields a continuous chain of circulations. If a number of such circulations with variable l resulting from the Fourier series are superimposed on one another, we obtain a single circulation of definite horizontal extent. Thus, this extent becomes solely a function of the form of the land-water temperature difference. When the influence of friction (Guldberg-Mohn's friction equation, where σ is the coefficient of friction) and the Coriolis parameter ($f = 2\Omega \sin \phi$) are taken into consideration, the equations of motion become

$$\begin{aligned} \frac{\partial u}{\partial t} &= fv - \sigma u - \frac{1}{\rho}\frac{\partial \tilde{\omega}}{\partial x}, \\ \frac{\partial v}{\partial t} &= -fu - \sigma v, \\ \frac{\partial w}{\partial t} &= -\sigma w - \frac{1}{\rho}\frac{\partial \tilde{\omega}}{\partial z} + \gamma\vartheta. \end{aligned} \tag{1}$$

In addition to these equations we have the continuity equation in the form:

$$\frac{\partial u}{\partial x} + \frac{\partial w}{\partial z} = 0, \tag{2}$$

and the heat transfer equation which, with the omission of negligible factors, assumes the form:

$$\frac{\partial \vartheta}{\partial t} + \beta w = \kappa\left(\frac{\partial^2 \vartheta}{\partial x^2} + \frac{\partial^2 \vartheta}{\partial z^2}\right). \tag{3}$$

In these equations the y-axis is parallel to the coast, and the x-axis perpendicular to it, with the positive direction toward land. The letter ϑ stands for the potential temperature; $\gamma = g\alpha$, where α is the coefficient of heat expansion; β is the vertical gradient of the potential temperature; κ is the coefficient of turbulent heat conduction; and, as before, $\Omega = 7.292 \times 10^{-5}$ sec^{-1} expresses the day frequency. According to Rayleigh [64], $\tilde{\omega}$ is a quantity that fixes the perturbation pressure.

The solution may be assumed in the form:

$$\begin{aligned} u &= u(z)e^{i\Omega t}\cos lx, \qquad \tilde{\omega} = \tilde{\omega}(z)e^{i\Omega t}\sin lx, \\ v &= v(z)e^{i\Omega t}\cos lx, \qquad \vartheta = \vartheta(z)e^{i\Omega t}\sin lx. \\ w &= w(z)e^{i\Omega t}\sin lx, \end{aligned} \tag{4}$$

Then, by substitution in (1), (2), and (3), differential equations are obtained for u, v, w, $\tilde{\omega}$, and ϑ which are functions of z only and can be solved by exponential functions:

$$\begin{aligned} w &= Ae^{+az} + Be^{-bz}, \\ \vartheta &= Ce^{+az} + De^{-bz}, \end{aligned} \tag{5}$$

and similar expressions for u, v, and $\tilde{\omega}$.

The boundary conditions are

$$z = 0, \qquad w = 0, \qquad \text{and} \qquad \vartheta = M, \tag{6}$$

and for large values of z the circulation becomes negligibly small; then, the constants A, B, C, and D are fixed whereas a and b are determined by the day frequency and the other values given above.

The solutions for w and ϑ are:

$$\begin{aligned} u &= \frac{rM}{(a^2 - b^2)l}[ae^{+az} + be^{-bz}]e^{i\Omega t}\cos lx, \\ w &= -\frac{rM}{(b^2 - a^2)}[e^{+az} - e^{-bz}]e^{i\Omega t}\sin lx, \\ v &= -\frac{f}{i\Omega + \sigma}u, \\ \vartheta &= M\left[e^{-bz} + \frac{b^2 - s}{b^2 - a^2}\{e^{+az} - e^{-bz}\}\right]e^{i\Omega t}\sin lx. \end{aligned} \tag{7}$$

The factors r and s can also be expressed by the constants given above. It should be noted that all these quantities, including a and b, are complex numbers and that with $e^{i\Omega t}$ a separation of the real and imaginary terms would require extensive calculations.

When the solution (7) is worked out for latitude $\phi = 45°$ and various values of the friction coefficient σ, it yields circulation systems of the land and sea breezes that are in full agreement with observations. Table III lists the basic factors of the circulations for different values of σ with and without consideration of the Coriolis parameter. As is usually the case, the phases are referred to a maximum land-water temperature difference at 1200. It can be seen from Table III that the height of the land or sea breeze lies at roughly 400 m and rises with increasing friction from 320 m to 500 m. It is interesting to note that this altitude is somewhat reduced under the effect of the Coriolis force. Naturally, friction diminishes the velocity of the land and sea breezes to a considerable extent, namely from about 5.5 m sec^{-1} to 2 m sec^{-1} for every centigrade degree of temperature difference. For average friction conditions and a maximum land-water temperature difference of 5C over the distance $L/2$, we arrive at a maximum sea-breeze intensity of about 10 m sec^{-1}, which agrees quite well with observations. Under these conditions the vertical velocities reach maximum values of about 2 cm sec^{-1} per centigrade degree of temperature difference, which is also a reasonable value.

Of special interest is the phase of the land and sea breezes. If friction and the Coriolis force are neglected, the phase shift between the maximum temperature difference and the maximum intensity of the sea breeze is 4.7 hr. This shift decreases rapidly to 1.4 hr with increasing friction. In the case of $\sigma = 2.5 \times 10^{-4}$ sec^{-1} the maximum intensity of the sea breeze follows the maximum temperature difference closely, as is borne out by most observations. The influence of the Coriolis force on the component perpendicular to the coast is small, as is to be expected. Naturally, a cross velocity v appears instead, whose phase shift with the velocity perpendicular to the coast is 10.9 hr, or nearly 12 hr. This phase shift stays constant up to the height of the zero layer and then changes sign. Figure 6 is a vector diagram for the case $\sigma = 2.5 \times 10^{-4}$ sec^{-1} and $f = 1.031 \times 10^{-4}$ sec^{-1} ($\phi = 45°$). The figure shows clearly

the oblique position of the flow ellipse relative to the perpendicular to the coast, in good agreement with observations (see Fig. 2).

weak maximum that barely reaches a quarter of the intensity of the land and sea breezes near the surface. Theoretically, further circulations exist above this circu-

*Approximate.

Above the zero layer there is a countercurrent whose vertical extent exceeds that of the land- and sea-breeze layer by a factor of 4 to 5. This countercurrent has a

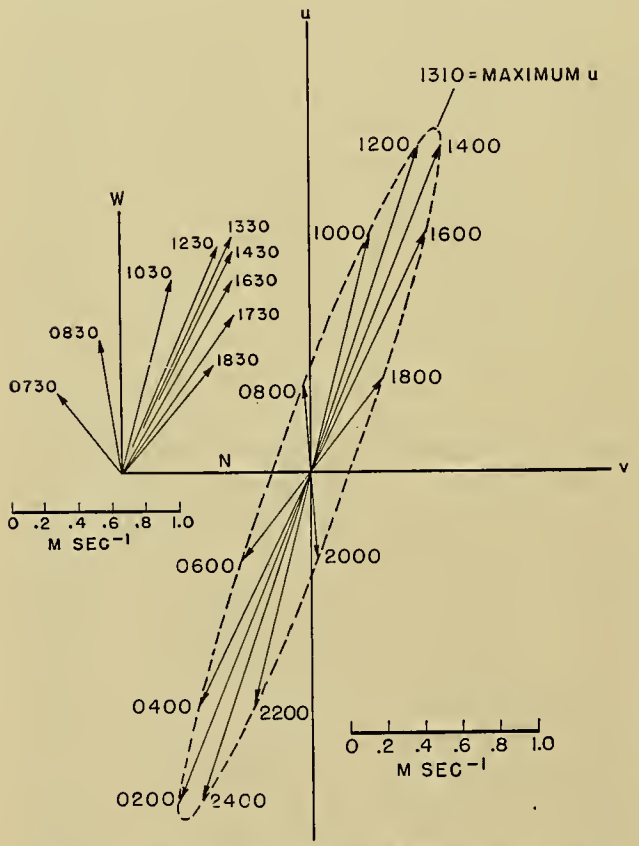

Fig. 6.—Theoretically calculated flow ellipse of the land and sea breeze under the influence of friction ($\sigma = 2.5 \times 10^{-4}$ sec^{-1}) and the Coriolis force ($f = 2\Omega \sin \phi = 1.03 \times 10^{-4}$ sec^{-1}; $\phi = 45°$) when the maximum temperature difference between land and sea is at 1200 LMT. The vector diagram at the left shows the mean winds during the sea-breeze period (0730–1830 EST) at Logan Airport, Boston, Mass. (based on 40 cases). (*After Defant* [18].)

lation cell of land and sea breezes and its countercurrent. However, their intensities are so low as to be negligible for all practical purposes. Thus, in contrast to others, this theory fixes a definite upper boundary to the land- and sea-breeze circulation. This upper boundary is, according to the theory, independent of the intensity of the land-water temperature contrast and a function only of the structure of the atmosphere, the Coriolis force, and the turbulent heat transfer. Friction tends to raise this boundary, while the Coriolis force tends to lower it.

MOUNTAIN AND VALLEY WINDS

The Mountain-Wind Circulation and Its Components. As in the case of coastal areas, local temperature and wind conditions occur in the vicinity of large mountain ranges that are often so strong in their effect that, locally, they modify or even obscure the general weather conditions. Here, thermal differences create a circulation system which, in daytime, consists of a lower current toward the mountains and an upper current in the opposite direction. In the region of the European Alps, Burger and Ekhart [12] have actually shown that this upper compensation current flows away radially from the mountains toward the neighboring plains in daytime. A corresponding flow system was found on the east slope of the Rocky Mountains by Wagner [71] and Ekhart [23]. This upper compensation flow is naturally less pronounced (speeds of the order of 15 cm sec^{-1}) than the lower current, since it is more strongly affected by the wind system determined by the general pressure distribution, the influence of which is difficult to separate from the local effect. Figure 7 shows these conditions schematically.

The Thermal Slope Wind. The difference in temperature between the air heated over the inclined mountain slopes and the air at the same altitude over the center of the valley causes the phenomenon of air rising in daytime along the slopes of moun-

tains, well known to every mountain climber. These winds start one fourth to three fourths of an hour after sunrise, and blow uphill in daytime. They

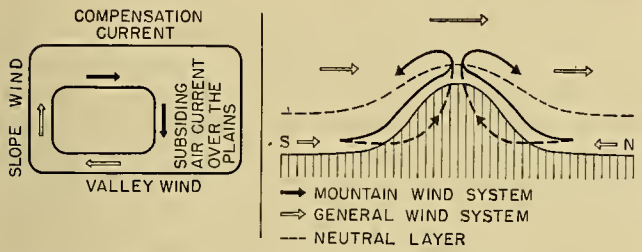

FIG. 7.—Schematic illustration of the air circulation during daytime in a cross section through the Alps. (*After Burger and Ekhart* [12].)

reach their greatest intensity at the time of maximum insolation and reverse their direction in the evening (about one fourth to three fourths of an hour after sunset). Because of the stronger insolation, they are especially well developed on the southern slopes and are weaker or almost nonexistent on the northern slopes. This wind prefers the ravines and gullies of the usually eroded slopes and is hardly noticeable on the projecting ridges. Numerous pilot-balloon observations in the up-and-down drafts on the slopes of the mountains north of the Inn valley near Innsbruck [43–45, 65] have clearly demonstrated the existence of such currents.

Here the thickness of the slope wind layer, as measured perpendicular to the slope, varies periodically with the wind intensity. Maximum values up to 260 m have been measured. However, as a rule, the thickness of the layer lies between 100 and 200 m. The thickness is less for the nocturnal downslope wind. The uphill wind continuously entrains, along its path, air from the space over the valley, so that the thickness of the affected layer is steadily increased in the direction of the uphill flow, and the layer becomes wedge-shaped. Naturally, the intensity of these slope winds varies greatly with the local differences in the slope and its exposure. Also, these winds can seldom be observed in their pure form and are often weakened or strengthened by extraneous wind conditions. On the average, the slope-wind speeds in the direction of the slope amount to about 2–4 m sec^{-1}, according to measurements. Projecting parts of the slope cause a detachment of this current from the slope and thereby an increased vertical movement which can be utilized by soaring pilots to gain altitude. In fact, the entire phenomenon of thermal slope winds is of greatest importance in soaring. The existence of thermal slope winds is often indicated by isolated cumulus clouds over summits or chainlike cumulus formations along ridges. Velocities of 13 m sec^{-1} have been measured in these updrafts. The nocturnal downslope wind shows a lesser vertical extent and lower velocities.

The highest velocity of these slope winds does not occur close to the slope surface, but at a definite distance from it. Higher up, it rapidly decreases again or is supplanted by other wind conditions. The current is extremely sensitive to changes in the insolation, and a temporary shading of the slopes will cause an immediate response by the wind. Also the difference in the starting time of the current is determined by the varying time at which insolation begins on slopes of different exposure. Thus, the phenomenon is often weakened at the time of the maximum temperature because of shadows cast on the slopes by extensive cloud formations.

Little is known about the thermal structure of the affected layer, because temperature measurements normal to the slope would be necessary for its actual determination. Such measurements have been made only up to about 20 m above the slope, since greater heights are difficult to reach. It is known that the layer of air adjacent to the slope shows strong superadiabatic gradients. During the cool downdraft at night, on the other hand, a strong increase of potential temperature (inversion) is often noticeable. The time span during the reversal of the wind is characterized by an isothermal air layer near the ground. At present, we have only a theoretical picture of the structure of the entire slope-wind layer, which, however, is probably very close to reality (see Figs. 11 and 12).

A variant of the thermal slope wind is the *glacier wind.* This wind, a shallow downdraft along the icy surface of the glacier, continues all day regardless of insolation. Its thermal cause is the continuously present temperature difference between the glacier surface and the free air at the same altitude. For this reason, the glacier wind has no diurnal period as does the slope wind. Since the wind is a function of this temperature difference, it reaches its maximum intensity and greatest vertical extent (between 50 m and 400 m) in the early afternoon, according to measurements by Tollner [69] and Ekhart [21]. The glacier wind always appears, even on cloudy days. In daytime, it fades out soon after leaving the glacier because its kinetic energy is dispersed by the ground friction. The glacier wind often collides with the upvalley wind and then slides under it. At night, after leaving the glacier, it blends into the mountain wind which has the same direction. A characteristic of the glacier wind is its strongly turbulent flow which, in a more moderate form, is also a feature of the nocturnal slope wind.

The Mountain and Valley Winds. The phenomenon of the daily wind change along the axis of large valleys is known in all mountainous countries. In daytime, from about 0900 to 1000 until sunset, an upvalley, or so-called valley wind blows. At night an opposite downvalley or so-called mountain wind appears which continues into the early morning hours after sunrise. Numerous investigations of this phenomenon, including soundings of its vertical structure, have been made in many mountainous countries [19]. Mountain and valley winds are best developed in the wide and deep valleys of the Alps. The shape of the valley's cross section and the inclination of the valley bottom are of little influence on these winds. As a matter of fact, in fairly level valleys, such as the valley of the Inn River in Tirol, these winds are particularly well developed. They occur most frequently during persistent high-pressure situations in summer and are thus a typical fair-weather

phenomenon of summer. Nevertheless, mountain and valley winds may also occur on cloudy days and in winter when they become manifest mostly in a modification of the general wind. The vector diagram of the winds in the Inn river valley near Innsbruck in Fig. 8 shows a good example of mountain and valley winds.

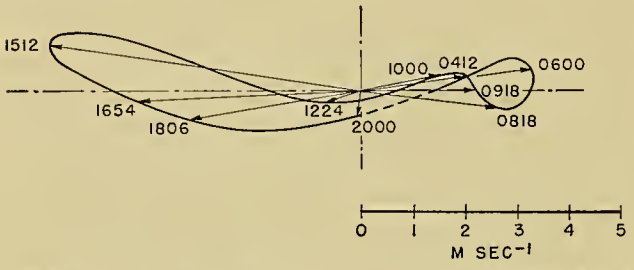

FIG. 8.—Vector diagram of the mountain and valley winds in the Inn valley (Innsbruck) on June 19, 1929, 100 m above the valley bottom. The dash-dotted lines indicate the axes of the Inn valley; upstream is to the left. Numbers indicate local mean time. (*After Ekhart* [19].)

This diagram of the wind conditions in the course of a clear day, June 19, 1929, shows that the maximum of the valley wind with speeds of 5–6 m sec^{-1} occurs shortly after 1500. The maximum of the mountain wind with speeds of 3–4 m sec^{-1} in the opposite direction occurs at around 0700. In general, the winds blow in the longitudinal direction of the valley's axis.

As an example of the height and intensity of the mountain and valley winds at Innsbruck, an isopleth diagram by Ekhart is reproduced in Fig. 9. The wind

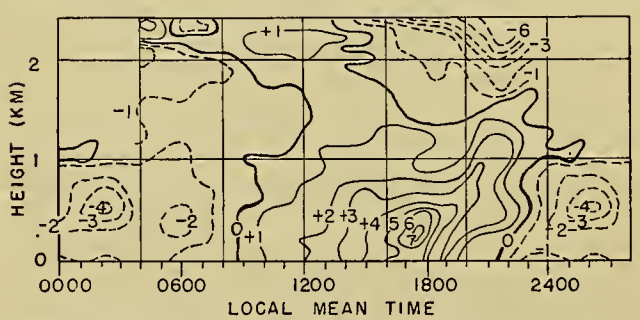

FIG. 9.—Mean velocity isopleths of the mountain and valley winds at Innsbruck (numbers are wind speed components (m sec^{-1}) in the direction of the valley; + upvalley, − downvalley). (*After Ekhart in Hann-Süring*, Lehrbuch der Meteorologie, *5. Aufl., p. 552.*)

velocity distribution shows the characteristic transition from mountain to valley wind. The values are averages of several fair summer days in 1929 and 1931. According to the diagram, the wind maximum is to be found at an altitude of about 200–400 m, while the velocities near the ground are reduced because of the influence of friction. This increase of the valley wind with altitude is characteristic of all valley winds, as is the fact that their average velocities are higher than those of the nocturnal mountain wind. Furthermore, the diagram shows that the valley wind starts almost simultaneously in all layers up to relatively high altitudes. The starting time of the valley wind is closely related to the width of the valley and thus to the size of the mass of air involved. This starting time changes with the season, that is, with the magnitude of the diurnal temperature variations.

The height of the valley wind usually reaches to, or somewhat above, the flanking mountain ridges. The more stably stratified mountain wind, on the other hand, is confined to lower levels. The upper boundary of the mountain and valley wind system usually arches several hundred meters over the mountain crests. There, the transition into the general wind system usually takes the form of an abrupt wind shift or a calm.

The Maloja Wind. The Maloja wind, named after the windshed between Engadine and Bergell, Switzerland, where it appears particularly well developed, is a variation of the mountain and valley wind [4, 6, 7, 10, 35, 36, 39, 50, 58, 59, 72, 74]. It is a mountain wind which blows downvalley both day and night. The phenomenon must be attributed to the fact that the valley wind of one valley reaches over a pass into another valley. In the mountain and valley wind system there, it acts as a disturbance, or, more specifically, as an abnormal development of the valley wind. The development of this anomaly is decisively determined by which one of the valleys involved has the larger diurnal temperature amplitude and thus effectively extends its circulation into the other valley across the pass. The question has not been satisfactorily answered whether this phenomenon can be entirely explained by the further increase of the diurnal temperature variation beyond the pass, or whether it is a purely inertial extension of that valley wind which is the more strongly developed. Sometimes, as was shown at the Arlberg Pass in Tirol [22], a strong upslope wind in one valley can, after crossing a pass, augment a valley wind in another valley.

Even in the absence of a pass, the interplay between thermal slope winds and typical mountain and valley winds sometimes produces considerable anomalies of the latter. Veering or backing of the valley wind on respective orographic slopes and cross circulation in narrow valleys, owing to strong insolation on one slope, have been observed. Cyclic wind shifts in the course of a day are caused by the fact that the upslope wind starts before the valley wind, and the downslope wind before the mountain wind.

The Theory of Mountain and Valley Winds. The development of the theory through many decades [15, 27, 33, 34, 50, 66, 74] finally culminated in the work by Wagner [71–73], who made an intensive study of the daily pressure and temperature variations in the free atmosphere within the valleys of the Alps. These investigations led to the result that at a certain altitude above the valley, usually at about the height of the surrounding ridges, the otherwise different diurnal pressure variations are completely equalized. This level of equalization was designated by Wagner as the "effective ridge altitude." A further important result of these investigations was establishment of the fact that the diurnal temperature variations in the valleys up to the

height of the ridge were more than twice as large as the variations within a similar layer over the plain. As a consequence, a pressure gradient from the plain to the valley must exist during the day, whereas the reverse gradient must appear at night. The equalization of pressure differences at the effective ridge altitude requires that the pressure differences be largest close to the valley bottom and that they decrease with height so as to disappear completely at the effective ridge altitude.

From these deductions an adequate theoretical explanation of the mountain and valley winds can be derived. In full accord with observations, the unequal rates of decrease in the amplitude of the temperature variations over the plain and the valley bottom create a pressure gradient of the observed magnitude whose direction is toward the valley during the day and away from it at night. The air current thus generated fills the entire valley and decreases with altitude in accord with observations. Thus, there is a thermal cause for the pressure differences, and the air current is theoretically established as a circulation with a reversal of direction at night. This theory also includes the observed circulation between the plains and the mountains and the necessary existence of the upper compensation current. Furthermore, the pressure gradient, according to Wagner, is the result of the combined effects of the inclinations of valley bottom and ridge line. A nonparallel course of these inclinations, such as a downslope of the valley bottom and simultaneous upslope of the ridge line, would cause an extension of the existing gradient. In other words, if the ridge line rises beyond the pass altitude toward the neighboring valley, the gradient existing in the first valley would run in the same direction also in that neighboring valley beyond the pass. In this case the wind would reach over the pass as a Maloja wind. Thus, this abnormal phenomenon of the mountain winds also fits into Wagner's theory.

This theory furthermore requires two wind systems to preserve the stationary condition in the valley. One of them consists of the horizontal inflow of the valley wind, produced by the static conditions; the other one is the thermal slope wind system which takes care of the outflow over the flanking ridges. The combined wind systems have an additional effective source of energy in the heat given off by the heated slopes. The slope winds have a further important function in that they continuously add heated slope air to the air over the valley through that branch of the slope-wind circulation which descends over the valley center. Thus, the temperature in the center of the valley cross section is continuously increased during the day and decreased at night, when the heating conditions are reversed.

The mechanism interlocking the upslope and downslope winds with the mountain and valley winds in the course of a day, described in great detail by Wagner [73], is shown in Fig. 10. The great importance of the thermal slope winds as integral members of the larger circulation between plains and mountains is obvious. On the basis of a theoretical treatment of the stationary slope wind by Prandtl [62], the present author recently extended these considerations to the nonstationary case [17].

Prandtl's theory has particular significance, because a deeper insight into the mechanism of the thermal slope-wind current was gained through the introduction of turbulent heat conduction and turbulent friction. A disturbance of the temperature field, as well as static instability, always appears in the air layer above a heated surface and thus tends to establish turbulence.

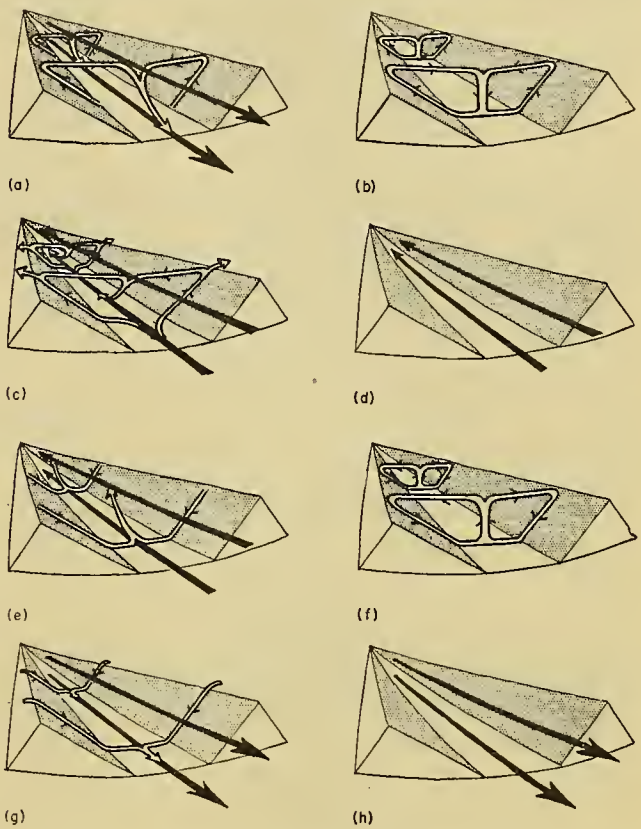

FIG. 10.—Schematic illustration of the normal diurnal variations of the air currents in a valley. (*After F. Defant* [17].)
(*a*) Sunrise; onset of upslope winds (white arrows), continuation of mountain wind (black arrows). Valley cold, plains warm.
(*b*) Forenoon (about 0900); strong slope winds, transition from mountain wind to valley wind. Valley temperature same as plains.
(*c*) Noon and early afternoon; diminishing slope winds, fully developed valley wind. Valley warmer than plains.
(*d*) Late afternoon; slope winds have ceased, valley wind continues. Valley continues warmer than plains.
(*e*) Evening; onset of downslope winds, diminishing valley wind. Valley only slightly warmer than plains.
(*f*) Early night; well-developed downslope winds, transition from valley wind to mountain wind. Valley and plains at same temperature.
(*g*) Middle of night; downslope winds continue, mountain wind fully developed. Valley colder than plains.
(*h*) Late night to morning; downslope winds have ceased, mountain wind fills valley. Valley colder than plains.

Let us assume the spatial distribution of the potential temperature ϑ, together with the temperature disturbance which stems from the heat transfer along the heated slope, in the form:

$$\vartheta = A + Bz + \vartheta'(n), \tag{8}$$

where A is a constant at $z = 0$, B is the lapse rate of potential temperature, z is the vertical, n is the normal to the slope, and ϑ' is the disturbance in potential temperature caused by heat conduction in the direction n. We can then expect the velocity w of the stationary current along the slope to be a function of n only.

The interplay of heat transfer and heat conduction furnishes the differential equation,

$$g\beta\vartheta' \sin\epsilon + \frac{\nu\kappa}{B \sin\epsilon} \frac{\partial^4\vartheta'}{\partial n^4} = 0, \qquad (9)$$

where β is the coefficient of expansion, $g\beta\vartheta' \sin\epsilon$ is the acceleration in the upslope direction, ϵ is the angle of the slope, ν is the coefficient of turbulent friction, and κ is the coefficient of turbulent heat conduction.

The usual solutions of equation (9) are

$$\vartheta' = Ce^{-n/l} \cos\frac{n}{l}$$

and

$$w = C\sqrt{\frac{g\beta\kappa}{B\nu}}\, e^{-n/l} \sin\frac{n}{l}, \qquad (10)$$

where

$$l = \sqrt[4]{\frac{4\kappa\nu}{g\beta B \sin\epsilon}},$$

and C is the temperature disturbance at the surface of the slope. The actual form of the solution is shown schematically in Fig. 11.

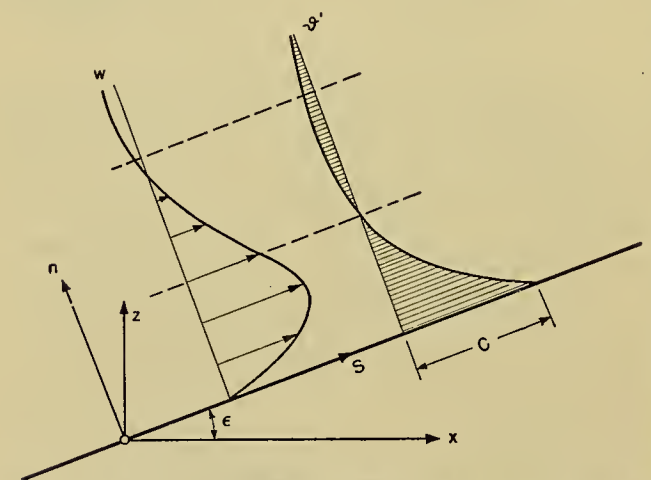

Fig. 11.—Schematic profiles (normal to the slope) of the wind speed w and temperature ϑ'. (*After Prandtl* [62].)

I have checked the correctness of these theoretical results by a detailed comparison with actually measured average values of ϑ' and w and have found a splendid agreement, except for the disturbing gradient influences in the upper layers. Furthermore, it is noteworthy that the resulting values of the austausch due to impulse transport (virtual friction) and of that due to transport of the heat content (virtual heat conduction) are of a plausible magnitude. Figure 12 presents the theoretical distribution of the potential temperature during upslope and downslope winds, respectively, for which no observations are available. The characteristics of the stratification become very apparent.

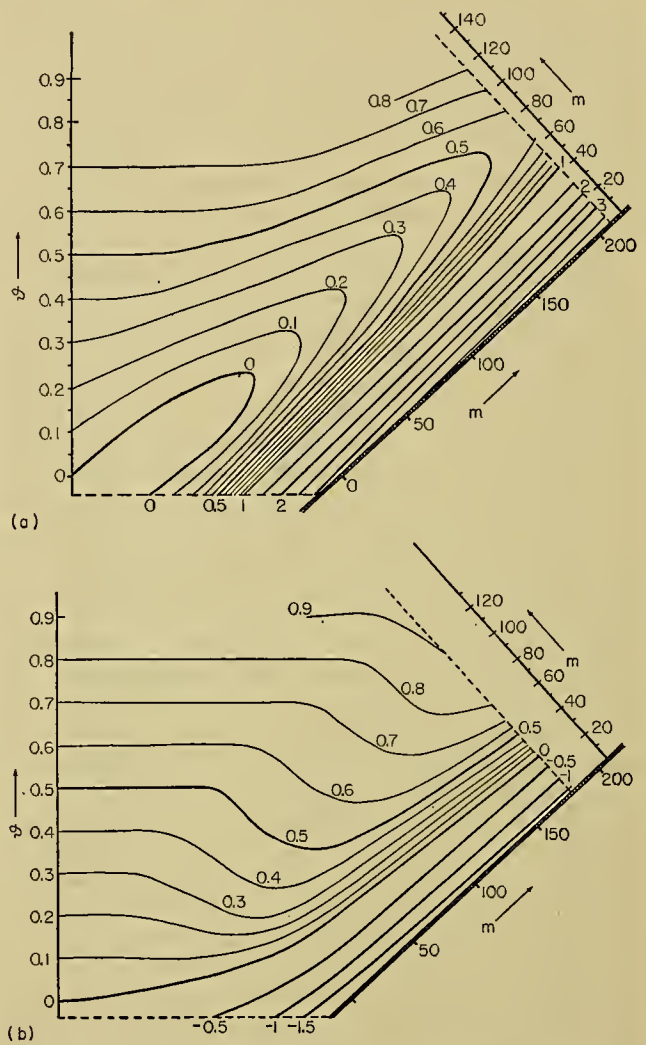

Fig. 12.—Theoretical distribution of the potential temperature over a mountain slope during (*a*) upslope wind and (*b*) downslope wind. (*After F. Defant* [17].)

The theory can be extended to include the oscillatory nature of the slope wind by simply multiplying, as a first approximation, the solutions (10) of the stationary case by the factor $\cos \Omega t$. Because of the fourth root in the expression for l, variations in the values of ν and κ [17, pp. 441–444] are of little influence on the solution.

The average air transport by the slope winds can be roughly computed from the calculated and the observed average profiles of the slope wind. We can then estimate how long it would take until the rising heated slope air has replaced the air masses over the valley bottom. The interest of this question becomes apparent if we consider that this process of warming the air in the valley center has an effect on the pressure gradient and thus on the generation of the mountain and valley winds. Calculations show that a slab of air 1 m thick, 1500 m long (the width of the valley), and 1750 m

high (the height of the valley) is completely replaced in a closed circulation by heated slope air in 4½ hr.

Thus, if we assume the heating to begin at 0830, the maximum pressure gradient between plains and valley would occur at about 1300. This time would be the beginning of the main phase of the valley-wind development. A comparison with the time of the valley-wind maximum at Innsbruck (between 1500 and 1600) proves satisfactory if we consider the distance traveled by the air from the valley entrance to Innsbruck. These results confirm the importance of the return of the upslope wind to the valley center for the theory of the mountain and valley winds, as postulated by Wagner.

DISTURBANCES OF THE WIND THROUGH OROGRAPHIC INFLUENCES

The Foehn. In almost all mountain areas, conspicuous local winds can be observed which blow from the ridges down into the leeward lowlands. At times these winds can assume gale intensity. Their chief characteristics, after reaching the plains, are abnormal temperature rise and dryness, which are of climatic significance over a more or less wide belt in the lee of the mountains. These local winds have become known under various names; however, today the general term *foehn* is used.

Although particularly well developed in the European Alps, especially in Switzerland and Tirol, such foehn winds blow also in Greenland from the inland ice over the mountain ranges down to the coast. In North America the foehn, known as the *chinook*, has a climatic influence on a very wide belt east of the Rocky Mountains. In Argentina, this wind is known as the *zonda* and blows down from the Andes. Local winds with foehn characteristics are also well known in Japan, New Zealand, and in eastern and central Asia. There is hardly a mountain range where the foehn is completely lacking. After all, the foehn will appear wherever prevailing winds must pass over a mountain barrier. Such barriers thereby become great divides of weather and climate.

The foehn is also noted for characteristic weather elements other than high temperature and low humidity. There is always extraordinarily good visibility; the mountains appear unnaturally close and clear and assume steel-blue to purplish hues. The clouds associated with the foehn are lens-shaped (*lenticularis*) at medium altitudes, and elongated banks often suggest wave formation. The peaks of the mountains and the upper part of the windward slope are shrouded in rather flat, cumuliform clouds. These clouds, the so-called "foehn wall," are in a continuous process of forming and dissolving, because they remain stationary in spite of strong winds.

The foehn is a gusty wind, and temperature and humidity curves therefore always show irregularities to a varying degree during a foehn. In the Alps the foehn is always strongest where north-south valleys open into the plains or into large east-west cross valleys. This latter form is characteristic, for instance, at Innsbruck. It was there that the investigation of this phenomenon was most intensively pursued (see, for example, the work by Trabert, v. Ficker, A. Defant, Ekhart, and Pernter [14, 20, 24, 26, 60]).

During the winter, the great increase in temperature causes a rapid melting of the snow. However, floods seldom occur because the melting is very localized and decreases rapidly with altitude. Also, during a foehn, evaporation is very rapid because of the low relative humidity, and precipitation is confined to the passes, the peaks, and the windward side of the mountains. This distribution of precipitation is the chief characteristic of the foehn and has decisive climatic consequences for the areas on both sides of the range.

The thermodynamic explanation of the foehn is essentially due to Hann [32]. Since the theory belongs to the basic principles of theoretical meteorology, the reader is referred to pertinent textbooks. In general, it can be said that observations are in good agreement with Hann's theory: On the windward side, cloud formation (particularly the stationary foehn wall) and precipitation must occur at a certain altitude as a result of the condensation. This removal of moisture together with the compression of the air during its descent on the lee must cause dissolution of clouds, warmth, and dryness there.

When air flows across a mountain range it is subjected to the above-mentioned foehn processes, as explained by Hann, and exhibits foehn characteristics on the lee side of the mountain. Such an air flow normal to the mountain ridge can be maintained only by a pressure gradient that is parallel to the ridge. Accordingly, such an air flow exists only when the general weather situation has a very definite pressure pattern, as shown schematically in Fig. 13. The sinusoidal deformation of the isobars, characteristically produced by the thermal pressure effect, forms a bulge of the isobars toward the high pressure on the lee side of the mountains and toward the low pressure on the windward side (often called the "foehn nose").

Depending on the orientation of the mountains, the air currents, after passing through the thermodynamic process, show the foehn phenomena to a greater or lesser extent. In the case of mountain ranges oriented from west to east (*e.g.*, the European Alps or the Pyrenees) a south wind will blow across the mountains if the low pressure is to the west and the high pressure to the east (see Fig. 13*a*). Because of its original warmth, the air from the south is well suited to the development of very marked foehn phenomena. For this reason, the *south foehn* is the most striking type of foehn from the viewpoint of the meteorologist as well as of the layman (see v. Ficker [28, pp. 25–37]). If low pressure lies to the east and high pressure to the west, air from the north is transported across a mountain range oriented west-east (see Fig. 13*b*). The cold air piles up to the top of the mountains and then descends on the lee side while undergoing the thermodynamic process. This air, however, exhibits foehn properties only when the foehn process changes its cold-air character to such an extent that, upon arriving on the lee side of the mountains, it

is markedly warmer and drier than the air that was there before. This type of foehn, called *north foehn* [25; 40; 29, pp. 48–53], is relatively rare.

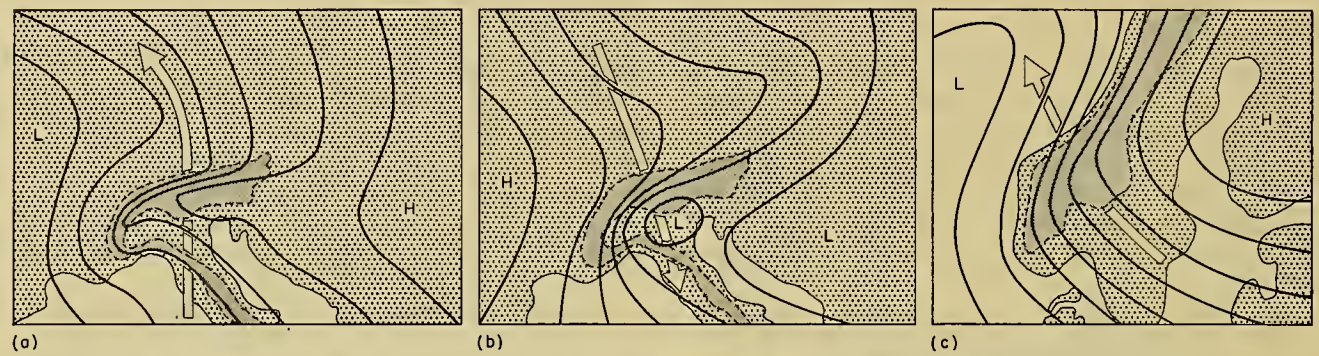

FIG. 13.—Windward and leeward effects of mountains on the isobaric pattern at sea level (schematic): (*a*) south foehn in the European Alps, (*b*) north foehn in the European Alps, and (*c*) southeast current over the Scandinavian mountains.

In the case of a north-south orientation of a mountain range, the development of a foehn requires low pressure to the north and high pressure to the south, or vice versa. Then, a west-east current passes across the mountains (*e.g.*, the Rocky Mountains, the Andes, or those of Greenland, New Zealand, and Scandinavia) (see Fig. 13*c*). On the lee side, considerable temperature differences in the meridional direction occur; for example, in western Canada the broad warm foehn current, after passing the Rocky Mountains, meets the extraordinarily cold Canadian polar air. The result is increased cyclogenesis or rapid deepening of existing cyclones, which must be considered a consequence of the foehn process. This phenomenon, which is to a much lesser extent associated with the south or north foehn, has perhaps an analogy in the formation of the Genoa cyclone south of the Alps and the Apennines.

The thermal pressure effects during foehn cause in all cases a great increase of the horizontal pressure gradient in the direction of the mountains (as much as 9 mb per 100 km at sea level or at the level of the valleys). The mountain barrier prevents the transformation of such gradients into air motion; or, in reverse, the establishment of such gradients is made possible only by the mountain barrier. Although this gradient is less strong at the level of the mountain ridges, it cannot be explained by the thermal contrast alone.

The factors determining the various types of foehn are the general synoptic situation, the orientation of the mountain ranges, and the type of air masses passing over the mountains. In turn, the thermodynamic foehn process causes changes in the pressure field and in the properties of the air masses involved, which affect the general weather situation.

The warming and drying of air, observed in anticyclones, bear great similarity to the foehn and are caused by the dynamic heating during the descent of air from aloft. As with foehn, clouds dissolve and fair weather without precipitation sets in. In these cases, warm air is always present aloft as is evident from observations at mountain stations or from aerological soundings. This warm air rests on the cold air that lies in the valleys and in most cases shows up as a sharp inversion and decrease in humidity. The descending motion is very slow and must be ascribed to a divergent flow at the surface, directed away from the mountains. This phenomenon is called *high foehn* or *free foehn* in the literature [28, pp. 53–58]. Since an anticyclonic situation usually precedes the south foehn, the free foehn over the mountains often forebodes the subsequent development of a foehn current.

The warm foehn current on the lee of the mountains descends into the lowlands rather than ascends as one would expect. The cause of this descent into the valleys is a meteorological problem. Following older concepts, v. Ficker [28, pp. 34–37] has answered this question by resolving the foehn development into several phases (preliminary phase, anticyclonic phase, stationary foehn phase). A period of foehn is generally preceded by an anticyclonic weather situation as the *preliminary phase*, with very stable vertical temperature distribution. Cold air lies in the valleys, with dry warm air above it and separated from it by an anticyclonic subsidence inversion. Before the onset of the foehn, the cold air moves out of the valleys and away from the mountains under the influence of the pressure distribution. The upper boundary of the cold air is thereby lowered, and warm air from aloft supplants it. When this warm air reaches a station, the *anticyclonic phase* sets in for this station. The temperature rise and humidity drop connected with very little air motion indicate the anticyclonic foehn. Thus, the warm air does not actually break through the cold air to the valley floor, but follows the cold air which must first flow out of the valley into the plains while its upper boundary subsides. Only when the foehn wall forms on the windward side of the mountains and the horizontal pressure gradient is increased in the direction of the mountains, does the *stationary foehn phase* set in. In this phase, the foehn proceeds as explained by Hann.

The foehn does not always reach the valley floor as a warm current. If a remnant of shallow cold air remains in the lowlands, the foehn current moves over it. Occasionally, some cold air remains in certain parts of the valley, and the warm air reaches the valley floor only at certain *foehn islands* which are of great climatic significance. Also at night, when the intensity of the

foehn current diminishes and the cold air remnants in the valleys are augmented, these remnants may again combine into a shallow cold-air layer covering the entire valley floor. The foehn current then lifts from the valley floor, a fact that shows up in meteorological recordings as marked temperature and relative humidity jumps called *foehn pauses*. Figure 14 shows a particularly good example of the temperature and humidity records during the foehn period from February 2–5, 1904, at four alpine (Inn valley) stations at different altitudes. In this figure all features of the individual foehn phases, foehn pauses, and the characteristic response of the stations to the south foehn are evident.

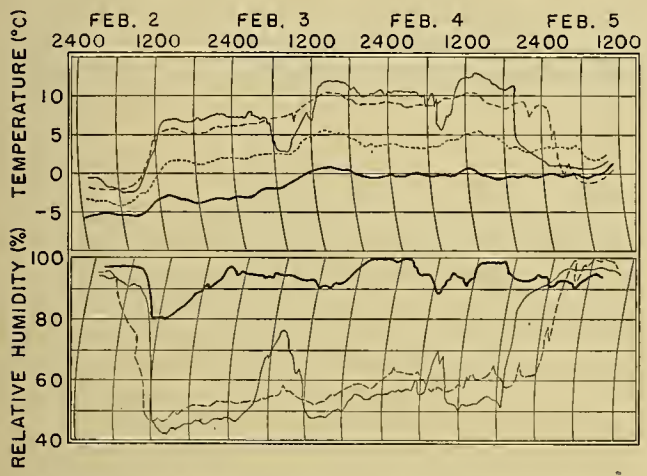

Fig. 14.—Typical south foehn registrations from the Innsbruck foehn area from February 2 to 5, 1904. Thin solid line—Innsbruck (573 m); dashed line—Igls (876 m); dotted line—Heiligwasser (1240 m); thick solid line—Patscherkofel (1970 m). (*After v. Ficker* [24].)

According to A. Defant, remnants of cold air in valleys form closed systems and may be excited into oscillations (similar to waves on lakes) by the passage of a foehn current over them. These oscillations show up as temperature fluctuations that are not to be confused with the short, periodic pressure fluctuations that occur during foehn.

Of special interest is the wave form of the air flow in the free atmosphere on the lee side of hill chains, mountain ridges, or other extended elevations of the ground. When the wave crests of this leeward current reach above the condensation level, the stationary wave becomes visible as a fixed "Moazagotl cloud" on the lee side of the mountains. The Moazagotl cloud consists of one or more cloud banks parallel to the mountain barrier; it forms continuously on the windward side of the wave and dissipates on the lee side. Sailplanes may reach great altitudes in the Moazagotl updraft. Prandtl, Küttner, and recently Lyra [55] have conducted theoretical investigations of these Moazagotl or foehn waves in the lee of mountains. In the development of the theory an increasing number of factors have been taken into consideration; Lyra's recent extension of the theory to include any polytropic stratification brought the theory of sinusoidal air currents on the lee side of barriers to a preliminary conclusion. Figure 15*a* shows the theoretically computed streamline pattern over a mountain barrier. Such foehn waves with their attendant cloud systems have been observed over numerous mountains. The waves caused by the Rocky Mountains in the northwestern United States have been investigated in detail by Hess and Wagner [38]. A particularly interesting case, in which the waves on the lee side reach an altitude of 40,000 ft, is shown in Fig. 15*b*.

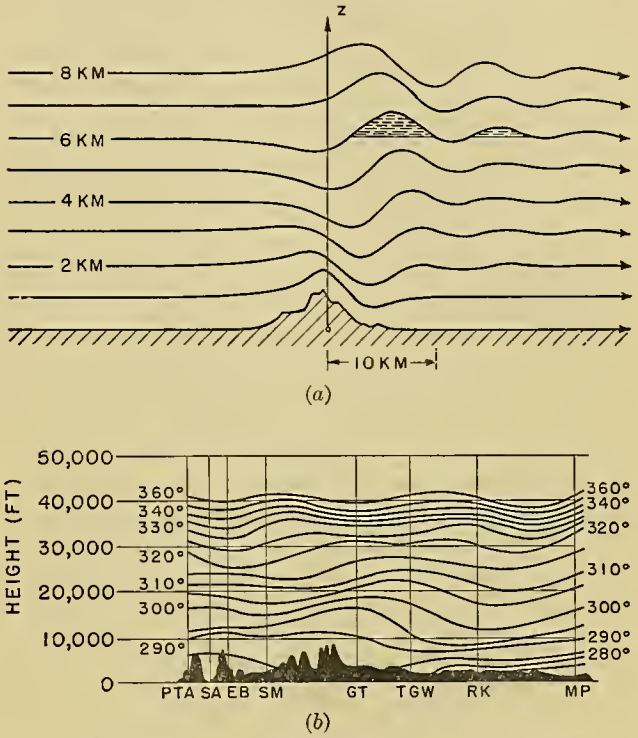

Fig. 15.—Stationary waves in the free atmosphere on the lee side of mountains. (*a*) Streamlines across a mountain range with Moazagotl clouds on the lee side. (*After Lyra* [55].) (*b*) Cross section from Tatoosh Island, Wash., (PTA) to Minneapolis, Minn., (MP) for 0300Z, January 14, 1945; isolines of potential temperature in degrees absolute. Vertical scale: units of pressure-altitude (ft) of U. S. standard atmosphere. (*After Hess and Wagner* [38].)

During well-developed foehn currents, marked physiological disturbances in men and animals occur on the lee side of mountains. These disturbances are ascribed to the short-period pressure fluctuations during foehn [28, pp. 65–105], but their causes have not been completely explained as yet.

The Bora. Hann's theory, which includes all fall-wind phenomena in the mountains, must also explain the cold fall-wind phenomenon. If a very cold air mass passes over a mountain barrier, or if it blows from the interior of a cold land mass over a plateau, the dynamic temperature rise during its descent on the lee side may not suffice to turn this fall wind into a warm foehn. Rather, this wind will be cold upon its arrival in the plain and is called *bora*, after the best-known of these local winds, which occurs on the coast of Dalmatia [48, 49, 57]. There, the cold, continental outbreaks of winter air from Russia find their way through Hungary and over the mountains of Dalmatia to drop over a

low, but relatively steep, slope to the otherwise warm coast of the Adriatic Sea.

The outstanding characteristic of the bora is its extraordinary violence, which often causes heavy damage. The cause of these stormlike fall winds is the liberation of potential energy when the cold air begins to drop to the sea. There are calms between violent gusts of 50–60 m sec^{-1} called *reffoli*, and barometric fluctuations of 4 mm *Hg* are not rare in these cases. The bora does not extend far over the sea. However, it induces a heavy sea and atomizes the wave crests to such an extent that a cloud of mist (*fumarea*) is formed over the ocean. The bora of the Adriatic Sea has a pronounced diurnal period of intensity and frequency of occurrence. The maximum intensity occurs between 0700 and 0800, the minimum around 2400. It occurs most frequently about 0600 to 0700, most rarely about 1400.

We may distinguish between cyclonic and anticyclonic bora, according to the origin. The cyclonic bora is dependent on the existence of a low-pressure area over southern Adria, with an especially warm sirocco blowing from the south over the front portion of this low and aloft over the bora. Consequently, the sky is usually cloudy, and there is precipitation. The bora then blows more steadily and covers the entire Adriatic Sea. For an anticyclonic bora to develop, a strong high-pressure area must exist over central Europe with an extension of high pressure over Dalmatia which need not be opposed by a cyclone with closed isobars in the south. In that case the bora exhibits a violent character, but does not extend far out to sea (about 10 nautical miles). The sky remains clear, with the exception of a foehn wall over the mountains.

Under favorable conditions, well-developed local winds of bora character occur in many areas in the world. These conditions are (1) a short topographic drop, and (2) a sharp climatic division between a cold plateau and a warm plain so that, under suitable pressure conditions, cascading of the deeply chilled continental air can take place. Especially well known are the bora winds of Novorossiisk on the northern Caucasian shore of the Black Sea [1, 3] and those of Novaya Zemlya [75].

A. Defant [16] has dealt theoretically with the question of the drainage of cold air along a slope. His method of attack, in which he bases a somewhat schematic model on the equations of motion and continuity in a doubly stratified atmosphere, allows a very good estimate of the influences of gravity and pressure gradient on this drainage of cold air masses. It is interesting to note that these two influences are of almost the same order; in other words, not only gravity, but also the pressure gradient, has an influence on the drainage of the cold air. If the steady current is disturbed, it may remain stable up to a critical slope angle, in which case small initial disturbances propagate as waves with a definite period and eventually fade out under the influence of friction. If the critical angle is exceeded, small initial disturbances grow exponentially with time, and the current assumes an unstable and turbulent character. A ground slope of 1:100 seems to be the critical value, fully confirmed by observation. An example of a stable current is the orderly, nocturnal outflow of the mountain wind through slightly inclined valleys; one of unstable flow is the extremely turbulent bora in Dalmatia.

The Mistral and Jet-Effect Winds. The bora-like local wind of Provence and the French coast of the Mediterranean up to Perpignan [5, 29, 51] is called the *mistral*. It is a combination of a bora and a wind that is increased through the so-called jet effect. The mistral is due to the drainage of cold air initiated by a high-pressure ridge which frequently extends from the Azores to France, and by a permanent low-pressure area over the warm Gulf of the Lion. Its intensity is increased and its duration prolonged through the constriction of the geographic gate between the Pyrenees and the western Alps. If fresh polar or arctic air enters the Mediterranean basin in the rear of a cyclone that moves off to the east, the bora and the jet effect build up the mistral to a destructive intensity. It should be noted that it is not the shallow cold surface air of the plateau of central France, but the deep break-through of polar air into the western Mediterranean basin that favors the development of the mistral. Similar fall winds and jet-effect winds are caused on the Pacific coast of North America by the break-through of polar continental air; they are known as *northers* [41].

The jet effect, that is, a purely local increase in wind intensity because of certain orographic configurations, is observed in many localities. The convergence of streamlines in a constricted path necessitates a substantial increase in wind speed. The pressure gradients responsible for the jet-effect wind extend only over very short horizontal distances and can be detected only by special investigations. A very detailed study of such conditions in the Vienna basin was made by Margules [56]. In that area, the air masses that stream through the gate between the Kahlenberg and the Bisamberg during a west wind display all the phenomena of the jet effect, and the corresponding pressure disturbances are clearly revealed by barograms.

SURVEY OF DESIRABLE STUDIES OF LOCAL WINDS

Land and Sea Breezes. Further intensive investigation of the vertical structure of land and sea breezes on especially suitable coasts by means of continuous aerological measurements over land and water at various distances from the shore would be most desirable. As regards the theoretical aspects, the problem appears adequately solved.

Mountain and Valley Winds. Accurate aerological cross sections along favorably situated slopes up to the ridge are still needed. Likewise, systematic upper-air soundings should be carried out in a particularly favorable valley location from its deepest recesses out into the plains. Special attention should be given here to the interrelation between the slope wind and the valley

wind. Such investigations should cover the entire cross section of the valley up to the ridges of the flanking mountain chains.

The cell circulation for an inclined slope and the connection of the slope-wind circulation with the system of the mountain and valley winds still constitute a theoretical problem.

Foehn Winds. As an extension of the work of W. Schmidt [68], a comprehensive monograph on the occurrence of the foehn in all areas of the world, with special emphasis on its climatic importance, is needed.

As far as the foehn theory is concerned, its thermodynamic aspects appear to be completely explained. The dynamic side of the problem, which is a purely hydrodynamic problem, can be advanced only by special aerological investigations in the different mountain ranges of the world. Special attention should be paid to the problem of wave formation in the lee of the range.

TORNADOES AND RELATED PHENOMENA

By EDWARD M. BROOKS

Saint Louis University

Introduction

Definition. The word "tornado" comes from the Spanish *tronada* (thunderstorm). In western and north central Africa, "tornado" refers to a thunderstorm. But elsewhere it means an intense spiral motion around a vertical or inclined axis, averaging about 250 yards across, with its lower part [17] often characterized by a narrow pendant cloud [12] extending from a cumulonimbus cloud base to or nearly to the ground.

Frequency. A tabulation of tornadoes which have occurred over a long period of years is needed to determine frequencies. Unfortunately, many severe windstorms are difficult to classify correctly. The number of tornadoes is erroneously decreased by unreported tornadoes and by tornadoes classified as other storms, and it is erroneously increased by nontornadic storms reported as tornadoes [20].

Tornadoes occur on all continents, but are rare except in Australia and the United States. The numbers of tornadoes reported in these two countries [1] average about 140 and 145 per year, respectively, and the frequencies per unit area are similar. Australian tornadoes, however, do not become as severe. In the United States the highest annual frequencies per ten thousand square miles are found in northeastern Kansas (3.2), central Arkansas (3.0), and throughout Iowa (2.5 to 2.3). However, some of these differences between states may be due to their different methods of classifying windstorms. Because the area swept by a tornado averages only about two-thirds of a square mile, the probability of a tornado's hitting a given square mile of the Midwest is generally less than 1 per cent per century.

The number of tornadoes in any one year may vary considerably from the annual average. The seasons, listed in order of tornado frequency for the United States, are spring, summer, fall, and winter. May has the greatest number; December, the least. For an individual state, the month of maximum tornado frequency is usually one month before the maximum hailstorm frequency and two months before the maximum thunderstorm frequency. Tornadoes appear most frequently in the following months: in the southern states in March; in the central states in April or May; and in the northern states in June or July [12]. Multiple tornadoes within a general cyclone are most likely in April or May [12].

Over 80 per cent of reported tornadoes occur between noon and 9 P.M. This preponderance of afternoon storms seems to be least pronounced in winter.

Weather Conditions Associated with Tornadoes

Synoptic Situations. The usual United States weather map, favorable for tornadoes, shows a deep extratropical cyclone with central sea-level pressure below 1002 mb located in the central or northern part of the country, usually with a curved trough extending generally southeastward from it and having a large wind shift across it. The most likely place for tornadoes is within the portion of the trough generally 100–600 mi southeast of the center of the parent low. Tornadoes rarely occur within 50 mi of the primary, or parent, low center, but when they do they are usually very violent.

The following extratropical frontal conditions are associated with many tornadoes. Along the trough there is usually a cold front aloft, or a surface cold front where a maritime tropical air mass is being displaced by a modified continental polar or maritime polar air mass in 90 per cent of the cold front cases and by a fresh continental polar air mass in 10 per cent. Sometimes the trough contains an occluded front or a warm front instead.

Other tornadoes occurring with a deep parent cyclone are not located on a front. Tornadoes occasionally occur in the maritime tropical air warm sector southeast of the parent low center. These tornadoes might be located on a squall line, or at the points of intersection of two or more squall lines [21], or on several closely associated squall lines separated by relatively quiet areas. Sometimes tornadoes occur on the north or west side of the parent low center in the polar air cold sector which may have maritime tropical air over it. Occasionally the parent cyclone is a tropical hurricane, in which tornadoes occur in maritime tropical air usually north rather than southeast of the center. About four-fifths of the tornadoes in the United States are "cyclonic" and the rest "convective." By definition, "cyclonic" tornadoes occur with a well-developed parent low, whereas "convective" tornadoes are either frontal or nonfrontal and occur in a weak parent low, in a weak pressure trough, or even in a high-pressure area. Tornadoes are known to occur along a tropical or intertropical front [9].

Typical aerological soundings [19] of the maritime air in which tornadoes develop show that it has high relative humidity usually only up to about 1–3 km. A thin stable layer, which may be an inversion, separates the maritime air from the dry superior air aloft, which is characterized by a steep lapse rate. The thin layer is convectively unstable because of the rapid decrease of humidity with height.

Nearby Weather Conditions and Preliminary Signs. Tornadoes are not to be expected unless there are some preliminary signs of cumulonimbus activity, since the pendant cloud, sometimes not visible, extends downward from a cumulonimbus cloud base. The under side of the cumulonimbus frequently exhibits a mammatus appearance before the tornado [9]. Along the path of a

single tornado, repeated reports of two cumulonimbus clouds or thunderstorms coming together just before the tornado appears indicate that the junctions are a result rather than a cause of the tornado circulation [11]. In the absence of much light coming through the thick clouds from above, reflections from the ground presumably cause the green- and yellow-tinted clouds near tornadoes. The cumulonimbus clouds are often very dark because of their great vertical extent.

Often a tornado is preceded by a violent thunderstorm (northeast of the tornado) [11]. More often a tornado is followed by a thunderstorm (southwest of the tornado), often a severe one. Or a thunderstorm center may follow a path parallel to the path of the tornado (usually northwest of the tornado). Green-colored lightning and even ball lightning have been reported. On the other hand, sometimes a tornado occurs even though no thunderstorm is reported.

Rain almost always accompanies a tornado [17], but heavy rain is not likely within the tornado itself. Heavy showers are common, especially following a tornado, and frequently yield the greatest precipitation just northwest of the tornado path. Hail is also common [17], sometimes occurring as much as two hours before and/or after a tornado, often northwest and sometimes southeast of the tornado track. Its duration is shorter than that of rain, but it may cause more damage than a minor tornado. Very large hailstones [6], ranging up to discs 7 in. in diameter (weighing 3 lb), and hail accumulating to a depth of several inches have been reported near or even along tornado paths.

The air preceding a tornado is usually warm and humid, whereas the air following it is usually cool and dry. Research at Parks College of Aeronautical Technology showed that 111 out of 142 tornadoes occurred on the line of highest surface dew point. The drop in temperature with the arrival of the first thundersquall usually exceeds the difference between the temperatures of the preceding and following air masses.

Within a few miles outside the tornado path it is not unusual for pressure drops of over 3 mb to occur, and in extreme cases the change amounts to about 10 mb. This indicates that the tornado is surrounded by a low-pressure area which, with its attendant winds, has a radius of about 5–10 mi [2], which is intermediate in size between the parent low and the tornado. In this respect, the tornado is similar to an ordinary thunderstorm, which has an inflow current coming from as far as about 5 mi away from the edge of the active cloud [22].

A tornado is usually preceded by a general southerly wind and followed by a general westerly wind. Research at Parks College showed that 92 out of 132 tornadoes occurred on the line of highest surface wind speed. Winds in the vicinity of the tornado are likely to be strong and variable, sometimes reaching full hurricane force outside the tornado proper. The reasons for these strong winds are that (1) the parent cyclone causing the prevailing winds is more intense than is usual for a cyclone, (2) the secondary low surrounding the tornado has steep pressure gradients, (3) there may be heavy thunderstorm squalls, and (4) small local whirlwinds are often present. Any one of these effects alone or in combination with the others may account for a zone a few miles wide with scattered damage to buildings and trees.

Properties of Tornadoes

Central Pressure and Wind Speed. The pressures and winds within a tornado must be determined largely by indirect methods since there are very few instrumental measurements. These methods include a detailed analysis of the tornado damage and a theoretical study of the relationship between wind and atmospheric pressures. Two fundamental causes of damage are (1) the terrific winds, exerting pressures and suctions, and carrying missiles, and (2) the sudden changes of the prevailing atmospheric pressure. Since both are related to pressure, the combined pressure effects observed on structures cannot be attributed either to atmospheric pressures or to wind pressures alone without the introduction of errors. Cracks in the ground [12] and completely smashed objects cannot be used in estimating wind pressures when the true causes of the damage are unknown.

Although Hazen [11] thought that tornadoes were local high-pressure areas, barographs in tornadoes show pressure drops usually up to 25 mb. In one case an aneroid barometer fell 200 mb (Minnesota, Aug. 20, 1904). The actual atmospheric pressure drops are probably greater because the pressure changes inside buildings are sluggish and because the buildings may not be in the exact center of the tornado path. Espy's experiments [4] showed that low pressure was not the cause of the forced removal of feathers from chickens. Neither this denudation nor the breaking and peeling of bark from tree trunks can be used as an argument for such pressure. Explosions of windows, doors, walls, and roofs not under the direct influence of tornadic winds (when the vortex is just off the earth's surface) are clear indications of the sudden arrival of a very low atmospheric pressure and a very large horizontal pressure gradient. For a frictionless vortex with inflow, the gradient would be inversely proportional to the cube of the distance from the center (except very near the center).

Determinations of maximum wind speeds in tornadoes are rough approximations. Calculations of wind based on structural failures and impacts of flying objects yield values ranging from less than 100 mph to one case of more than 300 mph, enough to demolish the strongest buildings.

Ferrel [6] gives the following theoretical relationships between wind and atmospheric pressure in a frictionless vortex surrounded by a windless environment: The total kinetic energy of the wind is equal to the work that would be done by the pressure gradient in bringing the air into the vortex from the environment. The wind speed is the same as the free-fall velocity of an object dropped in a vacuum from the height having the same pressure in the environment as that at the ground in the vortex. For example, a pressure of 900 mb, or a decrease of 100 mb, would give a wind of about 300

mph. This depression is also equal to the theoretical wind pressure of the corresponding wind. Hence, the wind pressure and atmospheric pressure effects on closed structures should be of the same order of magnitude.

Flow Pattern. Although the rotation of air in a tornado is generally accepted as a fact today, there was no such agreement one hundred years ago [4, 17, 18]. With a few doubtful exceptions [12] the rotation in tornadoes is believed to be always cyclonic. The evidence for this is found in a wide belt of damage usually on the southeast side of a tornado path in the Northern Hemisphere. In this belt the tornado wind must be increased because of the prevailing wind (in approximately the same direction) which in some cases may be responsible for even more damage than the rotation.

Theoretically, the tangential velocity should be inversely proportional to the distance from the center for frictionless inflow, according to the principle of the conservation of angular momentum. Actually, the presence of a frictional torque acting against the wind makes the velocity profile somewhat less steep. Consequently, the vortex is not irrotational as it would be for zero friction, but has a cyclonic vorticity. The direction in which a house is twisted on its foundation is not a reliable indication of the sense of the tornado's rotation nor of its vorticity, as the twisting is dependent on variations (along the windward wall) in the structural resistance and in wind speed, which may be influenced by trees or by a strictly local whirl.

The radial motion in a tornado is inward near the ground. The winds in different tornadoes or even within one tornado probably blow inward at different angles to the radius, depending on the ratio of inflow and tangential speeds. Along many tornado tracks, evidence for the inflow is much clearer than evidence for the rotation, which suggests that, in these cases, inflow speeds may be greater than tangential speeds except near the center. The inflow winds are often strong enough to cause damage by suction over lee roofs or around lee walls, that is, on the side facing the tornado center [11]. This suction, added to the atmospheric pressure reduction, builds up an intolerable pressure deficit outside. On the other hand, the windward roofs and walls are damaged by excess pressure due to the wind (counteracted somewhat by the atmospheric pressure deficit) and by battering from missiles.

Continuity demands a strong vertical motion upward within the vortex. A remarkably strong upflow was once witnessed (Abilene, Texas, June 1938) when a tornado got ahead of its cumulonimbus cloud and immediately created a new cumulonimbus cloud which shot up to an elevation of 35,000 ft in one minute. The rapid vertical acceleration of the air requires a vertical pressure-gradient force upward much stronger than gravity. The central depression of the tornado must be much more pronounced just above the ground than at the ground. Buildings in the path of a tornado receive greatest damage in their upper floors.

Redfield visualized a double spiral, the air from outside the vortex spiralling first downward and inward toward the center, then within the vortex upward and outward. The latter motion was once observed [17]. Whirling air coming down at 1800 feet per minute has actually been encountered by a glider pilot in a desert dust whirl; and hot puffs of air about 20F warmer (because of adiabatic compression) than the prevailing air have been felt at the ground near some tornadoes.

The turbulence in tornadoes is extremely large because of strong surface and internal frictional effects. Mechanical eddies may contain destructive gusts of wind. In the central region of rapid convergence and upflow, speeds of secondary whirls increase as their radii decrease. The presence of such miniature tornadoes may be indicated by short pendant clouds overhead close to the main pendant cloud (for a photograph of this, see [7]).

Appearance and Visibility of a Tornado. A tornado may appear as two columns: (1) a pendant cloud extending downward from the general cumulonimbus cloud base, and (2) an ill-defined mass of dust and debris extending a short distance upward from the ground. The air within the pendant cloud has expanded adiabatically to pressures and temperatures lower than the condensation pressure and temperature of the air mass, which is assumed to have nearly uniform specific humidity before condensation. The freezing level [6] as well as the condensation level is lowered by adiabatic cooling. The core of a tornado felt ice-cold to one observer. At a central pressure of 900 mb the temperature could be as much as 10C or 18F cooler (rather than warmer [4]) than the surroundings.

The shape of the pendant cloud is determined by the slope of the condensation-pressure isobaric surface. The slope is usually steepest near the axis of rotation, but sometimes excessive friction greatly reduces the innermost slope, prevents the cloud from reaching the ground, and changes it from a funnel shape to a basket or balloon shape. If the air is dry enough or the central depression is weak enough for the central pressure to be just slightly below the condensation pressure, the pendant cloud is narrow, resembling an elephant trunk, a rope, or a serpent. After the waterdrops condense in the pendant cloud they tend to whirl outward from the center owing to their centrifugal force. This leaves a very small "eye" at the center [13], characterized by cloudless air and relatively light wind, as has actually been observed.

The dust column is usually wider than the pendant cloud and surrounds its base, because the wind normally reaches a speed great enough to raise dust before the pressure drops as low as the condensation pressure. Exceptions occur where the soil is too wet for dust or where the air is so moist that the pendant cloud is very broad, extending outward beyond the edge of the high winds. The black dust column may be mistaken for smoke rising from a fire. As it rises, most of the debris is thrown outward in all directions by centrifugal force, sometimes giving the appearance of a dark fountain. The condition for the occurrence of damage is not whether the pendant cloud strikes, but whether the usually dusty column of high winds strikes.

As many as nine pendant clouds have been seen from one place during a tornado situation [1, 12]. In many

cases, vortices have occurred about a mile apart [12]; and in extreme cases, only 150 or 100 ft apart. On the other hand, in some of the most destructive tornadoes, no funnel clouds were recognized. Either the pendants were much wider than their vertical extent or they were obscured by darkness at night or even during the day because of heavy precipitation or dust, a very low general cloud base, hills, or buildings. A higher percentage of funnel clouds are seen in the Great Plains than in the eastern part of the United States [12].

The axis of a tornado initially may be nearly vertical, but since the top and bottom usually progress at different velocities, the axis becomes tilted away from the vertical in the direction of the vertical shear until it may be nearly horizontal. The base usually drags behind, because the translatory wind is reduced by friction at the surface. Finally, it may become separated entirely from the cumulonimbus cloud originally over it.

Audibility and Scent. A tornado reaching the ground produces a roaring or buzzing sound which has been heard as long as one hour before it arrived [11] and as far as 25 mi away; this distance is comparable to that at which thunder can be heard, but is much greater than the ½ mi at which the sound of heavy hail can be heard. As this noise still occurs when a whirl is aloft (though to a lesser extent), it is not due entirely to the destruction being caused by the wind, but is due also to vibrations created by frictional effects in the strong wind shear of the whirl. Such sounds are augmented by long rolls of thunder, which may overlap to make a nearly continuous background of rumble.

During one tornado, the air seemed to have a suffocating and burning tendency. Odors during a tornado are rarely noticed. They have been reported as resembling the smell of ozone or burning sulphur. These odors are more likely to be due to the effects of lightning discharges [17] than to the effects of the tornado.

Paths. The diameter of a tornado, or width of a tornado path, which averages close to 250 yards, varies from zero up to about 1 or 2 mi. The length of a tornado path averages about 4½ mi, and ranges from only about 100 ft up to 300 mi. "Cyclonic" tornadoes usually have much longer tracks than "convective" tornadoes, because they move faster and last longer. The most common path length is only 1½ mi, probably because the vortex frequently rises and skips over a stretch of land before starting a new path. Repeated lifting of the funnel may even occur while the vortex is stationary (Miami, April 5, 1925).

About 90 per cent of all Northern Hemisphere tornadoes move in a direction from between south and west because they are embedded in and consequently move with the warm moist air [16], which usually blows from this quadrant. In hurricanes, tornadoes usually move from the east because of their location north of the center. Tornadoes sometimes move from the northwest, especially in Texas, where they may be steered by an upper wind blowing around the high aloft, characteristic of the southwestern United States in summer. A translation from unusual directions [12] may be found where the parent cyclone, if present, is not northwest of the tornado. Sometimes tornadoes within a single system move in widely different directions [12, 16].

The translation speed of a given tornado is not uniform [17]. Also the average translation speeds of different tornadoes vary, ranging from nearly zero to nearly 150 mph, with a mean close to 35 mph. The average tornado durations are computed to be ¼ min at a single point and 8 min on a path along the ground. An extreme duration of over 7 hr along the ground has been observed (Illinois, May 26, 1917).

The tornado path is often nearly straight when it extends for a considerable distance over flat country. For example, it may not deviate more than a mile or two in over 150 mi. Yet such a deviation would make the most common path (1½ mi long) appear to be strongly curved. There is no preferred direction of curvature as the vortex zigzags along. However, experimental research indicates that a vortex rotating in a cyclonic sense is forced to the left of a horizontal current (looking downwind). Possibly the path curves to the left if the tornado is moving faster than the accompanying secondary low, or to the right if moving slower.

Hills and even buildings make tornado paths more crooked. Like a dust devil [14], a tornado on the slope of a hill or ridge tends to be deflected upslope. When ridges and valleys are oriented at right angles to the direction of translation, the tornado tends to skip, but skipping can also occur over water or flat land [17]. It appears that leeward slopes of ridges are more often severely hit than windward slopes, and that valley bottoms [18] are no safer than hilltops. However, some meteorologists do not agree with these effects of topography on tornadoes [8]. Rough terrain destroys many tornadoes, but it sometimes creates whirlwinds by orographic convergence.

Many cases are reported of two or more whirls combining into a single whirl [11], or of one whirl breaking up into several whirls. Under these conditions there is usually only one major whirl.

Theories on the Generation and Maintenance of Tornadoes

Energy for Vertical Motion. A major problem in explaining the formation of a tornado is to find the source of the potential energy and the manner in which it is converted into kinetic energy.

In the nineteenth century, Hare [10] theorized that the chief source was electrical because of lightning in and around the funnel, the fiery appearance [4] of the funnel, the smoky appearance [11] of the dust column, and the scorched appearance [4] of vegetation (owing to the effects of the sun on broken plants) along the path. Hare [10] supposed that the surface air was electrically charged and, being attracted upward by an oppositely charged thundercloud, started a rapid upward motion. Such a flow would tend to wipe out the vertical gradient of electric potential, as lightning does in a thunderstorm. Electrical phenomena are usually considered a result [17] of severe convective activity rather than a

cause of it. Jones [15] finds that lightning in tornadic thunderstorms gives more intense radio static (sferics) than lightning in ordinary thunderstorms.

Espy [4] theorized that heat and latent heat of vaporization supplied the energy for the strong convection in a tornado. To supply thermal energy fast enough, a violent updraft of warm moist air would be required. Since the process cannot get started by itself, the heat of vaporization is a maintaining factor rather than the initial cause, which must be an external source of energy. In other words, the pendant cloud formation aids the tornado, but does not cause it. A California oil fire (1923) heated the surface air sufficiently to generate hundreds of whirlwinds, one of which was violent enough to kill two people and wreck a house.

Hail has been regarded by some meteorologists as being the result of vortex motion [17], and a tornado as being an unusually severe hailstorm cloud. On the other hand, Showalter [19] recently suggested that hail might be the initial mechanism that causes a tornado. Hail falling from the overhanging top of a cumulonimbus cloud would cool the layer of dry air below it by conduction and evaporation until the original dry inversion (or stable zone) would reach unstable equilibrium. As this instability would not extend above the cooled layer, the available convective energy would be concentrated in the lower atmosphere.

Horizontal Motion as a Source of Energy. Showalter [19] points out the necessity of lifting or horizontal convergence for the establishment of free convection. In either case, horizontal inflow is required. Concerning frontal lifting, Humphreys [13] states that vortex motion cannot usually be generated within the warm air mass being lifted, regardless of how much windshift there is at the front. For vortex motion to develop in the warm air it is necessary for the warm air itself to have angular momentum about the center of convection. This requirement may be fulfilled in the trough of a squall line. Horizontal convergence at a front is effective in producing vortex motion if both air masses rise, for in this case the frontal windshift supplies the necessary angular momentum. Humphreys [13] says this condition is best fulfilled at an upper cold front, which Willett [24] qualifies as having a small horizontal temperature contrast.

Taylor [20] regards a tornado as the extreme development of a small intense secondary low formed on a front. There is much evidence in favor of the existence of a secondary low ("tornado cyclone") around a tornado [2]. Before the tornado forms, there is ample angular momentum about the center of the tornado cyclone. To generate and maintain a tornado, a certain minimum rate of inflow is required to create an acceleration of the wind sufficient to outweigh by far the frictional losses.

Garbell [9] mentioned that a tornado may follow a combination of (1) strong vertical motion indicated by a rapidly growing cumulonimbus cloud, and (2) cyclonic circulation. Incipient vortices are present in most thunderstorms; it is only when the gyratory motion becomes very intense that they reach from the cloud base to the ground.

Wegener [23] introduced the theory that a tornado is the same as the rotating thunderstorm squall cloud, one end of which reaches down to the earth. Aside from insufficient observations to substantiate this theory, one objection is that the numbers of tornadoes rotating clockwise and counterclockwise are far from being equal, as would be required if there were no preference as to which end of the squall cloud would dip to the earth.

Cause of the Low Pressure in a Tornado. The biggest difficulty in explaining the maintenance of a tornado is to account for the failure of the low pressure at its center to disappear in the face of strong surface inflow.

A common explanation for the low pressure is that the pressure reduction is caused by the outward centrifugal force of the whirl. If the low pressure is caused by the whirl, the latter must exist first, probably developing between two strong countercurrents. For the low to develop there must be a slight outflow which, by the approximate conservation of angular momentum, would lead to a reduction in wind speeds to values less than those of the original countercurrents. The fatal objection to this explanation is that wind speeds in a tornado far exceed the speeds of the winds prevailing on either side of it.

If inflow rather than a slight outflow is assumed, the centrifugal force of the inflowing air is greatly increased (approximately inversely as the cube of the radial distance). Some have argued that such a terrific increase in centripetal acceleration requires a great strengthening of the pressure gradient and, of course, a very low pressure at the center. Actually the mass inflow would have exactly the opposite effect on the central pressure, namely, the filling of the low. After a slight inflow, the increase in winds would make the centrifugal force larger than the pressure gradient force, making the inflow zero or even reversing it. The fallacy is in the original assumption of unlimited inflow.

The foregoing discussion shows that a tornado cannot be generated by either inflow or outflow at the surface.

Hare [10] proposed that the volume of the uprushing air exceeds that of the inflowing air, thereby leaving relatively low pressure. Redfield disagreed, saying there is no such thing as "suction." A surface low-pressure area can be produced by excessive removal of air upward only if the pressure gradient force acting upward exceeds gravity before as well as during the tornado. This requires the formation of a low aloft, the generation of which still needs to be explained.

Divergence aloft is necessary [3] not only to generate and maintain the low aloft, but also to prevent inflow from filling the low at the surface. Since it is known that there is inflow at the surface and vertical ascent in the core, continuity demands outflow aloft. Such outflow may have been witnessed once before a tornado formed [17]. Espy thought there was enough eviction of air aloft to build up a ring of higher pressure in the surroundings. For deepening the surface low, the outflow aloft must exceed the inflow at the surface. This is possible due to the dragging away (entrainment) of

some of the environment by an upward current [3, 22]. It can also occur if the inflow is reduced, which would be the case with the development of a strong centrifugal force, as described above. Because of the smaller horizontal pressure gradient aloft, the centrifugal force of the whirl overbalances it, producing the outflow needed to maintain the tornado. This is an argument in favor of accepting rotation in addition to some inflow as a necessary feature of tornadoes. An analogy can be found in the case of water running down a drain, high horizontal water speeds being obtained only when there is a whirl. Redfield and Ferrel [6] in the nineteenth century realized that gyratory motion as well as an unstable condition was necessary for the formation of a tornado.

Protection of Life and Property

Forecasting and Tracking. Unlike the ordinary daily weather forecast, reliable specific tornado forecasts cannot be made at the present time [8]. At best, conditions may be found which are favorable for the development of tornadoes over a wide area. Ever since Finley [7] first attempted to limit this area to a quarter of a state, others have been trying to limit the area or time of occurrence by taking into account variations in surface and upper-air conditions.[1] For more than fifty years the U. S. Weather Bureau has been issuing warnings of severe local storms within the next 24 hr without mentioning tornadoes specifically.

Although the exact place and time a tornado will strike are not known, Lloyd [16] and others realized that, once a tornado had formed, its future course could be predicted with reasonable accuracy from a knowledge of winds aloft in the warm air mass. In some midwestern cities, the U. S. Weather Bureau has considered plans for the detection and tracking of tornadoes by telephone, by short-wave radio sets with independent power supplies, and on radarscopes. Identification and tracking should be improved by the use of sferics, a method now being tested experimentally [15].

Injuries, Loss of Life, and Public Safety Measures. The average annual death toll from tornadoes in the United States is about 245 [1]. Since the population of the United States exceeds 100,000,000, the average chance in the United States of being killed by a tornado in any given year is less than 1 in 400,000. Much of the loss of life and many injuries are caused by objects striking people's heads, and by fires starting after the tornado. The greatest loss of life in a single tornado was 689 (March 18, 1925) and the greatest on a single day was about 1200 (Feb. 19, 1884).

People can protect themselves better by learning to recognize local signs of a tornado and to watch the sky when public forecasts call for severe local storms. If a tornado cloud appears, it is advisable (if time permits) to shut off immediately the electric power and gas supplies and to extinguish all fires (in fireplace, furnace, etc.) so that a conflagration will not occur and burn to death someone trapped by heavy debris. The next step is to seek *shelter* quickly in a tornado cellar, or in the southwest corner of the basement of a frame house, or beside an inside partition on a lower floor of a reinforced concrete or modern steel building, but not in a house with brick walls. In a city, it is generally dangerous to try to get in a car and drive away from an approaching tornado because excessively high winds, often with flying debris and hail, could wreck the car and even kill the occupants. If a person is caught in the open without available shelter, to avoid injury or death he should lie flat in a ditch or culvert, hold on to a fixed object to keep from being blown away, and cover himself, especially his head, to protect himself from missiles.

Property Damage, Building Safety, and Insurance. The average annual United States property loss from tornadoes is over $11,000,000 [1]. The yearly damage is extremely variable, depending on the size of population centers hit. Also, the total amount of property and the value of the dollar undergo considerable changes over a long period of years. The greatest damage on a single day, with 57 tornadoes, was about $35,000,000 (Feb. 19, 1884); however, that much damage has been caused by only two tornadoes in St. Louis (1896, 1927). Indirect property losses are from fires and looting after the storm.

The Western Society of Engineers in 1925 recommended that a building be designed for wind pressures of 65 lb ft^{-2} with a factor of safety of 4, which would probably save it in a minor tornado or on the outer edge of a major tornado. A building, especially a public meeting place, should be better protected by being bonded together, being anchored to a basement, having sufficient openings or automatic vents to relieve pressure, and having a grove of large trees (preferably oak) on its southwest side to diminish the wind speed.

Finley, on the other hand, thought buildings should be constructed as if there were no tornadoes, and then be covered by insurance. Most tornado insurance is lumped together with all other windstorm insurance to avoid arguments about whether a windstorm was or was not a tornado. The highest risks in the United States are along the South Atlantic and Gulf Coasts because hurricanes there cause about seven and one-half times as much damage as do tornadoes in the Middle West.

Factors usually taken into account in writing windstorm insurance policies are (1) the location of the building, (2) the construction of the building, and (3) the susceptibility of the contents of the building to damage.

Other Whirlwinds

Since whirlwinds in general have received less attention than tornadoes, they are not well understood. The information given below is based on only a few good sources.

Both dust devils and waterspouts are, on the average, less violent and have higher central pressures

1. For an account of some recent work of this nature see p. 792 in "A Procedure of Short-Range Weather Forecasting" by R. C. Bundgaard in this Compendium.

than an average tornado. Yet, in special cases, they have been known to change into tornadoes.

Dust Devils. The dust devil [14, 25], ranging from less than 10 ft to more than 100 ft in diameter, is about $\frac{1}{100}$ to $\frac{1}{10}$ as large as a tornado. It has no pendant cloud, but a whirling column of dust or sand, in which the size of the particles increases with the distance from the center. Dust devils occur most frequently on very hot days over dry terrain, and are caused by strong surface convection in a slightly irregular wind field. Since the direction of rotation is accidental, it may be clockwise as often as counterclockwise. The horizontal rotation and upflow within a dust devil usually exceed 20 mph. The dust devil is reported to have an average height of 600 ft and to last approximately the same number of hours as it is thousands of feet high. If the prevailing wind is less than 3 mph, a dust devil tends to seek higher terrain rather than to travel with the wind.

Waterspouts. Waterspouts [13] fall into two classes: tornadoes over water, and fair-weather waterspouts.

Most waterspouts are tornadoes, with cyclonic rotation and the characteristic pendant from a cumulonimbus cloud. The spout may appear more transparent through its center than through its edges, because of the presence of a small eye, as in a tornado. Sometimes a waterspout appears to be double, the pendant of condensed water vapor being inside a spreading column, which appears to be a fountain of spray from the surface. Waterspouts frequently appear in groups, as many as thirty having been visible from a ship in one day. Owing to the small amount of friction over a water surface, the motion in a waterspout is more nearly tangential, with less inflow and upflow than in a tornado. The reduced friction and larger moisture supply over a water surface are not the chief factors determining intensity, for, if they were, waterspouts would be stronger than tornadoes.

The fair-weather waterspout, like the dust devil, is a low-level whirl, rotating in either sense. It is caused by irregular air flow and pronounced surface instability, more the result of high humidity than of high temperature.

The water surface under a waterspout is either raised or lowered depending on whether it is affected more by the atmospheric pressure reduction [17] or by the wind force. The waterspout does not lift any significant amount of water from the surface, as shown by the precipitation of mostly fresh water on a ship passing through a waterspout on the ocean. It often dissipates on reaching a shore line because of the absence of sufficient inward acceleration to compensate for frictional losses.

Concluding Outlook

The subject of tornadoes is very old—the ancient savants Pliny the Elder, Seneca, and Lucretius wrote about them. Since then, progress in the study of tornadoes has been slow. Everdingen [5] noted that the literature on tornadoes in the United States in the last half century has, for the most part, been confined to compilations of such statistics as the distribution and frequency of occurrence and description of resulting damage. What is lacking is the application of satisfactory hydrodynamical theories to the frictional vortices of tornadoes, dust devils, and waterspouts. For example, the horizontal velocity profile could be found by an approximate solution of the differential equation expressing the rate of change of angular momentum of a fluid particle in terms of the net torque from surface and internal friction, as has been done for gaseous spray nozzles.

Suggested items for study are (1) the outflow aloft (method of removal and destination of removed air), (2) the formation by action of hail, and (3) the sense of rotation, as examples of explaining facts, checking proposed theories, and verifying accepted ideas, respectively. For this work, many more surface and upper-air observations are needed.

Since the tornado is a local circulation, the meteorological data ought to be gathered over micronetworks which could detect the development of a small secondary cyclone and would accurately locate squalls, thunderstorms, and hail showers with respect to the tornado.

After a tornado occurs, careful surveys should be made of the damage to determine winds and atmospheric pressure drops. A standardized questionnaire [11] should be used in personal interviews and should be published in local newspapers with a request for replies. Copies of local photographs should be obtained for analysis, the best photographs being those which include the top of the cumulonimbus cloud formation above the pendant cloud rather than the pendant alone.

A more complete knowledge of the small-scale circumstances attending tornadoes is needed for the understanding of the nature and causes of tornadoes. Such knowledge will put tornado forecasting and tracking on a firmer basis.

THUNDERSTORMS

By HORACE R. BYERS

University of Chicago

Introduction

Thunderstorms are shower clouds or aggregations of shower clouds in which electrical discharges can be seen as lightning and heard as thunder by a person on the ground. Discharges observed on airplanes flying in clouds do not constitute conclusive evidence of thunderstorms unless lightning is observed illuminating the cloud from another source, since most discharges on airplanes are believed to be autogenous in origin, that is, to result from an intensification of the electric field around the airplane brought about by the innumerable collisions with precipitation particles.[1] Since thunderstorms are showers that have reached a stage of producing lightning, it has been recognized for centuries that they represent an intense form of shower or an advanced stage in the development of convection in moist air. Modern observations indicate that thunderstorms will develop when large accumulations of condensed water, presumably liquid and solid, are being carried upward at heights where the ambient temperature is less than about −20C. It is only under conditions of moderate to high temperature and moisture that large accumulations of water can occur in the atmosphere below the −20C isotherm. Therefore thunderstorms are seldom observed without the occurrence of above-freezing temperatures through a considerable portion of the lower atmosphere. They are most likely in tropical air masses warmed from below in areas favorable for ascending motion, such as over mountains or in large-scale synoptic disturbances.

In summer, thunderstorms in the belt of the westerlies form two different distribution patterns easily recognized on long-range radarscopes. One consists of an irregular spacing of individual storms or masses of storms, and the other appears as a line of thunderstorms, usually running more or less parallel to the low-level wind flow. In low latitudes and in the tropics, the first type seems to predominate. In middle latitudes lines of thunderstorms are favored, as shown by the existence in Ohio of thunderstorm lines on thirty-two out of fifty-six days on which thunderstorms were observed by long-range radar. On only six of these days were the lines directly associated with fronts. Figure 1 is a photograph of the radarscope at Jamestown, Ohio, on July 12, 1947, at 3:25 P.M., showing both types of distribution. Thunderstorm echoes appear in irregularly arranged masses to the north and in a distinct line to the south and southeast.

The tendency for thunderstorms to form in lines, even in the absence of fronts, is not well understood.

Thunderstorms are sometimes observed imbedded within a general nimbostratus cloud cover. These are found in overrunning unstable tropical air in connection with warm fronts of extratropical cyclones. They are most common in spring. Sometimes thunder and lightning will be observed with the passage of a cold front or the center of a depression on a dark, stormy day in winter, even when it is snowing, but most commonly only with rain. In maritime climates winter thunderstorms are not unusual, occurring with fronts and depressions or with the characteristic showers of unstable polar-maritime air.

FIG. 1.—Thunderstorm radar echoes at 1436 EST July 16, 1947 of PPI scope at Jamestown, Ohio. Range circles are for each 50 miles; white area in center is local ground return.

The most thorough study of the nature of individual thunderstorms was that accomplished by the large U. S. Weather Bureau-Air Force-Navy-N.A.C.A. Thunderstorm Project from 1946 to 1949, reported in the government publication *The Thunderstorm* [43]. Most of the factual material given in the following pages is taken from that report, but some speculations, leading questions, theory, and new results are added.

Thunderstorm Structure and Circulation

Numerous investigators have noted that the thunderstorm consists of several cells, each having a distinctive convective circulation. Originally the cells have been separated but later they come together. After they have formed a single thundercloud mass the cells can be distinguished by the patterns of vertical motion measured on airplanes flying through them. The cell boundaries are identified as narrow zones of inactive or nonturbulent cloudy air.

1. Consult "Precipitation Electricity" by R. Gunn, pp. 128–135 in this Compendium.

The life cycle of the thunderstorm cell [7] naturally divides itself into three stages determined by the magnitude and direction of the predominating vertical motions. These stages are:

1. The cumulus stage—characterized by an updraft throughout the cell.

2. The mature stage—characterized by the existence of both updrafts and downdrafts, at least in the lower half of the cell.

3. The dissipating stage—characterized by weak downdrafts throughout.

Cumulus Stage. Throughout the cell there is an updraft which is strongest at the higher altitudes and increases in magnitude toward the end of this stage (Fig. 2). Converging air feeds the updraft not only from the surface but also from the unsaturated environment at all levels penetrated by the cloud. Thus, air is entrained into the cloud and is accommodated by the evaporation of some of the liquid water carried in the updraft. This entraining continues throughout all of the stages.

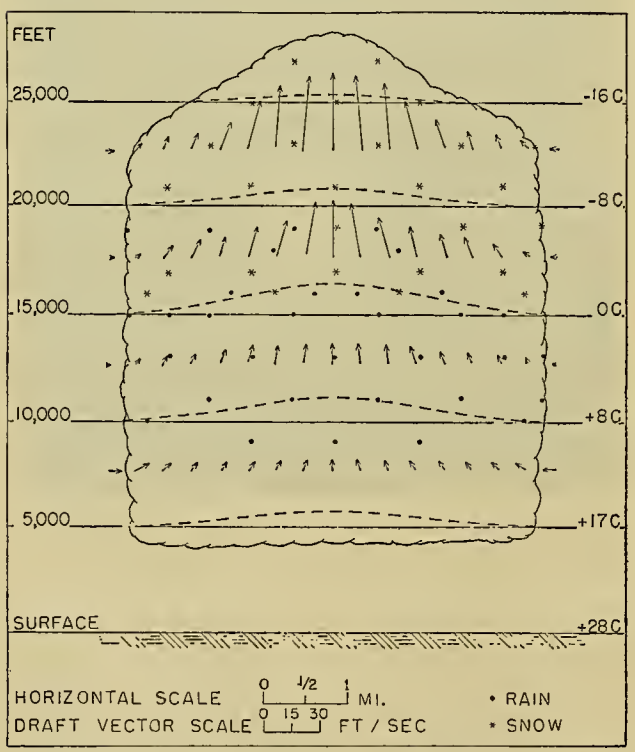

FIG. 2.—Vertical cross section in cumulus stage showing vertical motions, inflow, hydrometeors, and temperature distribution.

In-cloud temperatures in a strongly developing cell are higher than those of the environment at corresponding altitudes. The greatest differences between cloud and environment temperatures are in the regions of strongest updrafts, which are in the upper parts of the cloud and which are especially well developed at the end of the stage.

Although pilots flying through the clouds in this stage report rain or snow, particularly near the end of the stage, these condensation products appear to be suspended by the updraft, since no precipitation is observed at the ground. As a matter of practice, it is found that the end of the cumulus stage and beginning of the mature stage can be signalized by the occurrence of precipitation at the ground. In the cumulus stage there appears to be a considerable concentration of hydrometeors at or slightly above the freezing level in the form of liquid or solid or a mixture of the two. The stronger the updraft the greater is the vertical thickness of the transition zone between water and ice.

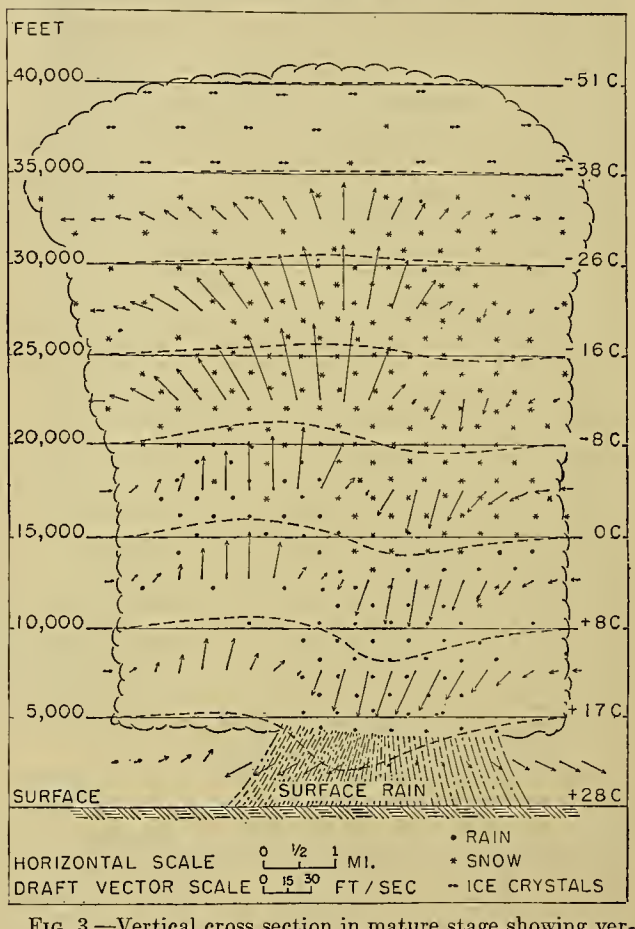

FIG. 3.—Vertical cross section in mature stage showing vertical motions, inflow, hydrometeors, and temperature distribution.

Mature Stage. The mature stage begins when rain first falls distinctly out of the bottom of the cloud. Except under arid conditions, the rain reaches the ground. The size and concentration of the drops or ice particles have now become so great that they cannot be supported by the updraft and they begin to fall relative to the earth. The frictional drag exerted by the precipitation helps to change the updraft into a downdraft which, once started, can continue without this frictional drive, as will be demonstrated later in the discussion of the thermodynamic process. The beginning of the rain at the surface and the initial appearance of the downdraft are nearly simultaneous. The downdraft appears to start in the vicinity of the freezing level, later growing in vertical as well as in horizontal extent (Fig. 3).

The updraft also continues and often reaches its greatest strength in the early mature stage in the upper parts of the cloud. Updraft speeds may locally exceed 80 ft sec^{-1}. The downdraft is usually not as strong as the updraft and is most pronounced in the lower part of the cloud, although weakening near the ground. The descending air is forced to spread laterally at the surface of the earth. Thus areas of rain, downdraft, and horizontal divergence are found together at the ground.

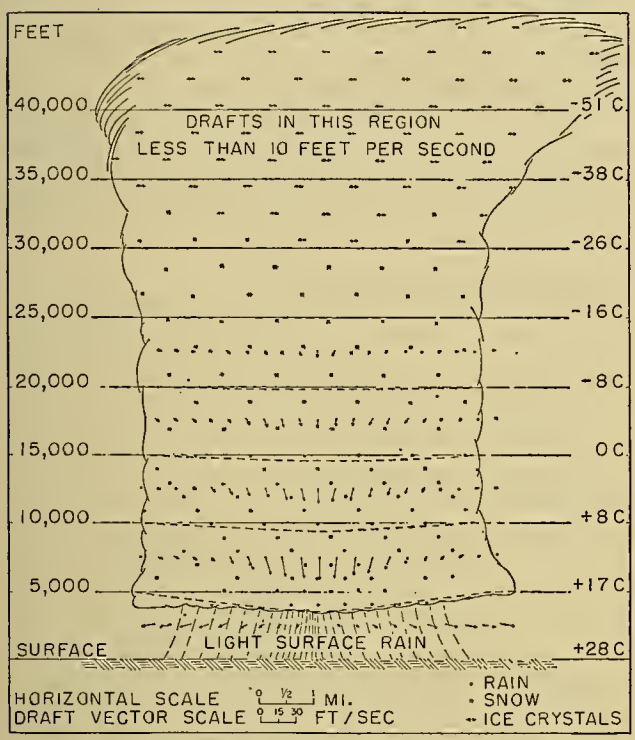

FIG. 4.—Vertical cross section in dissipating stage showing vertical motions, inflow, hydrometeors, and temperature distribution.

Temperatures are low in the downdraft, compared with the environment, and contrast especially with the updraft temperatures. The greatest negative temperature anomalies are found in the lower levels. As might be expected, there is a close association between strong updraft and high temperature and between strong downdraft and low temperature.

In the updraft, mixing of entrained air causes evaporation of some of the liquid water thus removing some of the heat gained from condensation. Instead of the simple wet-adiabatic rate, the updraft air cools at a somewhat greater "entraining-wet-adiabatic" rate. This does not permit the updraft air to become very much warmer than the environmental air. The downdraft seems to be characterized by reversible wet-adiabatic temperature increases in which evaporation counteracts to some extent the compressional effects. Since the downdraft starts out at a temperature very near that of the environment, its wet-adiabatic descent assures that it will be colder than the environment which has a lapse rate greater than the wet adiabatic. The cold downdraft spreads out at the surface as a cold air mass to form the well-known pseudo-cold front advancing against the warmer surrounding surface air.

The mature stage represents the most intense period of the thunderstorm in all its aspects. At the ground heavy rain and strong winds are observed while in the clouds the airplanes encounter at this stage the most severe turbulence, including in addition to the drafts the short, intense accelerations known in aeronautics as "gusts." Hail, if present, is most often found in this stage. From a study of radar echoes it has been concluded that parts of the cloud containing appreciable quantities of water in crystalline form extend to heights of 60,000 ft on some occasions. With very strong updrafts it is possible for liquid water to be carried well above the freezing level. On the Thunderstorm Project in Ohio one case of heavy rain at 26,000 ft, nearly 10,000 ft above the environmental freezing line, was reported.

Dissipating Stage. When the updraft disappears and the downdraft has spread over the entire area of the cell, the dissipating stage begins (Fig. 4). Dissipation results from the fact that there is now no longer the updraft source of condensing water. As the updraft is cut off, the mass of water available to accelerate the descending air diminishes, so the downdraft also diminishes. The entire cell is colder than the environment as long as the downdraft and the rain persist. As the downdrafts give out, the temperature within the cell rises to a value approximately equal to that of the surroundings. Then complete dissipation occurs or only stratified clouds remain. All surface signs of the thunderstorm and its downdraft disappear.

Thermodynamics of Entraining and the Downdraft

Computed and observed inflow rates in American thunderstorms show that the cumulus cloud which develops into a thunderstorm entrains environmental air at a rate of approximately 100 per cent per 500 mb of ascent, that is, it doubles its mass as it rises through a pressure decrease of 500 mb. This is a relatively low rate of entrainment.[2] With very much higher rates of entrainment, the updraft would be theoretically colder than the environment, but this is not found to be the case except in isolated or transitory conditions. Entraining rates greater than 100 per cent per 250 mb would prevent the growth of cumulus clouds to heights great enough to produce thunderstorms in American maritime tropical air. In less favorable air masses the critical entraining rate would have to be lower.

At the present stage of theory and observation of entraining, the updraft seems to follow the required thermodynamic pattern. The downdraft is a special case, however. In Fig. 5 the updraft entraining-wet-adiabatic rate in a typical, well-developed growing cumulus cloud is represented by line $A'B'$ and a typical environmental lapse rate for American tropical air is given by line AB. A saturated parcel displaced downward from C would follow the wet-adiabatic CD, if no

2. Consult "Cumulus Convection and Entrainment" by J. M. Austin, pp. 694–701 in this Compendium.

environmental air is entrained into it. With entraining it would warm at some other, less rapid rate, such as *CE*. If the parcel is dragged downward beyond *D* or *E*, it will become colder than the environment and sink. The frictional drag of the mass of liquid water provides the means whereby a parcel in a thunderstorm can thus be forced below point *D* or *E*, whence it continues as the thunderstorm downdraft. With a large quantity of liquid water available for evaporation, saturation can be maintained in spite of the increasing temperatures during descent and the parcels will reach the ground, arriving there with a temperature several degrees lower than the surface environmental wet-bulb temperature.

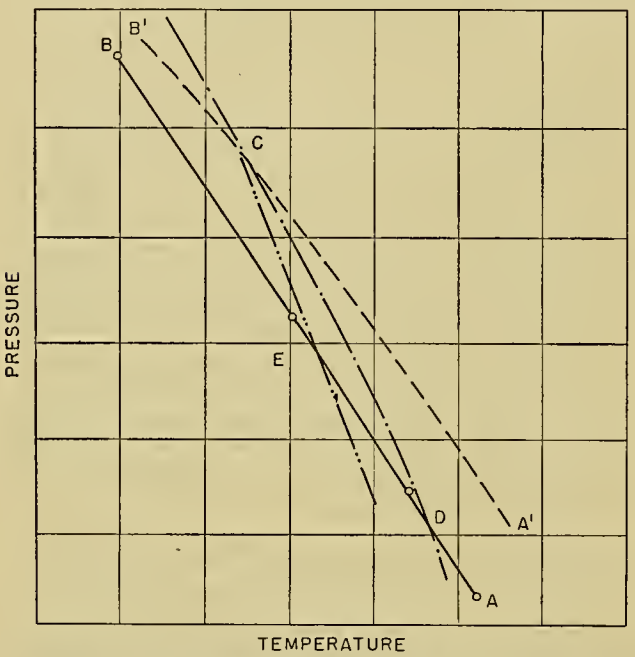

FIG. 5.—Diagram of temperature vs. logarithm of pressure, illustrating thermodynamic process in downdraft.

Thunderstorm Weather near the Surface

Rainfall. The rainfall pattern follows closely the arrangement of the cells and reflects to a considerable extent their stages of development. In some regions, such as the New Mexico area studied by Workman and co-workers [48], single, isolated thunderstorm cells are common. In more humid areas such as the eastern and southern United States, a single-celled thunderstorm is comparatively rare, and when it does occur, it is generally weak and not representative of the average thunderstorm. Usually a group of three or more cells join together to form a thunderstorm and each cell manifests itself in the rainfall pattern. Along with the downdraft and area of horizontal divergence, the rain from a newly developed cell first covers a very small area and then gradually spreads. However, the cold air of the downdraft is able to spread laterally from the cell while the rain falls directly to the ground, so that an expanding outer area of cold air without rain develops. In the dissipating stage this cold-air area continues to expand while the rain area contracts.

If the rainfall is considered with respect to the moving cell, it is found that the duration of moderate or heavy rain from a single cell may vary from a few minutes in the case of a weak, short-lived cell to almost an hour in a large, active one. At a fixed point on the ground the duration of the rain depends upon such factors as the number, size, and longevity of the cells passing over the point, the position of the point with respect to each passing cell, and the rate of translation of the cell. In the eastern and southern United States the average duration of thunderstorm rain at a given station is about twenty-five minutes, although it is highly variable from case to case.

The most intense rain occurs under the core of the cell within two or three minutes after the first measurable rain from that cell reaches the ground and the rain usually remains heavy for a period of five to fifteen minutes. The rainfall rate then decreases, but much more slowly than it first increased. Around the edges of the cell, lesser rainfall rates occur.

Wind Field. Early in the cumulus stage there is a gentle inward turning of the surface wind, forming an area of weak lateral convergence under the updraft. As the cell grows and a downdraft develops, the surface winds become strong and gusty as they flow outward from the downdraft region. The outward-flowing cold air underruns the warmer air which it displaces and a discontinuity in the wind and temperature fields is established. The discontinuity moves outward, pushed by the downdraft, resulting in strong horizontal divergence. Divergence values as high as 8×10^{-3} sec^{-1} or about 1000 times the values observed in intense cyclones, have been evaluated over a small area of the surface micronetworks of the Thunderstorm Project.

The outflow is radial in the slowest-moving storms but in most cases the wind field is asymmetrical with considerably more movement on the downwind side. The prevailing air movement of the lower layers nullifies the radial flow on the upwind side. With respect to the moving cell the outflow may still be radial in character, although not with respect to the ground. Thus the wind discontinuity in most cases is easily detected only in the forward portions of the storm, where it appears as a micro-cold front.

The cold dome of outflowing downdraft air has a form illustrated in Fig. 6. In this sketch the thunderstorm cell is considered to be in the mature stage and is moving from left to right. The cold air is represented as having spread out considerably farther on the downwind side of the cell than on the upwind side, as would be expected in a moving system.

In 15 to 20 min after the outflowing starts, the discontinuity zone has traveled about five or six miles from the cell center. The surface winds near the discontinuity are still strong and gusty but, well within the cold-air dome, the surface wind speeds have decreased so that the strongest winds are no longer underneath the cell itself. A continued settling of the outflow air, transporting momentum downward, causes the wind speed to increase as one approaches the discontinuity zone from within the cold air.

The most interesting of all surface weather features associated with the thunderstorm is the discontinuity zone, which everywhere marks the limit of the cold downdraft air. At a station passed by the cell core in the early mature stage, there is a sharp increase in the wind speed, occasionally to destructive force, and a marked reduction in temperature, occurring with the passage of the discontinuity zone. The sharp increase in wind has been termed the "first gust," since it often appears as the first major gust of a period of strong, gusty winds. After the cold air has spread outward from the cell core in the middle and late mature stage, the wind speeds near the boundary of this air decrease. It is often found that the discontinuity zone is displaced faster than the normal component of the winds immediately behind it. The rapid downflow of cold air toward the ground along the boundary zone thrusts the discontinuity surface forward with a momentum transported from above.

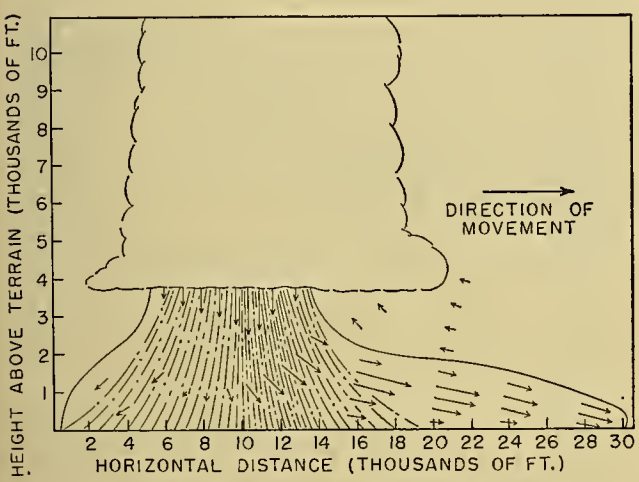

FIG. 6.—Schematic cross section showing formation of cold dome from downdraft. Stippling represents falling rain. Cold-air boundary outlined below the cloud.

With the discontinuity, the wind shows clockwise shifts in most cases. This is especially true in American tropical air currents in middle latitudes where the winds usually are from southwest or south and shift to west or northwest at the discontinuity.

Temperature. The "first gust" and the "temperature break," *i.e.*, the point on the thermogram where the temperature suddenly starts its drop, are two of the most pronounced features observed at the surface, and they occur essentially together. At the time of formation of summer afternoon thunderstorms in the United States the temperature is usually above 85F, often in the 90's. As a result of the rain and the downdraft, the temperature may reach a value as low as 65F without change in air mass. As the thunderstorm activity dies down after sunset, the temperature usually has recovered to an intermediate value representing a mixture of strongly cooled and less cooled or uncooled portions of the air mass.

The area affected by the cooling is many times greater than that over which rain falls, but the temperature change is, of course, most marked in the rain core (downdraft center). Cooling may be detected as much as fifteen to twenty miles downstream. Near the center of a mature cell the temperature reaches a minimum ten to fifteen minutes after the temperature break; farther from the cell the temperature drop is much slower. The amount of the temperature decrease observed in any given storm varies inversely with the distance of the observation point from a cell core. The temperature discontinuity is sharp and well defined under the core but is less pronounced farther away. Since the downdraft is only a few miles in diameter, the area over which the first and most rapid temperature fall occurs is relatively small. As a result, strong horizontal temperature gradients are created after the downdraft first reaches the ground. Gradients exceeding 20F per mile have been observed. As the storm ages, the cold air spreads out and the magnitude of the horizontal temperature gradient decreases. Regardless of the spread of the cold air, the area of minimum temperature remains in the general location where the cold downdraft made its first appearance at the surface, except in cases where a new cell with its own downdraft and rain core develops over another part of the cold dome.

Pressure. Early in the cumulus stage a fall in surface pressure almost invariably occurs. This fall is observed before the radar echo forms, and it is recorded over an area several times the maximum horizontal extent of the echo. When the radar echo appears, the pressure trace levels off in the region directly underneath it, but continues to fall, and frequently at a more rapid rate, in the surrounding areas. The pressure drops in the cumulus stage are usually small in magnitude—less than 0.02 in. (0.67 mb) below the diurnal trend—and take place over a period of 5 to 15 min. Following the fall, the pressure trace remains steady for as long as 30 min.

The pressure falls appear to be caused by the combined effects of vertically accelerated air motions, the expansion of the air due to the release of the latent heat of condensation, and the failure of the convergence near the surface to compensate fully the expansion or divergence aloft. Wind patterns in the vicinity of thunderstorms showed velocity convergence in the developing stages with divergence above 20,000 ft, suggesting a mass balance.

In the mature stage, two features of the pressure trace—the "dome" and the "nose"—are recognized. The dome is registered at all stations to which the cold outflow air penetrates. The pressure nose, the abrupt, sensational rise that some meteorologists regard as typical of the thunderstorm, really occurs only at stations that happen to be passed by the main rain and downdraft just after they have first reached the earth in the beginning of the mature stage. It is superimposed upon or may mark the start of the pressure dome.

The displacement of the warmer air by the cold outflowing air from the downdraft results in the pressure rise, initiating the pressure dome. A study of 206 thunderstorm pressure records from the surface micro-

network showed that in 182 of the traces there was a pressure rise associated with the arrival of the cold outflowing air. Since the rate and total amount of pressure rise depend on the slope of the cold-air mass, the temperature difference between the cold air and the displaced warm air, the depth of the cold air itself, and the speed with which the system travels, the most marked pressure changes are found near the cell-core and decrease with distance from it. The areal extent of the pressure dome is similar to that covered by the cold air. Therefore the pressure remains high for a period of from one-half hour to several hours, depending on the amount of cold air involved.

The distinction between the pressure nose and the pressure dome can be made only with difficulty on the conventional week-long barograph traces, but on the twelve-hour recording drums used on the Thunderstorm Project the distinction is clear.

At any given time the pressure nose was usually detected by but one station per cell in Ohio, indicating that the maximum diameter of the area in which it occurred was less than five miles It is thus apparent that it is caused by a transitory process which exists for only a brief period, namely the time of commencement of the mature stage when rain and downdraft reach the ground. Two effects which are thought to be important in creating the pressure nose are the weight of the suspended and falling water, and a lack of balance between convergence and divergence. Both of these effects are at a maximum at this time. An accumulation of an average of one gram of liquid water per cubic meter from the cloud base to 35,000 ft, a conservative value, would increase the surface pressure by about 1 mb, other factors being equal. When the downdraft becomes established, it reverses at least part of the vertical circulation pattern and reduces the divergence above 20,000 ft, or perhaps even reverses it to convergence. Should this happen before the divergence (outflow) in the surface layers becomes well established, a net increase in mass convergence could result in a substantial surface pressure rise. For example, an uncompensated convergence of 1 hr^{-1} (a conservative value for thunderstorm convergence) within a layer only 1000 ft thick at 20,000 ft would increase the surface pressure at a rate exceeding 1 mb in 3 min. Relationships of pressure changes to vertical motions in thunderstorms, which have been a favorite subject for theoretical treatment by meteorologists, could not be confirmed by data of the Thunderstorm Project. One of the difficulties is that a downdraft at the lower levels is under an updraft at a higher level, so that the vertical accelerations are opposed and tend toward compensating each other.

After the brief pressure nose, the pressure remains at the value of the pressure dome which prevails for the particular thunderstorm. The dome persists through the dissipating stage of the cell, after which the pressure returns to the trend prevailing before the passage of the storm. In the case of a thunderstorm associated with a cold front or a fast-moving squall line, the pressure remains high or even continues to rise as a result of cold-air advection or the passage of a wave in the pressure and wind fields.

Humidity. An extraordinary phenomenon is noted in the hygrograph traces from the surface micronetworks in the form of a sharp decrease in the relative humidity in the midst of the heaviest downpour of rain. With the onset of rain, the relative humidity rapidly approaches but usually does not quite reach 100 per cent, then, in many cases, drops suddenly to values as low as 60 or 70 per cent, returning to near saturation again in a few minutes. Such a fluctuation, termed the humidity dip, and illustrated in Fig. 7, is associated with the rain area. In practically all cases the humidity dip occurred in a region of divergence in the surface wind, therefore in the outflowing downdraft. The temperature was usually decreasing, but if it had already reached its lowest point, as was sometimes the case, a rise in temperature of 2 or 3F would sometimes accompany the humidity dip.

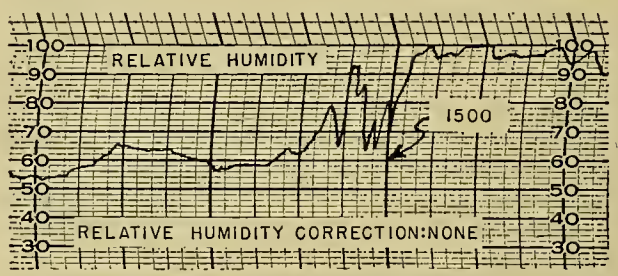

FIG. 7.—Example of humidity "dip" as shown on hygrogram during heavy rain under thunderstorm of August 14, 1947 near Wilmington, Ohio. Time divisions are for 5-min intervals.

The failure of surface air to become saturated during the heavy rain, together with the frequently observed relative-humidity dip, suggests that the downdraft air fails to maintain saturation as it descends, even in the presence of large concentrations of liquid water. Two processes are suggested: first, desiccation of the air by condensation on cold precipitation particles; second, a time lag in the evaporation of the waterdrops so that there is insufficient accommodation to the increase in the saturation mixing ratio as the air descends to lower levels.

Measurements of raindrop temperatures at three feet above the ground show that in afternoon thunderstorms the rain temperature in the first few minutes of the rain period is several degrees lower than that of the ambient air. This would be sufficient to keep the relative humidity from reaching 100 per cent. If the second process mentioned above is taking place, one would expect that the air of the thunderstorm downdraft would be heated at a rate between the moist- and dry-adiabatic and would reach the ground in an unsaturated state.

Development of New Cells. From a study of numerous cases of new cell development, the action of the cold outflowing air appears unmistakably as causing or contributing to the new growth. When two cells in the mature stage are within a few miles of each other, the cold outflows collide. The greatest frequency of new

cell development is in the area between two existing cells whose edges are three or less miles apart. A three-mile band downwind is next in importance, then the lateral edges, and least frequently the upwind or rear side.

In some cases the time interval between the beginning of the outflow and the appearance of the new cell on the radarscope is too short to permit explanation of the new development as a result of the underrunning cold air or similar time-consuming process. There are cases, as indicated by the radar echoes, in which one or a cluster of new cells comes into existence almost simultaneously with the initial or parent cell, which suggests that a preferred region of convergence and ascent favors the development.

Cloud Structure in Relation to Thunderstorm Electricity

Atmospheric electricity and its phenomenal aberrations in thunderstorms are treated in other articles in this Compendium.[1,3] A few observations might be made at this point relating the meteorological thunderstorm structure and dynamics to the electrical structure and electrodynamics.

In recent years abundant information has been presented indicating that thunderstorm electrification is somehow associated with the ice phase in the cloud or, more probably, with a heterogeneous mixture of liquid and solid condensates. For example, recent studies by Workman and Reynolds [48] and by the U. S. Thunderstorm Project [43] show that lightning does not occur until the visible cloud top has ascended to where the temperature is less than about −28C or the top of the echo seen on a 3-cm height-finding radar at a range of twenty miles has surpassed the isotherm of −20C. A number of studies indicate that the upper positive-charge center is located where the temperature is near −20C and the lower negative center is at a temperature of 0 to −10C (roughly). Between these two centers is the lightning hearth region, that is, the region where the first lightning develops. In these temperature ranges mixtures of liquid and solid precipitation particles are commonly observed in growing and established thunderstorms.

Workman and Reynolds [49] discovered an effect, earlier indicated indirectly by Dinger and Gunn [11], involving the freezing of water, which offers a clue as to the processes which might produce electrification in the freezing parts of thunderstorms. They found that water containing contaminants which are likely to be found in the atmosphere could produce, as it freezes, potentials of more than 150 volts across the ice-water interface. Extremely dilute solutions of the order of 10^{-6} to 10^{-3} normal, constituting very pure water by industrial standards, produce the desired effect. Calcium hydrocarbonate, $CaH(CO_3)_2$, formed from calcium carbonate in the presence of carbon dioxide, both found in the atmosphere, is observed to transfer negative ions across the interface to the ice, leaving the water positive and the ice negatively charged. Ammonium compounds and acids or substances with high *p*H produce the opposite polarity, that is, with the water negative and the ice positive. Workman suggests that in the cloud some of the water freezing around an ice pellet is torn off and carried upward as small droplets in the cloud while the frozen core, being larger and heavier, falls. If the cloud particles contain a contaminant, such as calcium hydrocarbonate, which produces positive water and negative ice in the freezing process, the carrying upward of the positively charged portion and the descent of the negative ice would produce the observed polarity of thunderstorms at these levels.

Observations by Weickmann [44] and Kuettner [19] on the Zugspitze in the Bavarian Alps, where the observatory was at or near the freezing level in most thunderstorms, indicate that a predominant form of solid precipitation other than ordinary snow is a graupel made up of an agglomeration of tiny supercooled droplets to form rime clusters. An ice core with a film of liquid around it, as might be expected in a hailstone, would be required for Workman's hypothesis. Further observations of the exact nature of precipitation particles in the freezing regions of thunderstorms are needed in order to clarify the discussion. The precise recognition of these precipitation forms is next to impossible from an airplane.

Kuettner also found that the region of greatest lightning activity coincided with the downdraft and heavy rain core. Furthermore in this center of activity there was frequently a small center of positive charge embedded within the main lower negative charge region and centered on the 0C isotherm. This corresponds to some extent with the picture given by Simpson and Robinson [32] of an isolated lower positive-charge center. Observations of what appeared to have been a lower positive charge in an area of heavy rain and downdraft were obtained in a series of traverses through the lower part of a thunderstorm on one of the Thunderstorm Project flights. This is another phenomenon that needs further investigation.

In seeking to explain the electrification of thunderstorms, most scientists have looked to aspects of the updraft. However, the Thunderstorm Project data indicate that the greatest lightning activity is in the region of downdraft and heaviest rain, as noted by Kuettner. It is not entirely logical to conclude from this, however, that the charge-generating mechanism occurs in the downdraft, because the boundary separating updraft from downdraft in the mature stage is not vertical and a region of updraft may be found over a downdraft.

On the Thunderstorm Project a study was made using recording point collectors located on the ground and a height-finding radar scanning the thunderclouds from a point about twenty miles away. The following conclusions concerning lightning were indicated by the data:

1. The cloud tops (echo tops) reach a height where the environmental temperature is around −20C before the first lightning occurs.

3. Consult "Universal Aspects of Atmospheric Electricity" by O. H. Gish, pp. 101–119.

2. The maximum lightning frequency occurs at the same time as the cell reaches its maximum height.

3. As the height of the cell top decreases, the frequency of lightning also decreases.

4. It appears that a greater cell height (or lower temperature of the cloud top) is necessary to initiate lightning than is required to maintain it once it has started.

5. In the life cycle of a thunderstorm the maximum frequency of lightning precedes the time of its maximum 5-min rainfall.

This last conclusion may have some meaning in connection with the possibility of the suspension of the raindrops by the electric field.

The Thunderstorm as Disclosed by Radar

A number of studies of thunderstorms have been made by radar. A large amount of useful data was obtained from the radars of the Thunderstorm Project. From the photographic records of the range-height-indicating (RHI) radarscope it was possible to obtain data on the altitude of first formation of 66 radar echoes from convective clouds. A graph was made of the frequency distribution of the differences between altitudes of the tops of the initial echoes and the concurrent heights of the freezing level. The distribution showed a pronounced mode at 1000 ft above the freezing level but the mean was at +2200 ft. In convective clouds the echoes appear abruptly after the cloud has been visible to field observers for some time, suggesting a sudden release of great quantities of large waterdrops after penetration above the freezing level, in accordance with the Bergeron theory.

It was found that the rate of vertical growth of the top of a radar cloud echo agrees closely with the updraft velocity measured in that portion of the cloud if a correction factor of about 3 ft sec^{-1} is added to the radar growth rate to account for the relative free fall of the attenuating snowflakes or other particles. The use of radar in this manner for measuring updrafts appeared to have a practical application in detecting hail possibilities, since all observed cases of hail accompanied strong updrafts.

It was noted that the thunderstorm tops ascended in a series of steps, appearing as the growth of new protuberances or "turrets," during their growth and, as a matter of fact, in 32 cases studied, the maximum height reached was correlated with the number of turrets thus formed by a coefficient of $+ 0.67 \pm 0.10$. Each successive turret was higher than the preceding one, and the mean lapse of time between successive turret peaks was 17.8 min. It is believed that each turret makes it easier for the following ones by increasing the moisture content in the cloud-top environmental air which must be entrained in further growth. Less heat of condensation is robbed from the new turret by entraining than would be the case if it were standing alone in a dry environment. Each turret underwent a growth period followed by an interval of subsidence. The growth period averaged about 16 min. The average vertical growth rate was about 18 ft sec^{-1} and the subsidence rate about 12 ft sec^{-1}.

The mean of the maximum heights reached by 199 Ohio storms as indicated from the radar was 37,500 ft. There was no significant difference in this respect between different types of thunderstorms, such as air-mass, squall-line, or frontal.

The boundaries of the radar cloud echoes were found to agree closely with the visible cloud limits except in the levels near the cloud base where non-echo-producing "outrider" clouds were common. Also the anvils and other layer-type lateral extensions usually did not return a radar echo. A positive correlation was found between the horizontal and vertical extents of thunderstorms; that is, the taller the cloud, the broader it was. The greatest areal coverage was at an altitude around 10,000 ft. The cross-sectional area was slightly less at the lower level and tapered at the top, forming a total cloud echo shaped like a rosebud.

From radar scans covering an area of over 55,000 square miles, it was found that on average thunderstorm days in Ohio 10 per cent of the area would be covered by cloud echo, and on a day of maximum thunderstorm activity, 40 per cent of the area would be covered. It is found from indirect comparison that at 20,000 ft the in-cloud areas would average 5 per cent and have a maximum of 22 per cent, indicating the better chance of avoiding thunderstorms by flying high. (Other measurements showed that these high levels are the worst choices for flights *within* thunderstorms.)

Effect of Environmental Wind Field

The causes and effects of vertical shear, including effects of entrainment and momentum transfer in the drafts, have been investigated by Byers and Battan [6] and Malkus [20].

With the aid of long-range radar and abundant upper-air wind data, the movements of thunderstorms in Florida and Ohio were studied in relation to the wind fields in which they were embedded. A method was devised whereby the translational component of the motion could be separated from the growth or dissipative component.

It was found that the motion of the storm corresponded most closely to the mean vector wind between the gradient level and 20,000 ft. The correlations were better in Ohio than in Florida owing to a stronger, more consistent wind flow in the former region. In direction, the correlations were 0.95 or better in both regions. It was found that the speed of the cloud was less than that of the vector mean wind from gradient to 20,000 ft. When the two speeds are plotted, a nearly straight line is formed, but the relationship is better represented as

$$U_w = 1.9 + 0.65U_c + 0.020U_c^2,$$

where U_w is the vector mean wind speed and U_c is the cloud speed.

Preferred Areas of Thunderstorm Development

The movement of thunderstorm cells is closely related to the question of preferred areas for their new develop-

ment, for movement is in part comprised of propagation which in turn results from new growths or extensions. In the preceding section, measurements were described in which the propagation and dissipation components were removed from the thunderstorm motions. When this is not done erratic motions are indicated. At the end of the section on thunderstorm weather near the surface it was shown how certain areas immediately surrounding existing cells are favorable for the formation of new ones. These frequently become attached to form a larger thunderstorm mass. In mountainous areas the propagation components in the motion usually outweigh the wind components. Thus thunderstorms are seen to propagate along a mountain range even though the wind is blowing across the range at all levels, and sometimes there will be few or no cells drifting into the valley so that the wind component in the motion is relatively ineffective.

Certain features of the earth's surface provide an ideal location for new thunderstorm development. Mountains and, in fact, rugged relief of any kind as contrasted with smooth terrain will be favorable. Islands, peninsulas, and other pronounced heat sources are favorable for the formation of afternoon storms. In Florida it is found that the convergence of the sea air over the peninsula from both sides in the afternoon is favorable for thunderstorm formation [10]. Locally on the peninsula the dry land areas as contrasted with the numerous swamps and lakes are most favorable for new formation.

In Ohio, a study of the initial appearance of 584 radar clouds on 21 days showed a larger number of echoes from day to day over the rougher parts of the terrain. However, plenty of new echoes formed over the flattest, smoothest areas. Neither in Ohio nor in Florida was it possible to find a well-marked region from which the first thunderstorm of a series would develop. The thunderstorm hearth (*Gewitterherde*) described by von Ficker [13] was not apparent.

In many parts of the world popular notions have developed concerning an apparent tendency for thunderstorms to follow rivers. The idea is often expressed that the moisture provided by the river favors propagation along the watercourse. Scientific studies indicate that, where thunderstorms propagate along rivers, conditions of the terrain rather than the presence of the water are the factors which are favorable for new growth. Many rivers have bluffs along their flanks and the immediately surrounding terrain is roughly dissected by tributary streams. In Ohio the maximum number of new formations occurred over the sharply dissected plains. The area studied is predominantly a peneplain at about 1000 ft through which streams cut down to the Ohio River (about 500 ft at Cincinnati).

Squall Lines

During the 127-day period from May 17 to September 21, 1947, there were in Ohio 56 thunderstorm days on which extensive radar data were obtained. On 32 of these days lines of thunderstorms were observed. The lines on 6 days occurred along surface fronts, on 19 days were ahead of surface cold fronts, and on the remaining 7 days apparently had no connection with the surface fronts. As is usual throughout the eastern United States, the pre-cold-front squall line was the predominating scene of thunderstorm activity.

It was found that the pre-cold-front squall line is not quite parallel to the cold front but has an orientation averaging 13 degrees clockwise from that of the front. Its orientation is somewhat counterclockwise from the orientation of the overlying 700-mb contour lines. The movement of the squall line, as distinct from the movement of the individual storms composing the line, is not very closely related to the speed of the following cold front; in many cases it moves faster than the front. The individual elements of the line, or storms, move with the prevailing upper winds as described in a preceding section.

The pre-cold-front squall line on the synoptic chart is frequently observed to last for periods as long as twenty-four hours, during which it may travel several hundred miles. When viewed on the radar, it was found that there is usually a zone of convective activity comprising several lines and, although the zone may persist for a considerable period of time, the lines within it are constantly undergoing change—new lines are forming and older ones are dissipating.

The elements in a line range from a single isolated echo one to two miles in diameter to a large aggregate of storms appearing on the scope as a single, more or less homogeneous echo having a maximum dimension of over thirty miles. The number of separate elements in a line varied from 4 or 5 small echoes in the early stages to as many as 40 or 50 at the time of maximum echo intensity. For the most part, elements were found to form and dissipate on a given squall line, suggesting the existence of a preferred line formation.

The squall line or, more properly, the squall-line zone was found to be at an average distance of 170 miles ahead of the cold front, with extreme values of 80 and 325 miles. Generally there was an area of relative inactivity between the cold front and the trailing edge of the squall zone; but on one or two occasions the convective activity finally extended back to the front itself.

Generally, the thunderstorms associated with the squall lines were little different from any others except for a tendency to be more severe, especially in producing effects at the surface, such as strong, gusty winds. Since the storms come in a line, there is a more or less connected discontinuity line from the cold outflowing downdraft which is often mistaken for a true front. The return to tropical air-mass conditions afterward shows the local character of the discontinuity. The pressure "dome" of the combined storms often results in the creation of a long pressure ridge along the squall line. Sometimes a squall line of this character may after a time produce a true frontal discontinuity involving more cold air than can be accounted for by the downdraft.

Of the seven squall lines that were not associated with fronts, three were related to some type of large-scale cyclonic disturbance, two were on the west side

of a warm anticyclone and the other two were in rather flat, uniform pressure fields. These lines were usually short compared with the prefrontal types and seemed to be less well defined.

Remarks on Thunderstorm Forecasting

It is not practical in this article to discuss all of the important points related to the forecasting of thunderstorms. The problem is intimately connected with the general subject of forecasting treated elsewhere in this Compendium.

Historically, thunderstorm forecasting has been of unique interest because it seemed to be the one atmospheric disturbance that could be treated quantitatively from a thermodynamic consideration of the buoyancy forces in an atmosphere in labile equilibrium. A series of rival thermodynamic diagrams was developed by different meteorologists, largely stimulated by the possibilities of forecasting convection through thermodynamic analysis of upper-air soundings. Refinements of the parcel method and finally the introduction of the slice method and variations of it were aimed at this problem.[2,4]

Some meteorologists drew attention away from the analysis of individual soundings to studies of upper-air charts which they believed would hold the key to thunderstorm forecasting. Namias [21, 22] introduced the isentropic chart as a means of forecasting thunderstorms, showing that the occurrence of summer thunderstorms depended on the presence of a moist tongue on isentropic surfaces in the vicinity of a potential temperature of 315K, usually found at an altitude around 3 to 4 km in the eastern United States in summer. The moist tongues, with dry "tongues" or areas between them, occur over tropical air masses that are more or less homogeneous horizontally in the low levels. Thus the upper-air humidities appear to be critical. Namias' work implied a mechanism similar to what is now known as entrainment in order to account for the arrested growth of convection in a dry upper-air environment.

The picture seems to be somewhat as follows. While on the lower isentropic surfaces there seem to be only slight gradients of water-vapor content within the tropical air masses, there is great variability of moisture on the surfaces around 315K. These variations can be tracked from one isentropic chart to the next in the form of moving moist and dry tongues. Analyses of separate soundings in terms of stability may lead to error because a dry tongue may replace a moist tongue or vice versa in the forecast period at a station.

If a strong dynamic cause for ascent exists in the tropical air mass, water vapor will be carried aloft to isentropic surfaces where it existed only in small quantities before. Thus, in addition to a chart of the moist tongues existing aloft some study of the possibilities of strong low-level convergence with accompanying ascent should be included in the forecast preparations. There is evidence to indicate that the two main summer moist tongues of the United States are caused by convergence and ascent over (1) the Mexican Plateau [45] and (2) the Florida Peninsula [10]. Some meteorologists conclude that thermal instability may be a necessary condition for thunderstorms but is not a sufficient one. A dynamic process, inducing ascent, is also considered to be required. If remote convergence and ascent which supplies the extensive moist tongues is included in this dynamic process, the conclusion probably is correct. Direct studies of the wind field disclose local areas of low-level convergence if their size is in the proper relationship to the density of the observation network.

The Thunderstorm and the Airplane

Besides the usual difficulties of flight in clouds, the thunderstorm presents the additional, unique hazards of lightning, hail, and heavy turbulence. Flight records show that turbulence is the most predominant danger in thunderstorms and may be the principal cause of thunderstorm accidents. The difficulties of maintaining proper flight attitudes or air speeds within highly turbulent clouds may lead to loss of control or structural damage. It is believed that hail damage is second in importance as a hazard, and that lightning is third. Since hail and lightning are covered in other articles in this Compendium, thunderstorm turbulence effects will be emphasized here.

It is convenient to recognize two classes of turbulence —gusts and drafts, corresponding to two fairly distinct types of response experienced on an airplane and measured by two different techniques. In a draft, the airplane is displaced in altitude in one direction over several seconds of time because of the mean upward or downward motions of the air. Gusts subject the airplane to a series of sharp accelerations without a systematic change in altitude. These accelerations are caused by abrupt changes in velocity of the drafts and by small vortices or whirling masses of air. The larger gusts are invariably associated with strong drafts. If the airplane is flown at constant power setting, attitude, and air speed, the draft velocities can be measured by rates of vertical displacement shown on a recording altimeter. The gusts can be obtained from an accelerometer trace. The techniques of both measurements have been developed to a high degree of reliability by the Gust Loads Section of the National Advisory Committee for Aeronautics and are described in N.A.C.A. publications [12].

In order to provide a gust measure that is applicable to studies of the gust loads imposed on airplanes, aeronautical engineers determine the "effective gust velocity." In simplest terms, this may be defined as the vertical component of the actual velocity of a "sharp-edged gust" that would produce the acceleration in question on a particular airplane flown in level flight at a known air speed and a given air density. The effective gust formula is of the form

$$U_e = K \frac{a}{\rho_0 V (\rho/\rho_0)^{\frac{1}{2}}} \text{ ft sec}^{-1},$$

4. Consult "Thermodynamics of Clouds" by F. Möller, pp. 199–206 in this Compendium.

where K combines a number of factors relating to the airplane used, a is the acceleration increment in g units, ρ and ρ_0 are air density at flight level and sea level, respectively (slugs ft^{-3}), and V is the true air speed (ft sec^{-1}).

The relationship shows that a given effective gust velocity will produce a greater acceleration the higher the speed of the flight. Through substitution of the values of airplane characteristics contained in K, the accelerations produced on one airplane can be translated into the accelerations on another of different characteristics.

From 1362 traverses through thunderstorms on the Thunderstorm Project it was determined that if on any one of these traverses the mean maximum U_e per 3000 ft of flight exceeded 8 ft sec^{-1} and four gusts per 3000 ft, the aircrews reported the turbulence as heavy. The flights were made by crews highly experienced in bad-weather flying. This information proved useful in convincing pilots and meteorologists that data collected by N.A.C.A. in which gust velocities rarely exceeded 25 or 30 ft sec^{-1}, really represented violent thunderstorms. The highest gust velocity recorded on any of these flights was 43 ft sec^{-1} which, incidentally, exceeds the maximum gust load that many airplanes are built to withstand at cruising speeds, free of maneuver loads. By contrast, sustained drafts of greater than 30 ft sec^{-1} were not uncommon and on a few occasions the values were in the vicinity of 90 ft sec^{-1}.

A significant difference among the different levels flown was noted in the magnitudes of gusts and drafts and in the frequency of high values. The lowest values of both gusts and drafts were, in the mean, found at the lowest standard flight levels of the project—6000 ft above ground in Florida and 4000 ft above ground in Ohio. A statistical treatment of the data shows a tendency toward increasing turbulence with height up to the highest levels flown (25,000 or 26,000 ft), but the differences between the various levels from 10,000 ft upward in this respect is slight. The draft velocities showed a distinct maximum at the highest levels. In general, the values of both types of turbulence were greater in Ohio than in Florida, possibly due to a more successful effort to get the airplanes into the thunderstorm before the very intense early-mature stage had passed. The mean of the maximum effective gust velocity above 4 ft sec^{-1} in 3000 ft of traverse in Ohio was 9.4 ft sec^{-1} and in Florida 8.9 ft sec^{-1}.

By the use of a range-height-indicating radar, measurements have been made on the rate of growth of thundercloud tops, some of which have been observed to extend above 55,000 ft. These measurements show that the mean rate of growth, up to an altitude about 10,000 ft below the top of the individual storm, increases with height. The rate of growth of these cloud tops is also a measure of updraft velocities. Therefore one might assume that the updrafts and, with them, the gust velocities, increase with height, at least during the growing stages, up to a level about 10,000 ft less than the maximum height reached by the storm cell.

Finally, it has been shown that areas of highest water concentration in a thunderstorm are the areas of heaviest turbulence. This supports the idea that radar can be useful for avoiding areas of excessive turbulence. In flights below the cloud base, the heaviest turbulence will be found where the darkest rain columns are seen.

Unsolved Problems and Future Research Needs

Although the research in the three years from 1946 to 1949 added more details to our knowledge of thunderstorms than had been accumulated in many decades previously, it also focused attention on a number of unsolved problems.

Some of the questions can be settled by further detailed observations or measurements. One question of detail having fundamental importance for the whole circulation and energy problem is brought up by a finding of the Thunderstorm Project that the strongest downdrafts as well as updrafts are frequently found in the upper parts of the cells. No rational picture of a thunderstorm cell with the downdraft decreasing downward has been devised. Additional data should be gathered, since the number of measurements of downdrafts is small at the high altitudes. Because of difficulty in maintaining the attitude of the airplane, more than 30 per cent of the drafts could not be evaluated. Another detail that could be studied concerns entrainment. It is not known to what extent entrainment involves lateral mixing. This could be solved by obtaining the horizontal gradient of water vapor from some distance outside the cloud up to its very edge by means of an airplane carrying a sensitive dew-point hygrometer. Further measurements are also needed concerning the tendency toward desiccation of the downdraft air, as indicated by the "humidity dip" at the ground in the rain core.

Additional observations should be made on thunderstorms in arid regions, especially in those cases where the condensation level is very high and the rain may sometimes evaporate before reaching the ground. The water and energy budgets of such cells must be radically different from those of humid regions. The problem of hail has not been solved in relation to thunderstorms. Hail, unless in the form of stones more than a centimeter in diameter, is hard to detect in a fast-flying airplane, since heavy rain itself makes a great deal of noise. The Thunderstorm Project did not obtain data from the region of maximum hail occurrence of the Great Plains and Rocky Mountain states. The problem of hail in the generation of thunderstorm electricity is a critical one. In spite of the nearly 200 years that have elapsed since Benjamin Franklin discovered that lightning was a form of electricity, we still are not sure what causes it.

The squall line and tornadoes in relation to thunderstorms are a wide-open field for investigation. Tepper [37] and Newton [23] have attacked these problems from novel viewpoints. The dynamics of the pre-cold-front squall line—whether it is a hydraulic jump phenomenon as emphasized by Tepper or has other special characteristics—need further investigation. In this connection it is interesting to note that, from radar photographs, it appears that squall lines crossing the isobars

at a slight angle and therefore having a spiral appearance, also occur in hurricanes and typhoons. Is there some predisposition for extreme convection in the atmosphere to occur in lines? If so, why?

At this writing, computations of the water budget and the energy budget reveal problems of a fundamental nature. One finding is that under average conditions only 10 per cent of the total water involved in a thunderstorm reaches the ground as rain. This is not only of significance to hydrologic studies but also places limitations on computations of the amount of precipitation producible by artificial nucleation. Computations of the energy budget of the thunderstorm show that ideas about thermal instability and its prognostic value not only need to be revised but may have to be abandoned altogether.

Two factors having no very direct connection with the thermal stability of the atmosphere appear to be important for the formation of thunderstorms: (1) the occurrence of local regions of convergence, often too small in area to be detected by the existing network of upper-wind stations, and (2) the absence of low moisture in the vicinity of the 315K potential-temperature surface. Why other potential-temperature surfaces are not very critical in American summer conditions is not understood. Perhaps the question is related to the fact that 315K is about the potential temperature of the dry-adiabatic midafternoon lower troposphere over the western plateaus. The importance of the Mexico-Arizona-New Mexico moist tongue is well known. It should again be pointed out, also, that convergence and high-level moisture are related.

The studies point to the desirability of undertaking further investigations of isentropic or similar charts and of using a net of upper-wind stations with a 50-mile or, at most, 100-mile mesh to obtain usable divergence-convergence charts.

Finally, one is not sure why thunderstorms should ever occur. The atmosphere seems to be able to take care of the vertical heat exchange without such violent manifestations. Since thermal instability seems to be a necessary but not a sufficient condition for thunderstorms, ordinary cumulus convection appears to be capable of taking care of the situation. As the thermal instability increases, why can't the necessary overturning be accomplished by a great number of fast-circulating cumulus of small diameter rather than a few big thunderstorms which never seem to cover more than about 50 per cent of an area of about 55,000 square miles such as shown on radar at ranges between 20 and 50 miles? The occurrence of convergent wind flow and forced ascent seems to be the answer.

CUMULUS CONVECTION AND ENTRAINMENT

By JAMES M. AUSTIN

Massachusetts Institute of Technology

Introduction

Cumulus clouds are the visual evidence of the overturning of the atmosphere which follows the establishment of an unstable state of equilibrium. The unstable state may be created by such processes as the following:

1. The heating of the lower atmosphere through its contact with a warm surface gives rise to the cumulus clouds which appear on a summer afternoon and to the cumulus clouds which often develop when a cold air mass flows over a warmer surface.

2. The cooling of the middle troposphere may produce an unstable condition in the lower atmosphere. The nighttime cumulus which forms over oceans may be attributed, in part, to this process.

3. The saturation of a layer of convectively unstable air results in the development of convective cells. A good example of this process is the cellular pattern of the precipitation in convectively unstable air of tropical maritime origin.

Following the establishment of the unstable condition the atmosphere overturns and thereby transports heat upward. The manner in which an unstable layer of fluid overturns has been the subject of experimental and theoretical investigations.

Bénard has described the convection cells which appear in a horizontal layer of fluid which is heated from below. The experimental work of Bénard, Idrac, Terada, Mal, Walker and Phillipps, and others is reviewed by Brunt [5]. These experiments involved only very thin layers of fluid. The evidence of the existence of convective cells in the atmosphere, other than cumulus clouds, includes the observational work of Durst [8] and Woodcock and Wyman [16], and the measurements by radar and aircraft as reported by Wexler [15] and Byers and Braham [6].

The theoretical problem of the development of convective cells in an unstable medium of small thickness has been analyzed by Rayleigh and others. The theory is reviewed by Stommel [14]. However, a theoretical analysis of the development of cells of the dimensions of cumulus clouds is lacking. Some of the disturbing problems are the applicability of the linearized equations, the variability of the coefficient of eddy diffusion, the compressibility of the atmosphere, and the horizontal wind shear in the vertical plane. Also, the liberation of the latent heat of condensation in the cloud provides a heat source other than the ground. It would appear that the problem of cumulus convection should be analyzed from the standpoint of the development of cellular circulations. In the absence of a complete solution of this problem it has been necessary to make various assumptions as to the important aspects of the process.

Parcel and Slice Methods

Convective currents develop in an atmospheric layer which is in an unstable state of equilibrium because a perturbation then gives rise to an acceleration of air particles away from their original positions. The simplest approach to the convection problem is to consider that a parcel of air can be displaced adiabatically without any density change taking place in the environment. The stability of an atmospheric layer is then tested by comparing the density of a parcel which is displaced from its position of equilibrium with the density of the environment. This technique, which is referred to as the *parcel method*, is reviewed in many meteorological texts. The parcel method states that convective cells appear in nonsaturated air whenever the actual lapse rate of temperature is in excess of the dry-adiabatic rate, and in saturated air whenever the actual lapse rate of temperature is greater than the moist-adiabatic rate.

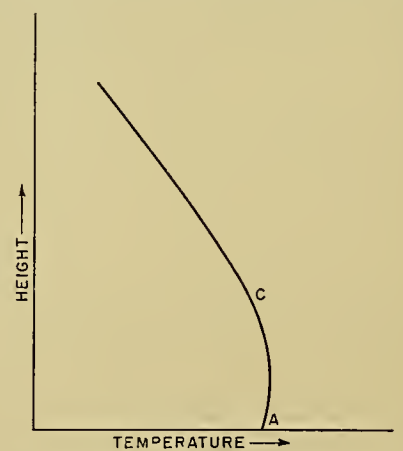

FIG. 1.—An idealized atmospheric sounding.

Cumulus clouds represent the condition where the rising air is saturated while the environment is nonsaturated. The parcel-method analysis then gives cumulus growth provided that (1) the surface layer AC in Fig. 1 is heated so that the convective currents in this layer give condensation at C (that is, C is the convective condensation level), and (2) the lapse rate of temperature above C is greater than the moist-adiabatic lapse rate.

One of the principal defects of the parcel method is the assumption of an undisturbed environment. The *slice method* eliminates the assumption of an undisturbed environment by assuming that there are compensating downward currents which are accompanied by adiabatic heating. This method gives the same stability criteria as the parcel method for the cases of a nonsaturated layer and an entirely saturated layer. However, for the

case of saturated rising air in a nonsaturated environment the two methods differ. The details of the slice method will not be treated here (see the discussion in Petterssen [11]). The principal difficulty in applying the slice method to the cumulus problem resides in the fact that the slice method considers slices of infinitesimal thickness whereas cumulus clouds are of finite extent. When it is assumed that the rising air cools moist-adiabatically there is generally some temperature difference between the cloud top and its surroundings and, therefore, the slice-method analysis cannot be applied beyond the initial stage at the cloud base.

One of the major defects of these two methods is the assumption that the vertically moving currents are isolated from their surroundings and that only adiabatic temperature changes occur within the cloud and its environment. The questionable nature of this assumption is well illustrated by the temperature observations within cumulus clouds. For example, the observations analyzed by Stommel [13] and Byers and Braham [6] failed to reveal moist-adiabatic lapse rates of temperature within the cloud. Instead it was observed that the cloud temperature was only slightly different from that of the environment. Also measurements indicate that the liquid-water contents are only a fraction of those which would be expected from the assumption of the moist-adiabatic ascent of air. The empirical data then demonstrate that there must be continual mixing between the rising current and the environment. This mixing of environmental air into the rising current of cloud air is referred to as *entrainment.*

Concept of Entrainment and Mixing

The concept of entrainment as the turbulent mixing of fluid from an environment into a jet stream has been analyzed by hydrodynamicists. Its application to the cumulus problem is discussed by Schmidt [12] and Stommel [13]. The difficulty of applying hydrodynamical jet-stream theories to the cumulus problem resides in the concept of the jet. In the atmosphere there is no mechanism to eject air into its surroundings and therefore the moving air column, or the jet, must originate from the vertical accelerations which are produced within the air itself. Such accelerations can be deduced from an assumption that the rising cloud air cools adiabatically. However, such an assumption is not very realistic. If air commences to rise so that its temperature decreases at the moist-adiabatic rate in an environment where the lapse rate of temperature exceeds the moist-adiabatic lapse rate, the virtual temperature T' of the rising air is higher than the virtual temperature T of the environment. As a consequence of the assumption that the pressure on the rising particle is equal to the pressure of the environment, the rising particle is accelerated upward and the acceleration is given by

$$\frac{dv_z}{dt} = \frac{T' - T}{T} g, \tag{1}$$

where g is the acceleration of gravity. Since the acceleration is positive the upward velocity of the rising air increases with height. At the same time the density of the rising air decreases with height and is determined by the variation of the virtual temperature T' and by the pressure of the environment. For any appreciable value of $T' - T$ the density decrease is less than the velocity increase. If the outer boundaries of the column of rising air form a cylinder, it follows that more mass is leaving the top portion of any section of the cylinder than is entering the base of the section. This state is impossible because it violates the condition of continuity. Continuity of mass requires that air be brought in through the sides of the cylinder, but this is not possible in view of the assumption that the pressure inside the cylinder is equal to the pressure outside. Alternatively, continuity may be satisfied by allowing the horizontal dimensions of the rising stream to decrease with height. This case does not appear physically real as a model for a cumulus cloud, since it leads to a very narrow current moving with a large velocity. Hence, when it is considered that the jet develops through the accelerations produced by the moist-adiabatic ascent of cloud air, it must be recognized that there has to be a horizontal inflow of air into the rising saturated current in order to maintain continuity of mass within the ascending stream.

Up to the present time a common approach to the entrainment problem has been to consider the extent to which the mixing changes the lapse rate of temperature within the cloud from the moist-adiabatic rate. With this approach three different aspects of mixing between the cloud and its environment should be considered, namely,

1. The horizontal inflow of environmental air into a cloud column which is assumed to grow upward in a number of adiabatic steps.
2. The hydrodynamical entrainment of environmental air.
3. The eddy diffusion of cloud particles into the environment. This aspect of mixing is present even when there is no general rising motion within the cloud.

The analysis has been restricted so far to a vertically moving stream in a stationary environment. In an actual weather situation the horizontal wind speed varies with elevation and it is now necessary to consider the effect of the vertical wind shear on the entrainment. This aspect of cumulus convection has been discussed by Malkus [9]. It is shown that the horizontal translation of an ascending cloud column relative to its surroundings affects the growth and motion of the cloud. For the usual case of an increase in the horizontal wind with elevation, the entrainment is greatest on the upwind side of the cloud while on the downwind side the liquid cloud is detrained from the field of rising motion. Thus the entrainment of outside air is asymmetrical. A further consideration is the horizontal variation through a cloud section of the mixing of environmental air with cloud air even in the absence of a vertical wind shear. This problem has been analyzed for the hydrodynamical jet stream, but it has not been solved for the other aspects of mixing which have been discussed here.

Finally, it is recognized that, as a consequence of the

downward motion, the environment is continually changing while the cloud grows upward and, therefore, it might be expected that the entrainment and mixing at a particular cloud level are changing with time. When this factor is added to the other aspects of mixing it is apparent that entrainment is a complex problem. At this point the question may be raised as to whether the problem of cumulus convection could be more readily solved by an approach which recognized the cloud and its surroundings as a cell rather than one which attempted to treat the cloud and environment separately.

Effect of Mixing on the Cloud Properties

Even though it is not yet possible to determine the precise details of the mixing of environmental air with the ascending cumulus cloud, an insight into the growth of cumulus cells may be obtained by a theoretical analysis of the effect of the mixing on such aspects of the cloud as its temperature and liquid-water content. A graphical technique for the determination of the lapse rate of temperature within the cloud is described below and will be followed by a thermodynamic analysis of mixing.

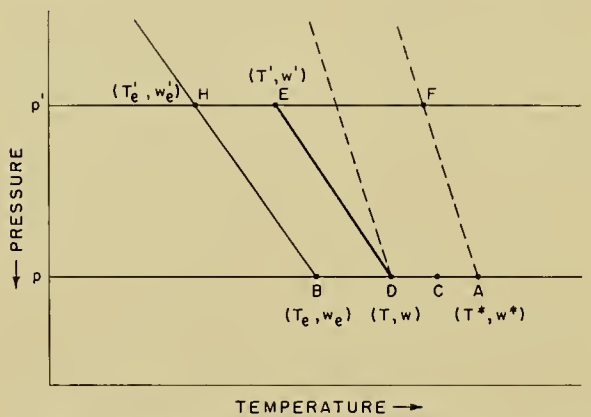

FIG. 2.—Graphical computation of the effect of mixing on the lapse rate of temperature. AF is a moist-adiabatic, BH is the environmental lapse rate, and DE is the lapse rate which arises from mixing.

Graphical Procedure. In the graphical procedure the following assumptions are made:

1. The clouds are formed as the result of heating at the ground.
2. Vertically moving columns of air are subjected to adiabatic temperature changes.
3. The rising air mixes with the air of the environment. The physical properties of the environmental air can be obtained from the radiosonde data.
4. When mixing occurs, the nonsaturated air of the environment becomes saturated at constant pressure by the evaporation of some of the liquid water of the cloud. This is saturation by the wet-bulb process.
5. The lapse rate of temperature within the cloud is obtained from the computed values of the temperature of the cloud top as the cloud grows upward from the condensation level. This assumption ignores the fact that the condition of the cloud is probably changing continually as a result of the influence of the descending currents upon the temperature and humidity of the environment.

The graphical procedure for the determination of the lapse rate of temperature within the cloud is illustrated in Fig. 2. Suppose that at some point in its ascent along the moist-adiabatic a cloud parcel (A in Fig. 2) is permitted to mix with its environment. If the mixing takes place at constant pressure and if some value K is assigned for the proportion of the environment entrained by the cloud, the temperature T_u and the mixing ratio w_u of the cloud air are given by

$$T_u = (T^* + KT_e)/(1 + K),$$
$$w_u = (w^* + Kw_e)/(1 + K), \qquad (2)$$

where (T^*, w^*) and (T_e, w_e) are, respectively, the cloud and environmental variables before the mixing occurs. As a result of the mixing, the cloud point on the thermodynamic diagram has moved from $A(T^*, w^*)$

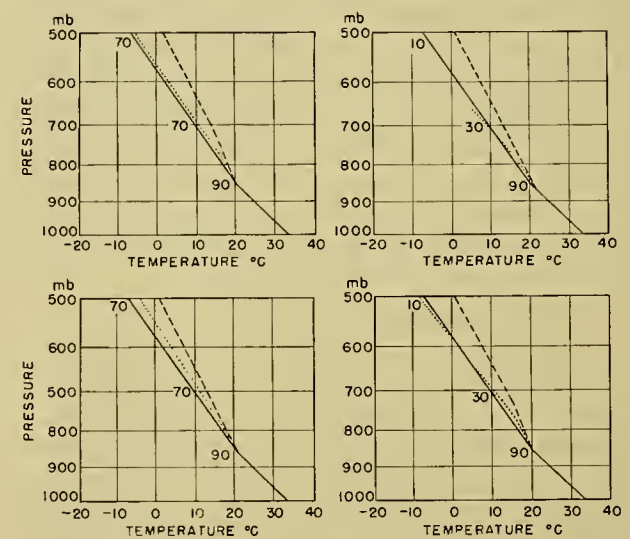

FIG. 3.—Cloud lapse rates of temperature which could arise through mixing. The solid lines, dashed lines, and dotted lines are respectively the environmental, moist-adiabatic, and cloud lapse rates of temperature. The numbers represent the humidity of the environment in per cent. In the two upper diagrams three parts of cloud air mix with one part of environmental air at every 50-mb step; in the two lower diagrams five parts of cloud air mix with one part of environmental air at every 50-mb step.

to $C(T_u, w_u)$, where the cloud parcel is no longer saturated. Let the parcel become saturated at constant pressure by the evaporation of the liquid water of the cloud. The final state of the cloud parcel is then given by the wet-bulb temperature T and the saturation mixing ratio at this temperature w.

Permit the cloud to continue its ascent but now along the moist-adiabatic through D, and at a pressure p' repeat the process of mixing and evaporation. The condition of the air in the cloud at a pressure of p' is then given by the point $E(T', w')$ on the thermodynamic diagram. The lapse rate of temperature within the cloud, between p and p', is given by the line DE.

Under the assumption of the parcel method the lapse rate of temperature within the cloud would be given by AF.

This graphical procedure has been followed for two different moisture distributions and mixing regimes (Fig. 3). The computed values of the lapse rate of temperature within the cloud provide an insight into the effect of mixing upon the growth of the cloud.

Thermodynamic Analysis. As a saturated cloud mass m rises a vertical distance dz, through a pressure change dp, let it mix with a mass dm of its environment. The ascent and mixing may be considered to consist of the following processes: an adiabatic temperature decrease of the cloud mass m; an isobaric cooling of the mass m and isobaric heating of dm; and evaporation of a portion of the liquid water of m in order to saturate dm so that the final mixture is saturated and has a uniform horizontal distribution of temperature, water vapor, and liquid water. The lapse rate of temperature in the cloud, γ_c, may be derived by considering the heat changes occurring in the rising mass. Austin and Fleisher [2] have shown that

$$m(c_p\,dT - RT\,d\ln p) = -c_p(T - T_e)dm - L(w - w_e)\,dm - mL\,dw, \tag{3}$$

and that

$$\gamma_c = \frac{\frac{g}{c_p}\left[1 + \frac{wL}{RT}\right]}{1 + 0.621\,wL^2/c_pRT^2} + \frac{\frac{1}{m}\frac{dm}{dz}\left[(T - T_e) + \frac{L}{c_p}(w - w_e)\right]}{1 + 0.621\,wL^2/c_pRT^2}, \tag{4}$$

where c_p is the specific heat at constant pressure, L the latent heat of evaporation of water, w the saturation mixing ratio at the temperature T, w_e the actual mixing ratio of the environment, and R the constant of the gas equation for dry air. If there is no mixing, $dm/dz = 0$ and the lapse rate of temperature in the cumulus cloud is the same as the moist-adiabatic lapse rate of temperature γ_m. Since $T_e < T$ and $w_e < w$, $\gamma_c > \gamma_m$, that is, the lapse rate of temperature within a cloud which is mixing with its environment is greater than the moist-adiabatic lapse rate.

The cumulus cloud ceases to grow either when the liquid-water content is zero or when the cloud becomes sufficiently colder than the environment so that the vertical velocity is zero. The variation of the liquid-water content w_l can be ascertained by equating the total water content before and after mixing:

$$dw_l = -dw + \frac{dm}{m}(w_e - w - w_l). \tag{5}$$

With the substitution of (5) in (3) an expression is obtained for the variation of the total mass of liquid water,

$$\frac{d}{dz}(mw_l) = \frac{mc_p}{L}\left[(\gamma_d - \gamma_c) + \frac{1}{m}\frac{dm}{dz}(T - T_e)\right], \tag{6}$$

where $\gamma_d = g/c_p$, the dry-adiabatic lapse rate of temperature. Consider the usual situation where $\gamma_d \geqslant \gamma_c$. Since $dm/dz \geqslant 0$, then $d(mw_l)/dz \geqslant 0$ as long as $T_e \leqslant T$, and the cloud does not dry through mixing. Therefore, whenever the lapse rate of temperature of the environment is less than the dry-adiabatic lapse rate, the cloud temperature becomes less than the environmental temperature before the liquid-water content reaches zero. It can be concluded that the factor which controls the termination of the cloud growth is the temperature of the cloud.

Cloud Properties. Because there is little information on the mixing process, equations (3)–(6) are of limited practical use. However it is possible to gain an insight into some of the cloud characteristics by considering the orders of magnitude of the various terms of these equations. The observations analyzed by Barrett and Riehl [3] and Stommel [13] show that the temperature difference between the inside and outside of a cumulus cloud is very small. Figure 4 is reproduced from the

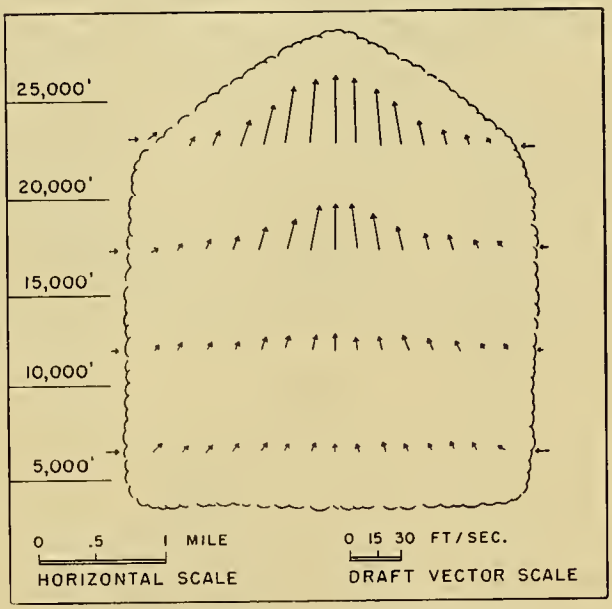

FIG. 4.—Circulation within a typical cell in cumulus stage. Inflow and vertical motion beneath the cloud are light and are not shown. (*After Byers and Braham* [6].)

work of Byers and Braham [6] who arrived at this typical picture from the analysis of extensive observational data. If the variation with height of the average vertical velocity is considered and if allowance is made for the force required to set the entrained air in motion, it follows that a virtual temperature difference of less than 1C is ample to explain the development of the cloud. Even when friction is considered it is probable that an average virtual temperature difference of 1C or less is sufficient to account for the upward force which causes the vertical development of most cumulus clouds. From this empirical information it may be concluded that the lapse rate of temperature within the cloud differs only slightly from the lapse rate of temperature within the environment.

With $T - T_e < 1$C, it follows that $\frac{L}{c_p}(w - w_e)$ is large as compared with $T - T_e$ except for a rare situation of a practically saturated environment. Hence the assumption of $T = T_e$ appears a reasonable one for the discussion of such factors as liquid-water content and the variation of cloud mass with height. With $T = T_e$ and $\gamma_e = \gamma_e$, equation (3) becomes

$$\gamma_e - \gamma_d = \frac{L}{c_p m}\frac{dm}{dz}(w - w_e) + \frac{L}{c_p}\frac{dw}{dz}. \qquad (7)$$

Let $w_e/w = H$, the relative humidity of the environment, and $\gamma_d - \gamma_e = \Gamma$. If Γ and H are considered as constants between elevations Z_0 and Z, the integration of equation (7) yields

$$\frac{m}{m_0} = \left(\frac{w_0}{w}\right)^{1/(1-H)} \exp\left[-\frac{c_p \Gamma}{L(1-H)}\int_{z_0}^{z}\frac{dz}{w}\right]. \qquad (8)$$

The variation of the cloud mass with different lapse rates and relative humidities is illustrated in Fig. 5.

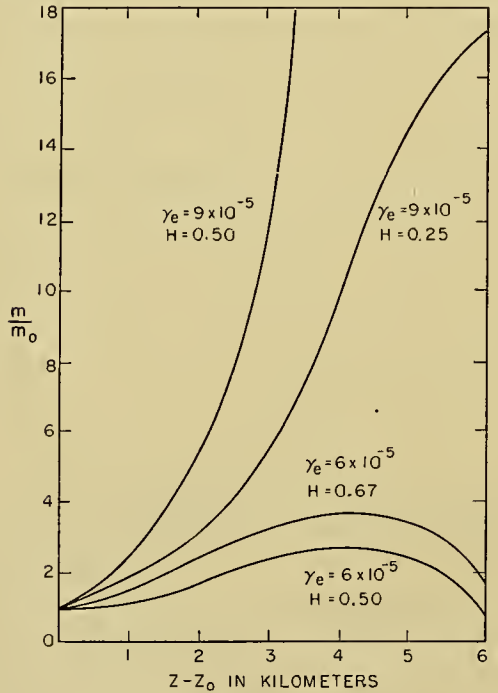

Fig. 5.—Dilution of cloud mass with elevation. m/m_0 is the ratio of the actual cloud mass m, at the level Z, to the fractional mass m_0 which originated at the cloud base Z_0, γ_e is the lapse rate of temperature, and H is the relative humidity. The cloud base is at 900 mb and 20C.

The mass increases more rapidly when the environment has a steep lapse rate of temperature and a high relative humidity. All these curves pass through a maximum, the location of which depends on Γ. These maxima occur at that height where the moist-adiabatic lapse rate becomes equal to γ_e, as can be seen from equation (4) if dm/dz is set equal to zero.

With the same assumptions equation (6) becomes

$$d(mw_l)/dz = mc_p\,\Gamma/L, \qquad (9)$$

thus,

$$w_l = \frac{c_p \Gamma}{Lm}\int_{z_0}^{z} m dz. \qquad (10)$$

The variation of w_l is illustrated in Fig. 6. The liquid-water content and cloud mass vary with Γ and H in a manner summarized in Table I. It is suggested that these general conclusions on the variation of m and w_l also hold for the case where the cloud air is slightly warmer than the environment; that is, the situation where there is a force to accelerate the cloud air upward.

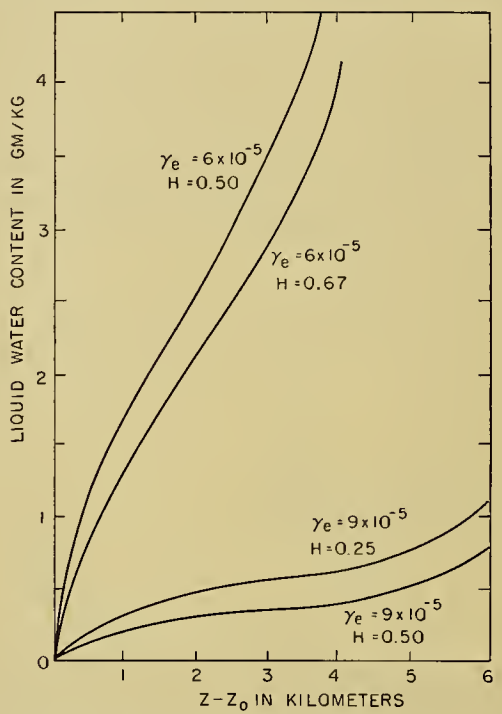

Fig. 6.—Variation of the liquid-water content with elevation for the same conditions as in Fig. 5.

For the application of the above results to the analysis of an actual cloud, consideration must be given to the horizontal variation of the amount of environment mixed with the rising column, the change with time of the lapse rate and the relative humidity of the environment, the change with time of the degree of mixing, and the significance of the internal circulation cells within the cloud. Also it has been assumed that the entire liquid-water content is carried upward, therefore the analysis cannot be applied to cases where precipitation occurs.

Table I. Dependence of Cloud Mass and Liquid-Water Content upon Lapse Rate of Temperature ($\Gamma = \gamma_d - \gamma_e$) and Relative Humidity (H)

	Γ increasing	H increasing
m	decreases	increases
w_l	increases	decreases

The graphs in Fig. 5 may suggest a peculiar cloud

shape since they indicate that the cloud mass continues to increase with height. These graphs should be interpreted as representing, at any elevation, the fraction of the cloud air which has originated at a lower elevation. For example, in the case $\gamma_e = 9 \times 10^{-5}$C cm^{-1} and $H = 0.50$ in Fig. 5, the air at 2 km above the cloud base contains one part of air which originated at the base and five parts of air which have come from the environment. However, this may not necessarily mean that the mass of the cloud at 2 km is six times as great as the mass at the base. In fact, it is probable that not all of the air which reaches a particular level continues to ascend.

Data on Convective Showers

In view of the eddy diffusion to which a cloud is subject, it seems probable that the ideal conditions for the persistence of a cumulus cloud are a high liquid-water content and large horizontal extent. For the development of the vertical accelerations to force the cloud upward it seems desirable that there be a steep lapse rate of temperature. The analysis, as summarized in Table I, indicates that it is not possible to satisfy all three conditions; for example, a condition which gives rise to a high liquid-water content does not appear to favor the development of vertical accelerations. Therefore, it should not be expected that a steep lapse rate of temperature in the environment is necessarily the most favorable condition for cumulus growth. Consequently, attempts have been made to obtain some empirical data on cumulus clouds which would give an insight into the mixing process.

Austin [1] studied the occurrence of convective showers in the vicinity of three radiosonde stations in the eastern United States. It was found that the relative humidity of the environment was as important a consideration for the development of showers as the vertical stability of the air. Chalker [7] confirmed this conclusion and showed that showers occur most frequently in regions where the lapse rate is about 6C km^{-1}, that is, only slightly steeper than the moist-adiabatic lapse rate. These studies were restricted to the occurrence or nonoccurrence of shower-type clouds. It would be desirable to have extensive empirical information on cumulus humilis and cumulus congestus clouds in order to determine more precisely the effect of the humidity of the environment on the cloud growth. However, at present, such information is not readily obtainable.

Prediction of Cumulus Development

Since the unstable state may be created in various ways, as pointed out in the introduction, the problem of forecasting cumulus development can conveniently be divided into two sections.

1. *Convectively Unstable Air.* Petterssen [11] has provided an analysis of cumulus development in convectively unstable air. In brief, if a layer of air is characterized by a decrease of the wet-bulb potential temperature with height and if this layer becomes saturated, an unstable state will exist. As a consequence of the instability, cumulus cells develop in the saturated layer. The prediction of this phenomenon requires first, a determination of the convective state of the air *before* it is subjected to some rising motion which produces the saturation; and second, an estimate of whether rising motion will occur. The convective state is determined from the distribution of the wet-bulb potential temperature. If a deep layer of the air is convectively unstable the forecaster must estimate the likelihood of the air being lifted to saturation. Rising motion may be expected in the vicinity of fronts, along mountain ranges, and in general regions of horizontal convergence near the earth's surface. The best example of the latter process is the horizontal convergence in the vicinity of isallobaric minima.

The principal defect of the forecast procedure is the vague qualitative approach. More information is needed on the manner in which a deep layer of air overturns and on the distribution of rising velocities. Radar observations [10] of precipitation areas have shown that the vertical extent of rain cells, and presumably that of convection cells, varies directly with the degree of convective instability. Hence it should be expected that highly convectively unstable air will give rise to tall cumulus cells of thunderstorm dimensions.

2. *Surface Heating.* Surface heating may arise from the transport of cool air over a warmer surface or from direct radiational heating. A method for the prediction of cumulus development may be applied to either type of heating.

The parcel-method analysis of the equilibrium state leads to a forecast method which involves the so-called positive and negative areas, as illustrated in Fig. 7.

Fig. 7.—The positive and negative area analysis for cumulus convection. The dashed line is a moist adiabatic and the dotted line is a dry adiabatic.

$ABPD$ is the path on an adiabatic chart followed by an air parcel which is lifted through an atmosphere $ALPMD$. The forecast method states that cumulus clouds will develop to shower dimensions provided that

the positive area is greater than the negative area, that the positive area extends beyond the 0C isotherm, and that the surface heating is sufficient to initiate the convection. This method is open to serious criticism since the cloud air does not follow the path *ABPD* and hence the positive and negative areas have no significance as regards the cumulus development. Furthermore, the negative area is zero when the cloud commences to develop.

A more appropriate application of the parcel-method technique is to determine the convective condensation level, *C* in Fig. 8, and to estimate the heating necessary to initiate convection, $T_H - T_A$. If this heating is expected, then cumulus clouds should develop to the level *D*. This method may be criticized on the same theoretical grounds that make the parcel-method analysis untenable. Furthermore, observations show that this technique overestimates cumulus development. Also this method offers no satisfactory explanation for the failure of cumulus clouds to develop whenever there is dry air in the middle troposphere.

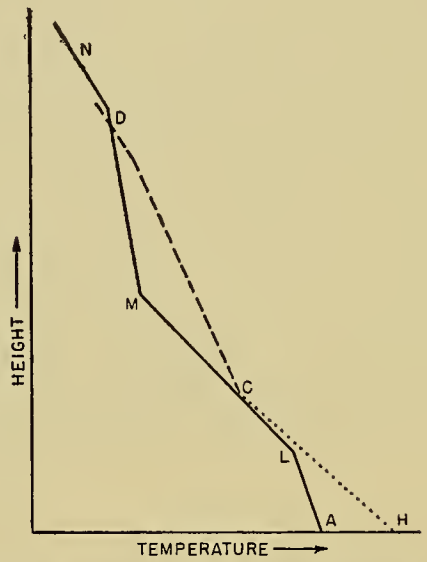

FIG. 8.—The parcel-method analysis of cumulus convection. The dashed line is a moist adiabatic and the dotted line is a dry adiabatic.

Beers [4] has proposed a forecast technique which is based upon the slice method. The method treats layers of finite thickness and, therefore, is an attempt to apply the slice-method technique to a deep layer of air. This method assumes that the cloud air rises adiabatically and hence it is open to question. However it may be possible to modify the method so as to allow for the mixing. The desirable feature of Beers' technique is the treatment of the cloud growth as the development of a circulation cell.

The concept of the entrainment of outside air suggests an alternate procedure for the prediction of cumulus convection through heating which may be summarized as follows:

1. The surface dew-point temperature to be expected about the time of cloud formation is estimated. This determines the convective condensation level. The heating necessary to initiate cumulus growth can be determined by drawing a dry-adiabatic from the convective condensation level to the ground. If it is expected that this heating will occur during the forecast period, some cumulus development may be expected. Since these temperature estimates are based on widely scattered observations, the forecaster should tend to overestimate the dew-point and maximum temperatures. This overestimation is justified as there are probably locations nearby which are more favorable for cumulus development than directly over the isolated reporting stations.

2. If the lapse rate of temperature above the convective condensation level is less than the moist-adiabatic lapse rate, no cumulus development is to be expected. If the lapse rate of temperature is in excess of the moist-adiabatic rate, the degree of cumulus development should be based upon the relative humidity distribution above the convective condensation level. The forecaster may be aided by the statistics given by Austin [1] and Chalker [7].

3. A layer with low relative humidity, or a layer with a lapse rate less than the moist-adiabatic rate above the convective condensation level, definitely disfavors cumulus development.

4. These estimations may be made from radiosonde observations taken prior to the forecast period, but here consideration must be given to the probable change in the lapse rate of temperature and relative humidity during the forecast interval. It is suggested that this estimate be based on the trend as illustrated by a stability chart which depicts the lapse rate of temperature from 850 mb to 500 mb and the relative humidity within the same layer (see Chalker [7]).

Suggestions for Research

The introduction of the concept of entrainment and mixing may be considered an advance in the analysis of cumulus convection. It recognizes that a cumulus cloud does not grow upward as an isolated column of saturated air which cools at the moist-adiabatic rate. However, many theoretical problems remain to be solved. No satisfactory procedure has been offered whereby the degree of entrainment and mixing may be estimated and recent analyses of entrainment have failed to take into consideration the disturbed state of the environment. As a consequence of this descending environment the cloud is continually in a state of change which presents serious theoretical problems if it is desired to know the physical properties of the cloud at a given time. More theoretical research is clearly indicated.

One feature of cumulus growth which requires more consideration is the significance of the surface heating. In the past the tendency has been to concentrate attention on the cloud after it starts to develop and to consider that the surface heating is only important insofar as it initiates the cloud development. However, it appears logical to expect that the degree of the surface heating, beyond that necessary to start cloud growth,

should affect the development of the cloud. The ground may be as significant a heat source as the latent heat released in the cloud. When this surface heating is considered it again appears that an approach like that applied to the Bénard cells may be more fruitful than recent attempts to handle entrainment and mixing. The author recognizes that there are serious theoretical problems in the cell approach. In many respects the question of convection is perhaps as complicated as the cyclone problem.

In conclusion, it appears likely that no major progress will be made with the forecast problem of cumulus convection until more knowledge is gained of the mechanics of cloud growth.

WORLD WEATHER NETWORK

By ATHELSTAN F. SPILHAUS

University of Minnesota

Introduction

To solve the problem of covering the earth with a meteorological network, international cooperation must be presupposed even though the present time seems inauspicious. However, meteorology has an enviable record of international cooperation which has withstood two major wars and has been maintained, albeit in a somewhat restricted manner, in times of severe international stress. Cooperation started as a means of exchanging observations between nations. The actual planning of networks has hitherto taken place on the basis of individual national needs. Consequently, an extremely uneven coverage is afforded the meteorologist who desires to study world-scale problems rather than regional synoptic meteorology. Air navigation, which now encompasses the earth, has given a new impetus to the international organization of weather networks. However, even here the planning is directed to the practical needs of air operations and seldom results in a network satisfactory for the study of the general circulation.

That the need for such studies is well recognized is indicated, for example, by the Southern Hemisphere map analysis project being conducted at the Massachusetts Institute of Technology by Willett [8]. Evidence of extensive consideration of the problem is indicated by numerous resolutions of the Conference of Directors at the meeting of the International Meteorological Organization in Washington, D. C., in 1947. Resolutions 21, 36, 109, and 210 [6], dealing respectively with meteorological reconnaissance in areas with inadequate coverage by other means, with various ways of amplifying the information from oceans, with the density of land stations, and with the proper utilization of suitable islands, point out the necessary steps in the direction of establishing a suitable world weather network.

Studies such as those being conducted in connection with the Southern Hemisphere project will reveal in detail the deficiencies in the world network. However, it is the purpose of this paper to look at the problem from a comprehensive point of view.

In general, the world weather network is deficient in the two polar areas and in the equatorial zone. Latitude for latitude, it is more lacking in the Southern Hemisphere than in the Northern; for a given latitude, it is always more inadequate in ocean regions than in land areas. Because of the general distribution of land and sea on the earth, the Southern Hemisphere at higher latitudes presents a tremendous and very difficult problem of weather coverage.

The Gaps

To localize the worst spots of meteorological terra incognita, so as to form the basis of the very long range planning which is needed in establishing the world weather network, certain assumptions can be made. Apart from the antarctic continent, it is comparatively simple, from a technical standpoint, to provide the requisite density of land stations, although the present closeness on land—particularly in equatorial areas north of 10°S—is very far from the 100–150-km spacing recommended in Resolution 109 [6]. The greater problem lies with the other two-thirds of the earth's surface which is covered by the oceans. Here the assumption is made that, for convenience and economy, suitably selected islands and reefs should be fully utilized before the further step is taken of arranging observations from the surface of the deep ocean.

The ideal situation, in which all strategically placed islands are suitably used for meteorological stations, is far from a reality. Because stations are established primarily for national regional synoptic needs, a number of islands which are highly important from a world-network point of view are not fully manned and equipped, meteorologically, since they are far removed from the sovereign nation which is, therefore, little concerned with their weather observations. Examples are St. Helena in the Atlantic which has no upper-air station and Clipperton in the east equatorial Pacific. Nevertheless, the meteorological occupation of some very important remote islands has been encouraging in the years since World War II (Marion and Amsterdam Islands being two recent examples).

To illustrate graphically the areas remaining after continents, islands, and reefs are properly turned to account, Fig. 1 shows a chorometric chart of the world ocean with isochors representing lines of equal distance from land of any kind at three hundred nautical mile spacing (five degrees of latitude). The base map used for this figure is that devised by the author in 1942 [11]. The data were revised by F. E. Lukermann, Jr., Geography Department, University of Minnesota, from a study of the islands missing both from the first chorometric chart published in 1898 [2, 7] and also from the later ones for the Atlantic, Indian, and Pacific Oceans [9, 10]. Because it is feasible to build structures for meteorological purposes on reefs which are either awash or covered by water less than five fathoms deep, these have been regarded in the same sense as islands in Fig. 1. Included in this category are reefs such as the Virginia Rocks (three or four fathoms) in the Atlantic Ocean; Saya de Malha (about two fathoms) in the Indian Ocean; and, in the Pacific Ocean, the Maria Theresa Reef (awash), the Ernest Legouvé Reef

(awash), Harans Reef (with a ship aground), and Filippo Reef (about two fathoms). Islands apparently missing from Schott's charts, which have been added, are, in the Atlantic Ocean, Rockall and Annobón; in the Indian Ocean, Scott's Reef, Rowley's Shoals,

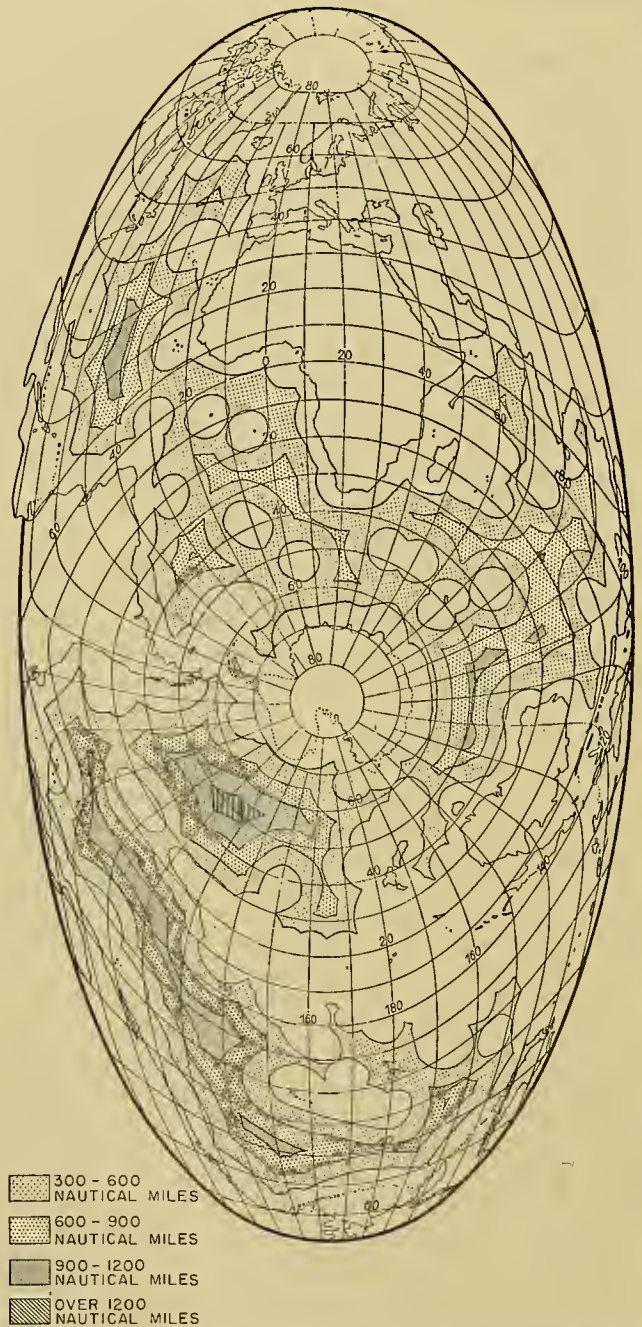

Fig. 1—Lines of equal distance from land at spacings of 300 nautical miles. (Aitoff equal-area projection centered at 70°S, 15°E.)

Bassas da India and Europa Island; in the Pacific Ocean, Palmyra, Kingman's Reef, and Beveridge Reef. Some islands, seemingly included in Schott's maps, but now established as nonexistent, have been eliminated.

Figure 1 shows clearly the regions of the great world oceans which are farthest from land—with two areas in the Pacific more than a thousand nautical miles from land or reef of any kind. It is interesting to note that the North Atlantic, where the most extensive weather-ship program is being operated, has less area distant from land of any kind than the other major oceanic divisions.

Ships' Reports

To cover the areas of the open ocean, there has for many years been a well-directed program enlisting the cooperation of vessels plying the oceans for other purposes. At least for regions traversed by the well-established sea lanes of commerce, ships' reports of this kind are of tremendous value even though their quality is sometimes questionable, and elementary observations, such as those of rainfall, are not taken. An idea of the coverage afforded by this means may be obtained by analysis of the grand total of observations for all months of the period of more than fifty years analyzed in the U. S. Weather Bureau's *Atlas of Climatic Charts of the Oceans* and summarized in Chart 1 of that atlas [14]. This chart shows the observations for all months distributed by five-degree unit areas over the oceans. Figure 2 shows the outlines of the areas in which there were less than five hundred observations in the 50-yr period ending in 1933 (average of less than ten observations per year). The steady increase of shipping of all kinds tends to increase the number of ships' reports. On the other hand, the effect of modern developments (canals, for example) for short-cutting sea routes and the increasing use of aircraft militate against the possibility of there being sufficient ships in these remote areas to provide regular observations. Even the increase in the general amount of shipping in the world occurs along established sea lanes and will not cover the untravelled areas of the ocean. Figure 2, therefore, may be accepted as a fair general indication of the areas which cannot be covered by normal ship-observation techniques. If Figs. 1 and 2 are superimposed, lines can be drawn delimiting parts which are more than 600 mi from land of any kind and which, in the 50-yr period mentioned, had less than ten observations a year. This chart, Fig. 3, gives a good idea of the regions (principally in the Southern Hemisphere) which need to be covered (from a world weather network point of view) with floating stations of some kind, whether they be weather ships or specially designed floating stations, automatic or manned. In these infrequently travelled regions which are far from land, some of the attempts at a solution may be [6, Resolution 36] the use of (1) fishing vessels, (2) aircraft reconnaissance, (3) stationary weather ships, or (4) automatic stations on buoys. To these should be added the less desirable, but also less costly, indirect methods of coverage afforded by sferics, radar networks, and ocean-wave analysis as applied to the location of storms [1]. One example of the gaps that could be filled by the use of fishing vessels is in the Southern Hemisphere where an arrangement for the use of whalers for meteorological purposes might be made. It is to be hoped that cooperation with the International Whaling Association

can be achieved along these lines before the whale becomes extinct. Aircraft reconnaissance has proved exceedingly valuable, particularly for special atmospheric phenomena such as hurricanes and typhoons, and also in its contribution to the knowledge of meteoro-

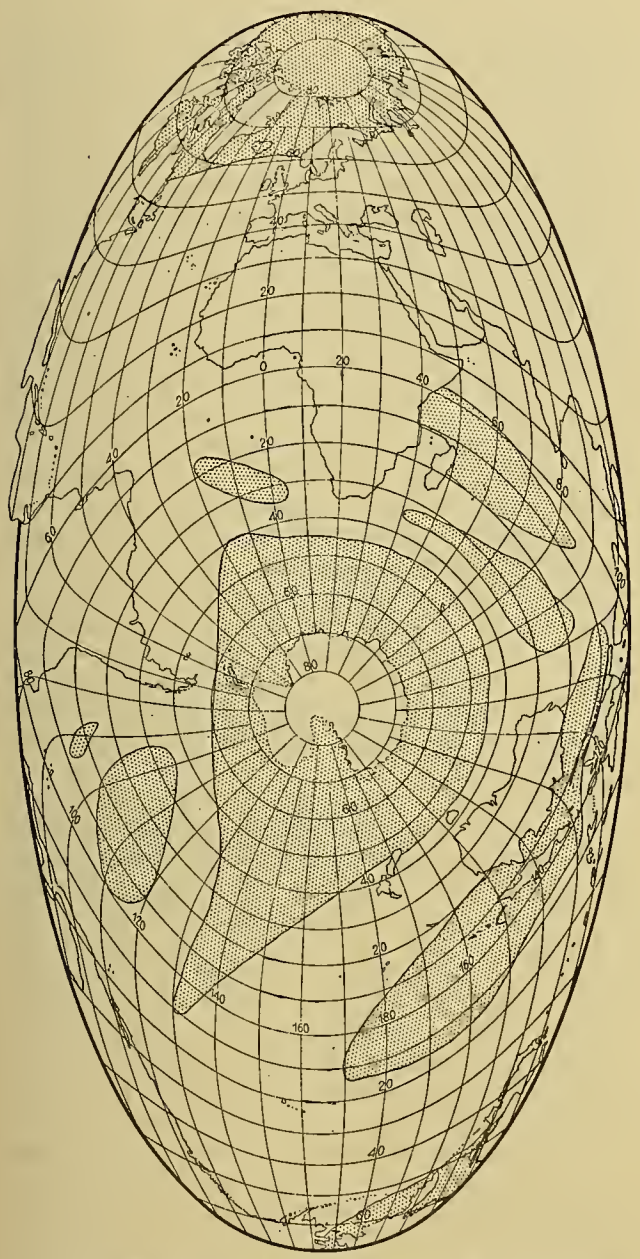

FIG. 2—Ocean areas (shaded) having less than 500 ships' observations in the 50-yr period ending in 1933.

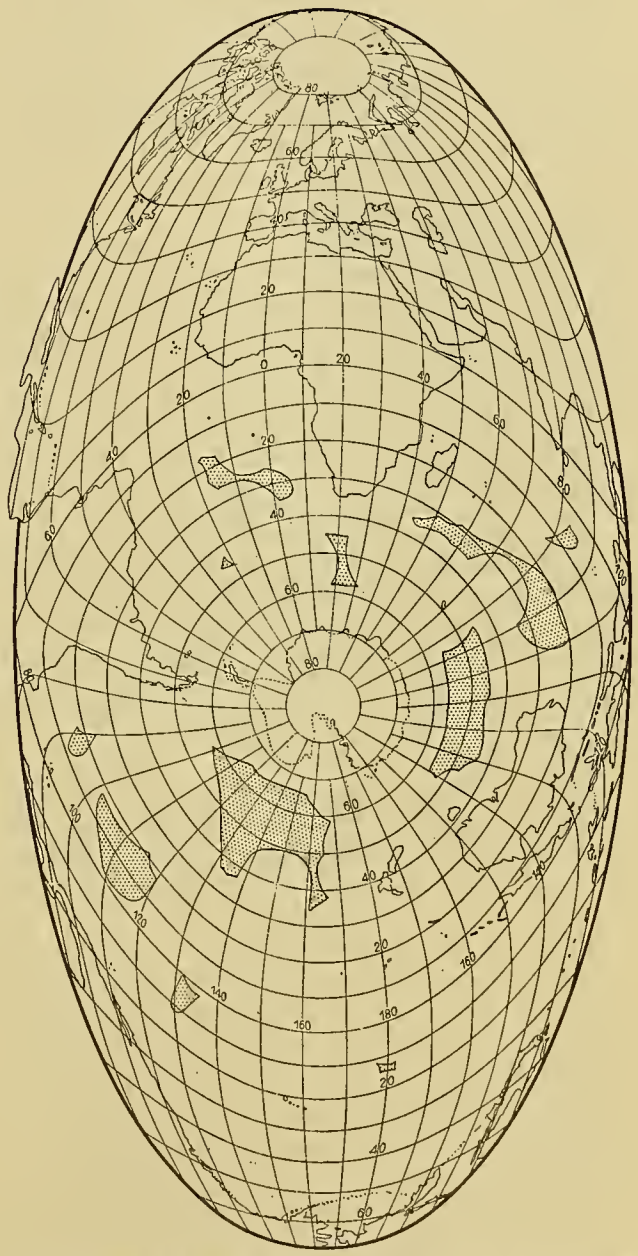

FIG. 3—Ocean areas (shaded) more than 600 nautical miles from land and having less than 500 ships' observations in fifty years.

logical conditions in areas which cannot yet be covered by ordinary observational means. An example of this is the regular weather flight from Alaska to the North Pole. It is important, however, to remember that to be fully effective aircraft reconnaissance of this latter type needs to be coordinated more closely with surface observations. Therefore, as is well illustrated by the North Pole flights, there is still a need for sea-level observations. The development of techniques of measuring winds and other conditions below the aircraft down to the surface gives promise that such techniques will be in routine use fairly soon. The occupation of surface stations, however, still remains essential. In regions very far from land in the Southern Hemisphere, aircraft reconnaissance would not be an economical way of obtaining the information. Stationary weather ships are a most satisfactory solution, except for the excessive cost of their maintenance if ordinary vessels are used for this purpose. The requirement, therefore, is for a specially designed floating vessel, manned or unmanned, which can be suitably anchored even in great depths of water. Work along these lines has proceeded as far as

the introduction of a bill into the Senate of the United States[1] to authorize the Coast Guard to construct an experimental nonpropelled seadrome ocean station. Although there are many questions concerning economy, logistics, and human factors involved in the floating weather station, it is feasible from an engineering point of view. The foregoing analysis shows that the development of a platform for meteorological purposes of this kind is necessary and must be encouraged. Continued development of fully automatic weather stations for use not only on such floating buoys (which could then be of far smaller size) but also on reefs and uninhabited islands is an important parallel endeavor.

Arctic and Antarctic Stations

As with the great oceans, so with the Arctic and Antarctic—the principal problems of filling out the network are not strictly meteorological ones. The prime difficulties in the Arctic and Antarctic are means of ingress and egress and methods of safe and suitable living in extremes of cold. Even if automatic stations are developed for polar regions (and this in itself presents far greater problems than the corresponding ones for temperate zones), the access problem in connection with the maintenance of the stations remains. In the oceanic Arctic, the problems are somewhat different from those in the continental Antarctic. The fact that the Arctic Ocean is predominantly covered with sea ice also presents problems different from those of temperate and tropical oceanic areas. Surface vessels such as ice breakers can penetrate only a limited distance into the ice fields and only at certain seasons of the year.

The most promising methods of getting to and from stations in the Arctic Ocean are by aircraft or submarine. Whether transportation is by aircraft over the ice or by submarine underneath it, methods must be available to surface on the ice. Studies of arctic sea ice will permit this. The submarine may come up between ice floes in open water or, by the use of some kind of boring device, afford access to its occupants through the ice. In the Antarctic, although aircraft are essential, especially designed surface vehicles are also necessary. Caterpillar tractors, designed to operate at extremely low temperatures, together with wanigans, such as are used in Alaska north of the Brooks Range, are of obvious utility. The various transportation methods for the Arctic and Antarctic (aircraft, submarine, and surface vehicles) have one thing in common and that is that none of them have been developed especially for polar operations. Even aircraft operation under the climatic conditions of arctic and antarctic regions is unsatisfactory. With the present intense interest in polar matters in all fields of science, it seems most opportune to stress the development of special vehicles and methods of operation.

With the solution of the transportation problem, or concurrently with its solution, the next problem is one of establishing and occupying semipermanent observing stations in the Arctic. For such stations, saucer-shaped vessels, which would ride up over the ice in much the same manner as did the *Fram*, have been suggested. A more logical approach, however, is to use the ice itself as the floating platform. There is evidence [3] of the existence of ice floes which are many miles across and of the order of a hundred feet or more thick. Such floes would be able to withstand crushing by the general sea ice in the Arctic, which is only 6–12 ft thick, and would be most suitable bases upon which to establish runways and stations. The use of ice as a floating platform would be a start in the direction of using materials in the Arctic itself for the establishment of stations there. It has been remarked that in the excellent stations which the U. S. Weather Bureau has established in cooperation with the Danish and Canadian governments (two above 80°N in the Ellesmere Islands and four at or above 75°N) the supply problem could perhaps be eased if more attention were paid to the utilization of local resources, such as situating the stations on coal deposits which are not far from the existing locations. Coal is not presently employed as a fuel in these operations. Ice, once its engineering properties are known, might be used for building, insulating, water supply, and fire fighting, as well as for many other purposes [5].

Evidence of an intensified attack on the antarctic occupation lies in the Norwegian-Swedish-British Expedition in progress at the present time and in the plans of the Argentine government to establish two more meteorological stations on the antarctic continent [4].

Interim Measures

It is evident that the solutions proposed above to the ultimate establishment of a world network present immense engineering problems and manifold questions of international cooperation which will clearly take many years to accomplish. The understanding of the mechanics of the general circulation of the earth's atmosphere is the "primary problem of meteorology on which scarcely a beginning has been made." It is on the solution of this "that all basic improvement of weather forecasting is now waiting," as Dr. H. C. Willett[2] has said. It is evident that work along these lines cannot await the completion of the world network as envisaged here. Several interim measures have been suggested and have, to a limited extent, already been implemented. For general circulation studies based on extensive synoptic observations, one of the most important things is the use of synoptic aerological data and, as Willett has pointed out:

> The observational basis of all study of the mechanics of the general circulation as a whole has been restricted to the troposphere of the Northern Hemisphere north of 20°N. This is particularly unfortunate when it is realized that probably this is the least important third of the atmosphere

1. U. S. Senate Bill S. 1009, February 17, 1949 (subsequently withdrawn).

2. Private communication: "The Needs in Synoptic Aerological Observations for the Study of the General Circulation," 1947.

dynamically and thermodynamically. The Southern Hemisphere circumpolar vortex is evidently a more intense dynamic phenomenon than that of the Northern Hemisphere and consequently might be expected to be the more important of the two as the seat of disturbances or changes of the general circulation as a whole.

He emphasizes also:

The tropics must contain the principal heat source of the general circulation and also constitute the zone of interaction of the two great hemispherical cyclonic vortices.

Yet it is in the tropics and in the Southern Hemisphere as a whole that our principal lack of aerological data lies and, pending the establishment of a good over-all world network, the distribution of upper-air stations along two or three selected meridians would be most helpful. Two sections which have been suggested by the author and which are largely in effect are (1) a maritime one, from the North Pole through Alaska, the Pacific Islands and New Zealand, to Antarctica; and (2) a continental section from the North Pole through Canada, the United States, Central and South America, to Antarctica [12].

Another measure which would be of great help to the basic theoretical studies of the general circulation is the provision for the right kind of measurements from ships and island stations for treating the heat budget of the atmosphere-ocean complex as a whole. To put it very simply, this budget necessitates knowing the ingoing and outgoing water at the ocean surface (rainfall and evaporation) and the ingoing and outgoing radiation at the same surface. While evaporation can be estimated from sea and air temperatures combined with wind speeds which are currently part of ship measurements, rainfall for the oceans is derived exclusively from the records of island stations. Consideration should be given to the measurement of rainfall on moving ships at sea. Even though the interpretation of the catch of rainfall from a moving vessel presents certain difficulties, it is probable that such measurements would prove far more satisfactory than the present practice of estimating ocean rainfall from island stations. Small islands in extensive oceanic regions usually exert a profound and a very local orographical influence and, therefore, properly interpreted rainfall data from ships in transit may prove far more representative.

The establishment of radiation-measuring stations on properly dispersed islands in the oceans and on a few selected ships seems also to be a desirable measure [13].

Summary

The principal lines along which further work should proceed in order to fill out the world network may be summarized as follows:

1. The development of automatic stations for land and ocean, tropical and polar use.

2. The filling out of the land station network in tropical areas.

3. The establishment of manned or automatic surface stations on suitable islands and reefs.

4. The establishment of upper-air stations on selected islands and reefs. These would be manned, but, at the same time, it would be desirable to initiate research on indirect methods of atmospheric sounding without flight equipment, which would lend themselves ultimately to automatic operation.

5. The development of buoys, which could be anchored in deep water, to carry manned stations or automatic stations for remote oceanic points.

6. The development of methods of getting in and out of arctic and antarctic areas and of maintaining manned stations and automatic stations in those regions.

These are tremendous engineering problems which the humility of the meteorologist may give him pause to urge or to undertake. It will be recalled, however, that the pioneering work on rockets in this country was undertaken with the meteorological sounding of the upper air as its primary objective. Furthermore, all such developments contribute directly to problems common to other geophysical fields and the support of these fields should be enlisted to justify the effort. The other aspect of the world network problem (that of international cooperation) is no less difficult of solution than the technical developments involved. It is, however, merely an extension and growth of the cooperation which is going forward in the International Meteorological Organization, the International Civil Aviation Organization, and in the North Atlantic (and other) weather ship programs. Only by beginning an attack on this immense problem of the world network will suitable data ultimately become available both for synoptic studies of the general circulation and for the kind of information which is needed in the objective weather-forecasting approach promised by the use of electronic computers.

MODELS AND TECHNIQUES OF SYNOPTIC REPRESENTATION

By JOHN C. BELLAMY

Cook Research Laboratories, Chicago, Illinois

Introduction

An ideal station model can be said to be one in which the synoptic observations are rapidly and efficiently plotted in such a way that (1) the analyst or forecaster can ascertain, with a minimum of thought or effort, the complete three-dimensional distribution of atmospheric conditions, and the time changes of that distribution, and (2) all meteorological observations made in a given region during a given time interval are readily available to the analyst or forecaster.

The latter condition is predicated on the fact that the basic station model is determined largely by the characteristics of the communication system which must serve the varied interests and requirements of all users of the meteorological observations. It seems improbable that there will be developed in the near future sufficiently general and accurate thermodynamic models that the number of observations desired by all users will be reduced.

Analysis of Present Techniques

If we use the characteristics of this ideal station model for purposes of comparison, the following inadequacies of present station models are apparent:

1. The manual transcription of all data from teletype reports to the present station models at all receiving stations is obviously neither rapid nor efficient. This is especially obvious when such charts as thermodynamic diagrams, hodographs, cross sections, and nonstandard constant pressure charts are considered. Such charts are not now used extensively because of the excessive manpower required for their plotting and analysis.

2. It is difficult for the analyst to ascertain the complete three-dimensional distribution of atmospheric conditions. Apparently, this is a result of the use of many different kinds of charts, or station models, on many pieces of paper. This difficulty is most serious when one parameter is considered alone. It is still present, however, even when dynamic or thermodynamic models are used to correlate two or more individual parameters. Following is a discussion of the shortcomings of present techniques with respect to the three major dynamic or thermodynamic models now in common use.

The Hydrostatic Equation. The hydrostatic equation can be considered as a dynamic model for correlating observations of pressure, temperature, and height. The common techniques now in use have the following shortcomings with respect to this model:

1. Only a small portion of the continuous pressure-height relationship in the vertical which can be obtained from radiosonde observations is used, since usually the heights of but a few standard-pressure surfaces are available to the analyst. The discarded data are very desirable for the accurate correlation of wind or cloud observations, which are made with respect to height, and radiosonde or aircraft observations, which are made with respect to pressure. These continuous data are also required for accurate aircraft altimetry.

2. Present hydrostatic computations are sufficiently complex that usually they are carried out quantitatively only at the radiosonde observation stations. This complexity limits the efficient correlation of representations of temperatures and heights to special cases and requires excessive experience and memory on the part of the analyst.

3. Present sea-level pressure values cannot be correlated directly with upper-air conditions since in general the particular values used for the reduction to sea level are unknown to the analyst.

The Gradient-Wind Equation. The gradient (or geostrophic) wind equation, in conjunction with the hydrostatic equation, can be considered as being a dynamic model for correlating the wind, pressure, and temperature fields. Present station models are not completely satisfactory for this dynamic model because of their inadequacies with respect to the hydrostatic equation. For example, at present the gradient-wind model can be applied easily only to a few standard constant-pressure surfaces and can be applied only indirectly to vertical representations. These limitations place serious restrictions on possible operational use of pressure-pattern navigational techniques and precise aircraft altimetry, and seriously hinder the assimilation of the three-dimensional distribution of wind, pressure, and temperature conditions.

Air-Mass and Frontal Analysis. Present station models have been designed largely for convenient air-mass and frontal analysis, and are quite adequate for that purpose. However, the efficiency of ascertaining the three-dimensional configuration and detailed characteristics of the air masses and fronts can probably be increased with improved station models.

Only a small fraction of meteorological observations are made available in convenient form for the analysts. Of the upper-air wind observations only the winds at a few predetermined levels and perhaps a few hodographs are plotted. Of the radiosonde observations usually only the observations at a few predetermined pressures and a few complete thermodynamic diagrams are plotted. Of the surface observations usually only the values at 6-hr intervals are plotted. The teletype reports of hourly surface observations are sometimes available, but their form is hardly conducive to efficient assimilation by the analyst. The observations of pressure, temperature, humidity, wind, ceiling, etc., which are

measured continuously in time at the surface, are not even transmitted over the present communication system.

Improved Techniques

Some new techniques and station models which were designed to eliminate most of the shortcomings listed above have been described [1, 2, 3]. Following is a discussion of the basic concepts of these new techniques as they are related to the previous considerations.

It is apparent that some means of automatically plotting the observations in final form is required to eliminate large plotting staffs. From an equipment-design point of view it is in general more convenient to represent the observations by plotting graphs automatically, rather than by printing numbers, on the appropriate maps or charts.

Facsimile communication equipment is already in use for automatically plotting some of the observations (a few thermodynamic diagrams) in graphical form. However, some serious limitations to the transmission of observations by facsimile are:

1. High carrier frequencies are required, thus limiting the usable types of transmission lines and complicating or eliminating the processes of storing, editing, and routing in the communication system.
2. All observations must be collected, probably by means other than facsimile, plotted in a standardized form, and retransmitted.
3. All automatic plotting is limited to a standardized form for transmission so that the individual analyst has little or no possibility of selecting those charts, parameters, or particular values which are best suited for his individual purposes.

A direct-writer type of communication system seems to be ideally suited to the transmission of synoptic observations. In this system, signals representing the coordinates of any desired graph are transmitted. These signals cause a pen to draw the graph, or, if desired, digital numbers corresponding to the desired observation at discrete points can be printed. Such a system has none of the limitations listed for the facsimile system, and it could also be used at least as efficiently as facsimile for the transmission of analysis of weather conditions. No such direct-writer system is as yet sufficiently developed for universal use, but there are no apparent serious technical difficulties to be overcome in its development.

In order to reduce the number of sheets of paper required for complete representations, station models which use the least space should be adopted. In this respect it is advantageous to use graphs, rather than digital numbers, since in a graph but one point is required to represent a given observation. This economy of space is best realized by choosing parameters for the description of the observations so that a minimum of grid, or reference, lines are required for their interpretation. This elimination of grid lines prevents confusion because of their overlapping when graphs for different stations or times are plotted close together.

Three-dimensional representations of the observations can be obtained with graphs arranged according to isometric drawing principles. For example, the height scales of all graphs can be drawn parallel to each other with their origins at points on a map corresponding to the positions of the observing stations. They can then be viewed as, say, telephone poles sticking up into the air. The values of observations at any given height can be represented by lines drawn from the graphs of the observations to the height scale. A three-dimensional illusion is then obtained by considering the lines to be crossbars on the telephone poles, with lengths proportional to the values of the observations.

This isometric technique can also be used to provide useful representations of the continuous time variations of surface observations throughout the region considered. Parallel time scales, with one particular time at the geographical positions of the stations, can be visualized as lying along the ground.

By placing both the time and height graphs on the same map, *all* the observations of a particular parameter or group of parameters made in a given region and time interval can be plotted on one piece of paper. Examples of this technique [3] indicate that it can materially aid an analyst in ascertaining the three-dimensional distribution of conditions as well as the surface time variations of these conditions. These examples also indicate that much analysis in the form of the drawing of isopleths can be eliminated when only a general concept of the spatial distribution of a given parameter is desired.

Graphs drawn according to these isometric principles have the useful property that the relative geographical positions of the observations are precisely maintained. This is seen from the fact that a given value of an observation at a given time or height is represented by a point which is displaced from the origin by the same amount at each station. This property permits convenient analysis of almost any desired conditions. For example, the height of and conditions on any desired constant-pressure surface, isentropic surface, inversion, front, etc., are readily available. Similarly, the conditions in any desired vertical cross section are represented on the isometric maps.

Additional advantages can be obtained by using special parameters for describing the observations in terms of dynamic models. Some parameters of this type are described below.

The Hydrostatic Equation. Useful continuous representations of the pressure-height relationship in the vertical can be obtained by using parameters defined in terms of deviations from arbitrary standard conditions [1]. These definitions amount to defining a standard column of air for use as a barometer. The parameter for describing the intensity of pressure then becomes the height z_p at which that pressure occurs in the standard atmosphere. Heights at which given pressures occur in the actual atmosphere can then be described either by the mean sea-level height z, or by the deviation from the standard height D, defined by

$$D = z - z_p. \tag{1}$$

The use of D eliminates most of the variation of pressure with height and very accurate pressure-height curves (D plotted as functions of z_p) require relatively small space. These curves permit rapid, easy, and accurate correlations between observations measured and plotted with respect to pressure z_p, and observations measured and plotted with respect to height z.

It is convenient to choose the standard atmosphere with which to define z_p to be that which is also used for the calibration of aircraft altimeters. The quantity D then becomes merely the additive conversion factor to be applied to pressure values z_p, as measured with altimeters, to obtain heights z. This choice of definition of the standard atmosphere provides an integration of meteorological and flight techniques which should be advantageous for all concerned.

In terms of the parameters D and z_p, the hydrostatic equation [1] is linearized to the form:

$$\frac{dD}{dz_p} = S^*, \tag{2}$$

where S^* is the virtual specific temperature anomaly defined by

$$S^* = \frac{T^* - T_p}{T_p}. \tag{3}$$

Here T^* is the virtual temperature at any given pressure, and T_p is the temperature at that pressure in the standard atmosphere.

If temperatures are represented by the parameter S, they are readily expressed as change of height D per unit change of pressure z_p. Accurate correlations between any temperature conditions and the corresponding pressure-height relationship are then immediately obvious. This change from the usual exponential form of the hydrostatic equation to a linear form appears to be even more advantageous than the comparable use of decibels in sound, light, or electrical measurements.

It appears that the use of D, rather than "sea-level" pressures, for expressing the values of surface pressure observations [1, 2] has several advantages. Chief among these are more accurate representations of horizontal pressure gradients near the surface of the earth and convenient exact correlations with upper-air pressure-height relationships.

The Gradient-Wind Equation. The use of parameters such as z_p, D, and S permits the continuous representation in the vertical of the wind, pressure, and temperature fields as related in the gradient-wind model. This possibility facilitates the assimilation of the three-dimensional atmospheric conditions. It also permits the convenient analysis of the contours of any desired constant-pressure surface so that the extensive use of pressure-pattern navigational techniques becomes feasible. Such representations would also be very useful for precise aircraft altimetry.

The present barbed-arrow type of representation of the winds does not seem to be suitable for exhibiting the continuous variations of wind with respect to time or height. Another more satisfactory method of representing such wind observations [2, 3] consists of drawing graphs of the east-west and north-south components of the wind as functions of height or time.

Air-Mass and Frontal Analysis. The techniques of isometric graphical representations can probably be applied with advantage to air-mass and frontal analysis. This is especially true of maps which contain all the temperature and humidity observations [3]. Such maps, together with similar maps of pressure, wind, and cloud conditions, should provide convenient means of increasing the ease and accuracy of both detailed and general analysis of air-mass and frontal distributions and characteristics. At present the major inadequacy of the isometric maps for this purpose appears to be the difficulty of plotting the cloud and state-of-weather observations from present teletype reports.

It is apparent that the efficient transmission of all observations can most conveniently be accomplished in terms of the continuous variations of the various parameters. For example, upper-air winds should be transmitted as continuous functions of height; radiosonde temperature and humidity observations and calculated heights should be transmitted as continuous functions of pressure; and surface observations should be transmitted as continuous functions of time. Of present observations, those of clouds and the state of the weather offer the most difficulty for this type of transmission, primarily because of the tremendous amount of such information available. Some techniques have been proposed [3] for the continuous representation of clouds, etc., which, though not yet completely satisfactory, do indicate that very useful results can be expected from this method of approach.

The use of a direct-writer communication system seems to be necessary for the transmission of all the observations since automatic segregation of particular observations from the great mass of data would undoubtedly be required. This segregated plotting would be feasible with direct-writer systems either in terms of graphs, proportional lines, or digital numbers, as desired by each individual analyst.

Conclusion

The inadequacy of present techniques of representing synoptic observations can be traced to three sources: the use of inadequate parameters with which to describe the observations, the use of inadequate methods of plotting these parameters on maps or charts, and the use of inadequate communication systems. It appears that most of these shortcomings can be eliminated with the following techniques: the use of parameters defined in terms of deviations from standard atmospheric conditions, the use of isometric graphical representations of the observations, and the use of a direct-writer type of communication system.

These new techniques are independent of each other, and could be adopted individually as opportunity or desire permits. For example, all radiosonde observations could be reported and plotted with present techniques in terms of z_p, D, and S. In fact, the parameters

D and z_p are now used for aircraft observations and reports. Similarly, thermodynamic diagrams are now being transmitted by facsimile. This transmission could probably be improved by altering its form to that of an isometric map. It might also be advisable to transmit all upper-air wind observations in a similar fashion with the present facsimile facilities. Finally, in view of the flexibility of direct-writer equipment in comparison to facsimile equipment, the former should be developed for the communication of weather information.

METEOROLOGICAL ANALYSIS IN THE MIDDLE LATITUDES

By V. J. OLIVER

U. S. Weather Bureau, Washington, D. C.

and M. B. OLIVER

Washington, D. C.

Introduction

Fundamentally there are two diverse analytical approaches to the treatment of data representing synoptic meteorological situations. One is the research approach. Here time is of no great consequence in the selection of the processing techniques to be considered in the analysis. The other approach is that of the synoptic meteorologist constrained by the exigent demands of time to select that part of the vast array of existent raw data and charts which may be assimilated expeditiously. The particular elements chosen must combine to give, with the greatest dispatch, the most accurate delineation of the meteorological complex. Limited time is, in effect, the crux of the problems present in daily synoptic analysis.

The analytical techniques selected for daily synoptic practice stem in reality from the methods formulated in the course of meteorological research, although it is frequently necessary to modify these methods to attain a maximum economy of the time and effort of synoptic analysts. Selection of analytical procedures must always be made with an eye toward comprehensiveness combined with operational simplicity. With these criteria as a basis the authors will attempt to present here a critique of the principal synoptic analytical practices.

In view of the significance of the whole problem of analysis it is well not only to review the techniques of analysis used at present and in the past, but also to attempt to appraise the meteorological research currently being pursued, estimating the measure to which each relevant scientific disclosure fulfills the fundamental requirements of daily synoptic analysis. Although an attempt will be made here to review the present and past analytical techniques in some detail, it is feasible to consider but a few examples of meteorological research with the purpose of evaluating the applications of such research to daily synoptic practice.

During the past twenty years, weather map analysis in the United States has undergone two major changes in technique. The first was the result of the adoption by United States meteorologists of the frontal technique of separating air masses of different properties. This classical system of analytical procedure, first suggested by the Norwegians [4], has been covered elsewhere in papers by Bergeron and Bjerknes. Their methods, now utilized by most meteorologists, satisfactorily delineate a large portion of the meteorologically significant motions of the atmosphere and ascribe, at least tacitly, the related weather phenomena to these causative motions. With the establishment of a network of upper-air soundings, the second major change in analytical procedure evolved: upper-air analysis, as an adjunct to Norwegian frontal technique, augmented the scope of meteorology by rendering the analysis systematically three dimensional.

Today the application of electronics to meteorology, including such adaptations as radar and sferics, portends a third progressive development in the field of analysis. The implications of a portion of these studies will be examined subsequently. But here it will suffice to say that the changes induced by electronics are far from reaching their full fruition, although exceptional advances have been made along these lines in the few short years since the use of electronics became widespread.

Paralleling the advances in the technical phases of analytical procedures, there has been a trend toward a new type of organization for meteorological analysis, an organization which permits of the more productive use of time in the field stations by eliminating duplication of effort. This trend has culminated in the rise of analysis centers and the transmission of charts by facsimile reproduction. It seems likely that the future will see an even greater specialization of meteorological personnel and a concomitant concentration of analytical work. Eventually we may even see in concrete form the now visionary picture of a fully automatic analysis center, in which the observational data are fed directly into a machine which will sort and evaluate them, with the resultant analysis proceeding without an intermediary into a vast electronic and mechanical "forecaster." The first rudimentary approaches to this type of analysis are being made by Panofsky [15] at New York University. But the distance to the ultimate goal is so great that in this paper we shall confine our discussion to meteorological centers operated by human beings. Granted even this limitation, we find that the importance of analysis centers cannot be fully actualized until there are improvements not only in the field of meteorology, but also in the field of weather communication.

Up to the present time the facsimile method of transmitting analyses has been the only technique of communication that has been put into operation which obviates the need for personnel to plot the incoming information at the receiving station. Such a method is commendably in line with the trend toward centralization and economy of human effort, but the particular facsimile method in use at this time has various drawbacks. In particular, it is too slow, and it cannot be used to transmit color. Moreover, the data as repro-

duced by the receiving mechanisms are so blurred as to preclude the transmission of meteorological reports from each of the stations of our present-day observational network. Since such methods of communication as automatic writing and electronic scanning and transmissions already exist and have been brought to a high level of efficiency and refinement in some of their applications, it seems likely that meteorologists will in the near future have available some improved communication system adaptable to detailed transmission work. Bellamy [3] has been working on this problem and his suggestions regarding it are discussed in an adjoining article.[1] The whole problem of the transmission and physical representation of meteorological data is pressing and should be an object of concentrated meteorological research.

Given an adequate method of transmission, with analysis centers located in strategic communication centers, even more specialized functions can be performed by the analysis centers. In addition to analyses, elaborate prognostic charts including information concerning precipitation and cloudiness along with isobars and isotherms could be sent out to the individual field stations to be reproduced there automatically. Local meteorologists at the field stations could apply objective techniques of forecasting to the various charts and data received, with the purpose of prognosticating the weather in detail for their respective limited areas.

In the past, one of the difficulties which has arisen in connection with almost all analysis centers is a lack of confidence on the part of the men in the field in the analyses and prognostic charts sent out from the centers. The best way to correct this is, of course, to see that the central analysts are drawn from the ranks of the very ablest meteorologists, and that they work without the undue haste necessitated by meeting ill-advised transmission deadlines. Needless to say, these expert meteorologists would make use of all the latest refinements in the techniques of applied meteorology.

We shall now consider some of these techniques more specifically. As has been pointed out, our present analysis is based largely on the concept of fronts originated by the Norwegian meteorologists. There are, however, certain types of weather which seem to lie somewhat beyond the scope of the classical frontal models. The sort of phenomenon we have in mind is the prefrontal squall line (or instability line as it is now generally known).

The Prefrontal Squall Line

The prefrontal squall line is a line of showers or thunderstorms, which often appears in the warm sector of a cyclone, extending in a line roughly parallel to the cold front. It is usually not more than five hundred miles ahead of the front and is most often noticed between one hundred and three hundred miles ahead of the cold front. Meteorologists at first believed this squall line to be either the principal cold front which some previous analyst had moved too slowly, or a weak cold front previously dropped, which, if it had been retained and moved along with the speed indicated by the baric field, would be at the present location of the squall line.

During the past few years the independent reality of prefrontal squall lines has become generally accepted. Airline meteorologists [9] and others have brought this phenomenon to the attention of meteorologists as a whole and have ascertained rather conclusively that the prefrontal squall line does not represent a misplaced cold front, as had previously been thought. At most analysis centers an attempt has been made to include these squall lines in the analysis and to use for the detection of these lines the criterion of persistence in time and space of a line of showers. Such a standard for detection may be depriving the forecasters of most of the prognostic value of the concept of prefrontal squall lines in that it fails to provide a means for the recognition of the precursors of the squalls. Because of the lack of knowledge of the mechanics of the formation and structure of these phenomena and the want of adequate observational techniques for their detection, there is much to be desired in the analyses. Recent investigations, however, give promise of an imminent improvement in this part of the analysis program.

These investigations have followed two avenues of approach. On the one hand, Fulks[2] and Williams [24] have constructed detailed descriptive models of the actually observed distributions of temperature, moisture, and atmospheric pressures associated with squall lines. On the other hand, a new theory of squall lines has been formulated, made possible by the introduction into meteorology by Freeman [8] of the concept of pressure jumps, the atmospheric analogy to the "hydraulic jump." Tepper [22], combining data of the types presented by Williams and the concept of pressure jumps in the atmosphere, has developed the theory that squall lines are caused by pressure jumps. He has demonstrated how squall lines and their concomitant weather can be initiated and propagated by pressure jumps and has further proposed that the intersection of two pressure-jump lines has properties which favor the formation of tornadoes. Currently, Tepper is testing this hypothesis by means of empirical data. The results of this work should make possible rapid improvement of our understanding of, and ability to forecast, squall lines and tornadoes.

An article by Freeman[3] describing in detail the results of this type of inquiry into the nature of prefrontal squall lines is included elsewhere in this Compendium. Here we shall restrict our discussion to only a portion of the new results emerging from this research, that is, to those properties of the pressure jump which are pertinent to the problem of analytical procedure.

Although still in a very early stage of development,

1. "Models and Techniques of Synoptic Representations" by J. C. Bellamy, pp. 711–714.

2. Consult "The Instability Line" by J. R. Fulks, pp. 647–652 in this Compendium.

3. Consult "The Solution of Nonlinear Meteorological Problems by the Method of Characteristics" by J. C. Freeman, pp. 421–433.

the investigations of pressure-jump phenomena show such promise that it seems timely to consider the steps which would have to be taken to revise our present procedures of atmospheric analysis with the purpose of taking full advantage of what we already know about this phenomenon. The first revision of synoptic practice that is indicated by this work would be at the observing level, namely, the development of the necessary instrumental and observational techniques for detecting the passage of a pressure jump at each meteorological station. Secondly, we would be obliged to codify and transmit the data pertinent to pressure-jump passages from the observation point to the forecast and analysis centers. In all probability it would be necessary to make use of the code for special observations to report the position of the pressure jump when it is initially noted. Subsequently its position could be included in our three- and six-hourly coded reports.

Finally, it would be essential that we decide upon conventions for detecting pressure-jump lines on our synoptic charts. This would entail, first, a symbol for entry on our synoptic charts to represent the pressure changes associated with pressure jumps and, secondly, a set of rules for enabling analysts to locate, uniquely, pressure-jump lines on our synoptic charts. The method of graphical representation of pressure, temperature, wind, and moisture data, suggested by Bellamy [3], appears to be well suited for showing the data pertinent to the detection of pressure jumps, while at the same time it lends supplementary emphasis to the other portions of the data used in the type of air-mass analysis customarily performed.

Bellamy's method for the graphical representation of data warrants the attention of all meteorologists since it constitutes, in point of fact, a convenient and practicable means for applying to analytical procedure the disclosures of many divergent investigations in the field of modern meteorological research. We have already touched upon the usefulness of Bellamy's method apropos of pressure jumps. Turning our attention now to an entirely different topic, namely, the meteorological significance of the results of recent radar studies, we find that again Bellamy's graphical plotting method may profitably be applied.

Use of Radar as an Analytical Tool

The advent of radar had sudden dramatic repercussions throughout the field of physical science. In meteorology A. Bent and R. Wexler [23] were among the first to apply this new scientific tool, utilizing radar in the investigation of the structure of precipitation clouds. Subsequently others have conducted further research along these lines.

Recent radarscope movies, produced by A. C. Bemis at the Massachusetts Institute of Technology, where this work has been carried on for several years, virtually compel us to adopt some new type of cloud analysis. These radarscope pictures refute the classical model of an active cold front attended by a rather solid line of cumulonimbus with occasional holes between the cells, frequently replacing this model with the picture of the cumulonimbus centers themselves, as well as the breaks in the clouds, organized in space in a series of rows, roughly parallel to each other and nearly parallel to the atmospheric flow above the frontal surface. Similarly, the disclosure that there are, as a rule, parallel bands of precipitation associated with warm fronts constitutes a marked departure from the accepted model. Bellamy's cloud graph, with height above the surface as the ordinate and time as the abscissa, permits inferences concerning the horizontal distribution of frontal clouds.

The same sort of graph has been used to represent the data obtained by turning a radarscope upwards to investigate the distribution in the vertical of clouds associated with fronts. At the time the radar studies were made, pilots and most meteorologists connected with airplane operations had already come to disagree with the model of the clouds associated with an approaching frontal system which is found in most textbooks: the familiar picture of cirrus gradually thickening and lowering, merging into altostratus, and finally stratus, with a solid cloud deck extending from the cirrus level down to the lowest cloud base. Radar studies have confirmed the findings of those who have maintained that the cloud pattern over a warm front consists of several distinct layers of clouds, generally not merging except over limited areas. Radar photographs of the vertical structure of clouds are now being made at the Signal Corps Laboratories in Belmar, New Jersey, under the able direction of Dr. Michael J. Ference. One of these pictures, illustrating the cloud deck in advance of a warm front from a coastal storm in the eastern United States, is reproduced as Fig. 9 (p. 1220) in the article by Dr. Ference in this Compendium.

In view of these findings, a systematic investigation of our classical model of cloud structure should be undertaken to determine details concerning the apparent wave pattern and layer structure. Certainly these changes should be brought to the attention of pilots and all those who are responsible for the meteorological training of pilots. We need, too, to perfect and put into operation the instruments needed to make observations of both horizontal and vertical cloud patterns so that such data can be transmitted in our regular synoptic weather codes. Once these data have been received in a weather station, Bellamy's method or some other method of graphic representation can furnish a practicable basis for the analysis of clouds.

Upper-Air Analysis

Since the structure of clouds is intimately connected with the configuration of upper-flow patterns, the revision of our model of cloud structure implies consonant changes in the technique of evaluating the data on upper-level charts to include the analysis of vertical motions. Although research meteorologists have already tackled this problem, unreliable data have forestalled its solution. For this reason we shall restrict ourselves to the consideration of the methods of analysis of upper-level charts in general use today.

Several diverse techniques of analysis exist, differing primarily in their method of attaining a verisimilar upper-level baric pattern over regions of sparse reports. In such areas upper-level contours are not uniquely determined by the wind and height data now available. Thus some sort of systematic extrapolation is necessary.

One such system is the technique of differential analysis. Approximately ten years ago the basic principles underlying this analytical method were formulated in the United States by Rossby and Starr and put into practice in analysis by Willett and Namias in extended-range forecasting. During World War II Petterssen [16] and the meteorologists of the United Nations who collaborated with him in England fully developed this technique into a powerful analytical tool in conjunction with forecasting high-level winds for bombing operations. Another form of differential analysis had previously evolved in Germany under the leadership of Scherhag [20].

The German method of differential analysis differs from the others in that it is based upon the partition of the atmosphere into layers chosen in such a way that the thickness of any one layer is approximately equal to that of adjacent strata. Below 500 mb, Scherhag's technique is virtually identical with Namias' method, which will be treated in detail below. For the very high atmosphere, Scherhag has compiled statistical tables relating the thickness of each of his selected strata with the height above sea level of the lower limit of the layer. By noting the difference between the statistical values for the thickness of the various layers and the observed thicknesses, where radiosondes are operated, Scherhag is able to extend the application of differential analysis up to the high stratosphere. Herein lies the significance of Scherhag's development. In this age of stratospheric aviation with its concomitant demands for wind forecasts at very high levels, Scherhag's method constitutes a systematic technique for extrapolating data throughout the stratosphere to obtain a logical, internally consistent, baric pattern.

For mid-tropospheric levels the best method devised for extrapolation of upper-air data is a combination of vertical extrapolation from individual reports, plus a horizontal distortion of normal thickness lines. This distortion must conform with all available reports at the level in question, the surface frontal configuration, the previously observed thickness pattern, the thermal winds, and the major atmospheric circulations at sea level and aloft. Such a method of differential analysis, described by Namias [12], is now used by the Weather Bureau for drawing the Northern Hemisphere daily charts for 700 mb and appears equally applicable to all levels below the tropopause. This technique makes use of monthly normal thickness maps, drawn at biweekly intervals on a transparent plastic material, which depict the normal thickness between the 1000- and 700-mb levels.

The actual procedure as developed by Namias is to superimpose upon the completed surface map the appropriate normal thickness chart. On top of both is laid the 700-mb chart, plotted on a tissue paper base, since the translucent tissue paper allows the analyst to see the lines on the two charts beneath it. Finally, the 700-mb chart is covered by a transparent plastic sheet on which the thickness lines for the current map are to be drawn.

Before the analysis begins, the following data are plotted on the 700-mb chart:

1. At all radiosonde stations—the 700-mb temperature, wind, and height, and the thickness from 1000 to 700 mb;
2. All available winds at 700 mb (lower levels if none are available for 700 mb);
3. At ships located in a region where the meteorological situation permits an accurate estimation of the lapse rate—the estimated thickness between 1000 and 700 mb;
4. In regions of sparse data—the thermal winds between gradient level and 700 mb.

With these data available, the analysis begins. First, the analyst draws lines of constant thickness in the regions where data are scanty. (Such regions now include the greater part of the oceanic areas of the Northern Hemisphere, Siberia, and most of southern Asia.) This is done by distorting the normal thickness lines to fit all the upper-air data, the thermal winds, and the circulation patterns of the surface chart, with due regard to the continuity of the mean temperature field. An example of an observed thickness pattern and the associated surface frontal and pressure fields is presented in Fig. 1. After the thickness lines are completed, the height of the 700-mb surface is determined by adding the thickness to the 1000-mb height. The latter is obtained by converting the sea-level pressure to the 1000-mb height. In actual practice the analyst computes the height of the 700-mb surface at the intersections of latitude and longitude lines, using a ten-degree spacing of both longitude and latitude. Thus a grid of 700-mb heights is obtained.

With this grid in the regions of infrequent reports, and with the radiosonde data elsewhere, the analyst can, with assurance, draw in the contours on the 700-mb chart. This method has the advantage of insuring horizontal as well as vertical consistency and combines expedition of analysis with maximum accuracy over land as well as over oceanic areas.

At present, however, this method has one serious shortcoming: lack of sufficient data precludes the construction of normal thickness charts in the upper layers of the troposphere and in the stratosphere. There is thus an empirical ceiling on the efficacious use of this method. Above 500 mb, Scherhag's system of extrapolating data for the construction of baric charts still is applicable, as is another method, based upon a study conducted by Riehl and LaSeur [19] of high tropospheric lapse rates. The general technique is little different from the long-standing practice of assuming a lapse rate at a point and thereby determining the pressures aloft at that point. For instance, the height of the 700-mb surface can be attained with reasonable accuracy by assuming a moist-adiabatic lapse rate up to 700 mb above a ship reporting a shower, but the choice of an appropriate lapse rate

in more complicated synoptic situations and at high tropospheric levels is not so easy. What Riehl and LaSeur did, essentially, was to determine an appropriate lapse rate between 700 and 300 mb for each typical synoptic flow pattern. Then using the 700-mb chart as a guide and the proper, calculated, lapse rates, Riehl and LaSeur were enabled to obtain reasonable estimations of upper-atmospheric pressures up to 300 mb. One decided advantage of their technique is that the lapse rates, being statistically determined, are obtained independently of the mean temperatures in the layer from 700 to 300 mb. Since, however, these two quantities are so closely related, mean temperatures may be used as a check on the accuracy of the extrapolated hypsometrical values of the 300-mb surface, contributing in no small way to the value of the subsequent analysis.

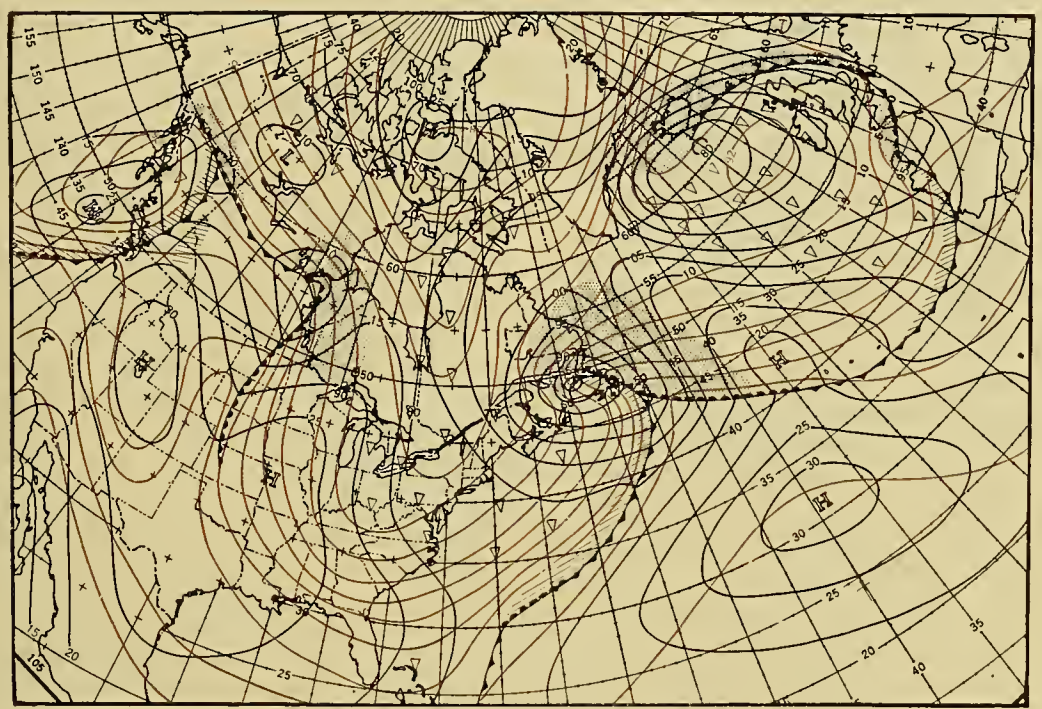

FIG. 1.—Example of observed thickness patterns in the vicinity of several different frontal systems. Red lines are 1000–700-mb thickness; black lines, sea-level isobars.

There is still another approach to the problem of the analysis of regions of exiguous data, based not on horizontal nor vertical extrapolation, but rather on extrapolation with respect to time. When the surface data are particularly scant, vertical extrapolation is possible only at widely separated points and is therefore incapable of providing sufficient data to insure a unique analysis. Likewise, under these particular circumstances the technique of extrapolation based on the horizontal distortion of thickness lines is of but meager productivity. When these are the circumstances, reliance upon extrapolation at a point with respect to time produces the optimum analytical results.

The quintessence of the information derived from the technique of time extrapolation is the structure of the pressure system passing a single point and, in addition, the direction in which that pressure system is moving. Notwithstanding the very definite limits of the spatial range throughout which the deductions drawn by this method can be validly applied, an analysis, which for practical purposes is unique, can be obtained for a considerable region about each point where the extrapolation with respect to time is carried out. This area for which the extrapolation is valid varies with the synoptic situation. Details of the interpretations of the changes of various data with time are found in the studies of single-station analysis made at the University of Chicago in the early 1940's [14]. More recent applications of this sort of extrapolation for daily analysis have been made in such diverse regions as the Aleutians, where time cross sections were used to aid in analyzing the vast unpeopled expanses of the Pacific Ocean, and in the tropics. Riehl [18] recently published a paper elucidating the use of extrapolation with respect to time in the solution of problems of tropical analysis.

In the field of analytical research, time cross sections are tools which have shed light on countless perplexing questions. In research, one particular class of time cross section has enjoyed widespread and manifold uses [10]. This consists of a graphical representation of some element (*e.g.*, pressure) plotted on a diagram in which time is used as an ordinate and a spatial unit (*e.g.*, longitude) is the abscissa. In this hypothetical case, lines could be drawn on the graph portraying the position of troughs and ridges with respect to time. The divergent uses to which this sort of analysis has been put attest to its value in clarifying significant meteorological relationships.

Coordinated Use of Sea-Level and Upper-Air Analysis

Having once arrived at a satisfactory analysis of both sea-level and upper-level charts, we come to what is perhaps the greatest problem facing the forecaster today: the coordination of the sea-level data with the upper-air data. Most meteorologists are now familiar with both the sea-level and the upper-level charts, and routinely take both into account before rendering judgments upon the development and motion of storm centers and their associated manifestations of weather. Despite this fact there still appears to be an appreciable difference between the scope of the synoptic meteorologist's general knowledge of weather processes and the part of this information which he actually applies in analysis or forecasting. It appears that many forecasts miss their mark not because of our over-all lack of understanding of the factors which control the changes in the weather, but because the coordination of all the various pertinent details at all levels of the atmosphere in a relatively short time interval is a task too difficult to accomplish satisfactorily with our present system of map display and data representation.

If we try to picture what is needed in order to coordinate with facility the meteorologically significant features of the higher strata of the atmosphere with those at the surface, we shall arrive at something like the following:

First and most important, all the various charts depicting conditions at the surface and at upper levels should be the same size. This proviso, though simple, is vital if the forecaster is to be able to compare one level with another quickly and accurately.

Second, the charts for all levels should be drawn on semitransparent paper in order that one may be superimposed upon that for an adjacent level to facilitate examination of the changes of meteorological features with height and to insure internal consistency in analysis. Furthermore, it is obvious that we should use the same units for data at all levels if the maximum ease in vertical synthesis is to be obtained. Consider, for instance, the disordered array of units in current use: centigrade and Fahrenheit temperatures; Beaufort scale, knots, miles per hour, and meters per second denoting wind velocities; altitudes measured in feet, meters, or dynamic meters; and pressure analysis hampered by the use of isobars on sea-level maps and contour lines on upper-level charts. The system of units proposed by Bellamy [2] is of a unitary type. As has been mentioned, he has also proposed a system for the graphical representation of data, which obviates the need for converting numerical values from one system of units to another. By means of simple transparent overlays, the numerical values of the data in any desired units may be read directly from the graphs.

Although complete standardization of all units is not feasible at this time, we may even now progress towards this goal by adopting a single system of units for pressure. In particular, the unfortunate duality of units with isobars drawn on the surface map and contour lines on the upper-level charts can be abolished without complexity by replacing the sea-level isobars with the 1000-mb contours; the observational stations could report the height of the 1000-mb surface as well as the sea-level pressure.

At present, in our attempts at vertical synthesis of atmospheric elements, we labor under a difficulty other than that occasioned by a multiplicity of units; we refer to the unfortunate time interval which elapses between surface and upper-air observations. As a result of this lack of synchronization, many of the fundamental charts upon which analyses and forecasts are based are, in effect, invalid. Rectification of the observational program must inevitably precede sound coordination of upper-level charts with surface data.

A further argument in favor of using uniform map scales and units plus transparent or semitransparent map bases is that they make possible the construction of a chart which we believe to be most effective in bringing out the relationship between surface and upper-air circulations. This is simply the sea-level chart with upper-level contours traced on it, preferably using for the upper-level contours some color differing from that of the sea-level isobars. This method seems to be the most satisfactory for relating the patterns at upper levels with the weather and pressure changes occurring at sea level [13]. Such a chart can be used to especial advantage by those who must issue forecasts or complete an analysis of the synoptic situation in a very limited time. When time is pressing, analytical comprehensiveness is all too frequently sacrificed as long as the surface and upper-level charts are kept separate, for even when both are carefully studied independently, the possible inferences to be drawn from the changes of flow with height can be assimilated only by a careful comparison which consumes more time than is now available to most operational meteorologists.

If this general concept for the coordination of surface and upper-air data is accepted up to this point, the problem then arises as to the selection of the upper-level chart most productive from the standpoint of the number of utile inferences deducible from the combined analysis. This set of upper-level contours depends to some extent on the primary purpose to which the charts will be put. If we consider that forecasting the appearance of the sea-level and upper-level pressure charts 24–48 hours in the future is the primary problem, then we should choose for analysis the upper-level chart considered to be most significant for the investigation of steering, cyclogenesis, and anticyclogenesis. At present many meteorologists prefer the 500-mb chart over all others for this purpose. It would therefore be proper to superimpose on the surface map the 500-mb contours at analysis centers whenever pressure-pattern prognoses constitute the chief forecast problem.

On the other hand, if the primary problem is to forecast the cloudiness and precipitation for the coming twenty-four to forty-eight hours, then the upper-level chart chosen should be the one best suited for the detection of advection and the motion of the moisture layers which are most intimately associated with the observed cloudiness and precipitation.

The problem of such short-range precipitation fore-

casting has been under consideration by many investigators during the past few years [5, 17]. The three factors which have been found to be most important for precipitation forecasts are the orientation and curvature of the flow patterns at the altostratus level (about 700 mb), the location of areas of pressure fall at sea level, and the extension of warm-air advection near the 850-mb level. Since the detection of advection between 700 mb and the surface can be accomplished at a glance all three of these charts the relation between the two sets of isopleths and the weather and cloud data throws into full relief the following information: the prineipal activating mechanisms of precipitation and cloudiness, the areal extention of warm and cold air advection, the movement and spatial distribution of pressure-fall areas on the surface map with respect to the steering flow aloft, the relationship between moisture sources and the orientation of the upper flow, the likelihood of vertical

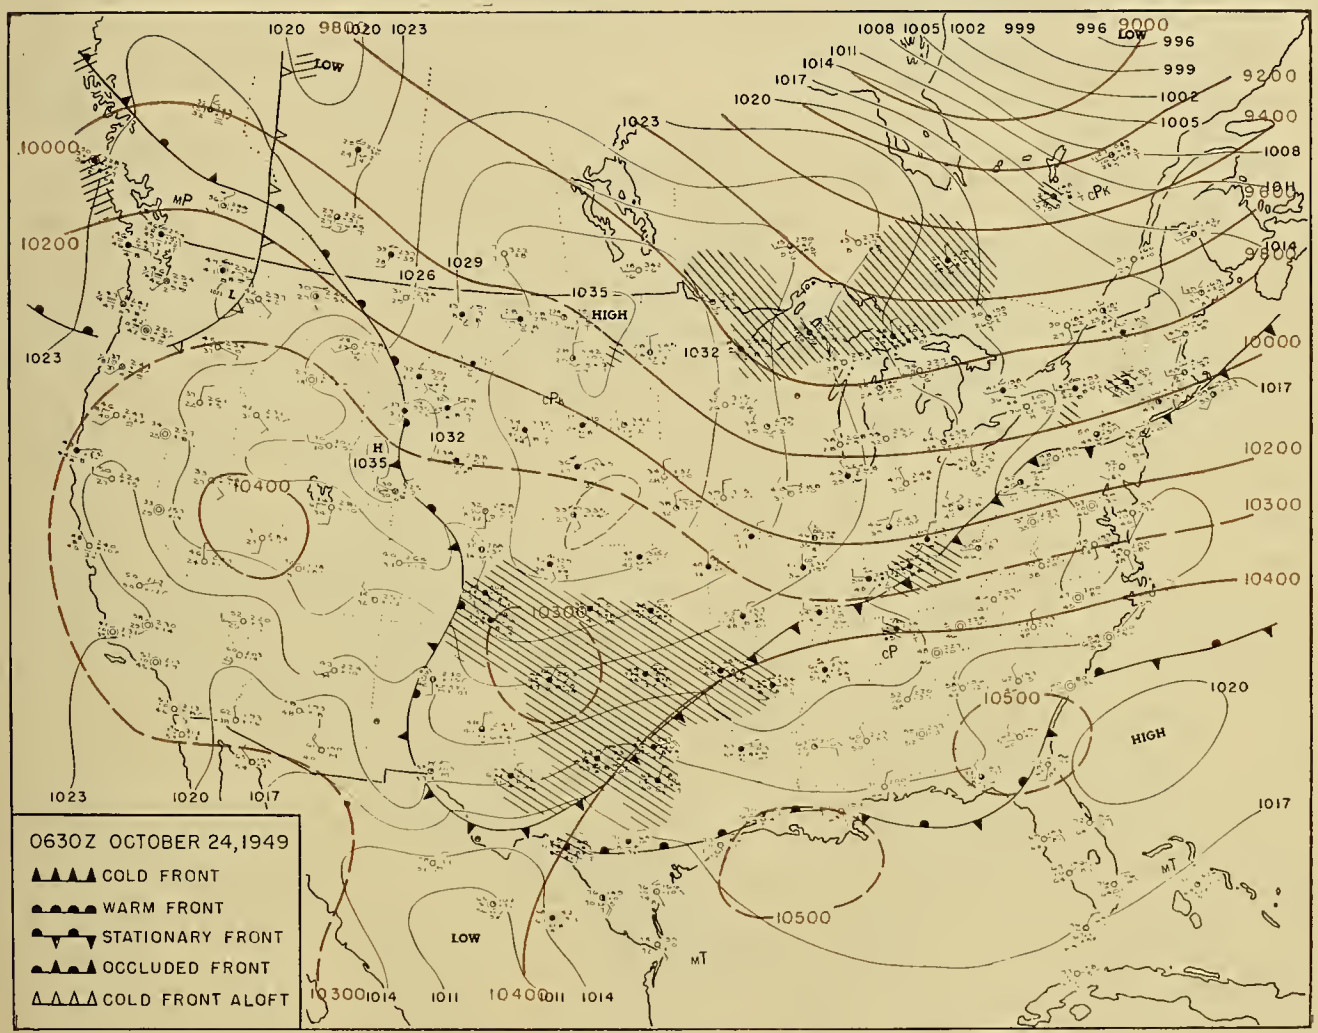

Fig. 2.—Combined sea-level and 700-mb analysis for the United States at 0630Z, October 24, 1949.

when the charts of these two levels are superimposed, and since the 700-mb contours represent the air flow at the level where most of the altostratus rain clouds are centered, the 700-mb chart superimposed on the sea-level chart is considered the most useful combination in giving a comprehensive view of the weather prospects in stations where issuance of 24- and 48-hr forecasts to the general public is the prime function. The authors feel that this is such an important subject that some examples of the combined analysis of surface and upper-level charts are presented here in detail.

These examples include three consecutive sea-level charts with the corresponding 700-mb contours superimposed upon them, constructed for 24-hr intervals. On displacement of an air mass above a front, and the areas along fronts where the meteorological properties of the atmosphere are most conducive to wave formation.

The most striking feature on the first of these examples (Fig. 2), is the large area of rain in the southern Great Plains States. The strong easterly flow indicated by the sea-level isobars in this area leads to the tentative assumption that the rain is caused by topographic upslope motion of the cold air mass as it moves toward the higher land areas of Colorado, western Texas, and western Kansas. In view of the configuration of the upper flow, however, it seems quite evident that the warm moist tropical air from the Gulf of Mexico is

moving northward and then northwestward over the advancing and deepening cold air mass. The explanation of the precipitation then, clearly brought out by the two combined charts, must be the enforced elevation of the tropical air, rather than orographic lifting of the cold air mass.

Other than that in the southern Great Plains, the only area of precipitation of any large extent is that indicated in the vicinity of Lake Superior. Here the obvious causative factor is the well-known heating effect of the Lakes. The important point here is the concurrence of cyclonic curvature of the sea-level isobars and the 700-mb contours with the area of shower activity. The intimate connection between the curvature of the flow pattern and the occurrence of such instability phenomena as the "Lake effect" stands out pellucidly by virtue of this particular method of superimposition of charts.

Turning next to the portion of the cold front extending from Tennessee northeastward to Massachusetts, we note two things: (1) that the flow from the west is stronger aloft than it is at the surface, indicating no lifting of the upper air mass by the eastward-advancing portion of the surface front and therefore little or no frontal weather; (2) that east of the Appalachian Mountains, the portion of the front which is moving slowly southward is parallel to the upper winds and should therefore produce lifting of the air above the frontal surface. In the area to the rear of this portion of the front some cloudiness and precipitation are in evidence. This is the only area where the combined analysis suggests the possibility of frontal precipitation directly behind the front.

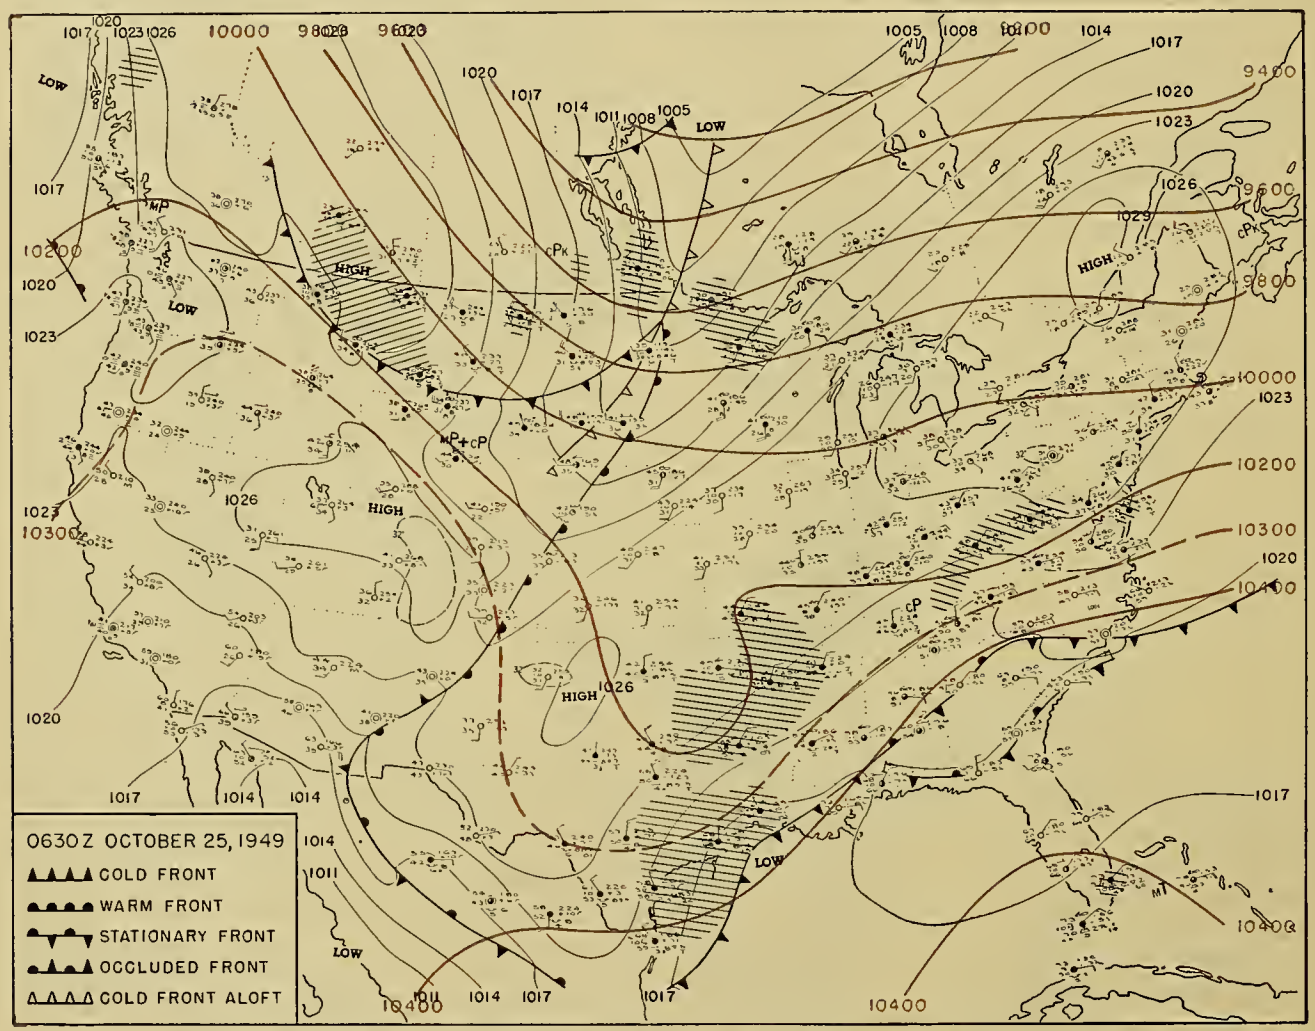

FIG. 3.—Combined sea-level and 700-mb analysis for the United States at 0630Z, October 25, 1949.

The front in the southeastern United States, with a wave along the coast of South Carolina, is in a position which often causes the weather along the coast to deteriorate suddenly. In this example, however, the presence of a closed high-pressure cell aloft near South Carolina clearly indicates that the front is lifeless and that the forecaster need have no worry lest it develop in the future.

Looking at the analysis again for the purpose of detecting the areas of warm- or cold-air advection, we come upon striking evidence that strong cold-air advection is occurring through Iowa, Illinois, Indiana, Ohio, and most of the area north of these states. Strong

advection of warm air is indicated only in eastern Montana. The sea-level pressure tendencies are rising throughout most of the area of cold-air advection and falling over the area of warm-air advection, as is usual [1]. Thus the distribution of advection may be appraised by only a cursory investigation of the combined sea-level and 700-mb charts.

This combination likewise promotes the ease with which the principle of steering may be applied to a specific meteorological situation. Examining Fig. 2 from the standpoint of steering, we can infer swiftly and with moderate assurance that the northern portion of the high-pressure area located in the northern Great Plains States should move southeastward and then eastward to near New York, while the portion of the cold-air dome which has moved south of the strong belt of westerly winds, into Texas and Oklahoma, will have to remain trapped in that region. The isolated low aloft over Texas is moving slowly eastward as is indicated by the sea-level pressure falls east of it and sea-level pressure rises west of it, but it seems clear that since it is now out of the westerlies it should not move far in the next 24 hr, and that any wave activity it might induce on the cold front could not move along the front to the northeast until after the passage of the rapidly moving high-pressure center in the northern Great Plains States.

The intimate connection between the upper-level circulation and the attendant weather is again dramatically illustrated in Fig. 3, the combined analysis for 24 hr later. Here in the South Central States we see that the precipitation and cloudiness from the weak wave in the Gulf of Mexico extends only as far north and west as central Missouri, while northern Missouri remains perfectly clear. Likewise the circulation around the upper-level center over Oklahoma shows that the moisture from the south is carried only to the same region in Missouri but no farther. The reason for the distribution of cloudiness and precipitation is not at all apparent from the surface map alone, while from looking at the upper-level map alone one would remain unaware of the actual distribution of weather. It is the combination of the two sets of data that presents the complete, pellucid picture of the synoptic situation.

If we examine the combined analysis over the southeastern states to elicit the explanation of the widespread cloudiness to the north of the stationary front, we find that the orientation and curvature of the upper-level contours with respect to the surface pattern is again rewarding. Considering first the orientation of the upper-level contours in this region, we note that the upper-level flow is essentially parallel to the surface front. This indicates that there is no downslope flow over the frontal surface, a circumstance which greatly enhances the likelihood of postfrontal middle clouds. In this particular instance, the existence of clouds in the area to the rear of the front becomes a certainty, since the upper-level flow emanates from a region of ample moisture supply.

Let us consider next the curvature of the upper-level contours over the South Atlantic coast. Directly under a portion of the anticyclonic flow we find on the surface map a wave on the front in South Carolina. Since the formation or perpetuance of a wave is unlikely beneath such a flow aloft, this wave should not be of much synoptic significance unless the upper-level contours above it change their characteristics of curvature, orientation, or both.

Over West Virginia the weak cyclonic curvature of the upper contours in conjunction with a certain amount of warm-air advection, seems adequate to have caused precipitation in that region. Again the surface and the upper-air analyses considered separately fail to give a lucid explanation for the distribution of cloudiness and precipitation; with both charts examined in combination, the causative factors stand out.

Let us continue our examination of the combined analysis in Fig. 3 with a view toward determining areas of temperature advection in the layer between the surface and 700 mb. The salient features of the field of advection are the strong warm-air advection from Iowa northeastward, the strong cold-air advection in North Dakota and Montana, and the cold-air advection in southeastern Texas, all so plainly revealed as to obviate further comment. Similarly the significant features of the steering pattern are apparent. The contours at the upper level indicate that the frontal system in the northern Great Plains States will continue to move rapidly eastward and that the trough associated with this system will in all probability overtake the slowly moving trough in Oklahoma. The wave located south of Louisiana is being steered to the northeast by the increasingly strong southwesterly winds over it. At the same time the combined analysis reveals the interesting probability of the development of this wave. Several circumstances favor this development: the wave on the surface is close to the upper-level center, with the flow above it cyclonically curved; there is air-mass contrast across the front; and the solenoidal field is being intensified by increasing cold-air advection to the rear of the wave with pronounced warm-air advection in advance of it.

The combined analysis illustrated here successfully expedites the analysis by making it easy to evaluate all these factors with the use of but one chart.

Figure 4 affords an even more vivid illustration of the use of combined analysis for bringing out the well-established but all too frequently unnoticed relationships between the upper-level flow and the concomitant sea-level patterns and weather phenomena. In Fig. 4 the difference between the two cold fronts in the central and southeastern portion of the country with respect to the extent of postfrontal middle cloudiness again correlates nicely with the characteristics of the upper flow over the frontal surface: Where the upper flow is parallel to the front and has cyclonic vorticity, there is rain; where the upper flow, increasing as it is with height, is nearly perpendicular to the surface, front the skies are clear. Along the Divide in Montana where the front is being overrun by westerly and northwesterly winds aloft, there is no precipitation. In this area the sharp anticyclonic turning of the upper-level flow suggests

that the front should remain inactive as far as cloudiness and precipitation are concerned.

A glance at Fig. 4 shows that the cold high has moved from northwestern Montana to northeastern Kansas, in accordance with the steering indicated by the upper-level flow.

It is the ease with which a truly comprehensive picture of the synoptic situation may be gained which commends the method of combined analysis presented here. With other methods the same results may, of course, be obtained in time. But the authors feel that the saving of time and energy effected by this method is of sufficient significance to warrant its inclusion in the standard operational procedure used for analysis.

Before leaving the problem of how best to facilitate the comprehensive, three-dimensional visualization of a synoptic situation, one further point should be considered: the total area of the meteorological map base being used must be so restricted in extent as to insure ease in superimposition together with ease in comprehension. A map whose areal dimensions are greater than about three feet square is difficult to handle and is too large in scope to see all at once. Meteorologists who are required to make two- or three-day forecasts need maps covering considerably more area of the earth's surface than is needed for shorter-period forecasts. If this additional area is achieved by increasing the size of the map, the map soon becomes so large that it is difficult to perceive the relationship between changes on opposite sides of the world. Such concepts as the spread of energy downstream from a newly formed storm or the creation of new troughs whose location is indicated by constant vorticity currents remain inaccessible to the synoptic meteorologist unless his working charts are small enough so that he can study a large area simultaneously.

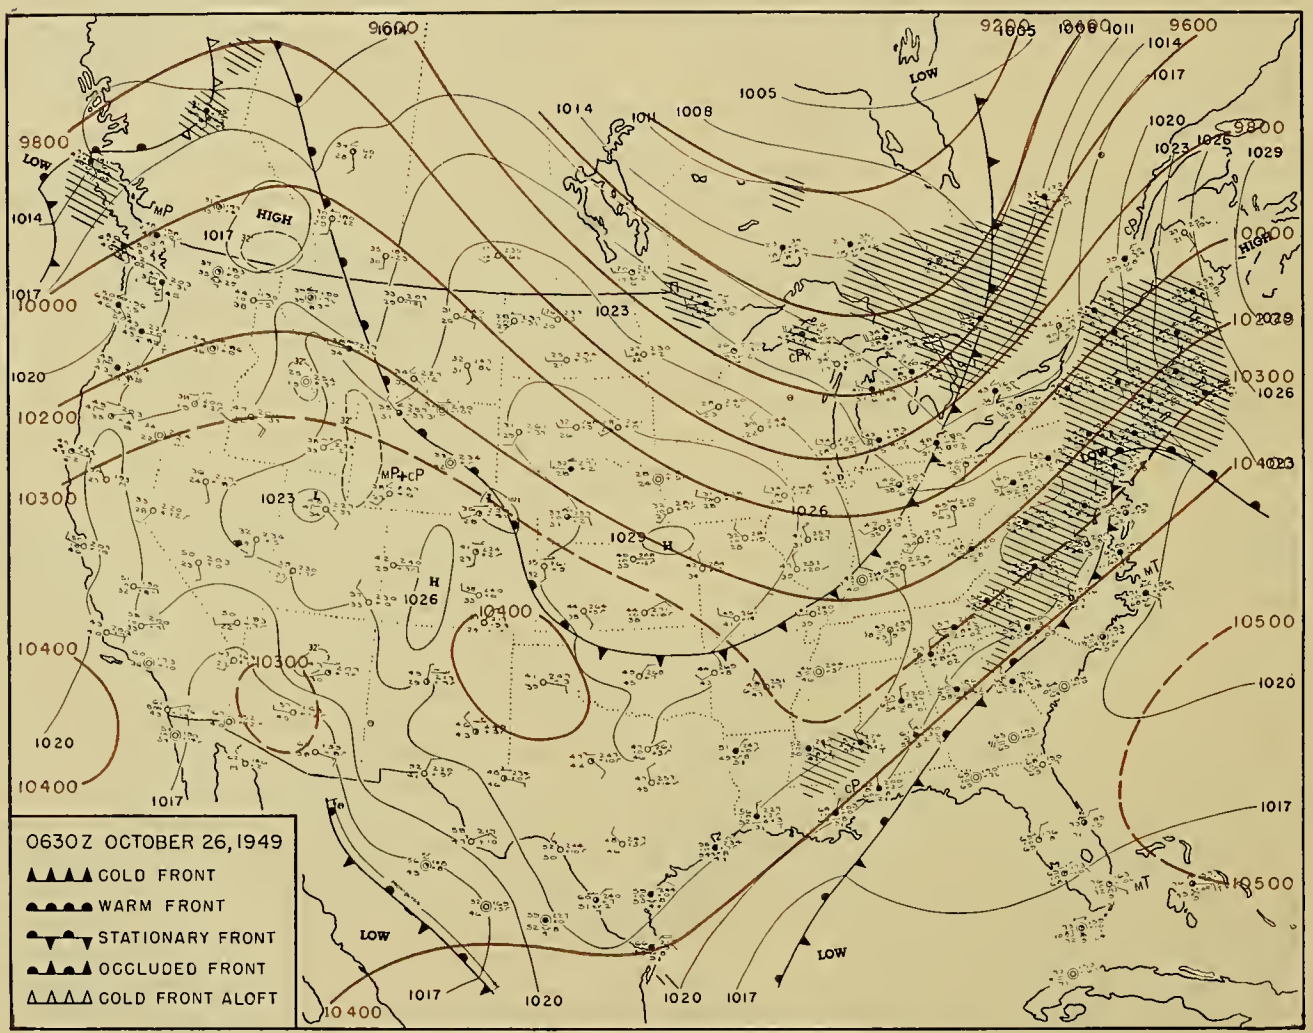

FIG. 4.—Combined sea-level and 700-mb analysis for the United States at 0630Z, October 26, 1949.

Although small-size, large-area maps are needed by the forecaster for predictions of two to three days or longer, the analyst who is responsible for a detailed analysis of a limited portion of the earth's surface, or the forecaster concerned with a local forecast, usually needs a different map base. This latter base must have a scale large enough so that the data from all the observational stations in the region may be conveniently represented on the map, since detailed data are necessary for the analyst to be able to locate pressure jumps, nascent waves on fronts, and poorly marked fronts.

Detailed analysis and study is likewise a requisite for short-period local forecasts. This whole question of the selection of a meteorological base map is not one which can be solved theoretically once and for all time; it is a recurrent practical problem, whose solution is contingent upon the specific conditions under which the map will be used. This specificity, which is characteristic of so many meteorological perplexities, renders the problem by no means unimportant.

Moisture Charts

Another equally specific, equally significant, difficulty is that of devising a chart, or charts, which will portray graphically those factors which are conducive to showers other than those associated with fronts or pressure jumps. Such a chart (or charts) would be the *sine qua non* of local forecasting, particularly in regions of high summertime precipitation. In an attempt to solve this problem, sundry types of energy diagrams have been developed along with techniques for computing the likelihood of showers. Empirical results have been disappointing to such an extent that it appears probable that our present methods for evaluating the energy due to thermal instability fail to take into account all the factors involved in the release of energy as shower activity. This is corroborated by the recent studies on entrainment of air into the sides of increscent cumuliform clouds. The findings of these investigations suggest that the occurrence of showers is not often due to pure thermal instability, pure air-mass showers being very rare. Indeed, evidence has been disclosed that a widespread convergent wind flow, a pressure jump, a mountain range, or some other type of trigger action is necessary to give well-developed shower activity. The recent studies of the thundershower activity in Florida and its relation to the convergent effect of the sea breezes from two edges of the peninsula afford a good illustration of how important such effects are on air-mass shower activity [7]. Certainly, this is a subject on which more research is sorely needed.

Although our knowledge of the relationship between the vertical energy distribution and subsequent shower activity is imperfect at present, there appears to be a more readily applicable relationship between the horizontal moisture distribution and the resultant showers. In the days before there were reliable upper-air soundings, an analysis of clouds and precipitation was the main clue to the distribution of moisture. But after the establishment of the network of suitably accurate radiosondes, many experiments were made to determine the type of chart (or charts) which would be best suited for portraying the horizontal distribution of moisture in the atmosphere and for following its successive variations.

At the present time the horizontal distribution of atmospheric moisture is usually studied by means of isopleths of dew point on either the 850-mb or 700-mb chart, or on both. The basic disadvantage of this procedure is that air particles frequently undergo vertical motions rendering it impossible to be sure that one is following from moment to moment the same parcels of air. This, of course, makes various invalid inferences very tempting. But even with the assumption of quasi-horizontal motion, this method for the analysis of atmospheric moisture is far from being completely satisfactory. Its value is impaired by the fact that the patterns produced by the dew-point isopleths tend to be indistinct and fragmentary on both the 850- and 700-mb charts. Through the study, however, of these particular isopleths, considerable valuable information may be obtained.

There is evidence that it is in the plateau and mountain regions of western North America that the most fruitful application of this procedure for moisture analysis can be made, a somewhat surprising disclosure since most analytical methods give their best results over oceans or over plains of low elevation. In the areas of these western plateaus and mountains we find that the 700-mb configuration of isopleths of dew point seem closely correlated to shower precipitation all during the warm season. In fact, many meteorologists feel that the wind and moisture patterns at 700 mb may be used alone to give satisfactory forecasts for showers in these mountain areas. Over relatively flat areas where the trigger action of mountains is lacking, more information is needed for the prediction of showers. In particular, it would be of benefit to know the location of areas where upslope or downslope motion of moist parcels of air is occurring.

Isentropic Analysis

This need for a more inclusive chart, designed to depict not only the distribution of atmospheric motion but also proximity of each air parcel to saturation, the location of areas where there are upslope or downslope movements, and the major flow patterns of the air, is met by the isentropic chart [11]. Besides its important property of inclusiveness, the isentropic chart is the chart best suited for following the motion of air particles since the particles of an isentropic surface are conservative for all adiabatic changes. The patterns formed by lines of equal condensation height, or pressure, on an isentropic chart are therefore less fragmentary and more persistent than the configurations formed by the isopleths of dew point on a surface of constant pressure. In short, on an isentropic chart the distribution of moisture is simply and vividly apparent and the analyst can, in general, validly follow a particular air particle in its day-to-day convolutions. Thus the isentropic chart is a potent addition to our tools for preparing optimum analyses.

Shortly after the upper-air network had become well established, the isentropic chart was introduced and tried out in all the meteorological centers of the United States. At that time it was the practice to transmit to the field stations, along with the other upper-air data, the data for three different constant potential temperature surfaces. The purpose of transmitting the data for three isentropic surfaces was to allow the local meteorologist to select for analysis the one isentropic surface most useful to his own locale.

During this period of experimentation the most im-

portant application of the isentropic chart proved to be its use in forecasting cloudiness and precipitation, including the evasive summertime showers. The chart was also found to be of especial value in predicting the occurrence of precipitation along the West Coast [6], where frontal analysis taken by itself is inadequate for this purpose.

Unfortunately the years of experimentation drew to a close with only a small portion of the meteorologists in the United States familiar with the applications of the isentropic chart. Subsequently the isentropic chart was abandoned by the Weather Bureau and the data for its construction were no longer transmitted over the teletype network. This was due in part to certain difficulties in communication, but to a larger extent it was due to the time factor inherent in the analysis itself. The isentropic chart is more difficult to draw correctly than are most of our other upper-level charts. For inexperienced men the analytical time consumption proved to be an unsurmountable obstacle to the realization of the usefulness of the chart. Experienced forecasters and analysts, however, who had become familiar with the isentropic chart generally felt, and still feel, that a long step backwards was taken when the isentropic analysis was abandoned.

With the present trend towards the concentration of analysis in large centers, with the increased accuracy of radiosondes, and with the advent of improved communication facilities, the time seems ripe for the reinauguration of the isentropic chart. It would be entirely possible for the analysis center to transmit to field forecast centers three complete isentropic charts, based on the same data that were previously transmitted from the observational network. With the advent of a means for transmitting colors, these isentropic charts could include not only streamlines, some sort of contour lines, and condensation height or pressure lines, but they could include, as well, moist tongues shaded in red, dry tongues in blue, and saturated areas in green in conformance with the conventions observed previously in the construction of isentropic charts. Thus the forecaster would be provided with a simple efficacious tool for studying the moisture distribution of the atmosphere. Moreover, instead of having one "homemade" isentropic chart, plus the raw data for two other constant potential temperature surfaces, he would be equipped with carefully executed analyses for all three surfaces, enabling him to investigate the changes with respect to height of all the data on the isentropic chart.

Such an investigation may be facilely accomplished through the use of another form of isentropic analysis devised by Starr [21]: the relative-motion chart. The aim of such a chart is to supplement the information given by streamlines at a single isentropic level. The relation between streamlines and contour patterns indicates whether there is upslope or downslope motion on the isentropic surfaces provided the wind near the isentropic level in question increases with height, as is generally the case. The function of the relative-motion chart is to give an approximation of the change in wind with height at the isentropic level being considered. Relative-motion charts are easily prepared, given the isentropic data. They could be drawn and transmitted from analysis centers as an additional tool for the use of the local forecaster. Such arrangements would benefit not only the synoptic meteorologist, but the research man as well, an important consideration since in the field of research, isentropic analysis is acknowledgedly of significant value.

Conclusion

In various specific contexts in this discussion of analytical techniques we have mentioned the value of the use of color in augmenting the clarity of analyses. Despite the habitual use of color on meteorological charts, its utilization has tended to be haphazard and accidental rather than systematized. To a surprising extent even simple uses of color have been neglected in the United States. The psychological effect of color and its use as an aid to analysis should in the future receive the attention it warrants.

Another neglected problem is that of the ideal arrangement for an analysis center or forecast station. As far as the authors can discover, the results of comprehensive studies of this subject have not been incorporated into actual practice. The optimum height of working surfaces, lighting, best selection of furniture, and the arrangements of furnishings and charts are considerations which lie outside the field of meteorology proper. But seemingly minor factors such as these (or such as the use of color mentioned above) may contribute appreciably toward better analysis. In order to improve forecasts, these problems must be solved along with those of a more strictly meteorological nature.

But beneath these specific analytical problems, and precluding their solutions, lie the broader barriers to rapid advancement in the field of meteorology as a whole. One of these fundamental obstacles is the confusion occasioned by the plethora of theories and operational practices, attending the sudden multiplication of reliable meteorological instruments, which has presented for the scrutiny of the forecaster an entirely new and unprecedented multiplicity of data. The other basic obstacle is the enigma of the processes involved in the general circulation of the atmosphere. Once a valid theory of this general circulation has crystallized, order should begin to appear in the present chaos of our secondary meteorological theories. However, until such time as this is accomplished, it behooves those of us concerned with analysis to follow up whatever lines of research seem promising, searching through meteorological theory for effective applications to analysis and seeking to better our analytical techniques through experimentation and critical discussions participated in by meteorologists all over the world. But despite our concern with the details of analysis, we must never lose sight of their dependent relationship to the larger and more fundamental concepts of meteorology.

THE FORECAST PROBLEM

By H. C. WILLETT

Massachusetts Institute of Technology

INTRODUCTORY REMARKS

The Unsatisfactory Progress of Weather Forecasting as a Science. Probably there is no other field of applied science in which so much money has been spent to effect so little real progress as in weather forecasting. Today the nations of the world spend many times what they did forty years ago to obtain the necessary observational data and to prepare weather forecasts. But the advance in weather-forecasting skill has not kept pace with the increased effort and attention devoted to forecasting. The variety of weather forecasts, as to time range and detail, as to the elements forecast, and as to the elevations and geographical areas for which forecasts are prepared, has been greatly increased in proportion to the increase in the observational synoptic data, to meet more exacting demands. Much has been done to meet these demands by the development of special types of forecasts, frequently forecasts of elements which were not even observed forty years ago. But in spite of all this great expansion of forecasting activity, there has been little or no real progress made during the past forty years in the verification skill of the original basic type of regional forecast, of rain or shine and of warmer or colder on the morrow, the kind of forecasting which first received attention.

The question naturally arises, Why has this great expansion of forecasting activity contributed so little to the basic advance of the science? There are a number of factors to which this lack of progress may be attributed. These factors vary somewhat in relative importance from country to country, but probably conditions in the United States (which has experienced perhaps the greatest multiplication of forecasting tools and techniques) may be taken as essentially typical of the entire field. On this assumption the principal reasons for the failure of forecast skill to keep pace with forecast practice are:

1. The expanding demand for trained forecasters. Since World War I, but increasingly during the thirties and with the outbreak of World War II, there has been a vast expansion in the number, the variety of service, and the trained-personnel requirements of weather-forecast centers. This greatly increased demand for forecasters has come from government weather bureaus, from commercial aviation, and from the military. Since the vastly increased demand for trained forecasters was not anticipated, the proper training of large numbers of forecasters was not provided for. Neither has sufficient salary incentive been provided (in proportion to the exacting nature of the work) to attract into this field, or to hold, the best-qualified men. As a result, thousands of meteorologists have been pressed into forecasting service, many of them after only one or two years of training, and many of them unqualified by interest or temperament for this work. One further circumstance which has been most unfavorable to the improvement of forecasting is that by and large there has been in operation no objective verification procedure by which the forecasting ability of these many inexperienced forecasters could be compared one with another or against any standard, as a basis for the elimination of the less competent forecaster.

As recently as twenty years ago in the United States the few official government forecasters were assigned to this duty only after many years of practice forecasting in objectively verified competition with the official and other practice forecasters. After assignment to forecast duty their records as official forecasters were continuously checked in the same manner. It is a sad commentary on the scientific status of weather forecasting that even today the methods remain so empirical and so dependent upon experience and subjective interpretation that the development of the best forecasters still requires years of experience and the right temperament and interest. The primary problem of weather forecasting remains that of removing the science from this subjectively empirical category and of making it scientifically objective.

2. Multiplicity of forecasting tools and techniques. The availability of rapidly increasing amounts of observational synoptic data, particularly of aerological data, has led to a great amount of experimentation with the use of various charts and coordinate systems for the synoptic presentation and analysis of the new observational material as an aid to the forecaster. Unfortunately this has led to the introduction into forecasting practice of a multiplicity of charts and diagrams which are largely redundant in that they present the same basic information in a variety of forms, the relative merits of which remain completely untested, and the variety of which leads only to a confusion of forecasting techniques and principles that interferes with the clear-cut formulation of any simple set of prognostic rules or criteria, such as is gained from long familiarity and practice with one minimum standard set of synoptic charts. At the present time routine forecast practice can undoubtedly be greatly benefited by the universal acceptance of a minimum standard set of simple synoptic charts, even though the selection of the standard aerological charts might not be the most effective that could be made. This selection of standard charts should be based on some real attempt at objective verification of their relative prognostic merits, a procedure which is equally necessary for forecasting techniques and for forecasters.

3. Failure to assess the essential forecast problem correctly. Probably the primary reason that more prog-

ress has not been made in recent years towards the improvement of basic weather forecasting lies in the failure to assess the essential nature of the problem correctly, with the consequent misdirection of much money and effort. Practical weather forecasting has been until very recently so exclusively a matter of extrapolation into the near future of current weather and weather trend, on the basis of synoptic experience, empirical rules, and statistical probabilities, that most thinking about weather forecasting is patterned in the same mold. Great amounts of money and effort have been expended in increasing the number and content of synoptic observations, in experimenting with new forms of synoptic representation, and in statistical or synoptic analysis of the data. But most of this effort has been expended without any planned attack on the basic problems of meteorology in the vain hope of finding short-cut empirical or synoptic forecast rules or statistical relationships which might radically improve weather forecasting. Forecasting progress has not been realized in proportion to this misdirected effort, and possibly it has even been hampered to some extent by a surplus of information which is poorly planned and inefficiently utilized.

The Scope and Essential Nature of the Forecast Problem. The ultimate practical goal of most meteorological research is to improve present knowledge and understanding of atmospheric processes to the point where accurate scientific weather forecasting becomes possible. The all-inclusive scope of the problem is evident from its essential character, comprising as it does primarily three questions, each of which must be answered in turn. They may be stated, in their simplest terms, as follows:

1. What is the weather? This question requires a knowledge of the distribution of the meteorological elements which constitute the weather and whose changes reflect the weather processes. Such knowledge is required both as the starting point or base from which to forecast the future weather, and as a means of verifying or evaluating past weather forecasts and forecasting techniques. All research bearing on the measurement and recording of the weather elements throughout the atmosphere is directed toward answering this question. It is in this technical field that meteorological research has been advanced out of all proportion to the utilization of the data which are obtained.

2. Why is the weather? This question requires the quantitative physical explanation, in scientific terms, of all weather phenomena and their causative or formative processes. This is the basic part of the forecast problem which weather-forecasting research has tended to neglect in the past, in comparison to the money and effort which have been expended upon the unsystematic accumulation and the routine synoptic or statistical analysis of observational data. It is, however, primarily on progress in seeking an answer to this question that the future improvement of weather forecasting depends.

3. What will the weather be? The right answer to this question constitutes correct weather forecasting. A satisfactory answer requires a comprehensive understanding both of what the weather is and why the weather is. It has been the attempt to bypass the second question, in the hope of finding short-cut empirical synoptic or statistical means of determining the future weather directly from the present weather, without understanding either, that has militated against progress in solving the basic forecast problem.

THE PRESENT PRACTICE AND PERFORMANCE OF FORECASTING TECHNIQUES

Types of Weather Forecasts—Time Range, Content, and Performance. Since most weather-forecasting practice consists essentially of the rather crude extrapolation of current weather patterns and tendencies into the future, it is axiomatic that the accuracy and justifiable detail of the forecasts decrease rapidly with increasing range. Consequently weather forecasts are prepared in a great variety of form and detail, depending upon the degree of detail and accuracy which is required by the specific purpose of the forecast. The forecasting techniques which are used vary greatly with the type (time range and detail) of the forecast. Therefore to discuss the practice and performance of forecasting techniques, it is really necessary to consider briefly the requirements and expected accuracy of the different types of forecasts. It must be emphasized, however, that the complete lack of any uniform objective verification of weather forecasts precludes the possibility of any reliable evaluation or comparison of the performance of the different forecast types and the respective forecasting techniques. All estimates of forecasting skill in the following discussion are expressed on a basis of 50 per cent verification by chance as representing pure guess work or zero skill. For the most part the figures represent rough comparative estimates of forecasting skill and are not based on actual extended series of numerical verification of forecasts.

Weather forecasts are most conveniently classified according to time range and basic character of the forecast in the following four categories:

1. Short-range forecasts, for periods up to eighteen hours from the issue of the forecast. Forecasts of this type have been developed almost entirely during the past twenty-five years, primarily in response to the demands of aviation, both civil and military, although short-range forecasts of local conditions of frost, snow accumulation, and icing of roads have also received increasing attention. Short-range airways forecasts require a high degree of accuracy, both in timing and in local detail of all elements affecting flight operations, particularly of terminal conditions. These elements include wind direction and speed up to an elevation of from ten to fifteen thousand feet, the state of turbulence of the atmosphere, ceiling heights, horizontal visibility, and the occurrence of condensation forms (notably when the danger of icing, fog, or thunderstorms is present). Because this is a relatively new type of forecasting, frequently of elements which previously were not forecast at all, because the usual extrapolation techniques are particularly suited to short-range forecasting, and because great effort has been expended in meeting the

sudden demand for accurate forecasts of this type, this is the one field of forecasting in which great improvement in forecasting skill has been demonstrated in the past twenty years. Although no verification figures for this type of forecasting are available, it is probable that the best forecasting organizations in this field perform in the 90–95 per cent range on a 50 per cent probability basis of verification. This performance does not represent any basic advance in weather forecasting, but merely the happy results of a sudden concentration of effort on the application of extrapolation techniques to very short-range developments.

2. Forecasts of the ordinary daily range, for periods of from twelve to forty-eight hours in advance. Forecasts of this type usually express in some detail, for specific geographical areas, the expected day-to-day sequence of all the aspects of weather which materially affect human activity and well-being. The forecasts are disseminated by press, radio, wire, and special warning systems to the public and to many special interests, both civil and military, including aviation, agriculture, shipping, manufacturing, merchandising, and utilities. It is this type of forecasting on which the greatest effort has been concentrated since synoptic forecast methods were first introduced nearly a century ago and in which, paradoxically, basic progress has been almost nonexistent in recent years. Forecasting activity has been vastly expanded, but the quality of the forecasts has not been basically improved. The accuracy and skill of this type of forecast as practiced by the best forecasters must diminish with increasing time range during the 12- to 48-hr period. The skill verification may be estimated to decrease through the range 90–70 per cent during the period.

3. Extended daily forecasts, for periods including from the second to the sixth or seventh day in advance. Forecasts of this type at the present time tend to assume a dual character, a combination of the ordinary daily forecasts on the one hand, and of the long-range forecasts on the other. In the first role they strive to extend to five or seven days in advance the same detailed forecast of the day-to-day sequence of weather that is offered by the ordinary daily forecasts up to two days in advance, while in the second role they specify the mean or average character of the 5- or 7-day period ahead in terms of the expected anomalies of temperature, precipitation, and possibly other elements, such as sunshine. In the first role these forecasts are expected to serve the day-to-day planning of the entire life of the community in the same manner as, only more in advance than, the daily forecasts, while in the second role they are useful primarily to agriculture, irrigation, flood control and power interests, and to the fuel industry. Forecasts of the extended daily variety have been issued for many years, but the principal recent advances in extended weather forecasting have come in the development of statistical-synoptic techniques for the forecasting of large-scale weather patterns and mean weather conditions. The forecasting of the day-to-day weather sequence shows negligible skill beyond the fourth day in advance, probably decreasing slightly in the 55–50 per cent range. It can be stated categorically that no claim to significant skill in forecasting the day-to-day sequence of weather more than five days in advance has been acceptably demonstrated, nor is it likely to be in the near future. The mean anomaly features of the more reliable extended weather forecasts today verify in the 70–75 per cent range for temperature, but little better than 60 per cent for precipitation. Precipitation, relative to temperature, becomes increasingly difficult to forecast as the time range is extended.

4. Long-range forecasts, for all periods extending beyond one week in advance. Forecasts of this type can deal justifiably only with mean conditions or period anomalies, usually of pressure, temperature, or precipitation. There is no legitimate basis whatsoever for extending forecasts of the day-to-day weather sequence more than one week in advance, frequent unverified claims to the contrary notwithstanding. Forecasts of the longer-period anomalies of temperature and precipitation, whether for weeks, months, seasons, or whole years, can be of very considerable value, insofar as they have real merit, for a wide range of interests, notably for planning effective agricultural production or merchandising campaigns, for the effective utilization of irrigation, hydroelectric and flood control facilities, and for long-range military planning. Unfortunately, however, no forecasts of this type have demonstrated any clearly significant degree of skill in verification. Probably under most favorable conditions the verification lies in the 55–60 per cent range.

Forecasting Techniques or Aids—Their Merits and Limitations. The following definition and evaluation of weather-forecasting techniques as they are practiced today can be only approximate at best, because of the multiplicity of techniques which are in use, the infinite variety of combinations in which they are applied by different forecasters for different and even for the same type of forecast, and the lack of any real effort towards the objective evaluation of these numerous forecasting aids. In the following discussion an effort is made to classify the individual forecasting techniques or aids, insofar as they are distinctive, as to their essential character; to indicate something as to their usual application in the four principal types of forecasts (time range); and to comment qualitatively on their merits and limitations.

Since the following classification of forecasting techniques is based on the essential character of the technique, rather than on the forecast type (time range) to which it is applied, and since the practice of any type of forecasting frequently involves the combination of a variety of techniques, the grouping by this classification is suited primarily to an evaluation of the techniques individually rather than in combination. It is quite impossible in a general discussion of this kind even to enumerate the many combinations in which these forecasting techniques are applied, much less to evaluate these combinations. But in general the skill verification that is obtained by combining forecasting techniques is of the same general order as that of the

best single technique. If the techniques are essentially different, then when their prognostic indications are inconsistent, the forecaster's judgment must enter into any selection between them. That judgment is likely to be prejudiced in favor of the one or two techniques which are believed best on the basis of past performance.

In the following classification of forecasting techniques all of those classified as *extrapolation* in type employ exclusively the current and past weather patterns, including usually trend and in a few cases acceleration patterns (first- and second-order time derivatives of the weather elements). Since most of these extrapolation techniques are employed for forecasts of more than one type (time range) they are classified by their essential nature, rather than by the type of forecast for which they are used, as *statistical* (dealing with the time sequences of weather in limited areas), *synoptic* (dealing with geographical weather patterns), or *mathematical* (dealing with the fundamental equations of motion, continuity, and state).

In contrast to the extrapolation techniques of forecasting, those techniques classified as *physical* are concerned primarily with conditions which are expected to impose modifying influences on the future development of the current weather pattern, influences which are not in evidence in the past development, hence cannot be considered in any procedure involving extrapolation only. These physical processes are further subdivided between those whose effects are specifically related only to the current weather pattern, hence are of significance only to the short-range or daily type of forecast, and those which are more permanent in their influence, affecting any weather pattern for some time to come, and which are therefore of primary significance for the extended or long-range type of forecast.

1. *Extrapolation Techniques*—based on the existing state and trend of the weather, exclusive of modifying physical factors.

a. Statistical techniques of extrapolation—based on the time sequence of change and association of the weather elements individually in restricted localities. The purely statistical, as opposed to synoptic, forecast aids are usually applied to the long-range forecasting of the mean weekly, monthly, seasonal, or even annual anomalies of pressure, temperature, or precipitation.

Statistical methods are occasionally applied to daily forecasts, usually to supplement the empirical climatological information of a forecaster faced with the problem of forecasting for a region with which he has had relatively little experience. For this purpose statistics can be prepared, on the basis of past records, to indicate the probability of any meteorological occurrence, or combination of occurrences, to assist the forecaster in choosing between alternative possibilities, or to decide the degree of severity which an anticipated condition is likely to attain. However, by virtue of long experience in forecasting for a given region the forecaster usually develops a strong sense of the probability of any weather occurrence in his district, and his judgment of the potentialities of a given synoptic situation is likely to stand him in far better stead in estimating its probable development than are the statistical probabilities. Consequently, purely statistical methods can make at best only a very dubious contribution to forecasting of the short-range or daily type, particularly in middle and higher latitudes where the weather is so erratically variable from day to day. Although climatology and the statistical probability of both time and space sequences of weather change may well be developed further for the guidance of the forecaster, it can be assumed with reasonable certainty that no amount of effort expended in this direction will lead to any radical improvement of the shorter-range types of forecast.

For the extended and long-range types of weather forecasting the statistical extrapolation techniques assume greater relative importance with increasing range, as their applicability and performance are relatively independent of the time interval to which they are applied, whereas the usual short-range synoptic extrapolation techniques rapidly become ineffective as the time range is extended. The statistical extrapolation techniques which are applied to the longer-range forecasting of mean pressure, temperature, and precipitation anomalies at selected points are quite simple in principle, being based essentially on persistence and trend, linear lag-correlation (regression), and periodic analysis. It is quite obvious that none of those statistical extrapolation techniques can be expected to forecast the exceptional or unusual weather occurrences that are of greatest practical importance, because they are all keyed to the most probable occurrence.

Pure statistical extrapolation techniques are identical, whether the length of the unit period involved is the day, the week, the month, the season, or the year. Linear regression equations, based on linear correlation, may be computed from past records to give the most probable numerical anomaly of any meteorological element for any selected station or district, on the basis of the values of the preceding one, two, or any arbitrarily selected number of periods. The simplest example of this technique is to compute the probability of simple persistence or reversal of the sign of an anomaly from one calendar month to the next. Usually such lag correlations are low, but occasionally in restricted areas and for certain seasons the correlation is high enough to have real forecasting significance. This method of statistical extrapolation is assisted by the fact that in many regions there exists high contemporary seasonal correlation between pressure, temperature, and rainfall, so that the forecast anomalies of these elements must be mutually interdependent in a meteorologically consistent manner.

An elaboration of the lag-correlation technique of statistical extrapolation is furnished by the use of lag correlation between current or past weather anomalies in one region, or in one branch of the general circulation, and subsequent anomalies in another region or another branch. This technique, which is capable of almost unlimited experimental application, has been used by many investigators, but it is only occasionally that

really significant correlations are found. It has been used widely by Baur [1] in Europe, by Wadsworth [16] to check contemporary and lag relationships between the positions and intensities of a number of the semi-permanent "centers of action" of the monthly mean Northern Hemisphere pressure maps, and most notably by Walker[1] in his classical study of weather relationships over the globe and in particular of the forecasting of the seasonal monsoon rainfall in India.

It is doubtful whether the highest degree of skill attained at the present time by forecasts based on the use of statistical extrapolation by correlation (as illustrated perhaps by some of Walker's seasonal forecasting by multiple regression equations derived from the Southern Oscillation) exceeds 60 per cent. This figure probably represents the best that is attainable by purely statistical extrapolation techniques in the absence of any physical understanding of the underlying cause and effect relationships.

Experience shows that without some real physical basis, the prognostic regression equations derived by random correlation almost invariably deteriorate significantly in their performance when applied to the forecasting of data other than that from which they were derived. This deterioration is doubtless caused in part by the fact that the few significant correlation coefficients which are used in the regression equations are usually selected from a relatively large number of predominantly insignificant coefficients computed on a random "trial and error" basis. Hence the selected coefficients do not possess the normal probability of significance. The deterioration is also partly caused by the fact, which is observed both statistically and synoptically, that not only the general circulation pattern itself, but also its pattern of variation, is subject to considerable change over a long period of years.

It is undoubtedly true that the area in which this technique of forecasting by statistical extrapolation may be applied can be extended by further statistical research, but it is doubtful if the present top level of performance will be exceeded appreciably. In other words, there is at present no reason to hope for any basic improvement of long-range weather forecasts by the routine statistical extrapolation technique under discussion.

A second technique of long-range forecasting by statistical extrapolation is based on the statistical analysis of long-term homogeneous records of pressure, and less frequently of temperature or precipitation, at selected stations, in the effort to establish some type of periodicity or repetition in the variation that can be used for extrapolation. A large amount of harmonic analysis or other techniques of smoothing of such records has been done in order to resolve the variation into simple component periods. A great variety of such periods, ranging in length from a few days to at least forty-six years, have been rather dubiously established. In particular the longer periods have been tentatively established as fractional or integral multiples of the sunspot period, notably by Abbot and Clayton. Another purported feature of the long-period pressure records at certain stations, first pointed out by Weickmann, is the occurrence at irregular intervals of so-called *symmetry points*, on either side of which the time graph of pressure varies in reverse sequence.

There is considerable doubt as to the physical reality or statistical significance of most of these periodic or symmetry characteristics which are supposedly established in time series of meteorological data. It has been shown that in some cases smoothing techniques impose on the data periodicities which do not exist in reality. Forecasts based on the periodicity and symmetry techniques of statistical extrapolation have proved significantly even less successful than those based on the correlation techniques discussed above. There is no evidence to indicate that a skill verification of even as much as 55 per cent has been attained by the periodicity techniques. Baur [2] has made an extensive statistical study of the periodicity and symmetry techniques of extrapolating pressure and other weather data for extended forecasting purposes. He came to the conclusion that these techniques do not merit the expenditure of additional effort. He produces statistical evidence that the great variety of periodicity and symmetry patterns which are derived statistically from time series of weather data probably are merely an incidental result of serial correlation in the data, and as such are presumably of no greater prognostic significance than the persistence itself. Certainly it can be concluded that no important improvement of weather forecasting is to be expected from further development of this technique of statistical extrapolation.

b. Synoptic techniques of extrapolation—based essentially on the extrapolation of synoptic weather patterns. The great bulk of weather-forecasting practice, both past and present, is of the daily, and more recently also of the short-range type. This common forecasting practice is usually based on a combination of techniques, rarely on one exclusively. During the earlier years the forecasting procedures were almost exclusively those of synoptic extrapolation. Since World War I the physical techniques discussed below (p. 739) have come into extensive use, and in recent years the techniques of mathematical extrapolation, discussed under *c* below, have also been utilized to a very limited extent to supplement other methods. But by and large it remains true today that common forecast practice is based primarily on methods of synoptic extrapolation, secondarily on physical considerations, and only slightly on purely statistical or mathematical extrapolation. It is this combination of synoptic-extrapolation techniques supplemented by certain physical considerations which currently effect a top skill verification of 90–95 per cent on short-range forecasting, for which extrapolation techniques are ideally suited, and of 70–90 per cent on the daily type of forecasting up to forty-eight hours in advance.

Except for the occasional use of statistical probabilities to compensate a forecaster's lack of practical experience, as mentioned previously, the entire short-

1. See *Mon. Wea. Rev. Wash.*, Supp. No. 39, pp. 1–26, 1940.

range and daily forecasting routine as commonly practiced today depends upon the effective synoptic presentation of current and past weather patterns, which serve as a basis of either synoptic or mathematical extrapolation, and of any physical forecasting techniques. These synoptic weather patterns usually present the two-dimensional distribution of the weather elements in selected planes. The primary patterns are those of the geographical distribution of the weather elements in horizontal or quasi-horizontal planes. A great variety of such weather charts may be plotted, starting usually with the sea-level or surface map. The upper-level charts may be plotted for selected heights, for selected isobaric surfaces, for selected isentropic surfaces, or for the thickness between selected isobaric or isentropic surfaces. Several upper-level charts are usually prepared, the highest one frequently being located near the top of the troposphere or the base of the stratosphere.

The synoptic charts for the selected levels are frequently supplemented by vertical cross sections through the atmosphere, which follow a line of upper-level observation stations, or at times by the use of individual point soundings through the troposphere. The essential purpose of the entire assemblage of synoptic charts, which, particularly at upper levels, may vary greatly as to number, form, elevation, weather data plotted, and geographical extent of the area covered, is to present as completely and effectively as practicable, in the area which is deemed necessary, the distribution of the weather elements in the form of two-dimensional patterns. It is the regular time sequence of a complete set of such synoptic charts, particularly the sequence of pressure and pressure-change patterns, to which are applied the various techniques of synoptic and mathematical extrapolation, and physical reasoning, by means of which the future, or prognostic, weather pattern is derived.

It is possible to enumerate here only the more frequently applied synoptic techniques of extrapolation, and to comment briefly on their potential effectiveness. This type of forecasting has been practiced on surface weather maps since the beginning of synoptic weather forecasting nearly a century ago, while its application to upper-level charts is a development almost exclusively of the past quarter-century, except that upper-level wind observations have been used to some extent to supplement surface reports since the early 1900's.

The simplest extrapolation procedure consists of the linear extrapolation, or continued displacement at the same speed as that in the preceding period or periods, of the various features of the sea-level weather map, such as isobaric or isallobaric centers, isobaric trough or ridge lines, or frontal discontinuities with the attendant frontal phenomena and air-mass weather characteristics. The linear extrapolation technique is applied also to change or acceleration tendencies such as the deepening or filling of pressure centers and troughs or ridges, changes in the direction or speed of movement of pressure patterns, fronts and air masses, and frontogenesis or frontolysis. The approximate effect on the pressure field of even the second-order time derivatives of the pressure may be anticipated by the deepening or filling of isallobaric centers, and by the proper use of 3-hr pressure tendencies corrected for the normal diurnal trend of pressure.

Since the upper-level pressure patterns are uniquely related to the sea-level pattern and the temperature distribution, and since the upper-level charts present the large-scale dynamic state of the atmosphere more clearly than does the surface chart, there has been a strong tendency in recent years, with the increase of aerological data, to treat the 700- or 500-mb charts as the primary forecasting tools and the surface charts as secondary. The same type of extrapolation procedure as outlined above for the sea-level map can be applied effectively to the simpler upper-level pressure patterns to obtain prognostic upper-level charts, which then serve as a basis for the prognostic sea-level chart. Particularly useful for this type of upper-level synoptic extrapolation, although not as widely used in practice as they deserve to be, are certain kinematical principles formulated by Rossby [10] relating the deepening and filling, and the movement of upper-level troughs and ridges of the isobaric pattern, to the phase relation of the corresponding isothermal pattern. In addition to these synoptic techniques some of the more recent mathematical extrapolation techniques discussed below are properly applicable only to the upper-level flow patterns.

Vertical cross sections through the atmosphere, notably meridional cross sections, also present synoptic information that should be most useful to physical diagnosis and prognosis of the weather, but up to the present time their incorporation into daily forecast practice has been limited primarily to the current and prognostic description of flight weather conditions along selected air routes.

The synoptic extrapolation technique of forecasting has been placed on a relatively routine basis by the method of kinematical extrapolation which was developed by Petterssen [7]. This method consists essentially of a quantitative determination of the instantaneous speed of displacement, in any selected direction, and the tendency toward deepening or filling, of characteristic features of the current horizontal pressure field which are being effected by the current pressure-tendency field. The calculated trend of movement, or of deepening, is assumed to continue unchanged. The method can be applied equally well to sea-level or to upper-level pressure patterns. In their complete form Petterssen's formulas do include acceleration terms which quantitatively evaluate the effect of the current change of trend of development. Unfortunately, however, these complete formulas are both time consuming and difficult to apply because the synoptic data inevitably are inadequate for their objective evaluation; hence so much is left to the judgment of the individual forecaster that the method loses its principal advantage —that of being objectively and routinely applicable by the inexperienced forecaster. Consequently, Petterssen's forecast method as it is usually applied is a quantitative method of routine extrapolation, which

is based on the expectation of a continued uniform trend of development of the synoptic weather pattern. In this character it is particularly susceptible to the basic weakness of all of the extrapolation techniques of forecasting—gross inaccuracy if extended beyond a very limited time range under rapidly or erratically changing conditions.

All of these synoptic extrapolation techniques, which in the past have constituted almost the sole basis of short-range and daily forecasting practice, and which even today are supplanted only occasionally and to a minor degree by techniques of mathematical extrapolation or physical reasoning, are limited by a ceiling of potential performance, which probably is reflected very closely by the best current forecasting. This ceiling is imposed by the failure, and presumable inability of this synoptic extrapolation procedure, even when supplemented by the best synoptic experience, to anticipate systematically or evaluate reliably the indecisively erratic or exceptionally abnormal changes of the synoptic weather patterns. The question may legitimately be raised, To what extent and over what periods of time is the succeeding weather pattern determined by the preceding pattern? or To what extent may factors quite external to the lower atmosphere play a determining role? But it appears certain that if either synoptic or mathematical extrapolation techniques are to lead to any basically substantial improvement of weather forecasting, it will be only on the basis of a much better physical understanding of the mechanics of the atmospheric circulation processes than is represented by the present-day models.

In recent years there has rapidly developed an extensive application of synoptic extrapolation techniques to extended and long-range forecasting, for periods of five or ten days, a month, or even a season in advance. Instead of applying the extrapolation techniques to the weather patterns on a sequence of daily synoptic charts, making use of 24- or 12-hr changes and the 3-hr tendencies, five-day, weekly, or monthly mean charts present the weather patterns which are extrapolated by means of weekly or half-weekly and monthly or half-monthly changes, and 24-hr tendencies. The techniques of extrapolation are not essentially different; basically only the time scale is changed. The maps which are used must be geographically extensive, covering at least half (meridionally) and preferably the whole of the Northern Hemisphere, thus making possible the analysis and characterization by circulation indices, such as the zonal westerly index, of the state of the general circulation as an integrated whole [14]. The synoptic extrapolation techniques are more effectively supplemented by statistical aids in this extended type of forecasting than in the daily forecasting, notably by lag-correlation statistics and by the comparison of prevailing with normal tracks of cyclones and anticyclones.

This type of extended synoptic extrapolation (by use of mean charts), supplemented by statistical and in some cases by physical considerations, forms the basis of the five-day and the experimental monthly forecasts disseminated by the Extended Forecast Section of the U. S. Weather Bureau [6], of the 5- and 10-day and longer-range forecasts of Baur [1] in Germany, of the composite-chart technique of the Multanovski-Pagava school in Russia, and of many others.

The statistical and synoptic extrapolation techniques as applied to extended and long-range forecasting are definitely limited in their potentialities. These techniques perform best for short-range forecasting, showing decreasing skill with increasing range. However, their performance in extended and long-range forecasting of mean weather conditions over extended periods goes far beyond anything that is attainable by the extrapolation of daily weather patterns. Probably 75 per cent for temperature and 65 per cent for rainfall represent approximately the top skill performance which can be hoped for as an average in the forecasting of mean conditions by these methods for one week in advance on the basis of our present limited understanding of the general circulation. Doubtless the skill margin of these potential ceiling performances should be cut in half for monthly forecasts, and possibly to one-third for seasonal forecasts.

Frequently the extended forecasts of the mean weather patterns are used as a guide by which, and framework within which, to extend the prognosis of the day-to-day sequence of weather patterns beyond the two- or three-day limit which is justifiable by the daily forecasting techniques. There is certainly some justification for making such an extension, possibly to five or six days beyond the current date, but beyond that, even though mean conditions can be forecast with some degree of skill, no detectable skill in forecasting the day-to-day sequence of change has been demonstrated, nor does it seem likely to be in the absence of some radical advance in the science of weather forecasting. This advance can come only from an increased physical understanding of the mechanics of the general circulation, not from additional statistical or synoptic manipulation.

The use of analogues represents a routine method of forecasting by synoptic extrapolation which has been rather extensively employed and which can be, but is not necessarily, applied quite independently of other techniques. This method consists essentially of classifying the large-scale synoptic weather patterns by their significant features in some manner such that past maps or conditions which are essentially similar to the current pattern may be extracted readily from files. The weather sequences which followed in the past under similar conditions, at the same season of the year, are then used as a guide to the prognostication of the current sequence. This extrapolation can be made by applying the statistical analysis of a number of similar synoptic patterns in the past (Baur's method), or by selecting from past patterns the single closest fit to the current pattern, and following in detail the weather sequence which resulted in that case (Krick's method). Usually analogue classification and selection is based primarily on sea-level maps, but upper-level charts may be given any desired weight. The method has been extensively

applied to daily forecasting, and to extended or long-range forecasting based on mean maps.

Analogue forecasting has not proved to be notably successful. It is better suited to daily than to extended forecasting, but even in the daily range the extensive effort in the United States to supply analogue information to all forecasters during the war years does not appear to have won many supporters for their use. For the more extended forecast ranges the method suffers the inevitable disadvantage of any routine technique of synoptic extrapolation—that of complete inelasticity in meeting rapidly and erratically fluctuating conditions. Essentially the method fails at two points:

(1) Our knowledge of the mechanics of the general circulation is completely inadequate to the task of establishing any analogue classification of the large-scale circulation patterns which is of basic prognostic significance. In the absence of such knowledge the establishment of sufficient analogy between two synoptic weather patterns to justify the use of the subsequent weather sequence in one case to forecast that of the second case in detail requires a basic similarity not only of the large-scale sea-level synoptic patterns, but also of the upper-level patterns and of the preceding sequence of development by which the analogous patterns come into existence. Needless to say such strict specifications can only rarely be satisfied in the selection of an analogue.

(2) In the absence of a prognostically determinative analogue classification, the selection of an analogue is of little or no assistance to the experienced forecaster. As with the use of statistical aids in short-range forecasting, the experienced forecaster will usually do better by judging the synoptic indications of each individual case in the light of his past experience. In extended or long-range forecasting, the case for analogues is even weaker. In other words, the use of analogues has even less to offer towards any real improvement of weather forecasting in the present state of our physical knowledge of the problem than do the other techniques of synoptic extrapolation.

c. Mathematical techniques of extrapolation—based on various manipulations of the equations of motion and continuity. Accurate weather forecasting by mathematical computation is an ultimate objective for the attainment of which nearly every meteorologist hopes, but as a practical reality it appears today to be quite as distant as when Richardson [8] made his classical contribution to the problem in 1922. Richardson failed completely to derive, from the theoretical equations, satisfactory forecasts even of the short-range (6-hr) changes of the meteorological elements. This failure was doubtless caused in part by his efforts to deal with all of the variables at once, which complicated his calculations to a point where he was unable to identify the sources of his errors, but also by the further fact, since proved by Charney [4], that his unit time interval (6 hr) was far too large, relative to his space grid, to permit a reasonable (convergent) solution of the equations.

Interest in the numerical prediction of weather has been greatly stimulated by the recent development of high-speed computing devices, which places the feasibility of lengthy numerical reckoning on an entirely new basis. In spite of initial optimism, however, as to the potentialities of these computing techniques, it is generally recognized at present by those who have been working on these methods that no radical advance in practical weather forecasting in the near future is probable. One difficulty lies in the great mass of observational data that must be treated in order to provide in time and space a sufficiently extensive and dense network of observations to compute the future state of the atmosphere a day or more in advance. However, that is a technical problem that doubtless can be overcome. A second difficulty lies in the magnitude of random local variations of the weather elements, variations which are large compared with the permissible tolerance of observational errors. Possibly this difficulty also can largely be overcome by smoothing techniques. But the principal difficulty lies in the fact that computing devices are not brains. They must be told what do to. At present our understanding of the mechanics of the general circulation is quite unequal to this task; there exists no practical conception of how the large-scale circulation processes work, to serve as a physical or theoretical basis of computation. Furthermore, as pointed out above, it is not even known to what extent the future state of motion of the atmosphere is determined by the preceding state, or to what extent internal or external energy sources need be taken into consideration. Hence the mathematical extrapolation techniques run up against the same obstacle as do the less rigorous extrapolation techniques—need of a better understanding of the mechanics of the general circulation. At present, high-speed computing machines may be very useful to test the applicability of physical or theoretical models to the large-scale atmospheric processes in nature, but certainly they do not in themselves offer any particular hope of solving the basic problem of weather forecasting, which is to acquire a better understanding of the irregularly fluctuating circulation patterns. Their practical usefulness will probably increase as this knowledge is gained.

A number of computational extrapolation techniques have been applied to practical weather forecasting, techniques which are based on various manipulations of the equations of motion and the equation of continuity in which certain simplifying assumptions are made in their practical application to the atmosphere. The most promising of these forecast aids are those based essentially on the tendency equation of Bjerknes [3], and on Rossby's use of the vorticity principle [9] to compute upper-level wave motions and air-particle trajectories.

Numerous efforts, involving the tendency equation, have been made to compute the fields of horizontal convergence and vertical motion in the middle troposphere from the observed wind field and to compare the thermal advective effects on the observed temperature field with the dynamic effects. Synoptic patterns computed in this manner are correlated with observed pressure changes, that is, cyclogenesis and anticyclogenesis,

and with the hydrometeors, in an attempt to find a numerical basis of extrapolation for forecasting of the short-range or daily types. The success of all such attempts has been notably indifferent, to the extent that none of them has found general quantitative application in practical daily forecasting. This lack of practical application is caused partly by the large amount of work involved and partly by the lack of encouraging results thus far obtained. This failure to obtain good results doubtless stems from the same difficulties which cause the failure of the more elaborate computational techniques: notably insufficient quantity and accuracy of synoptic observations, difficulty in smoothing out local disturbances, and insufficient physical understanding of the atmospheric processes. For these same reasons, equally little can be hoped from these efforts at present towards the solution of the forecast problem.

Rossby's vorticity technique has been applied to both the daily and the extended forecasting of flow patterns in the middle troposphere with enough demonstrable success so that it has received some routine application, notably by the Extended Forecasting Section of the U. S. Weather Bureau [6]. It has proved useful as an auxiliary forecasting tool under certain conditions, but the limitations which are imposed upon it, in part by the restriction of its use to clearly defined wave-patterns aloft, and probably more fundamentally by the necessary assumption of horizontal (nondivergent) air flow, are in themselves sufficient guarantee that this method cannot contribute significantly to the solution of the basic forecast problem.

2. *Physical Techniques of Forecasting the Weather*—based on a consideration of the physical factors which may actively modify the existing state and trend of the weather as it progresses. It was mentioned above under the discussion of synoptic extrapolation techniques that the usual short-range and daily forecasting procedure entails the use of a few physical considerations at least as a supplement to the purely synoptic extrapolation. In the same manner, certain physical factors frequently form the basis of some of the statistical extrapolation techniques in extended or long-range forecasting.

In short-range and daily forecasting the most effective use of physical considerations to supplement or modify the synoptic extrapolation techniques has developed from the Norwegian polar front theory, or as more commonly designated now, from air-mass and frontal analysis. The study of the physical properties of air masses, in particular the vertical distribution of moisture and the vertical stability, together with the physical factors which modify them, has proved most useful for the type of detailed local forecasting which is so important to aviation. The use of energy diagrams such as the adiabatic diagram, the tephigram, or the aerogram to indicate the physical probability of local convection, and the consideration of topographic influences, such as upslope or downslope motion, surface heating or cooling from land and water surfaces to change the air-mass properties, and the turbulence and mixing characteristics produced by wind and rough terrain—all of these are physically modifying influences which are normally considered in routine short-range forecast practice.

Likewise the physical concepts of frontogenesis and the accumulation of available potential energy supplied by air-mass convergence, of cyclogenesis by the development and occlusion of wave disturbances with all of the attendant weather cycle and sequences of hydrometeors, of the modification of frontal structure and condensation forms by orographic barriers and coast lines, all of these are physically modifying influences, the consideration of which has added much to short-range and daily forecasting.

However, the prognostic potentialities of air-mass and frontal analysis and related physical techniques of forecasting appear to have been largely realized. Probably some further refinement of forecasting detail may be effected along these lines, but no radical advance can be hoped for from this quarter. In fact, it can be asserted that the contribution of frontal and air-mass analysis to scientific weather forecasting has fallen far short of that which was hoped for in the early days of the development of this new school. The reason for the failure of frontal and air-mass concepts to solve more weather problems probably lies to a considerable extent in the following observational or hypothetical facts:

a. The utter complexity of atmospheric conditions which are not even approximately represented by such concepts as homogeneous air masses and frontal discontinuities.

b. The fact that cyclogenesis as a process probably rarely if ever closely approximates the ideal Bjerknes wave-cyclone model.

c. The fact that the primary impulse or drive of large-scale cyclogenesis and anticyclogenesis frequently originates far outside of the developing center, hence cannot be identified or anticipated by local conditions.

The physical factors which have been assumed to exert either modifying or controlling influence over the extended or long-period anomalous fluctuations of the large-scale weather patterns, and hence to require either secondary or primary consideration in extended or long-range forecasting, may be classified as follows:

a. Continental (orographic barriers, coast lines, and extensive snow cover).

b. Oceanographic (anomalous surface current flow, temperature, and polar ice conditions).

c. Extraterrestrial (sun, moon, and planets).

Of the continental factors mentioned, obviously the topographic features vary only during geological time, hence their influence is expressed in the seasonal normal patterns. It is only as the circulation pattern is markedly anomalous by reason of some primary disturbing factor that topographic influences find expression as secondary anomalous characteristics of the circulation pattern, notably in the windward and lee effects of a major orographic barrier on an abnormally strong cross-wind system. Likewise an extensively anomalous condition of continental snow cover doubtless contributes to a minor degree to the persistence or intensity of an anomalous weather pattern, but much statistical analysis has failed to establish any signifi-

cant correlation between snow cover and subsequent anomalous conditions of the large-scale weather patterns. Hence these continental factors are at best only of minor secondary importance in extended or long-range forecasting.

A great amount of statistical work has been performed by Helland-Hansen, Walker, C. E. P. Brooks, and many other investigators[2] in the effort to correlate anomalous conditions of sea-surface temperature and polar ice with contemporary, preceding, and subsequent anomalies of pressure (atmospheric circulation), air temperature, and rainfall. The upshot of most of this work can be summarized essentially as follows:

a. Anomalous conditions of sea-surface temperature and polar ice are explained in general by present and past anomalies of atmospheric wind and temperature.

b. Sea-surface temperature anomalies and cooling by melting ice are small in amplitude compared to air-temperature anomalies and show little tendency to persistence or displacement except as they are maintained by anomalies of the atmospheric circulation. They cannot conceivably, from any quantitative consideration, be the primary cause of contemporary or subsequent air-temperature anomalies.

c. Some significant correlation has been found between spring ice conditions in the Greenland Sea and Barents Sea regions and subsequent summer, autumn, and winter weather in northern and central Europe. Since the sea-surface anomalies are utterly inadequate to account for the subsequent weather anomalies, it appears that both must be related to some primary factor of weather control which is best expressed in the highly anomalous state of the general circulation by which extreme ice conditions are initially produced.

Certainly it is reasonable to conclude, granted the correctness of the above statements, that a further study of oceanographic influences is not a promising or direct line of attack on the basic problem of extended or long-range weather forecasting.

Solar control, either direct or indirect, of the normal seasonal features of the world weather patterns is axiomatic, but the question as to the extent to which the anomalous fluctuations of the general circulation are influenced or controlled by irregular solar activity is a highly controversial one. Literally scores of investigations, statistical, synoptic, and theoretical, have been directed toward one or another aspect of this problem. Relationships of world weather patterns to sunspots or solar constant have been investigated by Abbot, Baur, Clayton, B. and G. Duell, Hanzlík, Helland-Hansen, Köppen, Kullmer, Schell, Simpson, Tannehill, Walker, Willett, and many others. Direct solar effects on the higher atmosphere, notably on temperature, circulation, distribution of ozone, and ionization, have been observed or theorized about by equally many investigators, including among others Craig, Dellinger, Dobson, Götz, Haurwitz, Hulburt, Maris, Mimi, Shapley, Stetson, and Wulfe.

In spite of the great amount of effort which has been expended on this problem it remains unproved today whether solar activity plays a primary, secondary, or insignificant role in the irregular fluctuations of the atmospheric conditions of the troposphere (world weather patterns). There is no question whatsoever about the occurrence of numerous direct effects of sudden solar disturbances in the higher atmosphere, but any such effects in the lower troposphere, if they exist, are so indirect, masked, and complex that they have not been statistically confirmed. There is an imposing amount of statistical evidence for long-term fluctuations of the world weather patterns, particularly in the tropics, but also in the higher latitudes, that roughly parallel the single or double sunspot cycle. Since the parallelism is either not uniformly close or not consistent in phase over long periods of time, the evidence indicates that sunspots themselves are not a satisfactory index of the disturbing solar influences. It can be stated without qualification that up to the present no attempt to base extended or long-range weather forecasts directly on any solar index, usually sunspots or solar constant, has attained any significant success. Probably no primarily statistical attack on this problem can be expected to accomplish more at present.

Assuming that there is an ultimate control or direction of the major anomalous fluctuations of the general circulation by solar activity, then our failure to establish the reality or nature of this control is readily explained by our almost complete ignorance in the following three areas:

a. The physical nature and intensity of the disturbing solar influences which enter the outer atmosphere.

b. The qualitative and quantitative effects which these influences produce in the higher atmosphere.

c. The essential mechanics of the general circulation, including any possible mechanism of interaction between the troposphere and the higher atmosphere.

Probably the most representative opinion of meteorologists who have recently dealt with the broader aspects of the anomalous solar-weather relationships [1, 2, 17] can be expressed approximately as follows: Solar activity undoubtedly exerts some guiding influence, possibly even directing control, on the extended and long-range anomalous fluctuations of the general circulation. This influence or control is so indirect and so complex in the sum total of its manifestations that little progress is to be expected from any further primarily statistical attack on the problem. This problem calls for a major program of research in solar and atmospheric physics, a program which must be an integral part of any major attack on the basic problem of weather forecasting. Such a program must be directed at all three of the basic areas of ignorance noted above.

RECOMMENDATIONS FOR THE IMPROVEMENT OF WEATHER FORECASTING

Possible Immediate Technical Improvements. The general problem of the improvement of weather forecasting must be considered from two rather distinct angles. On the one hand there is the question of possible accomplishment in the immediate present or near future

2. See *Mon. Wea. Rev. Wash.*, Supp. No. 39, pp. 27–57, 1940.

within the framework of our present basic knowledge of atmospheric circulations and with our present forecasting techniques. On the other hand there is the question of the ultimate approach to true scientific weather forecasting by means of extended research in the basic problems of dynamic meteorology and the development of new objective forecasting techniques.

It is emphasized in the preceding discussion that important progress in the basic problem of weather forecasting is not to be achieved by mere extension, elaboration, or refinement of any of the present great variety of forecasting techniques. On the other hand, it is quite certain that some improvement of accuracy and uniformity of forecasting performance beyond that now attained can be achieved on the basis of our present basic knowledge and forecasting techniques. The possibility of the technical improvement of present forecasting procedures may be considered at three points:

1. *Weather Observations.* Our knowledge of present and past weather conditions, on which are based both the forecast of the future weather and the verification of past forecasts, depends almost entirely upon the analysis of synoptic weather observations. Obviously it is important that these observations be adequate for the uses to which they are to be applied. By and large it may be stated that observational techniques are far more advanced than forecasting techniques in meteorology, hence primary emphasis in meteorological research for forecasting purposes should definitely be shifted from the former to the latter. However, meteorological observations are far from being all that they should be. In this connection it can be stated that attention should be devoted primarily to the reliability and distribution of weather observations, rather than to increased accuracy, elaborateness, or density of observations in favored local areas. The greatest need, for the improvement of general or extended forecasting as well as for forecasting research, is for simple reliable observational techniques which can be applied uniformly to large areas of the earth's surface and to the upper atmosphere, to fill in the extensive global gaps which still exist in available synoptic information. This calls for instruments which are as foolproof and free of calibration difficulties as possible, and the further development of automatically recording and transmitting weather-station equipment for use in relatively inaccessible areas. Any possible simplification of raob and rawind techniques is highly desirable.

More elaborate or exact weather-measuring devices are not justified for general use because the small-scale random variability of weather conditions renders exact measurement of no significance. For example, useful as it would be to observe the field of vertical motion in the atmosphere, exact measurements of this quantity, even if they could be made, would be of little value because the local variations are very large relative to the prevailing motion.

It is only for short-range forecasting of local conditions for special purposes that it is possible to justify a dense network of special observations, such as the radar technique for the measurement of condensation forms. Insofar as it appears advisable, detailed study of local forecast problems and problems of atmospheric physics can be set up with full equipment in selected limited areas, but at the present time it is unlikely that such studies will contribute as much to the solution of the basic problem of general weather forecasting as will adequate observations to eliminate the great gaps in available synoptic information in many parts of the world. The primary inadequacy of our present forecasting knowledge lies in the field of the dynamics of the general circulation rather than in the field of atmospheric physics.

The proper implementation of an adequate world-wide network of synoptic weather observations is completely dependent upon the existence of a strong international meteorological organization which can specify uniformity in instrumentation, observational techniques, hours of observation, and the coding and transmission of synoptic data, even to the distribution of international funds to support such a program. There is no possibility of realizing the necessary world-wide network of synoptic weather observations except as it is internationally financed according to the ability of the different nations to support it.

2. *Standardization of Forecasting Techniques.* It is evident from the discussion of forecasting techniques (see p. 733) that there is practiced today a great variety of such techniques, many of which are overlapping, essentially redundant, or of very limited applicability, and for which little or nothing in the way of rigorous objective evaluation has been attempted. It was noted that the essential basis of almost all short-range or daily forecasting consists of the empirical extrapolation, in the form of two-dimensional prognostic charts, of the current two-dimensional synoptic weather patterns, influenced by certain physical factors such as topography and the modification of air-mass properties or of frontal structure, and occasionally aided by the use of some climatological statistics. The three-dimensional distribution of the weather elements, both current and prognostic, is expressed by the selection of suitable two-dimensional sections for analysis and prognosis. With increasing range of weather forecasts to the extended and long-range categories, the forecasting techniques are based increasingly on the extrapolation of mean synoptic rather than instantaneous synoptic patterns and on the use of statistical aids.

The greatest improvement of weather forecasting which can be expected within the framework of our present basic knowledge almost certainly is to be effected by the standardization and simplification of the multiplicity of techniques which are employed for the prognostic extrapolation of synoptic weather patterns, particularly in the short-range and daily forecast categories. This applies both to the techniques of extrapolation and to the preliminary presentation and analysis of the synoptic data. It is possible to present synoptic weather data in an infinite variety of forms, as regards the two-dimensional sections which are selected for analysis, the combinations of weather elements which

are selected for presentation, and the units or quantities in which the selected elements are plotted or combined. Most of the infinite possible variations of presentation and analysis of synoptic weather data appear to have been introduced into weather-forecasting practice at one point or another. The horizontal or quasi-horizontal distribution of the weather elements is on occasion represented in constant-level charts, isobaric, isentropic, or tropopause contour charts, isobaric or isentropic thickness charts, isopycnic contour charts, etc. Most of these charts, together with corresponding change charts, are prepared at more or less arbitrarily selected levels, contain varying combinations of the weather elements, and are subjected to variable analytical techniques. Similarly the vertical cross-section charts are plotted along selected meridians, selected latitude parallels, selected airways, or selected lines of raob stations; they are prepared alternately only for the lower flight-levels or through the tropopause, and they are analyzed for a great variety of combinations of the meteorological elements and quasi-horizontal surface intersections. Likewise the vertical structure of the atmosphere as obtained from raob soundings at selected points is represented by a great variety of energy diagrams, notably by the adiabatic diagram (Neuhoff or Stüve), the tephigram, the aerogram (emagram), the equivalent-potential temperature diagram (Rossby) and a number of other less frequently used permutations of the basic thermodynamic diagram.

What have been the consequences of this great profusion of synoptic-analytical tools? They have been essentially disadvantageous, for the following reasons:

a. There is extremely little gained, in proportion to the effort expended, by the preparation of a large number or great variety of presentations of the same synoptic data. It is true that specific requirements for different types of forecasts may best be met by some variation in the presentation of synoptic data, but this desirable variation is comparatively small and has little bearing on the great variety of synoptic tools which have been developed, and which are largely redundant, merely slicing the same information in different ways.

b. A great amount of time and effort, which might better be turned to more constructive use is consumed in the nonproductive manipulation of the elements, units, and coordinates used in the synoptic presentation and analysis of meteorological data. The same criticism of waste of time can be made of much of the effort to base weather forecasting on the statistically most probable or normal sequence of change or movement of the weather pattern.

c. The principal positive harm which this multiplicity of synoptic tools causes is that of confusing the forecaster. It is quite impossible to assimilate and integrate mentally a synoptic picture which is presented in too great complexity and on too many charts. Furthermore, synoptic and forecasting techniques vary so greatly from one forecast center to another that any forecaster is likely to be confused as soon as he leaves his own bailiwick or the system to which he has become accustomed Where forecasting is as empirical and as dependent as it remains today upon the forecaster's experience and his mental awareness of similarities and dissimilarities of synoptic patterns, this confusion and lack of precision and clarity in his mind with respect to comparative significant details of the synoptic patterns can be very demoralizing. This one factor, coupled with the relatively short forecasting experience of many forecasters today, probably accounts largely for the widespread failure of practical forecast performance in recent years even to begin to keep pace with the increase of available synoptic information.

The remedy for the present confusion of techniques for the presentation, analysis, and extrapolation (prognosis) of synoptic weather patterns obviously lies in elimination, simplification, and standardization. This is an immediate problem which should be faced on the basis of our present knowledge. The long-range problem of increasing our basic understanding of atmospheric circulations and of developing correspondingly scientific forecast techniques must be considered quite apart from the immediate problem of simplifying and standardizing present routine forecast practice.

The mere accomplishment of such simplification and standardization will doubtless be of far greater significance to the performance of short-range and daily weather forecasting than will the selection of one particular system of analysis and prognosis rather than another. However, any such program calls for a real effort to devise an objective system of verification by which forecasting skill can be rated and synoptic tools evaluated. The principal emphasis must be placed on simplification, to select from the great variety of synoptic charts and analytical techniques now in use a minimum number of charts and a technique of analysis which will present as clearly and comprehensively as possible the essential features of the changing synoptic pattern. This presentation must vary somewhat with the type of forecast desired and with the broad climatological zones, but such necessary variation should be kept to a minimum, and standardized at least to the extent that forecasters performing similar work in similar climatic zones can speak the same language to one another, which is far from being the case today. This standardization should not at all discourage practicing forecasters from doing forecasting research, particularly on local or regional problems, but it does mean that the performance and practical application of such research should always be supplementary to, and not a substitute for, the standard prognostic procedure, at least not until it has been officially tested and approved as part of that procedure.

Obviously, to be really effective, such a program of standardization of synoptic analysis and prognosis must be developed and applied on an international scale, by a strongly centralized international meteorological organization, and it should be coordinated, by this same organization, with the similar program for weather observations which is outlined above.

Probably less is to be gained in extended and long-range forecasting by standardization and simplification of the synoptic techniques of analysis and prognosis

than in the shorter-range categories, but a very real need also exists in those fields for the evaluation of synoptic techniques and the simplification of prognosis by the elimination of the less effective synoptic tools. It is highly probable, however, that relatively more is to be gained in these longer-range forecast categories by further statistical studies of the behavior and operation of the general circulation than in the shorter-range categories where statistics now contribute relatively little. On the other hand it is quite clear that statistics alone cannot contribute fundamentally to the basic solution of the problem of long-range weather forecasting. It is exactly in this field that basic research in the thermodynamics and mechanics of the general circulation, guided by synoptic observational statistics, is most necessary at the present time.

3. *The Selection and Training of Weather Forecasters.* It must be recognized that weather forecasting as practiced at present and probably for many years to come is essentially empirical and esoteric in nature. As a consequence of this fact, the practicing weather forecaster, whose primary occupation is the routine preparation of weather forecasts of the usual types, must draw extensively on a fund of highly esoteric knowledge which has been gained by long first-hand experience with weather forecasting of the type and in the region with which he must be concerned. Scientific theory plays little part in practical weather forecasting at the present time. Consequently, any forecast service which is concerned primarily with the regular issuance of ordinary types of weather forecasts of maximum accuracy will benefit notably by adhering rather strictly to certain principles with regard to the selection of professional forecasting personnel, in particular as follows:

a. The empirical and esoteric nature of most weather forecasting today places a high premium on the natural aptitude of the individual forecaster. This natural aptitude is invariably indicated by a strong liking for and sustained interest in weather forecasting for its own sake over a long period of time, and can be verified only by the routine objective verification of competing practice weather forecasters over a considerable period of time. It is a mistake to assume that merely because a man has passed a good professional course in meteorology creditably and has learned a certain amount of theory and practice he will be interested in forecasting or successful as a weather forecaster. In many cases he will not compare as a practical forecaster with a relatively untrained meteorologist who is absorbingly interested in practical weather forecasting. Under the pressure of wartime demand many meteorologists who were by aptitude and interest entirely unsuited for forecasting duty were pressed into it. Quite the contrary is true of the meteorologist whose primary concern is to do forecasting research. In that case the primary requisite is an extensive scientific background, including both theoretical training and an interest in and some first-hand experience with techniques of synoptic analysis and prognosis.

b. It is highly important that the forecaster's training and synoptic experience be such that he can assimilate a maximum amount of practical specific information of significance to the prognostic judgment of synoptic weather patterns. This can be accomplished only if he concentrates his attention on a minimum number of basically significant synoptic charts and prognostic techniques, rather than by dispersing his attention over an elaborate array of synoptic and prognostic tools. This is the problem of the simplification and standardization of forecasting techniques which was discussed above.

c. Weather forecasting is the exacting work of a specialist; it should be a full-time, long-term job. It may very well be combined with or alternated with related research in cases where the forecaster is properly qualified, and in any case ample opportunity must be given the forecaster for complete relaxation from the pressure of prolonged forecasting responsibility. In no case should responsible forecasting duty be combined with or alternated with any unrelated exacting job such as administrative or directive work, nor should an important forecasting assignment ever be made a temporary duty to which a man is assigned for a limited period, perhaps for two or three years, after which he is transferred to something entirely different. In this respect the military services are frequently particularly remiss.

d. The incentive to hold the good forecaster in his job should always be present. Specifically, in civilian (civil service) forecasting agencies the rating of forecasting positions should be at least as high as, if not higher than, that of comparable administrative or other positions which might be open to the forecaster. Obviously, forecast accuracy should be the first concern of any weather bureau. Furthermore, the forecaster should be subjected continually to an objective skill verification of his performance in competition with other official and practice forecasters, and there should not be any obstacle to the demotion of a forecaster to other work in case of a poor showing in competition over a long period of time (at least one year as a minimum). In the military weather services it should never be to the disadvantage of a successful forecaster to continue in his work. In other words, the meteorologist and responsible forecaster should always be a civilian technical expert, not a commissioned officer. Officers must take the responsibility for decisions based on the weather forecast, but in no case should the responsible weather forecaster be a commissioned officer whose chance of promotion is impaired by his becoming or permanently remaining a weather expert.

The remarks outlined above indicate a few measures which should contribute to the standardization and moderate improvement of present forecasting performance. However, the fundamental problem of achieving a reasonably scientific basis for weather forecasting will not be solved by any such routine elaboration of present techniques as that just outlined. If this fundamental problem is to be solved, that solution will be achieved only by basic research into the unsolved problems of dynamic meteorology, particularly into the thermodynamics of atmospheric circulations, and the

application of the knowledge thus gained to the development of entirely new scientific forecasting techniques. Obviously, it is quite impossible at this time even to suggest how such a solution is to be achieved, but the following remarks are offered as one meteorologist's opinion as to the direction from which the problem should be approached.

Approach to the Problem of Scientific Weather Forecasting. It is evident from the preceding discussion of the essential limitations of the present forecasting techniques that the primary inadequacy which they share stems from the fact that they are all essentially extrapolation techniques which, by one method or another, statistical or synoptic, qualitative or quantitative, attempt to derive the future or prognostic weather pattern from the current and past patterns. None of them is based on adequate thermodynamic concepts either of the operation of the basic drive of the general circulation, or of the energy sources or transformations which are involved in sudden accelerations or changes of trend in the development of the weather pattern. They all fail at the point of anticipating such frequent accelerational developments before the process is well in progress, when it is too late for anything but a very short-range forecast. The basic problem of forecasting research is to derive some quantitative physical model of the general circulation which fits the statistical and synoptic facts of weather observation.

There are two rather opposite points of view from which this primary forecast problem is most frequently approached. They represent two quite distinct philosophies of the basic character of the longer-period anomalous fluctuations of the world weather patterns. One method is to make an intensive study, by means of a dense network of complete and frequent synoptic observations within the area of the investigation, of the detailed structure and of the dynamic and thermodynamic activity of the atmosphere within a limited region from which complete data can be obtained. The purpose of such an investigation is primarily to determine the mechanics of operation of the dynamic and thermodynamic processes by which limited cellular circulations of the atmosphere are locally generated, transported, and dissipated. Intensive, relatively localized synoptic studies of this type tend to be favored because of the comparative ease of obtaining adequate observational data for restricted areas. It is more or less tacitly assumed in such studies that the entire developmental process of the local circulation is sufficiently self-contained so that it can be essentially explained by conditions within the limited field of observation [5]. If this line of approach to the basic forecast problem is selected, the choice implies that scientific forecasting can be realized at best only as a short-range accomplishment, that the general circulation in its entirety exists only as the integration of a number of individual cells or centers of action which operate independently and more or less at random such that the entire system lacks any unifying principle or control which makes its character or behavior over extended periods of time either distinctive or predictable.

The opposite line of approach to the basic forecast problem is to study the general circulation extensively, preferably over all of the globe from which even an approximate picture of the circulation pattern can be obtained. The time scale is likewise extended to deal with charts at 24-hr intervals or with mean charts for even more extended periods of time, to obtain a comprehensive picture of the large-scale fluctuations of the general circulation in its entirety over relatively long periods. The essential purpose of such an extended investigation is primarily to determine the mechanics of operation of the dynamic and thermodynamic processes by which the entire general circulation is maintained in its continuously and irregularly fluctuating pattern of intensity and form. Investigations on this scale tend to be avoided because of the relative inadequacy of observational data over large parts of the earth's surface, and the large amount of work involved in obtaining and processing the data for analysis. It is more or less tacitly assumed in such studies that the general circulation in its larger features, at least on either hemisphere, operates essentially as an integrated unified system which is functionally interrelated in all its parts.

If this second line of approach to the basic forecast problem is selected, the choice implies that scientific forecasting must be based primarily on a better physical understanding of the operation of the general circulation as a whole, and that the development and movement even of the secondary cellular circulations, and of all the attendant weather phenomena, the primary concern of the short-range forecaster, depends primarily upon the dynamics or thermodynamics of the hemispheric flow pattern and cannot be explained or anticipated on the basis of only the regional conditions in the sector of the development. This point of view indicates that the greatest improvement in weather forecasting is to be expected in the extended or long-range rather than in the short-range categories.

There are a number of indications, based on a great number of statistical, synoptic, and theoretical investigations in meteorology and in related fields, that this second approach to the basic forecast problem is essentially the correct one. This fact does not at all imply that nothing is to be gained from synoptic or theoretical studies of the secondary or tertiary atmospheric circulations, but it does imply that if this type of study is restricted to a limited sector of the earth's surface, factors of primary importance to the weather development probably will be overlooked. The primary evidence for the essential correctness of the global rather than the regional line of approach to the forecast problem may be summarized briefly as follows:

1. The failure of many years of intensive study of regional weather patterns to evolve either a physical model or a theory of cyclogenesis and anticyclogenesis (pressure changes) of any real practical value in forecasting regional changes of the synoptic weather patterns. Gross inadequacy of world-wide observational synoptic data has prohibited any corresponding study of the general circulation in its entirety.

2. The global extent of the persistent and systematically changing anomalous characteristics of the general circulation patterns, notably in their high-index (zonal, poleward displacement) versus low-index (cellular, equatorward displacement) features. The global, or at least hemisphere-wide, character of these basic index fluctuations is shown by significantly higher contemporary correlation between circulation indices for the entire Northern Hemisphere than between indices for the individual continental or maritime meridional quadrants of the hemisphere. The statistical improbability of this fact of observation makes it strong evidence against the primary independence of the individual regional cellular developments of the general circulation, but it is entirely consistent with recent studies of energy propagation in the atmosphere [11].

3. The occurrence of markedly similar anomalous fluctuations of the general circulation pattern between high- and low-index characteristics, fluctuations which are in phase in the Northern and Southern Hemispheres, and which increase in amplitude with the length of the period of oscillation. This fluctuating index character of the general circulation has paralleled the secular trends of climate during observational time, the greater changes of climate during historical time, and the extreme fluctuations between glacial and interglacial climates during geological time. The only single physical factor of climatic control which can possibly be made to account for this entire spectrum of synoptically similar patterns of climatic change is that of variable solar activity, presumably in the ultraviolet, and particle emissions which parallel the sunspot activity that is observed to be as erratically variable as the anomalous fluctuations of terrestrial climate [17].

4. The extensive evidence for the world-wide reaction of weather patterns to irregular solar disturbances, as shown by the anomalous fluctuations of monthly, seasonal, annual, and longer-period distributions of pressure, temperature, and rainfall in response to major phase changes of the sunspot cycle, and of the monthly mean distribution of pressure in response to anomalies of the monthly mean solar pyrheliometric values [1; 2; 18, pp. 31–86].

5. The fact that the theoretical investigations which have been most successful in the physical interpretation of the observed characteristics of the general circulation have without exception been based on some global or hemispheric mechanism of operation of the general circulation [9, 11, 12, 13, 15].

If it is accepted that the best line of approach to the basic problem of weather forecasting is by the study of the general circulation of the earth's atmosphere in its entirety, then the general direction that this approach must take is rather obvious. The first concern must be to establish the closest possible cooperation of the theoretical and the synoptic-statistical meteorologists such that all theory and hypotheses may be influenced and rigidly checked by the observational facts. The primary objectives towards which investigation should be directed include the determination of the primary energy sources and sinks in the atmosphere, as well as of the energy transformations and transportation from source to sink; the establishment of the entire dynamics and thermodynamics of the operation of the general circulation as a whole between energy source and energy sink, and an understanding of the mechanics of interaction between the zonal and cellular branches of the general circulation. Particular attention should be directed to the determination of the physical nature of the irregularly variable solar activity, to its direct effects in the higher atmosphere, and to the transmission of all such direct or indirect effects to the lower atmosphere, notably to the troposphere in the tropics, where the influence of the irregular solar activity on the weather is most directly in evidence.

All investigations of this general character, to be practically effective for the physical interpretation of the existing states and observed changes of the state of the general circulation, must be guided and verified by the synoptic and statistical analysis of reliable global observational weather data, and tested over as long a period as possible by extended series of past climatic data. Obviously, the efficient organization of a program such as that suggested above can be accomplished effectively only by a strong international meteorological organization, for its effective prosecution in all of its ramifications more or less of necessity entails the following procedures:

1. The establishment of a well-integrated world-wide system of uniformly distributed synoptically reporting stations, operating under the direct control and support of a strong international meteorological organization, as discussed above. Since the entire research program should be conducted by the same central organization, the details of the density, character, and distribution of the synoptic network of observing stations must be planned, and occasionally modified, with an eye to research requirements quite as much as to practical current forecasting requirements.

2. The development of more effective synoptic tools or techniques for the presentation and analysis of synoptic weather observations on a world-wide scale. Emphatically this development and standardization of synoptic techniques can be effectively implemented only by a strong central meteorological organization, as discussed above. However, the development contemplated as a necessary part of any program of basic research in weather forecasting goes far beyond the mere selection and standardization of synoptic techniques which already are in practice, as previously considered. This development should contemplate the evolution of basically new and improved synoptic techniques as an integral part of, and guided by the needs of, the basic research program.

3. The establishment of one central international meteorological research center, under competent direction, where leading meteorologists of all nationalities would be enabled to work under conditions of complete cooperation and exchange of ideas, with a maximum of readily available synoptic data and the necessary amount of clerical assistance. In this manner it should be made possible for the meteorologists with the most to

offer to forecasting research to make the greatest possible contribution irrespective of nationality or local resources, and to concentrate all available talent with the greatest efficiency on the primary objectives to be attained. Much of the efficiency of operation of such a research center would stem from the fact that the observational synoptic-statistical, and theoretical phases of the research program could be integrated and coordinated to the greatest advantage of the necessary basic forecasting research. A complete long-range program could be formulated and prosecuted under the combined effort of the best minds in meteorology and in the related fields. If eventually the problem of scientific weather forecasting is to be solved to some degree of satisfaction, the solution will be greatly hastened by a program such as that outlined above.

SHORT-RANGE WEATHER FORECASTING

By GORDON E. DUNN

U. S. Weather Bureau, Chicago, Illinois

INTRODUCTION

Literature. Literary productivity in meteorology during the past two decades has reached the highest rate in meteorological history. Much of it has been descriptive and theoretical in nature, some of it with forecasting implications, but remarkably little has been directly concerned with or has contributed significantly to the improvement of forecasting. Indeed, the few modern textbooks supposedly directed primarily toward analysis and forecasting devote comparatively little space to the practical problems of forecasting. A tendency exists for the theoretical meteorologist, and even the analyst, to remain aloof from the vicissitudes and discouragements of the practical forecaster. Research workers apparently believe their obligations have been fulfilled when their results and suggestions have been passed along to the forecaster, while the latter, as a rule, has neither the time nor the facilities to test the suggested practical applications of current research. Thus, unfortunately, the gap between the theoretical meteorologist and the forecaster remains unbridged.

The Forecasting Problem. The problem of forecasting may be divided into three separate but closely related phases: (1) analysis, (2) prognostication of pressure patterns, and (3) forecasting the weather. Airmass analysis may be defined as the study of preceding and current meteorological conditions over a prescribed area for the purpose of deriving a satisfactory and logical explanation of the physical processes and weather actually observed. The analysis should include a determination of the structure, location, direction and rate of movement of fronts, the characteristics of the various air masses with particular reference to temperature and moisture, and an explanation of any precipitation areas. Analysis of the area required for forecasting at the district level has become too great a burden for forecasters and the desirability of central analysis centers is now generally accepted.

In addition to the more normal functions, analysis centers (or extended-forecast units) should provide district forecast centers with analyses of broad or large-scale features of the general circulation as determined by the "centers of action" or "weather controls," which often lie some distance off the normal forecasting chart. These analyses would include hemispheric wave lengths and indications of blocking, since these often influence weather developments far away within very short periods of time.

Complete utilization of analysis centers must await further development of facsimile since the coding and decoding of analyses is time consuming and, more important, the consequent smoothing results in a serious loss of character in the analysis. However, transmission of prognostic charts and many types of analyses by facsimile is already satisfactory in the limited areas where this facility is in use.

The preparation of prognostic surface-pressure charts, with indicated frontal positions, and prognostic constant-pressure charts comprises the second phase of the forecast problem. These charts are derived by more or less mechanical means and are subjectively evaluated and modified at the analysis central and then transmitted to forecast centers. Duplication of the same process of analysis at individual forecast centers represents an excessive waste of time and a group of specialists, with an adequate staff for plotting the necessary additional maps and diagrams, should provide forecasters with better analyses than are obtainable by any other method. Prognostic surface charts for periods up to 30 hr now maintain a very high standard of accuracy and satisfactory progress is being made toward 54-hr surface prognostics. The preparation of the 700-mb prognostic chart has, apparently, not met, so far, with the success which might be expected from acquired experience and available techniques. The preparation of both surface and upper-air prognostic charts has not improved to the point where the district forecaster is relieved of the duty of checking and recomputing predicted frontal and pressure system positions for his own district on the basis of additional and later reports and his greater experience in his own area.

The third, and most difficult and important, phase of the forecast problem is the prediction of the weather. Because of the local nature of many forecast problems and the extreme variability and complexity of weather over any large area such as the United States, some decentralization of forecasting is required. This article will deal primarily with the preparation of prognostic charts and the prediction of weather, with particular reference to the middle latitudes, and will be concerned only casually with analysis. However, it should be emphasized that there is no distinct demarcation between these three phases of weather forecasting.

Present State of Short-Range Weather Forecasting. Douglas [19] stated in 1931 that, because of the staggering complexity of the atmosphere, forecasting was largely a matter of experience and judgment and thus almost wholly on an empirical basis. Byers [11] in his chapter on forecasting techniques remarks: "The ability to forecast weather accurately comes as much from experience as from study. The rules for prediction cannot be stated simply and it is extremely difficult to attain success in forecasting through formal study or instruction." In an earlier edition, he further said: "In general, it may be stated that . . . forecasting is the application of all the forecaster's knowledge of meteorology, augmented by thermodynamic calculation to the problem at hand." Willett [58] in a similar chapter and in like

vein declares: "The ordinary forecasting procedure makes no use of any mathematical or quantitative physical methods of diagnosis and prognosis." He had pointed out earlier that "the successful introduction of such quantitative physical methods into practical daily and longer range weather forecasting constitutes the ultimate goal of a large part of present meteorological research. But, up to the present time, the mathematical computation of local changes of weather elements on the basis of physical principles, as distinct from quantitative kinematical extrapolation, has been effectively applied to only a few cases of short-range forecasts at the expense of much time and effort. Really scientific weather forecasting is far from being an accomplishment of the present."

Although efforts to apply dynamic and thermodynamic principles to weather forecasting continue at an accelerating pace and some progress is being made, it must be admitted that forecasting is still largely an art and only in a relatively small part a science. It is difficult at times to explain past and present weather satisfactorily in terms of physical principles and almost impossible in terms of mathematical formulas. Indeed, only two such formulas are in general use in forecasting offices at the present time.

The principal change in forecasting techniques during the past three decades has been the elevation of air-mass characteristics to an importance equal to that of pressure distribution. That is, with the vast increase in upper-air observational data, the forecaster now has a greatly improved three-dimensional synoptic weather picture. However, it should be noted that in the second phase of the forecast problem—the preparation of the surface and upper-air prognostic charts—the emphasis remains on the pressure distribution, although a successful forecast of this characteristic of the weather map far from guarantees a successful weather forecast. As emphasized by Houghton [29] and others, there is no unique correspondence, but only a statistical relationship between the pressure field and the weather. While Houghton advocates further studies of this relationship, he points out the greater importance of the field of motion.

The principal progress in forecasting in the past two decades has been evidenced by a significant improvement in the accuracy of forecasts up to 8–12 hr, in the development of certain specialized types of forecasting, and in the detail currently attempted with some success. For periods from 12 to 48 hr, forecast accuracy has improved no more than 3 per cent. In regions of rapid and frequent weather changes, such as in most of the United States, the accuracy of weather forecasts diminishes 3 to 4 per cent for every additional 6 hr of the forecast period. In view of our better knowledge of atmospheric dynamics and thermodynamics and the vastly increased observational data, it must be admitted that the accuracy of short-term forecasting has not increased proportionately.

With the development of new electronic computing devices and recent work by Charney and Eliassen [14], there is currently renewed interest in the classical attempt of Richardson [44] to forecast the weather mathematically. There is, apparently, good reason for optimism that some practicable forecast aids may be forthcoming from this source. At the moment, however, the possibility of forecasting the weather wholly on an objective basis seems very remote.

The great amount of work completed and under way on the upper air encourages the belief that the development of practical applications of dynamics and thermodynamics, useful in forecasting, will continue. But for some time to come it seems likely that, in the words of A. H. R. Goldie, "forecasting will continue to be a combination of physical reasoning with the practical experience of the synoptic charts."

PROCESSING THE OBSERVATIONAL DATA

Observations. In accordance with international agreement, a basic surface observational network consists of stations spaced approximately 140 mi apart and denser national and secondary networks. Observations from the international network are taken over large sections of the world at approximately 00, 06, 12, and 18Z and distributed to weather centrals and to district and local forecast offices by means of teletype, radio, and other communication facilities. Observations from the national network are distributed to the analysis centrals and the district and local forecast centers and from the secondary networks to adjacent centers and to such other forecasting offices and centrals as may be required. In most areas, reports are transmitted, distributed, and plotted as rapidly as possible. The spacing of pilot-balloon and radiosonde observations depends largely upon the budget of the various weather services.

Charts and Graphs. The composition of the several types of weather observations as well as the station model for plotting data on the basic surface weather chart may be found in publications of the national weather services. The basic surface chart usually represents a compromise between the desire for both as large a scale and as large an area as possible. If possible, it should include all areas whence weather in one form or another can reach the forecast district within 48–60 hr. A Lambert conformal conic projection (standard parallels at 30° and 60°, and scale 1:7,500,000) is recommended for middle latitudes. Larger-scale charts may be required for local, airway, and other specialized forecasting.

Pilot-Balloon Charts. These charts contain observations of wind velocity and direction for specific levels from stations spaced about 150–175 mi apart in accessible areas. The levels normally include surface, 2000, 4000, 6000, 8000, 10,000, 12,000, 15,000, 20,000, and 25,000 ft above sea level. The charts are prepared at six-hourly intervals. Some stations attempt a streamline and trough-and-ridge-line analysis at the 0900Z and 2100Z observational periods between the regular radiosonde observations.

Thermodynamic Diagrams. Radiosonde observations are taken at 0300Z and 1500Z at stations 300–500 mi apart although this spacing is insufficient for detailed

upper-air analysis. Radiosonde observations provide pressure, temperature, and moisture data and values of these elements at significant points on the ascent curve are plotted on various thermodynamic diagrams. In the United States, the pseudoadiabatic diagram is commonly used.

Constant-Pressure Charts. To provide a horizontal picture over a given area, the same information is plotted for certain standard isobaric surfaces. At most district forecast centers, these usually include the 850-, 700-, 500-, and occasionally the 300- and/or 200-mb surfaces. Weather centrals will usually also prepare the 1000- and 100-mb charts, differential analysis charts or chart and a maximum potential-temperature chart.

Pressure Charts. Pressure and the 3-hr pressure change and characteristic are entered on the pressure chart directly from the coded observation, and the 12-hr pressure change, corrected for the diurnal variation in pressure, is computed and plotted. Three and 12-hr isallobars are drawn and maxima and minima are tracked.

Temperature Charts. Charts containing current and maximum or minimum temperatures are usually plotted at 1200Z and 2400Z and the 24-hr change from maximum to maximum, or minimum to minimum as the case may be, is computed. Departures from the normal temperature are usually entered.

Other Charts. Graphs of the zonal index and miscellaneous charts, such as snow-on-the-ground and the 24-hr precipitation, are prepared for various purposes.

USE OF SURFACE DATA

Basic Surface Chart. When entry of data on the surface chart has been completed, the analyst locates and defines the fronts, draws the isobars, and determines the air masses. Procedures in general use are described by Petterssen [42, Chaps. I and XI]. The current rate of movement, and the acceleration and deceleration tendencies of fronts and pressure systems are determined, and the previous paths of high and low centers are plotted. Local and district forecast offices use weather-central analyses but district offices make such modifications as their denser network of observations, special reports, and pilot reports may indicate. Areas of hydrometeors are indicated in accordance with uniform national custom or regulation. Conclusions on the causes of current and past weather, drawn from surface maps, are integrated and reconciled with those derived from the upper-air and auxiliary charts.

Pressure-Change and Other Auxiliary Charts. The necessity for the pressure-change chart arises from the large amount of data, particularly in bad weather, entered on the surface chart for each individual station. The severe deadlines imposed on analysts and forecasters in many weather services preclude close inspection and analysis of these data at each station. The pressure chart presents in clearly defined form 3- and 12-hr pressure trends. In summer, the true 3-hr pressure change is masked by the greater diurnal change, and the 12-hr change, corrected for the diurnal variation in pressure, is more representative.

Cook [16] has collected some hundred empirical rules for use of the pressure-change chart, many, however, of only regional value. The 12-hr pressure change represents the net change in surface pressure in that period of time resulting from all the physical processes which affect the weight of a column of air extending from the surface to the top of the atmosphere. The direction and rate of movement and changes in the intensity of the allobars can be forecast with the same accuracy as the highs and lows themselves and the relationship is obvious.

Whether the various areas of cyclogenesis and anticyclogenesis are undergoing intensification or weakening can be deduced rather quickly and accurately from the pressure-change chart by comparing the last 3- and 12-hr pressure changes with the same allobaric values 6 and 12 hr before and for other time intervals. The explosive effect as a surface pressure fall reaches an area under a cold upper-air low or when the leading edge of a new pressure fall reaches a moist stationary front is well known to all forecasters. Miller [35] has noted that cyclogenesis can be recognized on the Atlantic Coast by 12-hr pressure changes when 3-hr changes are indistinct. Cyclogenesis on the east slope of the Rockies can be handled much better on the basis of 3- and 12-hr katallobars than by actually following pressure systems as they move out of the Gulf of Alaska.

A snow-on-the-ground chart is necessary for forecasting the rate of modification of air masses as they move from snow cover to bare ground or vice versa and for the forecasting of maximum and minimum temperatures and drifting snow.

Some forecast centers maintain a graph of the zonal index, plotting daily values or using mean values provided by the extended-forecast section. The zonal indices provide a good indication of the broad-scale features of the general circulation and assist in forecasting changes in intensity or position of the centers of action. Attempts to correlate variations of the zonal index with the formation of arctic air masses have, so far, been unsuccessful and attempts such as that of Weiss [57] to determine the relationship, suggested by Rossby [47], between a large-scale flow of warm air northward in the eastern Pacific Ocean toward Alaska and marked anticyclogenesis over the Mackenzie Basin have generally failed. In this particular situation, anticyclogenesis appears to take place at more southern latitudes. Namias [36] has described a case where a general fall in index over Asia was followed by the progressive establishment of low-index conditions from west to east resulting in strong polar anticyclogenesis. It has been known for some time that an analogous condition may be initiated in Europe, developing westward into North America and resulting in the condition generally referred to as "blocking." Indeed, exceptionally strong and persistent arctic anticyclogenesis seems to form more often in the latter than in the former manner. These important trends are not often available to the district forecaster but fairly short-term forecast effects arise from them since it is not unusual for an arctic

front to accelerate from an almost stationary condition to 40–60 mph within 12–18 hr.

Temperature-change charts have relatively little forecast value but are required for weather bulletins for press and radio, for preparation of shippers' forecasts and other information for commercial and agricultural interests, and for the general public.

Analogues. The system of locating a number of previous weather charts which are most nearly analogous to the current chart, and then determining the prognostic chart by analogy, has been used successfully by a number of forecasters, particularly J. J. George. The past maps are known as "analogues." Weather charts for several decades are catalogued on the basis of their dominant characteristics, for example, Colorado lows or Alberta highs. If, for example, on some particular December day those are the two principal characteristics of the current weather chart, the December, and also the January and November, file of past situations is inspected and the five to ten charts with greatest similarity to the current chart are selected and studied. A choice of two or three is finally made, primarily on the basis of history and secondarily on the basis of detail. "Good" analogues should provide reasonably good prognostic charts since the numerous hydrodynamic and thermodynamic parameters that describe the current weather situation are conveniently integrated in the analogue. Where selection of the analogue is made mechanically (*i.e.*, by machine) the system has been a complete failure, since historical sequence is much more important than actual location and intensities of pressure systems. Manual selection, which permits consideration of both surface and upper-air patterns, does provide better results but time and patience are required. Because of the persistence of weather types, the best analogue may often be found from the charts within the three or four weeks previous to the current chart. The purpose of the analogue procedure is to provide the inexperienced forecaster with assistance, but, in practice, he does not have the experience required for the selection of the best analogues and for the recognition of the significant differences which are always present between the analogue and the current chart. The use of analogues will never prove satisfactory until the upper-air patterns and historical sequences are included in the parameters upon which their selection is based.

Types. Attempts have been made to type weather maps and situations since the beginning of forecasting. Many of these attempts have met with limited or no success because of the infinite variations of weather situations and the superficiality of some methods of typing.

Studies of storm types, frequencies, and normal storm tracks, such as those of Bowie and Weightman [7] in the United States and of Van Bebber [54] and Braak [8] in Europe, are widely used by forecasters. The San Francisco forecasters were moderately successful for many years in forecasting for the Pacific Coast by dividing their weather into three main steering types: northwesterly, westerly, and southwesterly. This typing was expanded and refined by the Meteorology Department at the California Institute of Technology under the leadership of I. P. Krick.

The C. I. T. typing method is based on the location of the "center of action," here the semipermanent eastern Pacific high. Krick, Elliott, and colleagues [12] have classified North American weather into five main types, with a considerable number of subtypes, depending upon the location of the Pacific high. It was found that a type tended to persist for six days (five to seven days) and then to repeat or change to another type. Composite charts, by seasons, were derived for each of the six days of each type. As indicated by Elliott [20], changes in index and in the various arrangements of the large upper-level waves (meridional flow patterns) and different degrees of expansion of the ring of strongest westerlies (zonal flow patterns) are regularly associated with the shift and change in intensity of the Pacific high. While typing of this kind is most helpful in extended forecasting, it has also been found of value in 24–72-hr forecasting as far east as central United States. It is understood that further investigations are under way to develop composite upper-air maps analogous to the composite surface charts and to determine the limits of variation of upper-air situations with individual surface types. The principal limitations of the type technique are (1) the frequent and extensive variations of a single type, and (2) the difficulty in recognizing some types in complex situations. Typing on a somewhat more circumscribed scale, such as that of Saucier [49] in connection with Texas-West Gulf cyclones, can provide the district forecaster with a valuable tool.

USE OF UPPER-AIR DATA

Radiosonde Diagrams. For a number of reasons, including the requirements for the preparation of certain specialized and detailed forecasts for very short-term periods as well as thorough analysis of local weather conditions, it is desirable and necessary to make a detailed analysis of individual radiosonde observations within and adjacent to the forecast district. The analysis enables the forecaster to locate cloud layers and their thicknesses as well as areas of freezing rain and snow (when present) and also to ascertain stability conditions in order to forecast the probability of cloud, cloud heights, and convectional shower activity. For convenience, the forecaster may wish to classify the lower troposphere according to the customary degrees of stability, namely, stable, conditionally unstable, and absolutely unstable. During certain periods and seasons, the forecaster will wish, as a matter of course, to determine the lifting condensation level, the convection condensation level, and the energy available. For a full discussion of stability and instability see any standard textbook, particularly Petterssen [42, Chap. II].

Two methods exist for determining the stability of the atmosphere: the *parcel* and the *slice* methods. The parcel method is less exact in that as a parcel of air rises, other air is entrained from the outside and when the air is conditionally unstable (when the exact degree

of stability is most important to the forecaster) the parcel method underestimates the resistance against lifting and overestimates the available energy. The slice method, first suggested by J. Bjerknes, does take into consideration changes in environment of the ascending air, but the method is too complicated for practical use.

Constant-Pressure Charts. At district forecast centers, constant-pressure charts are normally prepared for the 850-, 700-, 500-, and occasionally for the 200-mb surfaces. Fulks [22] has described procedures for the preparation of these charts which normally include entry of dry-bulb and dew-point temperatures, height of the pressure surface, and 12- or 24-hr height changes. Contours (isohypses) and isotherms are then drawn. At many centers, isolines of equal height changes are drawn and areas of certain moisture values, based on the dew points, are shaded. At weather centrals, other pressure surfaces may be useful, particularly the 1000-mb chart, as well as tropopause and density charts.

The 850-, 700-, and 500-mb charts are among the finest tools available to the forecaster. A large number of techniques and rules, mostly subjective, have been developed or formulated during the past few years for use in forecasting.

Constant-pressure charts, and the 850-mb chart in particular, can provide the forecaster with much of the information yielded by the isentropic chart. Since the isotherms are lines of potential temperature, they represent the intersections of isentropic surfaces with constant-pressure surfaces. Means [33] has found the warm air advection in the lower layers of the atmosphere (2000–8000 ft and above m.s.l.) useful in forecasting thunderstorms.

By far the greatest amount of work has been done on the 700-mb chart. During the past few years, however, the 500-mb chart has been finding greater favor with forecasters, since the field of motion is more conservative at this level, and for other reasons. The most important use of the 700- and 500-mb charts is the "steering" of surface highs and lows or pressure rises and falls indicated by the field of motion at these levels. "Steering" appeared prominently in the publications of German meteorologists in the 1930's particularly in the work of Baur [3], who found that the direction of motion of regions of rise and fall of pressure was controlled by the steering at 5 km. The mean duration of a broad-weather situation (*Grosswetterlage*) was 5 to 5½ days which, with the allowance of one transitional day, corresponds to the C.I.T. six-day type. Steering was broken down into four divisions:

1. Westerly steering (high index)—about 18 per cent of the cases.

2. Northwest and southwest steering (moderately low index and moderate troughs and ridges)—about 17 per cent each.

3. Northerly and southerly trough and ridge steering (very low index)—smaller percentages.

4. Easterly steering (very low index)—observed very infrequently. Presumably a number of cases could not be classified.

V. J. and M. B. Oliver [40] have summarized a large number of rules obtained from many sources for the use of the upper-air charts. Most of these rules have not been objectively tested but some of the more important of them, applicable to the 700-mb chart, are:

1. Surface cyclones move in the direction of the 700- and/or 500-mb flow.

2. Surface cyclones move in the direction of the 700–500-mb mean isotherms, inclining slightly toward the colder air.

3. If an upper isallobaric maximum (24 hr) is found in the direction in which the surface cyclone will move, the cyclone will move into the region, or just to the west of it, in 24 hr.

4. Surface cyclones will move along a line from the center of the isallobaric minimum (24 hr) in the rear to the center of the isallobaric maximum in front.

5. The smaller the angle between the upper isobars and the mean isotherms of the low troposphere, the closer the speed of the cyclone approaches the speed of the upper flow. But perhaps the most important and widely accepted rule in current use states: The surface low or surface katallobar moves with approximately half the speed of the 500-mb wind over it.

Table I. Average Deviation of the Direction of Movement of Cyclones from the Orientation of the Upper-Level Contours and Isotherms

Upper-level pattern	Comparison A		Comparison B	
	Average deviation	Number of cases	Average deviation	Number of cases
Contours, 850–700 mb	31°	212	24°	92
Contours, 700–500 mb	28°	216	21°	92
Isotherms, 850–700 mb	31°	215	23°	92
Isotherms, 700–500 mb	33°	218	23°	92
Contours, 200 mb	26°	159	21°	92

The forecasting value of rule 1, if valid, is obvious. Austin [1] has tested this rule by comparing the direction of movement of the cyclone on the surface with the orientation of contours and isotherms at various levels. This direction of movement was assumed to be given by the direction from the position of the center 12 hr before to the position 12 hr after the time for which the comparison was made. Austin's conclusions are summarized in Table I. Comparison A includes all observations, while Comparison B includes only those cases in which the speed of the cyclonic center exceeded 20 mph.

Table II. Frequency Distribution of the Deviations in Direction

Upper-level pattern	−180° to −46°	−45° to −16°	−15° to +15°	+16° to +45°	+46° to +180°
Contours, 850–700 mb	1	5	48	27	11
Contours, 700–500 mb	2	7	60	12	11
Isotherms, 850–700 mb	4	13	51	18	6
Isotherms, 700–500 mb	3	7	49	22	11
Contours, 200 mb	3	14	50	17	8

The frequency distribution (Table II) shows the spread of the deviations for the 92 cases in Comparison

B. A positive deviation means that the cyclone moved to the right of the upper-level contour or isotherm. The mean deviation was reduced to 19° by averaging the direction of contours in the layer from 700 mb to 500 mb with the direction at the 200-mb surface. Austin also found that a cyclone which was being steered tended to continue being steered, that the deviation appeared to be independent of intensity, that approximately 65 per cent of the cyclones moved to the right of the upper-level isotherms and contours, that the difference between filling and deepening cyclones was negligible, and that the average deviation was greater for the Rocky Mountain plateau than for the eastern United States. Forecasters will agree with Austin's conclusions that the forecasting principle of steering compares favorably with other prognostic procedures for determining the direction of movement of a cyclone and, indeed, is the best, although definitely not a precise tool, for this purpose. In this most useful study it did not appear that the speed of a cyclone could be determined from the geostrophic wind speed at any particular level, and it is believed that the poor correlation obtained came as a surprise to most forecasters.

In a somewhat similar study of cyclones and anticyclones, Longley [32] found the deviations given in Table III.

Table III. Mean Values for Classes Grouped According to the 700-mb Flow

Class	Number of cases	Mean deviation	Mean 24-hr movement (mi)	Mean deviation distance (mi)
Cyclones				
Closed centers aloft	87	44°	468	332
Troughs and ridges aloft	36	20°	537	310
Straight contours aloft	47	17°	628	295
Anticyclones				
Closed centers aloft	46	65°	311	295
Troughs and ridges aloft	30	37°	515	400
Straight contours aloft	33	27°	587	328

The frequency distribution of the deviation angle derived in Longley's study, which, for cyclones, is in good agreement with Austin's, appears in Table IV.

Table IV. Frequency Distribution of the Deviation Angle

	+180° to +50°	+45° to +20°	+15° to −15°	−20° to −45°	−50° to −180°
Anticyclones	14	13	38	20	24
Cyclones	22	35	82	22	9

Longley found that, of 47 anticyclones with a deviation of 45° or more, 33 were located over the Atlantic along a line approximately from 45°N and 30°W northeastward to 55°N and 20°W, and that a greater concentration of cyclones with large deviations existed in a rectangle bounded by the 40°N and 50°N parallels and the 50°W and 70°W meridians, or as the pressure systems approached the Atlantic high and the Iceland-Greenland low. Longley differed with Austin in regard to the tendency of a cyclone to continue to be steered if following the upper-air flow but agreed that the wind velocity at the 700-mb surface was not a good indication of rate of movement of the surface cyclone.

Palmer [41] obtained as good or better results on direction of movement by a simple graphical device employing the following parameters:

1. Normal 24-hr direction of movement based on data published by Bowie and Weightman [7];
2. The direction in which the cyclone moved during the past 6 hr;
3. The orientation of the major trough in the sea-level pressure pattern; and
4. The direction from the 3-hr anallobaric center behind the cyclone to the 3-hr katallobaric center ahead of the cyclone.

Tests indicated that this tool would be correct within 15° about 75 per cent of the time. Palmer considered only winter storms; summer lows might not yield as good results.

The procedures employed by both Austin and Longley perhaps do not provide a wholly fair test of the validity of the steering principle, but tests should be made of all forecasting techniques and rules which are held in high regard by all forecasters. In general, forecasters simply do not know the accuracy of many of the rules and techniques in use or the range of the possible deviation of nearly all of them.

In applying the results of Austin's study, the forecaster is faced with the determination of the probable direction of deviation from the steering indicated by the 700- and 500-mb charts.

The deeper the low, the less applicable the steering principle. Surface lows which have closed centers at 700 mb and higher tend to move with the upper center. The best indication of the direction of movement of closed lows at the 700-mb surface and higher is the 12-hr pressure change around the center; another method is the determination of the resultant of the wind circulation around the upper-level low. The calculation of the distance such a low will move in a given time is even more difficult and should be determined by the broad-scale weather processes going on.

Little has been written on the practical applications of the 200-mb chart to forecasting. Wulf and Obloy [59] have emphasized the importance of the compensating effects between the stratosphere and the lower troposphere and have suggested that stratospheric conditions may exert considerable influence upon frontogenesis and that advection and other processes in the lower stratosphere should receive consideration in prognosticating surface and tropospheric pressure patterns. Austin [1] found that the 200-mb chart is almost as effective a steering level as any other. Some forecasters have found the 200-mb chart helpful in determining displacement of shallow migratory troughs at the 700-mb level.

Under the tropopause, at approximately the 300-mb level, an extremely fast and narrow current has been noted which is called the "jet stream" by the University of Chicago group [53]. Large-scale mixing, interrupted

at a critical zone in middle latitudes, has been suggested by the Chicago group, and the "confluence" theory by Namias and Clapp [38], as possible explanations of the mechanism of this current. Which are the causes and which are the effects have not been definitely established. Riehl [45] has suggested that the ascent of tropospheric air below and slightly to the north of the jet might affect the distribution of precipitation. Starrett [52], investigating this relationship, found a significant concentration of precipitation activity under the jet stream, subject to the normal variations of local dynamical fields of convergence and divergence associated with the short baroclinic waves within the westerlies.

It seems probable that the jet stream and George's "isotherm ribbon" [26] are all manifestations of the same phenomenon, namely, the frontal zone, and that they are usually located along the same latitude at any one time and that this zone is favorable for cyclogenesis.

Pilot-Balloon and Other Upper-Air Charts. The principal use of the 6-hr pilot-balloon charts is obviously the forecasting of upper-air winds and, to a much lesser extent, surface winds. The interim charts between the regular constant-pressure charts are useful in checking the movement of troughs and ridges and the latest trends.

Isentropic analysis was introduced around 1937 by Rossby and collaborators [48]. Isentropic charts were prepared generally by forecast centers for a number of years in accordance with procedures outlined by Namias (see Petterssen [42, Chap. VIII]), but were eventually abandoned when forecasters failed to find in them the hoped-for precise tool for precipitation forecasting. The poor results have been blamed on the nonadiabatic processes common in the atmosphere, which tend to destroy the conservatism of isentropic surfaces, principally (1) radiational cooling and heating, (2) evaporation and condensation, and (3) convection. Also one thin, and often wavy, isentropic surface, arbitrarily selected, may be unrepresentative of the principal upslope area. In the Middle West, determination of the motion of air particles, some distance away from but in line of flow toward a station, relative to the contour lines of the isentropic surface over the station, was frequently very difficult. Contours might move in the same direction and at the same rate as the air particles and the expected upslope movement would not occur, with resultant failure in the precipitation forecast. There is some question whether isentropic analysis has been given a fair trial by forecasters, since (1) time was rarely available for careful construction and analysis, and (2) many forecasters never fully understood the meaning and significance of all the information on the isentropic chart.

Clouds. With the considerable increase in the amount of upper-air information now available to the forecaster, the importance of cloud data has decreased somewhat. However, as Brooks [10] states: "Clouds are indications of humidity, lapse-rate, (and temperature), direction and velocity (including shear and turbulence) in the free air. As such, they are, of course, valuable aids in air-mass analysis and forecasting." Thus, as indirect aerology, clouds provide the local forecaster particularly, and the district forecaster and analyst as well, with valuable information regarding the stability and moisture trends of the lower atmosphere. A close watch on the clouds as shown on the hourly sequences and interim charts will provide the forecaster with valuable clues on the rate of moistening of a previously dry trough.

PREPARATION OF PROGNOSTIC CHARTS

It is desirable to prepare, in a formal fashion, prognostic charts for 24-hr intervals. These charts should include isobars, frontal positions, high and low centers, and precipitation areas. The positions of fronts and pressure systems can be indicated informally on the regular six-hourly synoptic chart for six or twelve hours or for any other time interval. Upper-air prognostic charts should include contours and ridge and trough lines.

Preparation of the 700-mb Prognostic Chart. Because of their complexity and the time involved, the preparation of upper-air prognostic charts is logically a function of weather centrals and not of forecast centers. Techniques have been suggested by Starr [51] but a description of those in use by American meteorologists has not, as yet, been published for general distribution. However, the principal procedure appears to be extrapolation with a check for consistency by drawing the implied mean virtual temperature between the 1000- and 700-mb surfaces. The forecasting of mean virtual temperature and mean density patterns should provide a better indication of future height changes than pure extrapolation of changes at one level. Other techniques which might be used include:

1. Extrapolation of trough and ridge lines. The pattern at 700-mb is more conservative than at the surface and conservatism increases further with height.

2. Extrapolation of isallobaric centers, applying corrections for indicated intensification or diminution.

3. Application of the formula for the movement of long waves in the westerlies, developed by Rossby [47]. This formula is $c = U - \beta L^2/4\pi^2$, in which c is the speed of the wave, U is the zonal wind speed (best results are apparently obtained at approximately 600 mb), L is the wave length, and β is the rate of change of the Coriolis parameter northward with latitude. Recent studies by Cressman [17, 18] indicate that good to excellent results may be obtained if adequate daily 700-mb charts are available on a three-quarters or full hemispheric scale. Use of this formula is not practicable for an area as small as North America.

4. Isotherm-isobar relationship. Another principle based on the kinematics of wave motion provides some indication of the rate of movement of minor waves in the westerlies. Assuming that there is no convergence or divergence and that temperature is a conservative element, Rossby [46] derived the equation $U/(U - c) = A_T/A_p$ in which U and c have the same significance as before, A_T is the amplitude of the isotherms, and A_p is the amplitude of the isobars. It can readily be

seen that when the isobars and isotherms are in phase but the isotherms possess the larger amplitude, the wave will move with moderate velocity. In the same case but with isobars of an amplitude larger than the isotherms, the perturbations will move slowly or even retrograde. When the isobars and isotherms are 180° out of phase, the wave will move very rapidly. When cold air moves into the system, the wave will tend to deepen; when warm air moves into the system, the wave will usually weaken.

5. Minor waves tend to intensify as they move into a major trough although maximum intensity is usually found as they reach the midway point between the major trough and the major ridge downstream. Similarly, a pressure fall intensifies as it moves into a major trough and a pressure rise intensifies as it reaches a major ridge. However, care should be exercised if the pattern is changing.

6. Use of pressure tendencies at upper levels. Miller and Thompson [34] devised a method for the calculation of 3-hr pressure changes from pilot-balloon observations. It was hoped that these pressure tendencies might permit the use of Petterssen's extrapolation formula, but this has not become standard practice largely because of the work involved and because only advection is considered, while convergence and vertical motion (and any nongradient winds) are omitted from consideration.

7. Rossby's trajectory method. Rossby has developed a trajectory technique which is essentially the determination of the future path of a system of particles based on the change in vorticity with change of latitude while the absolute vorticity is conserved. Fultz [24] has described the technique and the attempts which have been made to apply it to forecasting the 10,000-ft chart. Tests have shown that the 10,000-ft trajectories can be computed by this method for winds in major flow patterns with a significant degree of accuracy up to 72 hr. Convergence and divergence are neglected in the equation and subjectivity is required in the selection or rejection of the computed winds. In certain situations wave computations are difficult and the constant absolute vorticity trajectory methods give better results. Use of this technique in extended-range forecasting is described by Namias [37].

8. Supergradient wind velocities. It has been noted that supergradient wind velocities in the eastern Pacific have often been attended or followed by an increase in pressure over the far western United States. The supergradient condition results in a net unbalanced force on each unbalanced particle directed toward the right and thus in a piling up of air on that side. This has been observed in other regions and has become known as "anticyclogenesis upstream."

9. "Cutoffs." Occasionally a rise of pressure will appear behind a trough, move eastward in the maximum westerlies and cut off the southern portion of the trough resulting in a closed circulation in that area. This tends to happen in preferred locations, for example, in the far southwestern United States. The closed low will either move southwestward off the coast of southern California and usually dissipate or remain stationary for around 48 hr awaiting the arrival of a new fall in pressure from the north. Somewhat similarly, warm highs may be cut off. Closed lows may develop in almost any section, usually building upward from the surface, and their prognostication is very important because of the extensive bad weather associated with them. This development may be detected 12–24 hr in advance when a slowly moving isallobaric minimum is located south of a weak westerly gradient.

For the most part, the 700-mb prognostic chart should be prepared independently of the surface prognostic chart since one of its principal uses is as a check on the latter. However, there may be a few elements of the surface prognostic chart which will be subject to little or no question and the 700-mb chart should be consistent with respect to these elements.

The usual order of operations followed by the analyst making the 700-mb prognosis in the Weather Bureau-Air Force-Navy Analysis Center[1] is as follows:

> The prognosticator makes a 700-mb analysis, and then draws a thickness chart (1000–700 mb) which also includes the 850-mb flow. While the thickness chart is being made, an assistant makes the 24-hr height change chart. A tentative prognosis is then made by application of the various techniques discussed in the following paragraphs. Then, in consultation with the surface prognostic analyst, a series of checks and adjustments of the two prognoses is made to make them mutually consistent, with special attention given to surface patterns and to trends determined from closer examination of old data or from a check of new three-hourly data. This informal discussion of the general situation is followed by a discussion of the points of difference or of inconsistency between the 700-mb and the surface charts and is participated in by the two prognostic analysts and the supervising analyst. This leads to the final version of the prognosis.

No one procedure or set of procedures is used regularly in making the 700-mb prognosis. Of the wide variety available, the choice depends upon the analyst and the occasion. Good judgment is of paramount importance in making a prognosis. The analyst relies on it in determining rather quickly to what extent pure extrapolation and persistence can be used with better results than a time-consuming physical forecast. Attempts to explain the physical basis for the processes going on in the atmosphere lead to involved discussions and arguments so that such attempts are limited to those features which are worth the valuable time required for them. Those features which, from the analysis, provide indications that extrapolation is a good prognosis, plus those features which show definite indications of persistence, frequently make up a large portion of the chart.

The semipermanent and characteristic points and lines serve as a starting point for the prognosis. Persistence is usually the best forecast in regard to the semipermanent systems: the Aleutian low, the oceanic highs, etc. However there is always the question of whether to move them or to fill or deepen them. A deep cold low, dominating a large area of the map, and the accompanying peripheral flow determine not only the features of the area of the low but also the course of any perturbations coming into the belt dominated by the

1. The author is greatly indebted to Mr. Charles M. Lennahan and Mr. J. R. Fulks of the Analysis Center for the outline and description of the procedures used there for the preparation of the 700-mb prognostic charts.

peripheral flow. The speed of these perturbations may also be inferred so that the pattern of the region in the vicinity of their prognosticated locations may be deduced. In this way persistence not only controls its own area but extends its influence and prognostic value to adjoining regions and, with diminishing influence, to more distant regions. The dominant warm highs have a similar role in the prognosis since they persist and tend to be blocking highs. Any cold trough which is strong enough to move a semipermanent warm high is usually so obviously strong that at least a slight movement of the high will be included in the prognosis.

As in all forecasting, the first step in pure extrapolation is to find some element that is conservative enough on the particular occasion to be used as a starting point. This element may very well be different from the one used on the previous day and may even be different *each day* for a week or more. Thus the speed of the front, the speed of the low, the speed of the isallobaric trough, etc., may be different from the corresponding points and lines of a high or ridge, and one may be conservative when the others are not.

With a sequence of good analyses as a basis, the prognosticator extrapolates the conservative characteristic points and lines, at uniform speed if they have been moving uniformly—with positive or negative acceleration if they have shown signs of accelerating. Trends have to be checked closely so that the beginning of transition periods between high- and low-index conditions can be detected and the prognosis adjusted to conform to the increase or decrease in displacement. A blocking high, whether one of the warm oceanic highs or a cold high over the continent, has to be considered in its effect on the flow.

The complex interrelations between sea-level isobars and 700-mb contours make any feature on the sea-level chart important insofar as it affects the 700-mb contours. Conversely, since one of the forecaster's main interests in the 700-mb prognosis is its value as an aid in forecasting surface wind, weather, and temperature changes, any important feature on either the surface or the 700-mb chart is usually an important feature on the other. It should not, however, be implied that the 700-mb prognosis is strictly dependent on the surface prognosis; often the reverse is true because some features aloft can be prognosticated with greater certainty, and in such cases the upper-air prognosis will influence the surface prognosis.

Because of the close coordination required between the surface and the 700-mb prognoses, it is difficult to separate completely the factors used in making the one from those used in making the other. One of the best aids that the person responsible for the 700-mb prognosis can have is a competent surface prognosticator working with him. A good surface prognosis is the best way to point up the inconsistencies in the 700-mb prognosis.

The 700-mb prognosticator must be familiar with the sea-level analysis and this familiarity influences him not only in the movement of systems at 700 mb but also in the deepening and filling of the systems. The 700-mb and sea-level analyses and prognoses require parallel and coordinated treatment. It is inherent in the whole prognostic procedure that the surface chart tends to be the dominant one, because the surface network of stations is much denser and provides more frequent reports than the upper-air network. Therefore, there is a tendency to start from the surface when making a 700-mb prognosis, and final revisions are usually made on the basis of the latest three-hourly map. Any system which is important enough to be included in the 30-hr surface prognosis is of sufficient magnitude to affect, even though slightly, the 700-mb contours.

The close connection between the sea-level pressure pattern and the 700-mb surface makes many studies of sea-level systems applicable indirectly in the prognostication of 700-mb contours. Thus Bowie and Weightman normals, C.I.T. types, Palmer's method, analogues, etc., all contribute to the 700-mb prognosis. However, here again good judgment is the prime factor; there is always the question of how much such objective measures should be modified or ignored. They cannot be used blindly. Considerable qualitative use is made of the characteristic behavior of storms in a typical sequence. The path and speed of the storms, the isobar and contour patterns, all contribute to the final version of the prognosis.

Any deepening of the surface systems will usually cause a corresponding deepening of the 700-mb systems. Therefore, any kinematic or dynamic effects which are known from experience or from theory to favor deepening of surface systems will have to be considered in making a 700-mb prognosis. Consideration must be given to such kinematic processes as the converging of two katallobaric systems or of the movement of a low in such a direction as to take it under progressively lower contours at 200 mb, and to such dynamic processes as the converging of fresh cA and mT air masses.

Sometimes an inactive front (the most pronounced cases are on the Texas and Louisiana coasts) will become very active and rapid cyclogenesis will take place on it because of the approach of a cold trough at 700 mb or higher and the subsequent coupling of the cold trough with the sea-level cold front. This coupling has the effect of steepening the slope of the cold front and of increasing its vertical extent. As a result, the total mass of air involved and the total temperature difference are much greater than those involved in the original front. The deepening storm quickly affects the 700-mb contours and a very important feature of the chart is created. These storms usually move fast since they are generated in well-developed upper troughs.

A frequently recurring feature is the movement of sea-level lows and highs into the region of the mean trough. This process usually causes a mutual deepening of the sea-level and of the 700-mb troughs; similarly it causes weakening of the sea-level high and a corresponding weakening of the 700-mb ridge.

Frequent use is made of the 200-mb contours in forecasting the deepening of surface lows. Often the high-level contours will be only slightly influenced by the surface system, and if the future position of a surface low is known, it is found from experience that when the low moves into a region of lower 200-mb height, it will deepen by approximately 60 per cent of the amount which would result from projection onto the ground of the change in height of the 200-mb level above the surface low. This effect causes a corresponding change in the 700-mb surface.

Contrary to the general rule that a fast-moving low will not deepen, lows in well-established troughs with a strong gradient on the warm side will move rapidly and if the movement has a good component northward, the storm will deepen. This feature of movement or steering with the upper winds is generally known but it has many modifying factors.

Cold air moving into the region to the rear of an upper-level trough will tend to cause the trough to retrograde. The timing of the action of the mechanism is of the utmost importance. If the initial trough is in a position where it will move (*i.e.*, where topographic and kinematic reasons favor its continued movement), the cold air will tend only to make the flow more westerly and cause the trough to move faster. Ordinarily, however, the cold air will cause the trough to move more slowly or even to retrograde.

Frequently supergradient winds are noticed, or strong winds

in a field where the contour pattern is expected to move slowly with respect to the winds, so that the strong winds will soon reach that part of the field where the gradient is much weaker than would be necessary to balance the velocity of the wind. In these cases the winds will tend to turn to the right because the Coriolis force exceeds the pressure-gradient force, and air will cross the contours toward higher values with a consequent decrease in speed. Usually the speed *decreases* more than enough to balance the gradient because the momentum of the parcel carries it beyond the point of equilibrium so that the parcel is turned to flow toward lower heights with an *increase* in speed. This cyclonic trajectory has the effect of forming a new trough or of deepening an already existing trough and intensifying the adjoining ridge; it also causes stationary or even retrograde conditions to prevail in that area of the map.

The use of the jet stream in the prognosis is very qualitative. Although the jet is at a much higher level, its effects are apparent in the stronger flow induced at 700 mb. Thus from a consideration of the confluence theory of jet-stream formation, it is apparent that any system moving into the vicinity of the strong flow will accelerate and usually will not deepen. Thus the effects of these storms on the 700-mb contours are limited to their contributions to the confluence and the speed of the jet. Also any storm moving in the vicinity of the jet will not cross it but will tend to move with it.

The 24-hr height changes at 700 mb are used in much the same way as sea-level pressure changes. Here again, however, the interrelation between the 700-mb and the sea-level charts must be studied in order to determine some criterion for using the height changes rationally. Any conservative feature common to both charts, whether of movement or of configuration, is helpful in deciding how much and where to apply the changes.

Along with the dominant role played by the surface analysis and the surface prognosis in the making of the 700-mb analysis and prognosis, it is important to note that the thickness chart constitutes an important check on the consistency of the prognoses. (The 1000-mb prognosis is quickly made by direct extrapolation from the sea-level prognosis.) Thus in the absence of strong vertical motions over the prognosticated area, the temperature field should change in the direction and with the speed of the flow in the "thickness" layer. The thickness lines are usually more conservative than the contours or than the sea-level isobars.

Lennahan concludes that it would certainly be pleasing to all if some good theoretical or objective method could be developed for preparation of the prognoses. However, for the present at least, it seems that we must be satisfied with our "cut and try" methods for short-term forecasts. In a review of Scherhag's new book,[2] E. Hovmöller remarks: "A theoretical meteorologist would probably, after reading this section [G of first part], feel discouraged once more by the contrast between the magnificent building of theory itself and the modest, almost crippled part of it which is thought to be applicable in the weather service." It is unfortunate that this is also equally true of so much of the recently developed meteorological theory.

Although, quantitatively, the 700-mb techniques appear to be equal to those available for the surface prognostic charts, and the higher-level chart is somewhat more conservative, most forecasters believe that the 700-mb prognostic charts are not as satisfactory; however, this belief is difficult to substantiate. The principal weaknesses are the forecasting of the development of closed lows and their future movement, the movement and changes in intensity of minor troughs, and the emergence of major troughs from mean troughs. The reasons for these inadequacies may be (1) nonutilization of all techniques, (2) lack of experience, (3) preoccupation with surface prognostic charts and with mean troughs and ridges, and (4) lack of satisfactory techniques for dealing with closed circulations. There is also considerable evidence of confusion in defining major, mean, and minor troughs. When does a minor trough become a major trough? The consideration of major troughs and ridges as synonymous with mean troughs and ridges by many forecasters and prognosticators is believed to be erroneous. There appear to be certain large-scale controls, not very well understood, which during the persistence of any given regime tend to result in trough (ridge) formation or intensification (weakening) repeatedly at some one geographical location. So long as the regime persists—and it may change suddenly—pressure falls (rises) intensify (weaken) as they approach the region of the mean trough (ridge). The result is a mean trough or ridge in the favorable location, but troughs or ridges may move out of the mean positions and, apparently depending upon the wave length, become migratory major troughs or ridges. The crux of the forecasting problem in such cases is whether troughs and ridges emerging from the mean positions will attain major intensity or remain minor waves.

Recent work by Charney [13, 14] and collaborators gives some promise that the new electronic computing devices will eventually provide assistance in prognosticating constant-pressure surfaces.

Preparation of the Surface Prognostic Chart. In the preparation of the surface prognostic chart, the pressure field is given primary consideration since an accurate pressure prognosis is the synthesis of all computations by, and experience of, the forecaster. The customary procedures used in the preparation of this chart include:

1. Determination of the movement of fronts and pressure systems. The six-hourly positions of significant fronts and highs and lows are plotted for the past 12 to 24 hr or more, and changes in direction and rate of movement are carefully noted. As a starting point, highs and lows might be typed in accordance with, and the 24-hr average direction and rate of movement ascertained from, some previous statistical study such as that of Bowie and Weightman [7] for the United States. From the previous history of the system, an immediate deduction can be made whether it is operating under the average steering indicated by the study. A second position may be obtained by modified extrapolation, sometimes called the "path" method. The six-hourly projected positions should be further modified in accordance with changes indicated by the general synoptic situation. Another predicted frontal position

2. Scherhag, R., *Neue Methoden der Wetteranalyse und Wetterprognose*. Berlin, Springer, 1948. Reviewed in *Tellus*, Vol. 1, No. 4, pp. 70–74 (1949).

can be obtained by the geostrophic wind method, which usually yields good results with cold fronts but must be used with caution with warm fronts. Petterssen states that warm fronts will move with 60–80 per cent of the geostrophic wind, while Byers in the North Pacific observed warm fronts moving with 50 per cent or less of the normal component of the gradient wind.

Further determination of the movement of fronts and pressure centers should be obtained by the Petterssen extrapolation formulas [42, Chap. IX]. These formulas give excellent results over oceanic areas, good results over homogeneous land areas, but rather poor results over mountainous sections. Since the movement of fronts and pressure systems is almost always changing with time, the formulas rarely hold good longer than 24 hr. After that time, the forecaster must rely on the normal evolution of pressure systems and the large-scale factors indicative of acceleration or deceleration. The direction and rate of movement of pressure systems as indicated by the steering shown by the upper-air charts—current and prognostic—should be determined. In computing the displacement of pressure systems, the forecaster should be careful that the estimated displacement of each individual system agrees logically with the simultaneous displacement of adjacent systems. In the United States, errors occur most frequently when (1) rapidly moving occlusions, in a period of high index, cross the Pacific coastline with at least moderate intensity but become damped out by the time they should have reached central North America, and (2) a storm with a marked allobaric minimum reaches the North Pacific Coast during a period of moderate or high index simultaneously with the development of a rather strong but poorly organized depression in the Great Plains and the Mississippi Valley. In the latter case, marked anticyclogenesis sets in immediately over the eastern Rockies and the Great Plains and the low frequently moves off more rapidly than expected.

A forecast rule in general use states that wave cyclones will move parallel to the warm-sector isobars when the latter are parallel to the isotherms and this movement is not inconsistent with the pressure tendencies. As a rule, in a family of lows, each low will develop a course farther south than its predecessor but, in strong northwest steering, successive lows usually trend toward a more northerly course.

Thus, a number of approximations of prognostic positions of fronts and pressure systems can be obtained. The results should be compared and a final approximation derived which, largely on the basis of experience, appears most logical from the physical processes evidenced by the most recent observations.

2. Forecast of changes in intensity of pressure systems. The forecaster will, of course, keep in mind the normal deepening and subsequent filling of the typical cyclone as it passes through its life cycle. Cyclones developing in middle latitudes will be attended by maximum deepening when the northward component in direction of movement is greatest. The relationship between direction of movement, intensity of meridional flow, and availability of moisture is obvious. According to Petterssen, the rate of deepening remains constant as long as a warm sector remains on the ground and for 6–12 hr after occlusion sets in. Changes in the three- and twelve-hourly pressure tendencies should be watched carefully since they provide a basis for estimating the rate of deepening and filling.

Intensification or weakening of pressure systems can be detected by inspection of central pressures in the systems on the last several regular and interim synoptic charts, and by the position of the maximum isallobar relative to the center, correcting for the diurnal variation in pressure.

Some significant rules for determining filling or deepening have been summarized by V. J. and M. B. Oliver [40] as follows:

a. A wave will deepen or a front become more pronounced if the 10,000-ft wind field possesses cyclonic vorticity and the wave has a temperature contrast through it.

b. A wave will weaken and a front will undergo frontolysis if the 10,000-ft wind field possesses anticyclonic vorticity.

c. If there are several waves along a front, the one with the most intense cyclonic vorticity aloft will develop at the expense of the others. This is usually the one nearest the axis of the trough aloft (at 10,000 ft).

d. Waves at the surface will deepen if the 700-mb contours diverge ahead of them

e. Waves at the surface will weaken if the 700-mb contours converge ahead of the wave.

Austin [1] found no definite relationship between the lapse rate of temperature above the center of cyclones and their future change in intensity. In the same study he tested changes in cyclone intensity with the spacing of isotherms at 10,000 ft and for the layer between 700 and 500 mb. That cyclones are observed in regions of strong temperature contrast was confirmed; otherwise no definite correlation was established. In this study, cyclones apparently were not classified according to the stage of development.

3. Determination of cyclogenesis, anticyclogenesis, frontogenesis, and frontolysis. Cyclogenesis, or the formation of wave cyclones on stationary or slow-moving cold fronts, is one of the more difficult problems facing the forecaster. There are certain preferred areas for wave development, such as the southern portion of mountain ranges where deformation of the cold front is induced. Under certain conditions, flat waves emerge from this region every 24 hr or so and move rapidly in a general easterly or northeasterly direction. These cannot be forecast in detail more than 12 hr in advance, and for longer periods precipitation should be forecast without attempting to define times of beginning and ending.

Waves form most frequently on stationary fronts or slowly moving cold fronts. The formation of a wave may be indicated by a new surge of pressure rises in the cold air, from the general pressure field, deformation of the front as it passes over mountain ranges, and cyclonic circulation such as may frequently be observed

on the Texas coast. Further deductions can be made from the distribution of clouds and precipitation.

The solenoidal field on the east coast of continents, in the Northern Hemisphere, is favorable for wave development in connection with stationary fronts. Techniques for handling cyclogenesis of this type have been described by Miller [35]. Byers postulates that no really primary cyclone forms entirely independently of other nearby disturbances and this appears to be correct for extratropical regions. The arrival of even a weak fall in pressure over a stationary front will almost always result in strong cyclogenesis.

Cyclogenesis tends to occur where there is a concentration of isotherms aloft (5000–15,000 ft) which provides considerable potential energy, and the wind field is favorable (*i.e.*, the wind blows across the isobars). Cyclogenesis (anticyclogenesis) tends to occur on the warm (cold) side of an area where isotherms are packed.

Baum [2] has described the Scherhag divergence theorem and states, on the basis of some informal experimentation with it, that it merits a trial by forecasters in the United States.

Anticyclogenesis can be detected by the pressure tendencies. For the forecasting of anticyclogenesis upstream, the transition from a cold to a warm high with resultant blocking should be carefully watched.

Frontogenesis and frontolysis are not, as a rule, particularly troublesome although there is, perhaps, a tendency to expect frontolysis too quickly. Over land areas, the forecaster must frequently deal with warm frontogenesis dynamically induced in the lee of mountain ranges and, less frequently, developing between two highs. The latter usually has some previous history. Important cold frontogenesis will occur in polar regions with the development and initial southward surge of arctic air masses.

The prognosticator finally completes the approximations of the future positions of fronts and the positions and intensities of the pressure centers. He then tests the consistency of these approximations with the upper-air synoptic and prognostic charts and the indicated extrapolation of mean isotherms between the 1000- and 700-mb surfaces. If inconsistencies appear, one or more of the factors used in the preparation of the surface charts has been incorrectly calculated or interpreted. Inconsistencies must be resolved by further checking or by according the greatest weight to the factors of greatest certainty.

In an effort to derive an objective method of forecasting the surface pressure pattern, Haurwitz and collaborators [28] investigated a number of procedures based on advection. Isopycnic lines were drawn for five levels between sea level and 14 km and forecasts of the density changes at these levels were prepared on the hypothesis that air moves with the geostrophic wind velocity, preserving its density. After allowance had been made for the thickness of each layer, the density changes were added together to obtain the sea-level pressure change. Vertical motions were not considered in the study. Correlation coefficients of significance were not obtained. This does not imply, however, that the subjective evaluation of advection in forecasting pressure change is not a helpful procedure. More recent research by Houghton and Austin [30], while furthering our knowledge of the mechanism of pressure changes, has failed, so far, to provide new tools for forecasting pressure changes.

No purely objective techniques are available for the preparation of prognostic charts and thus procedures remain generally subjective.

Vederman [55] has listed the techniques used in the preparation of prognostic charts and includes (1) vertical extent of highs and lows, and (2) temperature and height changes at various constant-pressure surfaces in addition to those discussed in this section. Some other procedures developed by American meteorologists have been described by Fulks and collaborators [23].

STEPS IN FORECASTING THE WEATHER

Preforecast Study. The organization of forecasting at a district forecast center should provide for at least two days' study of past maps each month. There are important month-to-month and seasonal variations in weather sequences, frequency of certain weather types, depth of surface heating, effect of nearby water areas, and many other similar influences which the forecaster must keep in mind. The forecaster can best integrate them in his mind by, for example, at the end of the month, running through several past years' charts for the following month and preparing practice forecasts for one or two areas or cities in his district.

Preliminary Steps in Forecasting. A certain amount of preparatory work is required for a forecaster when coming on duty. This may include:

1. Inspection of weather charts prepared since he was last on duty, or if he has been absent for an extensive period, for the last four to seven days, in order that he may bring himself up to date on the prevailing type of weather.

2. Briefing by the forecaster going off duty, who describes and explains the weather now in progress, the forecasts in effect and the basis for them.

3. Analysis of radiosonde observations from stations in the forecast district and in adjacent areas from which weather is approaching, for the purpose of ascertaining stability, cloud decks, freezing level, temperature and moisture changes, structure of moist layers, and indicated maximum temperature.

4. Inspection of the 850-mb chart for moist tongues, the general moisture pattern, advection of warm and cold air, and upslope areas.

5. Analysis of the 700-mb chart for depth of moisture, trends toward increased zonal or meridional flow, intensification of troughs and ridges, possible development of closed circulations, advection of colder and warmer air, pools of warm and cold air, and steering; checking the 700-mb prognostic chart from the weather central and modifying it as indicated.

6. Checking of the 500-mb and 200-mb charts, particularly the 500-mb, for the same features as given above for the 700-mb chart, except for moisture, which is not especially significant at the higher elevations. A

study of wave lengths with reference to the speed of movement of contour systems is especially important at the 500-mb level since this level is nearest the level of nondivergence. Also, when vorticity-trajectory computations are not made, some subjective study of the 500-mb chart with respect to constant vorticity trajectories is possible and helpful in forecasting movements and other developments.

7. Inspection of the latest pilot-balloon charts for trends and changes during the preceding six hours and for computation of the 6-hr trough and ridge movements. The forecaster should be familiar with the diurnal variation of winds under 8000 ft.

8. Checking the analysis of the last six- and three-hourly surface charts with the latest hourly sequences, noting recent frontal passages and movement of precipitation areas.

9. Reading the latest district forecasts from all available forecast centers, noting areas where precipitation and any unusual weather are forecast as well as any weather that does not seem warranted by the prognostic charts, and attempting to rationalize the basis for the differing forecasts.

10. Reading the synopses and forecasts from the various airway forecast centers, noting rate of movement given for fronts and pressure centers in the area where the forecast is made and also noting forecasts of unusual weather. Forecast centers in mountainous and distant areas are usually in a better position to determine these facts accurately than are remote centrals or forecast centers.

11. Inspecting the surface prognostic chart from the weather central and noting deviations from it by the preceding district forecaster and probable deviations from it by district forecasters in other forecast districts as indicated by the district forecasts. This check should be repeated when the new six-hourly synoptic chart is completed and analyzed.

Intermediate Steps in the Preparation of the Forecast. These may include:

1. Analysis of the new six-hourly synoptic chart, using weather-central analysis, modifying it in accordance with more detailed observational data which the forecast center may have in and near its own district.

2. Analysis of the pressure-change chart, forecasting future positions of each isallobaric center.

3. Using the 24-hr prognostic chart from the weather central as a basis, checking the positions and intensities of fronts and pressure centers, making such revisions as are indicated by the latest surface and upper-air charts, using techniques described earlier (pp. 750–758).

4. Final check based on subjective evaluation of broad-scale influences of centers of action, zonal indices and blocking highs.

5. Final reconciliation of all conflicting indications, objective, subjective, dynamical, and empirical. Weather processes are logical, and conflicting indications are evidence of an error in computation, in interpretation of the data and charts, or in reasoning. The original error may have been made by the observer, the computer, the analyst, or the forecaster but, in most calculations and chartwork, the error should be fairly obvious from the large amount of reasonably accurate information available. The forecaster should make the strongest possible effort to harmonize the prognostic information derived from a fairly large number of sources rather than to reject entirely a portion of it. Recomputation and re-evaluation may be necessary but, usually, the time required is well worth while. Most often a forecast error arises in the subjective weighting of the several factors from which the forecast is derived.

Steps Recommended by Petterssen. The following steps have been listed by Petterssen [42, Chap. XI]:

1. Displacement of pressure systems, fronts, etc.
2. Forecasting deepening and filling.
3. Determination of whether new systems will form.
4. Readjustment of displacements.
5. Determination of the position and properties of air masses—detailed analyses of clouds, hydrometeors, adiabatic charts, moisture patterns aloft. Constant-pressure charts will reveal physical and kinematic conditions of the air masses in question.
6. Determination of changes in air masses as they reach the forecast district. Possibilities of cooling, heating, depletion or addition of moisture, subsidence, etc.
7. Modification of local influences, mountain ranges, valleys, lakes, land and sea breezes, and other coastal effects.
8. Last re-examination: What can upset the forecast?
9. Wording of the forecast—clear and unambiguous —degree of certainty.

Influence of Main Centers of Action. By following the steps outlined above, the forecaster can, with the primitive tools at his disposal, complete the pressure prognosis for the first 24 hr of the forecast period. Because of acceleration and deceleration factors which are constantly operating, extrapolation becomes a progressively poorer tool with time. For periods in excess of 24 hr, the forecaster must expand his horizon in space and time. Data describing the instantaneous state of the atmosphere are inadequate to define, in any detail, the evolution of developments which may significantly affect the weather beyond 24 hr. Large-scale circulation changes cannot be ignored and important developments in one portion of the hemisphere may be compensated for in another far away. The forecaster must not become preoccupied with the latest hourly sequences or even the last six-hourly weather map.

The influence of centers of action was pointed out as early as 1881 by Teisserenc de Bort. The forecaster must keep close watch on deviations from the normal positions of the semipermanent areas of high and low pressure and the resultant position of the mean troughs and ridges and carefully consider their probable effects on migratory depressions and the preferred areas of cyclogenesis and anticyclogenesis under the prevailing type.

The centers of action are a conservative factor in the prevailing weather, that is, there is a tendency for a prevailing weather type to continue. An example of the

persistency of wet and dry weather has been given by Newnham [39] for Kew Observatory in England and Aberdeen in Scotland, as shown in Table V.

The forecaster should prepare a skeleton prognostic chart for each 24-hr period after the first 24-hr period,

Table V. Probability of a Rain Day

Station	Number of preceding successive fine days								
	1	2	3	4	5	6	7	8	9
Aberdeen	0.50	0.41	0.37	0.39	0.37	0.36	0.37	—	—
Kew	0.45	0.34	0.36	0.32	0.26	0.27	0.27	0.22	—
Station	**Number of preceding successive rain days**								
	1	2	3	4	5	6	7	8	9
Aberdeen	0.67	0.70	0.76	0.70	0.66	0.67	0.72	0.75	0.78
Kew	0.56	0.61	0.61	0.64	0.64	0.67	0.73	0.69	0.70

if one is not available from the weather central. The actual timing of frontal passages, wave development, precipitation surges and similar phenomena becomes increasingly difficult with time and, consequently, the forecast should be couched in more general terms.

Usefulness of Various Charts and Techniques. An analysis by Elliott, Olson, and Strauss [21] of questionnaires on the usefulness of certain charts and forecasting techniques returned by some 1460 forecasters in the military, civilian, and private weather services indicated the percentages of forecasters finding the several charts and techniques "often useful" or "occasionally useful" as given in Table VI. One may safely say that charts and techniques only "occasionally useful" are not regularly used in the preparation of forecasts. The question may be asked, Are forecasters using all the most valuable available techniques? If not, is it because of lack of clerical assistance, lack of time or lack of knowledge of how to use them, or do the few simple extrapolation and stability estimation techniques provide the same accuracy as additional checks using more complicated techniques?

Table VI. Usefulness of Charts and Techniques

	Often useful	Occasionally useful
Charts		
700-mb chart	95.3	3.0
500-mb chart	57.5	26.2
850-mb chart	37*	—
300-mb chart	22*	—
200-mb chart	16*	—
Cross sections	22.8	21.0
Thickness charts	10.4	9.6
Mean virtual temperature charts	5.0	4.2
Isentropic chart	2*	4.9
Adiabatic diagrams	92.0	4.0
T-ϕ diagrams	4.2	2*
Rossby diagrams	8.6	13.7
Other charts or diagrams	28.8	—
Techniques		
Petterssen's kinematic technique	10.3	26.4
Steering of surface system along upper-air flow	76.2	19.1
Extrapolation based upon history	81.0	15.1
Frontal movement from gradient winds	61.6	31.3
Upper-level isobar-isotherm relationship for movement of waves	37.6	36.1
Upper-level isobar-isotherm relationship for deepening or filling	53.5	29.4
Average cyclone and anticyclone tracks and movements	32.3	42.0
Analogues	4.7	17.5
Weather types	23.6	31.1
Rossby's constant-vorticity trajectory	2*	7.9
Other techniques	21.5	—

* Approximate per cent.

Prognosis of the Weather. The forecasting of the various weather elements is the last step in the preparation of the weather forecast but it is the most important and the most difficult. An understanding of the current weather, together with the surface and upper-air prognostic pressure patterns, forms in a general way the basis of weather forecasting. Tests have shown that forecasters demonstrate but little skill in forecasting the various weather elements when given a "perfect" prognostic pressure pattern alone.[3] One must again emphasize the *individuality* of each day's synoptic chart with the infinite variations of lapse rates, temperature and moisture, convergence, radiation, and all the other factors involved in future weather.

Cloudiness and Precipitation. Following the development of the concept of air-mass analysis by the Norwegian meteorologists, J. Bjerknes [4] in 1918 first described the arrangement of clouds and precipitation around a cyclone. The classical arrangement of hydrometeors around an idealized cyclone was described by Bjerknes and Solberg [5] in 1921 and was extended in 1922 [6] to include all stages of cyclone development. Since the ideal cyclone is rarely present on the daily weather chart, the marked variations in stability and moisture in the air masses normally found around the cyclone are of paramount interest to the forecaster. These elements frequently possess little relationship to the isobaric pattern. In many areas, the forecaster is faced with the complicated problem of determining where, as well as when, precipitation will develop in various sectors of a cyclone. No very satisfactory techniques are available for forecasting the transition of a dry to a wet trough other than by a rather subjective evaluation of moisture and stability factors.

In summer, particularly, the precipitation pattern is even more imperfectly associated with frontal and cyclonic systems. Pure air-mass thunderstorms may be forecast with fair success from the thermodynamic diagrams, but the general shower and thunderstorm activity, often nocturnal in nature, over large areas in middle latitudes, is very difficult to handle. Means [33] has suggested techniques for forecasting nocturnal thundershowers in the Midwest which show a slight increase in skill over more subjective methods, but the mechanics of the nocturnal thunderstorm in the Great Plains and upper Mississippi Valley are still imperfectly

3. It is not known whether, in this experiment, forecasters had access to the preceding weather charts. In any case it is not intended to imply that the prognostic pressure chart is not useful. Indeed, a good prognostic pressure chart is one of the most useful tools available to the forecaster.

understood and the forecasting of this phenomenon is still unsatisfactory. Verification of thunderstorms even in the relatively short-range airway forecasts (12 hr) is occasionally less than 20 per cent.

This summertime type of precipitation is of major economic consequence over many of the most important agricultural areas in the entire world and yet there is no comprehensive and satisfactory description of any reliable technique for forecasting it. Quantitative precipitation forecasts are needed by river engineers, hydroelectric power companies, and many other interests in commerce and agriculture. A rather primitive procedure for a forecast of this type has been devised by Showalter [50] based on the amount of moisture which will enter a given region and the unprecipitated amount likely to leave it. Verification is unsatisfactory since no precise methods exist for a rapid quantitative calculation of effective convergence over specific areas. The convergence of flow over mountain ranges is more susceptible to computation.

Klein [31] has correlated precipitation anomalies and the five-day mean 700-mb chart with considerable success but verification dropped from about 66 per cent on past weather charts to 25 per cent when his techniques were used on prognostic 700-mb charts. Although the technique was derived from five-day mean charts, it appears equally applicable to daily forecasts.

Precipitation results from the lifting of saturated air and is therefore associated with horizontal mass convergence in lower levels and horizontal mass divergence at higher levels, of which some of the associated factors are:

1. Frontal lifting, upslope or upglide.
2. Surface friction.
3. Topography.
4. Thermal instability.

V. J. and M. B. Oliver [40] have collected a number of principles of practical use in forecasting, which include:

1. Cloudiness and precipitation are prevalent under cyclonically curved isobars aloft (about 10,000 ft), regardless of the presence or absence of fronts on the surface chart.

2. In a cold air mass, the instability showers, cumulus, and stratocumulus clouds will be found only in that portion of the air moving in a cyclonically curved path.

3. In a warm air mass moving with a component from the south, cloudiness and precipitation will be very abundant under a current turning cyclonically or even moving in a straight line. (The importance of trajectories with increasing cyclonic curvature in producing convergence and heavy precipitation is stressed by all writers on this subject.)

4. Elongated V-shaped troughs will have cloudiness and precipitation in the southerly current in advance of the trough with clearing at the trough line and behind it.

5. Cold fronts will produce no weather when the component of the wind perpendicular to the front increases with height through the front.

6. If the 10,000-ft flow is parallel to the cold front, the front will be active and cloudiness and precipitation will extend as far behind the front as this condition obtains.

The applicability of all these rules is subject to the normal variations of moisture and stability.

Fog. The physics of fog formation have been discussed by Petterssen [43]. Fog is the subject of a separate article by J. J. George in this Compendium.[4] Techniques developed during the past two decades by George [25], based largely on analogues and statistics, provide the most practical methods of forecasting fog in middle latitudes.

Temperature. The main factors governing local temperature change in the free atmosphere are horizontal advection and vertical motion. The minimum temperature may be predicted by determining the location of the air expected over the station the following night and forecasting any indicated modification. The dew point of the expected air mass is a helpful indicator. Consideration must be given to modifications resulting from emergence of air from snow-covered to bare ground, trajectories over water, and such factors as wind and clouds. With clear skies and calms, the dew point of an air mass falls somewhat during the night as moisture is extracted from the air through the formation of dew.

The maximum temperature may be predicted from the sounding in the air mass expected to be over the station during the day. Depending upon the season, the lowest 800–1400 m will be warmed by heat transferred to the air from surface insolation. Although more refined methods are available, a satisfactory approximation of the maximum temperature may be obtained by following the dry adiabatic from a point on the sounding at the top of the area expected to be warmed down to the surface and picking off the temperature. Corrections must be applied for any indicated cloudiness and precipitation. In winter, diurnal insolation may have difficulty in overcoming even very shallow cold air inversions.

Wind. The gradient wind may be determined from the prognostic surface pressure pattern. The proportion of the gradient wind actually realized on the surface varies from 40 to 80 per cent or more over water with the variation dependent upon a number of factors, of which the stability of the air is most important. Over land areas the frictional effect is greater.

Synoptic situations, mostly in spring, favorable to tornado formation may be recognized by the forecaster, but any precise definition of the areas where tornadoes may occur has, so far, been impracticable. Recently E. J. Fawbush and R. C. Miller, in an unpublished paper,[5] have claimed some progress in defining the geographical areas in Oklahoma where tornadoes may occur by locating the intersection of areas of greatest instability, increasing dew point, narrow band of high

4. Consult "Fog" by J. J. George, pp. 1179-1189.

5. (*Added in press.*) These results have now been published in an article by Fawbush, E. J., Miller, R. C., and Starrett, L. G., "An Empirical Method of Forecasting Tornado Development." *Bull. Amer. meteor. Soc.*, 32: 1–9 (1951).

winds aloft (40 knots or more), and the trigger action associated with an approaching cold front. Tornadoes appear to move with the speed and in the same direction as the thunderstorms with which they are normally associated, that is, with the winds between 6000 and 12,000 ft. These winds will normally be from the southwest.

Verification. The primary purpose of any forecast verification system is to determine whether satisfactory standards of forecasting are being maintained, and, secondarily, to ascertain the relative skill of forecasters and forecasting candidates. The system should be rational, fair to the forecaster, and should not require more than a few minutes of his time in paper work. If too many elements are verified, too much smoothing will result and final values will have little significance. Except for very short-term forecasts, spot-check verification (*e.g.*, verification of specific elements at exactly 0200, 0400, 0600, etc.) should be avoided, since, after eight hours, values based on verification of this type will show no significant differences between good and mediocre forecasters, because of the variability of weather. The longer short-term forecasts (12–48 hr) should not be verified by methods involving a refinement of detail beyond the current ability of the forecasting profession. Verification of trivia should be avoided or at least handled with intelligence. One system of verification currently in use awards the forecaster 100 per cent for a measurable amount of precipitation (0.01 in.) and 0 per cent for a trace when precipitation has been forecast. In many countries a measurable amount is 0.1 mm, a unit only four-tenths of the one used in the United States. Over large areas of the United States, precipitation amounts of either a trace or 0.01 in. comprise 50 per cent or more of the total periods of precipitation, and, in a large proportion of these cases, it is fortuitous whether the observer records a trace or 0.01 in. Yet in this system of verification, the range in skill score is almost entirely dependent upon the forecaster's luck with these very trivial precipitation amounts.

Indeed, no substitute has been developed in the United States which is an improvement over the old U. S. Weather Bureau verification system. If a sufficient number of forecasts are included in the verification, chance coincidence and normal expectancies need not be considered since contributions from these sources will become equal for everyone and the differences in the final score will represent a satisfactory approximation of the differences in skill.

STATISTICAL AIDS IN FORECASTING

Objective Forecast Aids. Gringorten [27] defines an objective forecast as one that is made without recourse to the personal judgment of the forecaster. He further states meteorology is much too complex to allow one to believe that objectivity in forecasting will, eventually, completely replace subjectivity. To date, wholly objective forecast techniques are very rare and have shown improvement over accepted subjective methods only when the latter are exceptionally inadequate and verification is unusually poor, such as for certain types of precipitation forecasting, or when the forecaster is relatively inexperienced. Objective methods for forecasting minimum temperatures, in which subjective selection of certain parameters if often required, have at times equaled subjective methods but have rarely surpassed them. Vernon's study [56] of winter precipitation at San Francisco is an excellent example of a useful and reasonably objective forecasting technique. The study of wintertime precipitation for Washington, D. C., by Brier [9], while a commendable attempt to attack a difficult forecasting problem, cannot be regarded as particularly successful in providing the forecaster with an improved forecasting tool. Forecast methods of this type tend to meet with passive resistance from forecasters, who feel that the derived formulas and diagrams oversimplify the problem and that other contributory variables are frequently neglected.

Climatological-Statistical Forecast Guides. From time to time, and particularly in recent years, forecasters have been promised climatic guides which statistical climatologists claim will assist and improve forecasting. So far, few have been forthcoming, possibly because it is now realized that their value may have been overemphasized. Local forecasters soon know the earliest and latest dates of killing frost, after answering a dozen inquiries on that question, and district forecasters learn climatic normals and extremes of their forecast district as part of their training. It does not appear that any considerable amount of time and expense for this purpose is justified on the basis of results to date.

Climatological summaries were of considerable value during the recent war in forecasting for foreign areas where few or no weather observations were obtainable and, of course, are of great value for other purposes.

Tests of Empirical Forecast Rules. A large number of empirical rules have been developed and formulated since the beginning of forecasting. Some, such as those of Chromov [15], have been given wide distribution, but most forecast centers have their own collection in one form or another. Too many such rules are only confusing to the forecaster who, in the limited time available, may be unable to recall those applicable to the synoptic situation at hand. Rules may be classified according to seasonal, local, or broad-scale applications, types, etc. The value of many empirical rules might be enhanced by subjecting them to objective tests with further stratification.

ORGANIZATION OF FORECASTING

It seems doubtful that the accuracy of weather forecasting can be improved materially within the near future with present or anticipated new techniques. Some radically different approach to short-range forecasting will be required if any marked improvement is to be effected. Some significant, although slight, increase in forecast accuracy may be possible with feasible changes in forecast organization. Because of economic necessity, forecast organization in many weather services leaves much to be desired.

It is beyond the purview of this article to describe in any detail how forecasting should be organized, but all forecast organizations should provide for the following:

1. An adequate method of selecting forecasters. Demonstrated interest in forecasting, ability shown in a practice forecast program, temperament and general intelligence, among other factors, should form the basis for selection.

2. Verification of forecasts made by regular forecasters. The weather service should have some method of ascertaining whether proper standards are being maintained, and whether the accuracy curve of individual forecasters is rising or falling or has leveled off, as well as some method of determining the comparative skill of individual forecasters.

3. Satisfactory environment for forecasting. Adequate forecast performance requires a high level of concentration not possible in congested and noisy offices. Provision should be made for rapid preparation or receipt by facsimile of needed charts and maps, their efficient display, and the arrangement of other references and aids where they may be located and utilized quickly.

4. Sufficient time for the proper analysis of data, application of techniques, reconciliation of conflicting inferences from the several charts and diagrams, and for the preparation and wording of forecasts. An hour and a half is estimated as the irreducible minimum required on the average for the various forecast steps after completion of the six-hourly synoptic chart, and an additional sixty to ninety minutes is needed for the preparation of forecasts and warnings; communication schedules should be arranged accordingly.

5. A forecast staff large enough to permit a forecast schedule with time for research, study, and relief from forecasting. Forecasting requires energy, enthusiasm, and imagination and the work should never be permitted to become routine or the forecaster to become stale.

6. Freedom from interruption and from administrative and service work when on forecast duty. Although the forecaster is involved in problems of extreme complexity, he frequently must operate under conditions which permit constant interruption from phone calls and pilot briefing. Work performed under these conditions must inescapably be of inferior quality. Local forecasting can, of course, be combined with briefing and public service work.

7. Proper scheduling of forecasters. There are still differences of opinion between and within forecast services with respect to the type of schedule which will result in forecasts of the best quality and continuity consistent with proper health safeguards for the forecaster. Tests should be feasible.

8. Testing of suggestions, new ideas, and techniques for the improvement of forecasting. Each weather service should have one forecast center adequately equipped and staffed for testing suggested new techniques in actual forecasting.

NEEDED RESEARCH IN SHORT-RANGE FORECASTING

Some sixteen forecast units in the United States responded to an invitation from the author to indicate the areas of research of greatest urgency in short-range weather forecasting. The replies covered every phase of the whole problem of forecasting and reflected a general admission of the inadequacy of current techniques. There was general agreement that research should proceed along two main lines: (1) toward the discovery of fundamental truths about the atmosphere, with emphasis on the general circulation, and (2) toward the development of forecast techniques which would lead to improved forecasts in the immediate future.

There is little doubt that the first is the more important, and that the second should be given a secondary role. Certainly the yield from the large amount of research on practical forecasting during the past decade or two has been exceedingly meager.

Suggested topics for further research included:

1. The general circulation of the atmosphere. Although many forecasters feel that the large proportion of research at the meteorological departments of universities which is focused on the broad problems of the general circulation of the atmosphere has little immediate and practical application to the problems of forecasting, it seems likely that any marked improvement in forecasting must come from this quarter. One may hope that discoveries will eventually be made that will revolutionize current forecast methods, but, even earlier, it seems probable that new knowledge of the general circulation would permit the preparation of better prognostic upper-air charts and other forecast aids. Continued intense research on the general circulation should have the highest priority.

2. Aperiodic departures from the normal positions of centers of action and mean troughs and ridges. Of paramount importance to short-, medium-, and long-range forecasting are the causes of the departures of the centers of action from their normal location and intensity—anomalies which may persist for a matter of months. Of equal moment are the causes of the variations of the zonal indices, which in turn permit, at times, excessive zonal or meridional flow; it is likewise desirable to learn how these variations can be forecast.

3. The qualitative and quantitative forecasting of precipitation. All forecast units listed this forecast problem, and the majority described it either as the most difficult or as the most urgent. This problem includes:

a. Determining when and where precipitation will break out in a previously dry trough.

b. Accurately timing the beginning of precipitation 12–24 hr in advance.

c. Forecasting the nocturnal type of thunderstorm.

d. The degree of concentration of the convective afternoon thundershower.

e. The development of "bursts" of rainfall, instability lines (squall lines), and other zones of convergence.

f. Correlation of precipitation with upper-air patterns and the direction and movement of lows, and development of methods of forecasting the great variation in warm-sector precipitation.

g. Investigation of the whole problem of summertime precipitation, the causes of most of which are obscure. It is suggested that further relationships between showers and convective instability be developed to reduce the forecasting of showers to some practical numerical basis.

4. The causes of deepening and filling of pressure systems. This problem was second in order of priority on the forecasters' list. With it is the associated problem of wave development.

5. The speed and direction of movement of highs, lows, and fronts. Tolerable errors (15°) in forecasting the direction of movement will result in very serious errors in the weather forecast for 24 hr hence. Less complex methods of employing acceleration and deceleration factors are desired.

6. Treatment of cold upper-air lows; their formation, movement, and dissipation.

7. Bringing the historical weather map series up to date, including 700- and 500-mb charts.

8. Development of instruments which could measure vertical motions, and changes in moisture and stability aloft.

There are numerous other problems, local in nature, which are properly the subject of investigations at the district forecast center, and, of course, only a beginning has been made in the attack on forecasting problems in the tropics.

A PROCEDURE OF SHORT-RANGE WEATHER FORECASTING

By ROBERT C. BUNDGAARD

Air Weather Service, Washington, D. C.

INTRODUCTION

The practical procedure of short-range weather forecasting is simply the extrapolation, in a partly geometrical way, of sequential weather situations. On the other hand, the ideal mathematical prognosis is based completely upon physical considerations and uses only a single set of initial data. Since practical weather forecasting nevertheless aims at accomplishing the same effect as integrating the equations of atmospheric dynamics and thermodynamics, it too must take into account the physical relationships existing among the various meteorological variables, such as wind, pressure, and temperature. The extrapolation process therefore must also take physical considerations into account.

In this article we shall first consider certain general principles of practical weather forecasting. In order to make 24-hr to 36-hr forecasts, the complex analytic-prognostic process (leading from the observational data to the prognostic maps) must be centralized so as to permit the beneficial use of an operational procedure known as the synoptic cycle. By systematic use of the synoptic cycle the analysis as well as the construction of the prognostic maps is facilitated, since the prognostic maps form the first approximation to the analysis of the next set of weather maps. On the other hand, the prognostic-forecasting process (leading from the prognostic maps to the explicit forecasts) is decentralized so that the predictions of the different weather elements can be formulated locally. Such predictions can then be synthesized into explicit weather forecasts, such as general forecasts giving summary predictions for a large region, area forecasts giving more detailed local information, and special forecasts for various fields of human endeavor.

Although the involved procedure of weather forecasting should be undertaken systematically, it must necessarily vary with the prognostic region and weather situation under consideration. Still we have, partly for expository reasons, introduced a certain order of seven prognostic operations which can be recommended, in many cases at least, for use in temperate latitudes. This order serves to remind the forecaster of the many different rules, of a theoretical or practical character, which he should use. We shall see how the prognosis of the surface map can be based on geometrical extrapolation together with certain physical considerations. The prognosis of the upper-air maps will then be presented (geometrical extrapolation and physical considerations). Finally, we shall recapitulate the more important considerations to be borne in mind by the forecaster in predicting the various weather constituents: temperature; general hydrometeors; fog, stratiform clouds, and drizzle; cumuliform clouds, showers, thunderstorms, and hail; wind, turbulence, and tornadoes; and aircraft icing.

This article is essentially an epitome based primarily upon certain chapters of *Dynamic Meteorology and Weather Forecasting*, soon to appear as a publication of the Carnegie Institution. Most sincere thanks go to Professor C. L. Godske, who, as the principal author of the book, has so very generously and warmly approved the use of the book in this article. Some of the subject matter presented in this article has arisen through an intimate collaboration among C. L. Godske, T. Bergeron, and R. C. Bundgaard. Some new material has been introduced by the author, partly for the purpose of taking into account the scope and objectives of this Compendium. The author also wishes to acknowledge his deep indebtedness to Professors T. Bergeron, J. Bjerknes, and C. L. Godske for the great inspiration he has received through being associated with them.

THE GENERAL PRINCIPLES OF PRACTICAL WEATHER FORECASTING

The Synoptic Cycle. From just *a single initial state* of the atmosphere, its subsequent development can be mathematico-physically predicted by means of a certain system of differential equations and boundary conditions. Practical weather forecasting, on the other hand, is based upon prognostic maps, first sketched by geometrically extrapolating (in a purely formal way) a *sequence* of completely analyzed weather maps, and then improved and amplified by considerations based on experience and/or general physical principles. The forecaster should, therefore, first survey carefully the analyzed map sequences, to amend all recognized errors and to add the finishing touch to the maps if time limitations had forced him to leave them in an unsatisfactory condition. Through the complete, detailed, and correct analysis of the maps, dynamical and thermodynamical considerations can *indirectly* be taken into account in the preparation of the prognostic maps preliminarily based only upon pure extrapolation. Owing to the importance of map analysis as the foundation for the prognosis, we have introduced *a synoptic cycle involving the three basic operations of "epignosis," diagnosis, and prognosis.*

Let us first consider the synoptic cycle as it presents itself in connection with the upper-air maps. The observations at time $t = t_0$ are plotted on the prognostic upper-air maps referring to the time t_0 and prepared at $t_0 - 24^h$; we shall refer to these as maps I. These maps represent a first approximation to the analysis, which, like that of the surface map, has the form of

an "epignosis" of prognostic maps. When the diagnostic-analytic task is finished, the analyst centers his attention upon the prognostic upper-air maps, maps II, prepared at the time $t_0 - 12^h$ and referring to $t_0 + 12^h$; these maps are readjusted, both by performing the first stage of prognosis upon maps I and by using the curves already drawn and only checking and correcting them in the light of the new observations now available. Finally, using maps I and II, the prognostic maps, maps III, for the time $t_0 + 24^h$ are prepared. They form the basis for the forecast. At the next synoptic hour the analyst then starts with the maps II (prepared at time $t_0 - 12^h$ but readjusted at time t_0), on which the $t_0 + 12^h$ observations have been plotted.

The synoptic cycle described above not only improves the analysis and prognosis of the weather maps, but also shows the analyst to what extent the prognostic extrapolation has been successful in any particular weather situation. Thus, it reveals the influences that have been totally or partly neglected during the prognosis. In particular, we may hope that the application of the synoptic cycle may yield valuable information as to the nonadvective effects in the upper air.

For practical purposes it is necessary to employ several meteorologists for the simultaneous prognosis of the system of surface and upper-air maps; a certain subdivision of work thus becomes necessary. However, a strict partitioning should not be maintained in practice between the different parts of weather prognosis, for instance by dividing (as is often done) a weather analysis center into a "surface" section and an "upper-air" section. Instead, the upper-air prognosis should be regarded as part of a single procedure involving the surface-map prognosis. The forecaster continually improves the surface-map prognosis from the results of the upper-air analysis and prognosis. On the other hand, he builds his system of prognostic upper-air maps on the prognostic surface map and must continually adjust his prognostic upper-air maps so as to profit from the recent improvements in the surface-map prognosis.

The General Forecast. Over a very large *prognostic region*, the extent of which varies from one weather situation to another, a smoothed prognostic map is derived from the analyzed weather maps based on representative observations of a more inclusive *analytic region* (see Fig. 1). From this map system is issued the *general forecast*, which—for a *forecast period* more inclusive than the *prognostic period* of the maps—states in a semi-Lagrangian way the probable gross weather development, in the absence of marked local influences, for an entire administratively fixed *forecast region* situated within the central part of the prognostic region. In particular, the general forecast must tell specifically the *what* and *where* of the following weather phenomena, including their present state and position as well as their motion and development during the forecast period: (1) the main air currents, (2) the main cyclones and anticyclones, (3) the main air masses and fronts, (4) the main areas of cloud and precipitation that may occur within an air mass and at a front, (5) the regions of especially strong wind, and (6) the general temperature distribution. Valid mainly for the synoptically representative stations, the general forecast is primarily of interest only to the weather service and for the strategic planning of region-wide activities such as communication, transportation, and aviation.

The Area Forecast. The general forecast, which is quite insufficient for a specified smaller *forecast area* within the forecast region, must be amplified, detailed, and even supplemented by an *area forecast* which—although based on the maps and the general forecast for the region—takes into consideration important local effects that were purposefully neglected during the regional analysis and prognosis. At the area forecasting centers, the general analysis, prognosis, and forecast are received at 12-hr intervals from the regional analysis center by teletype and/or facsimile machines. In order to feel the pulse of the locally influenced present and

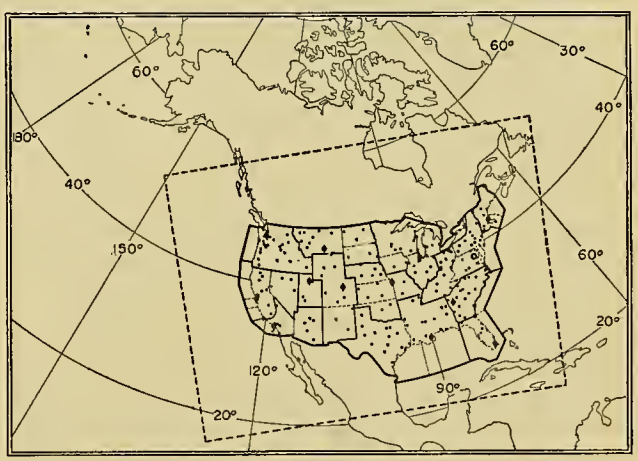

FIG. 1.—Analytic, prognostic, and forecast regions for the United States with its areas, districts, and localities.

past weather of his area, the area forecaster may often be obliged to prepare, mostly on a scale greater than that of the regional map system, his own sequences of more frequent and detailed maps (special maps, or even surface maps limited to the extent of his analytic and prognostic area). Being based upon the synoptically *unrepresentative* observations of a dense area network of primitive auxiliary stations which do not ordinarily belong to the international network, the area analysis forms a supplement to, not a duplication of, the regional map analysis. Moreover, the area forecaster is able, by the use of a network denser in time as well as in space and from more recent observational data, to fix the position of fronts, isobars, etc., in his area with greater accuracy than is possible at the regional analysis center. To further both these purposes he also, if residing within his area, makes use of such supplementary detailed "unwritten" observations as those he collects verbally from pilots and other contacts using the so-called local

method (see [1]). Fixing his attention upon the atmospheric fields within his area, the area forecaster predicts their form at any instant during his forecast period and thereby issues a more detailed and accurate area forecast, which describes in a semi-Eulerian way the local peculiarities of the weather and the time of arrival of the weather changes—the *what* and *when* of the weather.

The preparation of the general forecast is primarily the employment of the more theoretical aspects of meteorology for sketching in broad terms the probable future meteorological development and a rather idealized weather state associated with the development. The area forecast, on the other hand, applies the general forecast together with supplementary information so as to satisfy the requirements of its areas as to detailed predictions. The general forecast is a synthesis and a generalization, whereas the area forecast is a division and a specialization; they complement each other.

The area forecast bulletin should be perspicuously expressed, especially so as take into account the extreme local variability in time and space of the weather phenomena. Although brevity is essential, the forecast should not be resolved into such simple but ambiguous terms as "clear," "rain," or "snow." For example, a light cirrus overcast might be accepted as "clear" by the average person but would likely be regarded as "cloudy" by, say, a photographer. The ordinary area forecasts are regularly issued several times each day. Transmitted by radio, they are announced preferably by the forecaster himself (otherwise read *verbatim* by the radio announcer). Under the personal direction of the area forecaster, televised discussions of the map and other visual weather aids make possible a clearer presentation of the forecast than the verbal radio emission, and a more rapid dissemination than through the newspapers.

Further, the area forecast is particularized for each of several *forecast districts* into which the forecast area is subdivided. For delimiting the forecast districts on the basis only of weather similarity, it would be tempting to apply a rational method such as Schaffer's criterion [70], namely, the mean of the probable number of coincidences of rain days and of dry days for any two district stations. But at the present time the subdivision into districts is determined mostly by political reasons, so that the area forecaster must be at liberty to vary their extent whenever necessary. Although the district forecast bulletins are generally issued together in a prescribed order, it is sometimes advantageous to collect the districts into moving "zones" having practically the same weather (*e.g.*, a zone parallel to the general direction of an approaching front) and to give the same forecast for the whole zone.

The optimum extent of the forecast area and districts depends on its latitude and topography as well as the needs and activities of its inhabitants. To apply successfully the supplementary data furnished by the special area network of unrepresentative observations and by the local method, the area forecaster must be familiar with the degree of unrepresentativeness of the different meteorological stations within his districts and must possess an intimate knowledge of the local topographic factors affecting the weather in the vicinity of these stations. Then too, the forecasting work should not be unnecessarily complicated by having a forecast area so large as to be simultaneously influenced by different weather systems.

The Local Forecast. Although the area forecast is still partly a general forecast, it tends considerably toward specialization in the operational interests of such area-wide activities as communication, transportation, aviation, hydrology, and fire control, and especially of such district-wide activities as, say, fishing and planting. But if the area forecast were to be sufficiently detailed to meet the manifold needs of the populace of the area, it would be, especially in the United States, so voluminous and involved that the individual layman (*e.g.*, editor, shipper, farmer) could not easily extract from it for his particular needs. To localize, detail, and amplify further the area forecast for a particular *forecast locality*, and especially to specialize it for the benefit of various local endeavors, is instead the task of a locally residing forecaster, who, so to speak, acts as the local agent or representative of the weather service, supplying the local weather consumers with what they really need.

Every six hours the local forecast office receives from its forecast center the area forecast—but not the area map analysis or prognosis—which is then further detailed by the local forecaster as to arrival time of local weather phenomena (*e.g.*, showers, etc.) and is also amplified and specialized for the needs of the various and particular endeavors of his locality. The Eulerian considerations are thus, to a lesser extent, applied also by the local forecaster. Using mainly the district forecast of the area forecast center as guidance material, the local forecaster formulates his many local and special forecasts through an intimate knowledge of the weather peculiarities and activities of his locality. To some extent he also utilizes various supplementary, detailed, and reliable local observations that he himself can make up to the very moment of issuing the local forecasts when the area forecast may be up to three hours old. As a matter of fact, the local forecast office generally takes part in an observing program contributing to the area and/or international network, so that at least a part of these observations can be applied toward his local forecast problems. Although he does not prepare maps, he may often apply specialized techniques of analyzing and prognosticating locally the various weather elements, such as his locally and empirically developed diagrams for predicting minimum and maximum temperatures. Finally, the local forecaster must have, in addition to his intimate knowledge of the local topography as well as his in-station study of local forecasting problems [1], a thorough acquaintance with the various weather needs of his community and must be ready to supply special forecasts regularly and whenever called upon.

But the local forecaster himself cannot provide all the information wanted for special purposes. Therefore, in addition to the area forecast centers, *special fore-*

casting centers are needed to assist the local forecaster in issuing certain special forecasts. For example, we refer to such formal U. S. Weather Bureau organizations of the local forecast offices under special forecasting centers as the Corn, Wheat, Cotton, and Livestock Weather Service, the Hurricane-Warning Service, the Airways Forecasting Service, the Flood-Warning Service, the Fruit-Frost Service, and the Fire Weather Service. In addition we may mention the application of special forecasts to such enterprises as the shipping of perishable goods, the distribution of seasonal merchandise (winter clothing, ice cream, power, light, and fuel), the cinematic industry, the conservation of water, and irrigation.

The geographical extent of the forecast localities, of roughly a 40-km radius, generally should be somewhat irregular and should be subject to occasional changes because of the fluctuating administrative and professional functions of the forecast localities. Wherever there is no local forecast office to service new requirements, a nearby local forecast office is appointed to fulfill the service. Such an appointment is based on several factors in addition to the geographic one, for instance on the size and ability of the administrative and professional staff to handle the new task.

Summing up, we may state that map plotting, analysis, and prognosis—for reasons of economy—call for a certain *centralization of analytic and prognostic work*, especially of upper-air and routine work. On the other hand, the necessity of detailed forecasts (of different types) valid for restricted areas and localities leads to a demand for a *decentralization of prognostic and forecasting work*. The most practical compromise between these two tendencies will depend on the topography of the region, on the geographical latitude, and on the types of forecasts desired [41].

The Accuracy of Forecasts. Fronts, precipitation areas, etc., linearly extrapolated 24 hr to 36 hr ahead, may well have space errors from two to four times as large as do their analyzed positions, which can be fixed with an accuracy of from about one-half to one-fourth of the distance between adjacent synoptic stations, that is, with an analyzed accuracy of about 50 km. Depending on their velocity of propagation as well as on the errors in their analyzed positions, the inaccuracies of the arrival time of a fast-running disturbance moving, say, with a constant speed of 100 km hr^{-1} may therefore be of the order of magnitude of 2 hr. Further inaccuracies—the so-called "weather surprises"—are involved in the extrapolation of fast-running disturbances coming from a region where, owing to a sparse network, their positions have been analyzed inaccurately.

The value of a forecast depends upon its minutiae as well as upon its accuracy; a forecast proved correct according to purely formal methods is not necessarily the most useful forecast (for more details see [10, 18, 38, 52, 78]). Although it is not easy to verify a short-range weather forecast and to judge fairly the efficiency of a forecaster, statistics of success may be of some interest in weather services where the methods of analysis and prognosis are to a certain extent standardized. (For a survey of literature on the verification of short-range weather forecasts, see [54] and the discussion elsewhere in this Compendium.[1])

THE PROGNOSIS OF THE SURFACE MAP

The Geometrical Extrapolation of the Surface Map. *The first stage* in the order of operations for obtaining the $t_0 + 24^h$ prognostic surface map *is the geometrical extrapolation of the analyzed surface maps for finding the $t_0 + 3^h$ prognostic surface map.* In a sequence of surface maps carefully analyzed 3 hr apart,[2] the forecaster can determine directly the motion and development of their generally nonphysical features, such as isobars, pressure centers, ridges, troughs, and fronts with their cloud and precipitation areas: By superimposing on the tracing table the maps for $t_0 - 3^h$ and t_0, average values are found for the 3-hr period ending at t_0. Though less reliable than such direct determination of velocity, the kinematical formulas independently introduced by Dedebant during 1927–32 [19, 20], Angervo during 1928–30 [2, 3, 4], Wagemann in 1932 [81], and Petterssen in 1933 [58] are nevertheless of some use for determining, from the reported 3-hr pressure tendencies, the motion and development of features and systems which have just entered the analytic region. Valid only wherever there are no discontinuities in the space and time derivatives of pressure, these speed formulas should preferably be applied to sea-level systems without marked frontal structure. Thus, for determining the tangential speed of a frontal cyclone, Petterssen [60, pp. 398, 411] has recommended that the nonfrontal trough formula be based upon the pressure and tendency profiles poleward of its center where there are no fronts. The deepening and filling of sea-level pressure centers and cols, as determined either from the application of numerical formulas to the last surface map or from the last two available surface maps, must be corrected for an appreciable diurnal variation before being used for extrapolation.

By means of the average values thus found for the 3-hr period ending at the time t_0 of the last map, the forecaster extrapolates linearly and in a merely formal way the position, 3 hr ahead, of the map lineaments and the deepening and filling of sea-level pressure systems. A correction, which is next performed as part of stage one, consists in using the sequence of 3-hr maps from $t_0 - 24^h$ to t_0 in order to take into consideration higher-order terms in the extrapolation. Moreover, if the sea-level allobaric centers (preferably for 12 hr) move with approximately the same velocity as the pressure center, their past movement may be used to determine more surely the past movement of the pressure system. If this is not the case, the future velocity changes of the sea-level pressure systems are sometimes indicated by the recent movement of the corresponding sea-level allobaric centers.

As stage two, a rough sketch of the sea-level prognostic surface for $t_0 + 24^h$ is made by applying these geometrical

1. Consult "Verification of Weather Forecasts" by R. A. Allen and G. W. Brier, pp. 841–848.

2. Prior to 1930–35 the maps were prepared at 6-hr intervals.

extrapolation methods to the sea-level pressure maps for t_0 *and* $t_0 + 3^h$. After the completed prognostic surface map for $t_0 + 3^h$ has been used as an intermediate step for finding the sea-level prognostic surface map for $t_0 + 24^h$ (by reapplying the foregoing methods), it is laid aside to be used later as the next surface-map analysis.

The Physical Extrapolation of the Surface Map. As an analyst, the meteorologist is concerned with selecting models which can be fitted to the observations. As a forecaster, he considers how well the development of the chosen model fits the geometrical extrapolation described previously, and to what extent adjustments are necessary, either to this extrapolation or to the idealized development of the models during the forecast period. In both their ideal and deformed states, these tropospheric models are formulated from experience (in daily weather analysis) combined with special scientific investigations. Synthesizing, roughly, our increasing knowledge about atmospheric dynamics and thermodynamics, these models should not only be continually readjusted and improved but should also be supplemented by new models. Since no rigid set of tropospheric models exists, weather-map prognosis should not stiffen into a series of routine mechanical procedures.

The prognosis of the surface map can be facilitated by the following general considerations concerning the physical consistency of the tropospheric models. Air masses, fronts, cyclones, and anticyclones extend over large areas. In other words, the models must be *geometrically consistent*, a condition which leads to simplifications for the prognosis. Further, the displacement and deformation of the models during the prognostic period must be kinematically probable. Equipollently, the extrapolated position of a model must be *kinematically consistent* with the model at the present time and with the average field of motion during the prognostic period, both in the region covered or passed by the model and within the model itself. For example, a shallow, lenticular-shaped depression must be connected with an initial wave at a frontal zone, a deeper and rather circular one with an occlusion. Moreover, the structure and the stage of development of the chosen model must also be in agreement with the field of forces acting upon it during the prognostic period; that is, the model must be *dynamically consistent*. For example, a shallow and lenticular depression, implying small vorticity and a comparatively small supply of kinetic energy, will correspond to the initial stage of a frontal disturbance with a maximum of potential energy. On the other hand, the deep and circular depression, implying maximum vorticity and kinetic energy, could as a rule result only from the occluding process of a frontal disturbance. Finally, the chosen model must harmonize with the observed processes of radiation, heat conduction, condensation, and precipitation, that is, the model must be *thermodynamically consistent*.

The tropospheric models possess certain physical characteristics, found by theory and synoptic experience, which must be borne in mind by the meteorologist in making the map prognosis and the weather forecast. We shall now recapitulate these characteristics in the same order as the irreversible, cyclic development of the models, namely, (1) frontogenesis, frontal cyclogenesis, and anticyclogenesis, (2) the movement of sea-level pressure systems, (3) frontal occlusion, (4) degeneration and regeneration of cyclones and anticyclones, (5) local modifications of air currents, air masses, and fronts, and (6) frontolysis, cyclolysis, and anticyclolysis.

Frontogenesis, Frontal Cyclogenesis, and Anticyclogenesis. In an extensive quasi-stationary pressure col on the surface map, the forecaster should probably expect kinematic frontogenesis if the isotherms form a smaller angle with the axis of stretching than with the axis of shrinking (the part of the front marked "active" in Fig. 2). At least in the lowest layer, the general poleward decrease of temperature may sometimes be exceeded, especially along coastal regions, by the longitudinal temperature differences connected with the distribution of land and sea. Then, in these coastal regions, the cols with a north-south (west-east) axis of stretching give rise to frontogenesis (frontolysis).

Aloft, an accelerating jet stream in the direction of the frontogenetically effective axis of stretching aids in the upward extension of the frontogenetic field of deformation. Experience has indicated that a weak frontal surface will change in intensity (either by frontolyzing or by frontogenizing) wherever on a constant-pressure map one or more of the following conditions are observed: The *relative isohypses*[3] within the *frontal strip*[4] (1) have essentially the same spacing as they have outside the frontal strip, (2) are not parallel to the frontal strip, or (3) are not strongly curved in crossing the fronts.

For the quasi-stationary front thus formed, friction tends to increase the slope up to a certain height if the colder air is situated on the low-pressure side of the current—as is mostly the case with fronts in the westerlies and within the outskirts of an old, cold cyclone. A corresponding increase in sharpness and shear must be expected. This is one probable reason why such quasi-stationary fronts show a maximum (kinematic) frontogenetic tendency.

A front kinematically created along some thermal discontinuity at the surface of the earth may be thermodynamically conserved or intensified by prolonged temperature differences between, say, land and sea, snow-free and snow-covered land, or adjacent sea currents. In fact, it is quite probable that the atmospheric thermal discontinuity at the ice limit may in itself create a hyperbolic flow with a slanting surface of stretching. A cold front of limited extent may form within the lower layer of an air mass crossing a mountain range, and be intensified through cooling by its forced ascent and by the evaporation of the falling, orographically released precipitation. The forecaster should also expect the intensification of a quasi-stationary front when the isallobaric gradient is directed

3. For a definition of the aerological terms used in this text, see Table I.

4. The frontal strip is defined as the area of the map bounded by the intersections of a frontal surface with the boundary surfaces of a mandatory layer, as shown for instance in Fig. 3.

against it, and of a moving front as it approaches a deep pressure trough.

It has been known for some time that the formation of frontal waves is somehow partly initiated by a lessening of *dynamic* stability in the adjacent air masses, a decrease that has taken place through the preceding frontogenesis. For example, as observed already in 1909 by Guilbert [36] and subsequently affirmed by Hesselberg [40] in 1915, a cyclonic, subgeostrophic, and divergent flow with indraft is followed locally by a stronger pressure gradient and so by cyclonic deepening. A more complete and up-to-date theory of frontal wave formation has been presented in "Extratropical Cyclones" by J. Bjerknes, pp. 577–598 in this Compendium. The main points of his theory are as follows: The first formation of the frontal wave depends on the intensity that can be reached by organized upgliding and downgliding on the quasi-stationary frontal slope which, as a result of the preceding frontogenesis, has just acquired a tilt almost the same as the saturation isentropes. Organized upgliding of saturated air is dynamically restricted to those parts of the frontal slope where the geostrophic wind increases along the warm air streamline. It will be stronger the more nearly the isentropic anticyclonic shear of the geostrophic wind approaches $2\Omega_z$, where Ω_z is the vertical component of the earth's rotation. The latter condition is identical with the *lessening of dynamic stability*. That condition is satisfied along the eastward half of the axis of stretching of a col (the front portion marked "active" in Fig. 2), where the first active upgliding of the beginning cyclogenesis is most frequently found. The first organized downgliding will occur where the progressive frontogenesis has produced a large local decrease in the geostrophic wind on the cold side of the front. Such downgliding, following a dry isentrope of much flatter slope than that of the frontal zone, will form the first cold bulge on the quasi-stationary front. The warm sector of the nascent cyclone forms immediately east of that cold bulge. Wave formation thus is the combined product of warm-air upgliding and cold-air downgliding along neighboring front sectors, which, during the process, become the warm front and the cold front of the new wave.

The first cold push must be a shallow one. The first formation of the frontal wave therefore depends on trigger action from low levels and should be studied carefully on the surface map. With the colder air situated on the low-pressure side of the current, the frictionally steepened and sharpened quasi-stationary fronts in the westerlies and in the rear of large polar-front lows have attained the slope of a saturation isentropic surface and therefore present initial conditions favorable for wave formation (see Fig. 2). With the opposite temperature distribution (such as in high-latitude easterlies, in westerlies with poleward increase of temperature, and within the outskirts of anticyclones) the quasi-stationary fronts have a diminished slope and shear and therefore no cyclogenetic tendency. Waves are therefore to be expected along a quasi-stationary *polar* front between *principal* air masses, especially if the front has a west-east orientation with cold air poleward. Although a medium- or high-speed warm front is an *anafront* (for definition, see Fig. 2), the friction will tend markedly to diminish its slope, at least in the lowest kilometer of the atmosphere. Within strongly cyclonically curving easterly flow near a cold low, the low-layer convergence and lifting of polar air contributes to a steepening of the cold-front surface; here, however, cyclogenesis is generally prevented because near the center of the low the cold front becomes a *katafront* (defined in Fig. 2).

Since wave formation depends on the degree of lessening of dynamic stability that has taken place through the preceding frontogenesis, the parameter $2\Omega_z - \partial V_G/\partial y$ should preferably be checked on low-level aerological profiles constructed across the front part that is expected to produce a frontal wave. (On an isentropic plane the horizontal direction of its steepest slope is the y-direction, which is directed northward.) The increase of geostrophic wind in the warm air from the surface front to the front on the 500-mb map can also be used in a rapid estimate of $2\Omega_z - \partial V_G/\partial y$.

The determination of exactly where and when a frontal wave will appear is very difficult, because it is difficult to assess the surface maps for probable future lessening of dynamic stability in the vicinity of the front. So, the forecaster must usually be satisfied with just being able to detect, as soon as possible, an already existing frontal wave on his surface map. In this connection, he therefore should carefully assay the analyzed maps for *indirect indications* of even the slightest wavelike formation, which sometimes cannot be found directly, as the inaccuracies in the analyzed position of the front far exceed its initial wave amplitude. For example, he should (1) examine the analyzed limits of the altostratus-nimbostratus cloud systems for upglide clouds on the cold side of the front, (2) look for protuberance into the cold air of the isallobar which hitherto most nearly coincided with a slowly moving and almost rectilinear cold front, and (3) observe especially the almost rectilinear warm fronts slowly approaching mountainous areas where a forced wave flow may form as a result of orographic drag. On the other hand, he should (4) be mindful that slightly unstable short waves (200-km wave length), already formed, are susceptible to turbulent and orographic influences tending to break them up into smaller and dynamically stable, transient waves. Even waves less than 1000 km in length are generally stable. Only the longer, more unstable waves (1500–2500-km wave length), immune to small-scale local effects, will develop into cyclones.

When a frontal wave has been identified on the surface map, the forecaster must then decide whether or not it will develop into a cyclone. The meteorologist should first bear in mind that, according to synoptic-climatological experience, certain geographical regions are more favored than others for the occurrence of cyclones. For the 1899–1939 series of daily surface

maps, Petterssen has reported how the percentage frequency of cyclones and cyclogenesis is distributed over the whole Northern Hemisphere [62, Figs. 14–21]. He has also given the rate of alternation between cyclones and anticyclones, indicating the distribution of traveling disturbances [62, Figs. 22–23].

The frontogenesis builds up cyclonic shear vorticity which is transferred into vorticity of cyclonically curved flow at the apex of the frontal wave. Large initial frontal shear is therefore a sign of "stored" kinetic energy which, in being transformed to curvature vorticity, favors the evolution of the wave into a cyclone. The intensity of the frontal cyclogenesis may partly be conjectured by the forecaster from the observed horizontal velocity differences between the air masses. In particular, under the assumption of a normal air-mass stratification, sufficiently long waves are usually unstable provided that—according to an old rule—the wind shear along the front in knots is greater than four times the temperature discontinuity in centigrade degrees.

Qualitative examples of such reasoning concerning cyclogenesis due to the individual change of vorticity of traveling particles are demonstrated in Fig. 2. The

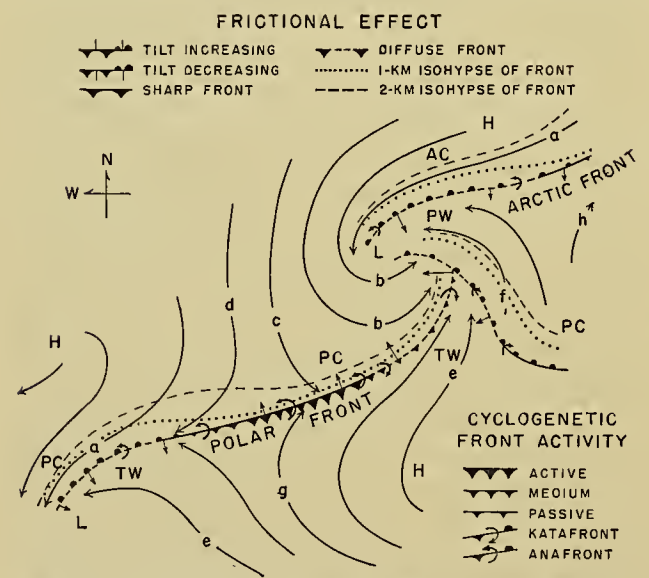

Fig. 2.—Frontal activity and passivity according to Bergeron, and vorticity dynamics of cyclones according to Bjerknes [33].

cold air sample *a* moves equatorward and partakes in the general convergence typical for the forward half of a cyclone. For both reasons cyclonic relative vorticity is acquired, which at first shows up on the surface map mainly as a horizontal cyclonic shear inside the cold air along the warm front. In passing the wave apex, this air maintains its cyclonic relative vorticity, which then is manifested as curvature vorticity. Within the strongly cyclonically curving easterly branch *b* of the cold current, a low-layer frictional convergence and lifting of the polar air contributes toward increasing the slope of the advancing cold front surface as shown by the frontal topography in the figure. Farther behind the apex the cold air samples *c* and *d* are in a region of horizontal divergence strong enough to make their cyclonic vorticity decrease or change into anticyclonic vorticity despite the southward displacement. During the growth of the cyclone, more and more of the cold air is able to maintain its cyclonic vorticity after passing the wave apex, such as represented by the life history *a–b*. Within the anticyclonically curving westerly branch *d* the low-layer subsidence combines with the effect of ground friction to decrease the slope of the front, as shown through frontal isohypses in Fig. 2. The samples *e* and *f*, although moving poleward into their respective cyclones, experience sufficient horizontal convergence to acquire some cyclonic vorticity. The warm air samples *g* and *h*, passing at greater distances from their respective centers, do not have enough horizontal convergence to prevent their acquiring anticyclonic vorticity through poleward displacement. Warm air also ascends to the base of the westerly jet stream aloft and at the same time arrives at the poleward edge of the region of maximum frontal upgliding. Hence, this warm air also gains anticyclonic vorticity from the effect of the vertical velocity terms, which under these conditions is appreciable even in comparison with the effects of both poleward motion and divergence.

Already in 1934 Scherhag [71] had pointed out that a cyclone with strong upper winds deepens. The stronger the upper westerlies have been built up during the frontogenetical period, the more they are apt to form unstable upper waves. A check on the possible occurrence of unstable anticyclonic curvature upwind from the cyclogenetic area will often give a clue to the deepening of the upper cold trough over the rear part of the cyclone. This shows up in the surface map as a deepening of the nonfrontal cold trough and the central part of the cyclone. (For more details, see pp. 587–597 in "Extratropical Cyclones" by J. Bjerknes in this Compendium.)

The instability of the wave varies also with the difference in the *static* stability of the adjacent air masses. In this connection we may mention that, in general, waves on a polar front are more often unstable than those on an arctic front. Since increasing instability of an air mass favors cyclonic deepening, cyclones can deepen in winter by motion from land out over the sea. Moreover, where (in the analyzed upper-air maps) both the *absolute isohypses*[5] and the *total relative isohypses*[5] are close together and the two sets of lines intersect approximately at right angles, cyclogenesis is often occurring in the region of higher *relative height*[5] and lower *absolute height*,[5] according to synoptic experience. In particular, if the spacing of the relative isohypses on the rear side of the low is less than that on the forward side—and this is the normal case—then, according to Pogade [64], the cyclone will deepen. (In the next subsection, we mention Petterssen's rule that the cyclones also tend to migrate toward this anterior concentration of horizontal,

5. For definition see Table I.

isosteric-isobaric solenoids.) The foregoing, rather well-known observation, which dates from 1938, has probably been considered of questionable value for some time, but it serves historically to introduce Sutcliffe's much more recent (1947) and reliable considerations in also applying the *relative hypsography*[5] for estimating sea-level cyclogenesis.

The development of sea-level systems can also be inferred from the relative hypsography. Using certain assumptions based on the vorticity equation, Sutcliffe [76, p. 204] has arrived at the following expression for the divergence of the thermal wind:

$$\text{div } \mathbf{V}' = \underbrace{-\frac{V'}{f}\frac{\partial f}{\partial s}}_{(i)} \underbrace{-\frac{V'}{f}\frac{\partial \zeta'}{\partial s}}_{(ii)} \underbrace{-\frac{2V'}{f}\frac{\partial \zeta_0}{\partial s}}_{(iii)}, \qquad (1)$$

where $\mathbf{V}'$ is the thermal wind vector defined by $\partial \mathbf{V}_\theta/\partial p$, f is the Coriolis parameter $2\Omega_z$, ζ' and ζ_0 are the vertical components of the vorticities of the thermal wind and the geostrophic wind at 1000 mb, respectively, and $\partial/\partial s$ represents differentiation along the relative isohypse. Term (*i*) may also be thought of as, for instance, the geostrophic divergence at 500 mb relative to that at 1000 mb. In other words, it is the divergence at 500 mb in excess of that at 1000 mb. It is thus directly connected with vertical motion.

Term (*iii*) is the so-called thermal vorticity or development term. It is on the basis of this term that we apply the relative hypsography for estimating sea-level cyclogenesis and anticyclogenesis. During the initial period of a quasi-stationary and developing sea-level system, term (*iii*) makes its maximum contribution, as shown empirically by Sawyer [69]. Positive centers of the computed field of term (*iii*) lie to the right, or east of the cold trough in the relative hypsography; negative centers, to the left. The pretrough areas on the surface map are cyclogenetic, the post-trough areas anticyclogenetic. A low will readily pass through a trough and intensify. On the other hand, a "self-developing" system is one with a low in the right half of the thermal trough and a high in the left half. Analogous considerations apply to highs and thermal ridges.

Next, let us apply term (*iii*) to a pattern of concentrated relative isohypses,[5] such as is found in a frontal strip, the so-called "thermal jet." The thermal jet has an "entrance" region and an "exit" region. An example of such a difluent-confluent jet is found in Fig. 3. According to term (*iii*), *there is sea-level cyclogenesis in the colder half of the difluent thermal jet and also in the warmer half of the confluent thermal jet.* (Similar considerations can be formulated for anticyclogenesis.) The genetic regions of the thermal jet thus favor the existence of lows in the confluent warmer half of the thermal jet and in the difluent

colder half, and favor the existence of highs in the confluent colder half and the difluent warmer half.

In the rear of a marked cold front of a more or less convex shape as seen from the warm-air side, a large cold-air outbreak, moving equatorward and invading regions of warmer air, spreads at the surface of the earth, a process which is connected with the production of *anticyclonic* vorticity in lower strata and the sinking of the center of gravity of the whole system of cold and adjoining air. It is obvious that such anticyclogenesis will be more efficient, all other factors remaining the same, the greater the temperature difference between the cold and the warm air and the more high-reaching and vast the cold outbreak. Although the *real* arctic air does not reach so high, synoptic experience seems to indicate that the outbreaks of arctic air often form more intense and stable anticyclones than polar air outbreaks. This may be explained by the fact that the whole process attending a pronounced outbreak of the arctic front equatorward leads to a much greater drop of temperature in temperate latitudes than a corresponding advance of the polar front. The arctic air and the overlying polar air in the former case have their origin in much higher latitudes.

Anticyclogenesis depends upon the supply of kinetic energy made available to it by the juxtaposition of tropical air over the polar air in which the anticyclone has first been formed. The forecaster should be on the lookout for regions on the constant-pressure maps where a zonal upper westerly with very high velocity is bounded (to the north and to the south) by two regions with relatively low zonal velocity. Elliott [23] has pointed out that an intensifying belt of abnormally strong upper westerlies exists for several days prior to the anticyclogenesis, and reaches a maximum just before it. Associating this development with an increased north-south thermal gradient across the region, he suggests that such anticyclogenesis is associated with excessive heat exchanges across the normal westerlies between tropical and polar air. There are sometimes other clues which are helpful in anticipating anticyclogenesis. On the surface maps, there is often the development of low pressure, a few days prior to anticyclogenesis, at half the distance of a stationary long wave (*i.e.*, about thirty degrees of latitude) upstream or downstream.

Using the quasi-static assumption, we see that the pressure change at the base of the atmosphere is associated with the depletion or accumulation of air aloft. In particular, the pressure tendency at the ground is generally decided as to sign by the horizontal (mass) divergence or convergence above the level of nondivergence (see the following paragraph for substantiating evidence). This divergence (or convergence), acting in the same sense through the stratosphere and the upper half of the troposphere, may thus be an important effect to consider in the development and movement of sea-level systems. The patterns of velocity divergence are of course determined by the distribution of the instantaneous ageostrophic upper flow. As will be shown in a following subsection on the prediction of winds, a relatively large indraft of the streamlines across the absolute isohypses occurs in the right half of the *entrance region* and large outdraft in the right half of the *exit region* (see Fig. 3*a*). On the other hand a relatively small angle of geostrophic deviation (indraft and outdraft, respectively) is found in the left half of the entrance and exit regions. Hence there is velocity divergence in the exit (or delta) region, convergence in the entrance (or confluence) region. Provided that the distribution of the horizontal mass divergence can also be represented by this "delta-divergence" and "confluence-convergence," then the pressure tendency at the ground should be positive

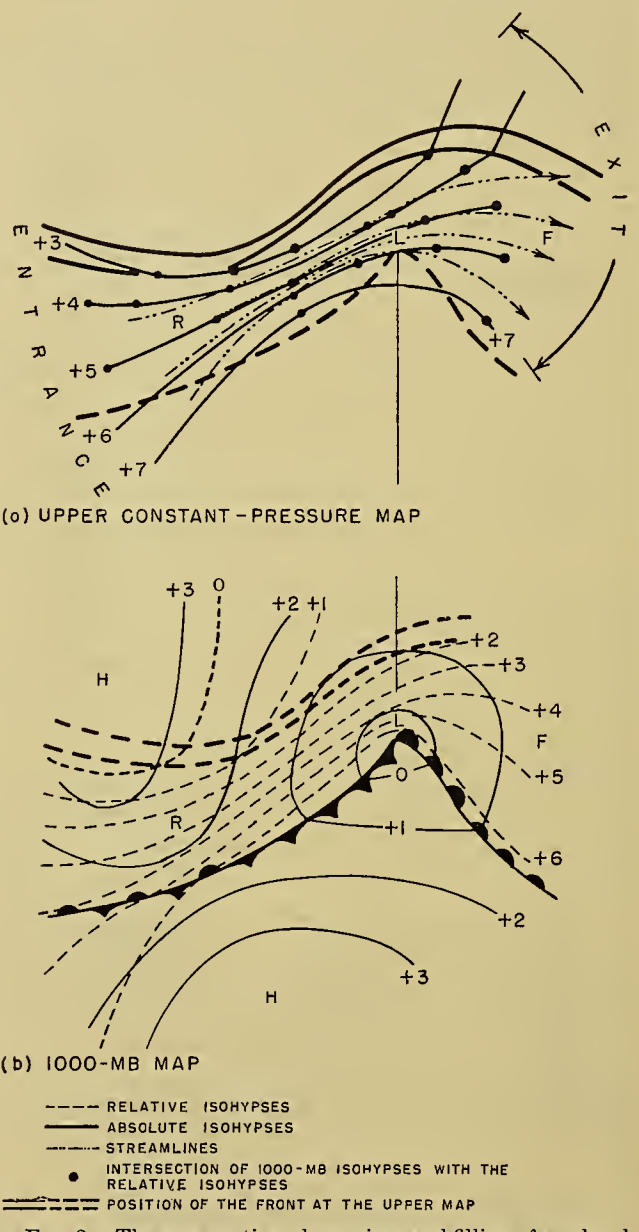

FIG. 3.—The propagation, deepening, and filling of sea-level pressure disturbances (*b*) as determined from the absolute hypsography (*a*) of an upper constant-pressure map, according to Ryd-Scherhag [71].

in the confluence region, negative in the delta region, as shown in Fig. 3*b*.

In a study of the relation between sea-level pressure change and the upper-air density change, Hess [39] has found that intensifying cyclones are associated with upper-air local density decreases, primarily in the stratosphere. Corroborating Hess's observations, Vederman [80] particularizes that the partial relative height of the upper one-third of the atmosphere (by weight) increases markedly over rapidly deepening lows. Moreover, Austin [5] observed that there is a tendency for the stability to increase over deepening cyclones in the lower stratospheric layers from 400 mb to 100 mb. These two relationships reported by Hess and Austin both corroborate the previously mentioned fact that the exit (divergence) region above a fairly low level of nondivergence determines the sign of the pressure tendency at the ground, namely falling pressure on the surface map. The entrance region similarly should be associated with rising pressure at the ground.

Upon the relationship between the ageostrophic upper flow and the local changes in sea-level pressure, Scherhag [72, pp. 23–26] already in 1943 had introduced some interesting rules for predicting the deepening and filling of sea-level pressure systems. These rules were formulated from his synoptic experience which had been guided somewhat by Ryd's earlier (1923) theoretical contributions on the subject. Although some of his rules still seem plausible in the light of Sutcliffe's more recent investigations [76], a good deal of skepticism regarding them now exists. Still, for historical and illustrative purposes, we have summarized below some of his more popular rules.

1. In the region where, on the constant-pressure maps, the absolute isohypses diverge markedly, such as at *F* in Fig. 3*a*, there is falling pressure on the surface map (*cf.* at *F* in Fig. 3*b*). On the other hand, the convergence of the upper absolute isohypses (*cf.* *R* in Fig. 3*a*) is associated with rising pressure on the surface map (*cf.* *R* in Fig. 3*b*).

2. If the divergence of the upper absolute isohypses is vertically above a low center (*i.e.*, if the low in Fig. 3*b* were displaced rightward to the position of *F*), then this center has a tendency to deepen. A high center beneath converging absolute isohypses likewise increases.

3. Cyclogenesis on the surface map usually occurs in those regions where, on an upper constant-pressure map, the absolute isohypses diverge. Anticyclogenesis is similarly associated with converging absolute isohypses. On the surface map, frontal waves which move toward the exit (entrance) region will intensify (weaken).

4. If (as in Fig. 3) the frontal strip, the jet stream above the frontal strip, and the entrance and exit regions of the jet stream all have the same orientation, then the sea-level cyclones will not deepen. Many stable waves on such a front are likely, but no waves are likely when the upper flow is mainly perpendicular to the front.

5. If, as indicated by the increased local crowding of the relative isohypses into the frontal strip (*e.g.*, the sharpening of the frontal zone by the approach of a new front), a front becomes more sharply defined, the jet stream is intensified, and so are the convergence and divergence in its exit and entrance regions. (As will be shown in the later subsection on wind (pp. 791), an increased local crowding of the absolute isohypses tends to produce large positive or negative angles of geostrophic deviation in the exit and entrance regions, respectively.) Then the *fall*[6] in the exit region and the rise in the entrance region will both intensify.

6. If, as in Fig. 3*a*, the warm-air advection in the exit region is less than that in the entrance region, the absolute isohypses in the upper jet stream then, according to Scherhag, diverge more in the exit region of the jet stream than they converge in the entrance region. As a result the wave cyclone *L* in Fig. 3 intensifies and deepens rapidly. Similarly, if the warm-air advection appears to be greater in the exit region than in the entrance region (strong warm front, weak cold front), the absolute isohypses in the upper stream then converge more in the entrance region than they diverge in the exit region. As a result the cyclone will weaken and fill.

With warm-air advection in the entrance region, the spacing of the relative isohypses decreases and their cyclonic curvature increases. With cold-air advection in the exit region, the spacing and anticyclonic curvature of the relative isohypses increases. Where there is a sharp reversal of the upper flow, the fall is usually weakened, the rises strengthened.

7. Deepening occurs in a low where there is cyclonic shear in the cyclonic flow aloft (Fig. 4*a*). A surface frontal wave does not develop where there is anticyclonic shear in the cyclonic flow aloft (Fig. 4*b*). Surface anticyclogenesis tends to occur where there is anticyclonic shear in the anticyclonic flow aloft (Fig. 4*c*). Highs do not develop where there is cyclonic shear in the anticyclonic flow aloft (Fig. 4*d*). If such a type of upper flow moves over a high, or if it forms there, the high will dissipate.

The foregoing rules may be modified by several compensating processes.

1. As will be shown in the later subsection on winds (see p. 791), the conditions for a relatively small ageostrophic flow (leading to small amounts of divergence) are (1) that the horizontal shear of the geostrophic wind be cyclonic or only slightly anticyclonic, and (2) that, if the horizontal shear is anticyclonic, the curvature of the path be cyclonic or only slightly anticyclonic. A pronounced cyclonic curvature of the absolute isohypses at a *stationary* trough must therefore be associated with their marked divergence. Long and narrow V-shaped troughs in the upper absolute hypsographies, such as in Fig. 5, should be quasi-stationary.

6. The expression *fall* refers to the center of maximum decrease in sea-level pressure. If, as in this case, the length of the period is not indicated, it is assumed that the change under consideration is valid for any period from three to twenty-four hours.

2. From the foregoing rule, as well as from synoptic experience, Rodewald [66] had observed (1937) that a rise (fall) is weakened as it approaches the position of the trough (ridge) in the upper absolute hypsography.

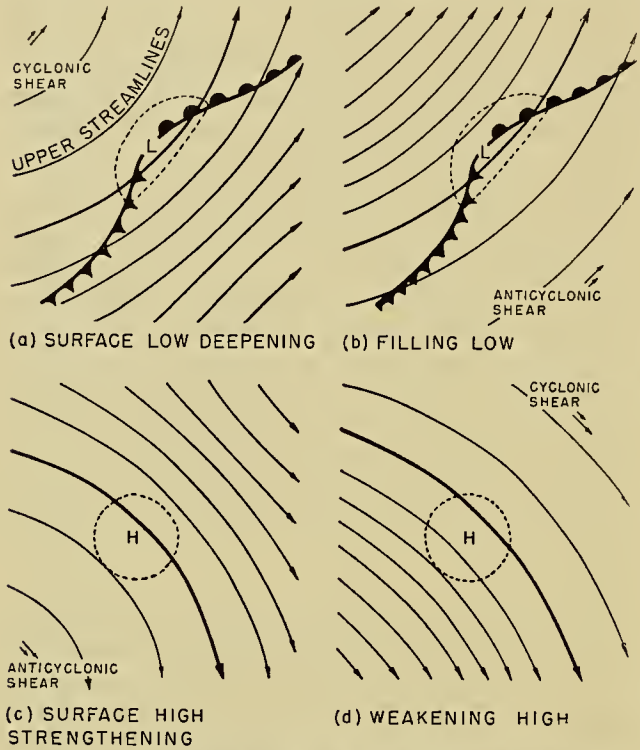

Fig. 4.—The deepening and filling of disturbances at sea level and the shear in the flow aloft.

3. A sea-level pressure trough or ridge will weaken if the surface and upper-air maps show that its axis is vertical or nearly so. This hypothesis, which follows

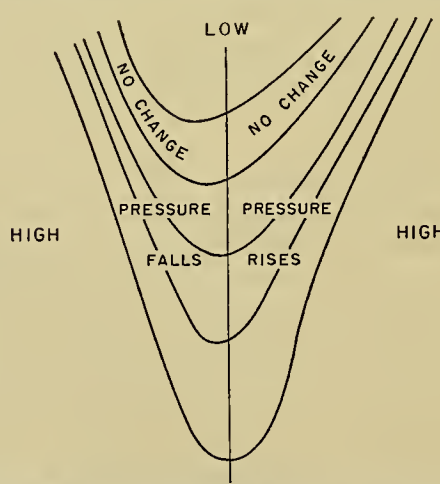

Fig. 5.—The compensating effects of the curvature and spreading of the absolute isohypses of a quasi-stationary upper trough. (*After Scherhag* [72].)

from the two foregoing rules, is correct if the frictional effect of the earth upon the surface flow is not compensated by other diabatic effects or by an appreciable transfer of angular momentum.

Finally, some physical reasoning should be involved in estimating accelerations in the deepening (filling) of the pressure system. If, for instance, the surface map shows a wave in its early stage of development, the forecaster would advisably use a *greater* average deepening per 3 hr for the coming 12 hr or 24 hr than the rate found either by formulas or from the map sequence at the past 3 hr. In other words, a "deepening acceleration" should be estimated according to the particular stage in the life history of the chosen tropospheric model and applied qualitatively as a correction to the simple first-order extrapolation of the actual pressure systems.

The Movement of Sea-Level Pressure Systems. A young cyclone generally propagates in the direction of its warm-sector isobars. An older low (high) with strongly diverging, noncircular isobars tends to have a straight path in a direction between its longer axis of symmetry and the isallobaric gradient (ascendent); the more the isobars diverge, the closer is the path in the direction of this long axis, according to Philipps [63]. A low (high) with approximately circular isobars progresses in the direction of the isallobaric gradient (ascendent), that is, normal to the isallobar through its center or, according to synoptic experience, sometimes a little to the left; it may also be extrapolated toward the domain of subnormal (supernormal) winds. Temperature, as well as pressure and pressure tendency, should be considered. For example, a stable wave progresses along a front in the direction of the warm-air flow, while a cyclone with sharply defined zones of temperature maximum and minimum moves normal to the temperature gradient. The center of an anticyclone shifts in the direction of most rapid decrease of temperature. In the usual case of cold air poleward of a front along which warm air is flowing eastward, the eastward paths of the successive members of a cyclone family—the duration of which is roughly 5–6 days—have a progressive translation equatorward. Anticyclones and ridges of high pressure which lie between cyclones move generally in the same direction and with the same speed as the frontal cyclones. But anticyclones which are cut off from a series have an equatorward component of motion. Moreover, a cyclone seeks to revolve in a clockwise sense around a neighboring stationary anticyclone, while two cyclonic disturbances of the same intensity tend to revolve about each other in a counterclockwise sense.

Centers with a linear pressure profile or a strong pressure gradient may be extrapolated with a constant propagation speed which, for a circular center, is directly proportional to the isallobaric gradient and inversely proportional to the curvature of the pressure profile. The speed of stable waves and of cyclones with weak pressure and isallobaric gradients is greater than that of a deepening cyclone, which in turn moves more rapidly than a filling cyclone. Centers with a strong pressure gradient move even more slowly; a center is quasi-stationary if it is concentric with a symmetrical isallobaric center. The cyclone should be extrapolated with an increasing (decreasing) speed of propagation

if the curvature of its tendency profile is anticyclonic (cyclonic). An anticyclonic center experiences an acceleration (deceleration) if the curvature of the tendency profile is cyclonic (anticyclonic). Often a depression with very strong winds on its forward side tends to become stationary and rapidly disappears.

The foregoing extrapolation of the motion of the sea-level pressure systems is based largely upon a recognition of certain events which had been observed to occur within the system in question (at the surface of the earth). However, the well-known *steering* "principle" or hypothesis had early been advanced that the ageostrophic upper flow, and the accompanying centers of change in the sea-level pressure, propagate with the real upper flow at a certain pressure surface, called the *steering surface*. Strictly speaking, this principle applies only to *rises* and *falls*, respectively, and not to the *highs* and *lows*. As a preliminary remark we caution that pressure changes represent processes and therefore are liable to undergo modifications. They are not systems passively drifting with the flow. Even so, the movement of the sea-level systems is assumed to be closely associated with the pressure field at the steering surface, that is, with certain events observed *outside* the systems on the surface map. The following historical and critical account of steering—introduced in 1910—considers the Scherhag complex and culminates in a discussion of Sutcliffe's practicable rules of thermal steering.

In 1931—three years before daily upper-air maps had been introduced in Germany—Mügge [53] had already formulated the loose rule that *the rises and falls follow downstream the 500-mb isohypses, the speed of their propagation being roughly half the 500-mb gradient wind.* The 3-hr rises and falls seem to move in the direction of the 700-mb flow, while the 24-hr rises and falls move with the 500-mb flow. The movement of rises and falls, which are associated with the young and shallow pressure disturbances (highs, lows, troughs, and ridges), is very roughly determined by Mügge's empirical relation so long as the development of the highs and lows in the hypsography of the steering surface is negligible. The falls have a tendency to follow the curved 500-mb isohypses better than the cuspal 500-mb isohypses, which the falls tend to cut across. On the other hand, the rises are inclined to follow the cyclonically curved 500-mb isohypses and to depart from those curved anticyclonically. By their thermal influence in transforming the upper pressure field, the falls swerve to the left, the rises to the right of the established upper flow. The rises and falls of the older and more developed disturbances are observed to move in the mean or predominant direction of the wave-shaped flow at about 400 mb to 300 mb. In this connection, constant-pressure maps higher than 500 mb should be consulted to select the steering surface with relatively straight absolute isohypses in the regions of the older and deeper disturbances. Pressure systems with closed isohypses up to the stratosphere, such as an occluded cyclone or a blocking high, are themselves considered steering centers, so that there is no well-defined relation between the 500-mb flow and the movement of their rises and falls. If a closed upper low is formed through a strong pressure fall at the surface of the earth, the fall tends to split, with the rapidly weakening part swerving to the left, the stronger to the right, of the old path (occlusion stage of development). The cold lows in the upper relative hypsographies (*Kaltlufttropfen*) are not steered by the upper flow, but their movement can be predicted from other considerations (see Fig. 6).

For preparing the prognostic map of 24-hr change in sea-level pressure, the following empirical relation was first suggested by Guilbert and Grossman and later formulated by Rodewald [66]. *The 24-hr fall (rise) for t_0 moves downstream in the direction of the 500-mb isohypses for t_0 so that its position at $t_0 + 24^h$ is on the axis of past 24-hr increase (decrease) in the 500/1000-mb hypsography*[7] *for t_0.*[8] The prognostic sea-level pressure map for $t_0 + 24^h$ can be immediately obtained by simply adding graphically the prognostic map of 24-hr change in sea-level pressure (obtained approximately by the Guilbert-Grossman rule) to the sea-level pressure map for t_0.

In 1939 Ertel introduced his theory of singular advection of the first order [26], according to which atmospheric pressure variations originate at discontinuities where changes of momentum occur. The best-defined and most persistent temperature discontinuity surface of the first order is the tropopause. By disregarding all other discontinuity surfaces (*viz.*, fronts), Lucht [50] has attempted to adapt and apply Ertel's theory at the tropopause in order to find how the upper atmosphere is associated with variations in the sea-level pressure. Essentially, the adapted equation of Ertel gives the individual sea-level pressure changes as a quantity depending on (1) the solenoidal field of the mean temperature of the troposphere, (2) the hypsography of the tropopause, and (3) the stability discontinuity of the tropopause. The tropopause discontinuity of the temperature gradient and inclination of the tropopause are apparently the most influential factors in deciding the speed of movement. The conclusions from Lucht's investigation indicate, for the rises and falls, that the direction of motion can be predicted from the hypsography of the tropopause and that Ertel's equation [26, eq. 50, p. 406] gives satisfactory values for the speed of motion. But Lucht's efforts to apply Ertel's equation are not persuasive, because of the sparsity of the data in 1939 for determining the slope of the tropopause and the permanent difficulties in determining its temperature discontinuity. Lucht has thus attempted to substantiate and refine the observations made already in 1926 by Stüve and Palmén [56] and by von Ficker [29] that the rises and falls move in the direction of the isohypses of the tropopause.

In an effort to extend the steering hypothesis to lows, Austin [5] has observed that the steered lows (1)

7. Defined in Table I.

8. Variously stated in [9, 66].

tend to continue to be steered (but nonsteered lows may eventually move parallel to the steering flow), and (2) usually veer relative to the steering flow. In this study, he has also observed that (3), especially for filling lows, the angular deviation of their movement from the steering flow is generally independent of their intensity (number of closed isobars) and less for cyclones than for anticyclones, and that (4) this angular deviation increases as the upper flow departs more and more from straight flow. Longley [49] has found evidence to state that strengthening highs move toward the left of the steering flow. It is also possible, as shown by experience, to predict the deepening and filling of the highs and lows.

The motion of sea-level systems can also be estimated from the relative hypsography. Term (*iv*) in equation (1) is the so-called thermal steering term. This term indicates *the tendency for the sea-level systems to be steered by the relative isohypses, that is, to move in the direction of the thermal wind with a propagation speed proportional to the thermal wind.* Sawyer [69, p. 113] has shown empirically that term (*iv*) becomes increasingly important as the sea-level system develops. In practice, the speed of displacement by thermal steering can at best be assessed by the forecaster only from experience and statistics. The failure in practice of term (*iv*) to give the correct propagation speed is due to the neglected (1) stabilizing control of the vertical motion, (2) diabatic processes, and (3) variation of the vorticity of the thermal wind (term *iii*). As we have already noted in the previous subsection, the genetic regions of the thermal jet thus favor the existence of lows in the confluent warmer half of the thermal jet and in the difluent colder half and favor the existence of highs in the confluent colder half and the difluent warmer half. Consequently cyclones tend to swing out of the thermal jet toward lower relative height, anticyclones toward higher relative height—and slow down.

The veering of lows relative to the steering flow, as cited by Austin [5], may not be in disagreement with the above-mentioned backing of lows relative to the thermal jet. In the baroclinic region just ahead of a low, the thermal jet veers relative to the steering flow (*i.e.*, the sense of the horizontal, isosteric-isobaric solenoids is negative). So, by combining Austin's observations with our interpretation of term (*iii*), we should expect the lows to move in a direction which is somewhere between that of the steering flow and the thermal flow. In other words, the lows move toward the concentration of horizontal, isosteric-isobaric solenoids. This tendency for lows to migrate toward the solenoid concentration has been physically confirmed by Petterssen [62, p. 136, eq. 12]. By applying the horizontal del-operator to the vorticity equation and considering only horizontal motion, he found an expression for the horizontal ascendent of the vorticity tendency. Lows, being centers of maximum relative vorticity, must move in the direction of this ascendent. According to Petterssen's expression for this ascendent, lows have a component of motion toward the concentration of horizontal, isosteric-isobaric solenoids; opposite considerations apply to the highs.

Frontal Occlusion. The frontal wave, even in the case of a long wave length, is a fairly long-lived system, whereas the so-called ideal cyclone with a narrow but unoccluded warm sector exists only for about 6–18 hr. Thus, a wave of a quite innocent appearance may well occlude into an intensive cyclone during the next prognostic period (t_0 + 24–36^h).

At the very first stage of occlusion, particularly in the lower layers and near the cyclonic core, the converging and ascending precyclonic air is colder than the diverging and subsiding postcyclonic air. These dynamic effects should favor the formation of a warm-front occlusion. Later, especially at higher levels and in the outer region of cyclones which are propagating eastward at temperate latitudes, the equatorward current of postcyclonic polar air is usually colder than the poleward, precyclonic current, either because it originates in higher latitudes or because its recent life history is colder. In Europe during the summer (winter), the continental precyclonic air of the ordinary west-east cyclone is warmer (colder) than the maritime postcyclonic air, so that the forecaster may expect the occlusion to be of the cold-front (warm-front) type. In the eastern United States the foregoing conditions should, of course, be reversed. For cyclones moving in other directions than towards the east, the forecaster can still predict the type of occlusion by systematically using the general temperature distribution as shown by the surface and upper-air maps. At the last stage of occlusion, the rapidly sinking tropopause and the marked anticyclonic motion within the upper air result in a general tendency towards subsidence and dynamic warming of the precyclonic air, while in the postcyclonic air a tendency exists towards ascending motion and dynamic cooling.

Whereas a cyclone neither occludes nor deepens so long as the warm-sector tendency is zero, according to Petterssen [60, p. 433] the occluding rate of a young cyclone is proportional to its deepening and to the negative tendency in its warm sector. Moreover, if a cold front flows slowly over a mountain range normal to its path, an orographic occlusion may occur. Upon occlusion the path of the cyclone deviates to the left, moving in the direction of the isobars of its warmest part (the "false" warm sector). Once the occlusion process starts, the propagation speed of the cyclone diminishes. If an occluded front approaches a stationary continental anticyclone from the west, its movement is retarded. Finally, the forecaster should watch especially for secondary disturbances often arising at the point of occlusion.

Degeneration and Regeneration of Cyclones and Anticyclones. The potential energy of adjacent air masses is gradually consumed during the occlusion process, so that the cyclone normally degenerates during this stage. But the occluded cyclone and its fronts may be regenerated either by the same general frontogenetical effects that, according to synoptic experience, create the secondary cold front at the end of the bent-

back occlusion or by the influence of the convergence at the front which causes ascent and the release of new potential lability. In Europe during summer and in the eastern United States during winter, these factors are especially effective at the cold-front occlusion. As a result of a "false" warm sector forming in its bent-back trough, the warm-front occluded cyclone acquires not only additional potential energy of horizontally adjacent air masses but also a mechanism (*viz.*, the bent-back occluding process) which can transform this potential energy into kinetic energy in the form of increasing cyclonic vorticity. The consequent conditional instability of the air mass within the false warm sector and the existence there of labile energy favors the regeneration of the cyclone. In the eastern United States this kind of regeneration is presumably more frequent in summer than in winter. A dying cyclone also deepens anew when it comes under the influence of a fresh cold air mass or when there is a general sharpening of its fronts. An apparent regeneration of the occluded cyclone often takes place when a new wave of the main front overtakes the occlusion. If an occluded cyclone regenerates, its speed of propagation is increased.

As the anticyclone develops, both its movement and its anticyclogenesis decrease, so that the anticyclone and cyclone cease to resemble each other in the manner of their development. In particular, the duration of the anticyclone is highly variable, from a week or so to a month or even longer. The anticyclone, now stable both physically and dynamically, assumes a semifixed geographical location. In the stationary anticyclone, the subsidence inversion intensifies and lowers, hindering convection. The transformation in properties of its air mass has reached a quasi-equilibrium state as the air mass, now thoroughly homogenized, is adapted to the various steady-state processes operative in its region. The anticyclone imposes decisive restrictions on the movement, development, and position of adjacent cyclone systems. Certain types of anticyclones exhibit a remarkable permanence, in time as well as in space. In mature anticyclones, the importance of this stability in regulating the remote weather is paramount. Persistent abnormal weather is usually an indirect consequence of the permanent nature of the mature anticyclone.
