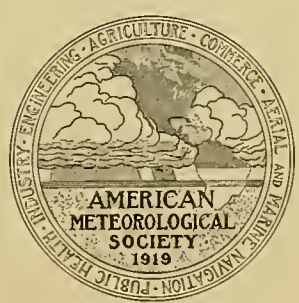
COMPENDIUM OF METEOROLOGY

COMPENDIUM
OF
METEOROLOGY

Prepared under the Direction of the
Committee on the Compendium of Meteorology
H. R. BYERS H. E. LANDSBERG H. WEXLER
B. HAURWITZ A. F. SPILHAUS H. C. WILLETT
H. G. HOUGHTON, Chairman

Edited by
THOMAS F. MALONE



AMERICAN METEOROLOGICAL SOCIETY
BOSTON, MASSACHUSETTS
1951

COMPOSED AND PRINTED AT THE
WAVERLY PRESS, INC.
BALTIMORE, MD., U.S.A.

PREFACE

The purpose of the *Compendium of Meteorology* is to take stock of the present position of meteorology, to summarize and appraise the knowledge which untiring research has been able to wrest from nature during past years, and to indicate the avenues of further study and research which need to be explored in order to extend the frontiers of our knowledge. Perhaps it is appropriate that this stocktaking should be made as we enter the second half of the twentieth century, for surely no one can read the pages which follow without experiencing the feeling that we are on the threshold of an exciting era of meteorological history in which significant advancements are possible toward a better understanding of the physical laws which govern the workings of the atmosphere. That this progress will not be made without some difficulty is quite apparent from the number of unsolved problems which still remain as a challenge to the research worker in spite of the centuries of study which have been devoted to the nature and behavior of the atmosphere. If this book will have clarified and defined these problems, it will have fulfilled the purpose of those who planned it.

The desirability of a survey of the current state of meteorology became apparent during the years following World War II, when research effort was being greatly intensified not only in meteorology but also in other fields of pure and applied science in which the importance of meteorological factors was coming into recognition. The idea that meteorologists and atmospheric physicists from all over the world might combine their efforts to prepare a work of this nature took definite shape in 1948 when the Geophysics Research Division of the Air Force Cambridge Research Center invited the American Meteorological Society to draw up plans for a book in which specialists in the several fields of meteorology would appraise the state of knowledge in their respective specialties. The general scope of the work was decided upon by representatives of the Society and the Geophysics Research Division, and support and sponsorship was provided by the latter under Contract No. W 28-099 ac-399 with the Society. It is understood, however, that the recommendations and conclusions presented in the articles which follow do not necessarily represent those of the sponsoring agency.

Capt. H. T. Orville, U.S.N. (Ret.), president of the Society from 1948 to 1950, appointed the Committee on the Compendium of Meteorology, under the chairmanship of Professor H. G. Houghton, to organize and supervise this undertaking. This committee sought and obtained suggestions from many eminent meteorologists and, in a series of meetings in the latter part of 1948, formulated the specific nature of the present work. One hundred and two authors were commissioned in 1949 to prepare the one hundred and eight articles which comprise this book. In most cases, more than one author was invited to contribute on a single broad topic. This was done intentionally, despite some slight duplication, to insure the presentation of specialized aspects of certain general subjects and to provide ample opportunity for the exposition of different viewpoints.

A logical grouping of papers on related topics has resulted in a division of the book into twenty-five sections. Since the composition and physics of the atmosphere are fundamental to a consideration of meteorological problems, the first part of the book is concerned with the field generally referred to as physical meteorology. Then comes a discussion of the upper atmosphere—a topic in which the interests of meteorologists and physicists are now converging—followed by a section which deals with extraterrestrial effects on the atmosphere and with the meteorology of other planets. The section in which is presented a general discussion of the dynamics of the atmosphere is followed by three sections which treat various aspects of the primary, secondary, and tertiary circulations, respectively. These papers provide a logical introduction to the treatment of synoptic meteorology and weather forecasting and to the discussions of the meteorology of the tropical and polar regions and the section on climatology. Hydrometeorology, marine meteorology, biological and chemical meteorology, and atmospheric pollution are fields in which the interests of meteorologists meet those of hydrologists, oceanographers, biologists and chemists, and engineers, and these topics are treated in that order. The topics of clouds, fog, and aircraft icing have been included in a single section because of their obvious relationship to one another. The discussions of meteorological instruments and laboratory investigations and the theory of radiometeorology and microseisms and their applications to meteorological problems constitute the final sections.

References to the literature are indicated by bracketed numbers in the text. A list of references is given at the end of each article. Some care has been exercised to insure complete and accurate bibliographic information. Abbreviations for the titles of periodicals have, with a few minor modifications, followed the convenient system used in the second edition of *A World List of Scientific Periodicals*, published by the Oxford University Press in 1934. When successive entries have one or more authors in common, dashes have been used to replace the name, or names, given in the preceding entry.

It is a pleasure to acknowledge the interest and cooperation, quite apart from the financial support, of the Geo-

physics Research Division in this undertaking. The Division's library was kindly made available for use in the editorial work and the friendly counsel and suggestions of Division personnel have been most helpful. Sincere appreciation is due to Professor Hans Neuberger for carefully checking and editing the papers translated from the German. Miss Eleanor Richmond and Mr. W. Lawrence Gates have labored long and faithfully in systematizing and checking the lists of references and in assisting with the editing and proofreading. The assistance of Mr. Jean Le Corbeiller in the editorial work and proofreading is also gratefully acknowledged, as is the careful proofreading by Mrs. William Greene and Mrs. Israel Kopp. Mr. Kenneth C. Spengler, executive secretary of the American Meteorological Society, his assistant, Mrs. Holt Ashley, and their staff have capably handled all of the administrative matters connected with this work. Preparation of the illustrations for publication has been efficiently accomplished by Mr. Chester Jancewicz.

TABLE OF CONTENTS

COMPOSITION OF THE ATMOSPHERE

The Composition of Atmospheric Air *by E. Glueckauf* 3

RADIATION

Solar Radiant Energy and Its Modification by the Earth and Its Atmosphere *by Sigmund Fritz* 13
Long-Wave Radiation *by Fritz Möller* 34
Actinometric Measurements *by Anders Ångström* 50

METEOROLOGICAL OPTICS

General Meteorological Optics *by Hans Neuberger* 61
Polarization of Skylight *by Zdeněk Sekera* 79
Visibility in Meteorology *by W. E. Knowles Middleton* 91

ATMOSPHERIC ELECTRICITY

Universal Aspects of Atmospheric Electricity *by O. H. Gish* 101
Ions in the Atmosphere *by G. R. Wait and W. D. Parkinson* 120
Precipitation Electricity *by Ross Gunn* 128
The Lightning Discharge *by J. H. Hagenguth* 136
Instruments and Methods for the Measurement of Atmospheric Electricity *by H. Israël* 144
Radioactivity of the Atmosphere *by H. Israël* 155

CLOUD PHYSICS

On the Physics of Clouds and Precipitation *by Henry G. Houghton* 165
Nuclei of Atmospheric Condensation *by Christian Junge* 182
The Physics of Ice Clouds and Mixed Clouds *by F. H. Ludlam* 192
Thermodynamics of Clouds *by Fritz Möller* 199
The Formation of Ice Crystals *by Ukichiro Nakaya* 207
Snow and Its Relationship to Experimental Meteorology *by Vincent J. Schaefer* 221
Relation of Artificial Cloud-Modification to the Production of Precipitation *by Richard D. Coons and Ross Gunn* 235

THE UPPER ATMOSPHERE

General Aspects of Upper Atmospheric Physics *by S. K. Mitra* 245
Photochemical Processes in the Upper Atmosphere and Resultant Composition *by Sidney Chapman* 262
Ozone in the Atmosphere *by F. W. Paul Götz* 275
Radiative Temperature Changes in the Ozone Layer *by Richard A. Craig* 292
Temperatures and Pressures in the Upper Atmosphere *by Homer E. Newell, Jr.* 303
Water Vapour in the Upper Air *by G. M. B. Dobson and A. W. Brewer* 311
Diffusion in the Upper Atmosphere *by Heinz Lettau* 320
The Ionosphere *by S. L. Seaton* 334
Night-Sky Radiations from the Upper Atmosphere *by E. O. Hulburt* 341
Aurorae and Magnetic Storms *by L. Harang* 347
Meteors as Probes of the Upper Atmosphere *by Fred L. Whipple* 356
Sound Propagation in the Atmosphere *by B. Gutenberg* 366

COSMICAL METEOROLOGY

Solar Energy Variations As a Possible Cause of Anomalous Weather Changes *by Richard A. Craig and H. C. Willett* 379
The Atmospheres of the Other Planets *by S. L. Hess and H. A. Panofsky* 391

DYNAMICS OF THE ATMOSPHERE

The Perturbation Equations in Meteorology *by B. Haurwitz* 401
The Solution of Nonlinear Meteorological Problems by the Method of Characteristics *by John C. Freeman* 421
Hydrodynamic Instability *by Jacques M. Van Mieghem* 434
Stability Properties of Large-Scale Atmospheric Disturbances *by R. Fjørtoft* 454

The Quantitative Theory of Cyclone Development *by E. T. Eady* 464
Dynamic Forecasting by Numerical Process *by J. G. Charney* 470
Energy Equations *by James E. Miller* 483
Atmospheric Turbulence and Diffusion *by O. G. Sutton* 492
Atmospheric Tides and Oscillations *by Sydney Chapman* 510
Application of the Thermodynamics of Open Systems to Meteorology *by Jacques M. Van Mieghem* 531

THE GENERAL CIRCULATION

The Physical Basis for the General Circulation *by Victor P. Starr* 541
Observational Studies of General Circulation Patterns *by Jerome Namias and Philip F. Clapp* 551
Applications of Energy Principles to the General Circulation *by Victor P. Starr* 568

MECHANICS OF PRESSURE SYSTEMS

Extratropical Cyclones *by J. Bjerknes* 577
The Aerology of Extratropical Disturbances *by E. Palmén* 599
Anticyclones *by H. Wexler* 621
Mechanism of Pressure Change *by James M. Austin* 630
Large-Scale Vertical Velocity and Divergence *by H. A. Panofsky* 639
The Instability Line *by J. R. Fulks* 647

LOCAL CIRCULATIONS

Local Winds *by Friedrich Defant* 655
Tornadoes and Related Phenomena *by Edward M. Brooks* 673
Thunderstorms *by Horace R. Byers* 681
Cumulus Convection and Entrainment *by James M. Austin* 694

OBSERVATIONS AND ANALYSIS

World Weather Network *by Athelstan F. Spilhaus* 705
Models and Techniques of Synoptic Representation *by John C. Bellamy* 711
Meteorological Analysis in the Middle Latitudes *by V. J. Oliver and M. B. Oliver* 715

WEATHER FORECASTING

The Forecast Problem *by H. C. Willett* 731
Short-Range Weather Forecasting *by Gordon E. Dunn* 747
A Procedure of Short-Range Weather Forecasting *by Robert C. Bundgaard* 766
Objective Weather Forecasting *by R. A. Allen and E. M. Vernon* 796
General Aspects of Extended-Range Forecasting *by Jerome Namias* 802
Extended-Range Weather Forecasting *by Franz Baur* 814
Extended-Range Forecasting by Weather Types *by Robert D. Elliott* 834
Verification of Weather Forecasts *by Glenn W. Brier and Roger A. Allen* 841
Application of Statistical Methods to Weather Forecasting *by George P. Wadsworth* 849

TROPICAL METEOROLOGY

Tropical Meteorology *by C. E. Palmer* 859
Equatorial Meteorology *by A. Grimes* 881
Tropical Cyclones *by Gordon E. Dunn* 887
Aerology of Tropical Storms *by Herbert Riehl* 902

POLAR METEOROLOGY

Antarctic Atmospheric Circulation *by Arnold Court* 917
Arctic Meteorology *by Herbert G. Dorsey, Jr.* 942
Some Climatological Problems of the Arctic and Sub-Arctic *by F. Kenneth Hare* 952

CLIMATOLOGY

Climate—The Synthesis of Weather *by C. S. Durst* 967
Applied Climatology *by Helmut E. Landsberg and Woodrow C. Jacobs* 976
Microclimatology *by Rudolf Geiger* 993

Geological and Historical Aspects of Climatic Change *by C. E. P. Brooks* 1004
Climatic Implications of Glacier Research *by Richard Foster Flint* 1019
Tree-Ring Indices of Rainfall, Temperature, and River Flow *by Edmund Schulman* 1024

HYDROMETEOROLOGY

Hydrometeorology in the United States *by Robert D. Fletcher* 1033
The Hydrologic Cycle and Its Relation to Meteorology—River Forecasting *by Ray K. Linsley* 1048

MARINE METEOROLOGY

Large-Scale Aspects of Energy Transformation over the Oceans *by Woodrow C. Jacobs* 1057
Evaporation from the Oceans *by H. U. Sverdrup* 1071
Forecasting Ocean Waves *by W. H. Munk and R. S. Arthur* 1082
Ocean Waves as a Meteorological Tool *by W. H. Munk* 1090

BIOLOGICAL AND CHEMICAL METEOROLOGY

Aerobiology *by Woodrow C. Jacobs* 1103
Physical Aspects of Human Bioclimatology *by Konrad J. K. Buettner* 1112
Some Problems of Atmospheric Chemistry *by H. Cauer* 1126

ATMOSPHERIC POLLUTION

Atmospheric Pollution *by E. Wendell Hewson* 1139

CLOUDS, FOG, AND AIRCRAFT ICING

The Classification of Cloud Forms *by Wallace E. Howell* 1161
The Use of Clouds in Forecasting *by Charles F. Brooks* 1167
Fog *by Joseph J. George* 1179
Physical and Operational Aspects of Aircraft Icing *by Lewis A. Rodert* 1190
Meteorological Aspects of Aircraft Icing *by William Lewis* 1197

METEOROLOGICAL INSTRUMENTS

Instruments and Techniques for Meteorological Measurements *by Michael Ference, Jr.* 1207
Aircraft Meteorological Instruments *by Alan C. Bemis* 1223

LABORATORY INVESTIGATIONS

Experimental Analogies to Atmospheric Motions *by Dave Fultz* 1235
Model Techniques in Meteorological Research *by Hunter Rouse* 1249

INDEX 1317

COMPOSITION OF THE ATMOSPHERE

The Composition of Atmospheric Air *by E. Glueckauf* 3

THE COMPOSITION OF ATMOSPHERIC AIR

By E. GLUECKAUF

Atomic Energy Research Establishment, Harwell, England

For many reasons it is desirable to have a complete knowledge of the composition of the atmosphere as regards both the molecular species present and their absolute quantities. This applies not only to the main components, but also to rare species of polyatomic molecules whose importance in the radiation balance is often quite out of proportion to their actual quantity. Any observed variation in the composition of air—with time, with geographical location, with height, with the seasons, or with meteorological conditions—seriously affects our conception of the processes in the atmosphere. It follows from this that the present article must lay its emphasis on facts in order to see where our knowledge is still inadequate.

SURVEYS OF VARIATIONS IN THE COMPOSITION OF THE ATMOSPHERE

Oxygen (O_2). The first "international" investigation of the O_2 content with adequate equipment was carried out as early as 1852 by Regnault [18] (see Table I). He concluded that atmospheric air presents only small variations.

TABLE I. SURVEY OF OXYGEN CONTENT
(*After Regnault* [18])

Location	Average O_2 (per cent)
Montpellier	20.95 ± 0.00
Lyon	20.94 ± 0.01
Normandy	20.95
Berlin	20.96 ± 0.01
Mediterranean*	20.94 ± 0.01
Atlantic	20.94 ± 0.01
East Indian Ocean	†
Arctic Ocean	20.91 ± 0.01
Paris	20.96 ± 0.01
Average	20.944

* Two samples from Algiers have been omitted.
† Greatly varying, mostly low.

Sixty years later, in a survey involving many hundreds of precision analyses, Benedict [c. 16][1] proved conclusively that during a period of about two years, which involved a great variety of weather conditions, no material variations occurred in the O_2 content of air at the Nutrition Laboratory of the Carnegie Institution of Washington. A statistical analysis of Benedict's data gives a standard deviation of ±0.006 per cent, while the repeated analysis of a bottled air sample gave a standard deviation of only ±0.0025 per cent. It is likely that the higher standard deviation of the former originated from minute variations in the sampling procedure.

Similar precision was obtained by Krogh [c. 16] whose analyses from October 4, 1917, to January 25, 1918, showed a standard deviation of ±0.005 per cent for O_2, ±0.0025 per cent for CO_2, and ±0.0020 per cent for O_2 plus CO_2, all in uncontaminated air. The absolute values for O_2 and CO_2 in dry air obtained by Krogh after careful calibrations are shown in Table II. This last figure—or the corresponding figure of 79.0215 per cent for the content of "atmospheric nitrogen" (*i.e.*, N_2 + rare gases)—is considered by Krogh to be a geophysical constant which does not vary more than indicated by the standard deviation observed (±0.0020 per cent).

TABLE II. OXYGEN AND CARBON DIOXIDE VALUES IN DRY AIR
(*After Krogh* [c. 16])

Constituent	Content (per cent)	
	Experiment I	Experiment II
CO_2	0.0305	0.0300
O_2	20.9480	20.9485
$O_2 + CO_2$	20.9785	20.9785

The absolute value of the O_2 content of air obtained by Benedict, taking into account a small correction resulting from the formation of CO from the pyrogallate, was later computed by Benedict and by Haldane as 20.952 per cent and by Krogh [c. 16] as 20.954 per cent.

While Benedict's experiments prove conclusively that only trifling changes occur in air observations at one locality, it is more difficult to show that there is uniformity over all the earth's surface. For such a survey it is necessary to bottle air samples, and changes of one or two parts in ten thousand can easily occur during transit of the air sample. Table III gives a summary of Benedict's analyses of air of various origins. It is not likely that significance can be attached to these small variations.

TABLE III. SURVEY OF OXYGEN CONTENTS
(*After Benedict* [c. 16])

Origin of air	No. of samples	O_2 (corrected) (per cent)
Boston, Mass.	212	20.952
Ocean air (Montreal to Liverpool)	7	20.950
Ocean air (Genoa to Boston)	36	20.946
Pikes Peak*	5	20.945

* The data for August 14, 1911 which showed abnormally low values have been omitted.

1. A "c" is used in front of reference numbers to indicate that detailed reference is given in the paper cited.

An oxygen deficiency in antarctic air, claimed by Lockhart and Court [c. 12], cannot yet be regarded as well established, since no check analyses with normal air were carried out.

In spite of Paneth's conservative estimate [16] that the second decimal is still not exactly known, the author feels inclined, in view of the agreement of the two best surveys with a recent redetermination by M. Shepherd [c. 16] which gave 20.945 per cent, to recommend an absolute value of 20.946 ± 0.002 per cent as the most likely figure for the O_2 content of uncontaminated air, in combination with an average CO_2 value of 0.033 per cent.

Apart from possible minor changes resulting from the greater solubility of O_2 than of N_2 in ocean water, all major variations of the O_2 content must result from the combustion of fuel, from the respiratory exchange of organisms, or from the assimilation of CO_2 in plants. The first process does not result in more than local changes of the O_2 content, while the latter two processes, though locally altering the CO_2/O_2 ratio, leave their sum unchanged.

Carbon Dioxide (CO_2). Though the extensive investigations of Benedict and of Krogh suggest that the CO_2 content of atmospheric air over land does not vary except within very narrow limits, significant variations of the CO_2 content have been observed by workers both before and after them.

In particular, Callendar [5] has drawn attention to an increase in the CO_2 content during the last fifty years which is best demonstrated in Fig. 1. This in-

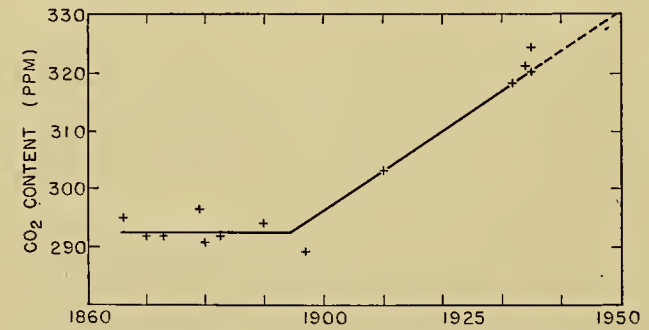

Fig. 1.—Increase of CO_2 in air. (*After Callendar* [5].)

crease in the total atmosphere of about 30 ppm (parts per million) represents a quantity of CO_2 (2×10^{11} tons) which is approximately equal to the amount resulting from the combustion of fuels produced during this period. This implies that not much of this excess CO_2 has been lost to the ocean water, an assumption which is justified in view of the fact that, apart from a thin agitated surface layer, the transport of CO_2 inside the water proceeds by diffusion and is very slow.

Variations of the CO_2 Content over the Sea. The variations of CO_2 over the sea are now well understood (Buch, Wattenberg [c. 5]). Because of an excess of strongly basic cations over strongly acid anions in sea water, CO_2 is soluble in sea water not only as dissolved CO_2, but also in the form of carbonate and bicarbonate ions, the quantities being roughly of the order 1:8:150. The result of this is that one litre of sea water contains about 150 times as much CO_2 as the same volume of air.

For a given content of total CO_2, the equilibrium pressure varies considerably with the water temperature. To give an example: For water with a chloride content of 1.95 per cent and a total CO_2 of 2.07×10^{-3} mol l^{-1}, the CO_2 pressures[2] in air at equilibrium at 0C, 10C, 20C, and 30C are 1.6, 2.5, 3.6, and 5.1 $\times$ 10^{-4} atm, respectively. Thus, far from having an equalizing effect on the CO_2 content of the air, as was believed during the last century and the earlier part of this century, changes in the surface temperature of the sea upset the otherwise comparatively constant CO_2 content of air. This explains the low values of the CO_2 content found near the polar regions. The lowest value (1.52×10^{-4} atm) was observed near Spitsbergen by Buch [c. 5]. This value corresponds roughly to the equilibrium value at 0C.

In the most northerly regions, particularly over polar ice, the CO_2 content is again normal, a feature which was explained by Buch on the basis of Bjerknes' scheme of the air circulation over the Atlantic. According to the latter, air in the Arctic is more or less constantly descending, and since it has by-passed at great height the cold-water regions on its way from the south, its CO_2 content would be expected to be near that of the temperate zones. Buch found 2.57 and 2.91 $\times 10^{-4}$ atm.

Equally complicated is the situation in regions where masses of water rise to the surface from greater depths. The CO_2 content of sea water, after falling slightly in the first 50 m below the surface (due to CO_2 assimilation), rises to a maximum at about 500-m depth where the CO_2 pressure may be as much as 11×10^{-4} atm (obviously due to decay of organic matter). If these CO_2-rich water masses rise to the surface (as observed near the west coast of Africa), the CO_2 content of air may locally rise to 7×10^{-4} atm. Similarly high values have been observed by Krogh [14] in the vicinity of West Greenland, and by Moss [c. 14] at latitude 82°27′N, though in these two cases the origin of the CO_2 was not traced, and the effect may possibly, but not necessarily, be spurious.

These phenomena apparently do not affect the air masses to a very great depth. Near Petsamo, Finland, arctic air (range 297 to 313 ppm) differs unmistakably from continental and tropical air (range 319 to 335 ppm), so that in this region the CO_2 content can serve as an indicator for the origin of the air masses. However, these differences become smaller as we go farther south. Thus the difference is still appreciable at Kew, England, where, on the average, subtropical air contains 19 ppm more CO_2 than polar and maritime air; but the mean difference is only 8 ppm near Dieppe, France, and Gembloux, Belgium [c. 5].

---

2. The CO_2 pressure in atmospheres is very nearly, but not quite, identical with the "parts per volume" unit, *i.e.*, 10^{-4} atm $\simeq$ 100 ppm.

The contaminations of CO_2 caused by large towns are also fairly localised. At Kew, about 6 miles west of the centre of London, on the average only 27 ppm more CO_2 are found in easterly than in westerly winds.

Argon (*A*). The constancy of the composition of air with respect to its minor constituents has been investigated in the cases of *A* and *He*. The former was investigated by Moissan [c. 16], who, after chemical removal of O_2, N_2, and CO_2 by calcium metal, measured the remaining rare gases and obtained for the *A* content the figures shown in Table IV. The standard deviation of these analyses (excepting the value of 0.949 over the Atlantic Ocean which must be considered erroneous) is ±0.002 per cent, or 0.2 per cent of the *A* content, and within these limits there are no significant variations.

TABLE IV. SURVEY OF ARGON CONTENTS OF AIR
(*After Moissan* [c. 16])

Location	*A* (per cent)
Odessa	0.935
St. Petersburg (Leningrad)	0.933
Athens	0.935
Ionian Sea (37°N, 15°E)	0.936
Vienna	0.938
Berlin	0.932
Venice	0.936
Mt. Blanc	0.935
Paris	0.934
London	0.933
Atlantic Ocean (37°N, 24°W)	0.932
Atlantic Ocean (43°N, 22°W)	(0.949)
Average (omitting the last value)	0.9343 ± 0.0006

Helium (*He*). Similar results were also obtained with *He* in spite of the fact that vast quantities of *He* constantly escape from the earth's crust, particularly from oil fields in the United States. It has been estimated that between eight and thirty million cubic metres of *He* are generated annually by radioactive processes. The amounts of *He* added to the atmosphere in this way are balanced by losses of *He* into the void of the universe, because *He*, owing to its lightness, is not permanently retained by the gravitational field of the earth.

A world survey covering all continents and oceans from the Arctic to the Antarctic [12] showed no significant deviations even comparatively near oil fields in the United States. The value obtained was 5.239 ± 0.002 ppm with a standard deviation of ±0.008 ppm [11]. It is apparent that the turbulence of the troposphere quickly eliminates any nonuniformity resulting from localised *He* discharge.

ATMOSPHERIC GASES OF CONSTANT PERCENTAGE

While surveys over large areas have been carried out only for the four gases O_2, CO_2, *A*, and *He*, the constancy in the total percentage of these gases makes it plausible that other gases too must have a constant total percentage, unless they are subject to vapour-pressure equilibria (as is H_2O) or to radiation equilibria (as is O_3), or are simply the result of some industrial activity (as are SO_2 and I_2).

Nitrogen (N_2). For the analysis of N_2 no direct precision method has been discovered. However, as the sum of nitrogen and rare gases (called "atmospheric nitrogen" by Krogh) has a constant value of 79.0215 per cent, and as this sum is constant to at least ±0.002 per cent, N_2 too must be constant to the same degree.

Neon (*Ne*). The most reliable data for the *Ne* content of air are (1) a single analysis by Watson [c. 11] who found 18.2 ppm, (2) three analyses by Glueckauf [11] who found a mean of 18.21 ± 0.04 ppm, and (3) recent analyses by Chackett, Paneth, and Wilson [6] who found 18.1 ± 0.08 ppm.

Krypton (*Kr*) and Xenon (*Xe*). Of the figures in the literature [c. 16], those by Moureu and Lepape and by Damköhler appear to be the most reliable. As these values are accurate only to ±10 per cent of their value, the *Kr* and *Xe* contents have recently been redetermined with a much higher accuracy by the author of this article. The figures in parts per million by volume are:

Moureu + Lepape (1926) *Kr:* 1.0 ± 0.1, *Xe:* 0.09 ± 0.01
Damköhler (1935) *Kr:* 1.08 ± 0.1, *Xe:* 0.08 ± 0.01
Glueckauf + Kitt (unpublished) *Kr:* 1.14 ± 0.01, *Xe:* 0.087 ± 0.001

Nitrous Oxide (N_2O). The presence of nitrous oxide in atmospheric air was discovered by Adel [15, Chap. 10] by means of an absorption band at 7.8 μ in the solar spectrum. Since then further atmospheric absorption bands have been discovered at 3.9 μ, 4.5 μ, and 8.6 μ. The recent chemical analysis by Slobod and Krogh [20] of N_2O in air at ground level gave a value of 0.5 ± 0.1 ppm, which is in agreement with the spectroscopic data.

Methane (CH_4). Methane was found by spectroscopic identification of its absorption band in sunlight modified by the passage through the earth's atmosphere over Columbus, Ohio (Migeotte), over Flagstaff, Arizona (Adel), and over Pontiac, Michigan (McMath Observatory) [15, Chap. 10]. From the latter data the CH_4 content of air has been estimated to be about 1.2 ppm (by weight), that is, about 2.2×10^{-6} by volume. It is possible that this figure is somewhat high, as during the process of distillation of air it is found that the *Kr* and *Xe* fraction contains only an amount of CH_4 roughly equal to that of these gases (1.2×10^{-6} by volume).

We are faced with the question of the origin of this CH_4 which is constantly destroyed by the ozone in atmospheric air. As a constant source of this CH_4 we may consider either decay of biological products, or gas escaping from oil wells, or both. The question of the relative extent of these two processes can be decided by determining the content of radiocarbon (^{14}C) in the CH_4 of air. Methane from biological sources contains 0.95×10^{-12} g of ^{14}C per g of *C*, while mineral CH_4 is inactive.

At the suggestion of the author, Prof. F. W. Libby at the University of Chicago analysed the ^{14}C content of

atmospheric methane and found it to coincide with that of biological methane. The analysis also places an upper limit of about 200 years on the mean lifetime of the methane in the atmosphere and suggests an annual production of upwards of 10^7 tons of methane from biological sources.

Hydrogen (H_2). The H_2 content of air is known only approximately. Paneth [16] concludes that it is a constant constituent of atmospheric air and that its amount can be assumed to be about 5×10^{-7} by volume. Recent analyses by the author and G. P. Kitt gave varying amounts of H_2 upwards of 0.4 ppm, and investigations are in progress to see whether these variations occur in the free air or are due to local contamination.

Summary. The figures believed to be most reliable for the constituents of dry air are listed in Table V.

TABLE V. NONVARIABLE COMPONENTS OF ATMOSPHERIC AIR

Constituent	Content (per cent)	Content (ppm)
N_2	78.084 ± 0.004	
O_2	20.946 ± 0.002	
CO_2*	0.033 ± 0.001	
A	0.934 ± 0.001	
Ne		18.18 ± 0.04
He		5.24 ± 0.004
Kr		1.14 ± 0.01
Xe		0.087 ± 0.001
H_2		0.5
CH_4		2
N_2O		0.5 ± 0.1

* Extrapolated to 1950 according to Fig. 1.

CONSTITUENTS OF VARIABLE CONCENTRATIONS
(Excluding Water Vapour)

A rough survey of some of these constituents is given in Table VI.

TABLE VI. VARIABLE CONSTITUENTS OF DRY ATMOSPHERIC AIR

Constituent	Origin	Proportion in ground air (range)
O_3	Ultraviolet radiation	0 to 0.07 ppm (summer) 0 to 0.02 ppm (winter)
SO_2	Industrial	0 to 1 ppm
NO_2	Industrial	0 to 0.02 ppm
CH_2O	Biological or oxydation of CH_4	Uncertain
I_2	Industrial	Up to 10^{-4} g m^{-3}
$NaCl$	Sea spray	Order of 10^{-4} g m^{-3}
NH_3	Industrial	0 to trace
CO	Industrial	0 to trace

Ozone (O_3). The bulk of atmospheric O_3 is contained in the stratosphere, where it is produced by the ultraviolet radiation from the sun. The problems connected with its production and occurrence there form the subject of a separate article in this Compendium.[3] We shall deal here only with observations of O_3 near the surface.

3. Consult "Ozone in the Atmosphere" by F. W. P. Götz, pp. 275–291.

Methods of Determination. The main difficulty in the determination of O_3 in atmospheric air lies in the fact that simple chemical reactions are not specific for O_3 and that gases like H_2O_2, NO_2, and SO_2 interfere with the chemical determination, the first two by increasing, the last by decreasing the analytical result. However, these gases occur only in the vicinity of human habitation. On the other hand, the spectroscopic investigation of surface air [7, 13], though accurate, is so time-consuming (due to the necessary photometry of the spectrograms) that it does not lend itself to routine observations. This also applies to the chemical method of Edgar and Paneth [c. 12] which relies on the separation of O_3 from all other gases by low-temperature adsorption on silica gel. However, two accurate methods have been evolved which give reliable results in a comparatively short time and thus make possible large numbers of determinations under quickly changing meteorological conditions. (See V. H. Regener [c. 17] and Glueckauf, Heal, Martin, and Paneth [c. 12].)

The results obtained so far can generally be explained on the basis that O_3 which is produced in the higher regions—mostly in the stratosphere and possibly some just below the tropopause—reaches the ground level through the turbulence of the air, and on its way down is gradually diminished and eventually destroyed by oxidisable materials of an organic and inorganic character.

Diurnal Variations. On days with little turbulence, the ground O_3 found during the day usually disappears at nightfall because of the increased stability of the air, but it remains unaffected at higher wind velocities.

Annual Variations. Pronounced maxima (7×10^{-8} by volume about May) and minima (2×10^{-8} about November) of the ground O_3 have been found by many observers. The fact that these annual variations are greater than those of the total O_3 may be due to the greater instability of the atmosphere during the summer months. There are some indications that at higher latitudes (*e.g.*, Abisko, Lapland) the high summer values of ground O_3 appear later, if at all.

Geographic Variations. Next to nothing is known about the geographical distribution of O_3 over continents and oceans. Almost all determinations have been carried out between the latitudes 45°N to 68°N over land. Usher and Rao [22], however, reported the absence of ground O_3 in India. This result may not be reliable, but there is obviously wide scope for further investigations.

Ozone during Depressions. The usually high wind velocity and atmospheric turbulence during depressions result in high O_3 contents (subject to the seasonal variations). However, low values of O_3 were found at Durham, England [10], even at high wind velocities in advance of warm fronts, and during occlusions of the cold-front type. Apparently under these conditions inversions are formed which restrict the turbulent interchange of air masses near the ground with the O_3 produced in higher regions. It is to be expected that such phenomena will be greatly reduced in regions with low industrial contamination (*e.g.*, over the

oceans), but no experimental data are available to check this argument.

Ozone during Thunderstorms. Dobson [c. 10] has observed many cases where the total O_3 increases during thunderstorms and during the passage of thunderclouds. There can be little doubt that these changes occur in the tropospheric air and are caused by electric phenomena. A continuous measurement [10] during a thunderstorm gave no indication of any abnormal increase of O_3 near the ground and on this occasion, at least, the O_3-bearing air masses did not reach ground level. Other observers [13], however, found abnormally high O_3 values in ground air on some thundery days.

Vertical Distribution of Ozone in the Troposphere. An increase of the O_3 content with height in the troposphere is shown by the data of Chalonge, Götz, and Vassy [7], who found an average of 1.7×10^{-8} at Lauterbrunnen, Switzerland (800 m), and 3.0×10^{-8} at Jungfraujoch, Switzerland (3450 m).

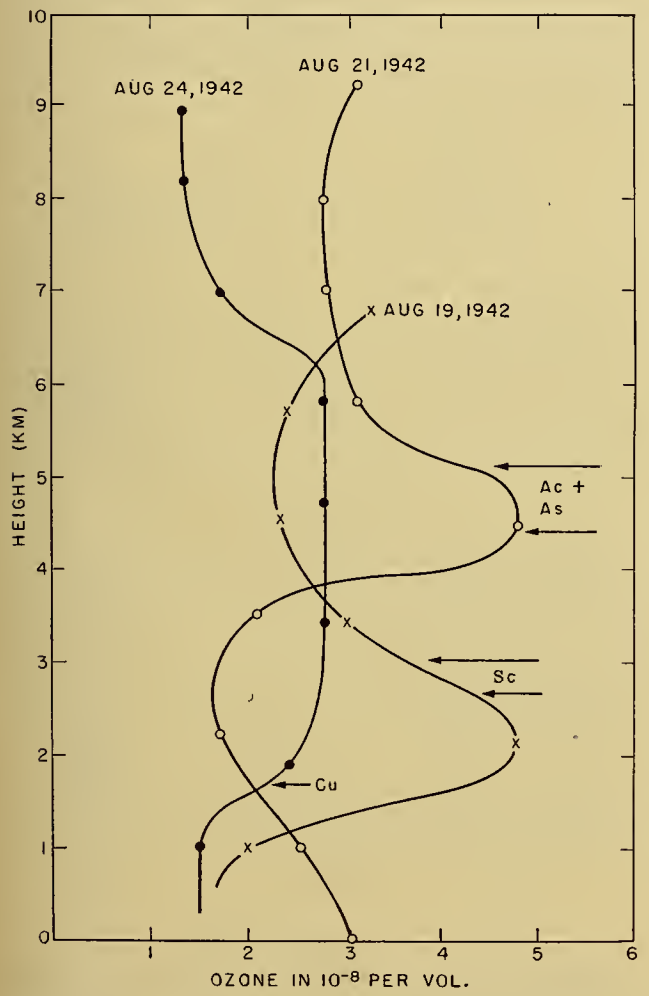

Fig. 2.—Vertical distribution of ozone in the troposphere. (*After Ehmert* [c. 17].)

Ozone determinations made in aircraft by Ehmert [c. 17] show a variety of features (see Fig. 2). In one case the air above cloud level has O_3 contents which, if measured in volume per volume, are independent of height. This would be expected if the mixing ratio is kept constant by turbulence. Much less obvious is the fact that the O_3 content is high in cloudy regions and reaches a maximum just below cloud level. Regener [17] explains these maxima as produced by advection, which may sometimes be the case. However, the repeated occurrence of stratified clouds near such an O_3 maximum seems to indicate that under these conditions O_3 may be produced by phenomena of an electrical nature.

Sulphur Dioxide (SO_2). The quantities of SO_2 found in air vary greatly according to the nearness of towns and the turbulence of the air. To give a few examples: An average of 0.033 ppm was found at the Boyce Thompson Institute (about 15 miles from New York City); at Chicago an average of from 0.06 to 0.27 ppm was found in residential districts and from 0.4 to 0.5 ppm in manufacturing districts. In the presence of O_3, air may be expected to be free of SO_2.

Nitrogen Dioxide (NO_2). No systematic determinations of this constituent seem to have been made. This is largely because of the small quantity present in air and the difficulty of analysis. A very reliable method of NO_2 analysis in air, based on the use of 2:4 xylen-l-ol was used by Edgar and Paneth [c. 12]. From the fact that on a large number of days the NO_2 content found in this way was below the threshold of sensitivity (5×10^{-10}), one is tempted to conclude that NO_2 is not a normal constituent of air. This may be due essentially to its high solubility in water. In large towns, however, where NO_2 occurs as a by-product from the combustion of nitrogenous matter, varying quantities up to 2×10^{-8} were found by a number of authors.

Ammonia (NH_3). The presence of minute amounts of NH_3 in atmospheric air over Michigan has been claimed by Mohler, Goldberg, and McMath [c. 15, Chap. 10] from absorption bands in the 2-μ region. But, as Migeotte and Chapman [c. 15, Chap. 10] have pointed out, the 10.5-μ fundamental band of NH_3 is much more suitable for testing the presence of atmospheric NH_3, and no evidence could be found in this region of absorption either above Flagstaff, Arizona, or above Columbus, Ohio. Moreover, NH_3 is very soluble in water and thus is not likely to be retained in the air for any lengthy period.

Carbon Monoxide (CO). This gas was observed spectroscopically by Migeotte [c. 1] over Columbus, Ohio, as well as on the Jungfraujoch (3580 m altitude) but, as none could be found by Adel over Flagstaff, Arizona [1], it is not yet certain whether it is a permanent constituent of the atmosphere.

THE UPPER ATMOSPHERE

The composition of air in the upper atmosphere is of considerable interest as an indicator of whether or not large-scale mixing of air masses takes place in the stratosphere. It is often assumed that the absence of a systematic temperature gradient in the stratosphere is incompatible with large-scale mixing. In the absence of turbulent mixing, however, diffusive separation of the gases should take place and the lighter gases should

become relatively more abundant with increasing height.

The most direct method of finding the level where diffusive separation begins is the chemical analysis of air samples taken at great heights, since the gravitational equilibrium should cause the O_2 content to decrease by 2 per cent per kilometre and the *He* content to increase by 14 per cent per kilometre. Air samples from the stratosphere have been obtained by manned and unmanned balloon flights. The results of these analyses are shown in Table VII.

TABLE VII. COMPOSITION OF AIR IN THE STRATOSPHERE

Height (km)	Helium variation (per cent)	Oxygen variation (per cent)	Source of data*
9–17		0	*c*
14.5		−0.14	*d*
16.5	+0.5 ± 0.5		*e*
18.0	+0.35 ± 0.1		*e*
18.5	+0.7 ± 0.3	0	*e,a*
18.5		−0.38	*d*
19.0	+0.55 ± 0.15	−0.24	*e,d*
21.0	+6.9 ± 0.7		*e*
21.5		−0.24	*b*
22.0	+4.1 ± 0.2		*e*
22.0	+1.95 ± 0.15		*e*
22.5	+5.1 ± 0.6		*e*
22.5	+1.9 ± 0.3		*e*
23.5	+4.0 ± 0.3		*e*
23.5	+0.3 ± 0.15		*e*
24		−0.86	*d*
25	+2.1 ± 0.3		*e*
28–29		−2.5	*d*

* Manned balloon flights
(*a*) Prokofiev, 1933
(*b*) *Explorer II*, 1936
Unmanned balloon flights
(*c*) Lepape and Colange, 1935
(*d*) E. Regener, 1936
(*e*) Glueckauf and Paneth, 1946

It appears from this table that there is no significant change in either the *He* content or the O_2 content below 20 km. The *He* surplus observed between 21 and 25 km averages 3.3 per cent, an enrichment which should be found at the top of a column of still air only 250 m high. The biggest O_2 deficit, at about 28 km, corresponds to a column of still air only 1100 m high. It is therefore apparent that at the heights reached by sounding balloons there is sufficient turbulence to reduce the changes in the *He* content to about $\frac{1}{40}$ of what one would expect from a gravitational equilibrium starting at the tropopause. The recent analysis by Chackett, Paneth, and Wilson [6] of three air samples collected by a V-2 rocket from a height of 50 to 70 km, gave variations of +0.3 to −4 per cent for *He*, variations of −0.3 to −0.7 per cent for *Ne*, and variations of −0.4 to +1.0 per cent for *A*. These results make it certain that no diffusive separation is maintained even at these great heights.

ISOTOPIC COMPOSITION OF THE ATMOSPHERIC GASES

Increased attention to the isotopic composition of the atmospheric gases is likely to throw light on a number of problems. The composition in most cases is very similar to that found in the same atomic species in other parts of the earth's crust[4] (see Table VIII).

Water Vapour. Because of differences in the vapour pressures, mainly of $^1H_2{}^{16}O$, $^1H_2{}^{18}O$, and $^1H^2H^{16}O$, the density of atmospheric water should be slightly less than that in the oceans from which it originates. This was confirmed by Riesenfeld and Chang [19] who found a deficit of 3.8 γ in the density of snow water, and of 2.5 γ for rain water ($1\ \gamma = 10^{-6}$ g ml^{-1}). These figures are approximately what would be expected from the known vapour pressures.

Oxygen. The differences in the composition of the oxygen in (liquid) water, gaseous oxygen, and carbon dioxide are much smaller, the densities being in the ratio 1:1.0000073:1.0000116 [23]. From this follows a slight enrichment of the ^{18}O isotope in the ratio 1:1.0033:1.0053. The difference of the oxygen density for atmospheric CO_2 and for that of carbonate rocks is negligible [9].

TABLE VIII. ISOTOPIC COMPOSITION OF THE MAIN ATMOSPHERIC GASES

Element	Atomic mass numbers (in parentheses) and percentages (in italics) of isotopic species
H in H_2O	(1) *99.98* (2) *0.02*
He	(3) *1.1* × 10^{-4} (4) *100*
C in CO_2	(12) *98.9* (13) *1.1* (14) *0.95* × 10^{-12}
N	(14) *99.62* (15) *0.38*
O	(16) *99.757* (17) *0.039* (18) *0.204*
Ne	(20) *90.00* (21) *0.27* (22) *9.73*
A	(36) *0.307* (38) *0.061* (40) *99.632*

Hydrogen. The difference in the isotopic composition between atmospheric H_2 and water vapour in air has not been determined, but if the two are in equilibrium (which is not necessarily the case), one would expect a considerably reduced deuterium-hydrogen ratio in the gaseous hydrogen, as $\frac{(D/H)_{\text{water vapour}}}{(D/H)_{\text{hydrogen}}} = 3.6$ (Suess [21]).

Helium.[5] Much greater differences are observed for the ^3He content of helium found in air, in rocks, and in oil wells (Aldrich and Nier [2], and Coon [8]), the ratios $^3He/^4He$ being 1.2×10^{-6}, 1.5×10^{-7}, and 3×10^{-8}, respectively. This clearly points to a different mode of origin of the two *He* species in the three cases. The ^3He in the atmosphere is suspected to arise from the reaction of nitrogen with neutrons derived from cosmic radiation. The ^3He in the lithosphere is presumably due to the action of neutrons on *Li* where the neutrons arise from known reactions of small atomic nuclei with the α particles of the natural radio-ele-

4. The questions of the origin and development of the atmosphere, though of interest to meteorologists, cannot be adequately dealt with in this paper. Attention is drawn to detailed articles by Chamberlin, Brown, and Kuiper [15, Chaps. 8, 9, 12], and by Wildt [24] where further references may be found.

5. (*Added in press*) See also the recent note by P. Harteck and V. Faultings on "The ^3He-Problem of the Atmosphere." *Nature*, 166:1109 (1950).

ments. The connection of ^3He in minerals with Li is borne out by the abnormally high $^3He/^4He$ ratio in spodumene, a lithium aluminium silicate.

Carbon. Another isotope which owes its existence to the neutrons from cosmic radiation is the radioactive ^{14}C, which is produced by $^{14}N + n \rightarrow {}^1H + {}^{14}C$.

As cosmic ray neutrons are produced mainly in the upper atmosphere, the ^{14}C starts its career as CO_2 and enters into all organic matter by the process of plant assimilation. After the death of the plant the radioactive carbon decays with a half-life of 5720 years, so that old coal and oil deposits are no longer radioactive. The proportion of radiocarbon was found to be 0.95×10^{-12} g of ^{14}C per g ^{12}C in living matter [3].

FUTURE DEVELOPMENTS

Oxygen and Carbon Dioxide. Our best values of the O_2 content or, for that matter, of the O_2 and CO_2 content of air date from 1912. Since then a number of improvements in the control of thermostats and in all manner of measuring devices have been made, which should render possible an increased accuracy. A redetermination is particularly desirable in order to get an idea of any long-term variations of the O_2 content of air.

There are, moreover, the unexplained O_2 values of Lockhart and Court in the Antarctic which should be either confirmed or refuted. This applies also to the high CO_2 values observed by Krogh in certain arctic regions, where the observed variations were very large, and further investigations are likely to bring to light some interesting phenomena responsible for such changes. Callendar's suggestion of a CO_2 increase during this century due to industrial CO_2 production requires that the CO_2 content of the Northern Hemisphere should be slightly larger than that of the Southern Hemisphere, a feature which should be subject to experimental verification by modern techniques.

The results of Buch and of Wattenberg make it fairly certain that there is a CO_2 circulation in the oceans involving uptake of CO_2 at high latitudes and its release at low latitudes. Some light on the time scale of this cycle might be thrown by a ^{14}C analysis of the CO_2 released from the sea at low latitudes, which, if the cycle exceeds 10^3 years, would result in a noticeable decrease of ^{14}C activity.

Methane. The CH_4 in the atmosphere, discovered only recently, still offers a few problems. Its percentage in air requires more accurate determination, and the question of its production requires further study.

Hydrogen. Our knowledge of the H_2 content of the air is so far inadequate.

Ozone. Large gaps still exist in our knowledge of the atmospheric O_3 near the ground. Its geographical distribution at ground level is quite unexplored; its dependence on weather conditions has only been touched on, and requires much more systematic investigation, particularly with reference to its vertical distribution. The increased occurrence of O_3 near cloud levels and its connection with thunder clouds also require more detailed investigation, including a study of its possible mode of generation under such conditions.

Upper Atmosphere. It now seems certain that the upper atmosphere has essentially the same composition as that found at the ground, at least up to heights of 70 km, though further confirmation of the rocket data is desirable and will no doubt be obtained in the near future. This uniformity means that turbulent mixing in the stratosphere is considerably greater than was formerly expected. An explanation for this turbulence has been suggested by Brewer [4] who assumes an air circulation involving a movement of air into the stratosphere at the equator followed by slow poleward movement in the stratosphere, accompanied by a slow sinking movement in the temperate and polar regions. As this hypothesis requires the abandonment of the idea of a stratosphere which is in radiative equilibrium, many new and interesting problems arise which require experimental confirmation.

SOLAR RADIANT ENERGY AND ITS MODIFICATION BY THE EARTH AND ITS ATMOSPHERE

By SIGMUND FRITZ

U. S. Weather Bureau, Washington, D. C.

The sun is the principal source of the energy which, by devious means, becomes the internal, potential, and kinetic energy of the atmosphere. The solar irradiation of a unit horizontal surface at the outer limits of the earth's atmosphere can be evaluated, at least in relative units, from astronomical and trigonometrical considerations [61]; thus on a relative scale, the diurnal and seasonal variations of this solar irradiation above the atmosphere are known. On the average, variations similar to these occur also at the earth's surface, and the associated diurnal and seasonal changes in atmospheric temperature are commonplace knowledge [52].

There are, however, additional changes in effective solar irradiation of the planet Earth which are superposed on the trigonometrical variations. These are of two kinds. The first is due to the change in the quality and quantity of energy which leaves the sun. The second is caused by changes in the reflectivity of the atmosphere (including clouds) and of the earth's surface; the solar energy which is immediately reflected to space cannot be meteorologically effective.

In contrast to the regular, astronomically induced changes in meteorological parameters (notably diurnal and seasonal atmospheric temperature changes), the large-scale meteorological consequences of these irregular changes in solar irradiation are far from obvious, if, indeed, any such meteorological effects can be shown to be induced at all by them. For example, changes of the first kind (*i.e.*, in solar output) have been invoked as possible causes of abnormal heating in the ozone layer with subsequent pressure changes at the earth's surface [44]; changes of the second kind (*i.e.*, in reflection by the earth or clouds) are important, for instance, in local turbulence of the air near the ground, but are rarely used to explain widespread meteorological phenomena. These as well as other solar-induced meteorological phenomena are discussed elsewhere in this Compendium. In this article we shall, for the most part, examine the solar energy itself and shall mention its meteorological effects only incidentally.

SOLAR RADIATION OUTSIDE THE EARTH'S ATMOSPHERE

The Sun. The sun, located about 93,000,000 miles from the earth, is a large, hot, gaseous mass. When viewed through a smoked glass it appears as a smooth circular disk which is called the *photosphere*, but when examined with the aid of more refined techniques, the photospheric surface appears highly granulated and is surrounded by a gaseous envelope which is commonly divided into three layers for descriptive purposes. Of these the one just outside the photosphere is the relatively thin *reversing layer*, so called because the spectral lines ordinarily seen as dark absorption lines in the photospheric spectrum appear as bright emission lines when examined in the reversing layer; still farther from the photosphere is the *chromosphere*; and beyond that is the *corona* [4]. The sun's "surface" and its surrounding atmosphere are by no means static. The presence of short-lived photospheric grains, dark sunspots, bright areas (faculae and flocculi), and erupting prominences indicate that the entire observable sun is in a state of considerable turmoil. This turmoil is associated with variations in the quantity and spectral intensity distribution of the solar energy which subsequently irradiates the outer limits of the earth's atmosphere.

Average Spectral Distribution of Sunlight. To calculate the solar energy available for meteorological processes, it is desirable to measure the amount of solar energy I_0 (the so-called *solar constant*) which reaches the outer atmosphere of the earth. To determine the interaction between our atmosphere and the sun's energy, the distribution of spectral intensity $I_{0\lambda}$ of the extraterrestrial solar energy is also required. For both of these quantities we are largely indebted to the Astrophysical Observatory of the Smithsonian Institution, whose determinations of I_0 and $I_{0\lambda}$ are monuments to the work of the Observatory.

Until recently, the sun's energy had not been directly observed below wave lengths of about 2900 A because of the absorption of energy of shorter wave lengths by the envelope of ozone which surrounds the earth up to about 50 km. For wave lengths greater than 2900 A, selective scattering and absorption, mainly by air, dust, and water vapor, modify the solar spectrum; these troublesome modifications must be eliminated from measurements made at the ground under cloudless skies to obtain the extraterrestrial spectrum. In the region from about 0.29 μ to 2.5 μ numerous measurements and extrapolations have been made. The Smithsonian Institution [3] is the main source of spectral information for the region above 3400 A, but its latest summary of data was compiled in 1923 [2]. Recently, V-2 rocket observations have extended the measured spectrum down to 2200 A [47].

Visible and Near Infrared Radiation. Both the total amount and the spectral distribution of the radiant energy emitted by a black body are determined by its temperature. It is therefore convenient to describe the radiant energy from a source in terms of the black-body temperature which would most nearly produce the observed energy. The sun *does not* radiate as a black body. Despite this fact, the average observed energy curve from about 0.45 μ to about 2.0 μ closely approxi-

mates the spectral-energy distribution of a black body (Fig. 1). It is therefore not unusual to speak of the black-body temperature of the sun as 6000K, although this numerical value may vary by several hundred degrees depending upon the method used to calculate it [4]. For example, the total energy emitted by a black body per unit area per unit time is given by σT^4, where T is its temperature in degrees absolute and σ is the Stefan-Boltzmann constant. The solar constant is commonly taken as 1.94 ly min^{-1} (where ly = langley = g cal cm^{-2}), and considering the distance from the earth to the sun, we can calculate the total energy emitted by the sun. Then, by introducing the sun's

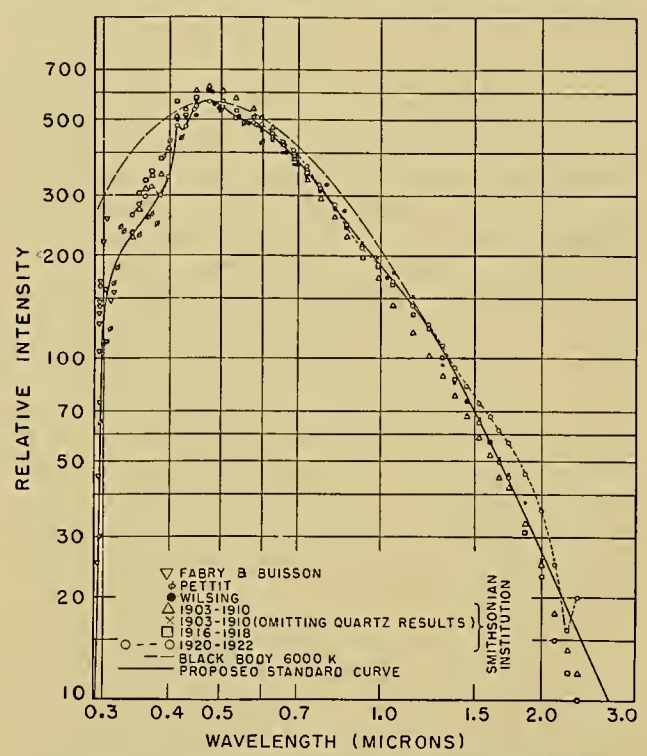

FIG. 1.—Spectral intensity distribution of solar radiation outside the earth's atmosphere. (*After Moon* [63].)

area, we calculate the energy radiated per square centimeter of solar surface. Placing that energy equal to σT^4, we get T = 5770K.

Another temperature estimate results from Wien's displacement law for black bodies: $\lambda_{max}\ T$ = const, where λ_{max} is the wave length of maximum intensity. Abetti [4] takes λ_{max} = 4740 A and finds T = 6080K.

It should be emphasized that at wave lengths outside the region 0.45 μ to 2.0 μ solar energy departs markedly from that of a black body at 6000K. Moon [63] has combined the results of several authors and obtained Fig. 1, which shows the relative intensity $I_{0\lambda}$ of the energy as a function of wave length.

Ultraviolet Radiation. The energy in the ultraviolet spectrum is well below that of a black body at 6000K; this has been established by several investigators [35, 37, 72]. Hulburt's curve [47] in Fig. 2 contains the Naval Research Laboratory rocket measurement at 55 km in which no ozone could be detected and was one of a series of spectra observed at levels up to 88 km. Other measurements from rockets up to 155 km [20] show results similar to those at 55 km and indicate that the energy is less than that of a black body at 6000K.

A recent curve by Götz and Schönmann [35], based on five observations in the region from 3300 A to 5000 A, lies far below (by a factor of 2 or more at 3400 A) Moon's curve of Fig. 1; this is also true of Hess's data [55, p. 324]. Perhaps these lower values are due to the fact that the Smithsonian observations were troubled by scattered light at short wave lengths. If the rocket data (Fig. 2) had been joined to the data of Götz and Schönmann, the resultant spectral curve would ob-

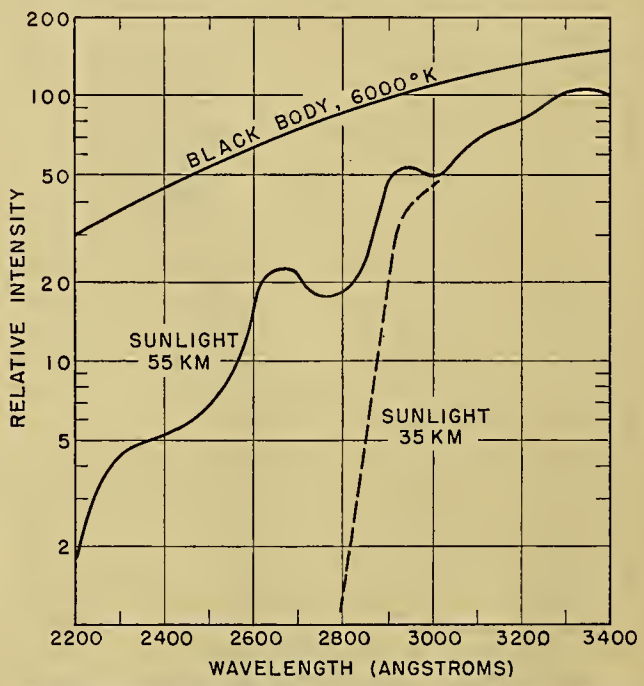

FIG. 2.—Spectral intensity distribution of ultraviolet solar radiation measured from a rocket. (*After Hulburt* [47].)

viously have been much farther below the 6000K curve. Future measurements will decide the true state of affairs.

Infrared Radiation. The near infrared has been observed many times by the Smithsonian Institution. Abbot and others [2] considered their 1920–22 curve as the best estimate. Their data exceed the black-body curve (Fig. 1) in the region near 2 μ, but Moon, also accepting the earlier data, adopted the 6000K blackbody curve as the true one beyond 1.25 μ. Beyond 2.5 μ, Adel [5] has observed the spectrum up to about 24 μ. He finds that the solar temperature is about 7000K in the far infrared.

Short-Wave Radio Radiation. Measurements up to 24 μ have been made by optical means. Recently the observations have been extended by radio detection instruments into wave lengths of the order of a few centimeters to a few meters [39, 62]. These observations indicate black-body temperatures of the order of 10^6K

or more. It should be pointed out, however, that the black-body energy is so small at those wave lengths—even during disturbed sun conditions—that radiation from a black body at 10^6K can contribute only a very small amount of thermal energy by comparison with the principal solar energy [39].

The Unmeasured Radiation. We turn now to an important region of unmeasured radiation, namely, the ultraviolet energy below 2200 A.

From a consideration of the ionized states of certain elements observed in the sun and from the consideration of the state of ionization of the earth's ionosphere, several investigators have concluded that in the region below 1000 A the sun radiates energy corresponding to temperatures above 6000K. Greenstein [37] mentions the uncertainty regarding the need for assuming such excess ultraviolet radiation and concludes that at least for $\lambda > 1215$ A the temperature corresponding to solar energy is probably less than 6000K and is near 5000K. For $\lambda \leqq 900$ A he discusses a suggestion by Kiepenheuer and Waldmeir that corona temperatures of 10^6K enhance the photospheric radiation by a factor of 2 at 900 A and by 2×10^6 at 600 A. For $\lambda > 900$ A no appreciable radiation is contributed by the corona. Superposed on the *average* radiations, measured and unmeasured, are the radiations from the "cool," dark sunspots (temperature about 4800K [4]), and the increased radiation from the bright areas, that is, from faculae and flocculi.

In addition to the electromagnetic radiation described above, the sun also emits particles which are responsible for such effects as the aurorae and some types of magnetic and ionospheric storms.

Summary. It appears then that in the optically measured spectrum, from about 0.45 μ to 24 μ the sun radiates as a black body whose temperature is close to 6000K, perhaps increasing to 7000K towards the higher wave lengths. For shorter wave lengths, at least down to 0.22 μ, the measured radiation corresponds to a considerably lower temperature of about 4000K to 5000K. For 1000 A $< \lambda <$ 2200 A this lower temperature may also apply [37]. But for $\lambda <$ 1000 A the hot corona may dominate, resulting in much higher effective black-body radiation. In the comparatively long wave lengths from 1 cm to 30 m, high temperatures (10^6K) are again indicated. In the region from 24 μ to 1 cm, no measurements seem to have been made.

Fluctuations of Emitted Radiation. The bright and dark markings and other manifestations of changes on the sun can be expected to produce spectral emissions which differ from the average solar emission. These spectral variations are indeed observed directly or indirectly in nearly all parts of the solar spectrum.

Far Ultraviolet. That there are marked changes in the far ultraviolet emission from the sun is evident from measurements of the reflection of radio waves by the ionospheric layers in the earth's upper atmosphere. These layers are regions where solar ultraviolet energy ($\lambda <$ 1000 A) has ionized the atmospheric gases, with the result that they have the property of reflecting radio waves of certain frequencies. The approximate heights [38, 62] and pressures of those layers are given in Table I.

Table I. Approximate Heights and Pressures of Ionized Layers

Layer	Height (km)	Approximate pressure (mb)
F_2	300	5×10^{-7}
F_1	200	1×10^{-5}
E	100	5×10^{-3}
D	80 to 50	5×10^{-2} to 1

The highest frequency radio signal which can be reflected is called the *critical frequency* f_o for the reflecting layer, and it can be shown that under certain assumptions [64, p. 59]

$$f_o^2 \propto N_i, \tag{1}$$

and that

$$N_i^2 \propto I_{0\lambda}, \tag{2}$$

where N_i is the maximum ion density of an ionized layer. Hence on combining equations (1) and (2),

$$I_{0\lambda} \propto f_o^4. \tag{3}$$

The critical frequency f_{oF_2} of the F_2-layer fluctuates considerably from day to day. When the measured daily value of f_{oF_2} at noon is plotted against the daily sunspot number, no significant correlation can be found [69]; on a monthly basis a small correlation may be present [13]. However, if a twelve-month running average of noon f_{oF_2} is plotted against the twelve-month running averages of sunspot numbers, a linear relation results with very little scatter of the points [64], and f_{oF_2} increases by a factor of about 2 from sunspot minimum to sunspot maximum. Similar results appear for the F_1- and E-layers; but for these latter layers, f_o increases by a factor of about 1.2 from sunspot minimum to sunspot maximum [9]. The D-region variation is apparently similar to the E and F_1 variation [64].

If equation (3) is applied to the smoothed data over the sunspot cycle, $I_{0\lambda}$ (which may be in a different wavelength region for each layer) increases by a factor of approximately 2 for the E- and F_1-regions [9, 64]. But since f_{oF_2} increases by a factor of 2, $I_{0\lambda}$ would increase sixteenfold in the F_2-region [64]. However, other relations have been mentioned for the F_2-layer. Mitra [62] indicates that instead of equation (2), $N_i \propto I_{0\lambda}$ applies here; this leads to $I_{0\lambda} \propto f_o^2$. Allen [9] prefers $I_{0\lambda} \propto f_o$. Mitra's relation leads to a fourfold increase in $I_{0\lambda}$, while Allen's relation leads to a twofold increase. We may conclude therefore that $I_{0\lambda}$, which produces the F_2-layer, surely increases from sunspot minimum to sunspot maximum and that the amount of the increase is at least twofold.

What is the significance of ionospheric heating for tropospheric meteorology? Since very little direct relation exists between the critical frequencies and the unsmoothed sunspot data, some effect (possibly solar)

other than sunspots must produce these ionospheric variations; only on the *average* is the ultraviolet intensity correlated with sunspots. We should expect therefore that the meteorology of the troposphere would not be correlated with sunspots on a daily basis if ionospheric variations were used as a criterion. What about longer periods? The wave lengths involved are of the order of 1000 A or less, so that the amount of energy is small and the pressure (about 10^{-3} mb or less) and density of the absorbing layers are so small that it seems unlikely that heating in the ionosphere by the increased ultraviolet energy can directly affect the meteorology of the lower atmosphere; at least that is the view of one school of thought [71, p. 504]. Therefore for longer periods also, if *only* the ionosphere were involved in variable ultraviolet absorption, no tropospheric effect would be noticed.

At present, one cannot specify the height at which anomalous heating in the upper atmosphere can affect the troposphere through dynamic processes. However, if in addition to an increase in the radiation which heats the ionosphere, increases also occur in the ultraviolet energy which can penetrate to lower layers, for example, to the top of the ozone region (40–50 km) where the pressure is of the order of 1 to 3 mb, then dynamic pressure changes caused by additional heating are more likely [44; 71, p. 504]. And indeed such ultraviolet energy increases *may* occur, but it is not certain at present that significant increases occur at wave lengths which can heat the ozonosphere.

There are several solar-induced effects in the ionosphere, as revealed by magnetic and radio data, and from the ozone-heating viewpoint at least one of these ionospheric phenomena deserves further mention. That phenomenon is the radio fade-out or sudden ionospheric disturbance (SID). SID's are caused when radio waves transmitted upward from the ground are strongly absorbed in the D-layer, so that they cannot be reflected back to the ground by the higher ionospheric layers. The increased absorption of the radio waves is caused by a sudden increase in the ionization of the D-layer; the increased D-layer ionization is caused by a sudden large increase in the solar ultraviolet energy which reaches and is absorbed by the layer. In short, SID's are caused by sudden increases in ultraviolet solar radiation and occur simultaneously with the appearance of visible bright solar flares on the sun (chromospheric eruptions).

Moreover, it is found that during SID's the F-layers are practically unaffected and the E-layer is only slightly affected. Hence the upper ionospheric regions are apparently transparent to the ionizing radiations in this case, while the lower D-region absorbs them strongly. The duration of SID's is of the order of a few minutes to a few hours, and their intensity is of course variable.

Here then is a phenomenon which produces short-lived intense ionization, and hence heating in the vicinity of 60 km. Since the upper layers are unaffected, the radiation must be of wave lengths such that the air above 80 km is transparent. Wulf and Deming [79] offer an interesting explanation of this ionization. Ozone absorbs very strongly in the region 2300 A to 2800 A, but this spectral region is transmitted readily by the atmosphere above 60 km. They suggest that partial absorption at the top of the ozone layer ionizes the ozone there. Increased solar emission at those wave lengths may therefore be responsible for the increased D-region ionization and hence for SID's. It should be pointed out however that the recent V-2 rocket measurements [47] could not detect any ozone above 55 km. Probably an amount of ozone smaller than could be detected by the rocket exists above 55 km and this is sufficient to produce the observed ionization.[1]

According to some writers, the increased emission during solar flares is contributed largely by specific elements, hydrogen and calcium, for example [25], although emissions from other elements have been measured. Hydrogen does not radiate in the wave lengths 2300–2800 A. Calcium and some of the other elements, on the other hand, do emit monochromatic radiation there, so that some increase in $I_{0\lambda}$ occurs during solar flares in this region—how much of an increase is still unknown.

Mitra [62] discusses some other SID explanations and prefers 973 A as the wave length of the ionizing radiation. Heating by such radiation in a narrow spectral band may be small and should not extend very far into the ozonosphere. But if, as Wulf and Deming suggest, increased radiant energy in the broad band 2300–2800 A is emitted, then the resulting increased heating, not only at and above 60 km but also lower in the ozonosphere, may have important implications for tropospheric meteorology [44]. It would therefore be highly desirable to measure the distribution of spectral intensity in this region at frequent intervals. Hulburt [47] reports that the solar spectrum near 2200 A was detected at 34 km from the V-2 rocket, and Brasefield [16] has described some temperature measurements from an unmanned balloon up to 140,000 ft (42 km). If such balloons could be equipped for constant-level flights at 40 km or higher and designed to carry spectral measuring equipment, it would be possible to determine the solar spectrum near 2200 A and for $\lambda > 2700$ A at frequent intervals during days of both disturbed and undisturbed solar conditions. Such measurements may determine whether current ideas regarding solar control of weather through heating of ozone have any basis.

Near Ultraviolet. In a series of optical measurements during the years 1924–32, Pettit [68] determined the intensity at 3200 A relative to the intensity at 5000 A and extrapolated in the usual manner to the "top" of the atmosphere. Presumably the intensity at 5000 A changed rather little, so that the variation in the ratio reflects the time variation in the intensity at 3200 A. His averaged data show a rather good agreement with the smoothed sunspot numbers, low sunspot numbers

1. At the January 1950 meeting of the American Meteorological Society in St. Louis, Missouri, R. Tousey of the Naval Research Laboratory reported a rocket measurement of small amounts of ozone up to 70 km.

corresponding to low ultraviolet radiation, as in the ionosphere, but at times the correlation was negative (June 1928 to June 1929). Since the intensity at sunspot maximum was about 1.5 times that at sunspot minimum, he felt that in general the range of the observed variations at 3200 A was too great and that an atmospheric effect might have been partly responsible for the range.

In support of Pettit's doubts, Bernheimer [15] found an annual trend in Pettit's data, and indicated that the observed variations may have been due to changes in atmospheric transmission, rather than to increased solar emission. As we shall see later, this difficulty of extrapolating through the earth's atmosphere is also a continual worry in determinations of variations in the solar constant.

Visible and Infrared Radiation. The fluctuations in ultraviolet radiation seem to be related to hot, bright areas, for example, faculae and flocculi [9]. These areas, which can be seen visually, cover rather small portions of the sun. As the temperature of a body increases, the intensity of the emitted radiation increases at all wave lengths, but the wave length of maximum intensity shifts towards shorter wave lengths. Hence, since the maximum intensity occurs at a wave length of about 4700 A in the average solar spectrum (Fig. 1), it might be expected that, as the sun's temperature increases, the relative increase of intensity at $\lambda < 4700$ A will be greater than in the longer wave length visible or infrared regions. Such is indeed the case; the intensity of the radiation in the visible and infrared changes by small amounts in response to the dark and bright markings on the sun.

Abbot [3, Vol. 6, p. 165] found that, on days with high solar constant, $I_{0\lambda}$ at 0.35 μ increased by about 5 per cent over its value on days with low solar constant. At 1.7 μ, $I_{0\lambda}$ *decreased* by about 1 per cent under the same circumstances. It should be noted, however, that solar-constant variations are not well correlated with sunspots [8].

Radio Waves. As stated earlier, radio-wave emission from the sun (from a few centimeters to a few meters in wave length) indicates temperatures of 10^6K; under disturbed conditions, radiation corresponding to 10^9K can be observed [60, p. 328]. However, the amounts of these energies are very small.

Summary. There is good evidence from radio measurements that large fluctuations in solar radiation occur at $\lambda < 1000$ A and at $\lambda = 10$ to 10^3 cm. The variations seem to appear in daily measurements and also appear systematically in the sunspot cycle. In the meteorologically important spectral region of 2000–2800 A there is a suggestion that at least short-lived large fluctuations may occur (SID) [79]; direct measurements of these fluctuations to determine their magnitude would be very desirable. At somewhat longer wave lengths, for example 3200 A [68], measurements indicate solar-controlled fluctuations, but doubts have been raised about the reality of their magnitude. That variations in the visible spectrum from parts of the sun occur can be seen from the bright and dark areas on the sun. However, these areas are small and the variations in the visible and near-infrared radiation represent only a small percentage of the average radiation from the entire sun.

The Solar Constant. So far we have discussed the *relative* spectral distribution of intensity in solar radiation. To describe the radiation it is also necessary to specify the *amount* of radiation on an absolute basis.

The "solar constant" is a measure of the total amount of heat which reaches the outer atmosphere of the earth. Specifically, it is often expressed as the amount of energy which, in one minute, reaches a square centimeter of plane surface placed perpendicular to the sun's rays outside our atmosphere when the earth is at its mean distance from the sun.

Methods of Measurement. To clarify the following discussion let us review the basis for the fundamental (or "long") method of the Smithsonian Institution for measuring the solar constant [3, Vol. 6, p. 30]. The intensity I_λ of parallel monochromatic energy transmitted through the earth's cloudless atmosphere is given by

$$I_\lambda = I_{0\lambda} e^{-k_\lambda m} = I_{0\lambda} a_\lambda{}^m, \tag{4}$$

or

$$\ln I_\lambda = \ln I_{0\lambda} + m \ln a_\lambda,$$

where k_λ is the extinction coefficient, a_λ is the atmospheric transmission with the sun in the zenith, and m is the optical air mass or the path length of the parallel light through the atmosphere measured in terms of the zenith path as unity.[2]

Except for large zenith angles Z, the value of m is given by sec Z. Hence m can be readily determined; I_λ is measured in relative units. If a_λ remains constant, then by equation (4) a graphical plot of ln I_λ against m will yield a straight line whose slope is ln a_λ and whose intercept for $m = 0$ (outside the atmosphere) is ln $I_{0\lambda}$; I_λ is measured nearly simultaneously for the spectral region $0.34\,\mu < \lambda < 2.5\,\mu$. This is repeated for several values of m, so that by the graphical method just mentioned $I_{0\lambda}$ can be evaluated at several wave lengths in the region. From the measurement and graphical extrapolation, a plot of I_λ vs. λ, and another plot of $I_{0\lambda}$ vs. λ can be made in *relative* units for the region 0.34 μ to 2.5 μ. We desire to find the areas $\Sigma I_\lambda \Delta\lambda$ and $\Sigma I_{0\lambda}\,\Delta\lambda$, respectively, under these graphs in *absolute* units. Therefore, by means of a pyrheliometer, a nonspectral measurement in absolute energy units is made of the total radiation I; I includes not only the energy which reaches the observer for λ between 0.34 μ

2. The value of m is ordinarily specified as unity for zenith path length at sea level. Values of m at sea level are given by sec Z for values of Z (sun's zenith distance) up to 70°; for larger Z, Bemporad's formula [56] is commonly used. To compute the air mass m_p for elevated stations where the pressure is p, the sea-level value of m is multiplied by p/p_0 where p_0 is the sea-level pressure. When I_λ is measured at one station, however, it is not necessary to correct m for pressure to find $I_{0\lambda}$ from equation (4).

and 2.5 μ, but also the energy for $0.29\ \mu < \lambda < 0.34\ \mu$ and $\lambda > 2.5\ \mu$ (since energy below 0.29 μ does not reach the ground). Hence, if to the area $\Sigma I_\lambda \Delta\lambda$ under the spectral curve is added the energy ϵ in the wave lengths which reach the ground but are not measured spectrally (namely $0.29\ \mu < \lambda < 0.34\ \mu$ and $\lambda > 2.5\ \mu$) then the area under the curve, $\epsilon + \Sigma I_\lambda \Delta\lambda$, will be proportional to the corresponding pyrheliometric measurement I.

The area I_{0a} under the curve of $I_{0\lambda}$ versus λ (for $0.34\ \mu < \lambda < 2.5\ \mu$) can now be converted to energy units, since

$$\frac{I}{I_{0a}} = \frac{\Sigma I_\lambda \Delta\lambda + \epsilon}{\Sigma I_{0\lambda} \Delta\lambda}. \tag{5}$$

It remains to add to I_{0a} the energy ϵ_0 for $\lambda < 0.34\ \mu$ and $\lambda > 2.5\ \mu$ in order to obtain I_0, the solar constant.

This "long" method implies that a_λ is constant during the period of measurements (2–3 hr), and also that I, the pyrheliometrically measured radiation, is known in absolute units (langleys per minute). In practice the corrections for all unmeasured spectral regions are applied together.

Equation (4) requires that the atmospheric transmission a_λ be constant during a series of spectral measurements which are performed during a period of a few hours (from air mass 5.0 to 1.5). To the extent that a_λ is not constant, errors will be introduced in $I_{0\lambda}$ and hence in the solar constant. Partly for that reason, the Smithsonian Institution devised a "short" method for measuring the solar constant. In this method, a_λ is determined by a measurement of the brightness of the sky in the vicinity of the sun and from an empirical relation between the brightness and the transmission coefficient a_λ.

The Numerical Value of the Solar Constant. Let us consider I. The standard of pyrheliometry adopted by the Smithsonian Institution in 1913, when applied to solar-constant measurements, leads to 1.94 ly min^{-1} as the average value for I_0. This is the value most often used at present. The Smithsonian standard was known to be about 3.5 per cent higher than the Ångström standard, but in 1932 and on subsequent occasions Abbot and Aldrich redetermined their standard and found that their 1913 standard was too high by 2.3 per cent [12], thus decreasing the disagreement with the Ångström scale. The new Smithsonian standard scale reduces the value of the average solar constant from 1.94 to 1.90 ly min^{-1}.

Before accepting this new value we should examine the corrections applied to the solar constant for the unmeasured spectral radiation [3, Vol. 5, p. 103]. In practice a correction is made for the unmeasured radiation in the interval $0.34\ \mu > \lambda > 0.27\ \mu$, and for this spectral region about 3.4 per cent of the total measured radiation is added. Apparently no energy is added for radiation below 0.27 μ. A composite curve of the 55-km rocket measurement and Smithsonian surface measurements indicates that the region from 0.34 μ to 0.27 μ comprises 2.9 per cent of the area between 0.34 μ and 2.5 μ and that about 0.5 per cent of the total radiation is included between 0.22 μ and 0.27 μ [56]; hence the energy ordinarily added for $\lambda < 0.34\ \mu$ is about right. We have assumed here that the 55-km rocket observation represents $I_{0\lambda}$ for $\lambda < 0.34\ \mu$.

In the infrared, 2 per cent is added for radiation beyond 2.5 μ during I_0 determinations. For a black body at 6000K this should amount to about 3.1 per cent. Hence if the energy beyond 2.5 μ is that of a black body at 6000K or more [5, 63], it would appear that a somewhat greater amount than 3.1 per cent is the necessary correction.

The area $\Sigma I_\lambda \Delta\lambda$ is adjusted to agree with I by estimating the unmeasured spectral energy. In this process of adjustment, errors in the estimated correction are offset somewhat by the adjustment mechanism itself. This adjustment process, however, does not account for errors in ϵ_0 in the spectral regions which cannot be observed at the ground. It is difficult therefore to say exactly what effect the substitution of new corrections would have on I_0. As a first approximation we might assume that the ultraviolet correction is about right and that the infrared correction is too low by 1 or 2 per cent, so that the computed solar constant can tentatively be given by $1.90 < I_0 < 1.94$, the range making some allowance for the uncertainty of the corrections. On the basis of the Smithsonian measurements there does not seem to be much justification for a solar constant of more than 2.0 ly min^{-1}.[3]

Variation of the Solar Constant. We turn now to a consideration of the following questions: (1) Does the "solar constant" vary with time? and (2) Do the measurements of I_0 indicate the actual variation? The controversy regarding these questions has been raging for a long time, and a definite answer to the second question cannot yet be given. The state of the controversy is shown in a criticism by Paranjpe [67] and a reply by Abbot [1]; Waldmeir [77] has summarized some of the earlier arguments. Two main points have been at issue: (1) Do the measured values at two or more widely separated stations vary in the same way with time? and (2) Do the I_0 measurements or the transmission coefficients a_λ vary seasonally? If so, one would expect that the earth's atmosphere is introducing the variations and that they are not true solar changes.

Abbot has pointed out on several occasions that the data from the various stations do agree for monthly means, but that daily values show appreciable departures. Paranjpe [67] states, however, that the data from the stations undergo statistical adjustment in such a way as to *make* the data between stations comparable. From this view, of course, interstation correspondence would have no significance. Abbot [1] states definitely

3. Karandikar [50] assumed a value of more than 2.0 ly min^{-1}. At the Ionospheric Physics Conference held at State College, Pennsylvania, in July, 1950, Dr. M. O'Day announced that a measurement from a rocket indicated a value of more than 2.0 ly min^{-1}. This measurement has apparently not yet been completely checked. See *Discussion* of the paper "Physical Characteristics of the Upper Atmosphere" by T. R. Burnight in "Proceedings of the Conference on Ionospheric Physics (July 1950)." *Geophys. Res. Pap.*, Air Force Cambridge Research Laboratories, Cambridge, Mass. (1951) (in press).

that this is not the case, but that the data are independent. It should be pointed out, however, that questions regarding the accuracy of data from all solar-constant stations except Montezuma have been raised from time to time by Abbot and his colleagues, especially regarding the data prior to 1920 [8].

With regard to the seasonal variation of solar constants, Abbot has made comparisons of differences between solar-constant measurements at Southern Hemisphere and Northern Hemisphere stations on a monthly basis and finds no seasonal variation in the differences. The season being opposite in the two hemispheres, this would indicate lack of seasonal variation in I_0. Although he found no twelve-month period in I_0 variations, Abbot has found fourteen other different periods in the solar-constant variations. Paranjpe questioned the existence of these periods, but Sterne [73], while supporting Abbot's claim as to the statistical significance of some of his periods, found a strongly significant period of twelve months, suggesting a possible terrestrial effect.

We see therefore that there has been considerable controversy regarding the reality of the variations shown by the solar-constant measurements, and numerous additional arguments, pro and con, could be unearthed. But the present state of affairs can be summed up as follows: The energy emitted by the sun does change from time to time. This is indicated by the changes which can be seen in the sun's surface and by the changes revealed by the ionospheric and radio measurements. However, the percentage change in the total energy output is small, amounting at most to 1 or 2 per cent [3], and whether the solar-constant measurements as observed from the earth's surface are sufficiently accurate to reveal the time and/or magnitude of such variations is still a debatable question.

This controversy may be resolved in several ways. The surest way would be to make the measurements from a satellite stationed outside the earth's atmosphere. If rockets could be adequately equipped, frequent measurements from them would also be satisfactory. Perhaps balloons may serve for this purpose. But if these methods are economically or experimentally remote, the establishment of a few additional surface stations might help. In science, important results ordinarily are not finally accepted until they have been corroborated by independent observers. Here too, if the questions raised as to the amount and time variations of the solar constant are to be answered, any additional stations should be operated by independent observers, as was long ago suggested by Marvin [58].

However, there is a more important parameter to measure than the variation of I_0; that parameter is the earth's albedo. From the meteorological viewpoint, the predominant interest is not in I_0 variations as such, but in the amount of energy absorbed by the earth and its atmosphere, and in the variations of this amount. As will be shown later, the solar energy reflected by the planet Earth varies so much that the energy absorbed may vary by ± 15 per cent or more from the mean absorbed energy. This is to be compared with a possible change of ± 1 per cent in the solar constant.

Extraterrestrial Solar Energy on a Horizontal Surface. Of fundamental importance for meteorology is the energy Q which reaches a horizontal area at the earth's surface. For purposes of comparison and to permit certain computations of Q, Milankovitch [61] computed Q_E, the extraterrestrial value of Q, from the relation

$$Q_E = \int_{t_1}^{t_2} \frac{I_0}{\rho^2} \cos Z \, dt, \tag{6}$$

where t_1 is the time of sunrise, t_2 the time of sunset, Z the sun's zenith distance, and ρ the radius vector of the earth. If we take $I_0 = 1.94$ ly min^{-1}, Q_E, in langleys per day, is given in Fig. 3.

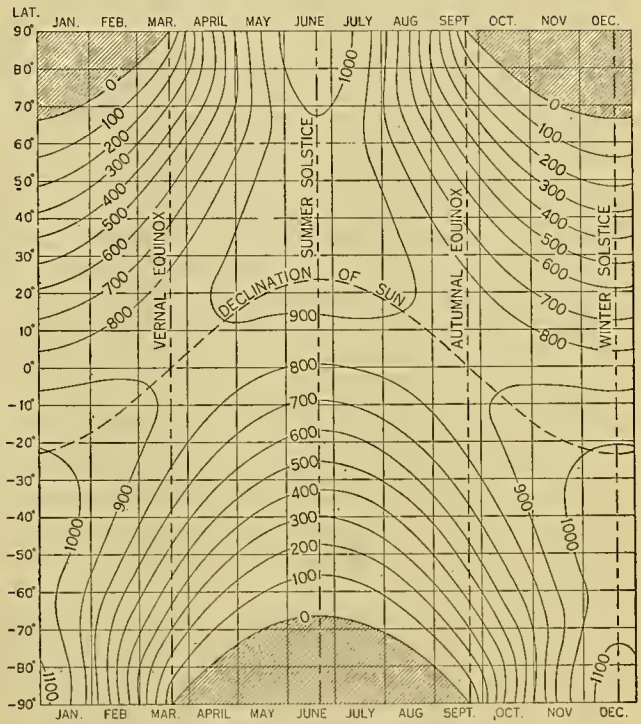

FIG. 3.—Solar radiation on a horizontal surface outside the earth's atmosphere (ly day^{-1}). (*After List* [56].)

TERRESTRIAL EFFECTS ON SOLAR RADIATION

Having considered the amount and the spectral intensity of extraterrestrial solar energy, we turn now to the effect which the earth and its atmosphere have upon the incident radiation. In general the atmospheric elements absorb and scatter part of the incident solar energy.

Absorption. At the outset it should be noted that $\lambda < 2900$ A (approximately) is not observed at the ground; nearly all energy of $\lambda < 2900$ A is absorbed and a small part is scattered back to space by the gases of the atmosphere.

The Ionosphere and Ozonosphere. Energy of $\lambda < 1000$ A is highly absorbed by O, O_2, or N_2 [62]; such energy is responsible for the ionization and heating of the ionospheric regions. For energy in the region from 1300 A to 3500 A, Craig [21] has made a thorough study

of the available absorption-coefficient measurements for O_2 and O_3; these absorption coefficients appear elsewhere in this Compendium.[4]

In equation (4), k_λ is the *extinction* coefficient; it includes the effect of both absorption and scattering. We can write

$$k_\lambda = \alpha_\lambda + s_\lambda, \tag{7}$$

where α_λ is the absorption coefficient and s_λ is the scattering coefficient. In places where s_λ is small, such as at high elevations in the atmosphere, the transmission can be written approximately

$$I_\lambda = I_{0\lambda}\, 10^{-\alpha'_\lambda x}, \tag{8}$$

where α'_λ is the decimal absorption coefficient, and x is the path length through the absorbing gas. The amount of absorbed energy is

$$I_a = \Sigma(I_{0\lambda} - I_\lambda)\Delta\lambda = \Sigma I_{0\lambda}(1 - 10^{-\alpha'_\lambda x})\Delta\lambda. \tag{9}$$

In the case of ozone, computations of I_a have usually been based on the distribution of $I_{0\lambda}$ in a black body at 6000K and give $I_a \approx 0.06\ I_0$. However, as indicated above, $I_{0\lambda}$ in the ultraviolet is considerably less than the value for a black body at 6000K. Therefore, I_a is correspondingly smaller. If one accepts the 55-km V-2 rocket and Smithsonian spectral measurements for $I_{0\lambda}$, then $I_a \approx 0.02\ I_0$ [30]. Should further measurements verify still lower values of $I_{0\lambda}$ [35, 55], I_a for ozone will have to be reduced even more.

Obviously, the assumption of 6000K black-body intensities will also yield values for the absorption at specific altitudes in the ozonosphere which are too large. Thus computations such as Karandikar's yield values that are too high for ultraviolet absorption [50]; Gowan [36] shows the effect of the lower absorption on the temperature of the air.

In addition to its absorption in the ultraviolet, ozone absorbs small amounts of solar energy in other spectral regions. One of these, the Chappuis band, extends through the visible region from 4400 A to 7600 A and has a peak at 6000 A. The absorption coefficient is, however, so much smaller than that in the ultraviolet that, despite the much higher solar intensity, the total absorption in the Chappuis band is about $0.007I_0$. In the infrared, absorptions are centered at 4.75 μ, 9.6 μ, and 14.1 μ, but $I_{0\lambda}$ is so small at those wave lengths that almost no energy is absorbed [50].

Spectral Absorption by Water Vapor. Among the atmospheric gases, water vapor absorbs the largest amount of solar energy, and for the most part our knowledge regarding these water-vapor absorptions is due to Fowle [26, 27]. For $\lambda > 0.9\,\mu$, energy is absorbed by water vapor with varying intensity in wide bands. Figure 4 shows the *positions* of these bands[5] up to about 2.1 μ and includes two bands (B and A) for oxygen absorption; Fig. 5 shows the *fractional transmission* of energy in the band widths indicated by broken arrow-headed lines at the bottom of Fig. 4. In addition to the bands shown in Fig. 4, several weak lines appear below 0.7 μ, and very strong absorption bands appear beyond 2 μ and particularly near 6 μ.

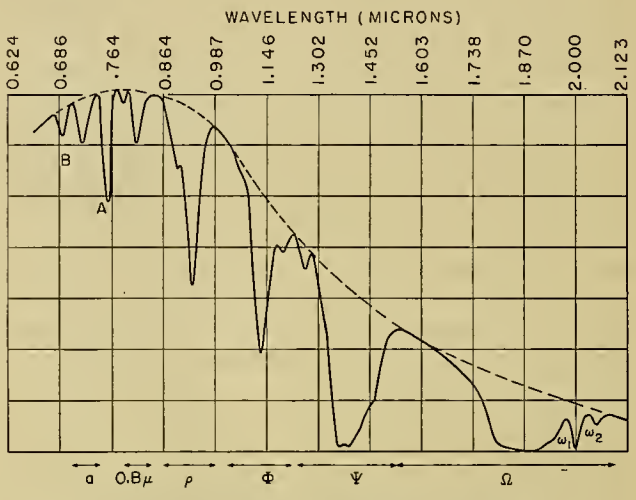

FIG. 4.—Location of absorption bands of oxygen (A and B) and of water vapor. (*After Fowle* [26].)

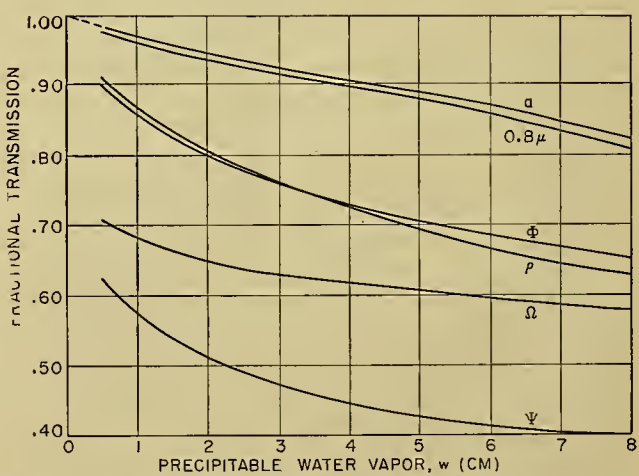

FIG. 5.—Fractional transmission of solar radiation by water-vapor absorption bands as a function of precipitable water vapor. (*After Fowle* [26].)

Fowle [27] measured the absorption in the regions 2–9 μ and some of his results are given in Table II.

Fowle's data were measured at atmospheric pressure. It has long been recognized that the fractional absorption by a water-vapor band depends on the total pressure of the air; and laboratory pressure measurements on two water-vapor absorption bands have recently been made, although the two sets of measurements lead to somewhat different results. Drummeter and Strong [24] examined the maximum and minimum absorption points in the 1.85-μ band and found that absorption at the maximum points (1.82 μ and 1.88 μ) in-

4. Consult "Radiative Temperature Changes in the Ozone Layer" by R. A. Craig, pp. 292-302.

5. The band labelled Ω really includes three bands, namely, Ω plus two small bands ω_1 and ω_2.

creased linearly with $p^{1/2}$. For the minimum points (1.87 μ and 1.90 μ) the same pressure relation existed up to p = 400 mm Hg; for higher pressure the absorption increased more slowly as $p^{1/2}$ increased. For each of the entire bands at 1.35 μ and 1.85 μ, Chapman, Howard, and Miller [19] find that the fractional transmission increases as a nonlinear function of $(p + p_w)^{1/4}$ where p_w is the partial pressure of the water vapor. They do not graph their functional absorption relation explicitly as a function of pressure.

Table II. Per Cent Absorption of Radiation by Water Vapor
(*After Fowle* [27])

Wave-length interval (μ)	Precipitable water vapor	
	0.008 cm	0.082 cm
	%	%
1.3 –1.75	6.1	18
1.75–2.2	13.6	29
2.2 –3.2	23.6	41
3.2 –4.0	21.7	37
4.0 –4.9	32.5	50
4.9 –5.4	18	42
5.4 –5.9	47	85
5.9 –6.4	64	97
6.4 –7.0	68	97
7.0 –8.0	25	62

The amount of solar energy beyond 3 μ is of course very small, and hence the absorption of that energy cannot greatly affect the temperature of the atmosphere. Karandikar [50] shows the amount of absorption in langleys per second in the various wave-length bands as a function of precipitable water vapor w for values of w from 10^{-4} cm to 1 cm and for bands in the region from 0.9 μ to 8 μ; he also gives the total amount of energy absorbed by water vapor in the stratosphere and shows that above 40 km the absorption is practically zero, but that at 30 km it approaches absorption by ozone (especially since the ozone absorption given is probably too high).

It should be pointed out that the data of Fig. 5 may not be used with Beer's law in the customary absorption computations, since the bands are too wide to be considered as monochromatic; the empirical data of Fig. 5 must be utilized. However, for many purposes the use of Beer's law will lead to practical results [63].

A few transparent regions exist in the far infrared. The region near 10 μ is relatively transparent with regard to water-vapor absorption, and although very little solar energy is available in this region, it has been used to measure atmospheric ozone which has an absorption band near 9.6 μ. Adel has found that the 17–24 μ region is also relatively transparent.

Total Water-Vapor Absorption. In order to determine the temperature change in the atmosphere produced by absorption of radiation by water vapor, a summation of absorption over all wave lengths is required, and such summations have been computed by several authors. For example, using Fowle's absorption data, Kimball [52] computed the total absorption as shown in curve (16), Fig. 6. The curve shows the fraction of I_0 absorbed by water vapor as a function of the water vapor in the sun's spectral path, that is, as a function of mw. By using data similar to these absorptions, Tanck [74] computed temperature rises of about 0.1–0.7 centigrade degrees per day at Hamburg depending on the season and the height (up to 6 km). The order of magnitude of the absorptions given by Tanck's equation agrees with airplane measurements [29].

Clouds. Thanks to Fowle and to some recent studies [19, 24], the status of water-vapor absorption is fairly well known; however, the absorption of solar energy by clouds is comparatively unknown. A few theoretical estimates have been published [45], but very few measurements have been made.

One method of measuring the amount of energy absorbed is to measure simultaneously, with pyrheliometers, the energy leaving and entering the cloud layer both at its upper and lower surfaces; the difference between the energy which enters the cloud and that which leaves it is the amount absorbed. Neiburger [66], using one blimp on which to mount two pyrheliometers, one facing upward and the other downward, made many vertical traverses through stratus clouds. When the blimp was below the clouds, he estimated the upward- and downward-flowing radiation at the top of the cloud. Because he lacked a second blimp, simultaneous measurements could not be made both below and above the cloud, and since the albedos of clouds vary appreciably over short distances and times, errors may have been introduced because of the lack of simultaneity. At any rate, Neiburger's measurements, which were probably the first absorption measurements made, indicate that in the mean about 5 to 9 per cent of the incident radiation is absorbed in stratus clouds, and that there may be large variations from the mean.

To measure the absorption in other types of clouds, especially over extensive cloud decks, the United States Weather Bureau, through the cooperation of the Air Force and the Office of Naval Research, has made measurements using B-29 airplanes as platforms for the two pyrheliometers. On a few occasions two airplanes, each equipped with two pyrheliometers, have been flown, one vertically above the other, with the cloud deck between them. When only one airplane was available, the plane, carrying two pyrheliometers, was flown above the cloud deck and above a pyrheliometer which was located on the ground. In the absence of ground snow cover, a good estimate can be made of the albedo of the ground; or if the ceiling is not too low, the albedo of the ground can be measured by flying the airplane below the clouds. Preliminary results from these measurements indicate that the absorption by these deep widespread systems averages about 20 per cent of the solar radiation incident on the cloud.[6] These measurements are still few in number and should be verified by additional determinations.

6. Reported by T. H. MacDonald at the January 1950 meeting of the American Meteorological Society in St. Louis, Missouri.

This amount of absorption is much higher than the maximum of 6 per cent which Hewson's theoretical computations indicate [45]. If it is assumed that the measurements are correct, the discrepancy can be attributed to several factors. Clouds are complex anisotropic physical entities, and the theory must make numerous assumptions to handle even isotropic clouds of *liquid* water drops. In particular, the theory does not include absorption by water vapor in clouds. A cloud whose liquid-water content is 0.5 g m^{-3} could easily contain 5 g m^{-3} of water vapor, and 10 g m^{-3} or more are quite possible. Hence with the radiation undergoing numerous reflections by the liquid water drops, the path length of a ray through the water vapor could easily be 10 to 20 times that of its path through liquid water. Furthermore, the fractional absorption of water vapor is by no means negligible by comparison with that of liquid water [6]. The absorption by the water vapor might therefore be comparable with that by liquid drops. Such an effect would bring computations such as Hewson's more in line with the measurements.

Another factor is absorption by the ice and snow particles which exist in cirrus and altostratus clouds. The mechanism of such absorption is unknown and has not been included in theoretical discussions. In view of these and other theoretical complexities, measurements for many types of clouds are required to establish firmly the magnitude of absorption by clouds. Apparently, relatively diffuse thick clouds (such as altostratus) will reflect a smaller amount of energy than less diffuse thick clouds, such as stratus or stratocumulus clouds of the same or even smaller vertical thickness [18, 32]. Mecke [59] has pointed out that, for infinitely thick clouds, high reflection will be associated with low absorption and vice versa. These ideas are in qualitative agreement with the relatively low absorption in thick stratus with its high albedo [66] and with the relatively high absorption in thick altostratus of extensive cloud systems with its low albedo.

The Earth's Surface. The energy which reaches the surface of the earth is either absorbed or reflected. The albedo of the earth's surface will be discussed later; it is the order of magnitude of the absorbed energy which should be emphasized here. In middle latitudes, at least, during cloudless conditions about 80 per cent of the energy Q_E incident in a day at the outer atmosphere reaches the ground. Except for snow-covered areas, an albedo of 10 per cent may be assumed for purposes of rough evaluation. Hence under these conditions, about 72 per cent of Q_E is absorbed by the earth's surface. This is very much larger than the absorption of 2 per cent by ozone, or of about 8 per cent by water vapor, or even of the 20 (?) per cent by extensive cloud systems. Of course, in overcast areas, the energy which is absorbed by the ground is smaller than 70 per cent and may be equal to or less than the energy absorbed in the cloud. But with average cloudiness, the ground absorption approaches about 50 per cent of the extraterrestrial radiation.

Therefore, although absorption by ozone may cause large temperature changes at 40 km because of the low atmospheric density at that height, by far the largest amount of energy which potentially becomes available for atmospheric processes is absorbed by the earth's surface itself.

Miscellaneous Absorptions. Several gases absorb minor amounts of solar energy. Oxygen, in addition to the important absorptions in the ionosphere and ozonosphere, has some minor absorptions in the near infrared (Fig. 4). Nitrogen compounds and CO_2 absorb small amounts. Carbon dioxide is, of course, of great importance in long-wave terrestrial radiation, but plays a minor role in solar radiation absorption [50]. The presence of methane has recently been announced by several authors [54]. Its role in the heat balance of the atmosphere has not yet been considered.

Scattering. In the absence of clouds, energy is depleted from the direct solar beam through absorption and scattering by air molecules, water vapor, and dust. Where absorption is negligibly small the scattering coefficient may be expressed as

$$s_\lambda = s_{a\lambda} + s_{w\lambda} + s_{d\lambda}, \tag{10}$$

where $s_{a\lambda}$, $s_{w\lambda}$, and $s_{d\lambda}$ are the scattering coefficients of pure dry air, water vapor, and dust, respectively.

Spectral Molecular Scattering. When the isotropic particles which cause scattering of energy are very small by comparison with the wave length of the light ($< 0.1\ \lambda$), the theory developed by Rayleigh [34] shows that the scattering coefficient depends on λ^{-4} or, if the mass of air in the vertical at sea level is taken as unity,

$$s_{a\lambda} = \frac{32\pi^3(n_\lambda - 1)^2 H\lambda^{-4}}{3N_a}, \tag{11}$$

where n_λ is the index of refraction of air for light of wave length λ, N_a is the number of molecules per cubic centimeter of air, and H is the height of the homogeneous atmosphere.

If scattering by air molecules alone is considered, the monochromatic energy which reaches sea level as the original parallel beam is given by

$$I_\lambda = I_{0\lambda} \exp(-s_{a\lambda} \sec Z). \tag{12}$$

Values of $s_{a\lambda}$ and of the transmission $a_{a\lambda} = I_\lambda / I_{0\lambda}$ for the Rayleigh scattering law are given by List [56]. For air molecules which are not spherical it might be necessary to multiply those values of $s_{a\lambda}$ by 1.04 [76].

Total Molecular Scattering. We are often interested not in the spectral transmissions but in the total transmission I/I_0. If equation (12) is integrated, we see that

$$\begin{aligned} I/I_0 &= (1/I_0) \int_0^\infty I_\lambda \, d\lambda \\ &= (1/I_0) \int_0^\infty I_{0\lambda} \exp(-s_{a\lambda} m) \, d\lambda. \end{aligned} \tag{13}$$

The data for $I_{0\lambda}$ are available from Smithsonian Institution measurements (Fig. 1), and several authors have computed I/I_0 from equation (13). Figure 6 shows such a computation by Kimball [52]. Curve (1), for $w = 0$,

is in excellent agreement with Linke's results [55, p. 248].

Spectral Scattering by Water Vapor. The atmosphere is, however, never pure nor dry; both dust and water vapor are ever present in varying degree. Fowle [28] examined the transmission of the atmosphere at wave lengths where water vapor does not absorb. At those wave lengths, if dust is neglected,

$$I_\lambda = I_{0\lambda} \exp(-s_{a\lambda} m) \exp(-s_{w\lambda} wm) = I_{0\lambda} (a_{a\lambda} a_{w\lambda}^w)^m = I_{0\lambda} a_\lambda^m. \quad (14)$$

Here the transmission coefficient through one dry atmosphere at vertical incidence is given by $a_{a\lambda} = \exp(-s_{a\lambda})$ and through one centimeter of precipitable water vapor by $a_{w\lambda} = \exp(-s_{w\lambda})$. From equation (14)

$$a_\lambda = a_{a\lambda} a_{w\lambda}^w, \quad (15)$$

or

$$\ln a_\lambda = \ln a_{a\lambda} + w \ln a_{w\lambda}. \quad (16)$$

A plot of $\ln a_\lambda$ against w should yield a straight line whose slope is $\ln a_{w\lambda}$ and whose intercept at $w = 0$ is $\ln a_{a\lambda}$. Hence, $a_{w\lambda}$ and $a_{a\lambda}$ can be determined.

As might be expected, for a given λ the observed corresponding values of $\ln a_\lambda$ and w do not fall exactly on a straight line. In order to remove random fluctuations Fowle compiled average values, but it is not clear whether he averaged values of a_λ or of $\ln a_\lambda$. At any rate, Fowle plotted his average $\ln a_\lambda$ against w. The points still scatter quite a bit, but the "best" straight line was drawn through the data, and the corresponding $a_{a\lambda}$ and $a_{w\lambda}$ were determined. His values of $a_{w\lambda}$ are given by List [56].

Fowle [28] assumed that the λ^{-4} law (equation (11)) applied also for scattering by water vapor and found that his transmission coefficients $a_{w\lambda}$ were such that the scattering is greater than might be expected from the number of water-vapor molecules. He concluded from this that the water vapor existed as aggregates of water-vapor molecules (see also [76]). Moon, however, using Fowle's data, plotted the logarithm of the average $a_{w\lambda}$ against $\ln \lambda$, and found that

$$a_{w\lambda} \propto \lambda^{-2}. \quad (17)$$

Any relation between $a_{w\lambda}$ and λ (such as equation (17)) should apply for a single set of measurements of $a_{w\lambda}$. It seems necessary therefore to plot $\ln \lambda$ against $\ln a_{w\lambda}$ and not against $\ln \overline{a_{w\lambda}}$. Differences in their procedure perhaps account for the difference in the wavelength laws obtained by Moon and by Fowle.

It should be pointed out that Ångström [11] questioned the validity of assuming that the water vapor was the actual scattering agent. If dust and water-vapor advection usually occur together so that an increase in one accompanies an increase in the other, it may be the dust which is actually performing the scattering. However, Fowle evaluated the effect of dust in his data, and found it to be only about one-half of 1 per cent for a_λ and 2 per cent for $a_{w\lambda}$ [28]. As these conflicting views indicate, the wave-length dependency of water-vapor scattering is not very well known.

Total Water-Vapor Scattering. Here again the total transmission is often desired in lieu of the spectral transmission. With the aid of Fowle's data for $a_{a\lambda}$ and $a_{w\lambda}$, Kimball [52] computed the fractional transmission of solar energy at normal incidence through a dustless atmosphere for various values of w. The computations, which include scattering but exclude absorption, are shown in Fig. 6 by the dashed curves (1) through (8) for values of w up to 6.0 cm. By adding the depletion due to water-vapor absorption, Kimball computed the transmissions shown in curves (9) through (15); the latter curves include the effect of both scattering and absorption.

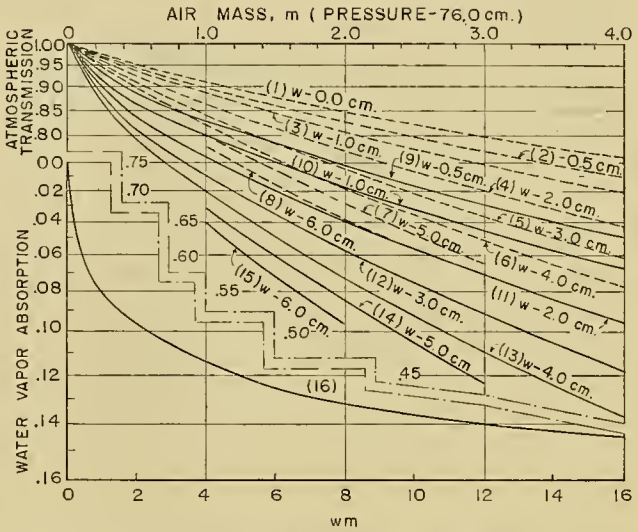

FIG. 6.—Fractional transmission of solar energy through the earth's atmosphere. Curves (1)–(8), scattering only; curves (9)–(15), scattering plus absorption by precipitable water vapor (w) amounts shown on curves; curve (16), fractional absorption by water vapor as a function of wm. (*After Kimball* [52].)

Dust. There remains the scattering from the direct solar beam by dust. Ångström [11] has derived a law for dust extinction,[7]

$$s_{d\lambda} = \beta \lambda^{-\gamma}, \quad (18)$$

where β is a constant representing the number of scattering particles, and γ another constant representing the size of the scattering particles. Ångström describes graphical methods for obtaining β either from a total radiation measurement or by filter measurement. By analyzing the spectral measurements of the Smithsonian Institution, he found $\gamma = 1.3$ on the average. From laboratory measurements of the relation between γ and the size of scattering particles, he showed that the average size of the scattering particles was 1 μ. Ives and his co-workers [48], however, have found from actual particle measurements near the ground in cities that the most frequent diameter size is near 0.5 μ. Their

7. Ångström's extinction coefficient, here designated by $s_{d\lambda}$, includes scattering by water vapor, but not absorption.

findings are valid only for particles larger than 0.2 μ in diameter because their microscope could not detect smaller particles. Recently Crozier and Seely [22], making measurements from airplanes, found the greatest frequency of particle diameter in the free air to be 3–6 μ; their instruments could not catch the smaller particles efficiently. Linke and von dem Borne [55] showed that γ varied with the altitude of the observing station and from place to place. In general, for higher altitude and less smoky areas, γ was larger than elsewhere, and hence the average particle size was smaller.

All these are average values, and both β and γ vary with time even at one observing station, for the number, size, and shape of the scattering particles vary continually. Also, at any time the whole spectrum of particle sizes ranging from below 0.2 μ to 1 μ and larger are to be expected.

This complex scattering by particles which are larger than molecules is a serious problem in spectral measurements. In particular, dust is troublesome in ozone measurements which ordinarily utilize light at 3000–4000 A where differential spectral scattering usually becomes an important problem. Ramanathan and Karandikar [70] found that peculiar ozone effects can easily be produced by improper assumptions regarding dust. They also found, as might be expected, that γ is not really constant and that in India it lies on the average between 0 and 1.3 in the region 3000–4450 A.

Another measure of the dust parameter, the "turbidity factor," was designed by Linke. He defines the turbidity factor τ from

$$I_\lambda = I_{0\lambda} \exp(-k_{a\lambda}\tau_\lambda m), \tag{19}$$

where

$$k_{a\lambda}\tau_\lambda = k_{a\lambda} + k_{w\lambda}w + k_{d\lambda}d,$$

$k_{a\lambda}$, $k_{w\lambda}$, and $k_{d\lambda}$ are the extinction coefficients of air, water vapor, and dust, respectively, and d represents the "quantity" of dust [55, p. 266]. He uses an "appropriate" average value and integrates equation (19), so that

$$I = I_0 \exp(-k_a\tau m), \tag{20}$$

where k_a and τ now represent mean values over wave length. Such averages cannot really be obtained, so that the discussion which follows represents an approximation.

Let I'_m designate the intensity of light transmitted through a pure dry atmosphere; then $e^{-k_a m} = I'_m/I_0$. Equation (20) can now be written

$$\tau = \frac{\ln I_0 - \ln I}{\ln I_0 - \ln I'_m}. \tag{21}$$

By means of equation (21), τ can readily be computed from a single measurement of I, for I_0 is a constant (generally taken as 1.94) and I'_m can be obtained from graphs such as Fig. 6.

In equation (20), τ can be interpreted as the number of pure, dry air masses which would produce the extinction observed in the moist, dusty atmosphere. It was found, however, [42, 55] that τ was a function of m and thus was not a reliable measure of turbidity. To overcome this defect, Linke [55] decided to relate τ, not to a dry air mass, but to a dustless air mass containing 1 cm of precipitable water vapor. Instead of I'_m in equation (21), we therefore introduce $I'_{m,w=1}$. The new turbidity factor becomes

$$\Theta = \Phi_m \ln (I_0/I) \tag{22}$$

where

$$\Phi_m = \frac{1}{\ln I_0 - \ln I'_{m,w=1}}.$$

Linke's values of Φ_m are given in Table III.

Table III. Values of Φ_m in Equation (22)
(*After Linke* [55])

m	0.5	1	1.5	2	3	4	6	8	10
Φ_m	23.35	13.57	9.60	7.97	6.04	5.02	3.80	3.10	2.63

With the aid of a single pyrheliometric measurement, Θ can be computed. According to Linke, it will vary relatively little with air mass; any observed diurnal variation of Θ will be a real variation in turbidity. Turbidity factors for portions of the spectrum have also been designed and can be measured with filters [55].

Neither Ångström nor Linke attempted to separate scattering by water vapor from scattering by dust, and indeed, as Ångström pointed out, it may not be valid to do so. However, Kimball [52] assumed that scattering by dust could be separated. He estimated w from either surface vapor pressure or radiosonde data. He measured I and computed the transmission $a = I/I_0$. From Fig. 6, he found $a_{m,w}$, the transmission through a dustless atmosphere containing w cm of precipitable water vapor. Then $a_{m,w} - a = d_d$, the fraction of I_0 which is depleted by the dust. The value of d_d, of course, varies with m. Klein [53] gives some values of d_d which vary from 0 to 0.09 for $m = 1$, and from 0 to 0.13 for $m = 2$.

Wexler [78] and Haurwitz [42] have discussed the turbidity factors of Ångström and Linke and conclude that neither is wholly satisfactory. These factors are, however, among the best simple methods available at present for determining the atmospheric turbidity quantitatively. Although expressions of the total turbidity such as Θ may have some specialized uses, for spectral measurements such as those involved in ozone and solar-constant measurements we shall have to know more about the way dust affects light of various wave lengths. This will probably involve determination of the size and number of dust particles above an observer, which in turn may be helpful in studies of condensation nuclei.

Scattering by Liquid Water Droplets. Scattering of light by spherical particles which are not very small in comparison with the wave length is given by the well-known Stratton-Houghton curve. Recently Houghton and Chalker [46] have extended the earlier computation; their results appear in Fig. 7. The extinction by spherical water particles (refractive index 1.33) is re-

lated to $\pi r^2 N K_s$, or K_s times their geometrical cross section, so that

$$I_\lambda = I_{0\lambda} \exp(-\Sigma \pi r^2 N K_s), \qquad (23)$$

where r is the radius of the drops and N is their number. Figure 7 shows K_s as a function of the parameter $X = 2\pi r/\lambda$. Equation (23) holds for nonabsorbing particles and is valid at wave lengths where water absorption is negligibly small; the summation is required over drop radii when the drop sizes are not uniform. For particles where $n_\lambda \neq 1.33$, K_s will differ from the values of Fig. 7; van de Hulst [76] shows some variations. From Fig. 7 it is important to note that for some ratios of particle size to wave length the scattering does not always increase with decreasing wave length.

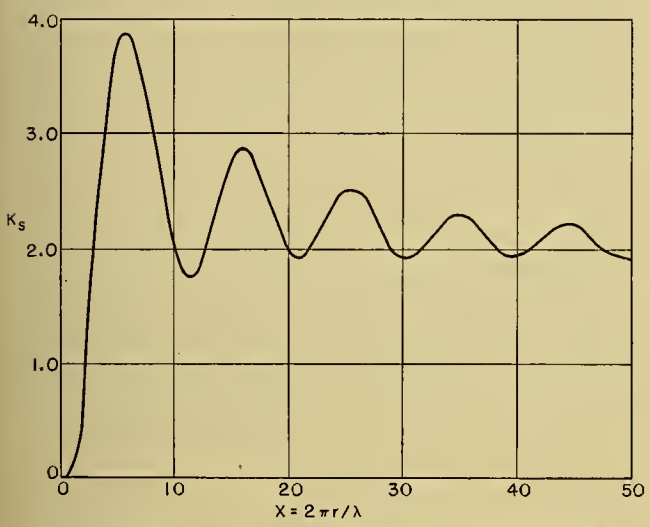

FIG. 7.—Scattering-area coefficient K_s for liquid-water drops in nonabsorbed spectral regions as a function of λ and of drop radius r. (*After Houghton and Chalker* [46].)

Multiple Scattering. In the case of pure Rayleigh scattering (if it ever can be said to exist in the atmosphere) the scattering is symmetrical about the particle so that, for example, the forward- and backward-scattered energy are equal. But as the particles become larger the scattering increases in the forward direction [34; 55, p. 161]. Calculations of the effect of such particles, especially for multiple scattering, become rather complex; however they have been undertaken by several authors [76].

The energy which is scattered from the original solar beam will in general be scattered more than once on its way down to the earth's surface or else out to space. From an empirical viewpoint, regarding the contribution of the cloudless sky radiation to the total radiation on a horizontal surface, Kimball [52] states that of the radiation scattered from the direct solar beam, half will be scattered down and half up. In a pure Rayleigh atmosphere this would be the case. But for the actual conditions of the atmosphere, it serves only as a useful approximation for average daily values of cloudless-sky radiation after the total scattering from the direct beam has been evaluated.

For instantaneous values, Kimball found the ratio of the direct sunlight component on a horizontal surface I_h to the total solar and sky radiation on a horizontal surface Q to be a function of the zenith distance of the sun (Table IV).

TABLE IV. VALUES OF I_h/Q AS A FUNCTION OF SUN'S ZENITH DISTANCE Z
(*After Kimball* [51])

Z (deg)	30.0	48.3	60.0	66.5	70.7	73.6	75.7	77.4	78.7	79.8
I_h/Q	0.84	0.84	0.80	0.78	0.76	0.72	0.69	0.67	0.65	0.63

Similar values have also been found by other observers [55, p. 356]. If we designate the diffuse sky radiation by D, then $D = Q - I_h$. As might be expected, the ratio D/Q increases where the atmospheric turbidity is high [55]. Measurements illustrating this point (*e.g.* illumination measurements) have often been made with instruments for relatively narrow spectral bands. It would be desirable to measure the ratio for nonspectral radiation with varying atmospheric transmissions or turbidity factors.

Albedo. By the albedo of a body we mean the fraction of the incident energy which is reflected by the body. Thus the albedo A of the planet Earth is the fraction of the energy incident at the "outer limits" of the atmosphere which is returned to space; the albedo of a cloud "surface" is the fraction of the energy incident upon the cloud which is reflected by the cloud.

The terrestrial entities which reflect solar energy are (1) the cloudless atmosphere, (2) clouds, and (3) the earth's surface. The sum of these three reflections is the total energy reflected by the Earth. Expressed as a fraction of the extraterrestrial solar energy intercepted by the Earth, this sum determines A.

The Albedo of the Cloudless Atmosphere. 1. *Pure Dry Air.* We have seen that within a few per cent the fractional spectral depletion of solar energy by molecular scattering is represented by the Rayleigh scattering law, and the summation over wave length is readily given as a function of air mass from curve (1) of Fig. 6. The earth as seen from the sun can be considered as made up of narrow concentric circular rings centered about the subsolar point. To an observer in a particular ring the sun is at a specified zenith distance, and hence in each ring the optical air mass m is known. From m and the area of the rings, together with the above-mentioned relation between scattering and air mass, the amount of energy scattered by the entire atmosphere can readily be calculated and found to be about 15 per cent of the incident energy [30]. This was calculated using Fowle's data; Fig. 6 gives a slightly smaller value. However, this energy is scattered in all directions. To determine the fraction scattered upward (away from the earth's surface) it is necessary to assume something about the angular scattering by each particle. Scattering by small particles, such as molecules, is symmetrical about the particle [34]. Hence as much energy is scattered up as is scattered down. Even for

multiple scattering this rule is closely obeyed. Consequently from 7 to 8 per cent of the incident solar energy would be scattered back by the pure, dry, cloudless atmosphere.

2. *Water Vapor.* The scattering by water vapor and questions concerning it were discussed earlier. If one accepts $1 - a_w$ as the depletion by water vapor due to scattering, then scattering for the total spectrum can be computed as a function of air mass, as was done by Fowle, and also by Kimball (Fig. 6). From this functional relation, the scattering by water vapor over the whole earth can be computed. But for this, of course, data on the distribution of water vapor with latitude are necessary. From a rough estimate of w, obtained from the distribution of surface vapor pressure, and after weighting the areas of the earth involved, it is found that 10 per cent of the incoming solar energy is reflected by water vapor [30].

This, again, represents the energy scattered in all directions, but the portion which is scattered back to space is not so readily ascertained as it is for air molecules. Fowle believed that the scattering particles were aggregates of water-vapor molecules; Ångström suggested that dust might be the scattering agent. In either case, it is recognized that if the size of the particles approaches the wave length, the forward scattering exceeds the backward scattering. At any rate, two extremes can be postulated: (1) Either half the scattered energy (5 per cent) is directed upward; or (2) none of the scattered energy is directed upward.

3. *Dust.* Concerning dust our knowledge is most meagre. Not only is the transmission coefficient for dust in doubt, but the distribution of dust over the world is inadequately known. Klein [53] gives a compilation of some values which serve as a guide, but even these "measured" values may be inaccurate in view of the inadequate understanding of dust depletion. From Klein's data one may estimate a depletion of about 5 per cent of the initial radiation on a world-wide basis. In view of the probable greater forward scattering and some absorption, less than 2.5 per cent is scattered back. An estimate of 1 per cent might be about right.

4. *Total Atmospheric Reflection.* A summation of the reflection by atmospheric elements gives a reflection lying between 8 and 13 per cent, depending on how much is allowed for upward scattering by water vapor and dust. There are not very many direct measurements which yield the reflection by the atmosphere. In the lower layers of the atmosphere, some airplane measurements [29] indicate that about 5 per cent of the energy incident at 10,000 ft is scattered upward by the air below 10,000 ft. These measurements were made with a solar zenith distance Z of 53° on a rather smoky day. At greater heights and zenith distances greater reflection presumably would have been measured. Teele [75] measured the visible energy scattered back at 72,000 ft. He interpreted his measurements as indicating that 6 per cent of the incident energy is reflected by the air when Z is 60°.

These measurements and calculations are valid for the cloudless atmosphere only. For the average condition of 0.54 cloudiness, calculation indicates that the cloudless portions of the atmosphere reflect about 6 or 9 per cent of the incident solar energy, depending on the assumptions made, when about 2.7 per cent is included for the reflection by the air above the clouds.

Clouds. Most of the solar energy reflected to space is reflected by clouds. However, the albedo of clouds is so variable, even for one type of cloud, and our information about the spatial distribution of cloud types is so poor that it is impossible, from individual cloud-albedo measurements, to specify an average value over time and space for the total reflection by clouds. Hence, in order to estimate the average albedo of clouds, it is necessary to measure the albedo of the whole earth first and then to subtract the contributions by the atmosphere and by the ground. The remainder is the albedo of clouds.

Table V. Albedo of Various Cloud Types

Source	Cloud type	Albedo (per cent)
Luckiesh [57] (visible light)	Very dense clouds of extensive area and great depth	78
	Dense clouds, quite opaque	55–62
	Dense clouds, nearly opaque	44
	Thin clouds	36–40
Fritz [32] (total radiation, extensive systems; cloud types below measured clouds not specified)	Stratocumulus, overcast	56–81
	Altostratus, occasional breaks	17–36
	Altostratus, overcast	39–59
	Cirrostratus and altostratus	49–64
	Cirrostratus, overcast	44–50
Aldrich [7]	Stratus, 600–1000 ft thick	78

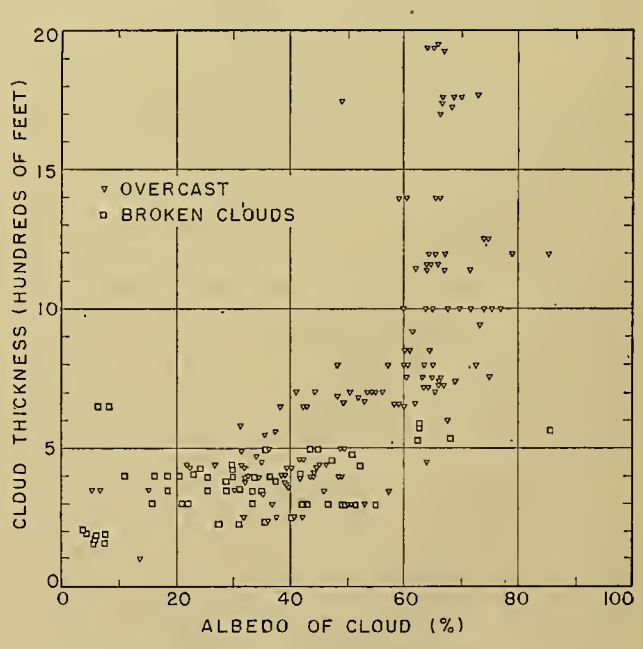

Fig. 8.—Observed albedo of stratus clouds. (*After Neiburger* [66].)

Such a computation [30], based on lunar measurements (to be described later), indicates that the average albedo of clouds is about 50–55 per cent of the energy incident on the clouds. This value may be compared with several series of measurements given in Table V and in Fig. 8.

It will be noted that 80 per cent seems to be a very high value, and that the 78 per cent which Aldrich [7] measured over a single stratus cloud is not a suitable average. According to Bullrich [18], for average clouds of infinite thickness the albedos by cloud types will be as follows: stratocumulus, 0.78; stratus, 0.74; and altostratus, 0.46. A low albedo (39 to 59 per cent) for the altostratus type of cloud can be seen in the measurements in Table V.

Albedo of the Earth's Surface. The albedo of the ground has a very wide range of values also. In general, the lowest albedos occur over water. Forests or other configurations which can trap solar energy act nearly as black bodies and therefore likewise have low albedos. On the other hand, snow-covered terrain has a very high albedo; values up to 90 per cent have been measured over fresh snow. As the snow becomes older or turns to ice, its albedo decreases markedly, and it absorbs more energy. Data for several types of terrain are given in Table VI. It will be noted that general terms such as "grass" give only an approximate estimate of the albedo, so that for investigation of such quantities as local turbulence near the ground, the albedo at the time and near the place in question will have to be measured.

Table VI. Albedo of Various Surfaces
(*After List* [56])

Surface	Albedo (per cent)
Desert	24–28
Fields, various types	3–25
Forest, green	3–10
Grass, various conditions	14–37
Ground, bare	7–20
Mold, black	8–14
Sand, dry	18
Sand, wet	9
Snow or ice	46–86
Water (direct sun* only) Z (degrees)	
0	2.0
20	2.1
40	2.5
50	3.4
60	6.0
70	13.4
80	34.8
85	58.4
90	100.0

* For reflection of sun *plus* sky radiation Ångström [10] gives:

Z (deg)	43.0	46.9	70.5	77.9	84.5
A (per cent)	3.9	5.7	13.8	30.0	46.5

The albedo of large water surfaces depends very largely on the angle of incidence of the light, or the sun's zenith distance Z. Under cloudless conditions, the direct solar radiation follows Fresnel's law of reflection very closely even when the wind is 10 mph [10]. For small values of Z (sun overhead) the reflectivity is very low, and it is not until the angle reaches about 65° that the albedo for solar and sky radiation becomes as much as 10 per cent. Under overcast skies the albedo of the sea surface is about 10 per cent, but changes a little even then with solar altitude and cloud thickness [65]. When the wind velocity is large enough to cause whitecaps, the albedo of the water increases, and Brooks [17, p. 460] gives 31 per cent as the albedo when the water surface is rough. Ångström states, however, that in ordinary geophysical problems the data of Table VI are applicable.

The low albedo of water and, in general, of land means that the contributions of the earth's surface to the total albedo of the planet Earth must be small. As a rule, areas which are snow-covered receive little sunlight; the same may be said for water areas which have a high albedo (low solar altitudes). The net result is that, when the average cloudiness is considered, the earth's surface contributes less than 4 per cent of the incident energy to the total albedo of the earth; this contribution is probably between 2 and 3 per cent [30].

The Albedo of the Planet Earth. The sum of the albedos of the various entities is the albedo A of the planet Earth. As stated earlier, since there is a variability of the albedo of clouds, and since clouds contribute most to the albedo of the planet Earth, A can be found only by measurements from or on bodies outside the earth.

Danjon [23] has made such measurements by viewing the moon with a suitable photometer. The moon is illuminated by two sources of light. The light side of the moon is illuminated directly by the sun; the dark side, by the earth. The light from the earth is *sunlight* which has been reflected by the earth to the dark side of the moon. Consequently, the brightness on the dark side of the moon, as compared with the brightness on the light side, is a measure of the sunlight reflected by the earth, that is, it is a measure of A. Of course, such measurements involve many difficulties, in addition to observational ones. For example, the spectral distribution of the earth's light is different from that of sunlight and doubtless changes with the albedo itself. Hence, any selective reflectivity by the moon would introduce errors. Another problem is the stellar magnitude of the moon. When his paper was already in press, Danjon learned of a new value of the moon's brightness which would somewhat alter his calculations. However, the value which Danjon originally used for the moon's brightness is still quoted in some astronomy textbooks, so his calculations may be correct. Danjon's average value of the earth's albedo for visible light (about 0.4 μ to 0.74 μ) is 39 per cent. But visible light comprises only about half, or even a little less, of the total extraterrestrial solar energy. Hence, to determine the total albedo, adjustments to his measured values must be made for the ultraviolet and infrared portions of the solar energy. Calculation of the corrections gives an albedo of about 28 per cent for the infrared, about 50 per cent for the ultraviolet, and 35 per cent for the total sunlight. The reflection in some portions of the ultraviolet where ozone does not absorb energy, as at 0.36 μ for example, may be considerably higher than 50 per

cent, which is the calculated reflection for the whole ultraviolet radiation ($\lambda < 0.4\ \mu$).

Several other estimates of A have been computed by assuming some value for the average reflection by clouds and/or by studying the average transmission to the earth's surface and estimating the amount of energy absorbed by the atmosphere and clouds. Notable among these calculations of A are the 43 per cent of Aldrich [7] and the 41.5 per cent of Baur and Philipps [14].

In addition to the average value of the earth's albedo, Danjon found large fluctuations of the albedo from season to season and among his individual measurements. Some average values of the visual albedo varied from 30 per cent in August to 50 per cent in October. This large variation is not too surprising. Nor does absence of a relation either to snow cover or cloud amount cast serious doubt on this albedo variability. The amount of solar energy incident on the snow-covered areas is small so that they contribute little to the total albedo. As for cloud amount, even if this latter quantity were known on a world-wide basis, it would not uniquely determine the contribution of clouds to the earth's albedo because the albedos of individual cloud types themselves are extremely variable.

The meteorological significance of this large albedo variation is obvious. If there is any possibility, as several authors believe, that variations in the solar constant of about 1–2 per cent could influence the state of the weather, then the much larger changes in the reflected energy and hence in the absorbed energy must be significant indeed. Only the absorbed energy can affect the atmosphere. Perhaps short-period changes in the solar constant cause changes in the earth's albedo, but such a causal relationship is not obvious a priori and would have to be established before it could be accepted. At any rate, whatever the cause of its change, measurements of the earth's albedo would indicate the *large* changes in the solar energy which is absorbed and potentially becomes available for meteorological processes.

The best way to measure the albedo, as with other solar-variation effects, is to mount instruments on a satellite stationed outside the earth. In the absence of such a satellite, techniques similar to Danjon's must suffice and his results will have to be verified. Danjon's technique would require a little elaboration. For example, from measurements in France, reflections from the Pacific Ocean area would not influence the moon's dark-side illumination. Hence, measurements from widely separated regions would be needed to determine the albedo of the whole earth. Also, as stated previously, an estimate of the ultraviolet and infrared albedo would also be required. However, the main changes in albedo from day to day would be given by visual albedos alone if the corrections should prove difficult to obtain.

Solar Energy at the Earth's Surface. We have considered the depletion of solar energy through scattering and absorption by the various constituents of the atmosphere. The remainder of the direct radiation reaches the ground, and of course, a considerable portion of the scattered radiation also arrives at the ground as radiation from either clear or cloudy skies.

Cloudless Sky. Figure 6 shows the fractional transmission at normal incidence to the sun as a function of air mass and of water-vapor content for a moist, dustless atmosphere. Multiplication by the solar constant will give the transmission in absolute units. For many purposes it will be of greater interest to determine the cloudless-sky energy Q_0 which reaches the horizontal

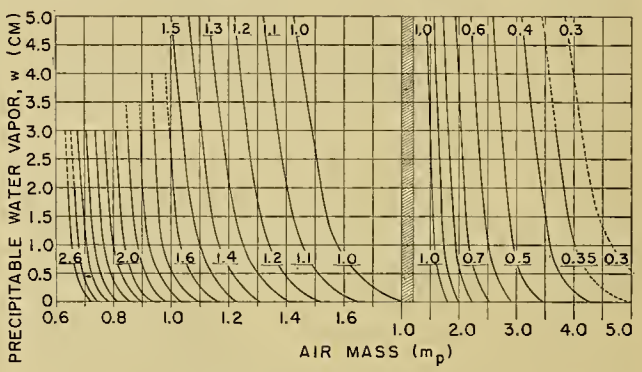

FIG. 9.—Intensity of solar radiation on a horizontal surface (ly min^{-1}) as a function of air mass m_p and precipitable water vapor w for a cloudless, dustless atmosphere. For elevated stations where pressure is p in millibars, multiply radiation by $p/1013$. Dashed lines represent extrapolated values. (*After Fritz* [31].)

ground. Figure 9 shows the radiation on a horizontal surface during dust-free conditions, as a function of optical air mass and precipitable water-vapor content. The computations are based on Fig. 6 and a combination of equations from Klein [31, 53]; it is assumed that half the scattered radiation reaches the ground. Much of the scattered radiation does reach the ground, but obviously this final result is only an approximation which agrees fairly well with observations and with other calculations. Summations over 24 hours (with the aid of Fig. 9) furnish daily totals which, when corrected by comparison with observations at several locations, show the geographic and seasonal variation of cloudless-day radiation over large areas [31]. Such computations indicate that in the United States about 80 per cent of the incident extraterrestrial energy reaches the ground during cloudless days.

Some variations from average values are naturally to be expected. In cities particularly, one would expect marked average decreases of the order of about 20 per cent [40]. For snow-covered terrain, increased radiation will be measured because the strongly reflected radiation will be partially scattered back to the ground by the atmosphere.

Transmission through Clouds. Clouds, however, will generally introduce the largest variations of the solar energy which reaches the ground. Haurwitz [43] has given the *average* solar energy transmitted to a horizontal surface through various types of clouds at Blue Hill, Massachusetts, and also the percentage of cloudless-sky radiation transmitted. His data are shown in Fig. 10 and in Table VII. Large variations about these

average values are of course to be expected for individual cases.

The effect of snow in increasing the solar radiation will be particularly pronounced for overcast conditions because the energy which is reflected by the snow will be strongly reflected towards the ground by the base of the cloud. This is shown for visible radiation in Fig. 11 [49]. For wider application the data of Table VII and

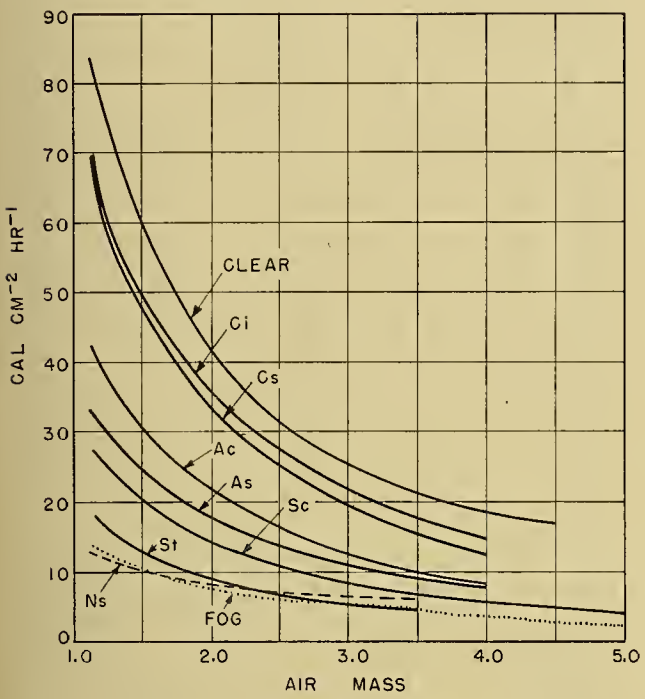

Fig. 10.—Solar radiation on a horizontal surface through the types of clouds indicated. (*After Haurwitz* [43].)

Table VII. Ratio of Solar Radiation with Overcast Skies to Solar Radiation for Cloudless Skies
(in per cent)
(*After Haurwitz* [43])

Air mass	*Ci*	*Cs*	*Ac*	*As*	*Sc*	*St*	*Ns*	Fog
1.1	85	84	52	41	35	25	15	17
1.5	84	81	51	41	34	25	17	17
2.0	84	78	50	41	34	25	19	17
2.5	83	74	49	41	33	25	21	18
3.0	82	71	47	41	32	24	25	18
3.5	81	68	46	41	31	24		18

4.5					30			19
5.0					29			19

Fig. 10 should be separated for conditions of snow-covered and snow-free ground. Also similar data should be computed for areas in which the climate is different from that of Blue Hill.

Average Conditions. We turn now to the estimation of the average solar radiation Q which reaches the earth's horizontal surface on the average for all days. It is commonly assumed that

$$Q = Q_0 (a + bS) \tag{24}$$

will give average values of Q; here a and b are constants such that $a + b = 1$, S is the percentage of possible sunshine, and Q_0 is the value of Q when $S = 100$ (clear skies). This was really already assumed implicitly by Kimball in 1919 [51]. From examination of the radiation on individual days, average values of a have been found for $S = 0$ and/or for $c = 10$ (overcast) by many

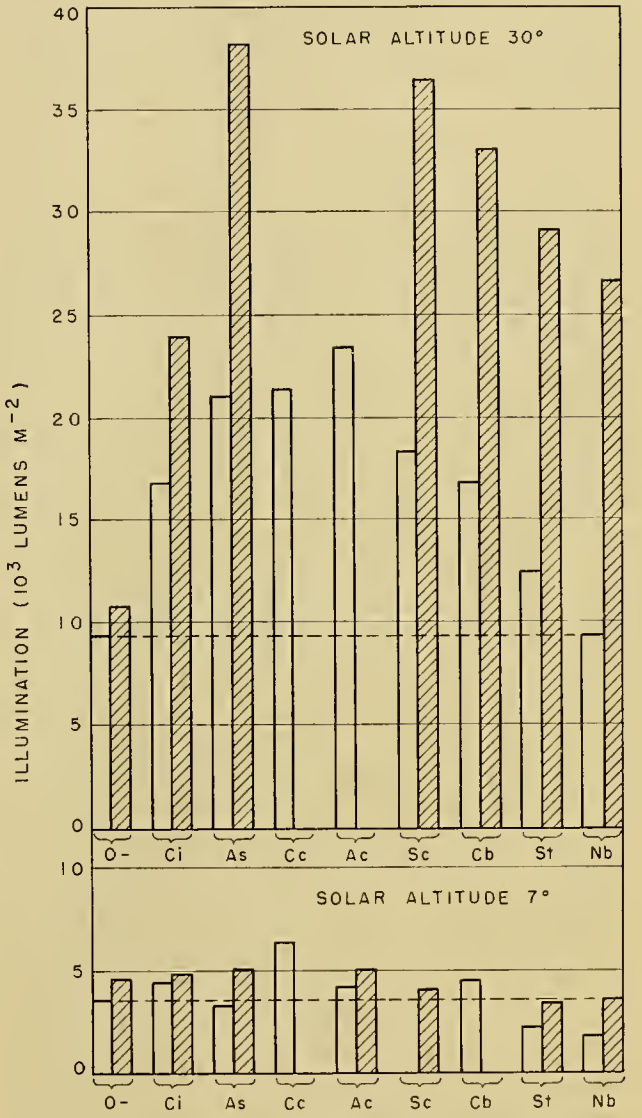

Fig. 11.—Diffuse visible skylight for different types of clouds (10/10 sky cover) above ground with snow cover (hatched bars) and without snow cover (clear bars) for solar altitudes of 7° and 30°. Dashed horizontal lines apply for clear skies. (*After Kalitin* [49].)

observers. Kimball found $a = 0.22$ for Washington, D. C., and obtained

$$Q/Q_0 = (0.22 + 0.78S). \tag{25}$$

Ångström found $a = 0.235$ for Stockholm; for annual values at Blue Hill, Haurwitz found $a = 0.22$ or 0.30, depending on the assumptions; Mosby obtained $a = 0.54$ for the Arctic [42]. Recently several other authors have found values of a which vary considerably. Never-

theless, when Q for average cloudiness conditions is desired, equation (25) is commonly used.

In equation (24), a is usually determined from measurements of Q for individual days on which $S = 0$ and $S = 100$. Very few places have an average of $S = 0$ or $S = 100$ for a period of a month, and it is not certain that equation (24) will yield average values of Q for periods which are made up of a mixture of clear, partly cloudy, and overcast days. A study of all suitable data in the United States [33] in which only monthly mean values of Q and Q_0 were used gave the equation

$$Q = Q_0 (0.35 + 0.61S), \tag{26}$$

with a correlation coefficient of $+0.88$ between Q/Q_0 and S. Here Q_0 is the cloudless-day radiation. An examination of the data (unpublished) revealed that in the western part of the country a was higher than in the eastern part.

That a should vary is to be expected from Haurwitz's data (Fig. 10). The frequency of cloud types is not often available, but it can be seen that areas with greater frequencies of high clouds will have higher values of a than areas with high frequency of low clouds. Hence, the application of one equation such as equation (25) or (26) everywhere should be expected to lead to some inaccuracies even when the *amount* of cloudiness or of sunshine is known. Fortunately, for a considerable range of S, equation (25) or equation (26) will give very similar results for Q/Q_0. Only in very cloudy or relatively clear areas will there be a difference in the result. For lack of more detailed information, Kimball applied equation (25) to the best cloud-amount data available to him and computed maps showing the distribution of radiation over the ocean area [52]. However, if the frequency of cloud types in some ocean areas is different from the average for the eastern United States, results different from those of Kimball should be expected.

The computations from any of these formulas can approximate only long-term average values. At any one place and time large fluctuations from the normal value occur. For example, at Washington, the total radiation on a horizontal surface for a particular February, say, may vary by as much as $\pm$ 20 per cent from the average for all Februaries and bear very little relation to S for that particular February. Ångström [11] notes that in the short interval 1923–28 the *annual* total of radiation at Stockholm varied by $\pm$ 10 per cent from the mean for the six-year period. There is ample evidence therefore of large variations in the radiation that reaches the ground at particular points on the earth's surface. If the variations which Danjon found in the earth's albedo are verified, large fluctuations also occur in the total radiation that reaches the *entire* earth's surface in a period of a month or even of a year. Except for regions where clouds are rare, areas of below or above normal radiation (or surface heating) may occur anywhere, being influenced predominantly by the prevalence of the amount and type of clouds.

GENERAL SPECULATION AND CONCLUSION

From the thoughts implied or expressed earlier, we can extract a few for amplification and emphasis.

Solar Radiation at the Ground. The solar energy Q absorbed by a unit area of the earth's surface is by far the largest portion of the absorbed energy. It is customary when discussing the average general circulation to consider that the greatest heating occurs at the equator where the air rises and that a whole chain of events takes place as a consequence. This equatorial heating is supposed to represent an *average* condition. Actually, even as an average condition, it is not a true picture for the summer hemisphere. In the Northern Hemisphere summer, average Q is distributed rather uniformly with latitude, so that there is no pronounced maximum of radiation near any one latitude, and the maximum, such as it is, probably occurs near lat 40°N rather than at lower latitudes. The maximum surface temperatures occur in the middle of the large cloudless land masses, not necessarily at the equator.

Let us speculate somewhat on the possible significance of the fairly uniform surface heating in summer in middle latitudes. In the annual cycle of temperature it is well known that in inland areas the maximum of the average surface air temperature lags the maximum solar radiation by about four to eight weeks. Since advection in summer is generally small, the heat balance at the ground *in situ* may be an important factor in determining the future average air temperature over a period of time such as a week or a month. In effect the ground acts as a heat reservoir; it gets hot to a considerable depth under the influence of the solar radiation which it receives, and it gives up its heat gradually to the atmosphere.

The lag between the average surface air temperature and the solar radiation at the ground occurs in the mean or normal situation. What happens in any particular summertime week or month? As indicated earlier, the amount of solar radiation which reaches the ground in a period of a week or month may differ markedly from the normal value of solar radiation. Suppose the solar radiation received during a particular June is much higher than normal. Perhaps we can assume that the ground would get hotter (over and above its normal rate of heating) than it had been in the previous May and that the effect of the hotter ground would be to modify the air temperature towards higher temperature in the following July.

Actually, we should of course examine the heat balance at the ground and not the incoming solar energy alone. The solar energy is regularly measured in many places, and in the United States the network of such measurements is now nationwide. But the heat losses at the ground are not regularly measured as universally. In the face of such an observational deficiency, is it justifiable as a first approximation to assume that the variation of incoming solar energy in summer predominates over other effects, such as variations in outgoing radiation? If this assumption is justified, and summertime advection is not a predominant effect, an ano-

malous solar energy Q might influence the air temperature in inland areas with a lag in the same way as the normal surface air temperature lags the normal solar radiation. If such an effect could be found, the forecasting value of the observed solar radiation would be obvious.

Other studies involving the observed anomalous radiation may be profitable. The average annual cycle of atmospheric circulation is of course related to, if not entirely caused by, the change in the gradient of solar heating of the earth's surface. Here again perhaps study of the observed anomalous radiation distribution for a week or a month may reveal it to be a factor in the *cause* of large-scale weather changes.

The Albedo of the Earth. To a certain extent the previous remarks concerning the significance of the distribution of surface heating apply also to the heating of the entire planet. The planet-wide heating cannot be observed at present from surface observations. However, by Danjon's technique the earth's albedo can be observed, although corroborating independent observations are highly desirable. Furthermore, by making observations from several longitudes it may even be possible to estimate the longitudinal distribution of the albedo and therefore of the heating. The variations of these albedos from their average values may be related to the subsequent exchange of heat and of masses of the atmosphere between latitudes and between longitudes.

Upper-Atmospheric Heating. The uncertainties regarding the extent of heating in the ozone layer were discussed earlier and a quasi-practical experiment to determine the fluctuation of radiation during SID's was proposed. It is, of course, possible to attempt correlations of numerous solar parameters with meteorological parameters. The number, size, shape, and polarity of sun spots, as well as faculae, flocculi, prominences, and coronal lines are but a few of the parameters which have been or could be used. However, it seems to the author that if any relation does exist between solar variability and tropospheric meteorology over a period of a few days or longer, those solar parameters which are *known* to produce effects somewhere in the upper atmosphere would offer the greatest promise, and it would be better to seek correlations not with the solar variation itself but rather with the known terrestrial effect which has been produced. Prominent among such solar-induced terrestrial effects are SID's and magnetic variations.

The suggestion then is that we measure the variation of solar ultraviolet radiation which reaches the top of the ozone layer, and the variation of temperature there. Until such measurements are made we cannot be sure that solar variation is heating the ozone layer significantly above its normal temperature. After the magnitude of ozone heating has been established, correlations of tropospheric effects with solar parameters which produce the ozone heating would obviously be indicated. In the meantime, the SID seems to be a parameter which is likely to be related to abnormal ozone heating; as such it *may* be related to surface pressure changes.

Absorption by Clouds. Since some of the measurements suggest large absorption of solar energy by clouds, it would be desirable to investigate the absorption further. This can be done from airplanes, as described earlier; but it may also be feasible to investigate the absorption from the ground. This might be accomplished by spectroscopic measurements on clouds from $\lambda = 0.5\ \mu$ to $\lambda = 2.5\ \mu$. On the basis of the data of Fig. 1 and our knowledge of the spectral distribution of clear-sky light [55], we can approximate the spectral distribution of the solar energy which irradiates the tops of clouds. Furthermore, Fig. 7 shows the extinction of parallel light by droplets in the *absence of absorption*, and shows that if the droplets are large ($2\pi r/\lambda > 50$), K_s becomes nearly independent of λ for the spectral region between $0.5\ \mu$ and $2.5\ \mu$. This ought to be true also for diffuse radiation such as that produced by clouds. At $0.5\ \mu$ the absorption coefficient of liquid water is in reality very small, so that the extinction by clouds at $0.5\ \mu$ is caused wholly by scattering. Consequently $I_{0.5}$, the measure of spectral intensity at $0.5\ \mu$, can serve as a standard against which to compare the spectral intensities at longer wave lengths such as $2.0\ \mu$.

From Fig. 7, together with some reasonable assumption about the droplet sizes in the cloud and the relative spectral irradiation of the cloud top, we can calculate $I_{2.0}$ relative to $I_{0.5}$ on the assumption that no absorption is present. The difference between the calculated $I_{2.0}$ and the observed $I_{2.0}$ might serve as a first approximation to the absorption. Greater refinement can probably be obtained from Mecke's theoretical discussions [59].

Conclusion. We have discussed the state of our knowledge in the field of solar radiation and speculated about some of the deficiencies in that knowledge and in its application to meteorology. On the question of the solar energy potentially available for "use," the suggestions (1) that the albedo (35 per cent) of the earth is smaller than the value (43 per cent) which has often been accepted, and (2) that the absorption by clouds is higher than formerly assumed may require a re-evaluation of the disposition of the radiation received by the earth in the mean. That the long-term average radiative balance controls the average weather pattern is, of course, not subject to question. The excess or deficit of absorbed solar radiation by comparison with the normal absorbed radiation should also significantly influence the weather elements averaged over relatively short periods. Whether a week, a month, a season, or longer is the required "relatively short period" remains to be investigated.

LONG-WAVE RADIATION*

By FRITZ MÖLLER

Gutenberg University at Mainz

Introduction

Long-wave radiation occupies a peculiar position in the science of meteorology in that its effects in the free atmosphere are known only through theoretical calculations and not through measurements. These calculations are, nevertheless, based on experiments in the laboratory and in the atmosphere. The atmospheric radiation is very seldom measured from balloons [3] or from aircraft [17], but quite frequently on the ground where the radiation from above is observed. It appears that part of the measurements from airplanes are in error; and the measurements on the ground have seldom found an evaluation that went beyond the formulation of empirical equations to approximate their average values. The theoretical deductions concerning the radiation in the atmosphere are much more extensive, and it would be most desirable to support them by careful measurements, especially since the experimental tools are available.

Initially, much was expected from the investigations of long-wave radiation in the free atmosphere. It was hoped that they would furnish an explanation for the latitudinal differences in the temperature and altitude of the tropopause, an interpretation of the variations of these values from day to day, and a physical elucidation of the origin of the inversions in the free atmosphere. In all these problems the solutions at times seemed to be near at hand, but then they receded. It appears to the author that today the emphasis of research is directed more toward the investigation of the radiative balance and heat budget in the atmosphere.

In the following, the techniques of measurement are omitted and little will be said concerning the mathematical-physical basis of the calculations, since two detailed treatises which are still up to date are available [14, 28]. They cover these subjects very thoroughly. On the other hand, we shall discuss in great detail the number of instances where long-wave radiation is involved in the problems of general meteorology.

Long-wave radiation is a heat radiation; its energy is derived from the kinetic energy of the molecules. The radiators of this energy are those atmospheric gases that have absorption bands in the temperature radiation range of 4 to approximately 100 μ, that is, water vapor, carbon dioxide, and ozone. The effect of the water vapor is restricted almost exclusively to the troposphere, in which carbon dioxide and ozone are of little significance. The latter two gases become of great importance in the stratosphere between 15 and 35 km. In addition, heat is radiated by the ground and the clouds.

* Translated from the original German.

The Absorption Laws

From the beginning, the theoretical calculations were set up in such general terms that it became possible to investigate the radiation properties of any atmosphere with any temperature distribution and any possible arrangement of radiating and absorbing media. This was done by the development of special radiation diagrams or radiation charts. This approach was justified by two facts: (1) The intensity of the radiation which is emitted by an element for a given wave length is proportional to the black-body radiation and is thus a function only of the absolute temperature; (2) this radiation is proportional to the mass of the radiating medium, which means, in the troposphere, to the amount of water vapor. It is of particular importance that the proportionality constant, that is, the absorption coefficient k, is really a constant in its first approximation and not a function of any other quantities. However, in reality such a dependence of k on the air pressure and on the temperature does exist and gives rise to particular difficulties in advanced investigations.

It should immediately be pointed out that the construction and application of radiation diagrams become impossible if there exist in the atmosphere two different media whose masses in a given volume element vary independently of each other from case to case, but whose emissive power at the same wave length is of the same order of magnitude so that the effect of the one medium cannot be neglected as compared to that of the other. Such conditions prevail in the stratosphere, for instance in the case of ozone and carbon dioxide. It is possible to consider two media in the same space element of the atmosphere only when one of the radiators is a gray radiator, that is, when its absorption coefficient k is the same for all wave lengths [31].

Parallel Radiation. If an absorbing medium m is penetrated by a beam of parallel rays, absorption takes place according to an exponential law. The emergent radiation I_λ is

$$I_\lambda = I_{0\lambda} e^{-k_\lambda m}, \tag{1}$$

where the subscript λ indicates monochromatic radiation, and I_0 is the incident radiation. The absorbed portion is

$$A = (I_0 - I)/I_0 = 1 - e^{-k_\lambda m}. \tag{2}$$

The length of the path which the radiation follows in penetrating m does not appear in this equation. This means that the absorption is only a function of the penetrated mass m, or that the absorption coefficient k_λ is independent of the density of m throughout the penetrated cylinder. If I_0 is black-body radiation at a temperature T, whose value is given by Planck's law,

$$I_0 = \mathfrak{E}(\lambda, T)\, d\omega,$$

(where $d\omega$ is the solid angle), and if the mass m has the same temperature T, then m radiates, according to Kirchhoff's law, the same amount of energy as it absorbs; that is, it emits

$$E = \mathfrak{E}(\lambda, T)\, d\omega \cdot A = \mathfrak{E}(\lambda, T)\, d\omega\, (1 - e^{-k_\lambda m}). \quad (3)$$

A mass element dm of temperature T therefore sends through the absorbing mass m the radiation

$$dE = \mathfrak{E}(\lambda, T)\, d\omega \cdot dA = \mathfrak{E}(\lambda, T)\, d\omega \cdot e^{-k_\lambda m} k_\lambda dm. \quad (4)$$

If the mass element has a different temperature T_1, the radiation is simply

$$\mathfrak{E}(\lambda, T_1)\, d\omega \cdot e^{-k_\lambda m} k_\lambda dm \quad (5)$$

in which it is assumed that k_λ is not a function of the temperature of the mass m.

Diffuse Radiation. The simple basic law represented by equations (3) and (4) holds essentially for all complications that appear in the atmosphere. First of all we must take into consideration the fact that the radiation is not parallel. Let us consider the radiation of a layer of air of infinite horizontal extent which is part of a uniformly stratified air mass and which is to contain the radiating mass dm over an area of one square centimeter. Then the radiation emitted from this mass will arrive on a receiving surface at all angles of incidence $0° \leq \varphi \leq 90°$. The integration of equation (4) over φ can be reduced to known functions and the radiation of the layer element is

$$dS = \pi \mathfrak{E}\, (\lambda, T)\, 2H_2(k_\lambda m)\, k_\lambda dm. \quad (6)$$

The radiation of a layer of finite thickness with a temperature T is then

$$S = \pi \mathfrak{E}\, (\lambda, T)\, [1 - 2H_3(k_\lambda m)]. \quad (7)$$

The functions H_2 and H_3 (called Ei_2 and Ei_3 by Elsasser) are tabulated [27], so that they can be used for exact calculations. The expression $A^d = [1 - 2H_3\ (k_\lambda m)]$ can be considered as an absorption function of diffuse radiation, and its differential is accordingly

$$dA^d = 2H_2(k_\lambda m)\, k_\lambda dm.$$

Within a large range the following approximations can be made:

$$2H_2(x) \approx 1.66e^{-1.66x} \text{ and } 2H_2(x) \approx e^{-1.66x},$$

which means that the laws for diffuse radiation between atmospheric layers are replaced by the laws for parallel radiation in which, however, the absorption coefficient is multiplied by $\frac{5}{3}$.

Radiation from a Spectral Line. A further modification of the simple absorption laws is required by the physical processes that take place when gas masses radiate. The absorption bands of the multimolecular gases are not continuous, but are resolved into numerous closely spaced absorption lines. The absorption coefficient is extremely high in the center of each of these lines, while it is smaller by about two orders of magnitude between two lines. Thus, even if we consider only a very small spectral band $\Delta\lambda$ which contains only a single line, we must take into consideration a variation of k_λ at a ratio of 1:100. This is most easily done by determining once and for all the absorption function of a line. The form of a spectral line, that is, the law of the decrease of the absorption coefficient from the center towards the edges, is known as the dispersion form:

$$k_\nu = \frac{k_0 \delta^2/4}{(\nu - \nu_0)^2 + \delta^2/4}. \quad (8)$$

(Instead of λ, the frequency $\nu = 1/\lambda$ cm^{-1} is used; δ is also given in cm^{-1}.) The significant values in this law are (1) the absorption coefficient in the center k_0, (2) the half-value width δ of the line, and (3) the distance between two adjacent lines $\Delta\nu$. The ratio $\delta/\Delta\nu$ determines to what fraction of k_0 the absorption coefficient k decreases between two lines. Neither δ nor $\Delta\nu$ has the same value in one band, let alone in different bands, of the same spectrum. The distance between lines $\Delta\nu$ varies irregularly, because of the overlapping of differing laws for the various spectral lines. Only very few values have been determined for δ, because the measurements are extremely difficult to make. Therefore, it is usually assumed that δ, as well as $\Delta\nu$, is constant for the entire spectrum. Although this assumption is only an expedient, there is no possibility of a more exact evaluation at the present time.

If we integrate the absorption laws for parallel or diffuse radiation over such a dispersion form of a spectral line, we arrive at new laws, that is, new absorption functions, which can be expressed by

$$L^d(k_0 m) = \frac{1}{\Delta\nu} \int_{-\Delta\nu/2}^{+\Delta\nu/2} \left[1 - 2H_3\left(\frac{k_0 m \delta^2/4}{(\nu - \nu_0)^2 + \delta^2/4}\right)\right] d\nu \quad (9)$$

for the radiating layer m, and by

$$L(\mathrm{k_0 m}) = \frac{1}{\Delta\nu} \int_{-\Delta\nu/2}^{+\Delta\nu/2} \left[1 - \exp\left(-\frac{k_0 m \delta^2/4}{(\nu - \nu_0)^2 + \delta^2/4}\right)\right] d\nu \quad (10)$$

for the radiating column. As before, the radiation of a layer element is the first derivative of this function with respect to m, that is, $\frac{\partial L\,(k_0 m)}{\partial m}\, dm$ for parallel or diffuse radiation. It is of no consequence whether this integral can be solved analytically or numerically. If it can be tabulated, it can be used for any further calculations. The two new equations, (9) and (10), contain as a parameter the ratio between the half-value width and the distance between lines, $\alpha = \Delta\nu/\delta$.

An approximate solution for L may be obtained, if we assume $\delta^2/4$ in the denominator to be negligible compared to $(\nu - \nu_0)^2$. In that case

$$L\,(k_0 m) \approx \sqrt{k_0 \pi m/\alpha^2}.$$

This indicates that the radiation of a gas layer of finite thickness m is proportional to the square root of m if the absorption occurs in individual lines. If, on the other hand, we were dealing with continuous absorption, we would arrive at an exponential function. Thus,

simply by plotting experimental absorption values against the square roots of m, or by the usual representation of ln $(1 - A)$, we can determine whether we are dealing with a continuous distribution of the absorption coefficient, or with a resolution into individual lines. It is important to realize that this method is applicable even if the apparatus is not sufficiently sensitive to resolve the individual lines. Strong [48] applied this method to entire bands whose separate lines may have very different values for k_0.[1]

Radiation Diagrams

The knowledge of the absorption of a spectral line gives us one basis for the calculation of atmospheric heat radiation. The second basis is the distribution of the values for k_0 over the various wave lengths. For water vapor, which is most effective in the troposphere, the available measurements have been tabulated by Elsasser [14] and Möller [34]. Callendar and Cwilong give analogous figures. The absorption shows very great differences. In the rotation spectrum, k_0 is of the order of 10^4 cm^2 g^{-1}; in the rotation-oscillation spectrum at 6 μ it is about 10^3 cm^2 g^{-1}; whereas it decreases in the "window" of the water vapor to 1 cm^2 g^{-1} or below. In spite of these large differences we can never neglect one spectral range as compared to another, because the intensive radiation in the range of large values of k_0 is readily absorbed even by very thin layers, whereas the low radiation intensities at small values of k_0 are scarcely absorbed. However, thick and distant layers can participate in the emission of this radiation. Therefore we need the cumulative effect of all wave lengths for comparison with measurements. Mügge and Möller [37] were the first to use a graphical method in which the integration over all wave lengths is computed in advance and represented in diagrammatic form. Elsasser [14] developed a similar diagram, which is the same in principle, but which differs somewhat in arrangement.

According to the foregoing discussion, the radiation at wave length λ of a thin layer of gas of temperature T is given by

$$dS_\lambda = \pi \mathfrak{E}(\lambda, T) \frac{\partial L^d(k_0 m)}{\partial m} dm, \qquad (11)$$

where k_0 varies from line to line. Even larger spectral ranges that comprise a number of lines can be combined as long as k_0 varies less than k_ν in the range of one line, that is, less than 100:1. Then the total radiation of a layer element dm is obtained by summation over all wave lengths,

$$dS = \pi dm \sum_\lambda \mathfrak{E}(\lambda, T) \frac{\partial L^d(k_0 m)}{\partial m} \Delta\lambda, \qquad (12)$$

and the radiation of a layer m of finite thickness upon a surface element situated in the one boundary surface of the layer m becomes

$$S = \pi \int_0^m dm \sum_\lambda \mathfrak{E}(\lambda, T) \frac{\partial L^d(k_0 m)}{\partial m} \Delta\lambda. \qquad (13)$$

This is the radiation of an atmospheric layer upon a unit area, for instance the radiation of the entire atmosphere upon the unit area of the sensitive surface of a measuring instrument placed on the ground. The integration over m is difficult at first, because the temperature T is in general not constant but a function of m, that is, a function of the radiating mass situated between an altitude above ground and the surface of the earth. If we consider an isothermal atmosphere of temperature T_0, then

$$S_{T_0} = \pi \int_0^m dm \sum_\lambda \mathfrak{E}(\lambda, T_0) \frac{\partial L^d(k_0 m)}{\partial m} \Delta\lambda = X_{T_0}(m) \qquad (13a)$$

will be a function X of m. If we now plot the absorption

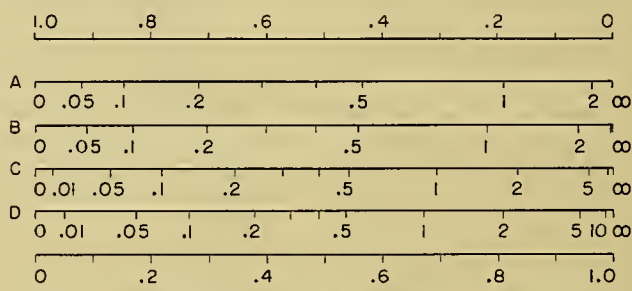

FIG. 1.—Absorption functions. The linear scale at the top gives the transmitted radiation. The linear scale at the bottom gives the absorptive or emissive power. Numbers on the function scales from A to D are the absorbing mass m.
(A) $1 - e^{-km}$ for $k = 1.66$. Parallel radiation.
(B) $1 - 2\,H_3(m)$. Diffuse radiation.
(C) $L^d_{\alpha=5.5}(k_0 m)$ for $k_0 = 6.5$. Diffuse radiation of a spectral line with $\alpha = 5.5$.
(D) $L^d_{\alpha=12}(k_0 m)$ for $k_0 = 20$. Diffuse radiation of a spectral line with $\alpha = 12$.
The values of k and k_0 are chosen so that for the same mass m the absorption will be 0.5 in each case.

function X as the abscissa and provide it with a scale of m, as in Fig. 1, we can read at the scale division m, the radiation intensity emitted by the isothermal layer of temperature T_0. However, X also indicates the amount absorbed by this layer when an infinite surface of temperature T_0 transmits black-body radiation through this layer. If k_0 does not vanish for any wave length, an infinitely thick layer ($m = \infty$) will have total absorption. Accordingly, the radiation emitted by an infinitely thick layer of gas is equal to the black-body radiation: the point $m = \infty$ of the scale lies at $X = \sigma T_0^4$.

It can be seen immediately that the radiation of a layer element dm of temperature T_0 is also given by the differential of X:

$$dS = \frac{\partial}{\partial m} X_{T_0}(m)\, dm.$$

In order to find the radiation of a layer element of a temperature other than T_0, a new evaluation of the

1. (Note added July, 1950.) Callendar [11] used an empirical absorption law $L(w) = w/(w + w_0)$ in which w_0 is a constant characterizing the degree of absorption; this law is easily applicable in theoretical investigations and covers the observations well. Using all experimental data of water vapor, Cwilong [12] recently deduced an empirical absorption function, but he gives numerical values only and not an analytic expression. The values of the function are available for narrow frequency intervals of the whole long-wave water-vapor spectrum.

summation over λ in (12) or (13) with T as a parameter becomes necessary. Let the ratio of the radiation of the two layer elements be y; then

$$y(T, T_0, m) = \frac{\sum_\lambda \mathfrak{E}(\lambda, T) \frac{\partial}{\partial m} L^d(k_0 m)\Delta\lambda}{\sum_\lambda \mathfrak{E}(\lambda, T_0) \frac{\partial}{\partial m} L^d(k_0 m)\Delta\lambda}. \quad (14)$$

We are now able to determine the radiation of the layer element dm of temperature T from the product

$$dS_T = y\,(T, T_0, m)\frac{\partial}{\partial m} X_{T_0}(m)\, dm. \quad (15)$$

From (15) follows the key equation of the radiation diagram

$$S = \int_0^m y(T, T_0, m)\, dX_{T_0}(m), \quad (16)$$

where T may now be any function of m, that may be given by observation or assumption. If we now plot y on the ordinate against X on the abscissa, we obtain a graph with curves for every value of T, in which $y = 1$ signifies that $T = T_0$, and $T < T_0$ gives values of y less than 1 (Fig. 2*a*). The radiation of an isothermal

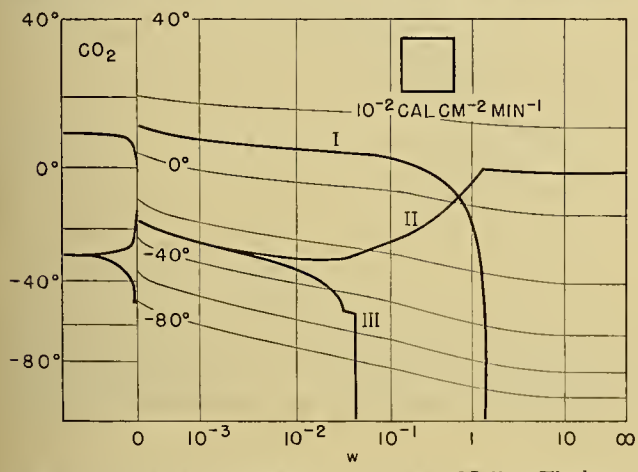

Fig. 2*a*.—Radiation diagram according to Möller. The heavy lines refer to downcoming radiation of the atmosphere at the ground (I), the radiation at 7 km received from below (II), and the radiation at 7 km received from above (III).

atmospheric layer is then given by the area bounded laterally by parallels to the y-axis through $m = 0$ and $m = m$, by the X-axis at the bottom, and the line T at the top. The radiation of a nonisotherma atmospheric layer in which T is a function of m can be found by plotting the temperature distribution $T(m)$ in the network of curves for m and T, and integrating. This is the basic principle of all radiation diagrams. Aside from the use of different absorption values, k_0, Elsasser's chart is an authalic transformation of this principle, in which the isotherms are made rectilinear, and, as a result, the lines of equal m-values become curved. The curvature is hardly noticeable, because the lines for $m = 0$ and $m = \infty$, which, as the boundaries of the graph, remain straight lines, intersect at the point $T = 0$. Thus the diagram assumes triangular or trapezoidal shape (Fig. 2*b*). Furthermore, abscissa and ordinate are interchanged by comparison with Möller's diagram.

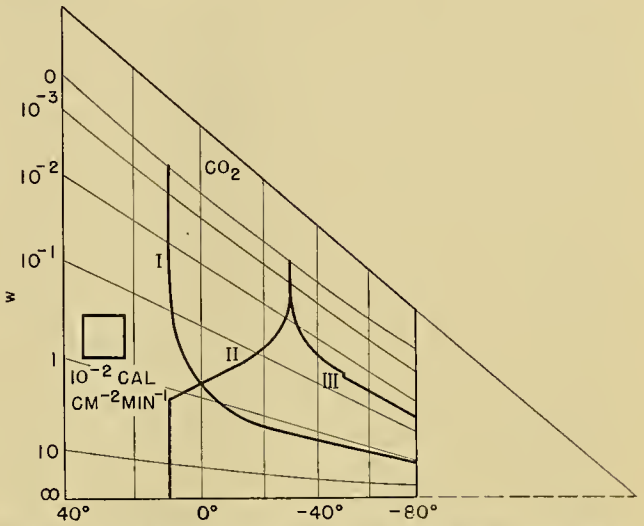

Fig. 2*b*.—Radiation chart according to Elsasser. The heavy lines correspond to those in Fig. 2*a*.

Even though the principle of the two radiation diagrams is the same, there are certain numerical differences. These are best illustrated by a comparison of the functions X_{40C} and X_{-80C} in the two charts. The values $T = +40C$ and $-80C$ are the highest and lowest temperatures shown. Table I shows that there

Table I. Radiation of an Isothermal Layer with a Water-Vapor Content w in Per Cent of σT^4 as Given by Elsasser (E) and Möller (M)

Temperature		w (g cm^{-2})						
		0 (CO_2 only)	10^{-3}	10^{-2}	10^{-1}	1	10	∞
		%	%	%	%	%	%	%
+40C	E	17.0	26.8	41.1	57.8	75.9	91.9	100.0
	M	13.3	24.4	41.5	58.3	72.7	89.0	100.0
−80C	E	16.6	38.1	58.0	76.1	88.8	96.6	100.0
	M	13.1	32.7	56.4	75.0	85.2	93.3	100.0

is good agreement with differences of less than 1 per cent in the middle range of amounts of water vapor between 3×10^{-3} and 3×10^{-1} g cm^{-2}. In the range of smaller or larger amounts of water vapor Möller's values are about 2 per cent lower than Elsasser's. (The first edition of Elsasser's chart, as well as the earlier edition of the chart by Mügge and Möller both showed radiation values 10 to 15 per cent lower in the middle range of water-vapor amounts. The agreement of the revisions made by both authors independently during the war is rather remarkable.)

There is more of a difference in the evaluation by the two authors of the radiation of carbon dioxide. For the amount of CO_2 normally present in the atmosphere, there is almost complete absorption in the extraordinarily intense band around 14.9 μ even by only very thin layers. The weak extreme boundaries of the band extend to 12.5 μ and 17.5 μ, respectively. Elsasser now

assumes that in the region from 13.1 μ to 16.9 μ the CO_2 always absorbs so strongly that we can assume total absorption, and that therefore the radiation emitted in that range by an atmospheric layer is equal to the black-body radiation at a temperature existing at the surface of such a layer. Möller [35] assumes a width of only 3 μ for this range, that is, from 13.5 to 16.5 μ, and estimates that within these wave lengths the absorption by water vapor is equal to that by CO_2 only when the specific humidity is 100 g kg^{-1} or more. Outside of these boundaries, however, the absorption by H_2O is greater than that by CO_2. Accordingly, the CO_2 absorption at 273K is 18.4 per cent according to Elsasser and 14.6 per cent according to Möller. In addition, Möller gives a scale in his chart which permits determination of the radiation effect of CO_2 for large temperature variations at low altitude (close to the ground) or for very low CO_2 content of the air (stratosphere).

Another point of comparison consists of the numerical values assigned to the absorption coefficient k_0 by Elsasser and by Möller. In the 6-μ band Möller's values are somewhat higher. The same applies to the absorption increase from 10 μ to the rotation band, while in the core of this band the values are lower. Elsasser first calculated his graph with the coefficients of his table. Later, however, he corrected it according to measurements of total absorption and concluded from these measurements that the k_0 values around 6 μ were originally too low, while those for 50 μ were too high. This makes the agreement of the k_0 values even better than a comparison of the numerical values would indicate.

Lately, an important objection has been raised against both radiation diagrams. The absorption functions for a spectral line, $L^d(k_0 m)$, which are used by both authors, contain the assumption that $\alpha = \Delta\nu/\delta = 5.6$, wherein δ was set at 0.5 cm^{-1} and the distance between lines, $\Delta\nu$, was assumed to be 2.8 cm^{-1} as the mean of the range investigated by Randall and his collaborators. According to recent measurements by Adel [1] on two lines near 16 and 18.6 μ, it was found that $\delta = 0.23$ cm^{-1}; from this it follows that $\alpha = 12$. The absorption function for a line L^d is also shown in Fig. 1 for $\alpha = 12$. The author suspects that the application of the new function will not lead to any important differences from the previous radiation charts, since the differences of k_0 at 10 μ, as compared to those at 6 μ and 50 μ, are so large as to render all refinements negligible.

The Downcoming Radiation of the Atmosphere

The simplest possible application of the radiation charts arises in the calculation of the downcoming radiation R of the atmosphere and of the effective nocturnal radiation $E = \sigma T_0^4 - R$ of the ground. Only a few direct comparisons of the measured and the calculated values are available.

Wexler [50] compared measurements made in Alaska and North America under winter conditions with radiation values calculated from Elsasser's diagrams and found that on the average the calculated outgoing radiation values were about 0.035 cal cm^{-2} min^{-1} higher than the observed values. This deviation, for which Wexler has no explanation, must probably be ascribed to the use of the earlier edition of Elsasser's diagram which, in the range of water-vapor content in question, furnishes a value for downcoming radiation approximately 10 per cent lower than the later edition of this chart.

F. A. Brooks [7] and Robinson [43] carried out comparative calculations for some cases of their numerous observations, but used them essentially to compute a radiation diagram on an empirical basis (see p. 40). However, in part of these observations in the free atmosphere only the total water-vapor content was used. So far, in most cases, no aerological measurements were made concurrently with the radiation measurements. Therefore only the variables measured on the ground such as pressure, temperature, vapor pressure, and cloudiness were used to organize the measurements and to develop interpolation formulas. The best known are those by Ångström and Brunt which give the ratio $R/\sigma T_0^4$ as a function of the vapor pressure at ground level only where T_0 is the air temperature at the point of observation. Numerous authors have derived the constants of this formula from their measurements, but the scattering of the constants given by the different authors is as great as the scattering of the individual measurements around the curves plotted by each author [28]. Only recently Bolz and Falckenberg [6] gave constants for Ångström's formula which result in values for the downcoming atmospheric radiation which are 7 per cent higher than the constants so far assumed as best values (Fig. 3).

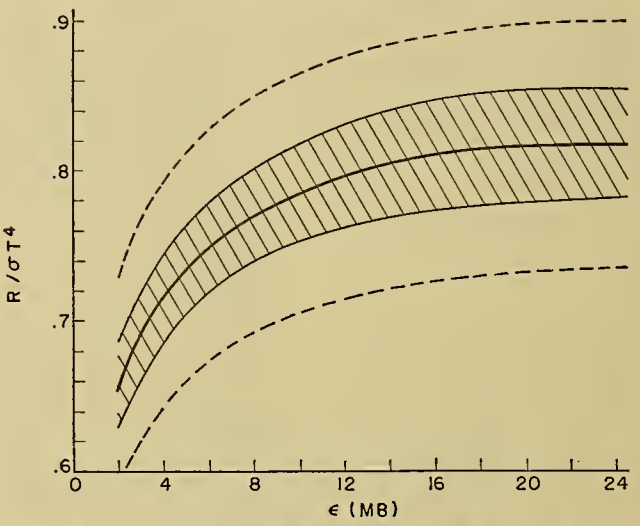

Fig. 3.—Scattering of the relative atmospheric radiation $R/\sigma T^4$ according to Bolz and Falckenberg [6]. Seventy per cent of all measured values lie in the hatched region, and ninety-eight per cent of all values lie within the region bounded by the dashed line.

If we assume a relative humidity that does not vary with height and a normal lapse rate of 6C km^{-1}, we obtain the values for R (at $T_0 = 283$K) given in Table II, according to Möller. These figures are higher than

comparative values [28] that can be calculated according to

$$R_A = \sigma T_0^4 (0.79 - 0.174 \times 10^{-0.041 e_0}) \quad \text{(Ångström)}$$

$$R_B = \sigma T_0^4 (0.48 + 0.60 \sqrt{e_0}). \quad \text{(Brunt)}$$

Three influences may cause the discrepancies and also the large scattering of individual measurements around the interpolation formulas. They are (1) the consideration of temperature, which is all too inaccurate, (2) the neglect of ground inversions, and (3) the additional effect of absorbers other than H_2O and CO_2. These three influences will now be considered in turn.

1. The formulas of Angström and Brunt give the radiation of the atmosphere as proportional to T_0^4. This law is taken into account in Möller's diagram by the fact that the area under a given isotherm T, which represents the radiation of an isothermal atmosphere with $w = \infty$ and CO_2-content $= \infty$, is equal to the black-body radiation σT^4. An isothermal atmosphere of 0C with the limited vapor content 3 g cm^{-2} has a radiative power $R = 0.826\ \sigma T_0^4$; a layer of equal content at +40C gives $R/\sigma T_0^4 = 0.804$ and at −40C, $R/\sigma T_0^4 = 0.866$. The variation of this factor, frequently

Table II. Calculated Downcoming Radiation R and Effective Terrestrial Radiation E
(For T_0 = +10C, ground-level vapor pressure e_0, and total water-vapor content W)

e_0 (mb)	1.23	3.7	6.1	8.6	17.3	20.0
W (g cm^{-2})	0.224	0.67	1.12	1.56	2.24	3.64
R (cal cm^{-2} min^{-1})	0.334	0.369	0.385	0.396	0.408	0.425
E (cal cm^{-2} min^{-1})	0.196	0.161	0.145	0.134	0.122	0.105
$E/\sigma T_0^4$ (per cent)	37	30	27	25	23	20

called emissivity, is caused by the changes of the ordinates of the T-lines in the diagram with w. The variation may also be expressed by the assumption that the radiation of such a limited vapor mass increases more slowly with T than with T^4. Accordingly, it appears that we can set

$$R/\sigma T_0^4 = C\,[1 - \gamma(T_0 - 273)],$$

in which T_0 = observed temperature near the earth's surface, and

$$C = (R/\sigma T_0^4)_{T_0 = 273}$$

is a function of the water content W of the atmosphere.

W g cm^{-2}	0.2	0.5	1	2	3	4
$\gamma\ 10^{-4}$ deg^{-1}	−2.0	1.0	4.0	7.0	8.5	9.5

It can be seen that measurements at high atmospheric temperatures, when they are taken as representative for 0C, yield too low a downcoming radiation, except when the vapor content of the atmosphere is exceptionally low. Brunt prefers presentation by an exponential law and finds the radiation as proportional to $T^{3.5}$ without indication of the vapor content. In the little-known formula of Robitzsch [45] for atmospheric radiation, R varies as σT_0^3.

2. On nearly all cloudless nights during which radiation measurements are made there exists a ground inversion, the magnitude and temperature of which are usually unknown. However, the layers next to the ground also furnish a considerable portion of radiation from above. (The values in parentheses in the following statement are percentages of the black-body radiation.) According to an estimate by Möller [28] for a normal atmosphere, 37 (28) per cent of the radiation proceeds from the layer 0–10 m, 71 (53) per cent from 0–100 m, and 88 (66) per cent from 0–500 m. Accordingly the effect of a ground inversion is great; an attempt at estimating this effect is shown in Table III. The downcoming atmospheric radiation R and the effective terrestrial radiation E are given for an atmosphere of T_0 = 273K and W = 1.12 g cm^{-2}.

This table indicates that a ground inversion can reduce the effective terrestrial radiation to $\frac{4}{5}$ its normal value, and under the extreme conditions found by Mosby during the polar night, to as low as $\frac{1}{2}$. Therefore, any comparison between calculation and observation becomes impossible if the vertical temperature

Table III. Downcoming Atmospheric Radiation R and Effective Terrestrial Radiation E in Relation to Vertical Temperature Distribution

Inversion thickness (m)	Temperature increase (deg C)	R (cal cm^{-2} min^{-1})	E (cal cm^{-2} min^{-1})
100	9.4	.360	.099
200	8.8	.356	.103
300	8.2	.353	.106
400	7.6	.351	.108
500	7.0	.350	.109
1000	0.0	.344	.115
Lapse rate	6C km^{-1}	.334	.125
	adiab.	.333	.126

distribution, especially that part close to the ground, is not known. Frequently, the temperature immediately contiguous to the ground will increase with altitude even more rapidly than assumed in the examples in Table III, and can thus cause an even larger positive deviation of the atmospheric radiation. Generally there will be no inversion over mountain stations, although so-called mountain inversions do occur. The diurnal variation of the temperature gradient may also explain the diurnal variation of the atmospheric radiation and its dependence on the air mass as demonstrated by Falckenberg [16].

3. Robinson [43] has carried out very careful evaluations of the measurements at Kew which included soundings of the free atmosphere. He found that on only few of the clear nights could the radiation values easily be fitted on a smooth curve that represented the relationship between radiation and the vapor content of the atmosphere. For other nights R rose to 0.03 cal, that is, more than 10 per cent higher. Such supplementary radiation appeared at times within an hour. It is impossible to seek an explanation in the variation of the content of CO_2 or O_3. It is rather more plausible to conceive a sudden development or advection of ground inversions or of very thin invisible cloud veils. Robinson suspects, rather, an additional radiation

caused by smoke or combustion gases from the chimneys of London. Quite similarly, Falckenberg [16] tried to explain the deviations he found for different air masses not by temperature gradients, but by the haze content which is not indicated by the water vapor. Volz [49] attempted to measure the emissivity of various substances in the laboratory.

Robitzsch [45] pointed out another as yet unexplained relationship. He established the formula

$$R = \sigma T_0^3 (0.135p + 6.0\epsilon_0)$$

which includes not only the vapor pressure ϵ_0 but also the air pressure p. This formula permits, in particular, the use in the interpolation equations of measurements on mountains or in the free atmosphere. Whether the term containing the air pressure can be attributed to an effect of the CO_2 content or to a diminution of ground inversion with decreasing values of p (anticyclonic and cyclonic conditions) would have to be determined by future research.

F. A. Brooks [7] and Robinson [43] developed radiation diagrams based upon observational data exclusively. The above-mentioned law for monochromatic radiation, according to which the radiation of an atmospheric layer is equal to that of a cylindrical column of air with $\frac{5}{3}$ times the water-vapor content, applies also to the "chromatic" radiation of the natural CO_2 plus H_2O atmosphere. Therefore, a radiation diagram for diffuse radiation can be used also for the investigation of linear or parallel radiation arriving from a definite zenith distance if we multiply the vapor scale by 1.66. The authors cited above proceeded conversely and developed from the measurements of a zonal sky radiation a graph that was then adapted to the use of hemispheric radiation.[2]

Atmospheric radiation finds an important application in the theoretical investigation of the nocturnal cooling process and in the prediction of frost. It has been shown by various authors that the nocturnal cooling cannot be traced essentially to a heat emission of the air by radiation (see the objections raised to this on page 45). The decisive factor is the heat loss from the ground by its effective radiation, and the distribution of this heat loss through conduction into the ground and through convection into the air. In the theoretical treatment of this problem the effective terrestrial radiation $E = \sigma T_0^4 - R$ was often assumed to be constant. However, σT_0^4 decreases with progressive cooling, and R decreases with the development of a ground inversion, but somewhat more slowly. Groen [21, 22] pointed out the necessity as well as the possibility of considering the change of E with T_0 by means of the radiation diagram in such a way that the equations for the nocturnal cooling continue soluble. His final equation represents an important step forward in the theory of nocturnal cooling, especially since he can include in his equation the different disturbing influences such as initial temperature distribution, condensation, and the influence of the wind on turbulent heat exchange.

The Absorption Coefficient as a Function of Pressure

So far we assumed the absorption coefficient k_ν to be independent of pressure and temperature. However, that is not exactly the case. True, the variation is so small that the downcoming atmospheric radiation at the ground is not materially changed, because 88 per cent of it originates in the lower 500 m of the atmosphere where the pressure differs little from that at ground level. At higher altitudes, however, the variation is more effective. The individual absorption line in a band spectrum increases its half-value width with increasing air pressure and temperature. Yet the "total intensity" of the line, that is, $\int_{\Delta_\nu} k_\nu d\nu$, is not changed. Only the shape of the line is altered. With increasing pressure it becomes wider and less intensive, with decreasing pressure it becomes narrower and more intensive. This means that, as the pressure decreases, the absorption increases even more in the narrow center of the line with a large value of k_ν, whereas k_ν becomes even smaller on the wings of the line [14]. As to the absorption by a line, it is found that, in thin layers, the radiation is absorbed almost completely in the core, whereas only in the case of thicker layers is the radiation also absorbed in the wings. With decreased pressure, the absorption in the core is increased and is very effective over the first part of the optical path length. However, subsequent absorption over the remainder of the path is diminished because of the small amount of radiant energy left to be absorbed. Since the initial segment can hardly be observed, the measurements indicate only that the mean absorption coefficient is reduced [46] in proportion to $\sqrt{p/p_0}$. In the absorption formulas k appears only in the product $k \cdot m$. Therefore, it is customary to apply the factor $\mu = \sqrt{p/p_0}$ not to k, but to the radiating mass m or to the densities of water vapor and CO_2. This correction is very important for all investigations into the radiation phenomena of the free atmosphere.

The intensity S of a line, $S = \int k_\nu d\nu$, remains unchanged with a change of the line width δ because of

2. (Note added July, 1950.) Robinson [44] recently published a detailed test of his diagram and of the Elsasser chart, for which he used numerous radiation measurements made at Kew. He found considerable differences which, to a great extent, are caused by the change in the emissivity of a vapor layer with temperature. According to his measurements, the emissivity increases with increasing temperature, whereas according to calculations by means of the Elsasser chart, it decreases by an amount half that of the measured increase (see numerical data on page 39). The prerequisites for the explanation of this discrepancy are as follows: (1) new experimental investigations are needed which would furnish the variation of absorption by vapor layers of finite thickness; (2) the theoretical computations must be checked; the change in radiation with temperature is derived (*a*) from the displacement according to Planck's radiation law, (*b*) from the change in the width δ of a spectral line with $\sqrt{T}$, and (*c*) from the change in the line intensity S with temperature. It appears that the last two influences have, to date, not been sufficiently considered.

the simultaneous change in k_0. Hence

$$S\Delta\nu = k_0\pi\delta.$$

If this expression is inserted into the square-root formula (page 35), we obtain

$$L = \sqrt{Sm\delta/\Delta\nu}.$$

The theory of line broadening by atomic collisions demands a simple proportionality of δ with p. Consequently, the absorption L must vary as $\sqrt{p}$. Schnaidt [46] emphasizes that the measurements by Falckenberg show a proportionality of the absorption *coefficient* k with $\sqrt{p}$. This means that, when an exponential law is used for *absorption*, $\sqrt{p}$ appears as a factor of m in the exponent. However, if the square-root law is used, the logical result is that $L \propto \sqrt{m\sqrt{p}}$ or $L \propto \sqrt[4]{p}$. Thus, there exists a contradiction between theory and observation. Nowadays the tendency is to place more confidence in theory than in measurements. Nevertheless, a repetition of the measurements would be desirable.

At the various wave lengths the transition from the absorption in the center to that on the flanks occurs with entirely differing thicknesses of vapor strata, because of the extraordinarily great differences of the absorption coefficients in the water-vapor spectrum. This leads to a complicated interspersion of absorption amplification and attenuation by the air pressure at the same level of the atmosphere. However, Möller [35] has shown by a rough calculation that, even on the assumption that $\delta \propto p$, the factor that must be applied to the vapor density of the atmosphere for use of the standard absorption equations (9), (13), and (15) has a value within the limits of p and $\sqrt{p}$ up to 100 mb (16 km). At still greater altitudes this factor increases again, because at the extremely low vapor content of the stratosphere only the center of the very strongest lines absorb. Möller proposes, instead of the factor $\mu = p/p_0$, a more complicated one, namely

$$\mu' = 0.985\ (p/p_0)^{0.8} + 0.015\ (p/p_0)^{-1}.$$

This factor has a minimum at around 100 mb and increases at higher levels. However, in the practical calculation of the cooling it is found that at these altitudes the radiation effect of water vapor becomes negligible owing to the greatly diminished vapor content, and that the radiation of other absorbers predominates. Therefore, the rigorous application of the correction factor μ' is unnecessary, as long as there are no better observations available for altitudes above 100 mb which would require more accurate calculations. Nevertheless, calculations to determine the effect of air pressure on changes of the shape of the lines have not been in vain; for, during the past few years, critics, on the basis of the necessary simplifications regarding this effect, questioned repeatedly the validity of calculations by means of the radiation diagrams [39].

Outgoing Atmospheric Radiation

By the use of the correction factor μ for the effect of the air pressure, the radiation diagrams become suitable for investigations of the free atmosphere. For a given level z_1, we can calculate the downward radiation R_1 from the atmospheric layers above it and, correspondingly, the upward radiation U_1 from the ground and from the atmospheric layers below this level. In the radiation diagram the ground is treated as an isothermal gas stratum having the temperature T_0 of the ground and an infinitely great content of water vapor and CO_2. The difference $E_1 = U_1 - R_1$ is then the net radiation which penetrates the reference level in an upward direction. The same calculation for another level z_2 furnishes E_2. The excess radiation $E_2 - E_1$, emitted by the air column $\Delta z = z_2 - z_1$ with air density ρ, causes a cooling

$$\frac{\partial T}{\partial t} = -\frac{1}{\rho c_p}\frac{E_2 - E_1}{z_2 - z_1},$$

which becomes for the limiting case:

$$\frac{\partial T}{\partial t} = -\frac{1}{\rho c_p}\frac{\partial E}{\partial z}. \tag{16}$$

Roberts' first studies [42] of the radiation flow E indicated that it increases with altitude. Normally this increase is very uniform with altitude in a cloudless atmosphere having a continuous vertical distribution of temperature and water vapor. However, the air density decreases with altitude so that the cooling rate which amounts to about 1C per day near the ground increases to two or three times that amount higher up in the troposphere. Only close to the ground and near the tropopause do special conditions prevail (see below).

It seems logical to interpret the cooling of the free atmosphere as a radiation into space. That, however, is not possible, for the shielding by the layers of water vapor above it is too great. It is, rather, a process similar to *heat conduction*. Basically, radiation, just as heat conduction, tends to equalize temperature differences. Therefore, we may also try to set up for radiation an equation that has a form similar to that for heat conduction, namely

$$\partial T/\partial t = K\ \partial^2 T/\partial w^2, \tag{17}$$

where K is a "virtual coefficient of conduction of the heat radiation," w is the mass of water vapor

$$w = \int \rho_w dz, \tag{18}$$

and ρ_w the density of the water vapor. This possibility was long ago developed theoretically by Falckenberg and Stoecker [18], and was later used as the basis of practical estimates by Brunt [9, 10]; here we shall use it only for an interpretation of the cooling. Substitution of equation (18) into (17) gives

$$\partial T/\partial t = K\gamma\rho_w^{-3}\,\partial\rho_w/\partial z, \qquad (\gamma = -\partial T/\partial z)$$

which is negative, because $\partial\rho_w/\partial z < 0$. In other words: The vapor masses at an equal geometrical distance above and below a given altitude are, to be sure, colder or warmer by the same temperature difference; but the

colder vapor masses are "nearer" than the warmer ones in terms of radiation, because the vapor density is lower above that altitude than below it. Therefore, more heat is emitted upward than is received from below. Thus, the cooling in the free atmosphere exists by virtue of the fact that T is not proportional to w.

This behavior of radiation, which is similar to heat conduction, is also clearly revealed by a break in the curve of vertical temperature distribution. There is an abrupt transition (schematically) from $\partial T/\partial z = -\gamma$ to $\partial T/\partial z = 0$ at the tropopause. Hence the vapor particle at this point receives radiant heat from the mass below, but cannot emit anything to the masses at equal temperature above. Therefore, in the absence of other influences, it should become warmer.

However, at higher altitudes the cooling does not depend only on a process similar to heat conduction, but in this case true emission occurs, that is, *heat is radiated to space*. Therefore, the amount of cooling is only partially due to the vertical temperature gradient and for the remainder to the mass of water vapor above and its screening effect on any heat radiation to space. The smaller this mass is, the greater the cooling. It was formerly assumed that the stratosphere had a high vapor content, or that the specific humidity remained constant with altitude.[3] This assumption leads to vapor contents that are too large and to contradictions between the magnitude of outgoing radiation and the actual temperature distribution. Today it is known from measurements by Regener [41] and by Dobson and others [13] that the relative humidity decreases sharply just above the tropopause. A more recent publication by Barrett and collaborators [5] also confirms these results. They found a decrease in humidity from about 10 per cent at the tropopause to about one per cent at 30-km altitude, but with a thin saturated layer interposed. Therefore, these altitudes are already close to the upper boundary of the "water-vapor sphere" and the radiation of the intensive absorption bands proceeds to space almost completely unscreened. Hence, the maximum of cooling lies at altitudes between 8 and 10 km. A calculation based on Elsasser's chart would shift this emitting layer to a somewhat lower level.

Probably, as a third factor, the *radiation by haze* at the tropopause must be considered. The troposphere is always filled with haze, whereas the stratosphere, contiguous to this hazy stratum, contains very dry and extremely clear air (as has been confirmed by numerous observations from aircraft). To be sure, the nature of this haze is not definitely known; but, whether minute droplets or solid particles constitute this haze, both are capable of emitting thermal radiation, even in the range from 9 to 12 μ, where the efficient "window" for outgoing radiation exists. Thus the haze boundary at the tropopause causes an additional cooling which may reach several degrees per day. Similar effects appear also at haze boundaries within the troposphere [31].

3. In the troposphere the decrease of the specific humidity with altitude indicates that vapor is lost and liquefied through cloud formation in the ascending currents of water vapor.

Cloud Radiation

The great effect of clouds on atmospheric radiation is also based on the fact that they radiate like black bodies in the wave-length range of heat radiation. Therefore, the upper cloud surfaces emit a very great quantity of heat in the range from 9 to 12 μ at every altitude of the atmosphere where they may occur; in these intervals there is almost no downcoming radiation from above. This produces an intensive heat loss, concentrated in a very thin layer. Naturally, this heat loss can become effective only if it is not counteracted by another process—as, conceivably, by an approximately equal absorption of radiant solar heat. However, 50 to 70 per cent of the solar radiation is reflected (Fritz [19]), and of the remainder only a very small portion is absorbed, whereas the greater portion traverses the clouds as a diffuse radiative flux and reaches the earth as scattered sky radiation (daylight). There is almost no absorption of solar radiation in the clouds and thus, the heat emission from cloud surfaces is not compensated by the solar radiation, *but acts unimpeded as a heat sink in the atmosphere*. Indeed, the higher such a cloud surface lies, the lower is the black-body radiation corresponding to its temperature. However, the atmospheric radiation which impinges on the cloud surface from above is diminished even more, for it decreases not only with temperature but also with the vapor content of the air situated above. Thus, the effective emission of the cloud increases with altitude.

A different process takes place at the lower boundary of the cloud. This surface receives from the underlying atmosphere, which is generally warmer, and from the ground, which is likewise warmer, a quantity of radiation that is greater than the black-body radiation emitted by the cloud in a downward direction. For this reason, the under surface of the cloud is heated by radiation from below. In this case there is also no compensation by other processes. The heating increases with increased altitude of the cloud, because of the increasing temperature difference between cloud and ground.

For a very thin cloud layer whose vertical extent must not exceed 100 m, both processes, the heat loss above and the heat gain below, can be considered together. Usually, the former is dominant, especially with low clouds such as stratus, and with middle clouds such as altostratus. If we assume that the heat budget of a thin cloud at an altitude of 5 km is distributed by turbulence and similar processes over a layer of air 1 km thick, we find a cooling of this mass of about 5C per day. A high cloud in the upper troposphere does not cool the air, because the radiation from below is relatively greater. In a tropical atmosphere, however, the conditions are quite different. The temperature difference between ground and cloud increase continuously up to about 18 km because of the normal decrease of temperature with height in the troposphere. Even if the assumption of a closed cloud cover is discarded and a scattered cloud cover of only $\frac{1}{10}$ is assumed, the heat balance of the cloud becomes positive at about 14 km. This means that even a thin cirrus cloud at this altitude

receives more heat than it emits. Thus it cannot exist as a cloud and must evaporate. This is probably the reason for the phenomenon observed in the tropics, namely, that the highest cirrus clouds are not found near the stratosphere, but at an altitude of about 14 km. Also the diurnal variation in the cirrus clouds (*i.e.*, dissolution toward noon, re-formation toward evening), which has been occasionally observed in the subtropical deserts, can probably be ascribed to the fact that the ground temperature is very high at noon [36].

A further consequence of the interaction between absorption of radiation from below and emission upward is the fact that a cloud layer must develop its own internal convection system. The absorption of heat in the lower portions will lead to an evaporation of the droplets, while the emission from the upper portions will lead to increased condensation and a descent of the heavier cloud. Thereby, the stratified cloud is resolved into individual convection cells, stratus is turned into stratocumulus and altostratus into altocumulus. This process may take place fairly rapidly. A stratified cloud ½ km thick, at an altitude of about 5 km, is converted and "destabilized" from the isothermal state to one with a temperature gradient of 0.5C per 100 m in approximately twenty minutes, whereas a similar cloud at a height of 2 km requires three quarters of an hour to complete the same change [32]. Keeping this in mind, it seems scarcely credible that an ordinary cloud layer can exist unchanged in the atmosphere for any length of time without being dissolved. If, in spite of the foregoing discussion, thin, closed, and stable altostratus cloud layers are observed, it becomes clear from the radiation calculations to what degree they must be sustained by a process which constantly re-forms them by new condensation. This process may be vertical austausch or upgliding, and its effectiveness must be considerable even in a cloud that appears to be stable and unchanging.

Synoptic Situations and Radiation of the Free Atmosphere

It is easy to survey schematically the radiation processes of an individual cloud. However, conditions become more complicated if it is desired to calculate approximately the effect of the clouds under different weather conditions or in different climatic regimes. Nevertheless, such calculations are necessary, since they offer the first possibilities for surveys. An attempt in this direction [36] is reproduced in Fig. 4. In this figure the average cloud conditions of a low-pressure area in middle latitudes are assumed, that is, 10 per cent of the area is clear, 20 per cent has clouds resting on the ground, 50 per cent has clouds with the lower level between 0 and 2 km, and 20 per cent has clouds with the lower level between 2 and 8 km. Correspondingly, in 40 per cent of the total low-pressure area, the upper cloud boundary is assumed to lie between 0 and 3 km, in 20 per cent between 3 and 8 km, and in 30 per cent between 8 and 10 km. In the average cooling curve shown in Fig. 4, the heat loss of the most important cloud levels at 2 and 9 km is distinctly noticeable, the lower by a cooling of almost 2C per day, the upper by more than 5C per day, for at this level the heat loss by the radiating upper cloud surface becomes more effective because of the reduced density of the air. The horizontal distribution in the low-pressure system cannot be distinguished, because the various factors are averaged over the entire area. However, the cooling rate must be about three times as great in the advance portion of the cyclone where the upgliding cloud screen lies as a closed, though loose and diffuse, cover at 8 km altitude. It is obvious that such a cooling of 15C per day will noticeably influence the weather development and the cloud dynamics. Further investigations of this kind should yield valuable insight into the thermodynamics of weather.

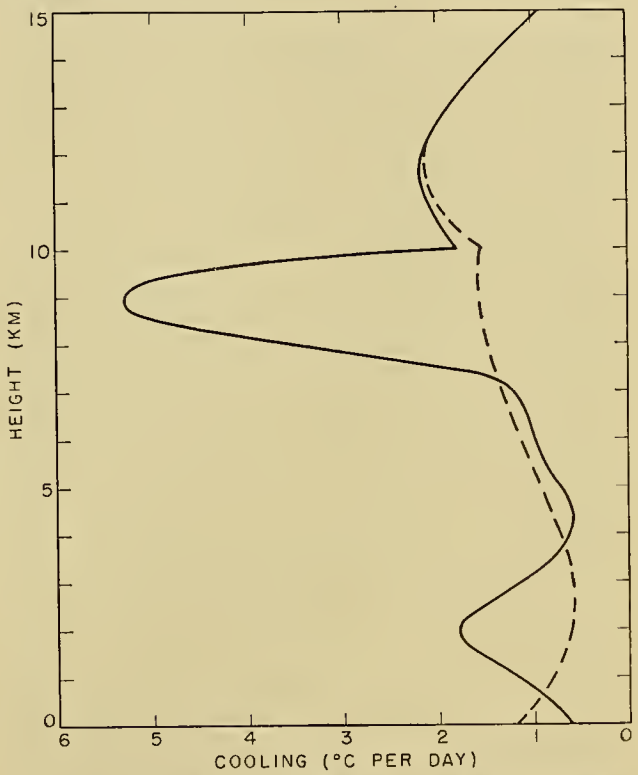

Fig. 4.—Cooling of the atmosphere by water-vapor radiation in degrees per day. The dashed line applies to a cloudless atmosphere and the solid line to an average distribution of clouds in a low-pressure area.

In 1935 the author tried to give a balance of all heating and cooling processes in the free atmosphere and their vertical distribution [29], in which not only the outgoing radiation but also the incoming solar radiation and the liberation of the latent heat of condensation were considered. The calculations for long-wave radiation will be revised here.

A normal temperature and humidity distribution for middle latitudes was assumed as a basis for the calculations. The cooling of the cloudless atmosphere, as now computed, differs from the earlier calculation. At that time, the cooling of the entire troposphere was found to be constant at 1C per day. In the new calculation (Fig. 5, curve *A*) it increases with altitude to 2¾C per day (at 9 km). The cause of this difference lies in

part in the use of the improved radiation diagram, but principally in the realization that the water-vapor content of the stratosphere is much lower than was formerly assumed. For this reason—as mentioned above—the main emission level is shifted down to the altitude of the tropopause. The importance of reliable measurements of the water-vapor content of the stratosphere for these investigations cannot be over-emphasized, for a higher water-vapor content sharply reduces the emission at the level of the tropopause. So far only two or three measurements of the frost point have been published. They show an unchanged decrease above the tropopause [13] sometimes interrupted by thin saturated layers [5]; however, we do not know whether, for example, the water-vapor content over low-pressure areas is higher than shown by these measurements. There is considerable evidence for this supposition, for otherwise how should the mother-of-pearl clouds observed in Norway develop in the rear portion of cyclones at an altitude of 28 km, if the relative humidity remains at 1 per cent and less from an altitude of 14 km upward? If the humidity is greater, the radiation processes of the tropopause are reduced considerably.

It is also very difficult to make any reasonable statements concerning the distribution with altitude of the upper cloud boundaries. It is here assumed that this boundary lies between 0 and 2 km in 15 per cent of all cases, between 2 and 5 km in 45 per cent, between 5 and 8 km in 30 per cent, and between 8 and 10 km in 10 per cent of all cases. For the lower cloud boundaries, 80 per cent are assumed to lie between 0 and 3 km, and 20 per cent between 3 and 10 km. Consideration of these values gives a cooling of the free atmosphere on completely overcast days as shown in Fig. 5, curve *B*, that is, there is a "radiation screen" in the lowest layers, but above 2 km there is an increase of heat loss of about 0.8 to 1 degree per day as compared to a cloudless atmosphere. On the whole, however, the difference between the cloudy and the clear atmosphere is small. The calculation made in 1935 (under the assumption of a somewhat different cloud distribution) gave the greatest cooling at an altitude of 4 km. This might well be taken as an indication of the importance for these investigations of more accurate data respecting the distribution of the clouds in the atmosphere not only on the average, but also for specific weather situations.

An example from an altogether different climatic regime also shows this very clearly. An entirely different temperature and cloud distribution must be assumed for a winter month at the earth's cold pole situated approximately in northeastern Siberia. On cloudless days (50 per cent of all days) the temperature at ground level is assumed to be −50C, rising to −25C at 1.5 km, and decreasing to −60C at 8-km altitude. In the presence of a cloud cover, the temperature between 0 and 2 km is taken to be constant at −30C. The clouds, which are seldom very massive (there are only two days of precipitation per month), are assumed to be restricted to the layer between 0.5 and 2 km. On clear, as well as on cloudy days, an extremely strong cooling layer results between 1 and 2 km, with an average of 5C per day (Fig. 5, curve *D*). Aloft the cooling is comparatively slight. Thus the vertical arrangement of the heat balance in this continental winter climate deviates considerably from that of our middle latitudes under maritime influence.

As a third example, a tropical atmosphere is represented (Fig. 5, curve *C*). There is little difference up to 7 km as compared to the temperate latitudes. The maximum of the outgoing radiation lies at an altitude of 13 km and is not affected by processes resembling heat conduction as in the temperate tropopause at 10 km. This appears to be an approach to a solution of

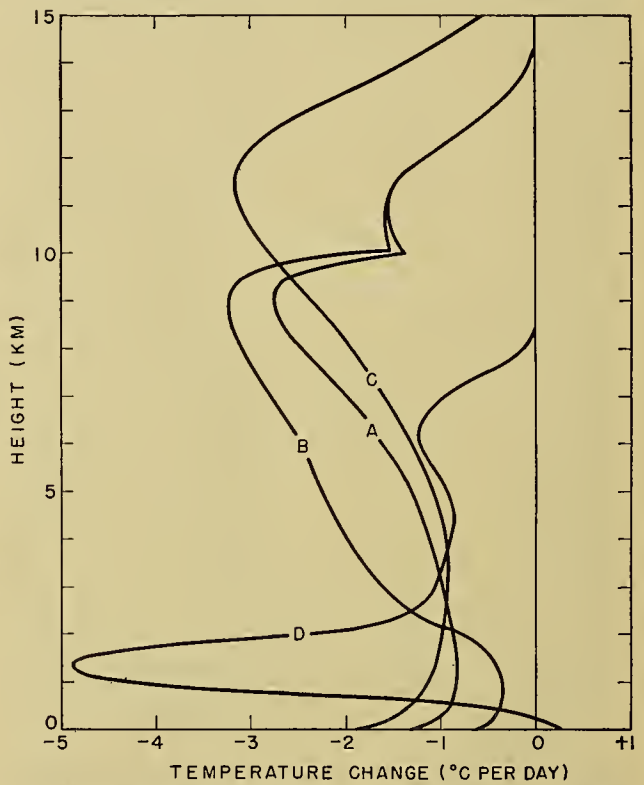

Fig. 5.—Temperature change of the atmosphere by water-vapor radiation in degrees per day.
(*A*) Normal atmosphere in middle latitude, cloudless.
(*B*) The same with an average distribution of clouds.
(*C*) Tropical atmosphere, cloudless.
(*D*) Temperature and cloud distribution at the cold pole.

the old problem concerning the origin of the tropopause. In middle latitudes we find the maximum of heat loss in the region of the tropopause. There, it may be a fair assumption to consider the water-vapor radiation as the cause of the tropopause. In the tropics, the layer of strongest cooling lies about 4–5 km below the tropopause. Thus, it is most probable that the tropopause is produced in a different manner in the tropics than in temperate latitudes. Whether steady-state dynamic phenomena play a role here, or whether the CO_2-radiation becomes important, remains as yet unexplained. Explanations which distinguish between the tropopause in temperate and in tropical regions have also been developed by Goody [20]. Finally, further indication is given by the abrupt discontinuity in the altitude of the tropopause at lat 30°, which was sus-

pected as early as 1935 [30] and which was recently demonstrated by Hess [23].

Radiation cannot be responsible for day-to-day changes in the tropopause of the temperate latitudes, since its effect is much too slow, as shown by Junge [26]; in this case dynamic processes are certainly important. On the average, however, radiation of water vapor is as responsible for the low temperature at the tropopause, as is the decrease of solar radiation from the equator to the pole for the meridional temperature distribution of the troposphere, although in the latter case, day-to-day variations are likewise considerable.

Numerical and Analytical Radiation Calculations

All calculations of radiation processes mentioned so far are based on the method of the radiation diagrams. There is no doubt that these are somewhat cumbersome. The determination of the heating and cooling processes via the radiation fluxes and their differentiation with respect to altitude seems especially laborious. Bruinenberg [8] has made a valuable contribution here toward attaining the objective directly. He puts the differentiation with respect to altitude, which can also be replaced by differentiation with respect to temperature, under the integral of the radiative flux in equation (13) or (15). Thus, after calculations of a scope analogous to those required for the construction of a radiation diagram, he arrives at expressions which are suitable for numerical integration or summation. However, these equations are less suitable for a graphical treatment. Therefore, Bruinenberg has calculated tables which permit very simply the determination and addition of the cooling or heating effects exerted on a given element by all atmospheric layers above and below it.

The principal advantage of the individual calculation is the fact that the cooling for points closely spaced along the vertical can be determined independently and with great accuracy. This leads to a result which, though not unexpected, has thus far been underestimated in its implications. Every break in the vertical temperature distribution is manifested as a sharp peak in the distribution of the cooling rate. Thus cooling peaks up to 3C per day project from the average cooling level of 1C per day in the lower troposphere at every break of the characteristic temperature curve directed toward higher temperatures, and heating peaks up to +1C or +2C per day where the characteristic curve breaks toward lower temperatures. Heating of +5C per day occurs below an inversion, whereas there is a cooling of 15C per day at its upper boundary. However all this holds true only in very thin layers. (Bruinenberg's method is so far applicable only to calculations in the lower and middle troposphere; for the tropopause, see p. 42.) At these points the radiation simply acts as a temperature equalizer in a manner similar to heat conduction. Every break in the characteristic temperature curve is equalized at an accelerated rate. From the foregoing discussion it follows again that if inversions or more or less sharp discontinuities in the temperature gradient persist for days, the ordinary radiation processes of the water vapor cannot be the cause. Thus the question whether long-wave radiation can produce inversions is decided partially in favor of the negative [4]. For the maintenance of existing inversions, some processes must be constantly active that recreate the inversion continuously against the equalizing effects of the radiation. Such processes are partly the additional radiation from the haze layers below the inversion which overcompensate the heating (see p. 42) and partly the dynamic processes of shrinking and subsidence. The intensity of these dynamic processes can then be estimated from the calculations of radiation.

An especially significant level is the earth's surface. For radiation effects, the ground may be conceived as replaced by an infinitely extended isothermal layer of water vapor or CO_2. In such a case the corresponding characteristic temperature curve extended into the ground has a break at the ground surface. If there is a temperature decrease with altitude above the ground, there must be strong cooling directly at the ground surface, whereas there is strong heating at the base of a ground inversion. Such radiative processes will scarcely become operative, since all observations disprove them. However, in every case, they will tend toward an isothermal state near the ground as an equilibrium condition. Even if this equilibrium is not reached, its quantitative consideration will possibly lead to a revision of the assumptions concerning the magnitude of the austausch near the ground as far as has been disclosed by measurements of the temperature gradient.[4]

Although the graphical and numerical calculation methods are carefully worked out, an analytical equation can be very advantageous at times because it permits combination of the radiation process with others that can be approached theoretically. Such a possibility is offered by the quasi-conduction of radiation introduced by Brunt [9]. However, this method will not include the processes at the ground surface which were discussed above. The complicated construction of a radiation diagram makes it apparent that a *complete* description by a single convenient equation is impossible. Simplifications must be made. One such simplification consists of running the temperature lines horizontally in the Möller diagram (in the water-vapor section). This means that we do not change the distribution of the absorption coefficients over the wave lengths, but that we do assume that the energy curve has the same shape for all temperatures, instead of assuming Planck's formula for black-body radiation. This would imply, for example, that, if we take the shape of the energy distribution at 273K, the radiation for a different temperature would be given by multiplying this curve by the factor $T^4/273^4$ which is not a function of the wave length. In the Elsasser chart this assumption would mean that the w-lines would be rectilinear and convergent to the point where $T = 0$K. If, in addition, we approximate the abscissa scale X of the Möller chart with any convenient function, new problems can be solved.

4. (Note added July, 1950.) In his newest publication, Robbinson [44] also comes to the conclusion that radiation processes are very important near the earth's surface.

An initial attempt of this type was made by approximating the function X by the sum of two exponential functions. This would mean that the absorption spectrum of the water vapor is not gray but "bichromatic." The investigation of the radiation equilibrium of the atmosphere was carried out by Emden [15] for gray radiation and led to an isothermal stratosphere of −68C. The calculation of the same problem for bichromatic absorption of water vapor does not lead to an isothermal stratosphere but yields a steady decrease in temperature with altitude down to −144C at the boundary of the atmosphere [31]! If it still were at all necessary to deal the death blow to the untenable theory of the radiation equilibrium of the water vapor in the stratosphere, this calculation would do so.

Another approximation of X is fundamentally more accurate. If we set $X = a \ln(w + b)$, where a and b are numerical values, we obtain an approximation that is especially good for small values of w and small amounts of CO_2. Then $dX = adw/(w + b)$, and from this simple formula the radiation equilibrium can be developed as a kind of integral equation and can be brought closer to numerical solution. This method appears important especially for the temperature distribution in immediate proximity to the ground because, under conditions of both midday adiabatic stratification and nocturnal ground inversion, this temperature distribution is a function not only of the austausch but also of radiation. Results of these calculations are not yet available.

Radiation in the Stratosphere

Investigation of radiation phenomena in the stratosphere is more difficult than in the troposphere for several reasons. First of all, the absorbing media are under very low pressure, and therefore a check must be made in every case to ascertain to what extent the absorption coefficients, as measured in the laboratory, may be used. In the second place, the concentration of the various gases is not known exactly. Finally, the radiation cannot be considered any longer as an individual process out of the context of the general physical phenomena. In the troposphere also, radiation participates everywhere, to be sure, in the general weather pattern, and in the presentation above, emphasis has been on showing that radiation participates decisively in all meteorological processes. However, the substances themselves are not changed in their molecular structure by absorption or emission. If, for instance, water vapor is brought to condensation and fog forms as a result of strong radiational cooling, it changes only its aggregate state, not its chemical structure. In the stratosphere, however, ozone offers an example of more drastic changes. It is only by the absorption of the solar radiation in the ultraviolet bands that the formation of O_3 from O_2 becomes possible, and it is under the influence of longer waves in the ultraviolet that the ozone again dissociates. It is indeed true that it is not the long-wave heat radiation but the short-wave solar radiation that controls the formation and dissociation of the absorbing medium. In addition, however, both processes participate in the heat balance with their thermal implications. Therefore, the radiation processes in the stratosphere cannot be separated from the multitude of physical atomic processes at those altitudes. If, in spite of this, such an attempt is made, it will necessarily be in full consciousness of the unreliability involved.

Above 10-km altitude the importance of water vapor as a decisive absorbing medium decreases more and more, and CO_2 and O_3 become significant. The water-vapor content of the air in the stratosphere is extremely small according to measurements by Dobson [13], Barrett [5], and others. For several kilometers above the tropopause the frost point falls steadily at the rate of its decrease with altitude in the troposphere, so that the relative humidity at 2 km above the tropopause has decreased to below 1 per cent. However, if we accept this low humidity as a generally valid fact, the radiation effect of the water vapor in the stratosphere no longer exerts any notable effect, since its total content drops to 10^{-4} g cm^{-3}. Dobson, however, thinks that its effect is to be considered equivalent to that of CO_2, but gives no numerical values for the amount of absorbed radiation.

Carbon dioxide has a very intensive absorption band around 15 μ. An extremely weak band around 10 μ absorbs only one per cent for layer thicknesses that equal the content of the whole atmosphere. An additional band at 4 μ lies at the boundary of the spectrum. The absorption curve in the 15-μ band is known. The dependence on pressure is usually estimated by the effect on the 4-μ band which is known from measurements by Wimmer [51]. From this Möller has derived a reduction factor $\mu = (p/p_0)^{0.74}$, whereas Elsasser uses the $\sqrt{p/p_0}$ law in the same manner as for the water vapor, and Goody a proportionality to p. A calculation of the processes is possible by means of the Möller diagram. Möller calculated the CO_2-radiation emitted by an isothermal stratosphere and found a maximum effect at an altitude of 26 km with a cooling of 1.5C to 2C per day. Since his assumption of a CO_2-content of 0.03 per cent is somewhat too high, the maximum lies probably a little lower.

In this calculation it was assumed that the ozone has no effect. But, as mentioned already, ozone has a very intensive absorption band around 14 μ which is situated at the same point as that of CO_2 and shows a curve with respect to wave length which is similar to that of CO_2. The line structure of ozone which probably differs from that of CO_2, is unknown, however, and probably does not enter into the calculations. Since half of the ozone lies at altitudes above 20 km, the radiation of the CO_2 is extensively shielded by its absorption, and the outgoing radiation in this range of wave lengths takes place only at higher altitudes and then as an emission of the ozone. Thus, these processes interact strongly with each other, and for this reason scarcely any attempts have been made to investigate them in greater detail [33].

Furthermore, the experimental bases for the ozone spectrum are not yet sufficient. In addition to the 14-μ band, there is another band around 9.6 μ, which

lies exactly in the "window" of the water vapor and which therefore can contribute to the effectiveness of the outgoing radiation emitted by the earth's surface despite the weak absorption and the small amount of ozone. Adel [2] measured the intensity of the solar spectrum at this wave length in an excellent experimental investigation and was able to detect the absorption in this band. Its maximum is about 50 to 70 per cent. The old laboratory measurements by Hettner and collaborators [24] were made on large amounts of ozone under high pressure. From their absorption coefficients and the normal amount of ozone in the atmosphere the maximum absorption found at 9.6 μ is only 14 per cent. This contradiction was explained by Strong [47], who made measurements with ozone under low total pressures. He was able to show that the supplementary atmospheric pressure greatly broadens the absorption lines of ozone, whereas an increased partial pressure causes only a minor broadening of these lines. It is for this reason that the absorptions measured in pure ozone without admixture of air are much too small in spite of large quantities of ozone. The application of the absorption values as measured by Strong leads to a maximum absorption at 9.6 μ, equal to that found in the solar spectrum. Though these processes are explained for the 9.6-μ band, this is not true for the 14-μ band for which similar measurements are completely lacking. In this case we must depend on analogous conclusions.

Through numerous investigations we are well informed concerning the amount of ozone in the atmosphere and its vertical distribution. Only recently were the optical determinations of this vertical distribution excellently confirmed by direct measurements. Previous calculations of the radiation phenomena in the ozone (Gowan, Penndorf) are based on the uncorrected laboratory measurements of the absorption by Hettner. The results are therefore incorrect. Recently, a new calculation was made by Oder [38]. He uses values for the absorption coefficient which in each case give only an average for the whole band. This incorrectly distorts the absorption function, and his results are therefore apparently inaccurate. However, the numerical values, which are presented in Table IV, are noteworthy. At an altitude of about 40 km the emission of radiant heat produces a cooling of about 8C per hour. It will not be very easy to explain what processes compensate for this large cooling, but they must be compensated somehow if the assumption that the temperature distribution remains stationary is correct. Goody [20] made the most important contribution to the theory of radiation of the tropopause. He assumed that in this region a discontinuity exists in the vertical temperature gradient, namely from 6C per km in the troposphere to isothermal conditions in the stratosphere. By means of separate calculations of the individual bands of the three absorbers, water vapor, carbon dioxide, and ozone, he investigated the radiation balances and their dependence on barometric pressure and temperature at the tropopause. He found that in middle and high latitudes an equilibrium exists between the heating effect of carbon dioxide and the cooling effect of water vapor; in the tropics, however, water vapor, because of its extremely small concentration, no longer has any effect. There, an equilibrium exists between the effects of carbon dioxide and ozone. At the great heights and the low temperatures of the tropical tropopause, however, carbon dioxide has a cooling effect, ozone a very faint heating effect. This led Goody to the remarkable concept that radiative equilibrium always depends on the contrast between two different absorbers, and that in the tropics the participating media are different from those in middle latitudes. The quantitative bases of these computations appear to be still inadequate. For this reason, verification would be most desirable. Also, it appears to this writer that the selection of the tropopause for these calculations is somehow not quite suitable because of the peculiarities of radiative processes at points of discontinuity in the temperature gradient. However, it is difficult to suggest altitudes that would be more suitable for such computations.[5]

Table IV. Radiational Heating of the Stratosphere (*According to Oder* [38])

h (km)	15	20	25	30	35	38	41	44	47
$\partial T/\partial t$ (deg C per day)	0.1	−0.6	−0.5	3.1	(−44)	(−120)	(−172)	−98	3.3
$\partial T/\partial t$ (deg C per hour)	—	—	—	—	−1.8	−5.0	−7.2	−4.1	—

Suggestions for Future Research

Though the foregoing exposition touched only briefly on the experimental foundations, it has nevertheless been shown that the most important lines along which research must now proceed are of an experimental or observational nature. The following appear to the author to be of particu'ar importance:

1. Absorption or emission of water-vapor layers of limited thickness must be checked by laboratory and free-air experiments. The available measurements seem insufficient to explain the variation with temperature that results from the variation of the observed atmospheric radiation. Such measurements are a very important basis for radiation diagrams and fo r all conclusions drawn from them regarding the free atmosphere.

2. Long-wave radiation, particularly in the free atmosphere, must be measured. Since there are filter substances available which are not only very good in the long-wave range but which are uniform for all wave lengths [25], there should be no basic difficulty in con-

5. (Note added July, 1950.) A recent investigation by Plass and Strong [40] may clarify this problem. However, only an abstract of this work has been published thus far.

structing instruments to be mounted in aircraft. This would shift investigations into entirely new channels.

3. Adequate data concerning the content of water vapor and carbon dioxide of the upper troposphere and the lower stratosphere are needed for investigation of tropospheric radiation by means of the familiar graphical methods. Spot checks are inadequate. Measurements are needed in such numbers that radiation changes with the weather situation become clear. The influences of the geographical latitude and of continents and oceans on the content of water vapor and carbon dioxide must also be determined. The same holds true for the determination of the upper cloud boundary for various weather patterns and various types of climate. Radiosonde observations are not sufficient for this purpose; direct observations from aircraft are needed. We must consider such observations as the principal demand which radiation research makes on the field of observational aerology.

4. The influence of pressure on the absorption by CO_2 and O_3 in the 15-μ band must still be investigated in the laboratory for application to the study of the radiation processes in the region of the tropopause. Only then can we approach an explanation of the radiation processes at these altitudes with any hope of success.

ACTINOMETRIC MEASUREMENTS

By ANDERS ÅNGSTRÖM

Meteorological and Hydrological Institute of Sweden

ACCURACY OF ACTINOMETRIC MEASUREMENTS

In actinometry, as in every other field of science founded upon some kind of direct measurement, the instrumental accuracy and the method of observation must be closely related to the character of the scientific problem under consideration.

Determination of the Solar Constant. Some scientists maintain that this so-called "constant" is subject to short periodic variations amounting to approximately 0.2 per cent on the average, with a maximum amplitude of about 1–2 per cent. It is evident that in order to investigate these variations our measuring devices must be sufficiently accurate to measure amounts of radiation below the smallest amplitude of the variations which we intend to determine, in other words, the instrument must measure accurately to at least ± 0.2 per cent.

Heat Exchange at the Earth's Surface. Considerably less accuracy is required in many other problems closely connected with actinometry. Suppose, for instance, that we wish to investigate the heat exchange at the earth's surface through radiation, convection, conduction, evaporation, etc. Here, the radiation enters into an equation in which the other factors involved can hardly be determined to an accuracy greater than 5–10 per cent. Even if we could measure them more accurately, it would be of little benefit, since the values have no general applicability. Convection, conduction, reflection from the earth's surface, and evaporation are all highly variable from place to place. Local measurements are seldom representative for more than very limited areas. An accuracy of ± 3 per cent seems in general quite sufficient for such purposes as actinometric measurements aiming at an evaluation of the heat balance at the earth's surface, ablation studies on glaciers and snow covers, and studies of similar geophysical problems.

Analysis of the Atmosphere. Actinometric measurements are, however, also an important means for the analysis of the content of the various atmospheric constituents. Through rather simple measurements of the total direct solar radiation and of the same radiation within a few selected regions of the spectrum, an evaluation can be made of the total water content in the path of the solar beam as well as of the turbidity (*i.e.*, the content of solid or liquid particles which scatter light in the atmosphere). The principles on which such determinations of the turbidity and water content are founded will be briefly summarized in the following paragraphs.

If the solar "constant" is regarded as a true constant and its relatively small variations are neglected, the variations of the incoming direct solar radiation Q_m at a given solar elevation (air mass = m) may be regarded as due to four principal causes:

1. The variable distance between sun and earth.
2. Molecular scattering.
3. Scattering and absorption by liquid and solid particles in the atmosphere.
4. Selective absorption by the gases of the atmosphere.

The variations resulting from the first cause are well known and easily computed. The scattering by the molecules may be computed from the theory of Rayleigh; the scattering coefficient thus determined is a continuous function of the wave length, being inversely proportional to its fourth power.

Scattering by the solid and liquid particles in the atmosphere may, as a first approximation, also be regarded as a continuous function of the wave length. Strictly speaking, if the physical nature of the particles is known in detail, the scattering coefficient may be computed as a function of the wave length, according to the classical theory of Mie. However, since we seldom or never have a complete knowledge concerning the variable nature of the scattering particles in the atmosphere, it seems allowable to introduce a simplification based on empirical results. From Abbot's extensive observations in various parts of the world the present author found that the scattering coefficient S due to liquid and solid particles in the atmosphere may, in general, be expressed by

$$S = \beta/\lambda^{\alpha}, \qquad (1)$$

where β has a value proportional to the number of particles, and α no longer has a value of 4.0 as in the case of the molecules but varies between 0.5 and 2.0, according to the size of the particles. The smaller the particles, the larger is the value of α. In general, an acceptable average value for α, that holds for ordinary conditions, seems to be 1.3. When the atmosphere has been polluted with larger particles, as after violent volcanic eruptions or through dust storms over deserts, the value of α is sometimes as low as 0.5 or even less. The particles influencing the visibility in the atmosphere near the ground are also evidently larger than the average particle causing the scattering of the solar beam. For these lower layers Schmolinsky [10] found an average value of about 0.9 for α.

These considerations hold approximately for the visible part of the solar spectrum, that is, for wave lengths in the range from 0.4 to 0.8 μ. They are, however, not applicable to the ultraviolet and the far infrared. Finally, the incoming solar beam is weakened also by the selective absorption by the various atmos-

pheric gases, especially by water vapor and carbon dioxide. This absorption is not a simple function of the wave length, but is concentrated in certain spectral regions. The conditions are, however, simplified by the fact that the selective absorption by the variable gases is almost entirely confined to the far red and the infrared, where the principal water-vapor and carbon dioxide bands occur. Only a small part, about 1–2 per cent of

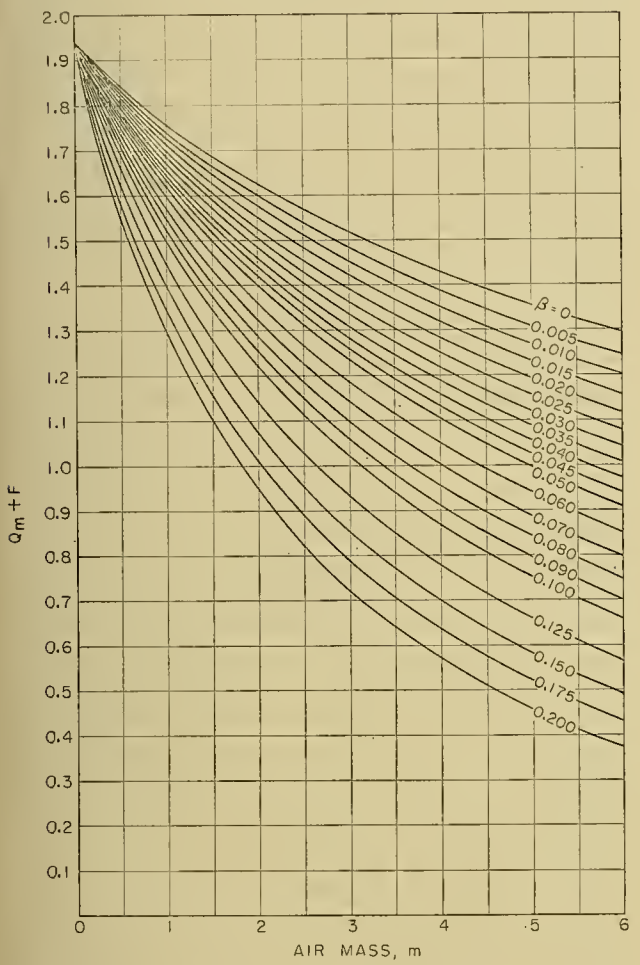

FIG. 1.—Atmospheric turbidity β according to Angström-Hoelper. Ordinate: total radiation measured (Q_m), with addition of water vapor absorption (F). Abscissa: air mass (unit vertical air mass at sea level and 760 mm). Actinometric scale: Smithsonian.

the total energy is subject to a variable absorption within the visible and the ultraviolet.

Consequently, the total incoming solar radiation Q_m, as measured for instance with a pyrheliometer, may be expressed as

$$Q_m = \int_0^\infty I_{0\lambda} q^m \exp(-\beta m/\lambda^a)\, d\lambda - F. \qquad (2)$$

In this equation we may assume Q_m to be known from measurements; $I_{0\lambda}$, the radiation outside the atmosphere at the wave length λ, is known from the elaborate investigations by the Smithsonian Institution (Abbot and collaborators);[1] q, the transmitted fraction of the incident energy for unit air mass (if only molecular scattering is considered), is computed from the theory of Rayleigh,[2] the air mass m is computed from the observed elevation of the sun (m is unity for zenith position of the sun). If we assume a to have a given value, the only unknown quantities are β and F. The total selective absorption F has been expressed by Fowle through the linear equation

$$F = 0.10 + 0.0054 e_0 m, \qquad (3)$$

where e_0 is the water-vapor pressure (mm Hg) at the surface of the earth, and m is the air mass. It is evident from several considerations that Fowle's equation must include rather rough approximations. However, if we accept it as a first approach, it is evident that the quantity β, which is a measure of the dust content, may be determined from equation (2) and a single pyrheliometric observation. In practice this determination is made by a graphical evaluation of the integral for various values of e_0 and m—made once and for all. The value of β which makes the value of the integral equal to the measured value of the radiation increased by F is then obtained from a diagram or from tables. We may effect the computation most simply by plotting the observed radiation, increased by F, on the diagram shown in Fig. 1 and interpolating the value of β.

We can, however, derive a similar result more accurately if we add another pyrheliometric measurement to the one covering the total solar spectrum. By using a colored glass filter—RG 2 or OG 1 for instance—we can examine separately a part of the spectrum covering all wave lengths longer than a given limiting value. The filter RG 2, for instance, lets through all radiation of wave lengths longer than about 0.6 μ. With due regard to the nearly constant reflection $(1 - \gamma)$ by the filter (where γ is the fraction of incident radiation transmitted by the filter, that is, its transmission coefficient), we obtain for the observed filter radiation Q_r, in perfect analogy with equation (2),

$$Q_r = \gamma \int_{0.6}^\infty I_{0\lambda} \psi(m, \beta, \lambda)\, d\lambda - \gamma F, \qquad (4)$$

where

$$\psi = q^m \exp(-\beta m/\lambda^a).$$

The value of F may here be assumed with good approximation to be the same as in (2). Hence, from equations (2) and (4), we obtain

$$Q_m - \frac{1}{\gamma} Q_r = \int_0^\infty I_{0\lambda} \psi\, d\lambda - \int_{0.6}^\infty I_{0\lambda} \psi\, d\lambda, \qquad (5)$$

or

$$Q_m - \frac{1}{\gamma} Q_r = \int_0^{0.6} I_{0\lambda} \psi\, d\lambda. \qquad (6)$$

1. Given for instance in F. Linke, *Meteorologisches Taschenbuch*, IV, Table 109, p. 238 (Akad. Verlagsges.) Leipzig, 1931.

2. See F. Linke, *Meteorologisches Taschenbuch*, IV, Table 113, p. 240.

On the basis of this simple theory, the present author, and later Hoelper [6], Tryselius [11], and Olsson [8], among others, have computed values for β and the total selective absorption from simple pyrheliometric observations.

This method for treating actinometric observations has been discussed in some detail because considerations in the foregoing discussion are apt to provide an answer to the question which follows. Suppose we wish to use the simple actinometric measurements of Q_m and Q_r to obtain some idea of the scattering and absorbing properties of the atmosphere (such a purpose is certainly an important justification for actinometric measurements in general), what is the accuracy that we should demand? It is perfectly clear from the simple theory presented here that, in order to make progress and obtain conclusions of importance, we are forced to introduce some simplifications in our assumptions concerning the laws governing atmospheric scattering. Such a simplification has been made in assuming a simple exponential expression for the dependence of the scattering on wave length. This simplification represents a rather rough approximation, and because of this there is very little use in attempting to determine values of β and α with an accuracy greater than about 5–10 per cent. This corresponds to accuracies in the values for the solar radiation Q_m and Q_r of about 1–2 per cent. For determinations of the scattering and absorption in the atmosphere by simple actinometric methods, this appears to be the desirable accuracy.[3]

Actinometry with Regard to Biological Problems. The importance of solar radiation for a number of phenomena of biological character, such as plant growth and photosynthesis, and the health of man, has to a large extent led to the organization of actinometric measurements in connection with research concerning such phenomena.

What accuracy is here required from the actinometric instruments? In trying to answer this question, we must keep certain facts in mind. It is evident that, in general, the radiation which we are able to measure or record is very seldom the radiation that is effective in the biological processes under investigation. Neither the radiation on a horizontal surface, recorded for instance by a pyranometer, nor on a spherical surface, nor on a surface perpendicular to the solar beam as in pyrheliometers, is equal or strictly proportional to the radiation falling on a given plant or other organism. Furthermore, it is seldom of much use to try to construct a perfect model of a plant or organism since the effectiveness of the radiation is, in general, quite different at different parts of the plant's surface. In addition, a number of other factors, of which as a rule we have a rather incomplete knowledge, are generally effective in producing the observed results on, for instance, photosynthesis or growth. Therefore, if we ask for the equipment which ought to be recommended for meteorological stations when we have biological or agricultural needs in mind, it seems more important that the instruments should be characterized by a certain simplicity and stability and that their results should be easily comparable with those from other stations, than that the instruments should be given some elaborate form in a rather vain attempt to imitate what can hardly be reproduced. Instruments which measure or record the radiation from the sun and sky on a horizontal surface and on a surface perpendicular to the solar beam thus seem to be able to satisfy more general needs. An accuracy of 5 per cent seems sufficient, provided that the instruments are not subject to systematic errors or systematic changes.

INSTRUMENTS AND MEASUREMENTS

Determination of the Solar Constant for the Purpose of Ascertaining Its Variations. From what has been said above concerning the accuracy which must be demanded from the instruments for determining the solar constant, it must be concluded that none of the standard types of pyrheliometers in current use strictly satisfies these requirements. The two instruments which should be given first consideration are the compensation pyrheliometer of K. Ångström and the silver-disk pyrheliometer of the Smithsonian Institution (Abbot). Both have been subjected to rather elaborate investigation and critical examination by various scientists and lately, in a very systematic way, by the International Radiation Commission. On the initiative of this Commission, Courvoisier [5] at the Observatory of Davos has made a complete theoretical survey of the principles of their construction, supplemented to some extent by experimental studies.

With regard to the Ångström compensation pyrheliometer, in the form in which it has been delivered by its manufacturers in Uppsala (Rose, now discontinued) and Stockholm (A. Lindblad), the following can be said of earlier as well as of more recent researches.

As shown by the present author in 1914, the instrument is subject to a small error called the "edge effect" arising from certain features in its construction. The "edge effect" is caused by the fact that one of the strips which constitute the sensitive part of the instrument is heated electrically throughout its entire length, while the other strip is illuminated by the solar radiation only to about $^9/_{10}$ of its length on account of the screening of a diaphragm inside the instrument. The error which thus arises is of the order of 2 per cent. It is, however, to some extent dependent on the convection in the air over the heated strips. Taking into account the conditions occurring in practice, we must conclude, from theoretical considerations supported by actual measurements, that the error arising from the edge effect may vary between the limits 2 ± 0.5 per cent.

3. For a more detailed presentation of the methods for determining atmospheric turbidity on the basis of actinometric measurements along the lines indicated above, reference may now be made to a valuable treatise by Dr. Walter Schüepp, published after the present article was written: *Die Bestimmung der Komponenten der atmosphärischen Trübung aus Aktinometermessungen.* Inaugural Dissertation, Wien, Springer, 1949.

To obtain measurements for computing the solar constant Abbot has constructed a special Ångström pyrheliometer in which the edge effect is reduced to practically zero. However, a detailed survey of the factors influencing measurements with this type of instrument leads one to conclude that errors of the order of ±0.3 per cent can hardly be avoided completely.

The silver-disk pyrheliometer has been extensively used, especially in connection with Abbot's earlier work on the solar constant. Courvoisier has subjected it to a very thorough theoretical examination, with due regard to the physical constants of the instrument. Some minor corrections must be applied to Abbot's theory on which the method of measurement is founded. These corrections may affect the absolute values obtained. What interests us here especially are the variable errors arising from the variation of different physical and meteorological factors. Strictly speaking, Abbot's theory holds true only when the instrument is maintained at semiconstant temperature during the periodical temperature variation to which it is subjected when alternately exposed to and screened from solar radiation. This puts a rather high demand on the precautions to be taken during exposure.

Further effects arise from the unavoidable fluctuations of the temperature of the surrounding air, which in turn affect the temperature of the cylindrical wooden cover by which the silver disk is protected. Courvoisier concludes that errors up to 0.3 per cent are possible on that account. Mörikofer [7] estimates the average error from various causes to be about 0.5 to 1.0 per cent.

Among the instruments rather widely used, the Michelson actinometer is especially convenient, since it is rapidly read and does not require auxiliary instruments. Its accuracy is less than that of the Ångström or the silver-disk instruments, the average error probably amounting to ±1.0–1.5 per cent. The Michelson actinometer should be checked at regular intervals since it is sometimes subject to deterioration. As the accuracy of the instrument seems sufficient for general meteorological purposes, it would be highly desirable that instruments of a similar construction should be built in greater number and at moderate cost.

Small differences exist between the indications of all actinometers in practical use for measuring direct solar radiation. They arise from the fact that the instruments receive not only direct solar radiation but also diffuse radiation from the sky in the immediate neighborhood of the sun, within certain aperture angles which vary with the instrument. Thus the silver-disk pyrheliometer has an aperture of 6° (formerly 10.5°), while the Ångström compensation pyrheliometer has a rectangular aperture with plane angles of 24° and 6° (more recently 10° and 3°), respectively. The Ångström instrument consequently receives in general somewhat more scattered light, and the difference between the readings of the Ångström ($\mathring{A}$) and the silver-disk (S) instruments can be approximately expressed by

$$\mathring{A} - S = -\Delta + f(q, \beta, a, m), \qquad (7)$$

where Δ is the difference which is to be expected at the limit of the atmosphere where no diffuse radiation is added to the direct radiation, and $f(q, \beta, a, m)$ is a function of the quantities q, etc. (notation as given earlier). The function $f(q, \beta, a, m)$ is equal to zero when q equals unity and β vanishes. According to experience recently acquired, this function seems to vary, at stations near sea level, between about 0.01 cal cm^{-2} min^{-1} for low values of β to about 0.02 cal cm^{-2} min^{-1} for high values of β. The difference $S - \mathring{A}$ therefore seems to vary between about 1.5 and 4.0 per cent, where the upper and lower limits correspond to extreme conditions (Ångström—uncorrected for edge effect; silver-disk—Smithsonian scale, 1934).

With due regard to recent investigations, we may, chiefly according to Mörikofer [7], give the following survey on the status of absolute actinometry. Setting the indication of the Ångström pyrheliometer equal to 100 per cent, we have:

Instrument	*Per cent*
Ångström (uncorrected)	100.0
Ångström (corrected for edge effect)	101.3 ± 0.5
Smithsonian scale, 1913	103.5
Solar Radiation Commissions (preliminary results) 1936 (see [3])	101.0
Guild, Physical Laboratory, 1934	101.3
Abbot (Smithsonian scale, 1934)	101.2

Actinometric Equipment at Meteorological Stations. It would be futile to attempt actinometric measurements, even at selected meteorological stations, for the purpose of computing the solar constant, and still more so for determining its possible variations. The required elaborateness and quality of the actinometric equipment are such that measurements for this purpose must be reserved for observatories with very high standards, at locations carefully selected with regard to atmospheric conditions.

On the other hand, the chief problems which actinometric observations from a meteorological network might help to solve are those which we have briefly discussed in the first section of this article. Thus, the measurements should (1) furnish data for an evaluation of the heat exchange at the surface of the earth and enable us to treat, on this basis, the fundamental problem of the energy transport within the atmosphere; (2) provide the means for a general optical analysis of absorption and scattering in the atmosphere; and (3) furnish the basis for correlation studies of the relationship between the radiation processes at the earth's surface and a number of biological phenomena such as the growth of plants, crop conditions, the health of man, and the incidence and spread of certain diseases.

It is clear from what has been said above that the accuracy required of our actinometric equipment for these purposes is much less than that for the determination of the solar constant. The accuracy and ease of operation of our present instruments are undoubtedly satisfactory for these general purposes.

The details of the organization must be based on a realization of the main problems, on experience or knowledge, otherwise gained, concerning actinometric instruments and their qualities, and finally on some acquaintance with meteorological observations in gen-

eral and with what can reasonably be demanded from the observers. On the basis of such considerations the following general pattern for the actinometric stations within a meteorological network is recommended. The proposed organization is based partly on the author's own experience, but is, to a very large extent, the result of discussions with colleagues.

Central Actinometric Observatory (CAO). It seems desirable that at least one such observatory should be established within every large country. Among its main objectives would be scientific investigations of actinometric problems of a geophysical character, or those with geophysical applications. A plan for such investigations will not be discussed here, since it must be based chiefly on the personal initiative and scientific ideas of the observatory personnel. Among the problems deserving general attention are especially the distribution of ozone and its determination by actinometric methods and also special investigations of ultraviolet radiation. The former problem is at present being vigorously pursued by G. M. B. Dobson at Oxford, and it seems probable that in the near future his investigations will result in the construction of apparatus which can be generally accepted for ozone measurements. The work at the Bureau of Standards by W. Coblentz and later by R. Stair and his collaborators will probably lead to similar results with respect to the measurement of ultraviolet radiation.

First we shall discuss the relation which should exist between the activities of the central actinometric observatory and the actinometric stations of the meteorological network, as they will be described below. The CAO must form a center for *calibration*, *standardization*, and *checking* of secondary instruments, and for this purpose such a central observatory should be equipped with absolute instruments. The actinometer perhaps most widely used for measuring direct solar radiation, the Michelson actinometer, is a secondary instrument and, because of a certain delicacy in its construction, it seems desirable that it be compared at regular intervals with an absolute instrument or at least with other instruments of greater stability. The silver-disk pyrheliometer of the Smithsonian Institution is also a secondary instrument. Its construction is much less delicate than that of the Michelson actinometer, and in several instances the instrument has retained its calibration unchanged during rather long periods. However, as a precaution against error, if the instrument is to be used daily, it should be compared from time to time with an absolute instrument or a secondary standard, preferably at least once a year.

The Ångström compensation pyrheliometer is strictly an absolute instrument. Its "constant," which is applied to the direct reading in order to yield the corresponding radiation values, can be determined through simple physical measurements of resistance, dimensions, etc., on the instrument. But in practice such measurements are very seldom made, and they can hardly be carried out without rather elaborate physical equipment. Therefore, the instrument is actually used at most stations simply as a secondary instrument relying upon the correctness of a standardization carried out prior to delivery of the instrument. It is clear, especially since the construction is rather delicate, that reliance on a single calibration involves the serious risks of collecting observational data of greatly reduced value. For this reason, a standardization, either through comparison with a central standard or through a physical determination of the constants of the compensation pyrheliometer, should be carried out at regular intervals. A central actinometric observatory would be the proper place for that purpose.

Second Order Actinometric Stations. Provided that absolute standardizations are carried out at a central observatory, second order stations do not need to be provided with absolute instruments. On the other hand, it seems advisable that they be furnished with double sets of actinometers for measuring direct solar radiation, in order that one instrument can, to some extent, serve as a check on the other. The following measurements are proposed.

1. Measurements of the direct total solar radiation at least three times a day when the sky is clear.

Instruments: Smithsonian silver-disk pyrheliometer, Ångström compensation pyrheliometer, or an instrument of the Michelson type. These are the instruments which have been most carefully examined with respect to various errors. However, other instruments may also be used, provided they are carefully standardized.

2. Measurements of direct solar radiation within special regions of the spectrum with the aid of colored glass filters of the type RG 2 or OG 1, through which the infrared radiation may be separated from the visible and ultraviolet (at least three times a day with a clear sky).

Instruments: Same as under 1.

3. Continuous measurements of the total incoming radiation from the sun and sky.

Instruments: Moll-Gorczynski actinograph with recording galvanometer, Kimball-Eppley actinograph, Ångström pyranometer with photographic recorder, Robitzsch actinograph, or instruments of similar construction.

Screening these instruments from direct solar radiation and comparing the reduction of their reading with the direct solar radiation, measured simultaneously, provides a check on these recording instruments. With this method, the first three instruments mentioned above will easily yield results accurate to about ± 5 per cent for individual days and ± 3 per cent for longer periods.

With regard to the Robitzsch actinograph, the construction of which is similar to a common thermograph with bimetallic elements, the following remarks may be made. The instrumental "constant" (the factor by which the deflection on the recording drum must be multiplied in order to give radiation values) is highly dependent on temperature. A temperature rise of one centigrade degree generally corresponds to an increase in the constant of about 1 per cent. Furthermore, the sensitivity is to some extent dependent on the elevation of the sun as well as on the orientation of the instrument

relative to the sun. Most important in the use of the instrument is a careful examination of its dependence on temperature. Under all circumstances, rather frequent comparisons with actinometers for solar radiation measurements must be made. It is difficult to avoid errors of less than about ±10 per cent for individual days and less than ±5 per cent in monthly means.

4. Measurements of the outgoing "effective" radiation.

Instruments: Ångström pyrgeometer with electrical compensation. Some of the errors inherent in this instrument are the same as for the compensation pyrheliometer. A variable edge effect introduces errors up to about ±3 per cent in single measurements. No recording device of suitable design can yet be recommended for general use. Some theoretical investigations by Prohaska and Wierzejewski [9] on the Bellani instrument for measuring incoming radiation seem to support the view that the Ångström "tulipan" instrument founded on a similar principle, that is, overdistillation of ether under the influence of outgoing heat radiation, may adequately serve its purpose of performing time integration of "effective" radiation. The necessary precautions seem, however, to be too numerous to allow a more general use.

5. Records of hours of sunshine. It is recommended that the duration of sunshine be recorded at all stations where the total radiation from sun and sky is recorded. Special studies of the relationship between the duration of sunshine and the incoming radiation at various stations will then provide a possibility of computing the incoming radiation from the hours of sunshine Q_s according to some formula, for instance, $Q_s = Q_0[\alpha + (1 - \alpha)S]$, where the constants Q_0 and α must be determined. Such studies may give us a means of interpolating radiation values for localities between actinometric stations from the number of hours of sunshine recorded at a much larger number of places.

Instruments: Most widely used are the sunshine recorders of Campbell-Stokes and the recording black-bulb thermometer used by the United States Weather Bureau. It should be emphasized that these instruments can under no circumstances be considered as instruments of precision. It is more important to correlate the data from the various types of sunshine recorders with the radiation balance than to attempt to standardize or correct the instruments so that a precise measurement of the loosely defined "hours of sunshine" may be obtained. With this guiding principle in mind, one may allow rather wide variations in the type of instrument.

Third Order Actinometric Stations. These stations should be equipped with sunshine recorders as well as with simple recording instruments such as the Moll-Gorczynski, Kimball-Eppley, or the Robitzsch type. The pyranometers should, however, be checked at regular intervals by comparison with secondary standard actinometers, either brought to the stations during inspection or kept at the station for use on special occasions. The frequency of these check measurements must, to some extent, be chosen on the basis of experience concerning the constancy of the recording device, which probably depends on the climate.

Regular Meteorological Stations Equipped with Sunshine Recorders. In general, it seems advisable that all actinometric stations of the second and third orders should also be meteorological stations of at least the second order. This will facilitate studies of the relation between radiation and other meteorological elements.

A rather wide network of stations recording simply sunshine duration is desirable so that they may act as interpolation stations with respect to the radiation balance. However, it is also recommended that other meteorological observations be made at such stations, at least observations of cloudiness, temperature, and precipitation.

CONCLUSIONS

Critique of Routine Actinometric Measurements as Hitherto Organized. It is generally realized that actinometric measurements are still in a state in which an organization according to systematic and generally accepted rules is lacking. The observations are, as a rule, limited to certain single observatories, and there is, in general, no possibility for a synoptic treatment of the results. Only very seldom are the observations made in a manner which permits separation of scattering and absorption in the atmosphere.

The recording devices, such as the Moll-Gorczynski instrument or the Robitzsch instrument, when used at field stations, are in many cases too infrequently checked, a fact which especially for the latter instrument is rather fatal, since its indications are highly dependent on the manner of exposure, and its constant is highly variable with temperature. Many observational data of no value have been collected in this way.

Measurements of the effective radiation, important as they may seem, are almost totally lacking, with the exception of the results from only a few observatories. Regular checks of the instruments in use are seldom made.

It is my opinion that our knowledge and experience of the instruments available are such, after the work on the subject particularly by the Smithsonian Institution and the International Radiation Commission in close collaboration with the Observatory of Davos, that the time is ripe for a systematic organization of an international actinometric station network within the meteorological organization. The technical and instrumental problems which still need to be solved and the improvements to be expected need not delay an organization which now seems highly desirable.

Special Problems. We have already briefly indicated the problems which such an actinometric network would primarily help to solve. They include the important problem concerning the energy exchange within the earth's atmosphere and the factors influencing it. If we consider a given vertical column extending from the

earth's surface to the upper limit of the atmosphere, the temperature of the air within this column is determined primarily by the incoming and outgoing radiation, by the transfer of energy through horizontal advection, and, to some extent, by evaporation and condensation processes. If we take a column of a sufficiently large cross section and consider a sufficiently long time interval, our problem of analyzing the factors influencing the temperature coincides with the problem of finding the causes for climatological temperature changes in general. Here, incoming and outgoing radiation are the most fundamental elements. Without a thorough knowledge of these factors, their distribution and variations, all speculations on climatic variations are reduced to rather vague guesses.

Another equally important problem, closely connected with the climatic variations, concerns the transmission of the atmosphere and its fluctuations. A clear

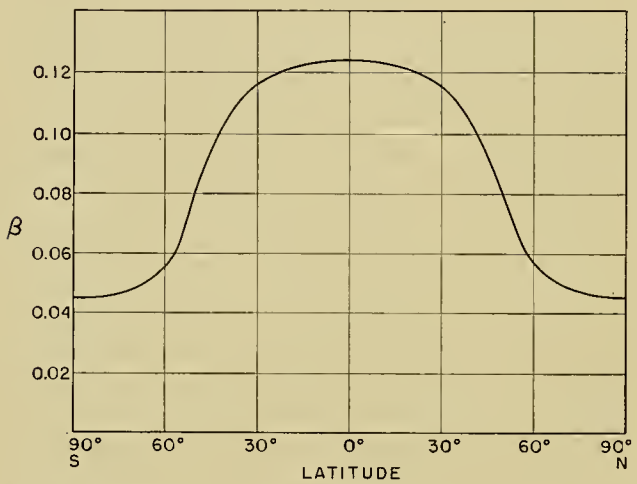

Fig. 2.—Preliminary curve showing variation of scattering coefficient β with latitude.

separation between scattering and absorption is necessary. The simplest way of accomplishing this is indicated above. If we take the coefficient β as a measure of the scattering of the atmosphere, the following remarks may be made. A rather summary treatment of available pyrheliometric data already shows that β is on the whole much larger in tropical and subtropical regions than at higher latitudes. The graphical representation in Fig. 2, taken from a previous paper by the author [2], shows this, but it may be taken only as a very rough indication of the general conditions. More extensive observational data, systematically treated, must be available before the distribution of β over the whole globe can be mapped. Intensive investigations may here solve the problem concerning the dust-producing centers at the earth's surface, the nature of the scattering particles, and their origin under various conditions. Investigations near desert regions seem to show that the scattering particles directly produced by storms over the desert are much larger than those which generally occur in the atmosphere. At all Northern Hemisphere stations investigated for an annual variation of β, the scattering coefficient reaches a pronounced maximum in the spring (April or May). The values of β obtained at Spitsbergen by Olsson [8] and at Abisko (northern Lapland) by Tryselius [11] are so low that the scattering there must be almost totally due to the molecules. Therefore, if we consider only the effect of scattering, the ultraviolet radiation at, for instance, 30° solar elevation in Lapland, must be almost as intense as at about 2000-m height in Switzerland for the same solar elevation. Only a few of the problems related to a more detailed synoptic investigation of scattering in the atmosphere have been indicated here.

The outgoing "effective radiation" should be the object of a closer investigation especially with respect to its distribution over the earth's surface. In general, it seems to be very closely related to two factors: (1) the temperature at the place of observation and the temperature distribution in the atmosphere, and (2) the content of water vapor in the atmosphere. This relationship is so close that it is doubtful whether there are any other factors whose effects do not fall within the errors of observation. On the other hand, there are some indications of a variation during the night, which might not be explained by a variation of the previously mentioned elements. Here is an important field of research from which perhaps some factor influencing the climatic variations may be discovered.

Finally, for the important studies of the relation between biological phenomena and radiation, an actinometric network has an essential task to fulfill. In all these studies in which special portions of the spectrum must be considered effective, a clear separation between scattering and absorption is necessary. When we know the scattering coefficient and its variations, we will be able to give a much more detailed picture of the variations in the different spectral regions of the sun's radiation. Such a detailed knowledge is probably necessary before the relation between biological phenomena and solar radiation can be investigated with success.

GENERAL METEOROLOGICAL OPTICS

By HANS NEUBERGER

The Pennsylvania State College

The phenomena of meteorological optics are not as generally well known as those of other branches of meteorology. For this reason, the subsequent sections are introduced with a brief description of the major phenomena and a summary of known facts. For abnormal variations the reader is referred to the multitude of meteorological, astronomical, and general science periodicals. Visible sound waves in the sky, frequently observed during World War II,[1] could not be considered here.

In order to keep the number of references within space limits, authors whose contributions have been discussed in standard works are, where possible without ambiguity, cited from these works; this is indicated by a "c" preceding the respective reference number.

SUBJECTIVE PHENOMENA IN THE ATMOSPHERE

The Apparent Shape of the Sky. When scanning the daytime sky, an observer perceives a more or less flattened vault. For some observers, this impression persists even at night, although the multitude of stars in their different magnitudes tends to convey the idea of a rather undefinable space. The variety of impressions is the result of a complex psychometric coordination of the visual and the physical space. This coordination is not a simple transformation of a geometric reality such as obtains for an overcast sky, because, in the case of the clear daytime sky, we look into an indefinite depth of the luminous atmosphere. Indeed, if we fix our sight in any elevated direction, we fail to perceive a "surface" on which our eyes may rest. However, if we let our eyes wander between zenith and horizon, the impression of such a surface is inescapable. The problem of the sky shape, although some of its aspects lie within the realm of psychophysics, is of meteorological interest because of its bearing on the practice of estimating cloudiness.

Smith [c. 42] introduced a method by which a numerical value can be assigned to the apparent flatness of the sky, by measuring the elevation angle α (Fig. 1) of the estimated position of point M that bisects the imaginary arc ZH from zenith to horizon. The *half-arc angle* α is then a measure of the flatness of the sky, becoming smaller as the sky appears flatter. Another method for expressing the sky flatness numerically is the estimation of the ratio of the apparent distances OH/OZ, which increases with increasing flatness of the sky. The estimation of this ratio is a more difficult task than bisecting the arc ZH and is a much coarser measure. Assuming, for example, a circular sky profile, we can compute corresponding values of OH/OZ and α [c. 42]; $OH/OZ = 1, 2, 3, 4$, corresponds to $\alpha = 45°, 33°, 25°, 20°$, respectively. Since most observations fall in the range $20° < \alpha < 40°$ and are reproducible within 1°, while OH/OZ can be estimated, at best, only in whole numbers, OH/OZ is obviously an inadequate measure.

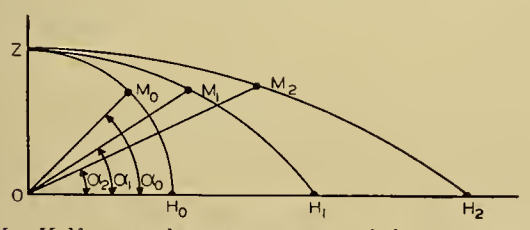

Fig. 1.—Half-arc angle α as a measure of the apparent shape of the sky.

Various authors have deduced the curvature of the sky profile as circular, elliptic, parabolic, hyperbolic, or helmet-shaped [8, 9, 22, 23, c. 42]. The angle at which the sky appears to meet the horizon plane is one criterion of the geometric form. This angle would be 90° only in the cases of elliptic and parabolic shapes, but more or less acute in all others. A parabolic profile would also be distinguished by the pointed appearance of the zenith sky. Another criterion is derived from comparison of observed overestimation of elevation angles of objects with those computed under the assumption of various sky shapes [42]. Variations of a psychological nature among different observers and physical variations of sky conditions undoubtedly preclude the assumption of any unique sky shape. For the discussion of observational results, consideration of the half-arc angle α may suffice.

Table I shows the effect of general sky brightness and cloudiness on the depression of the sky as seen by various observers. Although the large differences among observers reflect the strong subjectivity of the phenomenon, the same trend appears in the effect of the various sky conditions. The cloudy daytime sky looks flattest, the moonless night sky most arched. Some of the individual differences may be due to effects of locality, since the observations cited were made at different places and altitudes.

Table I. Average Half-Arc Angles for Various Sky Conditions

Observer	Daytime		Twilight clear	Clear night	
	cloudy	clear		moonlit	moonless
Dember and Uibe [8]	29.0°	32.0°	32.2°	36.7°	40.1°
Miller [37]	29.9	34.0	—	—	—
Reimann [c. 42]	21.0	22.5	—	26.6	30.0
Mendelssohn and Dember [33]	—	31.9	—	36.6	—

1. For example, see W. E. K. Middleton, *J. R. astr. Soc. Can.*, 38: 432 (1944).

The effect of the amount of cloudiness is demonstrated in Table II by the most recent observations [37]. In qualitative agreement with observations by Reimann [c. 42], these data show that even a few clouds in the sky materially increase its apparent flatness, whereas with sky covers of $> \frac{5}{10}$, the observer refers chiefly

Table II. Average Half-Arc Angle for Various Steps of Cloudiness

Clouds *tenths*	0	<1	1–3	4–7	8–9	>9
α (°)	34.0	32.6	31.5	30.6	30.2	29.9

to the cloud layer in forming his impression of the sky shape. Therefore, for cloudiness $> \frac{4}{10}$, the increase in flatness becomes practically negligible.

Miller [37, 38] seems to be the only observer to investigate the effect of cloud types (and ceiling height) on the apparent sky shape. Table III shows his results for various cloud types arranged in order of increasing average cloudiness for these types. The groups *Ac* and *As*,[2] and *Sc* make the sky appear flatter than would result from the implicit cloudiness effect. This has been attributed to the structure of the underside of *Ac* and *Sc*, which facilitates depth perception and makes the observer aware of the extension of these cloud layers beyond the terrestrial horizon. This apparent increase of the horizontal extent of the cloud layers causes a decrease in α.

Table III. Relationship between Cloud Type and Half-Arc Angle

Cloud type	Average cloudiness, *tenths*	Average α(°)
Cu, *Fc*	4	30.0
Ci, *Cs*	5	29.1
Ac, *As*	7	27.8
Sc	8	28.4
St	10	29.0

From Table III it is also obvious that the cloud height does not influence the apparent flatness of the sky, in the manner which might be expected from

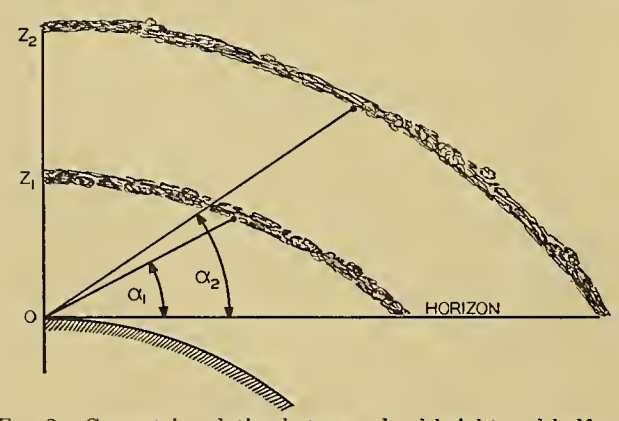

Fig. 2.—Geometric relation between cloud height and half-arc angle.

purely geometric considerations (Fig. 2). The *Ac*- and *As*-group, for example, is associated with a smaller α than is the *St*-group, whereas the reverse should be true according to Fig. 2 if the visual space were a simple transformation of the physical space. A comparison between Table III and the last three columns of Table II shows that the type of clouds has a greater effect than the amount of clouds.

In contrast to Dember and Uibe [9], Miller [37] found that the visual range has only a minor influence on the apparent shape of the sky, whereas the effect of the distance to the terrestrial horizon is very strong, as shown in Table IV. The differences in α between various

Table IV. Average Effects of Visual Range (V) and Horizon Distance (D) on the Half-Arc Angle (α)

V (km)	$D = 0.4$ km α(°)	$D = 12$ km α(°)
<6	33.3	30.7
6–10	32.1	28.8
>10	32.6	28.9
Mean	32.6	29.2

groups of visual range are considerably smaller than between different horizon distances. This result was confirmed by measurements of α at various distances from a mountain range [38]. In addition to the actual distance of the horizon, the facilities for subconscious estimation of this distance, such as is offered by suitable foreground configuration, have also proven of strong influence on the perceived sky shape [23, 37, 38]. For this reason, the sky dome cannot generally be considered a rotational geometric figure.

Related Phenomena. Closely related to the shape of the sky is the well-known enlargement of sun or moon when near the horizon [23, 42]. As can be seen from the shaded angles in Fig. 3, the same angular subtense intersects a greater portion of the flattened sky near the

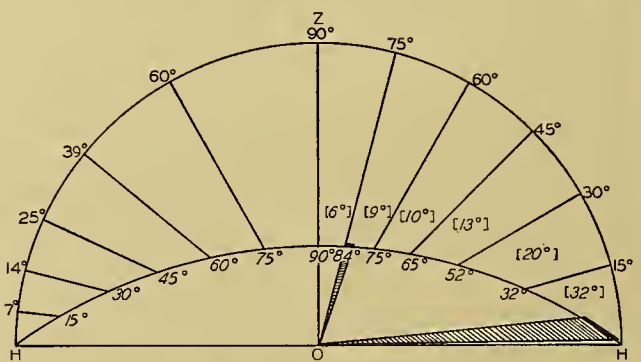

Fig. 3.—Relationship between true and apparent (slanted numbers) elevation angles and angles of subtense (bracketed numbers).

horizon than at higher elevations, and this portion becomes greater as the sky becomes flatter. The same holds true for the angular distance between stars. Jeffreys [25] raised an objection to this projection theory on the grounds that the sun or moon should appear elliptical with a long vertical axis, because only this axis would be distorted by the shape of the sky. However, the angular subtense is too small to permit detection of such a deformation; moreover, this effect is probably compensated by an opposite effect of the

2. *Ac* and *As* occurred simultaneously in almost all cases.

physical distortion owing to astronomical refraction. The size variation can also be explained by the general overestimation of angular elevations of terrestrial and celestial objects. On the left side of Fig. 3 the flat arc of the sky is divided into six equal segments corresponding to 15°-intervals of estimated elevations (slant numbers). The true elevations show by comparison that the relative overestimation is > 100 per cent for small elevation angles and decreases to zero at 90°. The absolute overestimation reaches a maximum at true elevations between 30° and 40° [23, 42]. The right side of Fig. 3, showing true 15°-intervals and their estimated equivalents (in brackets), indicates that a given angular subtense is overestimated when below roughly 30° elevation, underestimated when above 30°. Accordingly, the ½° - subtense of sun or moon appears larger near the horizon, smaller at higher elevations.

The overestimated height and steepness of mountains [22, 42] and the apparent ellipticity of circular halos [23, 34] are also related to this phenomenon, as is the incorrect estimation of the amount of clouds. The latter is of practical significance, because an observer tends to underestimate the amount of clouds overhead and to overestimate the amount of clouds near the horizon. This fact is qualitatively known, and in the observer's manual, measurements of angular elevations of clouds are suggested to eliminate this error for advancing or receding cloud layers and those surrounding the station. However, no such expedient is available for estimations of the more frequent nonuniform states of sky. This problem can be summarized as follows: The estimates of cloud covers of 0 and 10 tenths are usually correct. For all other cloud amounts, the error made by the observer is a function of subjective factors (experience, etc.), of the amount and type of the clouds, the distance of the terrestrial horizon, and the general brightness level (Tables I–IV).

Theories and Problems. All attempts to formulate an all-inclusive theory of the apparent shape of the sky have thus far been unsuccessful, chiefly because of the simultaneous involvement of physical and psychophysiological factors. Although physical and geometrical variables modify our impression of the sky shape, they do not suffice, in themselves, to explain the observed facts. The simple consideration of the geometric properties of a cloud layer at 2000 m, for example, would result in an $\alpha = 1°$, whereas α is actually observed between 20° and 30°, that is, the sky does not appear as flat as it should. A similar discrepancy arises for the clear sky [38]. From a physical standpoint, Dember and Uibe [9] attribute the sky shape to the distribution of sky brightness. They assume that the maximum distance from which scattered light reaches the observer is proportional to the square root of brightness. However, their theory not only implies that the brighter objects appear to be farther away, which is not true [42] (*e.g.*, brighter stars appear nearer), but also precludes any variations of the sky shape with the distance of the terrestrial horizon. Similarly, Humphreys [21] believes that the greater haziness near the horizon produces the impression of greater distance than is the case at more elevated regions of the sky. While this effect is undoubtedly present, its magnitude has been shown in Table IV to be of secondary order only. Purely psychophysiological explanations are similarly unsatisfactory. Gauss and others [c. 42] were of the opinion that, because our line of sight is habitually horizontal and normal to the body axis, the illusion of a variable moon size should disappear when the direction of sight is changed by mirrors or the body orientation altered. Not all results of pertinent experiments supported this theory. Also, the effects of physical variables would remain unexplained. Various attempts at a combination of geometric and psychophysical explanations have also been made. For example, v. Sterneck based his transformation of physical into visual space on the underestimation of distances according to a hyperbolic function, while Witte assumed that a straight line in physical space also appears rectilinear in visual space [c. 42]. According to Exner [42], the moon's visible area is compared to that of the fovea when the moon is high, but at low moon the respective linear dimensions are compared because of the attention commanded by the horizon line. This hypothesis, however, is incapable of explaining the sky shape or the variations in the moon's apparent size caused by external physical factors. Isimaru [23] combined, in his theory of the shape of the cloudy sky, the underestimation of distances with the overestimation of elevation angles. The same idea was followed by Hüttenhain [22] who reverted to v. Sterneck's theory. Both authors [22, 23] make the implicit assumption that the overestimation of angular elevations is independent of the sky shape, because it can also be observed in rooms [22]. However, since both phenomena are due to the properties of our visual space, they cannot be independent.

Fundamentally, all of the theoretical approaches to the general problem have hitherto been based on the assumption that the visual space is Euclidean and can be obtained by some unique transformation of the three-dimensional manifold of the physical space. However, Luneburg [30] has recently shown that the sensations produced by binocular vision represent a Riemannian manifold. From the analysis of certain optical illusions he concluded that the geometry of our visual space is the hyperbolic geometry of Lobachevski as had already been indicated by Škreb [49]. With this theory a differential equation for the apparent size of a line element in the horizontal plane was developed, which is, however, not immediately applicable to the problem of the apparent shape of the sky; at any rate, an extension of this theory to include this group of phenomena appears desirable. The major physical factors whose effects must be explained by such a theory may be tabulated as follows:

1. General brightness of the visual field and brightness distribution over the sky.
2. Cloud types and amounts.
3. Distance of terrestrial horizon, and facilities for estimating this distance.

In addition, there are several phases of the problem that have been insufficiently explored or are entirely

unknown as yet. For example, the practical problem of the mutual influence of sky shape and cloudiness estimation needs further exploration. Simultaneous photographic records of the sky, estimation of cloudiness, and determination of the shape of the sky (under all possible states of sky) may furnish an individual correction factor for adjustment of cloudiness estimates. In particular, the quality of cloudiness estimations for individual cloud layers in the presence of other cloud decks needs special attention, as does the effect of the configuration of the terrestrial horizon on such estimations. More observations are also needed on the following effects: possible seasonal variations; the terrestrial horizon distance in conjunction with the configuration of the visual field between horizon and observer; the measured brightness level and brightness distribution over the sky.

Wholly unexplored is the possible effect of an observer's altitude above the earth's surface on his impression of the sky shape and consequently the accuracy of his cloudiness estimation; this phase is especially of interest for meteorological observers on mountains or in airplanes. In this connection, the apparent shapes of the terrestrial surface and of cloud layers, as seen from above, deserve attention, because the quality of estimations of cloudiness below an aerial observer hinges on this problem.

REFRACTION PHENOMENA IN THE CLOUD-FREE ATMOSPHERE

In the subsequent discussions reference is made only to the visible portion of the electromagnetic spectrum, although analogous phenomena occur with other wave lengths. The refractive index n_λ of air for various wave lengths and its dependence on the air density is well known from laboratory determinations [31, 42]. An example of the magnitude of the dispersion and temperature effect on the refractive index in air at normal pressure (760 mm *Hg*) is given in Table V. Obviously,

Table V. Variation of $(n_\lambda - 1)10^6$ with Wave Length and Temperature
(*After Meggers and Peters* [31])

λ(A)	0C	15C	30C
3983	297	282	268
5569	293	278	263
7664	290	275	261

the effect of dispersion is small in comparison with that of temperature. The refractive indices of the various gaseous constituents of air differ even more significantly from each other, but since the composition of air varies only slightly, this effect is negligible for all practical purposes.

Phenomena due to Average Density Gradient. When penetrating the atmosphere, which is assumed to consist of concentric, equidistant isopycnic surfaces, an extraterrestrial light ray describes a curve whose well-known equation is

$$nr \sin i = k = \text{const}, \qquad (1)$$

where r is the distance of an isopycnic surface from the earth's center, i the angle of incidence, and the refractive index n (for white light) is a function of r, $n(r)$. In Fig. 4, $r_o = CO$ is the earth's radius; an observer at O sees a light ray L, that enters the atmosphere at P with the angle of incidence i, at the apparent zenith distance θ_o instead of the true zenith distance θ. The difference $\theta - \theta_o = R$, the *astronomical refraction*. In its general form, the equation of the ray curve PO in polar coordinates is

$$\varphi = \int_{r_o}^{r} \left(\frac{n^2 r^2}{k^2} - 1 \right)^{-\frac{1}{2}} \frac{dr}{r}, \qquad (2)$$

or expressed in terms of astronomical refraction:

$$R = \int_{n_H}^{n} \frac{n_o r_o \sin \theta_o}{n \sqrt{n^2 r^2 - n_o^2 r_o^2 \sin^2 \theta_o}} \, dn. \qquad (3)$$

The integrals, to be taken between the upper limit of the atmosphere (where $n = n_H$) and the earth's surface

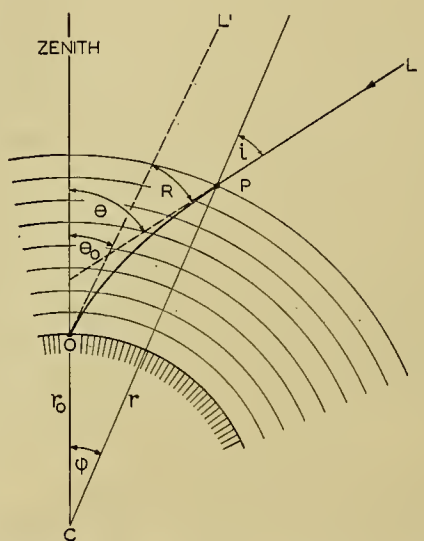

Fig. 4.—Schematic diagram of astronomical refraction.

(index o), have no general solutions, because the change of n with altitude must first be known.

Various authors made different assumptions regarding the function $n(r)$ and computed the astronomical refraction for various apparent zenith distances. Wünschmann [59], who compared several of the results, prefers Gylden's refraction data, because they are based on a hypothesis which agrees closely with data obtained from aerological ascents. Recently Link and Sekera [28] computed tables of various characteristics of the ray path for zenith distances from 75° to 90° and altitudes up to 60 km. They considered the vertical density distribution separately for summer and winter, using average density conditions as revealed by balloon soundings, sound propagation, and twilight phenomena. Correction tables for the effect of deviations from normal in local conditions of pressure, temperature, and humidity have also been variously computed [31, 42]. These corrections are important chiefly for apparent zenith distances up to 70°, for which the values of R

are sensibly independent of the assumption regarding the vertical density distribution and the concentricity of isopycnic surfaces [28, 42, 59]. Court[3] pointed out the inadequacy of these correction tables particularly for cold climates; he suggests the use, instead of air temperature, of "refractive temperature," *i.e.*, that temperature for which the correction obtained from tables is the one actually required, and he presents rules for estimating these refractive temperatures.

For zenith distances > 70°, Esclangon [12] attributes the greatest optical effect to the layer up to about 15 km, whereas according to Wünschmann [59] the mass distribution in the stratosphere between 15 and 45 km height and the orientation of the isopycnic surfaces in this layer play a dominant role. More frequent and systematic soundings of the upper atmosphere with modern equipment would enable us to solve this problem and to obtain more direct values of stratospheric density variatio ıs.

Wünschmann, by means of upper-air soundings, constructed charts showing the topography of the optical surfaces. He found that the influence of density variations in the lower troposphere up to 6.5 km is generally compensated by an opposite influence in the upper tropospheric region between 6.5 and 15 km, leaving an insignificant net effect of the troposphere. The inclinations of isopycnic surfaces owing to local horizontal temperature gradients, fronts, or orographic features, generally change the astronomical refraction by only a fraction of a second of arc.

The large astronomical refraction for zenith distances of 90° or more generally lengthens the day, since it causes the sun to rise somewhat earlier and set somewhat later than is computed from purely geometrical considerations. This is of practical importance for the prediction of illumination conditions in polar regions, where the strong density gradient, built up in the lower atmosphere during the winter night, may advance the date of sunrise by several days [42]. The great decrease in normal refraction with slight elevation above the horizon causes a deformation of the sun's or moon's disk; for the difference in refraction between the lower limb, touching the horizon, and the upper limb amounts to 6′, so that the vertical axis of the disk appears shorter by 1/5. The large refraction is connected with a relatively large prismatic dispersion which is of the order of 20 to 40 seconds of arc between blue and red wave lengths [19, 42]. This dispersion occasionally causes the last segment of the setting sun or planets [54] to appear green for a few seconds, the so-called *green flash* [21] or *green segment* [19]. Sometimes the color is blue or it changes continuously from yellow to violet. This phenomenon can occur only when the atmosphere is so clear that the shorter wave lengths are not attenuated. Whereas Hulburt [19] believes that normal dispersion is sufficient to cause this phenomenon, most observations seem to be associated with refractions in excess of the normal [35, 54]. To what extent selective absorption by water vapor [42] or other gases contributes to this phenomenon is still undecided.

The curvature of the rays from artificial lights is due to *terrestrial refraction*. In Fig. 5, an observer at A sees a point B in the direction of incidence AC of the curved light ray; the angle α between the straight line AB and the tangent AC is the terrestrial refraction. Similar conditions obtain for an observer at B sighting point A; in this case the terrestrial refraction is measured by angle β. The sum $\alpha + \beta = \epsilon$ is called the total refraction. For an average density gradient the terrestrial refraction increases roughly from 2″ to 42″ when the distance between the two points increases from 1 to 20 km [42]. The curve of the light ray can, in most cases, be assumed as a circular arc, so that $\alpha = \beta = \epsilon/2$. The path of the light ray is then determined by its radius of curvature r_L. In Fig. 5 the angular distance between points A and B is φ at the earth's center, and ϵ is the central angle of the arc AB. Since the heights of A and B above the earth's surface are small as compared to the

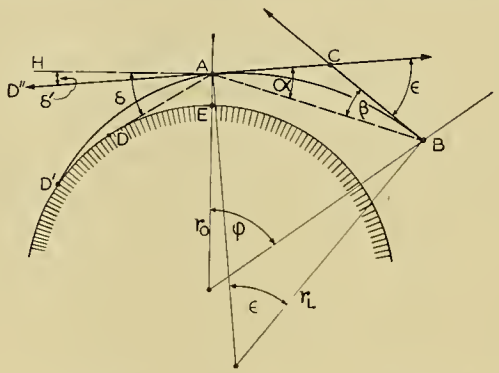

Fig. 5.—Schematic diagram of terrestrial refraction.

earth's radius r_o, and the angles ϵ and φ are small, the ratio

$$\frac{\epsilon}{\varphi} = \frac{r_o}{r_L} \qquad \text{or} \qquad \frac{\epsilon}{2} = \frac{\varphi r_o}{2r_L}. \tag{4}$$

As φ and r_o are known, the terrestrial refraction can be computed from the radius of curvature of the light ray. Its reciprocal, the curvature of the ray, is (according to Wegener [56]) determined by

$$\frac{1}{r_L} = (n_\lambda - 1)\,\frac{p}{T_v^2}\,\frac{273}{760}\,(\gamma' - \gamma), \tag{5}$$

where n_λ is the refractive index, p the barometric pressure in mm Hg, T_v the virtual temperature in °K, γ the temperature lapse rate (counted as negative in case of inversions), and γ' the autoconvective lapse rate. The curvature of the light ray is proportional to the barometric pressure and inversely proportional to the square of the virtual temperature, showing the dominating influence of temperature on refraction. The curvature decreases as the lapse rate increases, and the light ray becomes rectilinear for a homogeneous atmosphere ($\gamma = \gamma'$). For large lapse rates, however, the convective activity causes scintillation. For strong inversions ($\gamma << 0$) the curvature of the light rays approaches

3. See A. Court, "Refractive Temperature," *J. Franklin Inst.*, 247: 583–595 (1949).

that of the earth's surface, which ordinarily is several times larger, and total reflection (mirages) may occur.

The expansion of the horizon and the decrease of its angular depression is a usual consequence of terrestrial refraction. In Fig. 5, an observer at A whose horizontal plane is AH would, in case of rectilinear light rays, see the horizon at D, where his line of sight is tangent to the earth's surface and the geodetic depression is δ. Because of terrestrial refraction he normally sees the horizon at D' in the direction AD'' (tangent to the curved ray AD'), that is, at the depression δ'. The difference $\delta - \delta'$ represents the terrestrial refraction, and equations (4) and (5) apply to this case also. However, δ is generally determined by direct observation rather than computed from meteorological data and the known geometric quantities, because temperature and lapse rate in the air layer below the observer vary with the nature and contour of the underlying surface. The effects of these variables for air layers not in immediate contact with the ground were investigated by Brocks [2, 3, 4] who found that the terrestrial refraction can be quite accurately computed from meteorological data and that, in turn, the average lapse rate can be determined from the observed curvature of light rays. For a ray-path length of 30 km, a change in zenith distance of 1″ corresponds to a lapse-rate change of 0.04C/100 m. By means of mutual sighting from both ends of a ray path the absolute values of the lapse rate can be determined. However, this method is of limited practical value, because for steep lapse rates, with their attendant convection currents, the image fluctuations of the light beam would considerably decrease the accuracy of measurement.

Phenomena Due to Special Density Gradients. When the decrease in density upwards is greater than normal, a condition which may be caused by smaller than normal lapse rates, terrestrial refraction is increased and objects that are usually beyond the horizon come into view. This excessive extension of the normal horizon is called *looming*. The opposite phenomenon of *sinking* is due to an abnormally small vertical density gradient. As can be seen from application of equation (5) to the average conditions between observer and horizon point, the curvature $1/r_L$ of the light ray (AD' in Fig. 5) becomes smaller with increase in lapse rate γ; for $\gamma = \gamma'$, the curvature becomes zero and the observer sees horizon at D; for $\gamma > \gamma'$, his horizon would further shrink and end at a point between D and E, while the curvature becomes negative (ray convex toward surface). In this case it is not necessary that $\gamma > \gamma'$ over the whole range, although this often occurs over strongly heated surfaces; it is sufficient that the isopycnic surfaces be inclined upwards toward the observer, so that the air density is greater there than at the distant point on the horizon [42]. The great increases in, or the reversals of, the normal vertical density gradients are generally confined to the air layers near the ground.

When the light rays from the upper portion of a distant object LU in Fig. 6 (A) have a different curvature than those from the lower portion, the geometric angle s, that the object subtends at the observer O, appears changed. Exner [42] has shown that a linear change in refractive index n with height cannot lead to a noticeable change in the angle of subtense. When the decrease of n with height is slower than it would be according to a linear function as shown by case (A), the curvature of the ray LO is greater than that of UO, and the apparent angle of subtense s' between the tangents to the respective rays becomes smaller. This phenomenon, in which the object also appears elevated, is called *stooping*. An enlargement of s' combined with an apparent lifting takes place, when the decrease of n with height is more rapid than according to a linear function, as shown by case (B) which represents *towering*. Whereas these phenomena result from vertical density gradients (drop in density per unit height) that decrease (A) and increase (B), respectively, with height, case (C) shows a negative density gradient that decreases, and case (D) one that increases with height, causing s' to be enlarged and diminished, respectively.

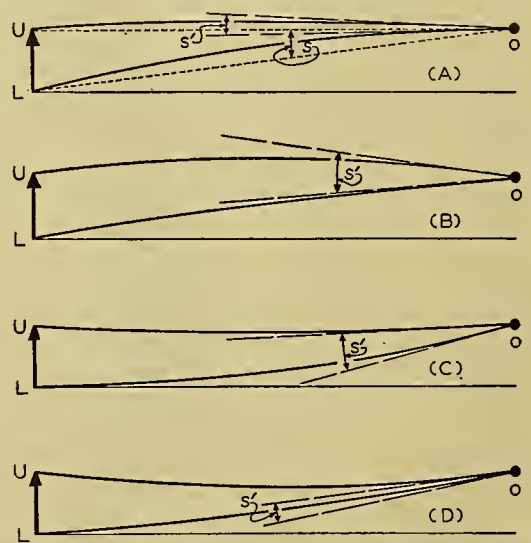

Fig. 6.—Effect of abnormal density gradients on the curvature of light rays.

Because of the increase in density with height, the rays are convex toward the ground, and the objects appear depressed. The mathematical theory for these phenomena, as well as for the corresponding ones involving horizontal objects, was developed by Exner [42].

In case the density distribution in the lower layers is such that the rays from an object reach the observer along two or more different paths, so that he sees one or more images of the object, we speak of *superior*, *inferior*, or *lateral mirages*, depending on whether the image appears above, below, or to the side of the object. The latter case can occur only when the isopycnic surfaces are vertical or nearly so, for example, in proximity to strongly heated walls. This phenomenon was theoretically treated by Hillers [17]. In case of a complicated density distribution in the lower layers, complex distorted images of distant objects, the *Fata Morgana*, may appear. General theories of mirages were developed by Nölke, A. Wegener, and others [c. 42], and

more recently by Fujiwhara and others [c. 21]. There is, however, still a thermodynamic problem connected with inferior mirages such as can be observed over heated highway surfaces. There, the vigorous stirring of the air by passing vehicles apparently has little effect on the existing density distribution. It would be interesting to study the "tenacity" of the mirage-producing air layer. Ives [24] has investigated larger-scale mirages of this nature and found that phenomena caused by steep lapse rates re-form, after disturbance, within a few minutes, while mirages produced by low inversions are more readily disturbed and "heal" much more slowly. Laboratory experiments, which permit control of the variables, and theoretical study of the heat transfer rate seem desirable to expand our knowledge of mirages.

Scintillation. Scintillation is due to temporal and spatial variations of density in the atmosphere. It consists of one or more of the following characteristics, depending on the nature of the object viewed. If the object is a point source, scintillation causes (1) apparent directional vibrations (unsteadiness in position of fixed objects), (2) apparent intensity fluctuations (light source may even appear to flash on and off), or (3) color changes (white light shows alternately its individual chromatic components). For extended objects, inhomogeneities in air density will cause (1) varying distortions of the contours or of internal line-structure of distant objects, thereby producing apparent expansion, contraction, or even disruption of the visible area; or (2) inhomogeneous brightness distribution, so-called *shadow bands*, over the surface of an object that is illuminated by a collimated light beam.

Astronomical scintillation involves extraterrestrial light sources. Its effect, in general, decreases with increase in angular elevation of the source. The amplitude of the vibratory motion of stars (or of the edge of the sun's or moon's disk) amounts to a few seconds of arc at the most, with a frequency of roughly 2 to 30 sec^{-1}, although the vibrations are seldom of truly periodic nature [7, 42, 55]. The relationship between the quality of star images in telescopes and weather elements has long been recognized [42]; the image quality deteriorates as wind speed, turbulence, or temperature lapse rate in the lower atmosphere increase [2, 55]. Respighi [c. 42] ascribed a greater effectiveness to the rotation of the earth than to wind, because he observed spectroscopically that stars on the western horizon pass through the spectral color sequence from red to violet, while those on the eastern horizon show the reverse. Pozdèna [43] shares this opinion, stating that the linear speed of the earth's rotation is much greater than the relative speed of the winds. Exner [42], however, pointed out that the observed phenomenon was due to the prevailing westerlies at higher altitudes and suggested that the argument could be decided by means of observations in regions with prevailing easterly circulation. There, the phenomenon observed by Respighi should appear reversed if wind is the dominant factor. Such a test has apparently not yet been made.

The explanation of chromatic scintillation, which has frequency characteristics similar to those of directional vibrations, was given by Montigny [c. 42] and is briefly outlined (Fig. 7). The difference in refractive index for the extreme visible wave lengths causes a white light ray L_1, entering the atmosphere at A, to send its red component toward O_1 at the ground, its violet component toward an observer at O. Another light ray L_2, which is lower than L_1 by a distance D and enters

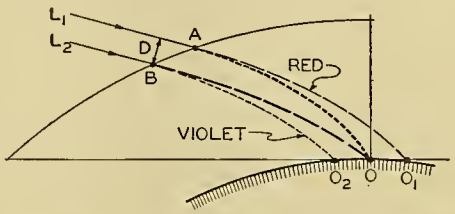

Fig. 7.—Dispersion of light rays by the atmosphere.

the atmosphere at B, sends its red beam toward O, while its violet beam falls at O_2. Other rays between L_1 and L_2 send the intermediate colors toward O, so that the observer there sees the entire color mixture as white, because the angular subtense of the spectrum is generally too small to be resolved by the eye. The distance D between rays of the extreme colors varies with the angular elevation of the light source and the height above the earth's surface. Table VI represents an abstract of the corresponding table by Exner [42]. The

Table VI. Variation of the Distance between Violet and Red Rays (in cm) with Zenith Distance (Θ) and Height (*After Exner*)

Θ(°)	Height in km				
	0.1	1	5	10	40
50	—	—	2	3	5
60	—	—	5	8	12

color separation for zenith distances of $< 50°$ is extremely small so that chromatic scintillation of stars is generally not perceptible. For greater zenith distances and for increasing heights, the rays' separation rapidly increases. Any air parcel that has a density different from that of its environment (density schlieren) and a diameter less than the rays' separations, will be capable of diverting individual color components into a different direction at different instants, thus causing chromatic scintillation. The size of these air parcels was variously determined as of the order of a few centimeters to a few decimeters [36, 42]. The size of the schlieren in relation to altitude, and the schlieren velocity, obviously determine the possibility and the frequency, respectively, of color fluctuations. For example, in order to produce chromatic scintillation of a star at 80° zenith distance, an air parcel must have a diameter of < 15 cm if at 1 km height, < 58 cm if at 5 km height, etc., whereas near

the ground such a parcel must have an extremely small diameter to cause scintillation.

The mechanism of intensity fluctuations was explained by K. Exner [c. 42] as follows: In Fig. 8, density schlieren around S are embedded at certain intervals in an otherwise more or less homogeneous field of density and cause concavities (or convexities) in an originally plane wave-front of light and, thus, divergence of the rays at A and A' and convergence at B and B'. If the system of schlieren moves horizontally, an observer—say at B—will perceive alternate increases in flux density where the rays converge, and decreases where they diverge. He will also see the light come from slightly varying directions, that is, apparent vibratory motions of the star. It is easily envisioned that the same variations occur if the schlieren system moves vertically. K. Exner measured the radius of curvature r of the wave-front deformation to be roughly between 2 and 20 km. In addition to discrete schlieren, we may also consider the wavy structure of surfaces of temperature or wind discontinuity as a cause of variations in flux density.

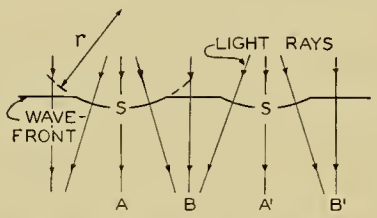

Fig. 8.—Scintillation resulting from density schlieren (*after K. Exner*).

The short-term fluctuations of images received from terrestrial light sources or objects, or *terrestrial scintillation*, is of great practical importance; in particular, strong scintillation may interfere with blinker signaling. Scintillation also limits the precision of telescope pointing and the useful magnification of telescopic devices [46]. Siedentopf and Wisshak[4] recently investigated the case of collimated light sources over a range f km long and 1 m above the ground, employing an objective receiver. With strong scintillation, the frequency of apparent intensity fluctuations was most often observed between 5 and 9 sec^{-1}, with lesser scintillation between 1 and 3 sec^{-1}. The whole range covered the frequencies between 1 and 50 sec^{-1}. The relative variability of the apparent intensity ranged between 0 and 100 per cent and did not materially increase with lengthening of the ray path[5] beyond 1 km. The mean frequency of intensity fluctuation was found to be independent of the path length. Shadow bands of from 5 to 10 cm width and several seconds duration were also observed moving horizontally with the wind across a screen several hundred meters from the searchlight.

The fact that an air column of 1 km length produces almost the entire effect of scintillation shows that the density discontinuities near the receiver are optically the most effective. Brocks [2] similarly found that the atmospheric conditions in the first tenth of a horizontal ray path (counting from the observer) are nineteen times as effectual in producing scintillation as the same conditions in the last tenth of the path. This seems to be the reason why various meteorological elements, observed near the receiver, correlate so well with the degree of terrestrial (and to a certain extent, astronomical) scintillation that predictions of atmospheric optical conditions are possible [4, 24, 42, 55]. Such predictions may not hold where, for example, thermal turbulence is present near the light source but not near the receiver. In this case, scintillation presumably could still occur, if, at the receiver, the angular subtense of the responsible air parcels were large as compared to that of the light source. Also, in cases in which the central portion of very long rays grazes the earth's surface, this portion is particularly exposed to density discontinuities that may not exist at the elevated end points of the rays.

The optical distortions by the atmosphere of nonluminescent, diffusely reflecting sources are generally referred to as *shimmer*, or *atmospheric boil*. Riggs and others [46] measured photographically the apparent lateral displacement of vertical linear targets and the distortion of rectangular grids at several hundred meters distance. They found angular deviations from the mean position of line elements of the order of 1″ to 5″. For targets separated by more than 3′ to 5′, there was no appreciable coherence of the observed deviations, that is, the horizontal dimensions of the schlieren subtended, at the camera, angles of less than 3′ to 5′. Unfortunately, no exact linear dimensions of the experimental arrangement are given, so that only the minimum size of the air parcels can be estimated (roughly 10 cm). In general, the characteristics of terrestrial scintillation appear to be very similar to those of astronomical scintillation; this fact indicates that the cause of the latter must lie predominantly in the lower layers of the atmosphere. Nevertheless, the extent to which the upper atmosphere contributes to astronomical scintillation must still be considered an open question, whose answer must come from direct exploration of the properties of the upper air.

The theories of scintillation by Montigny, K. Exner, and others [c. 42] explain qualitatively the observed phenomena. However, an exact mathematical expression of the relationship between the frequency and amplitude of apparent object motion, apparent intensity fluctuations, and chromatic effects on the one hand, and periodic time-space variations of meteorological factors on the other, remains undeveloped. There are also experimental problems as follows: The scintillatory behavior of uncollimated and diffuse light sources needs further investigation, although it is to be expected that diffuse sources will show a much lesser degree of scintillation than do collimated sources. Of particular interest would be an investigation into the size, shape, spacing, and transport velocity of schlieren in relation to the size, distance, and optical characteristics of the light source for various degrees of scintillation. Such studies

4. R. Meyer [36] cites their paper as unpublished and gives a concise summary of their results.

5. According to K. Exner's results, the minimum source distance that chromatic terrestrial scintillation is observable is about 10 km [c. 42].

could be made, for example, with the aid of a spatial arrangement of a field of light sources and receivers in connection with a dense micrometeorological network. For recording the apparent vibration of objects, motion picture cameras could be employed, whereas photoelectric devices seem to be preferable for measuring the apparent intensity fluctuations. The variation of scintillation with the altitude of the ray path above the ground, as well as with oblique upward and downward direction of the rays, is another problem which seems of practical interest for flight operations.

PHENOMENA DUE TO ATMOSPHERIC SUSPENSIONS

In this section, the sun is considered as the source of light, although the moon or artificial luminants may also produce the phenomena.

Halos. The term "halo," although implying ring shape, is generally applied to all optical phenomena that are produced by ice crystals suspended in the atmosphere and, occasionally, by those deposited on the ground [34, 36].

In Fig. 9, the sun is roughly 25° above the horizon *HH;* ring *A* represents the *22°-halo* (radius 22°), ring *B* the *46°-halo.* The two *parhelia CC* lie to the right and left of the sun at the same elevation, but at angular distances from the sun that vary between 22° and 32° for sun's elevations between 0° and 50°, respectively. The *parhelic circle DD* through the sun and parallel to the horizon is rarely seen as a complete ring; often only short segments of it extend outward from the parhelia. Tangent to the 22°-halo are the *upper* and *lower tangent arcs EE* and *E'E'*, respectively, which are only one of the metamorphic forms of the *circumscribed halo.* This halo is truly circumscribed only for sun's elevation of > 30°. For the various forms of this halo see pertinent literature [21, 34, 42]. The *lateral tangent arcs of the 22°-halo,* or *Lowitz-arcs, FF,* curve concavely toward the sun from the parhelia and touch the 22°-halo below its equator. The vertex (in the sun's meridian) of the *Parry-arc G* has an angular distance from the sun that decreases from 43° at 0° sun's elevation to tangency with the 22°-halo for sun's elevations between 40° and 60°, and then increases again for higher sun's elevations. The *circumzenithal arc J* is centered around the zenith and very near, or even tangent to, the 46°-halo. The *infralateral tangent arcs of the 46°-halo* are represented by *KK;* these arcs also are metamorphosed as their points of tangency move downward and meet at a sun's elevation of 68°, while at the same time their curvature (convex toward the sun) decreases and reverses itself for sun's elevations > 58°. The single arc separates from the 46°-halo when the sun is higher than 68°. The *sun pillar LL* lies in the sun's meridian and is, like the parhelic circle, generally white because of its origin by reflection, whereas the other halos are produced by refraction and thus more or less colored.

There are also other halos, such as the *circumhorizontal arc* that corresponds to the circumzenithal arc, but lies about 46° below the sun. *Supralateral tangent arcs* of the 46°-halo correspond to the infralateral arcs. On the sky opposite the sun, the *anthelion,* a bright spot on the parhelic circle, is sometimes obliquely crossed by *anthelic arcs.* Also rings of unusual radii, 8–9°, 17–19°, 23–24°, etc., have been observed on rare occasions, as well as skewed forms such as inclined pillars and parhelic circles, and secondary phenomena caused by reflection or refraction of light emitted from primary halos.

The geometrical optics of the various halo phenomena was theoretically treated by various authors [21, 34, 42, 44, 58]. In general, most phenomena can be explained by refraction with minimum deflection and/or by reflection involving simple hexagonal ice crystals of columnar or platelet shape, with various attitudes and, in some cases, oscillating motion while falling. The principal genetic features of the major halo phenomena are summarized in Table VII, in which the optical relationship, for example, between the circumzenithal arc and the infralateral arcs of the 46°-halo, becomes evident. There are, however, many phenomena that have been explained by different patterns of ray paths, or by more complicated crystals or crystal aggregates. Thus, for example, the optical origin of the anthelion, its oblique arcs [53], Hevelius' parhelia at about 90°

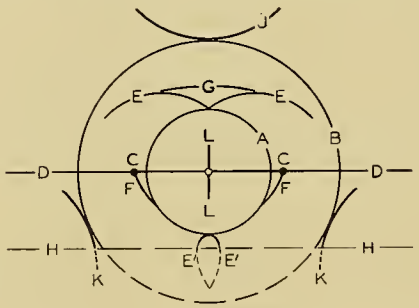

FIG. 9.—Schematic view of major halo phenomena.

from the sun, and other phenomena, is still uncertain; Bouguer's halo, a white ring of about 38° radius around the anthelic point, may even be a fogbow produced by very small supercooled water droplets [34, 47]. Decisive explanations will not come from additional theories, but from an accumulation of better observations. In particular, sampling of the ice crystals producing rare halos or those of uncertain origin would be most desirable. Many halos, theoretically established, have never been observed [58]; on the other hand, some phenomena, such as those observed by Arctowski [c. 42], are still unexplained. Meyer [34] discusses the various geometric problems of halo phenomena, and outlines as prerequisites for a complete theory the various physical aspects, such as the concentration of ice crystals in the clouds, and the brightness and polarization of the halos relative to those of the clouds in the environment. The physical optics of halos is almost entirely unexplored; in addition to refraction and/or reflection by ice crystals, diffraction plays a role in the formation of halos [34, 42]. Photometric observations, that have been introduced into halo investigations by E. and D. Brüche [5], would advance our pertinent knowledge of halos and the constitution of ice clouds [34].

The frequency of different halos, their diurnal and annual or seasonal variations, and their relation to weather situations, have been investigated [1, c. 34, 52]. The similarities or differences in the results can generally be ascribed to climatic characteristics. The relationship between halo occurrence and solar activity is, however, still quite problematic. Visser [52] found a decrease in halo frequency with increasing relative number of sunspots[6] up to 90 and then an increase for higher sunspot numbers. Archenhold [1] arrived at a direct linear relationship, and a halo periodicity of 27–28 days, which he associates with the rotation of the sun. This periodicity was shown to be spurious [39]. Although a certain degree of correlation with solar activity seems to exist, there is hardly a direct relationship (*e.g.*, corpuscular solar radiation furnishing sublimation nuclei), considering the prerequisites that must be fulfilled for a halo to be observable [34, 39].

Table VII. Principal Genetic Features of Major Halo Phenomena

Halo	Refracting angle	Orientation of principal crystal axis	Special characteristics (s = sun's elevation)
22°	60°	Random	Incident ray at 90° to principal axis.
Parhelia	60°	Vertical	Intensity rapidly decreases for $s > 50°$.
Circumscribed to 22°-halo	60°	Horizontal	Upper and lower tangent arcs join at $s \geqq 30°$. At $s \geqq 55°$ elliptic with long horizontal axis. At $s = 90°$ circular and coincides with 22°-halo.
Parry-arcs	60°	Horizontal	Pair of crystal sides vertical for $s < 30°$, horizontal for $30° < s < 50°$.
46°	90°	Random	Incident ray at 90° to principal axis.
Circumzenithal arc	90°	Vertical	Ray entrance at crystal base; limited to $s \leqq 32°$; also possible with horizontal axis and pair of sides horizontal, but rare.
Cricumhorizontal arc	90°	Vertical	Ray entrance at crystal side; limited to $s \geqq 58°$; also possible with horizontal axis and pair of sides horizontal.
Lateral tangent arcs of 22°-halo (Lowitz-arcs)	60°	Oscillating	Oscillation $< \pm 30°$ about vertical in plane that is parallel to sun's meridional plane. Limited to $25° < s < 55°$.
Infralateral tangent arcs of 46°-halo	90°	Horizontal	Ray entrance at crystal base. Limited to $0° < s < 68°$.
Supralateral tangent arcs of 46°-halo	90°	Horizontal	Ray entrance at crystal side. Limited to $0° < s < 32°$.

Rainbows. The colorful arcs around the antisolar point that appear on sheets of water droplets are called rainbows, although these phenomena may be produced by dew droplets on the ground or water sprays. The *primary rainbow* has an angular radius to the red outer border of roughly 42°; concentric to it is the *secondary rainbow*, whose radius to the red inner border is about 51°. Inside the primary and outside the secondary bow, *supernumerary bows* showing fewer and fainter colors are often visible. When the sun's rays are reflected by a smooth water surface before striking the suspended droplets, primary and secondary *reflection rainbows* may appear whose center lies as much above the horizon as that of the regular bows lies below it. Thus, the reflection bows intersect the respective regular ones at the horizon. When the reflecting water surface is undulated by a smooth swell, the reflection bow may deform into vertical shafts [57]. Droplets of radii $< 30\ \mu$ may produce a broad white band with faintly tinted borders, the *fogbow*, between about 37° and 40° distance from the antisolar point. Rainbows or fogbows produced by drops in a horizontal plane appear in the form of conic sections, that is, hyperbolic, elliptic, or parabolic arcs, depending on whether the sun's elevation is respectively smaller than, larger than, or equal to, the aperture of the cone (42° or 51°).

The well-known explanation by Descartes considered geometrical optics alone. Airy, basing his theory on wave optics, explained the variation of colors with droplet size and the supernumeraries as interference rings. His rainbow integral was also solved by others. The distribution of intensity, color, and polarization of

6. According to Schindler [c. 36], a relationship between sunspots and halos begins only at a spot number of 35 to 40.

the light after refraction and reflection by the droplets was computed, notably by Pernter and Möbius [c. 42]. Bucerius [6] developed an asymptotic method (in analogy to Debye's treatment of cylindric functions) by means of which Mie's theory of scattering of electromagnetic waves by dielectric spheres [c. 29] can be extended to large waterdrops. Applying this general theory to the rainbow phenomenon, he showed that it contains the older rainbow theories as approximations, and that the rainbow is an areal phenomenon that actually covers the entire region between the antisolar point and the first ring. Meyer [36] considers the classical diffraction theory still adequate, particularly for the intense rainbows that originate from comparatively large droplets. He developed this theory further to permit the determination of the luminous density of rainbows. He takes into consideration the total optical effect of all droplets contained in a surface element of the cloud deck, the thickness of the cloud, and the attenuation of the rays to and from the cloud. He finds the luminous density of the primary rainbow to be twelve times that of the secondary bow.

The theoretical advancement of our knowledge of rainbows appears to have surpassed our fund of observational data. Aside from older visual measurements, there are, to my knowledge, no results of up-to-date colorimetric photometry of rainbows available for application to the theoretical findings. In this connection an almost forgotten problem may be recalled, the fluctuations of colors during lightning and thunder [42], an observation requiring objective verification and explanation.

Corona and Related Phenomena. The sun shining through relatively thin clouds often produces one or more sets of colored rings, the *corona*, having diameters of a few degrees. When poorly developed, only an *aureole*, a bluish-white disk with brownish rim, may be visible. After violent volcanic eruptions, a broad reddish-brown ring of large radius (20° and more), *Bishop's ring*, has been observed in dust clouds [11]. We speak of *iridescent clouds*, when the colors are not arranged concentrically around the sun, but are irregularly distributed over, or follow the contours of, the cloud. This group of coronal phenomena around the sun is paralleled around the antisolar point by a similar group: An observer, seeing his slightly enlarged shadow, the *Brocken-specter*, on a fog bank or cloud, often finds the shadow of his head surrounded by one or more sets of colored rings, the *anticorona* or *glory*, well-known to pilots. If the shadow falls on a bedewed surface on the ground at some distance from the observer, the shadow of his head may be rimmed by a narrow white sheen, the *heiligenschein*, which also can be observed around one's head-shadow on a beaded projection screen.

The classical diffraction theory applied to the corona, under the assumption that the droplets are opaque, has been found to be in fair agreement with observations [42]. The well-known approximation formula by K. Exner [c. 42] for the angular radius θ of the circular intensity minima produced by particles of the diameter d in light of wave length λ, is

$$\sin \theta = (N + a)\lambda/d, \qquad (6)$$

where N is the order of the minimum counting from the center, $a = 0.22$ for spherical, $a = 0$ for nonspherical particles. Ramachandran [45] based his new corona theory on wave optics and included the wave-front portion that is transmitted through the droplets. In Fig. 10 the results of his calculation of intensities ($\lambda = 0.5\ \mu$) at various diffraction angles (θ) for small droplets (radii in μ ascribed to the curves) are reproduced. These curves indicate that the ring systems oscillate as the small droplets increase in size. Only relatively large droplets diffract like opaque disks of the same size, which explains some of the discrepancies formerly noted between the classical theory and observations. The position of the ring systems appears

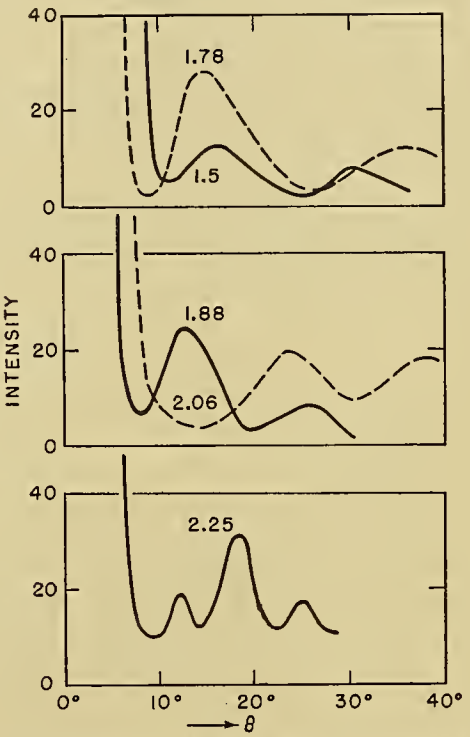

Fig. 10.—Intensity of diffracted light as function of angular distance from light source. (*After Ramachandran.* Ordinate scale presumably in relative units; numbers on curves are drop radii in microns.)

unaffected by the thickness and density of the clouds. Bucerius' work [6], mentioned above, also includes the application of the rigorous diffraction theory by Mie [c. 29] to both corona and anticorona. The anticorona was similarly treated by van de Hulst [20]. This theory yields the intensity and polarization of the diffracted light and the position of intensity maxima and minima. Table VIII gives a comparison of the values for the argument of the Bessel function at which corona maxima occur according to the old and the newer theories. It is noteworthy that in Ramachandran's theory the location and intensity of the maximum for small drops also depends on the value of $(\sin \xi)/\xi$, where ξ is a function of d/λ. For this reason the maxima oscillate as shown in Fig. 10. According to Bucerius [6, equation (47)], the argument contains twice the sine of half the angle between primary and diffracted rays.

instead of the sine of the whole angle θ. This is also true for the anticorona [6, equation (48)], the theory of which shows that it is produced by rearward diffraction, not by reflection of the primary ray with subsequent forward diffraction [Richarz, c. 42]. Bucerius' results may be summarized as follows: The intensity of the corona is $x^2 = (\pi d/\lambda)^2$ times as great as that of the anticorona; the intensity at the center of the anticorona is a minimum, that of the corona a maximum. Values for the angle θ of the successive intensity maxima of the anticorona[7] are determined by $2x \sin(\theta/2) = 3.05, 6.7, 10.0, 13.2, \cdots$; the minima are located at relatively the same position as are the corona maxima (Table VIII). This explains why the application of the classical corona formula (6) to the minima of the anticorona yielded values of the drop diameter d, that varied with the order of the minimum [c. 42, 47]. Also the decrease in intensity of successive maxima is much greater for the corona than for the anticorona; therefore, multiple glories are more frequently observable than multiple coronas.

The old controversy regarding the possibility of coronas and glories in ice-crystal clouds [21] now stands as follows: Multiple-colored rings generally indicate the presence of water droplets; however, the production of faintly colored glories by ice clouds has been established [47]. A statistical survey by Peppler [41] revealed that 78 per cent of glories were simultaneously observed with fogbows at temperatures between 0C and −4C; a maximum frequency of glories occurs at about −4C, that of halos at about −12C. Nevertheless, the frequency curves of anticoronas and halos overlap in a wide range of temperatures from about −2C to < −20C. At any rate, this problem cannot be considered solved. Statistical analyses of the occurrence of diffraction rings simultaneously with halos or fogbows reveal, at best, the relative frequency of diffraction rings in ice and water clouds, respectively, but are entirely inconclusive regarding the physical possibility of these phenomena in ice clouds. Moreover, Stranz [c. 36] by means of photronic cells, detected multiple coronas that were invisible to the eye. The theoretical objections to the possibility of diffraction phenomena produced by ice clouds were mainly based on the optical properties and orientation of ice needles, but other possible crystal forms must also be considered. Moreover, the occurrence of Bishop's ring in dust clouds shows that nonspherical particles are capable of producing diffraction rings. Unfortunately, none of the new theories considers diffraction by nonspherical particles, so that no final decision can be made.

Iridescence of clouds is explained as diffraction patterns produced by groups of uniform droplets that vary in size in different portions of the cloud. In view of the great sensitivity of the diffraction patterns to slight differences in size of small droplets [45] (Fig. 10), it is no longer difficult to explain the occurrence of iridescence at relatively large angular distances from the sun [c. 42]. The heiligenschein is considered the result of external reflection by the dew droplets [21, 42]; to what extent diffraction plays a role in this phenomenon is not known. Experimental data or intensity measurements are completely lacking.

The corona and anticorona have been widely employed in the study of cloud and fog elements. Measurements were largely confined to the angular radius of prominent rings and subsequent evaluation in terms of droplet radius. In view of recent theoretical developments [6, 20, 45] this geometric method seems unreliable; also the difficulty in visually locating diffuse rings, produced by inhomogeneous fogs or clouds, causes considerable uncertainties (see [5]). In the future it would be preferable to resort to objective monochromatic photometry of the entire zone around the light source (or shadow center), and perhaps, to determine the intensity of the diffracted light separately for the two components of polarization. Simultaneous determination of the droplet size by other means could serve as a check of the theory by making possible a comparison between observed and theoretical intensity distributions, rather than a comparison of only the minima or maxima.

Considering the rarity of homogeneous fogs, a theoretical and experimental study of inhomogeneous fogs appears of particular practical importance. Also, a final answer to the question of the possibility of coronas in ice clouds would give the observer on the ground a tool for the identification of the physical state of the clouds.

Table VIII. Comparison of Position of Corona Maxima of Various Orders According to Different Theories

TWILIGHT PHENOMENA

The investigation of twilight phenomena is closely connected with the study of the optical properties of the upper atmosphere, at least to a height of 60 km [18] and, thus, indirectly with the study of its density and dust content. The discussion of the temporal developments of the various phenomena is based on the sunset and the sun's meridian. Figure 11 shows the nomenclature for the significant astronomic-geometric features pertaining to the half-space above the observer and a schematic view of the major phenomena.

7. Bucerius (also [36]) gives here $2\pi x \sin(\theta/2)$, but refers to it as the argument of the Bessel function which, however, appears as $2\pi d(\sin\theta/2)/\lambda = 2x \sin(\theta/2)$.

Description. At, or shortly after, sunset, the *antitwilight arch*, a purplish band of some 3° or more in width, can be seen to rise above the solar counterpoint on the eastern horizon. At about 1° sun's depression, the gray-blue *dark segment* or *earth's shadow* begins to rise beneath the antitwilight arch. At approximately 2° sun's depression, the *purple light* appears as a purplish area above the solar point in the western sky. This area has a vertical angular extent of 10° to 50°, a lateral extent of 40° to 80°. Its upper boundary, which has an elevation of about 50° at the beginning, descends steadily to the horizon. The purple light reaches its maximum intensity at about 4° sun's depression and usually disappears at about 6° sun's depression. The rising antitwilight arch usually fades from view when the purple light is at its height, and shortly afterwards, the dark segment becomes indistinguishable from the rest of the darkening sky. Its transit through the zenith generally cannot be observed, but it reappears as the *bright segment*[8] or *twilight arch* above the solar point, when the sun's depression is about 7°. The bright segment disappears below the western horizon at about 16° sun's depression.

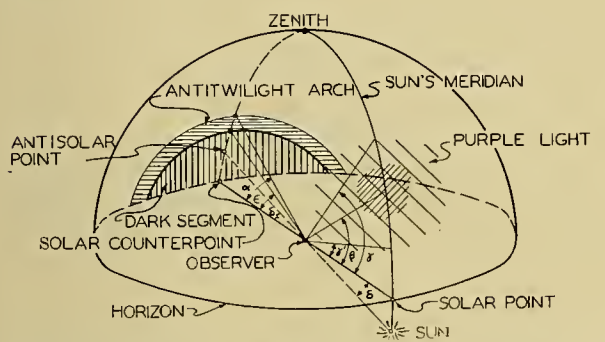

FIG. 11.—Schematic diagram of major twilight phenomena (elevation angles are α = antitwilight arch, β = maximum purple light intensity, γ and γ' = upper and lower boundary of purple light, δ = antisolar point, and ϵ = dark segment).

When the sun's rays are partially obstructed by clouds or mountain peaks, the purple light may assume a ray-structure because of the interruption by the shadow bands (crepuscular rays) which seem to converge towards the sun. Similarly, the continuation of these shadow bands (anticrepuscular rays) on the eastern sky may give the antitwilight arch a fanlike appearance. Colored illustrations of the various twilight phenomena can be found in [16].

During brilliant twilight phenomena, a secondary purple light may become visible after the main purple light has disappeared. Also a secondary antitwilight arch and dark segment may develop within the primary dark segment. These secondary phenomena are much more diffuse in outline and show fainter colors.

8. The descriptive term "bright segment" is preferable because of its fundamental identity with the dark segment and the basic difference from the "antitwilight arch." The term "earth's shadow" is physically incorrect [40] and does not readily permit differentiation between the phenomena on either side of the zenith.

For the measurements of twilight phenomena the following spatial and temporal aspects are generally considered: The elevation angle of the upper boundary of the antitwilight arch, of dark and bright segments, and of purple light; and the sun's depression at the time of beginning, end, and maximum intensity of the purple light. In addition, photometric measurements of the light intensity in various spectral ranges along significant portions of the sun's meridian are of major interest.

Results of Observations. The development pattern of the purple light has been found to be practically the same everywhere except at altitudes above 2000 m where the purple light ends at somewhat greater sun's depressions and where its upper boundary reaches greater elevations. A greatly detailed analysis of visual observations, such as made by Gruner [14] and Dorno [11], seems hardly warranted in view of the fact that the sun's depressions are computed without regard to the variable refraction, that the intensity is estimated according to a memory scale, and that the measurement of elevation of the diffuse boundary of the delicately tinted phenomenon is affected by subjective factors [50]. In Europe, a maximum frequency of bright purple lights occurs in autumn, a minimum in spring; this fact has been attributed to the corresponding frequency of anticyclones with clear skies in that area [51]. Otherwise no significant relationship between weather and purple lights has been found.

Secular variations of intense purple lights have been observed associated with dust produced by volcanic eruptions [c. 42, 50]. There exists, however, a time lag; for example, after the Katmai eruption in summer 1912, purple lights did not reach their maximum intensity until summer 1913 [11]; this delay was obviously due to the time involved in the sedimentation of dust particles necessary to produce the optimum concentration and size distribution for the formation of the purple light. For this reason, an absence of dust layers cannot be deduced from an absence of intense purple lights [50].

Although visual observations have long been recognized as inadequate, objective methods have been employed only in relatively recent times [13, 14, 32]. The techniques involved still need improvement and standardization. The results obtained at different stations from photoelectric [13] and photographic [32] intensity-measurements with color filters show a maximum red content of the sky light between 4° and 5° sun's depression, corresponding to the visually observed maximum relative intensity of the purple light. The absolute luminous density of the sky light decreases steadily in all spectral ranges with increasing sun's depression in contrast to the visual impression [14]. Whereas the results from visual observations were essentially confirmed by objective methods [13], the latter have shown the presence of the purple light when the spectral differences in intensity were below the threshold of visual perception [32].

Gruner [14] has indicated a method for determining

the height of the layer responsible for the purple light. By graphical approximation he arrived at values between 25 and 31 km for the upper boundary of the layer, and 18 km for the thickness of the generating ray beam, that is, a thickness of the layer of roughly the same magnitude. Smosarski [c. 14, 50] estimated the lower boundary at 8 km and the upper boundary at 17 km. The relationship between purple lights and high dust layers of volcanic origin seems to confirm at least the order of magnitude of these values. The possibility of a connection with the ozone layer is an unexplored question. Incidentally, Gruner [14], assuming the purple light to be a corona, also determined the order of magnitude of the particle diameter as between 1 and 1.5 μ. For these small particles, however, the classical diffraction theory fails [45] as was shown in the preceding section.

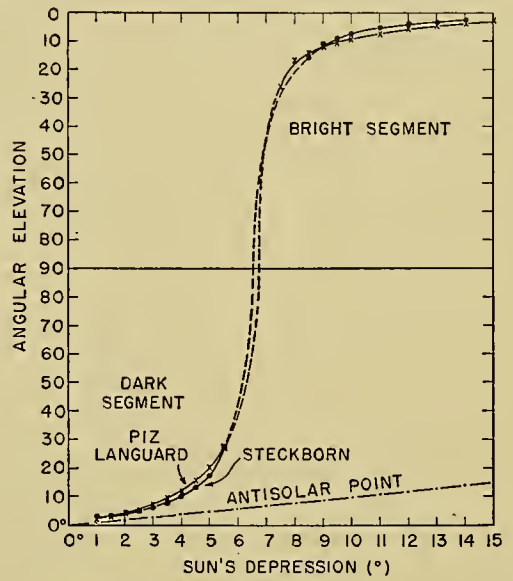

Fig. 12.—Average course of dark and bright segments at two Swiss stations.

Several series of geometric measurements of the elevation of the upper boundary and the width of the antitwilight arch have been made. The course of its angular elevation is similar to that of the dark segment (Fig. 12). Mendelssohn and Dember [33] made a few spectral measurements by photographic photometry, but their results confuse, rather than elucidate, the visual observation. The annual and secular variations of antitwilight-arch occurrence were determined by Smosarski [50] who found, in Poland, a maximum frequency in autumn and winter, a minimum in summer, and a good correlation with volcanic activities. A direct connection with the occurrence of purple lights does not seem to exist. According to computations by Smosarski [c. 14], as the sun's depression increases, the antitwilight arch is produced by the rearward scattering of sunlight by smaller particles at higher altitudes. However, according to Mendelssohn and Dember [33], the antitwilight arch is supposedly fixed in a layer between 4 and 9 km. This problem will be discussed below.

Of the many observations on the movement of the dark and bright segments, only the averages of two series obtained at Piz Languard (3280 m) and Steckborn (430 m) in Switzerland, as reported by Gruner [14], are shown as examples in Fig. 12. As the sun sinks below the horizon, the dark segment rises more rapidly than does the antisolar point; the ascent rate increases with the sun's depression, until the segment fades from view between 5° and 6° depression. Between 7° and 8° depression the bright segment appears at an elevation of roughly 25° above the solar point and descends, first rapidly then more slowly, to the western horizon. According to the interpolated (dashed) portions of the curves, the invisible transit through the zenith occurs at a sun's depression between 6° and 7°. This agrees well with observations of the zenith brightness by Brunner [c. 14] and Hulburt [18], and of global illumination by Siedentopf and Holl [48]; these authors present curves of brightness and illumination, respectively, versus sun's depression, that show a definite inflection point between 6° and 7° sun's depressions. This fact is involved in the problem of the height at which this phenomenon occurs. In this connection the change in relative variability of the dark segment's elevation at various sun's depressions deserves attention. It has been shown [26, 40] that the variability decreases rapidly until the sun's depression is about 2.5°, then more slowly, although the opposite trend was to be expected in view of the decreased accuracy of measurement at greater sun's depressions. This fact was interpreted as being caused by a transition of the dark segment at about 2.5° sun's depression into the stratosphere, where marked changes in turbidity from day to day are less frequent [40].

The sun's depressions at which the last traces of the bright segment disappear below the horizon have been variously used to compute the height at which the density of the atmosphere is sufficiently great to produce visible scattering of the direct sunlight. However, the resulting values of 50–65 km [14] are still quite problematic because of subjective factors involved in the perception of faint light and of the effects of attenuation of the direct light rays at various altitudes. Except for a slight increase in elevation of the dark segment in summer and with diminished transparency of the lower layers of the atmosphere, no clear-cut relationships between the turbidity of the air and the bright segment, nor a definite seasonal variation of either segment have been established [14, 16, 18, 26, 40].

Theories and Problems. Although many theoretical approaches to the problems of twilight phenomena have been made, no complete theory exists as yet. The theories of the dark and bright segments and of the antitwilight arch [15, 16] agree qualitatively with, but differ quantitatively from, the observations. For example, the elevations of the dark segment, computed from the spectral intensities of light scattered by a Rayleigh atmosphere (disregarding multiple scattering), were considerably smaller than the observed ones [14, 15]. The principal ideas underlying the explanations of

the segments and antitwilight arch are schematically demonstrated with the aid of Fig. 13 as follows: R_0 to R_3 are sun's rays passing through the atmosphere whose optically effective height may be E_3D_3. The lowest ray R_0 touches the earth's surface at O_0. Owing to scattering and absorption on their way through the air, any rays between R_0 and R_1 lose part of their short-wave components and their intensity is depleted, so that R_0 may not reach much beyond O_0, the next higher ray a little farther, and so on. The envelope of the end points of all these rays is represented by the curve $O_0D_1D_2D_3$. Consequently, the atmosphere to the right of this curve lies in the shadow of the earth. An observer O_1, for whom the sun's depression is δ_1, sights the vertex of the dark segment at D_1, the point of tangency of his line of sight O_1S_1 to the ray envelope. If he raises his line of sight slightly, he perceives light scattered from the still illuminated portion of the atmosphere near the envelope. This prevalently reddish light constitutes the antitwilight arch. Its upper boundary is seen when the line of sight at O_1 is further raised so that the diminishing light from the zone of red rays is compensated by the increasing light of shorter wave lengths from the higher

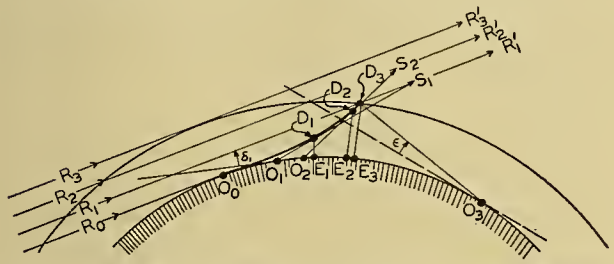

Fig. 13.—Schematic diagram for the dark and bright segments.

layers of the atmosphere. When the sun sinks further, the relative position of the observer shifts to O_2, where the line of sight O_2S_2 touches the envelope at D_2. For an observer at E_3, the passage of the dark segment through the zenith is imperceptible, because there is not enough contrast between the sky brightness to the right and left of the line of sight E_3D_3. Finally, the observer at O_3 sees the bright segment at an elevation ϵ.

The geometric aspects of this problem have been studied by various authors [c. 14, 40]. The results of computations of the heights of points D at various sun's depressions, although based on different assumptions, agree fairly well as shown by the examples in Table IX. According to these heights, point D moves into the stratosphere at a sun's depression between 2° and 3°, in agreement with the deductions made from the variability of the dark segment. However, the problem is essentially a photometric one [42]. An attempt at a physical solution was made by Dember and Uibe [10], who took into consideration the visibility as proportional to the square root of the measured sky brightness. Application of this theory by Mendelssohn [33] to photometric measurement yielded a constant height of the dark segment between 2 and 4 km. However, the transit of the dark segment would then have to occur not later than at about 3.5° sun's depression [40], which is contrary to observation. Nevertheless, the basic idea of including the attenuation of light along the line of sight is correct. This was suggested by Exner [42] who, however, based his formula on Rayleigh scattering alone and disregarded secondary scattering which undoubtedly plays a role in the brightness of the sky below the ray envelope [18].

Table IX. Height of Dark Segment at Various Sun's Depressions

δ(°)	Mohn [c. 14] (km)	Neuberger [40] (km)
1	—	2
2	11	8
3	21	17
4	31	27
5	40	38

The major problematic factors pertaining to the segments and antitwilight arch are as follows: Two influences on the ray envelope must be considered, that of atmospheric refraction which causes a vertical divergence of the sun's rays (shown as parallels in Fig. 13), and that of atmospheric attenuation of the rays near the ground. This attenuation tends to counteract the effect of refraction by eliminating the lowest, most refracted rays [27]. The position and shape of the ray envelope is, thus, primarily a function of the transparency of the atmosphere at and above the point of tangency with the earth's surface. As regards the intensity and color of the scattered light, most computations have been based on an idealized atmosphere in which Rayleigh's theory with its symmetric scattering function is valid [14, 15, 18]. However, the real atmosphere contains a large number of particles, especially in the lower layers. For this reason, the agreement between theory and observations is not satisfactory, and, in particular, the variations from day to day observed in dark and bright segments and antitwilight arch remain unexplained. According to Linke [29], the rigorous theory by Mie-Debye is more suitable for the theoretical approach to the twilight colors. However, this theory is difficult to apply to the problems at hand, because it still involves the assumption of spherical particles. In view of the new theories of the anticorona [6, 20], the consideration of rearward diffraction should be extended to the theory of the antitwilight arch.

The theory of the purple light which was recognized as a diffraction phenomenon by Kiessling [c. 42] was established by Gruner [14] along the lines suggested by Pernter [42] and others. This theory adequately describes the temporal and spatial development of the purple light; the basic ideas may briefly be outlined with the aid of schematic Fig. 14. The sun's rays R_0 to R_3 pass through a dust layer DD' in which they are deprived of their short-wave components. While R_0, passing through the dense lower layers, and R_3, having the longest path through the dust layer, may be completely extinguished, the rays around R_1 will emerge as a reddish beam of light and enter the lower boundary of the dust layer again at P_1, where the particles will

be relatively large. These particles may diffract the light dominantly at the angle φ_1 toward the observer O, whose horizon is HH', and for whom the sun's depression is δ. At the higher points P_2 and P_3, the prevailing sizes of the dust particles become successively smaller and the diffraction angles φ_2 and φ_3 correspondingly larger. Since the incident beam is reddish, the diffracted rays converging toward O will outline a reddish area in the sky. The observer sees only those diffracted rays that fall in his cone of vision (and are sufficiently intense); for example, a particle at P_1' of the same size as that at P_1 and one at P_2' of the same size as the one at P_2, will also diffract light toward O. It may be noted that an observer, for whom the sun is still above the horizon, may see Bishop's ring around the sun. Also, the light scattered and diffracted by the dust layer in the region of the purple light is sometimes sufficiently intense to cause a secondary purple light for an observer located farther on the night side of the earth (*i.e.*, to the right of observer O in Fig. 14). The red light diffracted by the dust layer and augmented by blue light scattered by the air in the region $S_1S_2S_3$ above gives rise to a purplish tone.

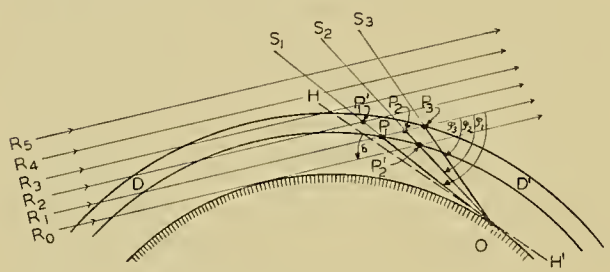

Fig. 14.—Schematic diagram for the purple light.

From the geometric aspects we can see that the areal extent of the purple light depends on the particle size distribution, the thickness of the layer, and absorption. The latter generally prevents the purple light from appearing as a circular arc. The theory does not predict the exact color and intensity of the phenomenon; these depend on the modification of the incident beam by its first passage through the dust layer, its further fate in the air below this layer, the specific effect of the dust on the beam after re-entrance into the layer, and, finally, the modification of the diffracted light on the way to the observer, in conjunction with the sky light from above. For a homogeneous dust layer, an optimum particle concentration and size distribution must exist, whereby the red component of the incident sunlight experiences a minimum depletion on its first passage through the dust layer and produces maximum intensity of diffracted light when again penetrating the layer.

In general, there are too many unknown variables, in particular the scattering function of the dust particles and attenuation of the direct rays, to render the problem as a whole accessible to an analytical solution, especially when multiple dust layers are involved. For the present, it appears most expedient to provide reliable observational material by means of which the available theories may be checked more adequately. In order to eliminate from such material all the subjective variables that are involved in visual observations, only objective methods of observation should be employed. The design of the spectrophotometric equipment should incorporate the features of very high sensitivity, to enable the use of filters with narrow transmission bands, and of rapid response, so that the major portions of the sky area could be scanned within a few minutes. By means of a wide station network, the question regarding the cause of asymmetric twilight phenomena that have been variously attributed to the shape of the atmosphere as a whole or the slope of the tropopause [14] could be answered. The problem of the height of the effective layers of the atmosphere and of the shape of the ray envelope could be approached by means of airborne photometric instruments to furnish vertical cross sections of the light flux at various altitudes along a latitudinal line to represent various sun's depressions. Spectrophotometry of clouds of known height may furnish information on the geometrical and optical properties of the sun's rays tangent to the earth's surface.

As regards determination of the terrestrial or possibly cosmic origin of dust layers [11, 14] that periodically produce striking twilight phenomena, only a long-range observational project on an international basis will lead to success.

SCATTERING OF LIGHT IN THE ATMOSPHERE

Scattering is the deflection of light quanta in a transparent medium such as the atmosphere. The atoms and molecules of the gaseous constituents cause the quanta of the incident light beam to be scattered more or less in all directions. In addition, there is scattering by minute particulate suspensions such as condensation nuclei. When a beam of this scattered light encounters further matter, it is again subject to (multiple) scattering; however, the contribution of multiple scattering to the total intensity of scattered light is small, except in very turbid air or in the absence of primarily scattered light, (*e.g.*, in the case of the dark segment).

The classical theory by Rayleigh [c. 21] was found to be only in approximate agreement with pertinent observations [c. 42]. The later theory by Mie and Debye [c. 29], which contains Rayleigh's theory as a limiting case, is more general, but difficult to apply to atmospheric scattering because it requires a knowledge of specific constants, the distribution, and concentration of the scattering substances. For a thorough summary of the theories of scattering as well as of methods and results of observations, the reader is referred to the work by Linke [29].[9]

It was shown that the scattering process was involved in some of the previously discussed optical phenomena; its more immediate manifestations are much less spectacular, but nevertheless of great practical importance. The essential consequences of scattering are: The restric-

9. See also Chap. 7 on "Die kurzwellige Himmelsstrahlung" in the same volume, pp. 339–415.

tions in visual range; the polarization of sky light; the depletion of direct sunlight; and the luminance of the sky in daytime. Only some aspects of sky luminance will be briefly mentioned here, as the other topics are treated elsewhere in this Compendium.[10]

The luminance of the sky represents a considerable portion of that direct sunlight which has been depleted in its passage through the atmosphere. A practical aspect of this luminance is the resultant illumination without which the earth's surface would be in darkness except where reached by direct or reflected sunlight. The most obvious characteristic of the sky's luminance is its blue color which is caused by the preference of the scattering process for the shorter wave lengths of the incident radiation. Far from being a pure blue, the color is composed of other wave lengths to an extent that varies with the state of atmospheric turbidity, because with increase in size of the scattering particles the longer wave lengths increasingly participate in the scattering process. In the sky light, the ultraviolet component, whose intensity may exceed that of the direct sunlight, has biological (erythematous and bactericidal) and technological (dye-fading, photographic) effects.

The luminance of the sky is significant from a meteorological viewpoint because it enters as a factor in the appraisal of the atmospheric radiation balance and serves as a criterion of the turbidity of the air. In this respect, even mere estimations of the variations in the sky blue have been shown to be of practical value.[11]

POLARIZATION OF SKYLIGHT

By ZDENĚK SEKERA

University of California, Los Angeles

Introduction

Since the discovery by Arago in 1809 that the light of the clear sky is polarized, interest in the problems of skylight polarization has varied greatly. At first, attention was concentrated more on the development of a suitable measuring technique to determine the magnitude of the polarization and its distribution over the sky. Arago first discovered a neutral point, named after him the *Arago point*, where the polarization disappears, about 20° above the antisolar point. The other neutral points were discovered in 1840 about 20° above the sun by Babinet and below the sun by Brewster. Because of the simplicity of the determination of neutral points, more attention was paid later on to their study and soon a complete picture of diurnal, seasonal, and secular variations in the position of the Arago and Babinet points was obtained.

Arago's discovery of a point of maximum polarization 90° from the sun in the sun's vertical was followed during the next two or three decades by studies of the variability of the maximum polarization at this point (Bernard, Rubenson, Crove, Cornu, etc.).

For several reasons, interest in atmospheric polarization culminated at the end of the last century. The photopolarimeter, constructed by Cornu in 1882, represents the highest point in the development of the visual measurement of polarization. The accumulated results of polarization measurements gave rise to a series of attempts to explain the observed facts theoretically, culminating in Lord Rayleigh's theory of molecular scattering.

The famous eruption of Krakatao (1883) showed the extraordinary sensitivity of skylight polarization to the presence of volcanic dust in the upper atmosphere. For several decades thereafter, the investigation of polarization was considered almost exclusively as a suitable tool for the study of perturbations of a similar kind. But since the last eruption of Katmai in 1912 no anomalies of this type occurred, and the interest in problems of atmospheric polarization rapidly decreased. Smaller fluctuations in the polarization were studied and the measurements were extended to rather narrow spectral ranges. Surprisingly, a great discrepancy was found between the results of different authors, and the only possible explanation for this is a large variability of the dispersion of polarization (variation with the wave length) with the size and number of scattering particles. As these quantities vary greatly with local conditions (weather, season, etc.), the corresponding variations in polarization follow. But if the presence of scattering particles of different size is admitted, the question arises whether it is the secondary scattering or the presence of larger particles (excluded by the assumptions of Rayleigh's theory) which is responsible for the observed deviations of the atmospheric polarization from expectations based on theory.

After Ahlgrimm's successful attempt to compute the effect of secondary scattering, in which he explained most of the facts better than he explained the observed variations, Milch in 1924 presented a theory in which the secondary scattering was neglected and the effect of larger particles was considered responsible for the deviations from Rayleigh's theory. The close relationship between Linke's turbidity factor and the degree of polarization, predicted by Milch's theory, was demonstrated in 1934 by Blickhan from simultaneous observations of polarization and turbidity. But he obtained much better agreement between the observed and theoretical values of the maximum polarization when he considered the effects of both secondary scattering and the presence of larger particles.

Even though Blickhan's results clearly pointed the way for further investigations, no appreciable increase of interest in this direction has followed. The reason for a recent slight increase of interest in problems of skylight polarization is quite different. First, the introduction of objective methods, such as the photoelectric techniques in photometry, showed the possibility of more accurate and systematic measurements. Then, after the first attempts to use optical methods for the exploration of the upper atmosphere, attention was brought to the polarization of the skylight during twilight and during the night. The great technical difficulties in the measurement of the extremely low intensities of the skylight during these hours led even to the use of searchlight beams in the study of atmospheric scattering. But since, during twilight, direct illumination from the sun is less and less intense, the secondary and multiple scattering become more and more important. And just at the present moment when there is a need for computation of the effect of secondary and multiple scattering, recent research in theoretical astrophysics offers help. The scattering by free electrons produces polarization of stellar radiation, the theoretical study of which led Chandrasekhar to develop an excellent method for computing multiple scattering exactly, suitable for application to the problems of atmospheric polarization. Thus we are now in a position to use a highly developed modern experimental technique, together with excellent theoretical tools for solving many problems of skylight polarization in such a manner that very useful information can be obtained.

Measurement of Skylight Polarization

In the measurement of skylight polarization, there occur two different problems: measurement of the degree of polarization and measurement of the position of neutral points.

The visual measurements of the degree of polarization were highly developed by Cornu in his photopolarimeter [17], and slightly improved by Martens [42]. This photopolarimeter contains a Wollaston prism as polarizer and a Nicol prism as analyzer. Both prisms can be rotated around the same axis and their mutual position and the position of the polarizer can be read off.

With the analyzer fixed 45° to the principal axis of the Wollaston prism the plane of polarization is determined by the position of the Wollaston prism in which both halves of the field in the eyepiece have the same intensity. The plane of polarization is then inclined 45° from the principal axis of the Wollaston prism. If the Wollaston prism is now rotated by 45°, one half of the Wollaston prism transmits the intensity normal to the plane of polarization, the other the intensity in the plane of polarization. While the Wollaston prism is kept fixed the Nicol prism is rotated until both halves of the field have the same intensity. The degree of polarization P is then equal to $\cos 2\omega$, if ω is the angle between the principal plane of the Wollaston and of the Nicol prism, usually readable by means of a scale outside of the instrument.

The precision of this method was discussed by Smosarski [62] and found to be most accurate for large values of P; for small values of P this method requires some modification. Errors due to incorrect settings of the polarizer or of the analyzer can be eliminated by taking successive readings with the prism in the position 90°, 180°, and 270° from the original position. In this way a precision of 1–2 per cent can easily be reached, provided the illumination of the field in the eyepiece is sufficient to enable one to distinguish the unevenness of its halves. Another disadvantage is a relatively long time interval (about six minutes) necessary for all settings and readings. Because of the failure of this method in the case of rapid fluctuations in polarization or of inadequate illumination (during twilight or night), visual methods are being replaced more and more by objective methods.

Because of the cumulative effect during longer exposures, photographic photometry is often used when the illumination is inadequate. By means of a Wollaston prism a double picture of the measured field is obtained, and the degree of polarization is computed from the ratio of the intensities of the separate pictures. The precision of this method is limited by the precision in setting the principal section of the prism in or normal to the plane of polarization and in keeping it in this direction during the exposure. Especially during the night, when the illumination is very weak, this procedure is very difficult. Another limitation of the photographic method is the great variability of the photographic material, which makes necessary a special sensitometric arrangement for the determination of a characteristic curve for each exposure. For exact measurement, a standard intensity scale must be simultaneously exposed on the plate or film, and after development, the characteristic curve from the measured intensities is determined by a visual or photoelectric photometer. This procedure, unfortunately omitted by several authors, makes photographic polarization measurement rather complicated without any gain in precision over the visual method (the accuracy seldom exceeds 5 or 10 per cent). However, if this procedure is not followed, the results are quite unreliable. On the other hand the photoelectric method seems to be more convenient for an objective polarization measurement. It offers not only the possibility of a fast and continuous measurement but also of measurement at low intensities. The continuous measurement can easily be made by measuring the intensity of light passing through a rotating Nicol prism or other analyzer [57]. If the prism rotates around its axis with a constant angular speed ω, then the intensity of the photoelectric current from the photocell situated behind the prism is proportional to $\frac{1}{2}I_n + I_p \cos^2 \omega t$, if the time is counted from the moment when the principal plane of the prism (the plane of transmitted vibrations) is normal to the plane of polarization of the measured partially polarized light, the polarized and unpolarized components of which have intensities I_p and I_n, respectively. For light of greater intensity the current can be recorded continuously, and the degree of polarization determined from two intensities (maximum and minimum) if the period and the decrement of the galvanometer or other recording system used is known. If the rotation of the prism is uniform and sufficiently slow, the direction of the polarization plane can also be determined by a very simple arrangement. By a suitable choice of the recording system even very rapid fluctuations in the polarization can be studied in this manner. The measurement of the polarization for low intensities can also be made without any basic difficulty if very sensitive photocells (photomultipliers) are used or if the photoelectric current is properly amplified. Since a-c amplification is more effective, it is desirable to produce photoelectric alternating current, for which purpose fast rotation of the prism can conveniently be used.

Because the spectral sensitivity of the human eye differs from that of the photocell or the photographic material, the results of the objective methods will in general be different from that of the visual measurement. It can be shown [58] that, if there is no dispersion of the polarization, that is, if P is constant for all wave lengths, there will be no difference in the results of these different methods. But if the dispersion occurs, that is, P is different for different wave lengths, the difference between P measured by different methods will be greater, the greater the dispersion of the polarization. Since the dispersion depends upon the turbidity of the atmosphere, the difference between the results obtained by the different methods may vary appreciably from day to day.

The measurement of the position of neutral points is

much simpler. Their elevation above the horizon is measured by standard procedures (usually by a pendulum quadrant or a theodolite); for finding the neutral point any type of polariscope can be used. The most convenient type is the Savart polariscope and its modifications. The main part of the polariscope is Savart's double plate (two plates of the same thickness cut under 45° from the optical axis of a quartz or any uniaxial crystal; one of them turned through a right angle from the other). If a polarized light passing through the double plate is observed through an analyzer with the plane of polarization bisecting the angle between the principal planes of transmittance of the plate, parallel color fringes appear. They have a dark or bright central band, depending on whether the incident light is polarized at right angles or parallel to the plane of transmittance of the double plate. The fringes disappear if the incident light is unpolarized. The modifications of Savart's polariscope differ with the type of analyzer used. In the original model a tourmaline plate was used. Its great disadvantage was a strong absorption resulting in a dark green color of the field. By using a Nicol or similar prism this disadvantage can be removed, but the field is then very small. Much larger fields and an extraordinary brightness of fringes can be reached in Voss's modification [69] with a Wollaston prism as analyzer. By a suitable adjustment of the thickness of the double plate and the Wollaston prism, the deviation of the ordinary and extraordinary rays emerging from the prism can be made exactly equal to the angular distance of the interference fringes. In this way the fringes in the ordinary and extraordinary system of rays coincide and their intensity is doubled. Because of its great luminosity the Voss polariscope is very useful for measuring neutral points late after sunset. Its colorless field makes it particularly useful for measurements within a narrow spectral zone. The advantage of a colorless field can also be achieved by using a polaroid plate as analyzer [45].

If the polariscope is set up with fringes parallel to the sun's vertical in the vicinity of a neutral point, the dark central band above the point continues as a bright one below with an interruption in the middle in the exact position of the neutral point. The elevation of this point is then measured. The position of the interruption in the fringes can also be determined photographically [6].

Distribution and Magnitude of the Polarization over the Sky

As already mentioned, the degree of polarization of skylight reaches its maximum in the sun's vertical, 90° from the sun. Mean values of a large number of measurements of the polarization at this point taken in different years and at different places, agree relatively well, showing a decrease of the degree of polarization with increasing elevation of the sun (Fig. 1). Measurement of polarization at the zenith was introduced by Jensen [31] and performed by several authors because of the simplicity of having a fixed position of the observed direction independent of the sun's elevation. With the sun at the horizon, the zenith coincides with the point of maximum polarization. With the sun above the horizon, the polarization at the zenith decreases rapidly as the point of maximum polarization descends towards the horizon. The daily variation of the polarization at the zenith has thus the same character as that of maximum polarization, but with a much larger range of variation, as may be seen in Fig. 2. The measurement of polarization at the zenith, extended for negative sun's elevations h_s, gives an interesting result: the maximum polarization at the zenith is reached for

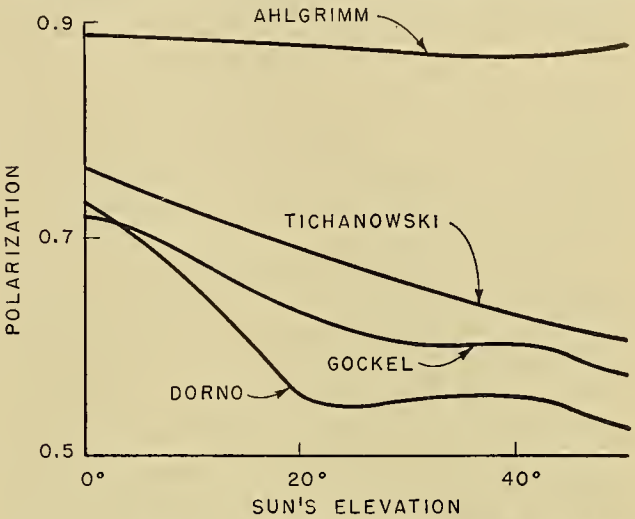

Fig. 1.—Polarization at the point of maximum polarization (in the sun's vertical, 90° from the sun) for different sun's elevations h_s. Observed values (Dorno, Gockel, Tichanowski) compared with theoretical values (secondary scattering according to Ahlgrimm).

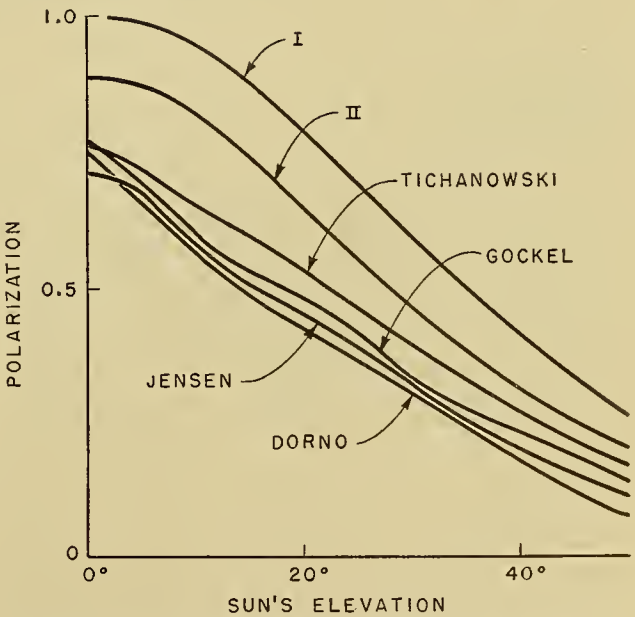

Fig. 2.—Polarization at zenith for different sun's elevations h_s. Theoretical values (I—Rayleigh's theory of primary scattering, II—secondary scattering according to Ahlgrimm) compared with observed values (Tichanowski, Gockel, Jensen, Dorno).

a sun's elevation between $-2°$ and $-4°$. The increase of polarization for $h_s < 0$ was found to be more rapid, the lower the value of the polarization at $h_s = 0$.

The distribution of the polarization over the sky was studied extensively by Dorno [22]. In a stereographic projection with the sun at its pole, the lines of equal polarization are nearly concentric circles around the sun. For corresponding P, the circles on the sun's side are closer to the equator (the line of maximum polarization) than on the antisolar side, showing a slight asymmetry of P in the sun's vertical, a fact studied and proved by Smosarski [62]. The distribution—surprisingly—varies very little with the elevation of the sun above the horizon.

The position of the plane of polarization was also measured and, at first, lines were drawn parallel to the direction of this plane. Later on they were replaced by the lines connecting points with the same inclination of the plane of polarization to the vertical (polarization isoclines). Since the inclination 45° to the vertical, called also a neutral line or Busch lemniscate, can easily be measured by the interruption of the vertical fringes in a polariscope (similar to the neutral points), it was studied extensively by Dorno [22] and Mentzel. Mentzel's measurements were recently revised by Dalhkamp and Kantus [20] and discussed with respect to the possibility of using the shape or the area inside the Busch lemniscate as a measure of the turbidity.

More attention has been devoted to the measurement of the position of neutral points than to the measurement of the degree of polarization. The reason for this, besides the great simplicity of the measurement, is the great variability of these positions, and their greater sensitivity to the turbidity of the atmosphere. The measurements mostly relate to the Arago and Babinet points; the position of the Brewster point has not been studied systematically because it is difficult to measure (below the sun, close to the horizon). The distance of the Arago point from the antisolar point and of the Babinet point from the sun vary in a characteristic way for small positive and negative elevations of the sun. If the distances of these points (A- and Ba-points) are plotted against the sun's elevations, then the curve for the A-point shows a minimum (or a secondary minimum) for small negative h_s, while—under normal conditions—the Ba-point curve shows a secondary maximum (*cf.* Fig. 3). These extremes in both curves are followed by a rapid increase for larger negative h_s. The position and the values of those extremes (for the Ba-point, even the whole character of the curve) change greatly with the turbidity; these quantities were therefore suggested by Jensen [30] as reliable indicators of atmospheric turbidity. Comparing the mean values for winter and summer from a period with a fairly normal condition, Jensen concluded that, with increasing turbidity, (1) the antisolar distances of the A-point increase, (2) the difference between the maximum and the secondary minimum for the A-point increases, and (3) the position of the minimum in the A-point curve is shifted to the negative h_s. The variations in the distances of the Ba-point do not follow such simple rules, being more sensitive to the conditions at much higher levels which are unaffected by the seasonal variations. Neuberger [45] studied the interrelationship between the extremes in the A-point curve and found a very high correlation ($+0.95 \pm 0.01$) between the difference in (2) and the distance of the A-point for $h_s = 10.5°$ or 13.5°, suggesting that a single measurement of the A-point distance for these values of h_s can be used as an indicator of the turbidity. When he compared the distance of the A-point at $h_s = 10.5°$ with the direct measurement of solar radiation, Neuberger found an increase of this distance with decreasing intensity of solar radiation; this would agree with the statement in (1) above.

As another indicator of turbidity, the difference between the points of the A- and Ba-point curves for the same h_s can be used. This difference increases with increasing turbidity, as is clearly shown in Table I, where the values of this difference, measured in a turbid atmosphere (Hamburg, Arnsberg), are compared with those measured in a much less turbid atmosphere (Davos).

Table I. Difference Between A-point and Ba-point Distances (in degrees)

	$h_s = 5.5°$	$h_s = 4.5°$	$h_s = 3.5°$	$h_s = 2.5°$	$h_s = 1.5°$	$h_s = 0.5°$	$h_s = -0.5°$
Hamburg, 1909–11	5.9	5.0	4.1	3.3	2.3	1.4	0.9
Arnsberg, 1909–11	6.3	5.6	4.6	3.8	2.9	2.1	1.6
Davos, winter 1911	0.1	0.3	0.5	0.5	0.1	−0.1	−0.2
Davos, spring 1912	0.9	0.0	1.0	0.6	0.1	—	—

Quite distinct is the effect of ground reflection on the curve of A-point distances. The maximum, which at a land station is usually very flat and is observed around $h_s = 12.5°$, shifts to smaller sun's elevations and decreases in value in the vicinity of large water surfaces [30]. If the reflection is strong, new neutral points appear, either below the ordinary points (as observed by Rubenson [54] below the Ba-point, and by Jensen [3] and Neuberger [44] below the A-point) or on both sides of the sun at the same elevation (Soret [63]). In a polariscope the fringes are visible even over the water surface, in the sun's vertical, with a dark central band (positive); in other directions they show a bright central band (negative). In a position closer and closer to the observer as the direction approaches 90° from the sun's vertical, the negative fringes change rapidly into the positive, suggesting the existence of a series of neutral points, or better, the existence of a transition zone (*Umkehrzone*, Jensen [3, 30]) between the negative po-

larization (the plane of polarization horizontal) on the horizon and the positive polarization (the plane of polarization vertical) over the water surface around the observer. Similar phenomena over land were observed by Brewster as early as 1841.

The biggest anomalies in the described distribution of polarization were observed after the volcanic eruptions of 1883–1885, 1902–1903, and 1912–1914. The effect of the volcanic dust present in the atmosphere could be noticed in the extraordinarily low values of the degree of polarization. In 1884, Cornu [18] observed the rapid decrease of the maximum polarization from 0.75 to less than 0.48; Dorno's mean values for the zenith and $h_s = 0°$ were $P = 0.557$ for 1913 and $P = 0.739$ for 1915. A very rapid increase of P during twilight also appeared (Kimball [38]). Much larger effects could be observed in the positions of neutral points.

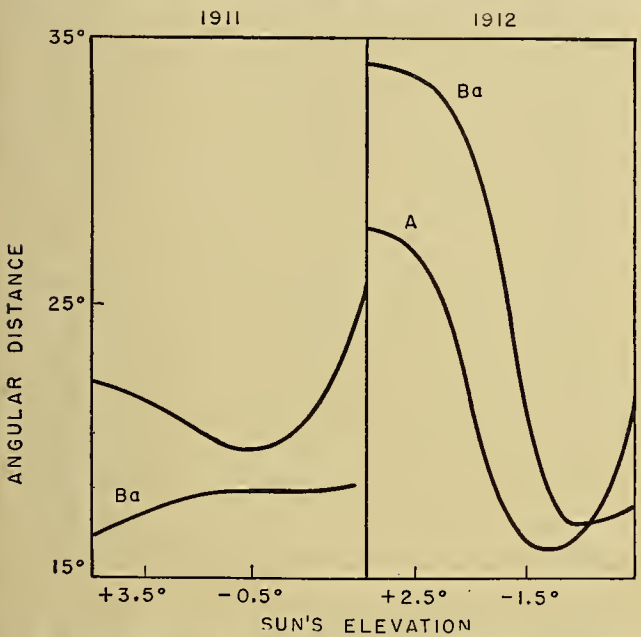

FIG. 3.—Distance of the Babinet point (*Ba*) from the sun and of the Arago print (*A*) from the antisolar point for different sun's elevations h_s. (Normal conditions—1911; after volcanic eruption of Katmai—1912).

Besides the ordinary *A*- and *Ba*-points, Cornu [18] observed four neutral points symmetrically situated at the same elevation on both sides of the sun and the antisolar point. The distances of the *A*-point and *Ba*-point increased; the largest increase, however, was observed in 1902, and was more pronounced for the *Ba*-point, as was also observed to be true in 1912. In Fig. 3 the mean values are compared for years with and without this effect; with respect to the *A*-point, the effect mentioned above, namely the increase of the distance, is clearly shown and the shift of minimum towards larger solar depressions also appears. The effect on the *Ba*-point curve is so great that its character is completely changed; the curve is shifted to the other side of the *A*-point curve.

Theory of Skylight Polarization

The first correct step toward the explanation of skylight polarization was made by Lord Rayleigh [50] in 1871. He explained skylight polarization as the scattering of sunlight on molecules and submicroscopic particles with diameters much smaller than the wave length of the incident ray of light. If it is assumed that the scattering process takes place only once (primary scattering) and if refraction is neglected, the degree of polarization of partially polarized light in the direction φ from the sun's rays,

$$P = (\sin^2 \varphi)/(1 + \cos^2 \varphi), \tag{1}$$

is a function of φ only. The maximum polarization occurs in the direction 90° from the sun, where the light is totally polarized ($P = 1$). There are two neutral points: one in the direction towards the sun, and one toward the antisolar point. Elsewhere the light is partially polarized with the plane of polarization defined by the sun, the observer, and the observed point in the sky. The theory agrees quite well with the observations with respect to the position of the point of maximum polarization and of the plane of polarization. But it does not explain the partial polarization at the point of maximum polarization and the existence of the observed neutral points. The assumptions of Rayleigh's theory are apparently not satisfied exactly in the atmosphere. The scattering particles are not isotropic and the theory should be modified for anisotropy of molecules (Cabannes [12]). The expression (1) then takes the form

$$P = (1 - a)\ (\sin^2 \varphi)/(1 + \cos^2 \varphi + a \sin^2 \varphi) \tag{2}$$

in which $a = 0.043$ is the coefficient of depolarization. Thus the maximum polarization at $\varphi = 90°$ is $P = 0.922$, but the position of the neutral points is not affected by the anisotropy of molecules.

The effect of secondary scattering, omitted in Rayleigh's theory, was studied as early as 1880 by Soret [64]. In the first approximation he considers only the light scattered by particles assumed uniformly distributed in a ring around the horizon. In the center of the ring, with the sun at the horizon, the intensity of the light scattered by all particles in the ring has the components

$$i_x = \pi b/4 = i_z/8, \qquad i_y = 3\pi b/4 = 3i_z/8, \qquad i_z = 2\pi b, \qquad (b = \text{const}). \tag{3}$$

Since the vertical component is predominant, the scattered light is negatively polarized in all directions along the horizon. In the direction 90° from the sun the component i_x is added to the primary scattered light, that is, the light is partially polarized. The neutral points are displaced to the positions where the positive polarization due to the primary scattering is compensated by the negative polarization of particles in the ring around the horizon. The distances of neutral points can be computed from relation (2) (*cf.* van de Hulst [68]). If P_1 and P denote the intensities of primary scattered light normal or parallel to the plane of polarization, and S_1 and S the intensities of secondary scattered light from the ring around the horizon, then a neutral

point appears in the sun's vertical at the elevation h, provided that in this direction

$$P_1 + S_1 = P + S. \tag{4}$$

For the sun at the horizon, $P/P_1 = \cos^2 h$. The intensities S_1 and S are normal to the direction h, and thus $S_1 = i_y$, $S = i_x \sin^2 h + i_z \cos^2 h$, and from (3)

$$S/S_1 = (1 + 7 \cos^2 h)/3. \tag{5}$$

In (5) the intensities can be expressed by the total intensities $(P_1 + P, S_1 + S)$, and then if the ratio $R = (S_1 + S)/(P_1 + P)$ is known, the elevation of the neutral point is determined from the equation

$$\sin^2 h/(1 + \cos^2 h) = R(7 \cos^2 h - 2)/(4 + 7 \cos^2 h). \tag{6}$$

The most probable value of R lies within the limits $R = 0.1$ and $R = 0.2$, which gives $h = 16.7°$ and $h = 22.4°$, in good agreement with observation.

Ahlgrimm [7] extended Soret's computation for arbitrary solar elevation, neglecting the extinction and assuming only that the distribution of scattering particles is the same in all azimuths. The unknown distribution of scattering particles with height appeared in the integrand of integrals which could be evaluated by means of the transmission coefficients. Using the measured values by Abney,[1] Ahlgrimm was able to compute the degree of polarization due to the primary and secondary scattering in any arbitrary direction. The values of maximum polarization as a function of solar elevation are reproduced in Fig. 1, values of the polarization in the zenith in Fig. 2.

Consideration of secondary scattering thus brings a great improvement in the qualitative agreement of the theory with observations under normal conditions, but a quantitative agreement still cannot be reached. Tichanowski [66] extended Ahlgrimm's computations, considering the anisotropy of molecules and even the reflection from the ground, but without any quantitative improvement. The effect of atmospheric extinction and refraction was taken into account by Link [39]. In such a case the integration for secondary scattering cannot be performed in any analytic form and requires a tedious quadruple numerical or graphical quadrature. Unfortunately the computations were made for the depressions of the sun for which no observations are available yet.

Comparison of the theoretical curve of the *Ba*-point with that obtained during the period after volcanic eruption suggests the presence of another mechanism which may be even much stronger than the effect of secondary scattering. The appearance of Bishop's ring and other twilight phenomena proved the presence of larger particles (according to Pernter [47] of a diameter from 3.2 λ to 6 λ) than assumed in Rayleigh's theory. The theoretical and experimental investigations of the scattering by particles of such a size, by Schirmann [55, 56] and later by Blumer [10], showed the possibility of neutral points already in the primary scattered light, and led Milch to the idea of using the presence of larger particles as an explanation of the deviation of the observed values from those given by Rayleigh's theory. Neglecting the effect of secondary scattering, Milch developed the following expression for the degree of polarization:

$$P = \frac{m_0 p + \mu_0 \psi f(h_s, T)}{m_0(p + n) + \mu_0(\psi + \nu) f(h_s, T)}, \tag{7}$$

where m_0 and μ_0 denote the number of molecules and large particles per unit volume at the ground; p and ψ, the intensity of the polarized part of the light scattered by molecules and by large particles respectively; $p + n$ and $\psi + \nu$, the total intensity in both cases of scattering; and finally, $f(h_s, T)$ is a function of the sun's elevation and the turbidity coefficient computed from the extinction values for different turbidities. This expression can explain all observed variation of the polarization with turbidity, but its use for the computation of P is very limited by the lack of knowledge of the functions ψ and ν. Assuming that at the point of maximum polarization ψ can be neglected with respect to p, Milch determined ν from the measured value of P for a given h_s, and computed the variation of maximum polarization with h_s. But the computed values showed a systematic deviation from the observed P.

In continuation of Milch's work, Blickhan [9] studied the correlation between the turbidity coefficient and the maximum polarization measured simultaneously. The values of P lie along a hyperbola $P = A/(B + T_k)$ in a (P, T_k) – diagram (T_k is the turbidity coefficient for short-wave radiation, and A and B are constants), in good agreement with the simplified formula (7). Extrapolating P by means of this empirical formula for an atmosphere without large particles ($T = 1$), he obtained a value of P for $h_s = 50°$, which is larger than that obtained for $h_s = 32.5°$, in agreement with Ahlgrimm's computation. From the difference between the extrapolated values and those computed by Ahlgrimm, assuming further that the light reflected from the ground is not polarized, Blickhan was able to compute the albedo $a = 0.132$, which is in good agreement with Dorno's values. For the computation of the daily variation of maximum polarization he used Milch's procedure, but with the difference that in (7) he inserted for p and n the values computed by Ahlgrimm. The values obtained in this way agreed with the measured ones much better than if the effect of the secondary scattering had been neglected. Other simultaneous measurements of polarization and turbidity were made by Wörner [70]. The polarization was measured this time at the zenith and was compared with the normal values computed by Jensen [2] (Fig. 2). The degree of polarization expressed in per cent of normal values

Table II. Polarization at Zenith (per cent of normal value) as a Function of Turbidity

T	2.0–2.5	2.51–3.0	3.01–3.5	3.51–4.0	4.01–5.0	>5.0
P	114.4	112.0	104.0	102.8	93.2	68.3

1. Abney's values are reproduced in [5].

shows a close correlation with the turbidity factor, as may be seen from Table II. Jensen's normal values correspond thus to the turbidity factor 3.9.

In connection with Milch's and Blickhan's work the recent investigation of Tousey and Hulburt [67] should be mentioned. The brightness and the polarization of the daylight sky were measured at different altitudes up to 10,000 ft. The curves of polarization with height showed clearly a much slower rise after a rapid increase within the first 2000 or 3000 ft, closely resembling the distribution of the turbidity coefficient with height [41]. They compared the measured values with theoretical values obtained on the assumption that the secondary scattered light is unpolarized, but taking full account of the extinction defined by a mean value of the theoretical extinction coefficient $\beta = 0.0126$ km^{-1}. They found that a somewhat better agreement for larger distances from the sun can be obtained with β increased to 0.017, 0.018, or 0.021 km^{-1}. The systematic deviations in the vicinity of the sun, expected by the authors, are caused by the assumption above, eliminating the neutral points around the sun. The increase of β proves without doubt the presence of larger particles, sufficient to increase the theoretical scattering by about 35 per cent. The increased values of β mentioned above correspond to the turbidity coefficient $T = 1.35$, 1.43, and 1.67, respectively. These values are in very good agreement with the measured values mentioned above [41], indicating the real presence of larger particles rather than a systematic error in taking too wide a spectral range, as suggested by van de Hulst [68]. In the theoretical computation the reflection by the ground was taken into consideration and the variation of the maximum and zenithal polarization due to the different values of the albedo is given in Table III.

Table III. Effect of Ground Reflection on Skylight Polarization

Albedo a	0.0	0.1	0.2	0.4	0.6
Tousey and Hulburt [67]					
P (maximum): $h_s = 30°$	0.85	—	0.755	0.667	0.612
P (at zenith): $h_s = 30°$	0.527	—	0.482	0.439	0.408
Chandrasekhar [16]					
P (maximum):					
$h_s = 0°$	0.918	0.903	0.885	—	—
$h_s = 13.9°$	0.906	0.860	0.801	—	—
$h_s = 39.8°$	0.906	0.796	0.673	—	—
P (at zenith):					
$h_s = 0°$	0.918	0.903	0.885	—	—
$h_s = 13.9°$	0.824	0.779	0.727	—	—
$h_s = 39.8°$	0.392	0.360	0.315	—	—

The mean value of the measured albedo, $a = 0.20$, was taken for the computation, and for this value the theoretical degree of polarization at zenith, $P = 0.482$ for $h_s = 30°$, and $P = 0.724$ for $h_s = 15°$ may be compared with the values of P computed by Ahlgrimm (0.469, 0.738); and for $h_s = 25°$ the observed value $P = 0.58$ may be compared with the theoretical value $P = 0.572$ (Ahlgrimm 0.558).

From the discussion above it is quite evident that a better quantitative agreement between measurement and theory can be achieved when the original Rayleigh theory is extended by a consideration of (1) the effects of multiple (at least secondary) scattering, extinction, and reflection by the ground, and (2) the effect of the presence of large scattering particles. The effects mentioned first can lower Rayleigh's theoretical values to the observed values and explain the existence of neutral points in observed positions; but for the explanation of the great variety and magnitude of diurnal, interdiurnal, seasonal, and secular variations the highly variable content of larger particles in the atmosphere must be considered. This is more evident if the dispersion of polarization is taken into account. The presence of larger particles can best be taken into account in the quantitative analysis, however, by separating and subtracting the effect of molecular scattering as a simpler and more nearly constant factor. For this purpose the recent theoretical investigations of similar problems in astrophysics offer excellent help. In a very elegant way, Chandrasekhar succeeded in reducing the exact solution of quite general multiple scattering to a solution of two relatively simple integral equations of a form suitable for successive iteration. Once the solution of these equations is known, the exact problem is solved. The great advantage of this method is not only that the extinction is very simply taken into account, but mainly that the effect of ground reflection can be included, as proposed by van de Hulst, and that the method can be extended for a more general law of scattering than in Rayleigh's theory [13, 14, 15].

Chandrasekhar has recently accomplished the numerical computation of the effect of multiple scattering and of the ground reflection in the skylight polarization for a special value of the optical thickness $\tau = 0.15$, corresponding to $\lambda = 450$ $\mu\mu$ under normal conditions [16]. The reflection on the ground affects the position of neutral points very little, in agreement with observation (Neuberger [46]). A much larger effect is noticeable in the degree of polarization at zenith or at 90° from the sun. It is evident from Table III that the ground reflection is responsible for the daily variation of the maximum polarization, namely for the decrease of P with the sun's elevation, in the sense of Fig. 1. The theoretical values for P are still much higher than the measured ones.

The observed distances of the neutral points are also much higher than the theoretical values obtained by Chandrasekhar (for $h_s = 0°$: A-point, 19.4° and Ba-point, 19.4°; for $h_s = 13.9°$: A-point, 20.9° and Ba-point, 18.7°). However a remarkable agreement was found between the theoretical shape of the neutral lines and the shape of neutral lines observed by Dorno [22]. Larger scattering particles apparently affect primarily the magnitude of the polarization, and the position of the neutral points, but have only a slight effect on the position of the plane of polarization. This fact is an interesting aspect of the physics of scattering by larger particles and as such should be studied more extensively.

Chandrasekhar's method of exact evaluation of the molecular scattering makes possible a quantitative

study of the presence and the nature of larger scattering particles. If the exact values of molecular scattering are subtracted from the observed values, the remaining part is the effect of larger particles, and it is quite evident that, for such a purpose, observations should be used in which the deviation from the theory is most pronounced. This seems to be the case in the dispersion of skylight polarization.

Dispersion of Atmospheric Polarization

The discussion of polarization in the preceding section refers to "white" light, as it is observed directly by the human eye. The measurement of polarization in much shorter spectral ranges was started very early in skylight investigations. In 1884, Cornu [18] found the degree of polarization to be different for different colors. During this period of volcanic anomalies the polarization at shorter wave lengths was much larger than for longer wave lengths. The dispersion of polarization has been studied since that time by several au-

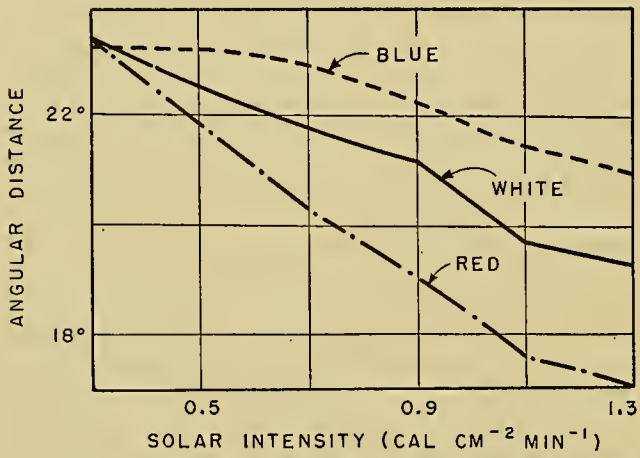

FIG. 4.—Distance of the Arago point from the antisolar point for $h_s = 10.5°$, in different colors for different intensities of solar radiation (*according to Neuberger*).

thors with one result confirmed by all, namely, the great variability of the dispersion with the turbidity, and thus with the weather, location, etc. Since the turbidity was not actually measured (except in the latest studies), the different results which have been attained are very difficult to compare. If the relativity of the terms "pure" and "turbid" atmosphere is admitted, then the contradictory results of different authors, even recently considered inexplicable [3], can be ordered to show a definite trend, confirmed by theoretical considerations. For very low turbidity (high altitude) the degree of polarization at the point of maximum polarization increases with the wave length [65]. With increasing turbidity, the maximum is shifted to the central part of the visible spectrum and the difference between polarization in the red part of the spectrum (P_r) and in the blue part (P_b) is decreased (for "pure air" in Gockel's definition the difference $P_r - P_b$ becomes smaller than the errors of observation). With still larger turbidity the maximum is shifted to the blue part, that is, $P_b > P_r$ [22, 25, 34, 48, 65].

The measurement of distances of neutral points in different colors was started by Jensen [1] in 1909. The results of his measurements were confirmed by Busch [11], who found that the distances of the A-point were larger the shorter the wave lengths. During the abnormal period 1912–14, just the opposite was found. This result was recently confirmed by Neuberger [45, 46] in his measurement of the A-point at $h_s = 10.5°$. Along with the A-point distances, the intensity of solar radiation, the blue color of the sky, etc., were measured and the variations of A-point distances with the turbidity were proved to be as shown in Fig. 4.

The dispersion of polarization is thus very sensitive to the degree of turbidity and could be used as another indicator of turbidity. But it can also be used for answering the question about the prevailing effect of the molecular scattering, or of the presence of larger particles in the atmosphere. It is evident that in Rayleigh's theory of primary scattering there is no dispersion, since the degree of polarization P is independent of λ. If it is assumed with Milch that the light scattered by large particles is unpolarized, the component of the total intensity due to the scattering on large particles can be expressed in the form $F_g = \lambda^{-\alpha} Nf(\varphi)$, where α decreases from 3.5 to 1 with increasing size of particles, N denotes the number of such particles per unit volume, and φ is the scattering angle. It can easily be shown [59] that the sign of the difference $P(\lambda) - P(\lambda_0)$ is determined by the sign of the expression

$$[p/P(\lambda_0) - 1](1 - \chi^4) + (\chi^4 - \chi^{\alpha-4})F_g(\lambda_0)/I_g(\lambda_0), \quad (8)$$

where p denotes the degree of polarization in Rayleigh's theory of primary scattering, given in equation (1), $\chi = \lambda_0/\lambda$, and I_g is the total intensity of the component due to the primary scattering. If the turbidity is small, $F_g \to 0$ and $P(\lambda) > P(\lambda_0)$ whenever $\lambda > \lambda_0$. With increasing turbidity ($F_g > 0$), the second term in (8), having an opposite sign from the first one, reduces the difference $P(\lambda) - P(\lambda_0)$ and for a sufficiently large turbidity reverses the sign of $P(\lambda) - P(\lambda_0)$. The variation of the dispersion with increasing turbidity can thus be explained in agreement with observation. But the discussion of the distance of the neutral points for different wave lengths shows clearly that the assumption made by Milch, that the light scattered by large particles is unpolarized, is not justified. If the light scattered by large particles is assumed to be unpolarized, the distance of neutral points is given by equation (4) written in the form

$$P_1(\lambda_0) \sin^2 h_0 = S(\lambda_0, h_0) - S_1(\lambda_0, h_0),$$

and for $\lambda \neq \lambda_0$,

$$P_1(\lambda_0) \sin^2 h = \chi^4 [S(\lambda_0, h) - S_1(\lambda_0, h)].$$

Since S_1 is actually independent of h, S can be expressed by S_1 and the ratio $S_1(\lambda_0)/P_1(\lambda_0)$ can be eliminated from these two equations. The resulting equation can be written in the form

$$\sin^2 h - \sin^2 h_0 = (\chi^4 - 1) \sin^2 h_0 \frac{5 - 7 \sin^2 h_0}{5 + 7(\chi^4 - 1) \sin^2 h_0}. \quad (9)$$

Since $h_0 < 30°$, the numerator and the denominator in (9) are always positive, and $h > h_0$ whenever $\lambda_0 > \lambda$. The distances in blue are larger than in the red part of the spectrum, in agreement with the observation made for very low turbidity. However, the computed difference $h - h_0$, for a given h_0 and given wave lengths λ, λ_0, is about twice as large as observed. What is more serious, the great variability of this difference with increasing turbidity cannot be explained by (9). The effect of increasing turbidity can be taken into consideration only by increasing h_0, but the right-hand side of (9) increases with h_0 instead of the observed decrease to negative values. This may serve as a proof of the incorrectness of the assumption made above. For a complete discussion it is necessary to include the polarized component due to the scattering by large particles also. This can be done only by using the Mie-Debye theory, as discussed in detail elsewhere [59]. By constructing a special model of the distribution, size, and optical properties (refractive index) of the large particles, the dispersion of polarization can be computed and compared with the observed values through a procedure similar to that used in the study of atmospheric haze [28, 51, 60] and thus a model of the distribution which best fits the observations can be found.

Polarization Anomalies During Twilight

The same information concerning the size, nature, and distribution of scattering particles in the atmosphere can be obtained from any deviations of observed values of skylight polarization from those to be expected from Rayleigh's theory. Particular emphasis has been placed on anomalies during twilight (because of the easily determined changes in illumination along the vertical line to the zenith) with the hope that more information can be obtained about the vertical distribution of scattering particles in this way. But the use of twilight anomalies is not as simple as it would seem. The first difficulty is the rapid decrease of the intensity of skylight, which causes serious difficulties in polarization measurement. Visual methods quickly become uncertain and are very seldom reliable for solar depressions beyond $h_s = -5°$ or $-6°$. The photographic method requires longer exposures during which the eventual fluctuations in the degree of polarization and in the position of the plane of polarization may cause large systematic errors.

In theoretical investigations the atmosphere can no longer be considered as plane-parallel, and refraction must be taken into consideration at least to the extent of estimating the limit of the earth's shadow. The ground reflection, acting for low solar depressions only on one side of the horizon, and the different extinction values in the solar and antisolar regions make the computation of the sky polarization rather complicated. With respect to the effect of secondary scattering, it is valid to offer the same criticism which was presented against the use of the zenith intensity for optical sounding of the upper atmosphere. As Hulburt [27] pointed out, the intensity of the secondary scattering increases rapidly in comparison with the intensity of primary scattering, so that for solar depressions larger than 8°, the secondary scattering from the lower level has a greater intensity than that of the primary scattering from the upper levels still illuminated by direct rays from the sun. Hulburt's estimate of this effect was based on the measured intensity of skylight near the western horizon; the presence of larger particles was thus taken into consideration. This may explain the much larger values for the ratio of the intensity of the secondary and primary scattering (I_{prim}: I_{sec} = 1:185, $h_s = -10°9'$) than computed by Link [39] (I_{prim}: I_{sec} = 2:1) under the assumption of molecular scattering only. For this reason it is quite difficult to explain the high correlation of the polarization anomalies (sudden or nonmonotonic decrease of P in the zenith for sun's depressions larger than 10°) with the changes in the ionization of the E- or F-layer, as observed by Khvostikov and a group of Russian scientists. The first attempt to explain the anomalies as being associated directly with the increase of anisotropy of the ions as compared to neutral particles [35, 36, 52] was found by Ginsburg [23, 24] to be unacceptable because of the predominant effect of the secondary scattering. The polarization caused only by secondary scattering under such conditions was recently estimated by Rosenberg [53] as being even larger than observed. The observed rotation [49] of the plane of polarization from the direction given by the position of the sun cannot be explained simply by the asymmetry in the solar illumination and should be studied more closely in relation to the problem of fluorescent luminescence or other types of emission of the night sky. For the study of the emission layer the scattering of the emitted light is very important and can be used for the determination of the height of the emission layer [8]. Since the secondary scattered solar radiation may be superimposed upon the light from the emission layer, the dispersion of polarization of the twilight or night sky could be used for separating the phenomena of the lower atmosphere from those of the upper levels. Because of experimental difficulties there is little hope for the effectiveness of this method in the near future. The only possible way of separating the intensity of the polarization produced in lower levels from the phenomena related to upper levels is to compute these quantities using the extinction coefficient and other parameters of scattering in lower levels, obtained by independent measurements. For this purpose the method of an artificial light source seems to be quite adaptable. The searchlight beam has been used and information about the type and the law of scattering has been derived mainly from the total intensity measurement [28, 29, 33, 51, 60]. More information can be obtained, however, if the measurement of the polarization is added, as has been done by Khvostikov [35]. But since the brightness of the searchlight beam decreases with the distance from the source, the secondary scattering in lower levels should be carefully taken into consideration before any conclusions are made about scattering in higher levels.

The searchlight-beam method definitely offers quite new possibilities and if properly used may contribute

largely to the solution of the problem of light scattering in the atmosphere.

Unsolved Problems and Future Research

As was shown in the preceding sections, much valuable information can be obtained from a comparison of measured and theoretical values. Therefore future research depends primarily upon the development of both experimental and theoretical methods. First, there is a definite need for better equipment for measuring skylight polarization. Such equipment should permit objective, fast, and precise measurements of the degree of polarization and of the position of the plane of polarization, in comparatively narrow spectral ranges, in all directions over the sky, with special provision for measurement of weak polarization, thus being adaptable also to the measurement of the neutral points. Speed in measurement is required not only for almost simultaneous measurements at different wave lengths and at different places in the sky, but mainly for the possibility of recording the shorter fluctuations observed in the degree of polarization [57] as well as in the position of neutral points [45, 46]. These fluctuations, not observable by the older methods or eliminated by improper smoothing, seem to precede cloud formation in a clear sky, and might be used in the study of condensation processes in incipient clouds. With sensitive photomultipliers and with a proper amplification, the sensitivity of measurement can be increased beyond that of the human eye, and observations can be extended far into the twilight or used for optical sounding by searchlight beams.

From the theoretical standpoint, Chandrasekhar's computations can easily be completed, and skylight polarization due to multiple molecular scattering can be computed, in all directions and for all wave lengths, for larger solar elevations when the atmosphere can be considered as plane-parallel. But the greatest advantage of this method is that it can be extended in such a way that almost all currently unsolved problems of atmospheric polarization can be solved. In the case of reflection at the ground, if, for example, the polarization according to Fresnel's law were taken into consideration as observed in the vicinity of large water surfaces [26], the anomalies mentioned earlier could be explained theoretically. If the Mie-Debye theory of large-particle scattering could be simplified in such a way that the corresponding scattering matrices could be computed without essential difficulties, the effect of large particles could also be taken into consideration. So far Chandrasekhar's theory has been limited to a plane-parallel atmosphere, and twilight anomalies have been unaccessible to theoretical investigation of similar type. Chandrasekhar [14, 15] already has shown the way to extend the theory for a spherical atmosphere. It is necessary only to work out the suggested method in more detail. The exact theory of twilight phenomena cannot, however, be developed without the consideration of refraction and the corresponding bending of light paths in the atmosphere. This part of the problem does not represent any special difficulty since complete refraction tables, with all the parameters necessary for such a computation, are now available and can be conveniently used for this purpose [40].

Hence, many problems quite accessible by modern facilities are open to further investigations. In the review given above, the list of problems to be solved is not exhaustive; new problems may easily arise as the study of skylight polarization progresses further. For this reason atmospheric polarization deserves more attention than it has received up to now.

VISIBILITY IN METEOROLOGY

By W. E. KNOWLES MIDDLETON

National Research Council, Canada

Introduction

This discussion will be devoted to a brief study of those interrelations between the optical properties of the atmosphere and the characteristics of human vision which determine how far a given object can be seen at such and such a moment. This important distance, when referred to the ordinary objects which lie around the horizon of a meteorological observer, is called by meteorologists "the visibility"; it is not with any hope of changing this terminology, but only in the interests of logical discussion, that the same quantity, applied now to *any* object, will here be given the name *visual range*. The term is self-explanatory.

The theory of the visual range is by this time in a fairly satisfactory condition, largely because of very extensive researches conducted during World War II, especially in the United States. As in many other divisions of meteorology, however, the extreme complexity of atmospheric conditions makes it difficult to apply the available theory to actual instances, especially in the important case of visual range along inclined paths. Even the instrumentation necessary to measure the appropriate optical constants of the atmosphere has not been developed to the point where it is in general use at meteorological stations. Theory is well in front of practice.

We are unable to refer the reader to any very up-to-date summaries of the whole field; in fact to nothing later than 1941 [33, 35]. In view of our restrictions on space we must assume that at least one of these two monographs is available to the reader. It is to be hoped that before very long a more up-to-date general account will be published.

The Behavior of Light in the Atmosphere

Light, by its interaction with the atmosphere, produces many beautiful phenomena which are dealt with elsewhere in this book. Our concern here is only with the way in which it is attenuated in its passage through the air and with the manner in which it is diffused by scattering.

As far as any practical interest is concerned, we may neglect those rare occasions when the air is nearly free from particles larger than the molecules of gases, in view of the fact that the visual range in such a pure atmosphere would be several hundred kilometers at sea level. The reader may be referred to Cabannes [10] for a masterly discussion of such molecular scattering. On all occasions when the visual range is of any practical importance, by far the greater part of the effect of the atmosphere on light is produced by particles much larger than molecules, which may be thought of as the disperse phase of an atmospheric colloid or aerosol.

These particles are of many kinds, but from our standpoint the most interesting of them are the liquid droplets, generally aqueous solutions of hygroscopic substances, which in various radii from about 10^{-6} to 10^{-1} cm form the obscuring matter in haze, fog, and mist. The actual nature of the hygroscopic nuclei involved is one of the great unsolved problems of meteorology, and has become the subject of a controversy, for the details of which the reader should consult Wright [52, 53, 54, 55, 56], Simpson [43, 44] and Findeisen [21]. Whatever their nature, they increase in size with increasing relative humidity, as more and more water condenses on them. Up to a radius of about 0.5 micron (5×10^{-5} cm) they show selective scattering in visible light which makes them appear bluish by reflection, and we call them *haze*. With further increase in size, this selectivity practically disappears, and we have *fog*, which is typically colorless. We must now consider in a little more detail the scattering of light by such spherical particles.

For particles of radius a in the range $0.1\lambda < a < 10\lambda$ (λ = wave length of light), which includes most kinds of haze and some fogs, the theory of Mie [38][1] has been found entirely adequate. Starting with the electromagnetic theory, Mie was able to calculate the intensity I (lumens per steradian per particle per lumen per m^2 illuminance) in a direction making an angle ϕ with that of the incident light. This is a function of $2\pi a/\lambda$ and of m, the index of refraction of the particles (1.33 for water). To show the large variation of the polar diagram of the scattered light with the radius of the particle, Fig. 1 is presented, the limiting value as $a \to 0$ being shown by a dotted curve (Rayleigh atmosphere).

By integrating $I(\phi)$ over the sphere, the total amount of light scattered may be calculated, and it is found that this is generally greater than that incident on the droplet. For large droplets the ratio K of these quantities approaches 2, and the explanation is to be found in diffraction. Since K has been calculated [30, 47] as a function of the parameter $2\pi a/\lambda$, the coefficient of attenuation by scattering for an atmosphere containing N droplets per m^3, each of radius a, is

$$b = NK\pi a^2 \quad \text{meter}^{-1}. \tag{1}$$

In such droplets, as has been shown by Zanotelli [57], absorption is negligible, so that the extinction coefficient σ is also given by equation (1).

The correctness of these ideas is now acknowledged, and they have been remarkably well verified in natural haze by Dessens [15, 16], who caught haze particles on minute spiders' webs.

For the larger droplets of fog, Bricard [8, 9] has

1. Concisely set forth by Stratton [46, p. 563].

produced an adequate geometrical theory of scattering, serving as an extrapolation of the Mie theory. Many workers, notably Houghton and Radford [26] and Bricard [6, 7], have measured the size distribution in natural fogs, obtaining unimodal curves with maxima in the region between 4 and 10 microns radius. Such fogs should be nearly nonselective. All these researches may be criticised on the basis of sampling, especially since Driving and his co-workers [18] have presented indirect evidence for the presence of large numbers of very small droplets. Such evidence is hard to obtain because, as Dessens [15] points out, the total optical effect of these small particles is not very important.

The researches of Dessens should be repeated and an attempt made to extend them to natural fogs in order to decide this point. It is also possible that the use of the electron microscope in such work might settle the controversy about the nature of the nuclei. Another line of research which might be undertaken in some sparsely inhabited region concerns the explanation of

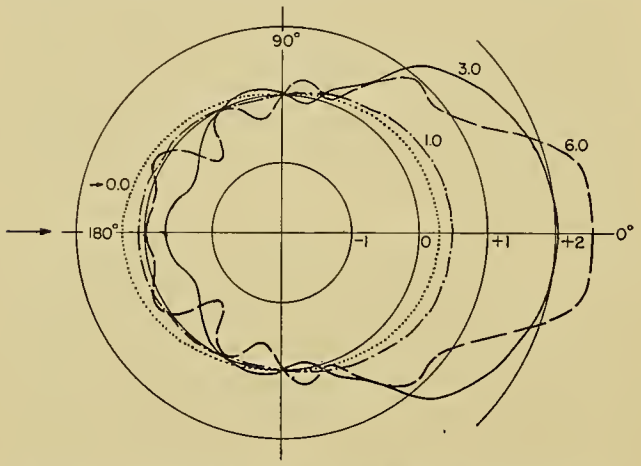

FIG. 1.—Polar diagram of scattering by water droplets, normalized at 90°. The radii are in log units. The numbers on the curves refer to values of $2\pi a/\lambda$.

the surprisingly low selectivity shown by very clear air such as occasionally permits a visual range of 150 or 200 km. Observations, chiefly in Europe, never seem to show anything like the inverse fourth power of the wave length demanded by the theory for pure gases. As a hypothesis, one may assume the effect of a comparatively small number of relatively large particles.

The Reduction of Contrast by the Atmosphere

The common observation that the more distant an object, seen in daylight, the greater its luminance, was first reduced to mathematical form in 1924 by Koschmieder [29]. The simplest case is that of a black object of intrinsic luminance zero seen against a horizon sky of luminance B_h. On the assumption of a uniform atmosphere having a scattering coefficient b_0, and illumination by the sun and a uniform (overcast or cloudless) sky, Koschmieder showed that such an object seen at a distance r will have an apparent luminance

$$B_b = B_h(1 - e^{-b_0 r}). \tag{2}$$

He further showed that an object which is not black, but has an intrinsic luminance B_0, will at a distance r have an apparent luminance

$$B = B_0 e^{-b_0 r} + B_h(1 - e^{-b_0 r}). \tag{3}$$

We cannot calculate B_0 without knowledge of the distribution of light, even if we know the properties of the object.

In these equations no mention is made of absorption, and while it is customary to write similar equations using σ instead of b, it is not immediately obvious how such an extension can be justified. Actually a more detailed analysis, using the concept of the space light B_a, which is a function of the scattering properties of the air and of its illumination, does lead to an equation

$$B = B_0 e^{-\sigma_0 r} + B_h(1 - e^{-\sigma_0 r}). \tag{4}$$

Such an analysis has been carried out by Duntley [19], who also threw off the restriction of horizontal vision and introduced a quantity $\bar{R}$ which he called the *optical slant range*, which "represents the horizontal distance in a homogeneous atmosphere for which the attenuation is the same as that actually encountered along the true path of length R" [19, p. 182]. The equation for downward oblique vision becomes

$$B = \frac{B_a(0)}{\sigma_0}(1 - e^{-\sigma_0 \bar{R}}) + B_0 e^{-\sigma_0 \bar{R}}, \tag{5}$$

in which $B_a(0)$ and σ_0 are the values of B_a and σ corresponding to the air near the ground. In the horizontal case it turns out that B_h is to be identified with $B_a(0)/\sigma_0$.

A more useful statement of the law may be made in terms of *contrast*. If B_0 and B_0' are the inherent luminances of two objects adjacent in the field of view and B_R and B_R' their apparent luminances, then defining contrast in the usual way,

$$C_0 = \frac{B_0 - B_0'}{B_0'}, \qquad C_R = \frac{B_R - B_R'}{B_R'}, \tag{6}$$

we may write two equations such as (5) and simplify to obtain

$$C_R = C_0(B_0'/B_R')e^{-\sigma_0 \bar{R}}. \tag{7}$$

This is completely general. If we confine ourselves to objects seen against the horizon sky, $B'(= B_h)$ is independent of distance, and (7) reduces to

$$C_r = C_0 e^{-\sigma_0 r}. \tag{8}$$

We have not space to expound the theory further in its applications to oblique vision, but it should perhaps be pointed out that practical situations generally require information which, at best, has to be estimated.

Equation (8) has been tested more or less thoroughly by many workers, and there is no longer any doubt about its adequacy. A matter about which there is some disagreement, however, is the exact nature of the extinction coefficient σ. In deriving equations similar to (5), Duntley [19] has made use of a theory originally developed by Schuster [41] which dealt with the distribution of diffuse radiation in stellar atmospheres. The

extinction coefficient used, which was introduced by Duntley, is that pertaining to diffused radiation. The present writer believes that this is incorrect. The only portion of the light from an object which goes to form an image of it is that which reaches the eye from the direction of the object and it would seem logical to use the extinction coefficient for directed light in such a discussion. It seems probable that the choice of the other quantity was conditioned by a desire to explain some results of Douglas and Young [17] which suggested that the value of σ determined by the photometry of a projector is slightly less than that calculated from (8). The author has recently shown [37] that the discrepancy may arise from other causes. It would nevertheless be a comfort to have a long series of simultaneous measurements of σ by the two methods, especially in fog.

The Relevant Properties of the Eye

If we are to use equations such as (7) to determine the visual range of objects, it is obvious that we need to know the least value of contrast that the eye can appreciate. Similarly, if we are interested in the visual range of light signals, we need data on the threshold illuminance E_t at the eye. This can easily be transformed into a contrast limen, so that one set of data is really sufficient for both problems.

The eye can exist in two states of adaptation, known as the dark-adapted and light-adapted conditions, the transition taking place at a field luminance of about 2×10^{-3} candles m^{-2}. The reader may be referred to Stiles, Bennett, and Green [45] for a discussion of the properties of the eye in the two states and we shall only note here that color vision is restricted to the light-adapted state.

It has been known for a long time that the threshold of contrast increases at low values of luminance and for objects of small angular subtense. In meteorology it has become a sort of convention to adopt a value $\epsilon = \pm 0.02$ for ordinary objects in the daytime; but there is no doubt that this is frequently far from the truth. During World War II a very extensive investigation was made at the Louis Comfort Tiffany Foundation, and reported by Blackwell [4]. This report covers 450,000 observations of circular objects ranging from 0.6 to 360 minutes of arc in angular diameter, and over a very wide range of background luminance (5×10^{-4} to 4×10^{2} candles m^{-2}); Fig. 2 shows one set of curves interpolated from some of the results. Note the straight portions of the curves; over this range of visual angle the product of the area and the luminance of a stimulus (*i.e.*, its candlepower) is a constant; this is the range in which the signal can be considered a "point source," and values of threshold illuminance may easily be derived from the curves.

These curves refer to the contrast required for 50 per cent probability of detection by an observer using both eyes under natural conditions. For almost certain detection the values of contrast should be multiplied by 2 or at most by 3.

A recent field investigation by Blackwell [5] makes it highly probable that these laboratory values will also apply under field conditions, provided that the factors of attention and search do not enter. Other experiments [2, 11] indicate that vision through binoculars follows the same laws, provided that allowance is made for the reduction of contrast by the optical system.

The factors of attention and search remain to be investigated, as does the enormously complicated phenomenon of *recognition*, which also brings in the question of visual acuity, and is a matter worthy of the interest of any number of extremely able psychologists.

There have been many investigations of the threshold illuminance of lights and its dependence on field luminance (see [45]). While satisfactory absolute values can be derived from the Tiffany data, "practical" values have been sought, with the general result of about 0.2 lumens km^{-2} for fixed, achromatic sources on a moonless night. If the light is flashing, a somewhat greater illuminance is required for equal conspicuity, depending

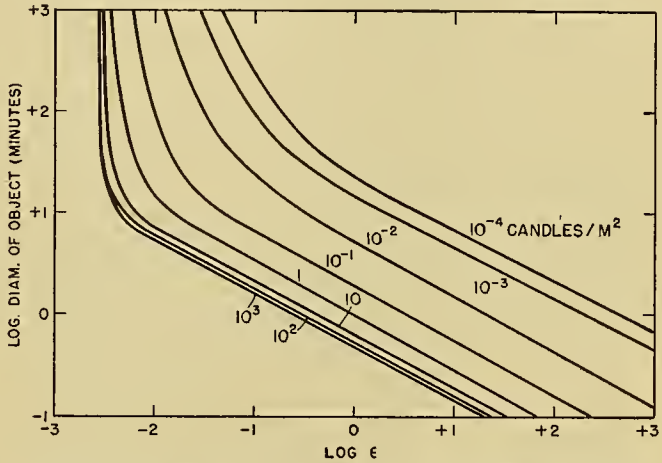

Fig. 2.—Threshold of contrast of circular objects, from the Tiffany data. Each curve refers to the background luminance marked.

on the time of the flash; this has been investigated by various authors (see [45]). Threshold illuminance varies with the color of the point source, and there are some papers [24, 25, 34] dealing with the recognition of colored lights. The general result of these investigations is to show that only red and blue-green are "safe" colors near their threshold illuminance.

The Calculation of the Visual Range

We are now in a position to combine the results of the last three sections and calculate the visual range of objects or of lights. For either computation we must know the extinction coefficient σ, and in the case of an inclined path of sight we must also know or estimate its variation in the vertical. We must know the contrast threshold appropriate to the angular size (and probably the shape) of the object and to the field luminance; or the threshold illuminance for a light of the characteristics concerned, against the existing background. There is really no fundamental difference between the

two cases, but it is simpler not to think of contrast when dealing with a point source of light.

Dealing first with the visual range of an object seen against the horizon sky, the problem is simply to put the proper values of C_0 and ϵ in equation (8) and solve for r. For a given object, which looks smaller as it becomes more distant, ϵ is unfortunately an empirical function of r.

The standard procedure, used by all writers until very recently, is to restrict the problem to "large" objects in full daylight; that is, to the approximately vertical portions of the curves at the extreme left of Fig. 2, so that ϵ may be considered constant. Meteorological writers have adopted a quantity variously called the *standard visibility* [53], *Luftlichtweite* [32] and, more recently, the *meteorological range* [20], calculated on the assumption that $\epsilon = \pm 0.02$. Let us call this V_m, and note that if it is referred to a black object ($C_0 = -1$) against the horizon sky, it is just a convenient substitute for σ_0; because if we write (8)

$$-0.02 = -e^{-\sigma_0 V_m} \tag{9}$$

and take natural logarithms, we obtain

$$V_m = 3.912/\sigma_0 . \tag{10}$$

The "meteorological range" is defined as "that distance for which the contrast transmittance of the atmosphere is two per cent" [20, p. 238].

If now we break away from the restrictions of a "large object" and full daylight, we immediately run into the difficulty that equation (8) can be solved only by a process of successive approximations. The awkwardness of this led the workers at the Tiffany Foundation to devise a remarkable series of nomograms [20], prepared for various levels of field luminance from overcast starlight to full daylight, from which the visual range of an object of any area may be read directly if its inherent contrast and the meteorological range are known. These nomograms were based on the actual Tiffany data referred to previously, and therefore correspond to a 50 per cent probability of detection. It is hoped that further nomograms will be forthcoming, based on a probability of detection much nearer unity, though the existing ones may be used for many purposes by dividing the inherent contrast of the object by 2 before entering the nomogram [20, p. 249].

The estimation of the inherent contrast of the object remains a stumbling block, except for the ideal black object. If we had a grey object of luminance factor β standing vertically under a sky of *uniform* luminance B_h, its inherent luminance would be $B_0 = B_h\beta/2$ and its contrast $C_0 = \beta/2 - 1$. A white object, for example, would have a contrast of $-\frac{1}{2}$, and this quantity has been used in a great deal of theory under the mistaken assumption that a densely overcast sky is uniform. Unfortunately its luminance is about three times as great at the zenith as at the horizon [39] and it has been shown [36] that, for a vertical white object, this results in values of C_0 between 0 and $+1$, depending on the reflectance of the ground. The complications naturally increase when the sun is shining.

Turning now to oblique paths of sight, we have the remarkably ingenious theory of Duntley [19] and the nomograms based on it [20]. The reader is asked to consult the two papers concerned, especially the first, which is far too long to summarize here, and to make up his own mind as to the practical utility of the theory. It may be that some "operational" research is indicated.

The visual range of lights at night presents a simpler problem. The illuminance from a source of I candlepower at a distance r in an atmosphere of extinction coefficient σ_0 is

$$E_r = Ir^{-2}e^{-\sigma_0 r}, \tag{11}$$

and the visual range is then given by introducing the threshold illuminance E_t:

$$E_t = IV^{-2}e^{-\sigma_0 V}. \tag{12}$$

A suitable nomogram may easily be constructed for the solution of (12). If oblique vision is involved, the problem of measuring or estimating σ remains.

Instruments for the Measurement of the Visual Range

Before we can calculate the visual range of any particular object or light signal, we must have a knowledge of σ or of V_m. A large number of different instruments have been designed for the measurement of these quantities, some requiring photometric settings on the part of the observer, others completely objective or even automatic, but none of them seem to be in use at any considerable number of meteorological stations.

Nearly all these instruments fall into four classes: (1) devices which measure the transmittance of a more-or-less extended sample of the atmosphere; (2) instruments which measure the reduction of known contrasts; (3) instruments which measure the light scattered from a small sample of air at one or many angles; and (4) empirical meters of various types which do not measure σ directly.

Transmittance meters form a fairly numerous class, which may be divided into two subclasses depending on whether they are usable only at night or at all times. Those for use only at night are generally visual telephotometers and may make use of a distant light, as for instance that of Collier and Taylor [13], or of a beam of light projected from the instrument and returned by a distant mirror, as that of Foitzik [22, 23]. For a very excellent discussion of visual telephotometers and their limitations the reader may be referred to a paper by Collier [12].

A similar duality of optical systems is found in photoelectric transmittance meters, which are often usable throughout the day and night. Those with a distant mirror, represented by that of Bergmann [3], can easily make use of a modulated light beam and a tuned amplifier to make them insensitive to daylight, and a null method of measurement to reduce the effect of fluctuations in the supply voltage. They have the disadvantage of complexity and very high cost. Simple photometry of a distant projector [17] is cheaper.

All telephotometers suffer from a serious contraction of their scales as the visual range becomes greater. It has also been shown by Middleton [37] that the beam must be made extremely narrow if very large errors are to be avoided in some kinds of weather.

Telephotometers have been devised which measure the ratio of the luminances of a distant object and the horizon sky just above it, as for example that of Löhle [31]. Difficulties of eliminating stray light, at least in any simple routine of observation, limit the precision of such instruments. Somewhat more practical, particularly with modern photoelectric circuits, is the measurement of the apparent luminance of a nearby deep black box, specially constructed for the purpose.

Scattering meters are not numerous. The "polar nephelometer" of Waldram [48, 49] which measures the light scattered by a sample of air in almost any direction is an excellent example. The "Loofah" [1] measures the scattering at 150°, which has been found to approximate a mean value under many conditions, especially at sea. All such meters fail under urban conditions because they take no account of absorption.

Finally there are any number of empirical instruments (Jones [28], Wigand [51] and others) which operate by the addition of "veiling glare" to the distant scene. Of these, the type most sound in theory was devised independently by Shallenberger and Little [42] in the United States, and by Waldram [50] in England. It is called the "disappearance range gauge" by Waldram, and presents the observer with two images of the horizon one above the other, of which the fainter may be made to disappear by turning a control. It is at least a valuable aid to visual estimation.

In spite of the very large number of instruments which have been devised, the problem remains open for solution; and perhaps it is largely an economic problem. The writer hesitates to predict the advent of a useful instrument at such a cost that meteorological services will give it wide distribution.

The Visual Range in Practice

In the absence of instruments, meteorological observers estimate "the visibility" by observing whatever objects (or lights at night) may be available around their stations. It is officially recommended [27] that dark-colored marks should be used in the daytime, and that they should be visible against the horizon sky whenever possible; also that they should be of reasonable angular dimensions. The Conference of Directors at Washington in 1947 also recommended a table [27, p. 118] which relates the visibility of lights to the daytime visibility code. This table was prepared on the basis of equations (10) and (12), using three different and highly arbitrary values of E_t, "pending the results of further investigation." We shall return to this matter in a moment, but first we wish to refer to resolution 169 of the same conference [27, p. 220], which sets forth the "Table for VV (Visibility)." This table proceeds in steps of 20 meters from 20 to 200 m, which is probably useful; but then it continues in steps of 200 m up to 16 km! It is unfortunate that the framers of the code omitted to provide instructions which would tell the unhappy observer how he is to distinguish between a visibility of 15.6 km and one of 15.8 km. Among the workers in this field it would be difficult to find one optimist who would expect even the most elaborate instrument to perform such a task.

In the absence of absurd requirements such as the above, the estimation of "visibility" in the daytime is a fairly satisfactory procedure if a reasonable series of suitable marks is available—not necessarily one for every distance in the code. It is otherwise at night. The central difficulty of night observations lies in the unknown and variable adaptation level of the observer's eye, accentuated by the fact that the observer has recently come from a brightly lighted room. In the absence of an instrument the observation is often the merest guess, and a suitable objective meter is greatly to be desired for use at night.

We shall close with a brief remark on the treatment of visibility observations as climatological data. The usual procedure is to count the number of occurrences of each code number, but it has been pointed out by Poulter [40] and by Wright [53] that this gives an undue prominence to the greater visual ranges. The expedients adopted by these two workers to improve the situation are very different. Poulter multiplied each frequency by the reciprocal of the range of distances embraced by the corresponding code number; Wright calculated what amounts to the mean extinction coefficient. Neither of these procedures involves much extra work and they should be given consideration by the climatologists.

Possibilities for Progress

It will be evident from what has been set down above that any further progress is likely to be made in the direction of experiment rather than theory. Our most hampering uncertainty concerns the value, or range of values, of the threshold of contrast actually entering into meteorological observations of "visibility," and some serious effort should be made to clear this matter up. The questions of attention and search are also in this domain of psychophysics, and could be the subjects of an immense amount of work. However, they are of military rather than meteorological interest.

On the physical side, the elegant researches of Dessens should be extended, and the question of the origin of the nuclei needs further expert attention.

There is also a need for new instruments: a simple, inexpensive one for use at many stations mainly, or even exclusively, at night; and a more elaborate telephotometer or other such "visibility meter" for important stations like aircraft carriers and large airports. In order to be of any use at all, an instrument of the latter sort would have to be very accurate, sensitive, and stable.

Finally, the applause of all meteorologists and aviators is certain to greet anyone who devises a really practical method of measuring the transparency of the atmosphere as a function of height for at least a few

thousand feet above the ground. This is certainly our leading practical problem in this subject.

UNIVERSAL ASPECTS OF ATMOSPHERIC ELECTRICITY

By O. H. GISH[1]

Lincoln, Nebraska

One becomes aware of weather through sensibility to heat or cold, calm or storm, brightness or gloom, but one's unaided senses do not reveal the ever-present universal aspects of atmospheric electricity. Of course one sees lightning and hears thunder, but these are heralds of an impetuous, stormy aspect of atmospheric electricity which is not universal. Lightning is seldom seen in the polar regions and even in temperate latitudes it is seen only a small fraction of the time. The study by Brooks [8] indicates that on one-fourth of the earth's surface thunder may be heard on less than one day in a hundred.

But everywhere on the earth, electric forces in the open atmosphere are readily detectible with instruments. Many measurements made in most representative regions of the earth show that (1) during fair weather the average electric field strength or potential gradient is usually more than 100 volts per meter, (2) the electric potential increases with elevation above the surface but the field strength, or the potential gradient, decreases, and (3) the direction of the electric field in fair weather is such that positive ions in the air drift towards the earth and negative ions drift away. One must infer from these observations of the electric field that the electric charge on the surface is always negative everywhere on the earth, except in the vicinity of thunderstorms or where drifting dust or some other local charge-generating process temporarily disturbs the normal aspect.

Another fact of fundamental importance is that air, in the open, is not a perfect insulator: Although the electrical conductivity of air is so small that for most practical affairs it need not be considered, this property does play an important role in determining the electric state of the atmosphere. For example, because of this property and the existence of an electric field, an electric current flows from air to earth and the average magnitude of this current, based on numerous measurements, is such that 90 per cent of the negative charge on the earth would be neutralized in thirty minutes. Despite this, the charge at the present time doubtless is about the same as it was one hundred years ago when Sir William Thomson (later Lord Kelvin) made the first reliable quantitative measurements of electric field strength.

How is the negative charge of the earth or the corresponding electric field maintained? or, in other words, How and where is negative electricity supplied to the earth at the rate required to compensate, on the average, for the loss by electric conduction? Many attempts to answer this question have been made since the problem was first recognized, about the beginning of this century, but most of the answers have been definitely confuted. The challenge presented by this problem seemed to some to call for radical measures. Several eminent physicists thought that the answer might require some modification of basic laws of physics or might depend on some physical entity or property that had not yet been discovered [1]. These nonclassical suggestions were made at a time when all other proposals seemed inadmissible, but since then some evidence has been found which lends support to the suggestion that thunderstorms supply negative electricity to the earth at a rate which is adequate to maintain the negative electric charge of the earth and the electric field of the atmosphere.

According to this view, each thunderstorm which has developed sufficiently acts as a generator of electricity and all the thunderstorms of the earth, acting as generators connected in parallel between the earth and the high atmosphere, provide the supply current which maintains the high atmosphere at a potential of several hundred kilovolts positive with respect to the earth. The requirements which this supply current must satisfy will be seen better after the review, which follows, of the chief universal aspects of atmospheric electricity, but from what has already been said it will be evident that the more general requirements are (1) the supply current generated in the thunderstorms must flow upward into the high atmosphere and then spread out and return to earth as a more or less uniformly distributed air-earth conduction current, (2) the magnitude of the supply current must equal the total current from air to earth in all fair-weather areas of the earth, and (3) the variations of the total supply current should correspond to the variations in the total air-earth current. Whether or not the net electric current which flows between the earth and thunderstorms meets these requirements has not been definitely ascertained because the electrical circumstances under thunderstorms are so complex that it has not been feasible to make the measurements which are needed.

The foregoing requirements are clearly indicated by extensive measurements of air-earth current density which have been made in representative areas of the earth, and it is from these measurements that the magnitude and characteristics of the supply current may now be inferred.

Values of the air-earth electric current density i, although very small, have been obtained satisfactorily at several places for a number of years by automatic registration. The value of i may be obtained either (1) by a "direct" method [19] in which the current is "collected" on an insulated plate set flush with the earth's

1. Retired from Department of Terrestrial Magnetism, Carnegie Institution of Washington.

surface, or (2) by an indirect method[2] which involves the measurement of three factors: (*a*) potential gradient or electric field strength E, (*b*) the electrical conductivity of the air attributable to the positive ions λ_1, and (*c*) the conductivity attributable to negative ions λ_2. The electric current density then is obtained from the relation

$$i = (\lambda_1 + \lambda_2)E. \qquad (1)$$

The sum $(\lambda_1 + \lambda_2) = \lambda$ will here be called the *total conductivity*, or simply *conductivity* when the latter entails no ambiguity. The technique for making automatic registrations of these three factors is now more satisfactory than that for registration by the direct method. This, and the advantage for analytical purposes of knowing how the several factors vary, is the reason that the indirect method has been used in most long series of registrations.

ELECTRICAL CONDUCTIVITY OF AIR

The conduction of electricity in air and other gases became a concrete conception in the last years of the nineteenth century. Coulomb found in 1785 that an electrically charged body when exposed in air loses charge at a rate given by the law which bears his name. However, his discovery received little attention until 1887 when W. Linss made measurements, two times each day for two years, of the proportional rate of dissipation, or the coefficient of dissipation a, of electricity from a charged body exposed in the open air. The coefficient a is defined by Coulomb's law, namely, $dQ/dt = -aQ$, where Q represents the quantity of electricity on the body and dQ/dt represents the rate at which charge is lost. These measurements showed that, in present-day terminology, (1) the electrical conductivity of air, which is roughly proportional to a, varies considerably from time to time, (2) it is greater in summer than in winter, and (3) during the year the conductivity on the average varies inversely as the potential gradient. This inverse relationship is frequently found. It implies that the electric conduction-current in fair weather tends to vary less than at least one of the two component factors, namely, potential gradient and conductivity. But at some places where the air conductivity is small the air-earth current density is considerably less than normal.

The conductivity of air was earlier thought to arise from the presence of impurities, such as particles of dust, smoke, fog, or water in its various forms, until J. Elster and H. Geitel, about 1895, from their numerous measurements of electrical dissipation, showed the reverse, namely, that air generally conducts electricity best when pure and relatively dry. These observations were clarified when the conception of gaseous ions was introduced near the end of the nineteenth century.

But how are ions formed in the open air? Elster and Geitel, in search for an answer to that question, discovered that the air over land generally contains radioactive matter, that most of the important constituents of the earth's crust contain measurable amounts of radioactive matter and that the former is doubtless derived from the latter. Since it had recently been found that radiations from radioactive substances form ions in the surrounding air, the conductivity of the air over land, but not of that over the oceans, seemed to be largely accounted for.

The first clue of the ionizing agent which is active at sea appeared when Elster and Geitel and C. T. R. Wilson in the first years of this century found that air from which radioactive matter had been carefully removed continued to be somewhat conductive. These observations apparently stimulated a series of investigations by other physicists, which eventually led to the discovery of what are now commonly called cosmic rays. That these ionizing rays are of extraterrestrial origin was first clearly indicated by observations made by V. Hess (1911) during ten balloon flights. These observations were verified and extended by W. Kolhörster in 1913.

Beginning in 1915 many measurements of the cosmic radiation were made on all oceans during cruises of the *Carnegie*. These showed that the intensity is about the same at sea as at sea level on land. Furthermore, measurements over the open seas showed that there the radioactive content of air is not more than two per cent of that found on the average over land. Other measurements made on these cruises showed that the amount of radium in sea water, far from land, is less than one per cent of the amount found in the soil. The results of these observations strongly corroborated those of Hess and Kolhörster and showed that this radiation is doubtless of universal distribution and constitutes the preponderant ionizing agent over the oceans.

Furthermore, balloon observations of the several factors involved indicate that everywhere in the troposphere and stratosphere, at altitudes greater than one or two kilometers, the air is ionized almost exclusively by the cosmic radiation. This radiation is, accordingly, an all-important factor in determining the character of the universal aspects of atmospheric electricity.

But this statement does not apply in the region above the stratosphere, namely, the ionosphere extending upward from an altitude of 60 km. There the electrical conductivity is much greater than would prevail if cosmic radiation were the only ionizing agent. The intense ionization of the ionosphere is attributed to ultraviolet light and corpuscular radiation from the sun. Perhaps the comparatively great electrical conductivity in the lower part of the ionosphere plays a part in promptly distributing the supply current from the thunderstorms to remote areas over the earth, but this has not yet been proven. This distribution may occur at a lower level.

Since, aside from the possibility just mentioned, the ionosphere is presumably not involved in the phenomena which are usually regarded as belonging in the category of atmospheric electricity, the interesting elec-

2. Methods of measuring the elements of atmospheric electricity are described in the article in this Compendium by H. Israël entitled "Methods and Instruments for the Measurement of Atmospheric Electricity."

trical properties of that region will not be discussed here. This subject is treated in references [1] and [5].

Without the conductivity of the troposphere and stratosphere, which depends chiefly upon the cosmic radiation, atmospheric electrical phenomena would undoubtedly be very different, and the universal distribution of the fair-weather electrical phenomena that are now observed would doubtless not occur.

At sea level the cosmic radiation forms ions in pairs, one positively the other negatively charged, at a rate, depending upon magnetic latitude, of 1.5 to 2.0 ion-pairs per cubic centimeter per second. This is practically the complete rate of ion formation over much of the ocean area and doubtless also over land in the polar regions, but in the lower atmosphere over most land areas the birth rate of ions is several fold greater than this on account of the additional ionization there by radioactive matter. The magnitude of the ionization rate near the earth over land is not readily determined and estimates vary between wide limits, but 10 ion-pairs per cubic centimeter per second may perhaps be taken as an approximate representative average value.

Despite the greater rate of production of ions, the electrical conductivity of the air over land generally does not exceed that at sea, and at some places, especially near large cities, it is much less. For example, in the outskirts of Washington, D. C., it is about one-seventh the value at sea. This apparent paradox was resolved when it was found that in air which contains certain impurities, the normal small ions are transformed into large ions which drift more slowly in the electric field and thus contribute less to the conductivity. These large ions are indeed so very sluggish that if all the small ions were transformed in this way the conductivity would be reduced to a very small fraction of the normal value.

The electrical conductivity of a gas which contains ions of various types may be expressed as

$$\lambda = e \sum k_i n_i, \tag{2}$$

where e is the electronic charge, k is the ionic mobility, and n is the concentration of ions of each type. All ions are here assumed to carry a single electronic charge. The mobility varies as the inverse of the density of the gaseous medium and depends upon several factors including the character of the ion species, the sign of the ionic charge, and the "size" of the ion. Values ranging from 0.0003 to 0.0007 $cm^2\ v^{-1}\ sec^{-1}$ for the mobility of large ions have been reported, whereas an average value for the small ions in the atmosphere at sea level is about 1.4 $cm^2\ v^{-1}\ sec^{-1}$, but the standard deviation of these values is rather large. Measurements made in the laboratory indicate that the mobility of the negative ion in air is about 1.3 times that of the positive ion.

Since in the atmosphere the large ions appear to be formed chiefly at the expense of small ions, the air conductivity is reduced when air is polluted with substances such as some products of combustion, which occur as molecular aggregates with a diameter of the order of 10^{-6} cm. These, upon capturing small ions, become large ions with such low mobility that they play an insignificant role in the conduction of electricity. The result of this is that the conductivity is reduced because the terms kn (equation (2)) which apply for small ions are decreased more than the corresponding terms for large ions are increased.

The concentration of small ions n, when equilibrium is established between the rate of production and the rate of destruction, is given approximately by the relation

$$q = \alpha n^2 + \beta n N, \tag{3}$$

where q is the rate of production of small ions (ion-pairs per cubic centimeter per second); n is the concentration of small ions, either those positively charged or those negatively charged; N is the concentration of the positively charged, the negatively charged, and the electrically neutral large-ion constituents; α is the coefficient of combination for small ions, with a value, at standard temperature and pressure, of about 1.6×10^{-6}; β is a parameter whose value is of the same order as that for α, but this value apparently depends upon some factors which are not yet identified. An average of values for β determined from the data of Cruise VII of the *Carnegie* is about 2×10^{-6} [20].

In deriving this form of the ionic equilibrium relation, which is a simplification of more general relations [15],[3] assumptions have been made which restrict its application. But in many cases where the data used for N are the values measured with an Aitken nuclei counter, and those for n are the measures of small ion concentration, this equation seems to be satisfied. The term containing N in (3) usually is dominant in the lower atmosphere over land and, especially in the vicinity of large cities, the term in n^2 is negligible, but at altitudes greater than 1 or 2 km in the free atmosphere, the latter term apparently is dominant during fair weather. These two terms are of about equal importance for the average conditions which prevail in the air near the surface over the oceans (N about 2000). Thus the equilibrium value of n is given by $n = \sqrt{q/\alpha}$ for clean air and by $n = q/(\beta N)$ for air that is polluted with many Aitken nuclei.

The magnitude of air conductivity λ not only varies from place to place at sea level but it also varies from time to time. The average value of λ measured over the oceans on Cruise VII of the *Carnegie* was 2×10^{-4} stat mho. Values over land are sometimes greater than those over the oceans, but smaller values are found at most places where measurements have been made. These values for land are so variable that an average has little significance. At Kew Observatory in the vicinity of London, λ appears to be about one-twelfth the value at sea and the variations are dependent to a large extent upon the varying pollution of the air. At the Huancayo Observatory near Huancayo, Peru, located at an altitude of 11,000 ft in a valley between ranges of the Andes mountains, the average λ is large—about three times the average for the oceans—but it is less than should be expected for a station at that alti-

3. Consult "Ions in the Atmosphere" by G. R. Wait and W. D. Parkinson, pp. 120–127 in this Compendium.

tude even if cosmic radiation were the only ionizing agent. At Huancayo, λ undergoes an 80 per cent decrease in about one hour between 6 and 8 A.M. during the dry season (Fig. 5). The low value continues during the daylight hours and is followed by a gradual increase which begins at about sunset. The abrupt decrease of λ is accompanied by a corresponding increase in the count of Aitken nuclei.

Apparently on the days when this occurs a shallow stratum of very stable air is established at night. The nuclei, initially present in the air near the surface, coalesce and settle out during the night and any radioactive matter exhaled from the ground is entrapped. Thus there are two factors which tend to gradually increase the conductivity at night. In the morning when the stable air layer breaks up and mixing sets in, nuclei presumably come down from the higher air and such radioactive matter as may have been entrapped is dispersed throughout a greater depth of air. Measurements indicate that the rate of ionization in daytime is about 80 per cent of that for nighttime at this station. Accordingly, the greater part, about 80 per cent of the abrupt decrease of λ in the morning, is attributable to a corresponding increase in the pollution of the air by substances which can form ions which drift very slowly in the earth's electric field.

These are examples of the kind of information now available which seems to justify the statement that most of the large changes of air conductivity, not only changes with time but also with position, are associated with changes in the purity of the air.

Temperature and pressure, although important factors where change of altitude is involved, effect only minor changes in air conductivity at sea level. The fact that the conductivity is greater in summer than in winter at a number of places may be attributable partly to a temperature effect. Calculations indicate, however, that for an annual temperature range of 30C, the corresponding range of conductivity for pure air would be 18 per cent of the mean, but the actual range is much greater than this—other factors apparently are involved.

Some observations indicate that the content of radioactive matter in the air over land is greater in summer than in winter and the greater conductivity in summer is probably in part a consequence of this, but the information about the annual variation of the radioactive content of air, or about the rate of ion formation q, is at present insufficient for making an appraisal of the quantitative importance of this factor. One would expect an effect of this kind only in regions where the exhalation of radioactive matter from the soil is hindered more during the winter season than during summer, owing to the prevalence of such conditions as a snow cover, frozen damp soil, or unfrozen waterlogged soil. The chief part of this annual variation of λ in the vicinity of large cities is attributable to a corresponding variation in the pollution of the air and there is some evidence that this factor plays a dominant part in effecting the annual variation of conductivity at most places on land where observations have been made.

The air conductivity near the earth is also affected by the electric field. During normal weather the concentration of negative ions near the surface decreases as the field strength increases. This occurs because negative ions drift away from the earth when the potential gradient is positive (field strength negative) and few, if any, such ions are supplied to the air from the earth. This effect of the electric field upon air conductivity is very pronounced when, as during storms, the field strength is large. Examples are given in Figs. 4 and 6. In Fig. 6, beginning at about 14^h the negative conductivity (λ_2) is negligible during most of the following hour while the positive conductivity (λ_1) is about normal. But shortly after 15^h15^m, λ_2 abruptly returns to a normal value and at the same time λ_1 almost vanishes. This condition continues for about fifteen minutes, then, at 15^h30^m, λ_2 again vanishes and λ_1 returns to a normal value. Six other such alternations occur before the storm ends at about 17^h20^m.

Most of the changes of the electric field, which cause these marked changes in conductivity, are not clearly seen on the electrogram for potential gradient in Fig. 6. That correspondence is better illustrated in Fig. 4 during the interval 0^h to 3^h when the electric field, being less intense, was clearly recorded most of the time.

Many of the changes of air conductivity are not accompanied by noticeable changes in air-earth current density. It is only when the change in conductivity extends throughout a considerable range of altitude that a marked correlation is seen. These cases must be taken into account when one is examining data for the broader universal aspects of atmospheric electricity. For example, in estimating the magnitude and the character of the variations of the supply current from measurements of i, allowance must be made for abnormalities which depend wholly upon local circumstances. The most significant of these abnormalities, for areas of fair weather, depend upon local modifications of the distribution of air conductivity with altitude.

Air conductivity depends upon altitude in a complicated way. The value at an altitude of 18 km (60,000 ft), during the notable flight of the balloon *Explorer II*, was 100 times the average for sea level. The chief factors involved here are (1) the intensity of cosmic radiation increases with altitude, (2) the rate of ion formation for a given ionizing radiation decreases directly as the air density, (3) the mobility of the ions varies inversely as the air density, (4) the rate of ion destruction in pure air of a given ion concentration decreases with altitude, varying directly with the $\frac{1}{3}$ power of pressure (approximately) and inversely as the $\frac{7}{3}$ power of absolute temperature, (5) the concentration of radioactive matter exhaled from the earth over land decreases with altitude, (6) the pollution of the atmosphere usually decreases with altitude, and (7) the dependence of β (equation (3)) upon temperature and pressure doubtless plays a part of unknown magnitude in determining the variation of λ with altitude in the lowest kilometer or so.

The last three factors apparently are relatively insignificant at altitudes greater than one or two kil-

ometers during normal weather but, in the vicinity of storms, effects which may be attibuted to these factors (particularly the last two) were observed by O. H. Gish and G. R. Wait at considerably higher altitudes.

The rate of ion formation q, when cosmic radiation is the only ionizing agent, depends on factors (1) and (2). Values for q as a function of altitude are shown in Fig. 1. These computed values are based on observations of cosmic radiation reported by Bowen, Millikan, and Neher and on average data for temperature and pressure for each of the two latitudes. The value of q increases from a low value at sea level to a maximum at an altitude of 12 to 13 km. The maximum for the higher latitude is more than two times that for the lower latitude.

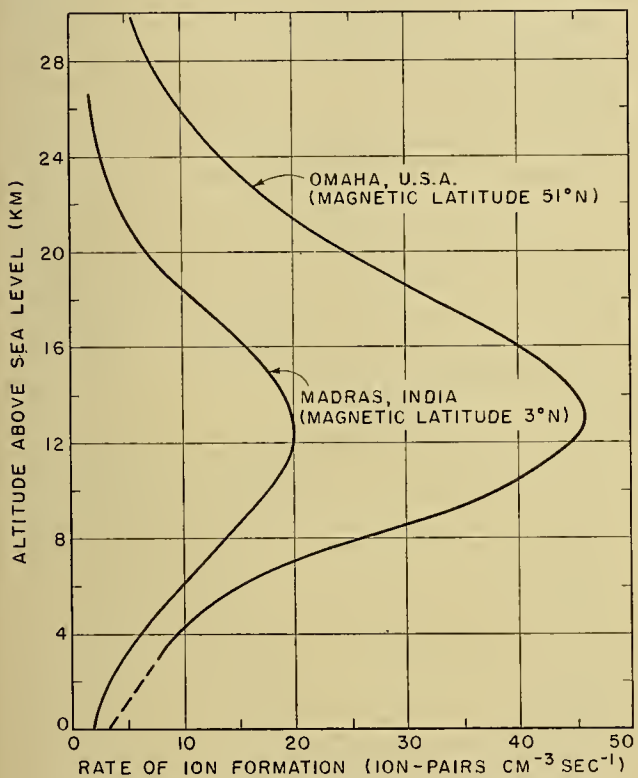

Fig. 1.—Rate of ion formation by cosmic radiation for middle and low latitudes. (*From data of Bowen, Millikan, and Neher.*)

An increase of conductivity with altitude was first shown by measurements of λ made on twelve balloon flights during the period 1905–20. Eleven of these started in Germany and one in Russia. The maximum altitude at which measurements were made was less than 6 km except for one in which it was nearly 9 km.

Continuous registration of λ up to a maximum altitude of 22 km was made during the flight of the stratosphere balloon *Explorer II* [14]. The results for this flight are shown in Fig. 2. The crosses on graph *A* represent direct measurements of λ_1, and the circles represent values derived from direct measurements of λ_2 by multiplying the latter by 0.78. This factor is the ratio of the mobility of positive ions to the mobility of negative ions. The smooth graph *B* represents values calculated from measured values of cosmic radiation and of temperature and pressure, the latter two observed during the flight. During this flight the conductivity increased from the surface up to an altitude of 18 km (60,000 ft) where it was about 100 times the value at the surface. In the altitude range 18–22 km, it varied irregularly but in general decreased with altitude. This

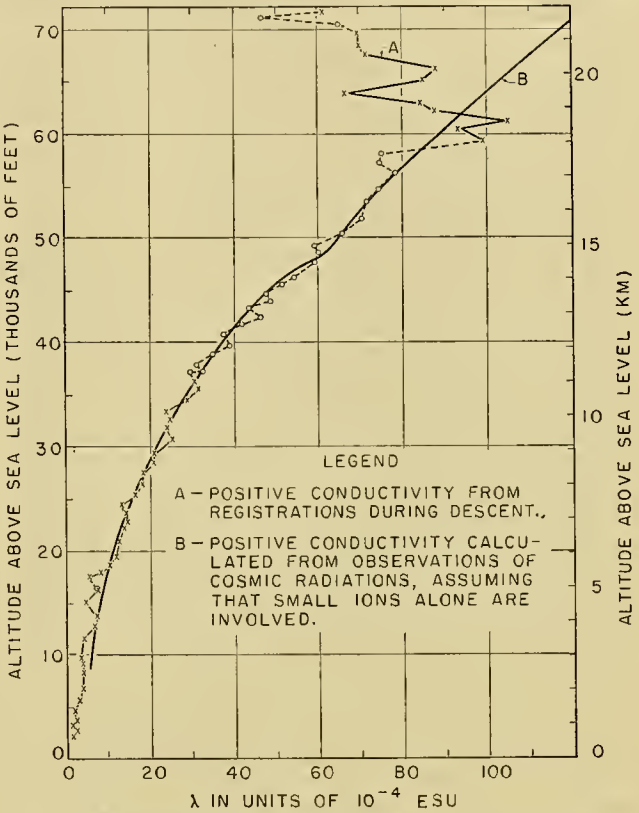

Fig. 2.—Air conductivity, flight of *Explorer II* near Rapid City, South Dakota, November 11, 1935.

last feature may be attributed to the presence there of substances (perhaps Aitken nuclei) which served for the formation of large ions. This decrease of conductivity is in the same region where ozone was simultaneously found to be especially abundant. Whether this feature is universal, whether it is generally associated with ozone, and whether there are factors in the atmosphere at yet higher levels which effect a similar diminution of the conductivity are questions which have important bearing on other than electrical aspects of the atmosphere. Therefore, further investigation of the conductivity of the high atmosphere is called for. At present, there is indirect evidence which indicates that this diminution of conductivity at high levels is either not universal or else is rather limited in vertical extent. The unexplored region to which this statement applies extends from 22- to about 60-km altitude. Above 60 km the concentration of ions has been determined at a number of places on the earth by quantitative studies of the "reflections" of radio waves. Such observations demonstrate that the air above that level is extraordinarily conductive.

Other measurements of λ up to an altitude of over 14

km (48,000 ft) were made in 1948 by Gish and Wait during ascent or descent for electric surveys over thunderstorms (a joint project of the U. S. Air Force and the Department of Terrestrial Magnetism of the Carnegie Institution of Washington). These unpublished values are on the whole consistent with those shown here except that they tend to be smaller.[4]

The values of λ versus altitude, shown in graph B (Fig. 2) were calculated for the case in which the air contains no large ions and the cosmic radiation is the only ionizing agent. The agreement between these and the measured values is one of the considerations which leads to the conclusion that throughout much of the high atmosphere pollution is negligible and cosmic radiation is the chief ion-producing agent.

The relatively large air conductivity at high altitudes and the increase with altitude are features upon which several other aspects of atmospheric electricity depend. For example, (1) the suggestion that thunderstorms are the source of the supply current could not be seriously considered if λ were not a rapidly increasing function of altitude, and (2) the decrease of electric field strength with altitude and the character of the diurnal variation and that of some of the other variations of field strength depend on these aspects of λ.

For cases in which the electric field strength or the air-earth current, or both, depend upon the over-all effect of the conductivity throughout a vertical column of the atmosphere, it is convenient to use the concept of electric resistance, rather than electric conductance, of the column.

The resistance of a vertical column of the atmosphere of 1 cm^2 cross section and extending from the earth's surface up to a certain height is obtained by integrating the reciprocal of λ from the surface up to that height. A value of "columnar resistance" r, obtained in this way from the values of λ shown in Fig. 2, is 10^{21} ohms for a column extending from sea level to an altitude of 18 km. If this is regarded as representative for the whole earth, the total effective resistance R from the surface to the 18-km level would be 200 ohms. Most of this resistance is offered by the lower part of the column. The highest eight kilometers contribute only five per cent of the total, whereas the lowest two kilometers contribute 50 per cent.

Estimates of r up to altitudes considerably greater than 18 km, based on observed values of cosmic-radiation intensity and the indicated trend of that radiation at altitudes not yet explored, indicate that the value of r for a column extending up to the ionosphere would not exceed by more than 10 per cent that for 18 km, provided the small ions at those higher levels are not transformed into larger, less mobile types, in appreciable number. Such estimates may at least set a lower limit for r between the earth and the ionosphere. An upper limit, not exceeding by as much as 50 per cent the value up to an altitude of 18 km, seems to be indicated by the extent to which air pollution of local origin—say from a city like Washington, D. C.—diminishes the air-earth conduction current through diminution of air conductivity in the lower atmospheric strata.

The columnar resistance is apparently 15 to 20 per cent greater near the equator than in middle latitudes, owing chiefly to a dependence of the vertical distribution of cosmic-radiation intensity upon latitude (Fig. 1). This is of interest here because it provides an explanation of the tendency, found by S. J. Mauchly, of the potential gradient measured at sea to be about 17 per cent less in the equatorial belt than in belts of higher latitude, whereas the air conductivity at the surface was found to be practically independent of latitude. This variation of r with latitude is not, however, as large as the variation from place to place on land. Over an urban area the value of r may be several times that in the relatively pure air over open country.

When all these circumstances are considered, it seems likely that an average value of r is about 10^{21} ohms and that the effective resistance R over all fair-weather areas of the earth is not far from 200 ohms. Here R is equivalent to r/S where S is the area of the earth. It is assumed here that the total area over which electrical storms are in progress at a given instant is negligible—the data for thunderstorms of the earth collected by C. E. P. Brooks indicate that the total storm area is usually less than $0.008S$.

The electrical conductivity of air in the ionosphere is apparently so great that electric fields there must be very small and can be disregarded in this discussion. No direct measurements of λ have been made in the ionosphere, but a reliable estimate of the order of magnitude is obtained by using the measurements, made by "radio" methods, of the equivalent ion density, together with estimates of air density at the corresponding altitudes. The value for λ, estimated in this way for an altitude of 70 km, near the lower boundary of the ionosphere, is about 10^7 stat mho cm^{-1}, or the resistivity, the reciprocal of conductivity, is less than 10^5 ohm cm. According to this estimate, the relaxation time, namely $1/(4\pi\lambda)$, at this altitude is less than 10^{-8} sec. This means that a local concentration of free electric charge cannot persist here for an appreciable time; it would, indeed, be diminished to 0.01 per cent of the initial value in 0.1 μsec.

Similar circumstances occur in the earth: The resistivity of most of the material near the earth's surface is less than that for air in the lower ionosphere—that of ocean water is less than 100 ohm cm. Even for geological structures where the highest values of earth-resistivity (10^6 to 10^7 ohm cm) have been measured, the relaxation time is of the order of microseconds. In contrast to this, the relaxation time for air near sea level is generally greater than 400 sec while for air at 18-km altitude it is about 4 sec. Because of these circumstances it seems permissible to describe the world-wide aspects of atmospheric electricity with the aid of a spherical condenser model as follows.

4. Subsequent to the preparation of this article, results of the measurements described above have been published and will be found in "Thunderstorms and the Earth's General Electrification," by O. H. Gish and G. R. Wait, *J. geophys. Res.*, 55:473–484 (1950).

The earth and the ionosphere, or possibly the upper stratosphere, serve as the inner element and the outer element, respectively, of a spherical electrical condenser. Because the air between the inner and outer elements is conductive this condenser has a "leakage" resistance R. A difference of potential V between the elements is maintained by the supply current. The leakage current I is V/R, and for steady conditions this is also the magnitude of the supply current. For $I = 1800$ amp and $R = 200$ ohms (values based on observations), $V = 360{,}000$ v. A somewhat lower value of V is obtained from measurements of potential gradient made on balloon flights at altitudes ranging from sea level to about 10 km (see equation (4)).

Apparently I and V are the chief variables in this relation and of these V is regarded as the independent variable. No appreciable variation in R is indicated by the data now available. Although the average conductivity measured on Cruise VII of the *Carnegie* (mean epoch, 1929) was only 74 per cent of that for Cruise VI (mean epoch, 1921), the average air-earth current density did not differ significantly, that for Cruise VII being 107 per cent of the value for Cruise VI. This indicates that I, and consequently V/R, was essentially the same for these two epochs. This fact does not necessarily exclude the possibility that V and R were related as dependent and independent variables, respectively, because if R had increased but the supply current had remained constant, V would have varied directly as R. But there are no grounds for thinking that R varies appreciably owing to variation throughout the atmosphere in the rate of ionization, the chief factor. The chief ionizer, the cosmic radiation, seldom varies by more than a few per cent of the mean; variations in amplitude as great as 3 to 4 per cent occur infrequently, usually during magnetic storms, and last only from a few hours to a day or two. On only four occasions in more than a decade have increases of more than 10 per cent of normal (at sea level) been observed [12]. Perhaps on these occasions a detectible decrease in R occurred. This should be revealed by a simultaneous increase of λ at widely distributed stations and a corresponding decrease of E. No such world-wide changes of λ and E have yet been definitely detected, but a special examination should be made of the four cases just mentioned.

Apparently the only possible source of world-wide changes in λ, amounting to more than a few per cent and continuing for long periods, is corresponding changes in the pollution of air with nuclei which serve for the formation of large ions. Even if such extensive changes do occur near the earth's surface, there would be no comparable change in R unless the change in λ occurs throughout most of the troposphere. A decrease of λ from the surface to a considerable altitude apparently does occur over limited areas especially in the vicinity of cities or industrial centers where there is notable pollution of the atmosphere. The extent of this is such that the columnar resistance r appears to be increased severalfold but the total area involved is doubtless such a small part of the earth's surface that only immeasurable effects in R may be expected. Periodic changes in r, such as diurnal variations, are also in evidence at some places, but these depend mainly upon local circumstances and apparently do not affect R appreciably.

These statements about variations in r are based on information obtained by an indirect method which depends upon the assumption that $ir = V$ is the same everywhere on the earth at a given instant. If i is measured simultaneously at two places, then according to this condition the ratio of the value of r at one place to that at the other place is equal to the inverse ratio of corresponding values of i. The efficacy of this method of analyzing such data also depends upon the circumstance that at some places, notably over the oceans, r seems to be much more nearly constant than at some places on land. This device has been used chiefly for estimating the average diurnal variation of r [21, 22]. The results are at least plausible.

That the more prominent variations of λ occur chiefly in the lower part of the atmosphere is indicated by the reciprocal relation, frequently found, between λ and E (electric field strength), namely, $\lambda E = i$ where i is approximately constant. This indicates that in these cases r is not modified much by the changes in λ, and that accordingly the vertical extent of the changes in λ and E is relatively small. The height of the air stratum involved has been estimated in several ways. At Paris a height of 200 m or less was indicated by the observation that variations of E near the top of the Eiffel Tower were chiefly of the universal type, whereas at a nearby ground station the variations were much more complex. Heights for the region of abnormal conductivity of the order of one to two kilometers have been estimated for other situations, in which r is appreciably modified.

Of the features of air conductivity discussed here, those of chief importance for the broader aspects of atmospheric electricity are (1) electrical conductivity of air is a universal property, (2) this property increases with altitude and at some altitude, probably less than 60 km above sea level, is so great that at a given instant the electric potential at that level is essentially the same everywhere over the earth, and (3) the electrical conductance between the earth and the high atmosphere, or the reciprocal of this, the resistance R, probably is not subject to appreciable variation.

THE ELECTRIC FIELD OF THE ATMOSPHERE IN FAIR WEATHER

Many observations of the electric field in the atmosphere have been made during the nearly two hundred years since Franklin made his famous kite experiment in 1752 and Lemonier, later in that year, first observed an electric field in the atmosphere during clear weather. Before the end of the eighteenth century a number of the characteristics of the electric field were correctly inferred from qualitative observations made chiefly in Europe. Quantitative measurements of the electric field strength came into vogue after Sir William Thomson in 1860 stressed the need of measurements which could

be compared even though made by different observers and at different places.

During this latter period, measurements have been made on most of the representative areas of the earth, including a number of series for the polar regions, many widely distributed measurements on the oceans, and measurements made during balloon flights (all in Europe). Continuous registration has been used at most land stations since about 1910 and was also successfully employed at sea during Cruise VII of the *Carnegie*. The features of the electric field which are clearly shown by these data are as follows for fair-weather conditions.

The electric field strength E is negative, or the potential gradient is positive, wherever and whenever fair weather prevails. The exceptions to this are rare and transitory. For example, a positive field (negative gradient) is registered while a dust whirl passes near the station. An example of such an effect appears on Fig. 5 between 14^h40^m and 14^h50^m. Since at the surface of a conductor $E = -\partial V/\partial Z = 4\pi\sigma$, where $\partial V/\partial Z$ is the potential gradient along the outwardly directed normal and σ is the surface charge density, one concludes that the charge of the earth in fair-weather areas is negative and that the potential of the air increases with altitude.

The potential gradient (or $-E$) at the surface varies considerably from place to place. The average potential gradient at sea during Cruise VII of the *Carnegie* was 130 v m^{-1}. At some places on land an average considerably less than 100 v m^{-1} has been reported, but values larger than that for the oceans are prevalent in densely populated areas: at the Kew Observatory near London the average value exceeds 300 v m^{-1}. In the polar regions and in open country, far from sources of atmospheric pollution, the average is about the same as that for the oceans. Apparently a value of about 130 v m^{-1} is a fairly representative average for the preponderant part of the earth's surface.

The potential gradient decreases with altitude. The measurements of gradient made on 57 balloon flights, mostly over central Europe, as summarized by Schweidler [17], satisfy the following empirical equation:

$$\partial V/\partial Z = 90 \exp(-3.5z) + 40 \exp(-0.23z), \quad (4)$$

where $\partial V/\partial Z$ is expressed in volts per meter for z, the altitude in kilometers. There is a sharp decrease from the surface up to about 1-km altitude followed by a slower decrease. The value at $z = 0.5$ km is less than half the value at the surface, and at $z = 9$ km it is less than 4 per cent of the surface value. The data for altitudes less than 1 km are scattered much more about the general trend than are those for higher altitudes. This may be due to variable pollution in the air near the earth, a circumstance that is indicated by other types of atmospheric electric observations such as the contrast between measurements of E made on the Eiffel Tower and of those made at a neighboring ground station.

A decrease of E with altitude, if widespread and of the magnitude and character indicated by these data, doubtless is attributable chiefly to a corresponding increase of air conductivity. For these conditions $\lambda E = i$ is independent of altitude if the electric space-charge density ρ does not vary with time and provided convection plays a negligible part in the transport of electricity in the atmosphere. The latter conditions doubtless are satisfied during most fair weather. The drifting of snow, or of dust, however, is accompanied by the generation and convection of electric charge and although this is a source of conspicuous modifications of the electric field near the earth on some occasions, for average fair-weather conditions the magnitude of electric convection-current density calculated on the basis of available data is negligibly small.

Measurements of both λ and E were made on only a few balloon flights. For these the product λE was not invariable with altitude, but this result is probably attributable to a variation of the air-earth conduction current with either, or both, time and position [10].

The potential gradient of fair weather also decreases with altitude in the lowermost few meters owing to a depletion of the negative ions in this region, the so-called *electrode effect*. Under the action of the electric field, negative ions drift away from the earth and since such ions are not emitted from the earth at an appreciable rate, the flux of negative ions, and accordingly the concentration, must vanish at the surface. But for steady conditions, the flux of positive ions from air to earth is nearly continuous in the lowermost few meters, and at the air-earth boundary is equal to the total electric flux at higher levels. Two attending conditions are (1) positive ions predominate or a positive space charge prevails in air that is contiguous with the earth, and (2) the potential gradient decreases with altitude. These general aspects of the electrode effect may be modified or obscured when either or both the electric convection-current component and the displacement-current component are appreciable, or when the vertical distribution of air conductivity near the surface is abnormal. The conclusion that the electrode effect is a universal characteristic of the electric field of the atmosphere depends chiefly on the observed fact that λ_1/λ_2 is usually greater than unity in fair weather and that it increases as the gradient increases.

The temporal variations of potential gradient are usually of complex origin, however there are types which may be classified on the basis of origin, as follows. From the several equivalent expressions for air-earth current density, namely $+\lambda E$ and $-V/r$, one obtains the relation

$$E = -V/(\lambda r), \quad (5)$$

which is valid except for the rather unusual condition that i is dependent upon altitude, or that the displacement current is appreciable. On this basis the following four types of change in E may be adopted: type (a) in which E is independent of V, λ, and r, but λ depends upon E; type (b) in which $E \propto 1/\lambda$, with V and r constant; type (c) for which $E \propto 1/r$, while both λ and V are constant; type (d) in which $E \propto V$, while λ and r are constant. In this discussion E and λ are generally used to denote values observed in air practically contiguous with the earth, V denotes the potential of the ionosphere (or upper stratosphere) relative to the earth, and r denotes the columnar resistance—the elec-

trical resistance of a vertical column of air 1 cm² cross section extending from the observation point up to the ionosphere.

Variations of the first three types generally are marked by local characteristics; many occur at irregular intervals but some follow a diurnal or other periodic routine, which varies much from place to place. The only thing in common among these variations is that usually factors of local origin tend to increase the gradient during daylight hours more than at night, but the contrasts in the amplitude and character of these variations at different places are remarkable. An example of the contrast between periodic local variations of this sort may be seen by comparing an electrogram for potential gradient (Fig. 3) obtained at the Watheroo Magnetic Observatory, Western Australia, with a corresponding electrogram (Fig. 5) made at the Huancayo Magnetic Observatory near Huancayo, Peru (observatories established and operated by the Department of Terrestrial Magnetism of the Carnegie Institution of Washington). In the latter electrogram, the gradient at

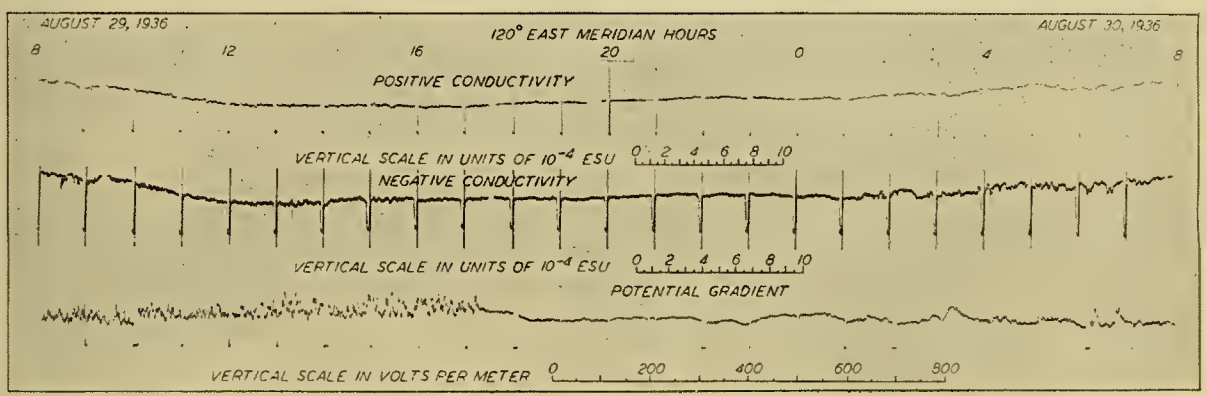

FIG. 3.—Electrograms, Watheroo Magnetic Observatory, "quiet" day.

8^h30^m (local time) is about five times the value registered two hours earlier. In the former, there is a relatively small and gradual increase of gradient, beginning at about 8^h local time and continuing throughout the daylight hours. The universal diurnal variation, which will be discussed later, is, of course, present in both these cases, but allowance for that would not change the order of contrast seen here. Analyses of such records from these two stations indicate to the author that the local aspect of the diurnal variation of potential gradient at Watheroo is largely of type (*c*) while that for Huancayo is chiefly of type (*b*).

At the Kew Observatory, where the influence of local air pollution is prominent, a semidiurnal variation of gradient of local origin appears with maxima at about 8^h and 21^h local time. These apparently are a combination of types (*b*) and (*c*) with type (*b*) dominant in the morning and type (*c*) coming into evidence later in the day [22]. The latter is an interesting example of a local influence which may be explained as follows.

The introduction into the air in the general vicinity of the observatory of substances which serve as nuclei for the formation of large ions proceeds at an enhanced rate during the period 4^h to 20^h. Near the surface the concentration of these nuclei increases rapidly between 6^h and 8^h in winter (3^h to 9^h in summer) and as a consequence λ decreases; then as convection and turbulence increase during the day, the local contamination decreases somewhat, and λ increases; but when the air becomes more stable in the evening, local contamination increases and λ decreases again until checked when, after 20^h, both the rate of introduction of the nuclei and their concentration decrease. Throughout the daylight hours the columnar resistance r increases to a maximum at about 19^h. This doubtless indicates that the content of nuclei in the air column has been increasing during this period. A decrease of r which occurs during the night is doubtless the combined effect of (1) decreased rate of supply, and (2) scattering and other modes of dissipation of the nuclei.

Potential gradient variations of type (*a*) are most prominent during stormy weather. Examples of such effects are exhibited in Figs. 4 and 6. These figures are reproductions of unretouched electrograms obtained at the Watheroo Magnetic Observatory and at the Huancayo Magnetic Observatory, respectively. Figures 3–6 inclusive are samples selected from the thousands of such registrations made during the years 1922–46 at Watheroo and 1925–46 at Huancayo. Points for zero gradient are recorded each hour. Ordinates above this line of "zeros" correspond to positive values of gradient. During the 24-hr period of record shown in Fig. 4, three periods of rainfall were indicated by the station rain gauge. These are indicated at the top of the figure. The corresponding storm effects in potential gradient are exhibited in the lowest electrogram. Most of these were of moderate intensity on that day, and varied from positive to negative values of gradient.

During the ten-minute period beginning at 18^h10^m the gradient was entirely negative and at its greatest intensity exceeded 400 v m^{-1}, the limit of registration. During the period 0^h to 0^h50^m, several changes from negative to positive gradient occurred. The trace of these may not appear in the reproduction—the changes were rapid and the extreme values exceeded the limits of registration, namely, −400 and 700 v m^{-1}. But fortunately, in cases where the trace for potential gradient is not clearly shown, the sign of the gradient can usually be ascertained by an examination of the traces for con-

ductivity, because of the electrode effect previously discussed. A characteristic of that effect is that a low value of negative conductivity and a normal value of positive conductivity should accompany a large positive potential gradient, while for a large negative gradient the roles of positive and negative conductivity should be interchanged. There is abundant evidence as well as a rational basis for this rule, but such evidence is not clearly shown in Figs. 4 and 6 during periods of greater activity because the original gradient trace was very dim when rapid changes of gradient occurred and was "off scale" for considerable periods. However, the reader doubtless can see evidence of trends of this character in these figures.

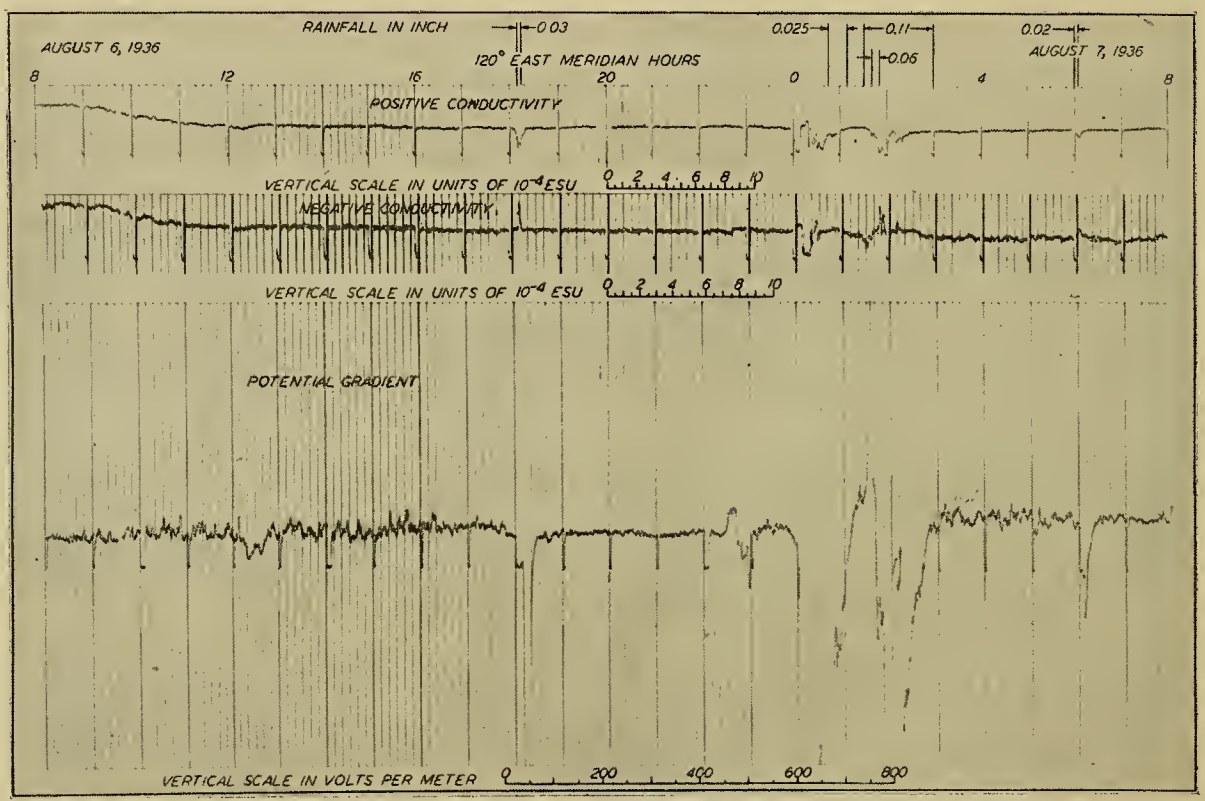

Fig. 4.—Electrograms, Watheroo Magnetic Observatory, with periods of light rain.

With the aid of this rule one can readily see that during the periods when intense electric fields prevail the sign of the gradient varies. The record shown in Fig. 6 covers two storms in a 24-hr period: one in the interval 20^h to 22^h, approximately, on March 17, the other beginning about 14^h March 18 and lasting more than three hours. During the former period, a negative gradient was recorded for more than one hour but an intense positive gradient for only 10 min is indicated. During the latter storm an intense positive gradient prevailed during the first 75 min. This was followed by an intense negative gradient which continued about 15 min. In the next hour and three-quarters, eight abrupt reversals of sign occurred.

Such characteristics of potential gradient must be attributed to considerable masses of electric charge or "charge-clouds" in the vicinity of the observatory—a charge-cloud does not necessarily coincide with a visible cloud. Ten such charge-clouds are indicated by the record for the latter storm. So many alternations of potential gradient in one series (barring changes which accompany lightning discharges and which are of too short duration to register with the apparatus used here) is somewhat unusual. They appear more frequently in records for the Huancayo station than in any other records available to the author.

The suggestion that such a series of changes in gradient may be attributed to a number of charge-clouds drifting by in tandem array may be an oversimplification. The only model of this sort which could account for the abrupt change of sign—within about one minute—and the intense field, continuing for 10–15 min or more between reversals, is one in which the charge-clouds are at an elevation which is small compared with their lateral dimension, and the array of clouds, charged alternately positive and negative, is closely packed. It is doubtful whether such a model is compatible with several physical conditions which seem to be required to maintain the charge of such clouds. Any further discussion of phenomena of which this case is representative should come under the category of the thunderstorm electric field, a topic which is discussed very briefly in this article.

Another example of a field change of type (*a*) is shown on the trace for potential gradient in Fig. 5, just before 14^h50^m. This is a characteristic "dust whirl" or "dust devil" effect. The sign of the field change indi-

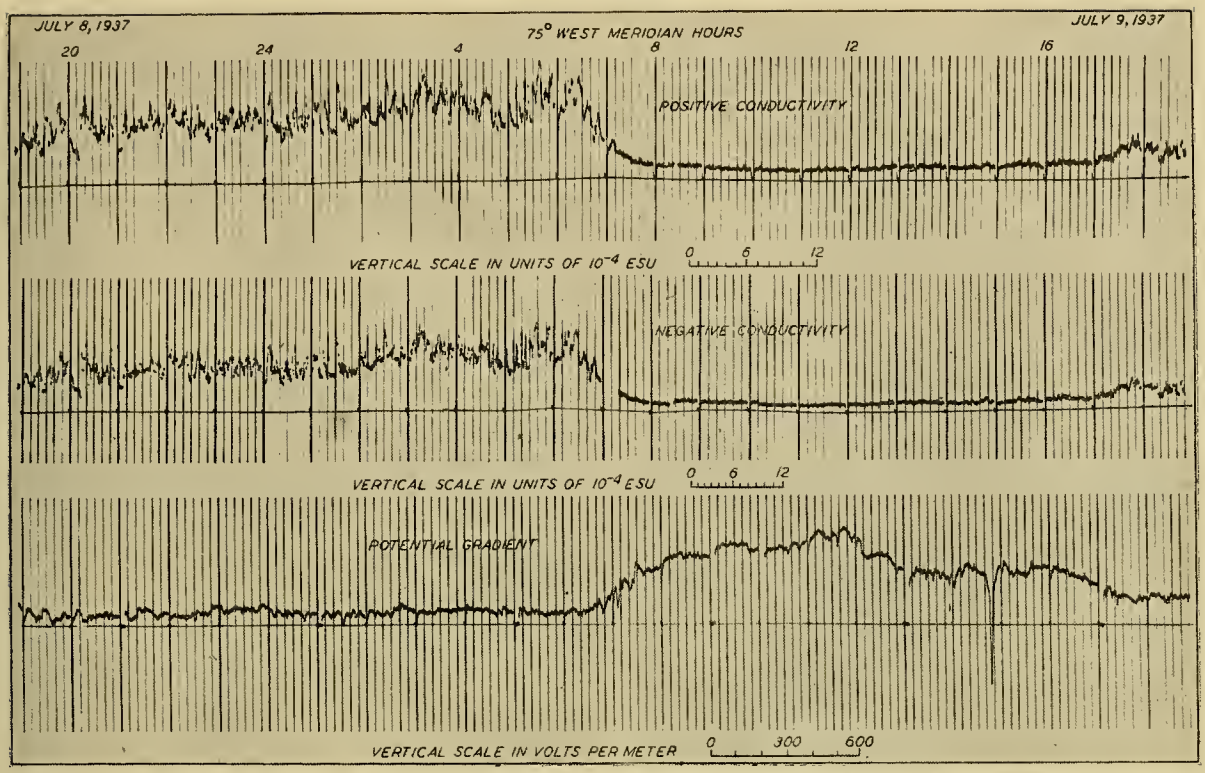

FIG. 5.—Electrograms, Huancayo Magnetic Observatory, "quiet" day during dry season.

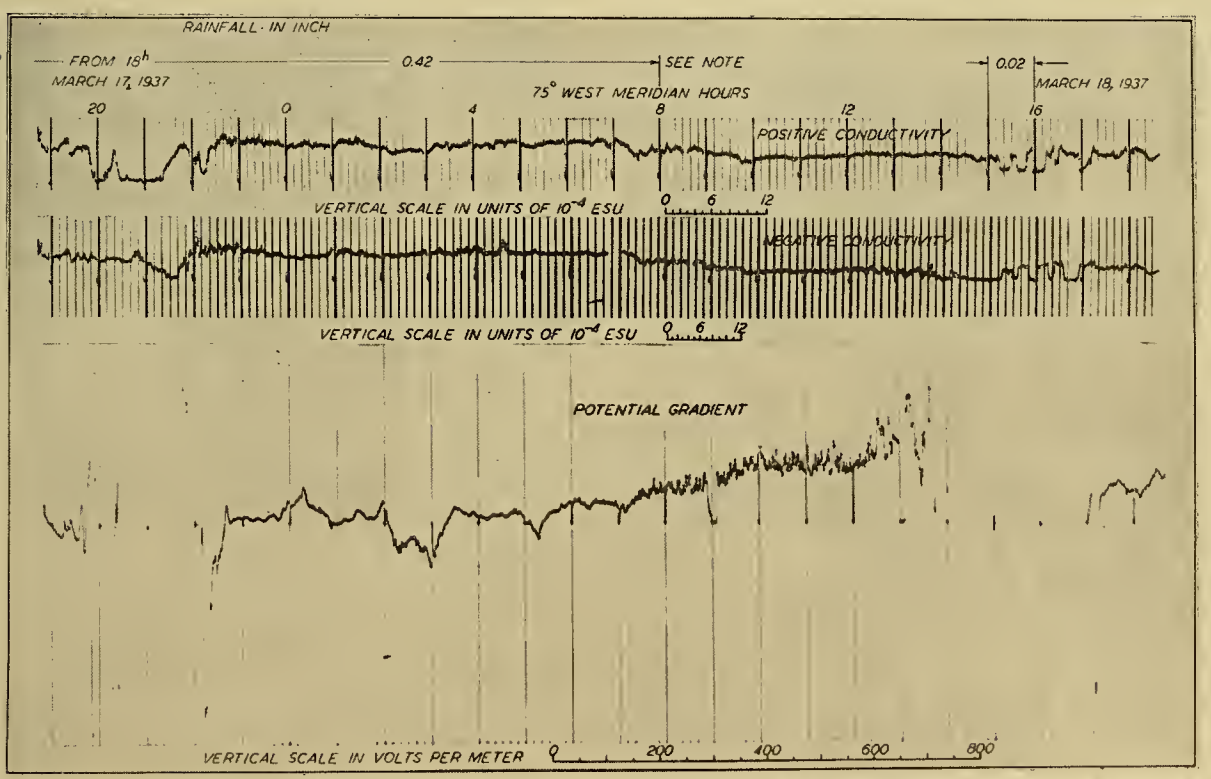

FIG. 6.—Electrograms, Huancayo Magnetic Observatory, rainy day. (Note: Clearing in morning after 10.5h; early afternoon March 18, increasing cloudiness, distant rain, and thunder to southwest at 14h.)

cates that the electric charge of the dust in this whirlwind is preponderantly negative.

The relatively small and rapid variations of electric field, which are common during daytime at the Watheroo Magnetic Observatory, are illustrated in Fig. 3. This effect, apparently of type (*a*), is clearly correlated with wind strength and wind variability. Presumably the fine sand, prevalent in this semiarid region

of Western Australia, is agitated enough by the wind to introduce puffs of electric charge into the air near the surface. There is some evidence that small variations of conductivity are associated with the field changes and the former are doubtless dependent on the latter. The drifting of snow, like the drifting of sand or dust, also modifies the electric field, but during the former, positive charge is introduced into the air.

A description of field changes of types (*a*), (*b*), and (*c*) is relevant here chiefly because these phenomena must be recognized for what they are and must be distinguished from the universal aspects of the electric field in order that the latter may be identified.

Changes of type (*a*), which are prominent during storms, have importance for the clues they provide

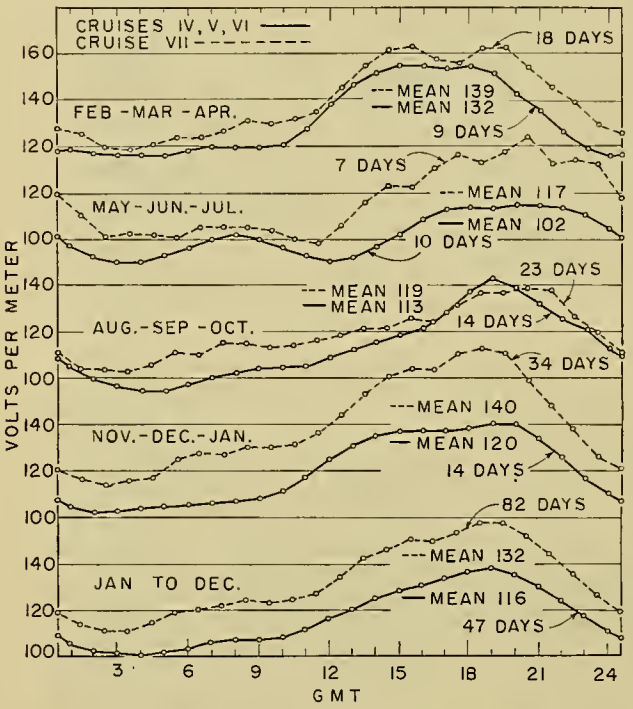

FIG. 7.—Diurnal variation of potential gradient on the oceans, *Carnegie* Cruises IV, V, and VI, 1915–21 and Cruise VII, 1928–29.

concerning the electrical constitution of storms, but changes of types (*b*) and (*c*) are of minor interest as geophysical phenomena, especially when they depend upon the activities of man.

The discovery of the *universal diurnal variation of potential gradient* was delayed because most of the atmospheric electric observations, prior to about the year 1915, were made near cities or at other places where field changes of types (*a*), (*b*), and (*c*) are prevalent. This feature, first noted by Mauchly in 1921 [6], has great importance for the subject. His analysis of the data for potential gradient over the oceans, obtained on Cruises IV, V, and VI of the magnetic survey yacht, *Carnegie*, showed that the diurnal variation of the gradient at sea proceeds according to universal time, not according to local time.

This is illustrated by the results which are exhibited in Fig. 7. Average values of potential gradient, in volts per meter, are there plotted as ordinates against the hours of the Greenwich day, counting from midnight to midnight. The combined results for Cruises IV, V, and VI are shown separately from those for Cruise VII. The latter, although generally of greater amplitude, vary in nearly the same manner as the former. If attention is fixed on either of the two lowest graphs, which represent hourly averages for the year, it is to be seen that the gradient is smallest about four hours after Greenwich midnight and greatest at about 19^h. That this feature varies somewhat throughout the year is shown by the other graphs which represent different quarters of the year. When these same data are averaged for hours of the local day, no significant diurnal variation is disclosed. Thus the change in gradient during the day does not depend upon daylight and darkness or other factors which vary in a manner directly related to the elevation of the sun at a given place. Another way of viewing this universal aspect is as follows. The negative charge of the earth as a whole in fair weather is greatest at about 19^h GMT and least at about 4^h GMT, and the total air-earth current I varies in a similar manner. The latter depends partly upon the fact that over the oceans the diurnal variation of λ is negligible.

This universal variation in potential gradient is also manifested in the diurnal variation of potential gradient at most places on land. But factors of local origin there often introduce component variations which may preponderate, especially in or near centers of population where the conductivity of the air is affected by atmospheric pollution. The concentration of these impurities is, of course, dependent not only on the rate at which they are supplied to the atmosphere but on the strength and direction of the wind, on rain, or on other processes which scatter these substances or carry them to or from the place at which the electrical features are considered. Variations of the content of radioactive matter in the air over land also result in variations of the concentration of the small ions, upon which the conductivity of the air chiefly depends. Over land the air conductivity and the gradient may, therefore, be expected to vary during the day in a manner and to an extent which is often dependent upon a complex and variable set of local circumstances.

The average potential gradient of fair weather, the universal diurnal variation of gradient, and doubtless some other temporal variations are of type (*d*), that is, they depend directly upon V, which, in turn, is presumably dependent upon the supply current.

The universal aspects of the electric field of the atmosphere which are of chief importance may be summarized briefly as follows: (1) the electric potential gradient in the atmosphere during fair weather is positive everywhere on the earth and the average value is about 130 v m^{-1}; (2) the value near the equator is about 80 per cent of the value at higher latitudes; (3) the gradient decreases with altitude in free air, rapidly in the first kilometer, then more slowly, till at an altitude of 10 km it is about 5 per cent of its value at the sur-

face; (4) the gradient at the surface varies during the day according to a universal routine with a minimum at 4^h GMT and a maximum at 19^h GMT and a diurnal range equal to 35 per cent of the daily mean; (5) the character and amplitude of this universal diurnal variation and also the daily mean apparently vary during the year. Exceptions to the last two statements are conspicuous at some times and places, but on a world-wide view the exceptions are presumably insignificant.

THE AIR-EARTH CURRENT

The electric current which flows from air to earth in fair-weather areas is predominantly an electric conduction current. Although it is conceivable that electric convection, as in the case of charged rain falling to earth, or electric displacement which depends upon the rate of change of electric field strength, may sometimes play a part in determining the electric current density between air and earth, yet estimates of the magnitude of the effects of these factors indicate that in fair weather they are usually small and of such character that they need not be considered in this brief review of the phenomena of atmospheric electricity. This is corroborated by several tests in which values of i determined by the direct method were found to be about the same as those determined at the same place and time by the indirect method. The air-earth current density i is, therefore, essentially equal to λE, and the description of it is implied in the foregoing discussions of λ and E.

The average values of i derived from measurements over the oceans on cruises of the *Carnegie* are, in the opinion of the author, fairly representative for the earth as a whole. The bases for this opinion are largely as follows: (1) the geographical distribution of these measurements is much more extensive than that for all other data, and (2) the data are much freer from large and persistent local effects than those for most land stations. It should be noted, however, that for some land stations far from centers of human activity, and notably for those in the polar regions, the data are relatively free from such local effects and have about the same characteristics as those for the oceans. It is on this basis that the following statements rest. The average value of i derived from measurements of λ and E at sea is about 10^{-6} stat amp cm^{-2}. There is no clear evidence of any trend toward either a higher or a lower value in the 15-yr period, 1915–29, to which these data apply. But there is an indication that near the equator i is somewhat less than at higher latitudes [20].

The annual and the diurnal variation of i at sea have about the same character and relative magnitude as the potential gradient because only a small diurnal variation of λ is indicated by the observations and the latter is probably a local time effect. Also there is no definite evidence of an annual variation of λ at sea.

The total electric current I from air to earth for all fair-weather areas is i multiplied by the area of the earth. That the error incurred by neglecting here the area of thunderstorms is less than one per cent may be inferred from the data assembled by Brooks [8].

The mean value of I obtained in this way is about 1800 amp. The error in this estimate is probably not greater than 10 per cent. The diurnal and possible annual variation of I are of the same character and relative magnitude as the corresponding characteristics of the average for i. This total current from air to earth must have a counterpart which "completes the circuit." The term "supply current" is used here to denote this counterpart, an elemental universal feature of atmospheric electricity. Where and how is the supply current generated? The answer to that question has been sought during the last fifty years. The status of that search at the present time is discussed in the following section.

THE SUPPLY CURRENT AND THUNDERSTORMS

Many proposals have been made to account for the fair-weather aspects of atmospheric electricity. Most of these were soon found to be untenable. The one surviving proposal which may give the answer as to *where* the supply current is generated is credited to C. T. R. Wilson. This is the suggestion that the supply current is generated in thunderstorms. If this is the case, the answer as to *how* it is generated doubtless must await the development of an acceptable theory for the generation of electric charge in thunderstorms. This section is devoted to an appraisal of Wilson's suggestion.

The universal aspects of atmospheric electricity which should be recalled in this connection are, expressed in terms of the more comprehensive element I, as follows: (1) the yearly average of the total current I from air to earth in fair-weather areas seems to be nearly constant at a value of about 1800 amp; (2) the daily mean of I probably varies during the year, being greater in the six months from November to April than in the rest of the year; (3) the diurnal variation of I is such that on the average during the year the maximum occurs at about 19^h GMT and the minimum at about 4^h GMT; (4) the character and range of this diurnal variation vary during the year.

The magnitude of the supply current and the character of its annual and diurnal variations must be the same as those listed here for I. Near the earth the supply current must flow upward, from earth to air, (opposite to that for I) but at some undetermined altitude, probably in the high stratosphere and below the ionosphere, the vertical component vanishes and the current is dispersed laterally. Then it returns to earth as an air-earth conduction current which is nearly uniformly distributed over the earth. The circuit is completed through the earth to the source, or sources, of the supply current, which may be located in thunderstorms. The fact that the air conductivity increases with altitude and has relatively large values at high altitudes seems to be of vital importance for the existence of such an electric circuit.

The first evidence in favor of Wilson's suggestion that the supply current is generated in thunderstorms was obtained in an analysis, made by Whipple [22], of the thunderstorm data for the world, assembled by Brooks [8]. That investigation indicates that thunderstorm activity, for the earth as a whole, varies during the Green-

wich day in the same manner as does the air-earth current of fair weather. This evidence is exhibited in Fig. 8, where the ordinates represent the area over which land thunderstorms are in progress at the time of the Greenwich day denoted by the abscissae. By comparing this graph with either of the lowest graphs for potential gradient in Fig. 7, a remarkable similarity will be noted. Whipple also concludes that the character of the diurnal variation changes during the year in about the same manner for the two phenomena. This result indicates that if the net current generated in the representative thunderstorm is directed upward from the earth to the high atmosphere, and if the total current from all storms is great enough (average 1800 amp), the supply current would satisfy the requirements listed above. It is surprising, in view of the character of the data and their scantiness for large areas of the earth, that this result could be obtained. Whipple apparently used satisfactory methods in his analysis. Maybe this result indicates that thunderstorms over the oceans and in sparsely settled regions of the earth do not contribute much to the supply current.

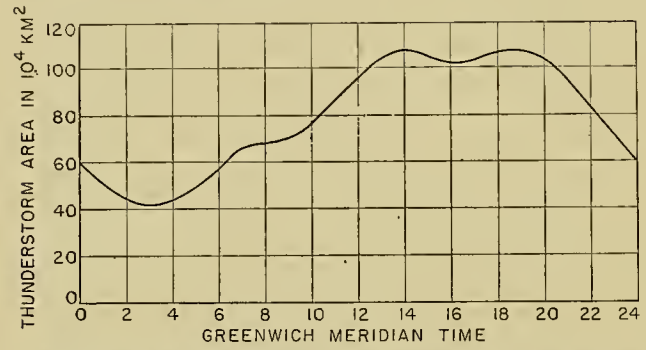

FIG. 8.—Diurnal variation in prevalence of thunderstorms. The ordinate is the estimate of the average area of land-thunderstorms in progress on the whole earth. (*After F. J. W. Whipple and F. J. Scrase.*)

Other methods should be used to check Whipple's results. It seems that it may be practicable now by the use of suitably designed atmospheric recorders at a comparatively small number of well-distributed stations to make a complete "sweep" of the earth and with satisfactory registration for one year to obtain the required data. From such data one would hope to derive a record of lightning frequency as a function of Greenwich time which may be more suitable information for this purpose than records of thunderstorm occurrence.

Although Whipple's results seem to show that *if* thunderstorms are the seat of the supply current, the diurnal and annual variation of that current would each be of the right type, it is yet to be ascertained whether the thunderstorms do contribute a current of the right sign and magnitude to the circuit previously described. In principle this may be ascertained either by making measurements of the required elements at the earth's surface beneath storms or by making the proper survey over the top.

No adequate survey beneath a thunderstorm has ever been made. However, T. W. Wormel made part of the required measurements at Cambridge, England, which he used together with data obtained elsewhere by other observers to draw up a balance sheet of the quantity of electricity lost and gained by 1 km^2 in a year. Wormel's balance sheet is as follows:

Negative charge gained	Coulombs km^{-2} yr^{-1}
1. By natural point discharge	100
2. By lightning discharge	20
Total negative charge gained	120
Positive charge gained	
3. By atmospheric conduction	60
4. By precipitation	20
Total positive charge gained	80
Net gain, negative charge	40

Although it is interesting to see what comes from an attempt to strike such a balance it may not have much significance for the problem at hand. Item 3 is the best-determined one, but Wormel uses the small value obtained at a few places in England whereas the electric surveys of the Department of Terrestrial Magnetism, Carnegie Institution of Washington, indicate a value almost twice this for representative areas of the earth. The interpretation of the data from which Item 1 was obtained may be questioned and, furthermore, it certainly is much too large for vast areas of the earth—especially the oceans and the polar regions. In addition to questioning whether Items 2 and 4 are representative it should be noted that uncertain elements enter into their estimation. This approach to the problem seemed so difficult that another way was sought.

Surveys of the electric current density over the tops of thunderheads seemed to the author to be feasible when in 1946 pressurized aircraft became available for use in scientific projects. Owing to the absence of precipitation and the rarity of lightning in the clear air above a thunderhead, electric circumstances there are simpler than beneath the storm. This was the basis for expecting that the transfer of electricity in the air above the storm occurs chiefly by electric conduction and that, as a consequence, measurements of the vertical component of the electric current density made at short intervals (2 sec) on a number of traverses over a storm would constitute an adequate basis for estimating the magnitude and direction of the total current from a storm. Surveys of this sort were made in 1947 and 1948, as a joint project of the Department of Terrestrial Magnetism, Carnegie Institution, and the U. S. Air Force. A technical report is being prepared by O. H. Gish and G. R. Wait.[5]

Successful surveys of twenty-four storms were made. In these storms the current was directed upward, that is, positive charge was transferred upward. This is favorable to Wilson's suggestion. The magnitude of the current ranged from zero to 6.5 amp. The average current for all storms was 0.6 amp, and that for all except the one unusually large value, was 0.3 amp.

Is an average current per thunderstorm cell of 0.3 to 0.6 amp adequate to satisfy the requirement that the total supply current be 1800 amp? It would be, if the

5. See "Thunderstorms and the Earth's General Electrification," by O. H. Gish and G. R. Wait, *J. geophys. Res.* 55: 473–484 (1950).

average number of thunderstorm cells or centers of electric activity in progress on the earth were between 3000 to 6000. This is several times Brooks' estimate of 1800. The latter estimate is, however, not applicable here for the following reasons. The data used by Brooks consisted of reports of thundery days—days on which thunder was heard—and there is no indication that he took into account the fact that at some places two, and occasionally more, visually distinct thunderstorms occur within hearing distance of a station on the same day. Neither was it considered that in a given thunderstorm there are sometimes several well-separated centers of electrical activity in progress simultaneously. These considerations indicate that a world population of between 3000 and 6000 centers of electrical activity may be admissible, and, that the answer to the foregoing question is "Probably, yes."

This provisional answer is, however, subject to another condition, namely, that the values for total current obtained from these surveys may be too large because part of the current, represented by the measurements, may flow in a local circuit either to the lower pole of the cloud or to bound charge on the earth in the vicinity of the storm. An adequate evaluation of this effect has not yet been completed. Until this is done and until a more reliable estimate can be made of the world population of centers of electric activity, one can say only that the available evidence is favorable for the view that the supply current is generated in the thunderstorms, but much more investigation is required in order to reach a definite and reliable conclusion. This theory has at the present time no serious rival. No other theory known to the author has the potentiality of accounting for the universal, diurnal, and annual variation of I.

An interesting corollary of this theory is that if the supply current originates in thunderstorms, the universal, diurnal, and other variations may be regarded as a measure of the thunderstorm activity of the whole earth. It accordingly seems likely that the record of i at a station where local disturbances are small would constitute an approximate record of the thunderstorm activity of the earth, showing how it varies from day to day and perhaps even from hour to hour. Small local effects are more likely to obscure the latter than the former. Such effects could, however, doubtless be largely eliminated from the data if i were registered at a moderate number of suitably selected stations. Such records might be valuable in the study of some problems of world meteorology. For example, they might provide answers to questions such as, Does world thunderstorm activity vary from year to year and is it correlated with sunspot activity? The data now available for i apparently point toward a negative answer to these questions.

How is the supply current generated? How are the electric charge-clouds of thunderstorms developed? These are two questions which doubtless have a single answer, provided that the supply current is generated in thunderstorms. In the author's opinion, no adequate answer to these questions has yet been published. Because of this circumstance the discussion which follows is limited to an outline of important aspects of the theories which have been proposed, the chief electrical features which must be accounted for, and some other conditions which must be satisfied.

The electrical cycle of a thunderstorm may be regarded as consisting of the following parts: (1) an initial separation of charge, a small-scale phenomenon in which some particles of precipitation become charged with electricity of one sign and the adjacent air, or some of the smaller particles, becomes charged with the other sign, (2) a large-scale separation of charge, possibly occurring in several steps, by which large charge-clouds of several cubic kilometers in volume are formed at more or less definite levels in the thundercloud, (3) the initiation of discharge from a cloud, namely, the mobilization of the charges residing on particles widely distributed throughout the charge-cloud, thus preparing for the succeeding steps which constitute (4) the lightning discharge.

The last of these, the lightning discharge, has been comparatively well elucidated in recent years. It is the subject of a separate article in this Compendium[6] and will not be discussed here.

Knowledge regarding the other steps, however, is in an unsatisfactory state. More factual evidence is required before theories of these aspects of the electric cycle of the thunderstorm can be securely established.

The initiation of a lightning discharge—the getting together of the charges which are widely distributed on ice particles or raindrops or both—although one of the unexplained aspects of the thunderstorm has little relevance to the development of the charge-cloud, and will be dismissed with the statement that the glow discharge, which starts at the surface of charged particles, is presumably involved. When the glow discharge spreads throughout a sufficient volume of the charge-cloud, the discrete charges on the particles are mobilized for the lightning discharge. However, there is little direct evidence to support this surmise.

The electric structure of the thunderstorm is often so complex that exact descriptions, such as could be made with the aid of general harmonic analysis when adequate data are available, have not been undertaken. One might say, however, that in the classical work of C. T. R. Wilson a fair estimate of the principal moment was obtained. An advance beyond this was realized in the work of Workman, Holzer, and associates [23]. The results of these and other investigators are in fair agreement on the gross aspects of the electric charge-clouds. These and some other features which bear on the later discussion are listed here.

1. There are two principal charge-clouds in the typical thunderstorm. The positive cloud is usually located at an altitude greater than that of the negative cloud. An altitude of 6 to 7 km for the former and of 3 to 4 km for the latter has been estimated.

2. Charge-clouds tend to be cumuliform rather than stratiform.

6. Consult "The Lightning Discharge" by J. H. Hagenguth, pp. 136–143.

3. The size of a charge-cloud which has developed to the stage where lightning of average intensity may occur is comparable to that of a sphere of at least 1-km diameter and probably is several times that dimension. For a cloud of smaller size, having a charge of 20 coulombs, the dielectric strength would be exceeded in air containing water drops, ice pellets, or crystals.

4. The region of primary electrical activity (location uncertain) where the initial charge separation and the large-scale separation occur jointly, doubtless has a cross section less than that of the charge-clouds.

5. The average cloud charge developed between lightning flashes is 20 to 30 coulombs.

6. The average rate of regeneration for charge-clouds, after lightning discharges, is about 4 amp but values as great as 20 amp are sometimes indicated. In regeneration the charge approaches an equilibrium value in approximately an exponential manner. One may accordingly speak of a relaxation time. An average value of the latter is about 5 sec. The relatively small departure of individual values from this average seems to have some significance.

7. No convincing evidence has been found of abnormally large electrical conductivity of the air above thunderclouds or under thunderclouds at the earth's surface.

These items will be referred to by number in later paragraphs.

The initial separation of charge has been attributed to various processes: The disruption of drops of pure water will effect a separation of electric charge with positive charge on the drops and negative charge in the air (a few thousandths of one per cent of some salts as an impurity annuls this effect). G. C. Simpson developed a theory which depended on this process. This theory was in vogue for more than a decade, but it became untenable when it was found that the positive charge-cloud is usually above the negative cloud.

Ion-capture is the fundamental process in a theory developed by C. T. R. Wilson. This process may be illustrated as follows. A water drop located in the normal electric field will have a positive charge induced on its lower surface and a negative charge on its upper surface. If the atmosphere contains ions (large ions assumed by Wilson), the positive ions will drift downward and the negative ions upward both with a velocity much less than that of the falling drop. The negative ions will be attracted by the positive charge on the bottom of the drop and those located in or near the path of the drop will be captured. The positive ions, however, will be repelled by the charge on the bottom of the drop and escape capture because when such an ion is in position to be attracted by the negative charge on the top of the drop, that attraction is not great enough to effect a capture. In this way larger drops may acquire a net negative charge. The larger drops with their negative charge will accumulate in the lower part of the thundercloud while positive charge, without involving the ion-capture process, will accumulate at a higher level. This is a favorable aspect of Wilson's theory, since it is in accord with the observed orientation of the principal charge-clouds. Although there are reasons for thinking that pellets or crystals of ice may also capture ions in this way, this requires more investigation if the ion-capture process is to be considered active in the region of sub-zero (centigrade) temperature where the principal charge-clouds are found. This ion-capture process requires that a relatively large concentration of ions, preferably of low mobility, obtains in the electrically active part of a storm cloud. Such a condition has not yet been observed, except as a local phenomenon of relatively rare occurrence, namely at times when glow or brush discharge (St. Elmo's fire) occurs. Unless there is some potent source of such ions other than the glow or spark discharge, Wilson's ion-capture process can act only in a secondary role after fields capable of initiating glow discharge have been developed by another mechanism.

The collision of ice particles has been suggested as a process for the initial charge separation. Charge developed by drifting snow (positive in the air) is more conspicuous than that for splashing rain but it is doubtful whether this process is effective in the atmosphere remote from the earth's surface.

Evaporation, condensation, and sublimation acting singly or in combination have been assumed as primary processes [11, 16]. Findeisen's experiments [11] indicated that these processes are much less effective than is the process which is involved in the formation of sleet (*Vergraupelung*). Dinger and Gunn [9] found an effect associated with the freezing of water and the melting of ice. Gunn [16] also assumed that a raindrop is essentially a concentration cell, and he indicated how it may acquire a net negative charge during condensation and a net positive charge during evaporation. Frenkel [13] developed a theory in which the electrokinetic potential of a raindrop, or cloud droplet, was proposed as the basis for the initial separation of charge. The fundamental element of this theory is similar to that of Gunn's theory.

A very active process of charge separation was discovered by Workman and Reynolds [24]. This occurs during orderly freezing of water in which very small quantities of certain salts are dissolved. The effectiveness and the direction of the process depend upon the concentration and nature of the solute. In most solutions for which a pronounced effect was reported, negative ions are captured by the ice. A prominent exception to this was found in solutions of the ammonium salts for which the solid phase acquires a positive charge.

The charge developed by this process in the freezing of one cubic centimeter of water is extraordinarily large for a number of solutions which were examined. For solutions of *NaCl* the greatest effect was for an 0.83×10^{-4} normal concentration. This gave a charge of 9.2×10^{4} stat coulombs from the freezing of one cubic centimeter of solution. The solid phase acquired a negative and the liquid phase a positive charge. The largest value reported was for a *CsF* solution of 11.1×10^{-4} normal concentration. This is 44×10^{4} stat coulombs cm^{-3}. These values are of a much greater order of magnitude than the largest value reported by Lenard and

associates for the violent disruption of a water drop, the latter being about 2 stat coulombs for each cubic centimeter of water that is involved. Perhaps the results reported by Findeisen and by Dinger and Gunn are in part attributable to the orderly freezing of water.

Other investigations of Workman and Reynolds indicate that cloud droplets may contain solutes of the right type and in suitable concentration for this process to occur in the atmosphere. Favorable results were also obtained in an experiment designed to imitate the growth of hail.

The advantage which derives from the relatively large amount of electric charge separated in the orderly freezing of suitable solutions may be illustrated by the following simple calculation. If the amount of charge separated in the formation of one gram of hail or sleet is 10^4 stat coulombs (about 2 per cent of the largest value reported), then in order that the rate of charge regeneration of a charge-cloud be 4 amp, or 1.2×10^{10} stat amp (Item 6, of the foregoing list), it is necessary that at least 1.2×10^6 g (about one short ton) of hail be formed each second in the region of primary electrical activity. In contrast to this, the mass of water drops that would have to be violently disrupted each second, if the breaking-drop process were the basic factor, would be at least 6×10^9 g or more than 6500 short tons. This apparently shows that the breaking-drop process is not adequately active, but that generation of charge by orderly freezing may be sufficiently active provided that, among other conditions already indicated, hail is always a large constituent of the hydrometeors in a typical thunderstorm.

None of the other primary processes so far proposed has yet been shown to have the generating capacity required. Acceptance or rejection of either Gunn's or Frenkel's theory depends on whether or not the relaxation time of the process is adequate, that is whether $1/(4\pi\lambda)$ in the region of primary activity, is, on the average, about 5 sec (Item 6). This is equivalent to saying that these theories are not acceptable unless the air conductivity in the region of primary activity is at least ten times that for normal air at an altitude of 5 km. At present it seems unlikely to the author that this condition is satisfied, but since this opinion is based chiefly on indirect evidence, more direct exploration in the future may bring forth evidence which contradicts this view.

The ion-capture process which is elemental in C. T. R. Wilson's theory also postulates that a relatively high concentration of ions prevails in the region of primary activity, where the initial separation of charge occurs. Since these ions are assumed to have a very small mobility, it seems likely that the air conductivity would be abnormally small in some parts of the cloud. This postulate cannot be definitely refuted by evidence now available.

The large-scale separation of charge which follows the initial step in charge generation must also proceed at the rate of 4 amp for each typical center of electrical activity. In all theories mentioned in this article it is postulated (1) that after the initial step the larger drops, or particles of precipitation, tend to have an electric charge of sign opposite to that of very small particles or of air ions, and (2) that, principally under the action of gravity, large particles fall away from the small ones at a velocity v which is equal to the difference in the terminal velocities.

Although there are no obvious alternatives to these postulates, there seems to be some ground for doubting whether the second is acceptable. This is illustrated in the following paragraph.

Let ρ denote the total net charge on the large particles in a cubic centimeter of air; v, the average velocity of these particles relative to the smaller ones; and A, the cross-sectional area, normal to the direction of v, of the region of charge separation. The total current I' from large-scale separation then is $I' = \rho v A$. Now in order that the value of I' may be 4 amp, $\rho v A$ must equal 1.2×10^{10} stat amp. The space charge ρ is limited by several circumstances. One which is amenable to simple treatment is that for no considerable proportion of the drops or particles shall the charge q of each drop of radius r be greater than $100r^2$. Larger values lead to electrical discharge. If there are n drops in each cubic centimeter, all of the same size and same charge, the maximum admissible space charge is $\rho_m \leqq 100nr^2$.

The mass of drops m in 1 cm^3 of air is also limited, and in terms of this m, the foregoing expression for the upper limit of ρ may be written $\rho_m \leqq 300m/(4\pi r)$. Now v is an increasing function of r, but in such a way that $\rho_m v$ *decreases* with an increase of r if m is constant. For a very large value of m, namely, 5×10^{-6} g cm^{-3}, $\rho_m v$ is 0.25 for hailstones having a diameter of 3 cm, and is 1.1 for droplets of 0.4-mm diameter. If the intermediate value 0.5 for $\rho_m v$ is used, one finds that $A \geqq 2.4$ km^2. Such a value for A is of satisfactory magnitude, but in view of the assumptions made here this estimate is doubtless much smaller than is actually required. It seems unlikely that in nature a large proportion of the precipitation particles are highly charged at a given time, and it is also doubtful whether such a large concentration of water, in either the liquid or the solid phase, occurs in a typical thunderstorm. The effect of the electric field, which tends to reduce v, especially if the particles are small, is also not considered here. Because of these and other considerations it seems evident that the value required for A is much larger than 2 or 3 km^2. But if this conclusion is correct, that would entail the difficulty of accounting for the size, structure, and orientation of the charge-clouds—features which are, at least roughly, indicated by measurements of the electric field above thunderclouds, within them, and below them at the earth's surface.

The object of the foregoing statement is to indicate how unsatisfactory is the present status of theories regarding the large-scale separation of charge in thunderstorms. No theory is yet secure if settling under the action of gravity is assumed to be essential in the large-scale separation of charge. If observations eventually show that the concentration of water in the typical thunderstorm is considerably greater than 5 g m^{-3}, at least in the region of primary electrical activity, this

difficulty might be removed. But it may be that some force other than gravity effects the separation of the larger from the smaller charged particles. A combination of centrifugal action and straight wind has been suggested, but it is not yet evident that the wind structure of the thundercloud is suitable for this.

This discussion of selected electric features of thunderstorms and of theories which have been proposed to account for those features was designed to show that at the present time there are only a few clues as to how the charge-clouds are developed. One of these is the recent discovery that the orderly freezing of very dilute solutions of certain salts is a very effective process for the initial step in the generation of electric charge. The potency of this process is such that if conditions in the thunderstorm are favorable, the charge on the precipitation particles may be maintained at a value so near the maximum, limited by electric breakdown, that the prospects of accounting for the large-scale separation of charge will be improved. More observations of electrical and other conditions, especially within thunderstorms, and more carefully controlled speculation are required to find the answer to the question, How are the charge-clouds in thunderstorms developed?

Until the foregoing question is answered, the added question, How is the supply current generated? will probably also remain unanswered. This statement depends upon the fact that with the evidence now at hand one may entertain the view that the supply current is generated in the thunderstorms of the earth. Before this view was advocated, the fair-weather aspects of atmospheric electricity and thunderstorm electricity were regarded as unrelated geophysical phenomena. Now, since it seems likely that the universal aspects of atmospheric electricity derive from thunderstorms, a more unified exposition of the subject is feasible.

From a remote position in space an ideal observer, whose acute vision could encompass the whole earth, might see in the broad prospect of atmospheric electric phenomena the following features: first, the numerous thunderstorms in progress on the earth—usually several thousand of them. He would notice that they are very scarce in the polar regions and especially abundant in the afternoon on land areas in middle and low latitudes. If each hour throughout a year he should count the total number of electric storm centers, he would probably note that, on the average, the count tends to be greatest for the hour when it is mid-afternoon at about longitude 75°W and least for the hour when it is mid-afternoon at about longitude 150°E. Other variations in the count would doubtless also be found.

If this observer had a special sense with which he could "see" a flux of electricity, he would not only notice the lightning flashes in and about the electric storm centers, but would also see a complicated pattern of electric flux in, about, and beneath each electric storm center. But the most alluring feature would be a narrow stream of the electric effluvium which emerges from the top of the upper charge-cloud, flows upward and along its course, widens and becomes less dense until it merges at a high level with similar streams from the other storms to form a world-wide ocean of electric effluvium. From this ocean a much more tenuous but nearly uniform electric flux could be seen to proceed downward to the earth everywhere except in and about electric storms. The circuit continues through the earth and back to the storm centers. The density of this universal flux from air to earth would be seen to vary during the day, from day to day, and during the year, in about the same manner as does the corresponding count of storms. But apparently it varies little, if at all, from year to year.

This is an impressionistic sketch of the broad prospect of atmospheric electricity as it is seen by the author in the light of evidence now available.

OUTSTANDING PROBLEMS

In the broadest sense there are two main problems in the field of atmospheric electricity:

1. To locate the source of those universal aspects which are epitomized in the concept, supply current.

2. To elucidate the mechanism which generates the supply current. If, as now seems likely, the supply current is generated in thunderstorms, the last-mentioned problem and that posed by the electric aspects of the thunderstorm have much in common.

It is of course necessary to have an adequate quantitative description of the phenomena before the rationale of the subject is developed. In this respect there are many minor and some major inadequacies. Some of the more important observations required in order to fill this need are:

1. Measurements of air conductivity in the high atmosphere, especially in the altitude range 18 km to 60 km. New techniques would be required to make the measurements in the upper part of this region.

2. Measurements of air conductivity, and counts of Aitken nuclei in thunderstorms. These items are suggested, rather than measurements of small-ion and large-ion concentrations, because measurement of the latter elements is more difficult. The technical difficulties of making reliable measurements of air conductivity from aircraft, during flight through clouds, have not yet been overcome.

3. More extensive, or more comprehensive, information about the population of the electric storm centers that are in progress on the earth. Until this information is available, no reliable estimate can be made of the average current which a typical electrical storm center must contribute to the make-up of the supply current. It is desirable that data be collected to verify, or to refute, the diurnal variation in storm population reported by Whipple. Perhaps this could be done by radio methods used for measuring atmospherics and "background noise," with some modification to adapt them for use in a world survey of electric storm activity. Apparently it would be necessary to make such measurements at a relatively small number of well-distributed stations.

4. More data for the air-earth current density i or for the elements λ and E, in order to ascertain whether, and in what manner, the supply current varies during

the year. The evidence now at hand is inadequate for a reliable determination of even the qualitative aspects of this feature. Except for measurements made on the cruises of the *Carnegie*, data for i have been obtained at only a few places.

5. Information which will help better to ascertain the electric structure of the thunderstorm. More measurements of electric field in the vicinity of thunderstorms (made simultaneously at a number of stations) are required for more types of storms. More measurements, made within storms, of the electric charge distribution are desirable.

6. More determinations of the rate of regeneration of charge, after a lightning discharge. Although the data now at hand appear to be comparatively reliable, they should be checked because they set a requirement which may not be satisfied by any theory which depends upon the force of gravity for the large-scale separation of charge.

7. Determination of which of the various known processes of initial charge separation occur in a thunderstorm. It will doubtless be difficult to find a definite answer to this, but the answer should be sought.

8. Information on how the widely scattered discrete charges in a charge-cloud are mobilized for the lightning discharge. This is another question for which a more definite answer is awaited.

These are some of the matters in atmospheric electricity which deserve attention. Others have been indicated in the body of this article.

REFERENCES

This brief list of treatises and papers is designed chiefly to serve as a guide for the reader or investigator who desires to read more comprehensive discussions of the subject. Technical articles which contain good bibliographies have been given preference. These citations, however, should not be used as a basis for assigning priority of or credit for discovery.

IONS IN THE ATMOSPHERE

By G. R. WAIT

Carnegie Institution of Washington

and W. D. PARKINSON

Johns Hopkins University

In considering the subject of atmospheric ions, it has been possible, because of space limitations, to consider only those conditions of the atmosphere which are regarded as normal and to include in the discussions, which are of necessity brief, only those items which are most important. References to investigations have also been restricted to those regarded as most pertinent to the subject at hand.

It has been known since late in the eighteenth century that an insulated charged body left in the air will slowly lose its charge by a process other than leakage across the supporting insulators. This process of gaseous conduction of electricity was interpreted by J. J. Thomson [42] as due to the presence in the gas of charged particles which, by analogy with the conduction in electrolytes, were called "ions."

The concentration of ions in the atmosphere is measured by an instrument called an *ion counter*. In principle the instrument is simply a charged cylindrical condenser through which air is drawn at a known velocity. The rate at which the charge on the central electrode changes provides a measure of the number of ions in the air stream and consequently the ion concentration of the air. If the voltage between the electrodes is sufficiently high, all ions from the air stream will be collected. Normally this voltage difference is selected so as to collect all ions of a particular mobility group and as few as possible of the less mobile ions. If a measure of the concentration of a lower-mobility group is desired, interference from ions of higher mobility may be avoided by first passing the air through another cylindrical condenser operated with sufficient voltage to remove the more mobile ions but only a small proportion of those to be measured. The theory and operating details of ion counters are discussed in special articles and texts on the subject [6, pp. 252–258; 10, 28, 41].

Ionic Mobilities

An electron is released in the formation of a pair of small ions, but remains free for only a short time. The fact that no high-mobility group of negative ions is found shows that very few free electrons are present in the lower atmosphere. Small ions of the atmosphere have an average life of the order of a minute, so they are thoroughly aged during most of their lives, and are subject to the influences of many atmospheric constituents existing in minute quantities. According to the picture recently given by Overhauser [34], an atmospheric small ion can be imagined as a charged molecule which is continually associating with, and dissociating from, one or more other molecules. The time a certain type of molecule remains associated with an ion depends on its electrical properties.

The average velocity with which an ion drifts through a gas under the influence of an electric field is proportional to the strength of the field. The ratio of the velocity to the field strength is called the *mobility* of the ion. The unit of measurement (referred to hereafter as centimeters) is centimeters per second per volt per centimeter.

Numerous mobility measurements on gaseous ions have been made in the laboratory [22]. The value of the mobility is found to depend upon both the ion and the gas through which it moves. It also is affected by the presence of very slight traces of water vapor and other impurities. The ion can apparently become attached to, or lose its charge to, an impurity molecule. Some molecular impurities are known to associate readily with a positive ion, some with a negative ion, and some with either. In most laboratory measurements, an effort is made to remove all traces of water vapor or other impurities so the values may be representative of the gas. For freshly formed positive and negative ions in air, Erikson [5] obtained a value for the mobility of 1.87 cm. In a few hundredths of a second the positive-ion mobility had decreased to 1.36 cm, due, he believed, to the ion becoming attached to a neutral air molecule. Bradbury [3] obtained what he considered a more representative value for each sign after taking extreme precautions to remove practically all traces of impurities. Values obtained by him were 2.21 and 1.60 cm as the negative and positive ion mobilities, respectively.

This requirement for such a high degree of purity for the air in mobility determinations leads one to question the extent to which laboratory-determined values can be accepted as the values of the small-ion mobilities in atmospheric electric work.

Mobility determinations of the small ions in the atmosphere have been made by various methods. Probably the method most frequently used is the ratio of air conductivity to small-ion content. This will not result in high precision unless proper precautions are taken to eliminate various errors which can easily enter and unless a correction is made for the lower-mobility ions caught by the ion counter.

The published values [14] of mobilities of small ions in the atmosphere, from measurements made many years ago, show a great deal of scatter. There are reasons

for believing that in many of these determinations the precision was not especially high, and in some cases it seems probable that considerable error resulted from the collection of lower-mobility ions by the ion counter (resulting in too low a value for the mobility). The latter was probable because at one time it was customary to apply to the ion counter a rather high potential, frequently as much as several times that required for small-ion saturation. A list of a few mobility values in air, from measurements where it is known that precautions were taken to avoid various possible errors, is given in Table I. The several values are in quite good

Table I. Some Mobility Values for Small Ions

Reference	Station	Period	Mobility in cm sec^{-1}/volt cm^{-1}	
			$k+$	$k-$
[44]	*Carnegie*, Cruise VII	1928–1929	1.30	1.39
[39]	College, Alaska	1932–1933	1.45	1.75
[14]	Canberra, Australia	1934	1.29	1.40
[29]	Glencree, Ireland	1937	1.28	1.40

agreement, especially in view of the very large difference in meteorological conditions at the various stations and the possibility that such conditions might affect the mobility of the atmospheric ion.

Since the mobility of an ion is affected by impurities in the gas, it seems likely that atmospheric ions may be affected by impurities in the air. A sudden change in mobility, believed to be due to such causes, was found by Parkinson [35] at Huancayo, Peru (altitude 3300 m, mean pressure 518 mm). From carefully controlled mobility determinations and from simultaneous measurements of air conductivity and ion concentrations which were corrected for the lower-mobility ions caught by the ion counter, it was found that a sudden drop in mobility took place each morning at about seven o'clock local time. This drop occurred at the precise time when there was a large influx of molecular impurities into the atmosphere. The average values of $k+$ and $k-$ for the 7-hr period before the influx of impurities were 2.40 and 3.46, respectively. The mean values for the 7-hr period immediately following the influx were 2.00 and 2.35, respectively. The change in negative-ion mobility was nearly twice as great as the change in positive-ion mobility. Thus it appears that the molecular impurities at Huancayo associate more readily with the negative than with the positive ion.

Impurities in the atmosphere tend to be graded as to size, so that ions of a mobility lower than that of the small ion are often, although not always, found within rather narrow mobility ranges. Pollock [37] in Sydney, Australia, observed a group (intermediate ion) with a mobility between 0.1 and 0.02 cm. A similar mobility group has been found in other localities [14, 16, 47]. In some localities, on the other hand, there appears to be no such group [52, 56]. A lower-mobility group (around 10^{-4} cm) first detected by Langevin [21] has since been observed in a number of localities, and the ions in this group are now called the "Langevin," or large, ions of the atmosphere. Ions of still lower mobility have been observed in some localities [17].

Pollock found that the mobility of the intermediate ion was a function of the vapor pressure of the atmosphere, diminishing from around 0.1 to about 0.02 cm when the vapor pressure increased to about 17 mm, whereupon the ion was suddenly transformed into the large ion. Both Hogg [14] and Wait [47] examined this matter and neither found any tendency for the intermediate ion to be transformed into the large ion at any vapor pressure. Wait, however, found that the mobility of the intermediate ion was a function of the vapor pressure. At a pressure corresponding to 0 mm the mobility was about 0.5 cm while at 30 mm pressure it was only 0.05 cm.

Yunker [56] found a continuous mobility distribution in California. He presented a distribution in which the number of ions per mobility interval increases with increasing mobility. His results on artificially ionized air indicate that the concentration of ions of mobility down to 7×10^{-4} cm varies inversely with the nuclei concentration, which shows that the ions formed by charging of condensation nuclei have a still lower mobility.

Nature of Slow Ions

It is usually considered that a large ion is a charged condensation nucleus of the type discovered by Aitken [1]. This ion is usually singly charged, but multiply charged ions can exist [5, 15]. In general, nuclei appear to consist of some hygroscopic core around which a stable agglomeration of water molecules can form. Landsberg [20] has presented a detailed discussion of what is known of their properties. Sulphuric acid (a common product of combustion) and oxides of nitrogen probably play important parts in the formation of nuclei. Wright [55] discusses the matter of salt spray forming the core material for a nucleus which appears to be somewhat larger and is important in the atmosphere over the oceans and at some coastal places, but less important in most inland localities.

Pollock [37], in his announcement of the existence of intermediate ions, considered them to consist of a "rigid nucleus enveloped by a dense atmosphere of water vapour." Since the intermediate ion appears to exist only in certain localities, its nature probably varies greatly. If, as found by Wait [47], its mobility varies with water-vapor pressure in accordance with Blanc's law, then the size of the ion is probably constant. This argues against a hygroscopic ion. Hogg [16], working in London, detected intermediate ions the sizes of which were multiples of an aggregate of some 2000 molecules. He assumed them to be composed of sulphuric acid.

Rate of Ionization

The term *ionization* as used here refers to the production of ions, and not to ion concentration (as is sometimes the case). Small ions may be produced in air by a variety of methods, such as by chemical and mechanical means, by ultraviolet light of sufficiently short wave

length, by breaking drops, and by drifting snow and dust. Under particular circumstances one or more of the above-mentioned processes may add appreciably to the ion population of the air. None of these, however, are normally important as ionizers of the atmosphere. The chief ionizer in the lower stratosphere and the troposphere, except in the lower atmosphere over land, is the cosmic rays. In the lowest kilometer or so over land, ionization of the air is due chiefly to radiations from radioactive matter in the earth and in the air.

The average rate of ionization of the atmosphere q, over land and near the earth's surface, has been estimated by Hess [10, pp. 167–171] at about 10 pairs per cc per sec. This value is based on the average amount of radioactive matter in the earth and in the air and is summarized in Table II. According to this estimate, approximately half of the total ionization is due to radioactive matter in the air, one third is due to radioactive matter in the soil, and one sixth due to cosmic rays. The ionization due to cosmic rays and radioactive matter in the soil is probably more or less constant with time at a given station. That due to radioactive matter in the air, however, is subject to variations, since the quantity of radioactive matter in the air varies with time. The amount of radioactive matter in the air depends upon two factors: (1) the rate at which it is dissipated in the atmosphere, and (2) the rate of exhalation from the soil.

Table II. Ionization of the Air Near the Earth's Surface Over Land in Per Cent of Total

Ionizer	Ionizing ray				Total	
	α	β	γ	Cosmic rays		
Radium } in air	30	1	1		32	51
Thorium } in air	18	1	—		19	
Radium } in soil	—	1	32		33	
Thorium } in soil						
Cosmic rays				16	16	
Total	48	3	33	16	100	

The rate of exhalation of radioactive gas from the soil is subject to considerable variation, being affected by such factors as temperature of the soil, wind force, dryness of soil, and covering on the ground [4, 57, 58]. The rate of dissipation in the atmosphere depends upon several factors, but particularly upon air turbulence. Zeilinger found a diurnal variation in the rate of exhalation from the soil, a maximum occurring in the morning hours and a minimum in the evening. A diurnal variation curve with similar characteristics has also been found for the radon content of the atmosphere [57].

A systematic diurnal variation in the rate of ionization of air near the earth over land would be expected, with a maximum occurring in the morning and a minimum in the evening. Continuous observations on the rate of ionization have been reported at three stations, Canberra, Australia [13], Washington, D. C. [48], and Huancayo, Peru [35], in which diurnal variation curves were obtained. A curve for each of the three stations is shown in Fig. 1. The curves are of the type expected when each is plotted on local time. Slightly different methods were employed in measuring the ionization.

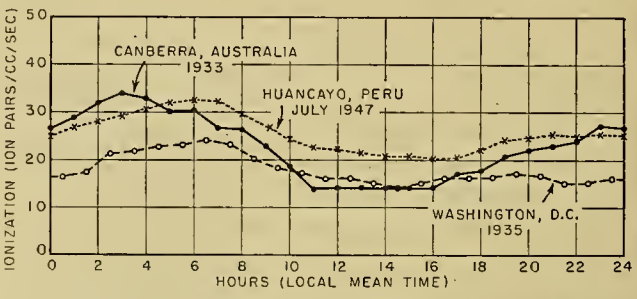

Fig. 1.—Daily variation in ionization of the lower atmosphere.

Hogg [13] measured the ionization of the air after it was drawn into a thick-walled sealed chamber. Wait [48] and Parkinson [35] measured the ionization in a thin-walled ionization chamber (the stopping power of the wall for alpha particles was equivalent to 1.5 cm of air). The values plotted for Huancayo represent the rate of ionization inside the chamber and must be multiplied by about 1.6 to correspond to the ionization of the atmosphere.

Small-Ion Balance

The processes of ion formation just described are balanced by the processes of small-ion destruction. One such process is the recombination between small ions of opposite signs. Ions of other mobility groups will also be active in neutralizing small ions. This is particularly true of the large ions. A third process is one not of neutralization but of the conversion of a small ion into a large ion by coalition of a small ion and a neutral condensation nucleus. The equation of ion balance for positive small ions, taking into account the processes mentioned so far, is

$$q = \alpha n_1 n_2 + \eta_{12} N_2 n_1 + \eta_{10} N_0 n_1. \qquad (1)$$

There is an analogous equation for the negative small ions. The symbols have the following meanings: q is the rate of small-ion formation (expressed in ion-pairs per cc per sec); α is the recombination coefficient for small ions; n_1 and n_2 are the concentrations of positive and negative small ions, respectively (in ions per cc); N_2 is the concentration of negative large ions; and N_0 is the concentration of neutral condensation nuclei. The constants η_{12} and η_{10} are known as *combination coefficients*.

In general the small-ion concentration is accounted for by such an equation. In some places it is necessary to take into account the effect of intermediate ions, but their effect is always small compared to that of the large ions and uncharged condensation nuclei. Over land, the term due to recombination is generally small compared to the other terms, and equation (1) can be written:

$$q = n_1(\eta_{12} N_2 + \eta_{10} N_0). \qquad (2)$$

Now the balance of large ions, shown later, requires that

$$\eta_{10}N_0n_1 = \eta_{12}N_1n_2, \tag{3}$$

and similarly for the negative ions:

$$\eta_{20}N_0n_2 = \eta_{12}N_2n_1. \tag{4}$$

If one further assumes that (3) is equal to (4), then (2) can be rewritten as

$$q = 2\eta_{12}n_1N_2, \tag{5}$$

so that, if changes in q are neglected, the value of n_1 is approximately inversely proportional to N_2.

Processes which cause the destruction of small ions other than those involving combination with small or large ions or condensation nuclei can play an important part under some conditions. Large particles such as smoke and dust can remove small ions [2, 48]. In the atmosphere over the oceans the most important process of destruction of small ions is recombination, but here the influence of nuclei is perceptible in the balance of small ions [44]. In this connection it is interesting to mention the results of a long series of observations of atmospheric conductivity over the oceans. A steady decrease has been noted since 1912, indicating that even here there is a gradual accumulation of atmospheric pollution, due apparently to the increasing industrialization over the world [48].

Recombination of Small Ions

This subject has been extensively studied, both theoretically and experimentally. The reader is referred to the exhaustive treatment given by Loeb [22], and by Jaffé [18]. The subject cannot be pursued here; however, a word about columnar recombination is in order. In the high ion-density track or column left by an alpha particle there will be a high rate of columnar recombination. Thus the effective rate of ion formation is less than that which actually occurs. Only those ions which escape from the column have a life of any appreciable length. The number escaping will be increased by winds and eddy diffusion. In atmospheric electricity this matter has received but little consideration. It has been discussed by Nolan [31].

The value of the effective recombination of small ions is usually taken as 1.6×10^{-6} cc per sec for air at atmospheric pressure [6, p. 178]. However, Luhr and Bradbury [23] give a value of 1.23×10^{-6}, Sayers [38] gives 2.4×10^{-6} and Nolan [31] gives a value of 1.4×10^{-6}.

Combination of Small Ions with Condensation Nuclei

The theory of small-ion combination with condensation nuclei or large ions has received less attention than has the theory of recombination. If all variables in the equations of small-ion balance were measured, it would be possible to determine the value of combination coefficients. Usually this is not done, but relations between parameters are assumed. If it is asumed that equation (3) is equal to equation (4), it follows that:

$$N_0/N_1 = \eta_{21}/\eta_{20},$$
$$N_0/N_2 = \eta_{12}/\eta_{10},$$
$$N_1/N_2 = \eta_{12}n_1/\eta_{21}n_2.$$

If we assume that $N_1 = N_2 = N$, we obtain the relationships:

$$N_0/N = \eta_{21}/\eta_{20} = \eta_{12}/\eta_{10},$$
$$n_1/n_2 = \eta_{20}/\eta_{10} = \eta_{21}/\eta_{12},$$

which were assumed by Nolan and de Sachy [26]. Whipple [53] has deduced the following equations, which are sometimes used as an auxiliary relation between parameters:

$$\eta_{12} = \eta_{10} + 4\pi ek_1,$$
$$\eta_{21} = \eta_{20} + 4\pi ek_2, \tag{6}$$

where k_1 and k_2 represent the mobility of the positive and negative small ion, respectively.

Almost every observer has used a different method of determining these combination coefficients. Gish and Sherman [9] gave a thorough discussion of these methods together with a table of values prior to 1940. More recent values have been summarized by Parkinson [36], and Table III shows representative values.

Table III. Combination Coefficients (in units of 10^{-6})

	η_{10}	η_{20}	η_{12}	η_{21}
Least value	0.4	0.6	2.2	2.5
Greatest value	6.8	7.6	8.7	9.7
Median value	0.6	1.1	2.4	4.5

It is not surprising that these values vary so widely when it is remembered that various methods of determination have been used. Also it is not reasonable to expect that the combination coefficients would be precise universal constants since they depend upon the nature (*i.e.*, the mobility) of slow ions, which will vary with conditions and hence from place to place. Also, no notice is usually taken of the distribution of mobilities involved in the ions responsible for the destruction of small ions, nor is an allowance made for intermediate ions as distinct from large ions.

Several investigators [32, 33] have found that the age of the large ion has an influence on the value of the combination coefficient, the coefficient becoming higher the older the nuclei. This is probably due to an increase in the size of the nuclei with age, owing to coagulation.

Large-Ion Balance

If we assume that a distinct group of large ions exists, then we can speak of their balance just as we do in the case of small ions. One method of formation of large ions is the process which has been mentioned above as one which destroys small ions, namely the fusion of a small ion with a neutral condensation-nucleus. The other process of destruction is the neutralization of charge by a small ion of opposite sign. There will also be a recombination term, similar to that for small ions, and a linear term ζN to account for diffusion [30]. We can write Q for the formation of large ions by other

methods; then the equation of positive large-ion balance becomes

$$dN_1/dt = Q + \eta_{10}n_1N_0 - \eta_{21}n_2N_1 - \gamma N_1N_2 - \zeta N_1. \quad (7)$$

There will be a similar equation for the negative large ions. In this case the value of Q will not necessarily be equal for the positive and negative large ions, for the situation is not as simple as for small ions where the formation is principally due to a process wherein an ion pair is produced.

Kennedy [19] and Nolan [30] found values of γ of the order of 10^{-9}. Hogg [12] reported a value about ten times this, but failed to take into account coalition of neutral nuclei and diffusion or falling out of larger nuclei as a means of dimunition of nuclei. Wait and Torreson [51] found that the value of γ varies with the age of the ion. In a later study, Wait [48] found that for singly charged ions the value of γ could be expressed as a function of the mobility k of the ion. A provisional value of this relationship is given by the equation

$$\gamma = 1.25 \times 10^{-6} k^{3/4},$$

which appears to hold for all mobilities between that of the large and that of the small ion. The measured value of γ for $k = 3.2 \times 10^{-4}$ was 3.1×10^{-9}. In the free atmosphere away from sources of large ions the terms Q, γN_1N_2, and ζN_1 are usually so small they can be neglected, and (7) reduces to

$$dN_1/dt = \eta_{10}n_1N_0 - \eta_{12}n_2N_1,$$

and for large-ion equilibrium conditions,

$$\eta_{10}n_1N_0 = \eta_{12}n_2N_1,$$

which is equation (3). Equation (4) represents the analogous equation in the case of the negative large ions.

Ionic Concentrations in the Lower Atmosphere and Their Variations

Both large- and small-ion concentrations vary considerably from place to place and from time to time at a given place. Over land, the two usually vary systematically but in opposite directions, both during the day and throughout the year.

The large-ion content (in ions per cc) of the air over the oceans averages only a few hundred of each sign. More extensive measurements have been made of the condensation-nuclei content of the air over the oceans from which estimates may be made of the large-ion content. Landsberg [20], making use of all available measurements at the time, estimated that the average nuclei content of the air over the oceans was 940. Hess [11] more recently found an average over the Atlantic, between America and Europe, of 527 on one leg of a cruise and 659 on another leg. On Cruise VII of the *Carnegie* [44], the average nuclei concentration was 1370 over the Atlantic and 2350 over the Pacific. From all of these results one would estimate between 100 and 200 large ions of each sign for the air over the Atlantic and two to three times this number over the Pacific. The large-ion content over the oceans, as estimated on the basis of the number of small ions found during Cruise VII, is around 180 of each sign [44], which is in reasonably good agreement with the estimates above. No diurnal variation was found in the condensation-nuclei content of the air over the oceans during Cruise VII, from which one might surmise that the large-ion content would likewise be constant through the day.

Over land, Landsberg [20] estimated that the average condensation-nuclei content of the air in country districts was around 10,000 per cc, in towns around 30,000, and in cities around 150,000. The corresponding large-ion content might accordingly be estimated at between 1000 and 2000 for a country area, between 5000 and 6000 for a town, and between 20,000 and 30,000 for a city. These must be regarded as rough estimates only.

Most observations on the condensation and large-ion content of the air over land have been taken in the vicinity of human habitations. Both the annual and diurnal variations as well as the absolute values are greatly affected by human activities. When observed sufficiently far from industrial activities of man, the large-ion content, like the condensation-nuclei content of the air, shows a maximum during the winter when heating of homes is greatest, and a minimum in the summer. For a similar reason, the condensation-nuclei content of the air generally shows a maximum during the middle of the day [15, 20, 26, 46, 56]. The diurnal variation in large-ion concentration obtained by Yunker [56], on the other hand, was more or less opposite to this. The curve for large ions found at Washington [49] is likewise quite opposite and similar to Yunker's curve, both being plotted on local time. Torreson [43] first pointed out the discrepancy between the condensation-nuclei curves and the large-ion curves at Washington, and Wright [54] suggested an explanation based upon a variation in size of the condensation nuclei with relative humidity. Sherman [40] could find no evidence of a diurnal variation in the ratio of uncharged to charged nuclei in the air, as required by Wright's hypothesis. This apparent paradox has not yet been explained, but it raises the question whether condensation-nuclei counts tend to include relatively large particles while the large-ion counts include smaller particles. Additional experiments will be required to find an answer to the question as to why the two curves are of such different character and to ascertain if a similar difference is to be found at other places.

Over the oceans, even though the rate of small-ion production is less than that over land (only 10 to 15 per cent as great), the small-ion concentration in the two areas usually differs but little. This is accounted for by a smaller number of large ions over the oceans and consequently a slower destruction rate of the small ions. Over the oceans, the average small-ion content of the air was about 500 and 400, respectively, for the positive and negative ions during Cruise VII of the *Carnegie* [44]. Over land the concentration of each sign varies from around 100 over polluted areas to about 1000 for areas unpolluted with industrial smokes and gases.

The small-ion content of the lower atmosphere is generally lowest during the winter months and highest during the summer, just opposite to that found for the large-ion content. The values usually reach a maximum during the morning hours and a minimum during the afternoon. This type of variation, while largely controlled by the variation in large-ion content of the air, also depends to some extent upon the variations in the rate at which ions are produced, which, according to the curves of Fig. 1, is greatest during the early morning hours.

Variation in Ion Concentration of the Atmosphere with Height above Ground

The value of the large-ion concentration of the atmosphere at various heights above the ground can only be inferred from the values of condensation nuclei obtained at various altitudes. Wigand [20] made fourteen balloon flights on which condensation nuclei were measured. A rapid decrease in concentration with altitude was found; at a height of 3 km the concentration was only 3 per cent of that at ground level.

Much more information is available concerning the value of the ratio n_1/n_2, how it varies and why, than there is concerning the ratio N_1/N_2. Moussiegt [25], from observations in the Alps, found mean values of 2214 and 2335, respectively, for N_1 and N_2, from which one would deduce a value of 0.95 as the ratio of N_1/N_2. Hogg [15], in Canberra, Australia, found a mean value for this ratio of 1.22. In Washington, D. C., continuous records (unpublished results) of large, small, and intermediate ion concentration of air, alternating each week between the positive and negative ions, were made during September and December, 1935. Since these data are not strictly simultaneous, the ratios can be regarded as only approximate. In view of the paucity of published data from which a comparison of positive- and negative-ion content can be made, a summary of these data seems worth while and is given in Table IV. The large-ion concentrations in ions per 10^{-2} cc are represented by N_1 and N_2, while M_1, M_2, and n_1, n_2 represent the positive and negative intermediate-ion and the positive and negative small-ion concentrations, respectively, in ions per cc. The ratios M_1/M_2 and n_1/n_2

TABLE IV. MEANS OF VARIOUS HOURLY VALUES OF VARIOUS ELEMENTS IN WASHINGTON

Means of	Elements									Month (1935)
	N_1	N_2	M_1	M_2	n_1	n_2	N_1/N_2	M_1/M_2	n_1/n_2	
5 largest	77.2	72.4	121	126	284	266	1.49	1.05	1.19	
5 smallest	35.8	27.3	94	91	180	145	1.00	0.95	1.01	September
All values	51.1	42.8	107	108	229	212	1.10	1.00	1.10	
5 largest	79.3	74.0	167	195	169	159	1.27	1.01	1.22	
5 smallest	46.8	38.5	139	139	128	108	0.98	0.90	1.01	December
All values	60.8	48.8	153	170	188	173	1.12	0.96	1.12	

The values of the small-ion concentration made on thirteen balloon flights by various observers and that deduced from *Explorer II* air-conductivity measurements have been summarized by Gish [6, p. 194]. He concludes that the concentration increases roughly by 1000 ions per cc (one sign) for each 2-km increase in altitude. This rate of increase is true up to an altitude of about 6 km, after which it gradually diminishes, according to the *Explorer II* data, to less than half this value at 14-km altitude.

Ratio of Positive-Ion to Negative-Ion Concentration

A relationship between the ratios N_1/N_2 and n_1/n_2 has been deduced by Gish [6, p. 183] from the equilibrium equations and is given by the equation

$$(n_1/n_2)^2 = bN_1/aN_2,$$

where $a = \eta_{10}/\eta_{21}$ and $b = \eta_{20}/\eta_{12}$. If one assumes that $\eta_{10}/\eta_{20} = \eta_{12}/\eta_{21}$, then from the equation above it follows that

$$(n_1/n_2)^2 = (\eta_{20}/\eta_{10})^2 N_1/N_2,$$

which is the relationship assumed by Nolan and de Sachy [26]

show no consistent diurnal variation, while the ratio N_1/N_2 varies more or less in a manner opposite to that of the large-ion content [49].

During fair weather the average concentration of positive small ions exceeds that of the negative small ions by 10 or 20 per cent. Particularly at certain stations, the ratio n_1/n_2 varies in a manner similar to the variation of the earth's field (electrode effect). This is due to the repulsion of negative ions by the negatively charged ground. During a thunderstorm, because of the intense electric field with frequent changes in sign, the ratio undergoes frequent changes in value, say from a very high to a very low value and vice versa, usually several times during a storm.

Mean Life of an Ion

The mean life of an ion is the time interval between formation and destruction of the average ion. For small ions the mean life τ_n in seconds, for the case when large-ion concentration is sufficiently small, is given by the equation

$$\tau_n = n/q, \qquad (8)$$

in which n represents the small-ion concentration and q, the rate of ionization (rate of small-ion formation).

When the large ions are numerous, then in accordance with the assumptions made in deriving (5),

$$\tau_n = \frac{1}{2\eta_{12}N_2} . \qquad (9)$$

Over the oceans the value of τ_n will generally be around 5 or 6 min. Over land, in areas where the large ions are few, the mean life τ_n may be expected to be only 10 or 20 per cent of the above. In localities where large ions are numerous, the value of τ_n will be still smaller, probably only 5 per cent or so of the ocean value.

The mean life τ_N of the large ion is given approximately by the equation:

$$\tau_N = \frac{1}{\eta_{12}n_1} .$$

Over the oceans and over land where the large ions are not very numerous, the value of τ_N may be between 15 and 20 min. In areas where the large ions are numerous, the value of τ_N may easily exceed an hour.

Because of the relatively short life of the small ion, the small-ion concentration may be expected to follow with little lag those factors which tend to produce a change in the concentration. Much greater lag may be expected in the changes of large-ion concentrations.

Outstanding Problems in the Field of Atmospheric Ions

A number of investigations have been carried out for the purpose of evaluating the factors which control or regulate the small-ion content of the lower atmosphere. There is growing evidence that some of the factors, for example the value of the combination coefficients between the small ions and the charged and uncharged condensation nuclei, may vary from place to place. This is probably due to a difference in character of the nuclei which results in a difference in nuclei size. A close correlation would therefore probably be found between the values of the combination coefficients and the mobility of the large ion. In future work, a recognition of this possibility may assist in harmonizing results which otherwise might appear to be inconsistent.

Another small-ion regulating factor which is difficult to evaluate is q, the rate of ionization of the atmosphere. Probably the most promising method of evaluating this factor is through the use of a thin-walled ionization chamber. This cannot be accomplished, however, without certain difficulties. Cognizance must be taken of the low radioactive content of the air within the chamber compared to that of the outside air and of the fact that the ionization within the chamber will depend upon the wall thickness and upon the particular voltage applied to the central electrode. The latter arises from the fact that complete saturation is never achieved, due probably to columnar ionization inside the chamber. A full discussion of this problem is not possible within the limits of this article.

It is quite probable that meteorological conditions play an important role in altering the efficiency of some or all of the small-ion regulating factors. Temperature, humidity, and pressure of the atmosphere, for example, are likely to exert an influence on such factors as combination coefficients, recombination coefficients, and the mobility of ions. There is urgent need for careful experiments designed to secure much-needed information along such lines.

Multiply charged large ions should be examined as to regularity of, and conditions of, occurrence and as to their effect on large-ion mobility and on establishment of small-ion equilibrium conditions.

PRECIPITATION ELECTRICITY

By ROSS GUNN

Physical Research Division, U. S. Weather Bureau

Introduction

Although atmospheric electricity does not play an important part in the control of world-wide weather phenomena, it does have considerable bearing on special weather problems. Because of the basic electrical nature of all matter, most mechanical and thermodynamical energy transformations are accompanied by some type of electrical phenomenon. It is not surprising, therefore, that the production of precipitation in the atmosphere frequently gives rise to interesting and important electrical effects. These phenomena share many of the peculiarities of weather because of the extreme complexity of charge production and transport processes in the atmosphere. One serious difficulty in the proper evaluation of precipitation electric phenomena is that the data thus far collected have been limited to a relatively few geographical regions and with few exceptions have covered only short periods of time. Many of the data are contradictory.

In view of the complexity of the electrical phenomena accompanying precipitation, it might appear that the most rapid progress on basic problems would be made if laboratory investigations were undertaken. However, it is apparent that this would be extraordinarily difficult for the same reason that investigations of weather in the laboratory have met with considerable difficulties. Electrification of the atmosphere and of precipitation is related to the characteristics and development of cloud structures, and these have not yet been successfully reproduced under controlled conditions. The scientist is forced, therefore, to collect data wherever and whenever available and to attempt to deduce from them the main characteristics and important processes of nature.

The principal practical problems of precipitation electricity that require intensive work are (1) to describe the detailed electrical processes responsible for the production of lightning, (2) to describe the mechanisms responsible for the maintenance of the observed negative free charge on the surface of the earth, and (3) to describe those processes that transfer free electrical charge to aircraft flying through natural precipitation and to devise a method for counteracting such processes. Solution of these practical problems requires a detailed understanding of other still more basic questions: (1) How is a free electrical charge placed on precipitation? (2) Why does charge of a selected sign appear principally upon the larger precipitation elements? (3) What are the mechanisms responsible for the separation of positive and negative charges? and (4) How large are the electric fields so produced? Quantitative understanding of these fundamental problems will provide a suitable foundation for the solution of the more practical problems.

Earth electrification processes that become manifest through easily obtainable measurements are intimately related to a dual basic process consisting first of the deposition of free charge on precipitation particles and then of the subsequent mechanical separation of charges having opposite signs. Mechanisms responsible for placing a free electrical charge of selected sign on the precipitation particles are not well understood, but they are basically related to atomic forces that are both physical and chemical in nature.

The occurrence of electrification and of coexisting available electrical energy implies the expenditure of mechanical work to establish the electrified state. In the earth's atmosphere this systematic mechanical work comes principally from gravitational forces and accelerations due to turbulent atmospheric motion, acting on precipitation particles. Large-scale separation of electrical charges will occur only when the acting forces operate on particles of one sign in a way quite different from the way they operate on particles carrying the opposite electrical charge. Because precipitation particles normally fall in the earth's atmosphere, the observed separation of charges always implies that the aerodynamic characteristics of carriers of the positive charge are notably different from the characteristics of carriers of the negative charge. This aerodynamic contrast between the particles carrying opposite charges is of importance in the description of all large-scale atmospheric electrifications.

Observed Free Electrical Charge on Precipitation

Early investigators were of the opinion that the free electrical charge carried to the earth by rain was adequate to replenish the normal discharge current observed in fair-weather areas throughout the earth. Later work has recognized that other processes are also important, but the original ideas stimulated the first measurements. The literature on the subject is contradictory in many cases, and the actual values of free electrical charge carried down by precipitation particles differ so much from place to place and with different meteorological situations that average values are of questionable significance. Better agreement between various observers is secured if the electrical characteristics of precipitation are classified in accordance with three distinct types of rainfall: (1) continuous or quiet rain (*Landregen*), (2) shower or squall rain (*Böenregen*), and (3) electrical storm rain (*Gewitter*). This useful classification was adopted by Gschwend in his measurements

of charge and mass of individual falling raindrops reported in 1920 [11].

Continuous or Quiet Rain. Quiet rain, usually associated with smaller droplets, carries relatively smaller charges *per drop* than storm rain and is more likely to be predominantly of one sign. The majority of experimenters have found that quiet rain is usually positive, although examples of continuous negative rain are known. The ratio of positive to negative charges reported generally varied from 1.1 to 1.5 when adequate samples were taken. In spite of the excess observed positive charge, it was found that the negative charge *per droplet* in most cases was greater than the positive charge per droplet. This implies, and measurements show, that usually a larger number of positively charged droplets fall. A dependence upon the rate of rainfall has usually been observed. A long series of measurements by Chalmers and Pasquill [4] in England showed that the number of particles carrying positive charges was some 70 per cent more than the number carrying negative charges, and that the total positive free charge delivered at the earth was some 30 per cent greater than the negative. It is interesting to note in this connection that, if data are collected over a sufficiently long period, the net free transported charge may be a small fraction of the total. For example, Scrase [23] measured the convected charge continuously for a two-year period. His results showed that positive charges predominated one year and negative the other, but for the entire interval the positive charge exceeded the negative by 10 per cent.

Shower or Squall Rain. Squall-type showers share the electrical characteristics both of quiet rain and of rain falling in typical electrical storms. Wide excursions in the electrical characteristics are normally observed. The analysis of rain falling from postthunderstorm showers and from those that have not quite proceeded to the point of active charge separation will be of the utmost value in determining the basic precipitation charging processes.

Electrical Storm Rain. The rain falling in a typical electrical storm is usually characterized by large droplets and large free charges that approximate a few hundredths of an electrostatic unit per drop. Gschwend [11] pointed out the remarkable fact that such rain frequently changes its sign. It has been found in active storms that after a very few consecutive droplets of one sign had been measured the chance of capturing a droplet having an opposite sign was very large. The free charge brought down by individual droplets falling from active thunderclouds has been measured on the ground by Gschwend [11], Banerji and Lele [3], and Gunn [12]. Gschwend found that the largest charges were associated with positive droplets, while the other experimenters found the largest charges associated with negative ones. In very active electrical storms, Gunn found a general trend connecting the charge on a droplet and its radius. The electrification of these droplets increased on the average until an electric field that approximated 2.5 esu cm^{-1} was established on the surface of the droplets. Negatively charged droplets were nearly twice as massive as the positively charged ones, and each carried about 25 per cent more charge.

The sign and magnitude of the integrated free charge transported to the earth by precipitation in electrical storms is uncertain. A number of measurements in thunderstorms have shown that negative charge is usually transferred to the earth by the acting mechanisms. For example, Banerji [1] has estimated that the excess negative charge convected to the ground by rain falling from an active thunderstorm in India was 2×10^3 coulombs.

The electrical state in an active storm is so complicated and confused that there is doubt as to the value of precipitation data as a guide to the interpretation of basic electrical processes. This uncertainty in interpretation has become serious as a result of a recent paper by Simpson [25]. He has presented evidence suggesting that the charge on falling rain is deposited by conduction or corona currents discharged near the surface of the earth by the electric fields usually present. Although a number of earlier experimenters looked in vain for such a correlation, Simpson now reports a good correlation between the sign of the free charge and the direction of the electric field. A careful check of the facts in this matter by independent observers is badly needed.[1]

Measurements taken in an aircraft at various altitudes up to 26,000 ft have been reported by Gunn [14]. These measurements were made in regions far above surface corona discharges and may be the only ones that give a clear-cut indication of the charge-producing mechanisms in the earth's atmosphere. In a weak cold front exhibiting no thunderstorm activity, positive charges averaging 0.033 esu per drop were observed from 10,000 to 26,000 ft. Negative charges averaging 0.040 esu per drop were measured between 4000 and 20,000 ft. Positive particles were not observed below 10,000 ft and negative ones were not detected above 20,000 ft. The freezing level during these measurements was at 11,000 ft. Direct measurement in the vicinity of the plane showed that the electric field did not exceed 25 v cm^{-1}, and therefore thunderstorm activity was negligible. A coherent set of similar data [15] taken in an active thunderstorm gave notably greater free charges on the precipitation and suggests that the interpretation of such collected data will be extraordinarily difficult.

Snow. Gschwend made a number of measurements of the charge carried by individual snowflakes. Positive charges, in general, exceeded negative charges, and it is important to note that the charge on newly formed snow is nearly one hundred times larger than the charge on quietly falling, and presumably aged, snowflakes.

Nakaya and Terada [20] found that snow carried a preponderately negative charge unless the flakes had frozen water droplets attached. Recently, Pearce and Currie [22] remarked on the large number of essen-

1. (Note added in proof.) W. C. A. Hutchinson and J. A. Chalmers have just published a paper, "The Electrical Charges and Masses of Single Raindrops," *Quart. J. R. meteor. Soc.*, 77:85–95 (1951), that provides needed data on this subject.

tially neutral snowflakes. However, of the flakes measured, they found free positive charges on twice as many flakes as carried negative charges. They also found that snow drifting over the ground was strongly negative. Chalmers and Pasquill [4] reported that snow is predominantly negative. It seems apparent from the literature and from other measurements that the sign and magnitude of the charge on falling snow depends critically upon its crystalline structure and mode of formation. As an illustration of this fact, this author found that snowflakes falling quietly with an average velocity of 48 cm sec^{-1} carried average positive charges of 0.00067 esu, whereas simultaneously falling negative flakes of average charge 0.0010 esu fell with a velocity of 80 cm sec^{-1}. The difference in sign was definitely correlated with the rate of fall. It is probable that the rate of fall is determined by the structure and density of the flake, which, in turn, is determined by its mode of formation. It is a fair inference from the data, therefore, that the opposite electrical charges result from grossly different developmental histories.

Average values of free charge carried by both positive and negative individual droplets of various kinds of precipitation, as measured by Gschwend [11], Banerji and Lele [3], Chalmers and Pasquill [4], and Gunn [12, 14, 15] are summarized in Table I.

Table I. Average Free Electrical Charge on Individual Droplets (esu $\times 10^3$)

Observer	Altitude (ft)	Charge	Quiet rain	Shower rain	Electrical storm rain	Quiet snowfall	Squall snowfall
Gschwend (1921)	surface	+	0.24	1.75	8.11	0.09	5.64
		−	0.53	5.43	5.88	0.06	4.78
Banerji and Lele (1932)	surface	+		6.4	6.9		
		−		6.7	7.3		
Chalmers and Pasquill (1938)	surface	+	2.2	1.3	3.7*		10.5
		−	3.0	2.3	9.2*		5.7

* Actual lightning activity doubtful.

Cloud Elements. If raindrops are formed by the association of cloud elements, it is obvious that the free electrical charge collected on cloud particles is of fundamental importance. A number of measurements have been made on the charges carried by clouds and fog, notably by Wigand [27]. He found that in a dry fog the cloud elements carried a positive electrical charge, but sometimes negative charges were measured. The magnitude of the charge varied from a few to a few hundred elementary charges. Using a specially instrumented aircraft [18], the author made a number of measurements of the charges on cloud particles in small swelling cumulus clouds and found that the charges were usually negative. The average charge on each element was estimated to approximate 22 elementary charges. Scrase [24] found that cloud elements in heavy wet fogs frequently carried a negative charge approximating 35 elementary units. Accumulation of information on the electrical charges carried by cloud droplets under various meteorological conditions is urgently needed.

Processes Responsible for the Electrification of Precipitation

Because all large-scale atmospheric electrifications derive their energy originally from expenditure of mechanical or gravitational work and because this work can be converted only when a free electrical charge is attached to some physical entity like a raindrop, it is of utmost importance to understand in detail the physical processes whereby free charge, of either sign, can be systematically deposited on droplets. One of the outstanding characteristics of precipitation elements in the atmosphere is the enormous surface area exposed to the atmospheric ions and to the chemical activity of the air. It has been noted frequently that precipitation elements in the air share many of the remarkable properties of a colloidal suspension.

Droplet charging processes may be divided into two major categories: first, charging processes which are of a basic nature and dependent upon the physical and chemical properties of water and air; and second, charging processes which are critically dependent upon special environmental conditions.

Basic Processes. As a common example of electrification by a basic process, one may mention the separation of electricity produced by friction. The rubbing together of materials having contrasting physical properties usually results in the selective transfer of electrons in the outer orbits from one material to the other. Dry ice crystals sliding along the metallic wing of an aircraft communicate large amounts of negative electricity to the aircraft and positive electricity to the ice crystal. It is well known that snow blowing along the ground acquires a strong negative charge which is very likely of similar frictional origin.

One of the important basic processes that produce electrical effects in the atmosphere results from the chemical adsorption of ions at the surfaces of precipitation particles. Systematic polarization and orientation of surface molecules frequently result. This orientation produces electrical double layers that are responsible for electrophoresis and a number of allied surface phenomena [9]. In pure water the polarization of the surface molecules is such that the outer surface is made up of negative charges, while some 10^{-8} cm below this negative surface a positive distribution of

exactly the same amount of electricity exists. Inside this double layer, a more or less random distribution of both positive and negative free charges is re-established. The net result of the double layer on the surface of a spherical drop is that the potential inside the drop may be greater than that outside by a fraction of a volt. This does *not* mean that free electrification is produced, since it must be remembered that exactly equal amounts of positive and negative electricity are encompassed by the double layer. However, if the double layer is subsequently broken and mechanical work is done on it or if ions are selectively captured, measurable amounts of free electrification may result.

One familiar charge-producing mechanism, intimately related to this double-layer process, is the so-called waterfall effect first studied by Lenard [19]. Subsequent experimentation has shown that when a droplet of pure water is broken up by mechanical means, the residual droplets carry positive charges while the adjacent air acquires both positive and negative ions. Electrifications produced by breakup, atomization, splashing, or bubbling are all intimately related to the double-layer characteristics; this subject has received much study [2, 5]. Although one widely quoted theory invokes such mechanisms to describe thunderstorm electricity, quantitative agreement with observation is quite unsatisfactory.

One aspect of double-layer electrification may be of importance in the atmosphere when hail is produced. Dinger and Gunn [6] discovered that when water freezes in the atmosphere a large amount of air is entrapped in the ice in the form of tiny bubbles. Upon melting, these bubbles are released, and upon breaking the surface they transfer to the adjacent air a negative charge of 1.25 esu gram^{-1} while the melted water droplet retains an equal and opposite positive charge. The free charge thus produced is appropriately distributed near the freezing level and is sufficiently large to explain the presence of active cloud electrification. These experimenters also discovered that the freezing of relatively pure water is accompanied by transient changes in the contact electromotive force amounting to 6 or 10 v. Because the charge distribution at the surface, responsible for the contact electromotive force, is in the nature of a double layer, they did not believe it contributed to a net electrification of a freezing droplet. Using special dilute solutions, Workman and Reynolds [29] have reexamined this latter process and report that potential differences exceeding even 100 v are produced under special circumstances.

It is important to note that the magnitudes of electrical effects in all double-layer phenomena depend *critically* upon the purity of the water. Banerji [2] has remarked that impurities commonly existing in precipitation in the atmosphere are usually sufficient to reduce the expected electrical effects to small values.

Environmental Processes. It is an observed fact that the atmosphere is pervaded by relatively large numbers of ions of both signs. The small negative ions move 10–40 per cent faster than the positive ions when acted on by the same force. Therefore, the negative ions usually determine the charge captured by an initially uncharged and insulated body.

It has long been known that an insulated conductor supported in an ion stream becomes charged due to the selective capture of ions. Pauthenier and Moreau-Hanot [21] have formulated this process in a quantitative theory that appears to agree well with experiment.

Wilson [28] has also pointed out that a droplet falling in an electric field is polarized, and as it falls it selectively captures, because of its motion, the more mobile ions in the volume it sweeps out. Experimental results confirm the reality of this process [10]. Since this important charge-separating effect depends upon the existence of an initial electric field, its application to the description of the electrical properties of the atmosphere is obscure. The mechanism is useful in describing changes in the electrical state subsequent to the establishment of an electric field by some more fundamental mechanism.

Electrification occurring when rime is deposited on a conducting surface or on graupel is considered important by Findeisen [8], who has based a theory upon it. The effect is real, but its quantitative relation to thunderstorms has not yet been completely worked out. The application of this mechanism is attractive because it correlates the observed high electrification occurring near the freezing level with theory.

An environmental process first investigated by Gunn [13] depends on the differential migration of atmospheric positive and negative ions under the influence of a systematic transfer of water molecules. He showed that the transfer of water vapor towards a condensing droplet results in a transfer of momentum to both the positive and negative ions in the vicinity and the establishment of a greater concentration of the most mobile ion adjacent to and upon the condensing droplet. The charge capable of being transferred to such a droplet is related to the vapor stream velocity and to the thermal kinetic energy of the molecules, and hence in the atmosphere is something less than 0.1 v. It should be clear that reversing the direction of the water-vapor stream will reverse the sign of the charge on the evaporating or condensing droplet.

Association Processes. In attempting to understand the basic mechanisms responsible for the surprisingly large electrical charge sometimes carried by precipitation, one process should be emphasized. Without discussing the details of association, it seems certain that rain produced below the freezing level results from the association of an extremely large number of cloud particles. In typical cases, the number of cloud particles associated to produce a single raindrop is surprisingly large, and if any process systematically transfers even small charges of a given sign to the cloud particles, then the total charge may be large. Gunn [13] worked out a complete "association theory" of electrical storm activity based on this idea. He remarked that a number of physical and chemical forces could be expected to transfer small charges to the cloud particles. To illustrate the theory, he adopted the notion that each cloud particle was an electrical concentration cell and that

the mean potential between the droplet and the outside air approached 60 mv. By estimating the total charge resulting from the association of typical cloud elements, relatively large free charges per droplet were calculated. It was found that precipitation electrical phenomena could be well described, both qualitatively and quantitatively, by such an hypothesis. The theory is not considered complete but it does serve to emphasize the probable importance of association mechanisms in the production of highly charged precipitation.

Separation of Free Electrical Charges and the Importance of Droplet Size

Although all matter is composed of an enormous number of electrical charges, it is a general rule that every small volume of space contains as many positive charges as negative charges. A short calculation will show that this indeed must be the case, because any systematic separation of charges of opposite sign immediately sets up surprisingly large electrical forces that always act in such a direction as to restore electrical neutrality.

An important exception to the general rule of neutrality occurs in the earth's atmosphere when free charges of one sign become selectively attached to the larger or smaller precipitation elements. As an example, suppose that, for some reason, all of the elementary cloud particles in a given volume selectively capture a positive (or negative) charge. When rain is formed, these cloud particles associate to form a highly charged raindrop. Suppose that, simultaneously, neutralizing negative (or positive) charges for each droplet are immediately outside and are attached to air molecules or other very small molecular aggregates. Gravity acts on both types of charged carrier, and they fall at a velocity determined by the acting aerodynamic and electrical forces. When the droplets are small, so that gravity does not give the particles high velocities, the neutralizing negative (or positive) charges are carried along with the falling positive (or negative) droplets as a result of electric fields. Thus, after a preliminary small separation, gross separations of the type observed in thunderstorms do not result.

Unfortunately, the literature does not contain an adequate discussion of the important problem of charge separation as influenced by the size of the droplet. Since the droplet size and the acting forces are of the utmost importance in understanding charge separation and lightning processes in the atmosphere, it has seemed worth while to discuss this matter here.

Consider a cloud of infinite extent, lying parallel to the earth's surface and composed of but two types of particles: (1) raindrops upon which positive charge, for example, is selectively deposited; (2) particles (assumed to be small) with a sufficient number of them carrying a total charge just large enough to neutralize the positive charge on the rain droplets. Assume, at first, that the whole cloud system contains exactly as much positive electricity as negative, each uniformly distributed. It will therefore be neutral and no electric fields will exist.

It is noted first that an electric field produced by the separation of charges always acts in such a direction as to prevent the separation. Thus, if positively charged droplets fall with respect to negatively charged droplets, the electric field thus produced acts to support raindrops while simultaneously it drags the small negative elements downward.

It is clear that the electric field can never grow to exceed a value greater than that of the field which will support the droplet. Thus, if E_m is the electric field when the droplets are completely supported by it, q is the charge on the droplet and m is its mass, while g is the acceleration due to gravity, one may equate the electrical and gravitational forces and write

$$E_m = \frac{mg}{q}. \tag{1}$$

This electric field is an absolute maximum in the atmosphere for droplets of a given size and is large enough in general to cause spark discharges.

The equilibrium electric field E_m, described above, is never realized practically because of the conductivity of the earth's atmosphere, which always acts to discharge and reduce any electric field so produced. In order that one may formulate quantitatively the actual equilibrium when the droplets are allowed to fall in an electrically conducting atmosphere, a one-dimensional solution will be obtained by considering the transfer of charge within a prism one square centimeter in cross section and extending vertically through the cloud. The electric current per unit area, i, due to the convected charges on the precipitation, is

$$i = \sum (n_+q_+v_+ + n_-q_-v_-), \tag{2}$$

where n is the number of charged particles per unit volume, q the charge on each particle, and v the velocity of fall, and where the subscripts denote the sign of the transported charge. This downwardly transported net free charge per unit time, i, not only charges the conducting earth below but also supplies charge to replace that conducted upward as a result of the normal ionic conductivity of the atmosphere and the generated electric field. If Q is the total free charge per unit area deposited on the surface of the earth, then, equating the rate of supply to the rate of loss of charge, one has

$$\frac{dQ}{dt} + \sigma E = \sum (n_+q_+v_+ + n_-q_-v_-), \tag{3}$$

where σ is the normal ionic conductivity of the earth's atmosphere, and E is the electric field generated by the charge separation. Under the assumed geometrical conditions, the surface charge density Q is related to the produced electric field E by the relation

$$E = 4\pi Q, \tag{4}$$

from which one may write, for regions near the earth's surface, that

$$\frac{1}{4\pi}\frac{dE}{dt} + \sigma E = \sum (n_+q_+v_+ + n_-q_-v_-). \tag{5}$$

Before integration of this expression is possible, the distributions and the velocities of fall must be expressed as a function of the gravitational forces and electric field. Under most conditions, the velocity of fall may be determined from the terminal velocity of fall of a spherical body in the earth's gravitational field together with known values for the electric field and the mobility of the particle. The terminal velocity of fall, V, for droplets of various sizes has been accurately determined and may be read from tables [6]. The mobility u is defined as the velocity of the particle in unit electric field, whence one may write approximately

$$v = V + uE. \tag{6}$$

Thus, droplets carrying charges of one sign move faster than their normal terminal velocity, while those of opposite sign move slower. Substituting this approximation in (5), assuming that the droplets are all the same, and integrating, one finds that the electric field increases with the time t in accordance with the following relation,

$$E = \frac{n_+q_+V_+\left[1 + \dfrac{n_-q_-V_-}{n_+q_+V_+}\right]}{\sigma - n_-q_-u_-\left[1 + \dfrac{n_+q_+u_+}{n_-q_-u_-}\right]} \left[1 - \epsilon^{-4\pi[\sigma - n_-q_-u_-(1+(n_+q_+u_+)/(n_-q_-u_-))]t}\right], \tag{7}$$

whence, approximating, the maximum *equilibrium* field is given nearly enough by

$$E = \frac{n_+q_+(V_+ - V_-)}{\sigma + n_-q_-u_-}, \tag{8}$$

where all quantities are now expressed as positive numbers. Attention is drawn to the fact that the selection of signs given above is arbitrary, and that in nature a negative instead of a positive charge frequently comes down on rain.

In interpreting equation (7), it is noted that when the positive carriers are small and have very low terminal velocities of fall, their actual velocities closely approximate the velocities of the carriers of negative charges. Thus the difference in terminal velocities becomes small, and the electric field approaches zero. In nonprecipitating clouds, therefore, one would expect that the measured electric fields would be very small; this is in accordance with direct observation [16]. When the rain droplets become reasonably large, the electric fields increase to large values. In fact, according to equation (7), the electric field is proportional to the rainfall intensity and to the free electric charge carried by the larger droplets. Since the negative carriers are very small compared to a raindrop, one may ignore their velocity and calculate Table II from equations (1) and (8), using the best available data [13, p. 94] to show how the equilibrium electric field increases with the size of the raindrop. It is interesting to note in Table II that, while cloud droplets produce a negligible field, the equilibrium field for large droplets is great enough to produce a discharge in air and thus initiate lightning. Equation (8) is therefore consistent with observation.

Using balloons, Simpson and Robinson [26] made measurements purporting to show that the electric fields inside active electrical storm clouds are "of the order of 100 volts/cm." This conclusion is seriously in error, for actual measurements in aircraft show that fields of 1000 v cm^{-1} commonly occur in such clouds without producing a lightning stroke [16]. The electric field on the belly of a B-25 aircraft at the beginning of an energetic lightning stroke has been measured as 3400 v cm^{-1} [14].

Table II. Electric Field and Droplet Size

	Droplet radius (cm)	Electric field to support droplet, (v cm^{-1})	Maximum equilibrium electric field (v cm^{-1})
Fog	5×10^{-4}	1,500	0.5
Drizzle	1×10^{-2}	24,000*	10.8
Medium rain	5×10^{-2}	24,000*	1,930
Excessive rain	1×10^{-1}	24,000*	24,300*

* Because the effective dielectric strength for long discharge paths in air approximates only 3000 v cm^{-1}, active lightning strokes would prevent such high values of electric field from maturing.

From equation (7) it can correctly be inferred that an increase in the conductivity of the atmosphere will reduce the generated electric field. It is not impossible that sudden localized increases in the electrical conductivity of the air, due to a lightning discharge or localized radioactivity, would so increase the conductivity that the generated electric fields would be small even with large droplets and big free charges. Thus, lightning would be suppressed. This matter requires further investigation and may be of importance in the artificial suppression of lightning discharges by localized dissipation of radioactive material into the atmosphere.

The analysis presented above properly emphasizes the dual and interrelated character of thunderstorm electricity as compared with charge production and separation. Electric storm fields would not exist if charges were not actively separated. The analysis shows that separation cannot take place unless the forces acting on the positive charges are different from the forces acting on the negative charges. This implies, in turn, the necessity for a selective deposit of a charge of definite sign on rain particles and a deposit of a charge of opposite sign on lighter cloud particles or air molecules.

Electrification of Aircraft Flying through Precipitation

It was found during World War II that aircraft flying in cold areas systematically lost all radio communication and navigational facilities whenever they encountered dry ice-crystal clouds or snow. Pilots flying through such precipitation in mountainous areas without usable radio navigational facilities continually faced dangerous situations that adversely affected the delivery of urgent war goods to Alaska.

Hundreds of flights made by the Army-Navy Precipitation-Static Research Team near Minneapolis,

through all kinds of precipitation and under varying meteorological conditions, established the basic mechanisms responsible for precipitation static. By using a specially instrumented aircraft, it was found that the two most important sources of electrification of the aircraft were (1) closely adjacent, highly electrified cloud centers, and (2) friction of snow and ice crystals as they slid over the wings at low temperatures. Ordinary rain or shower clouds showing little vertical convection were relatively inactive.

The Research Team was able to demonstrate that the interference with communications on the aircraft resulted from St. Elmo's fire or corona discharges from the aircraft antenna or closely adjacent structures. Because of the intermittent pulselike nature of the corona discharge, adjacent radio circuits were strongly shock-excited and rendered insensitive to the ordinary radio signals.

Normal thunderstorm activity produces large electric fields in the atmosphere; when the plane is in the vicinity of these fields, corona currents frequently are produced on the aircraft. Because an airplane traverses a typical electrically active cloud center in a relatively short interval of time, this type of disturbance (while especially severe) does not persist for long and therefore is not a serious handicap to navigational radio communication. The main difficulty arises from the fact that lightning sometimes strikes the aircraft or that very intense electric fields break down the insulating wire used on antennas.

The second type of electrification is self-produced by the aircraft as a result of frictional effects of snow or ice crystals as they slide over metallic parts of the aircraft. In frontal conditions this type of electrification may last for hours and, because radio navigational facilities must be constantly employed on aircraft, it is evident that such continuous electrification constitutes a dangerous operational hazard.

The frictional charge produced on the airplane proper when flying in dry snow or ice crystals is always negative, while flakes leaving the plane after sliding along its surface carry a positive charge. Experimental investigations have established the fact that the rate of charge production depends on the character of the metallic surface intercepting the precipitation. The charging increases with snow or ice-crystal density and with the cube of the air speed. As one might expect, the Research Team found that the charging rate was dependent upon the temperature, being relatively small near the freezing temperature and increasing as the temperature dropped to about −15C.

It is impractical to review the detailed effects that result from flying through precipitation. Interested readers are urged to read the extensive technical reports of the Precipitation-Static Project [7, 18].

As an illustration of the severity of precipitation static, it seems worth while to give some numerical results obtained off Yakutat, Alaska, in a typical upslope storm. Cloud and charging conditions were singularly uniform and serious electrification was observed for more than three hours. A four-engine B-17 aircraft, cruising at 165 mph, generated an average current of 750 μa. This current transferred a negative charge to the airplane and raised its potential to more than 450,000 v. The electrical energy dissipated, therefore, was 330 w. It was not surprising that corona discharge from the antenna was initiated causing such severe radio interference as to override urgently required communications.

Precipitation static is still a serious operational hazard because the present high operating speed of aircraft has greatly increased the charging rates that were already troublesome at low speed. The modern trend toward still higher speeds will ultimately demand housed antennas for communication purposes. Such construction will greatly assist in meeting future requirements.

THE LIGHTNING DISCHARGE

By J. H. HAGENGUTH

General Electric Company, Pittsfield, Massachusetts

The thunderstorm process and the theories relating to the formation of charges in the clouds are explained in another article.[1] This paper will contain information on the lightning discharge only.

The mechanism of the lightning discharge can be divided into three regions of interest: (1) cloud-to-cloud discharges, (2) cloud-to-ground discharges, and (3) phenomena on the ground end of cloud-to-ground discharges. From the practical point of view, the greatest effort has been devoted to understanding and interpreting the phenomena associated with the lightning stroke when it contacts man-made installations [1, 2]. Qualitative data have been obtained to give confidence in the principles of protection used to guard buildings and electrical transmission systems against the effects of lightning. It becomes progressively more difficult to determine the mechanism and physics of the lightning stroke as it occurs away from the earth.

Leaders

The study of the mechanism of strokes to ground has been accomplished primarily by means of photography [15, 16]. The lightning stroke starts at the cloud in the form of a stepped leader, as illustrated in the upper part of Fig. 1. The steps have an average length of 50 m. The time interval between successive steps is of the order of 50 μsec. The average velocity of the individual steps is of the order of 5×10^9 cm sec^{-1}, while the velocity of the total step mechanism is of the order of 1.5×10^7 cm sec^{-1}. Thus, the total time required for the stepped leader to reach the earth may be greater than 0.01 sec.

Table I. Characteristic Data for Leaders and Return Strokes

	Minimum	Average	Maximum
Stepped leaders			
Length of steps, *m*	10	50	200
Time interval between steps, μ*sec*	15	50	100

1. Consult "Precipitation Electricity" by R. Gunn, pp. 128–135 in this Compendium.

After the leader reaches the earth, the photographic film shows a much brighter illumination traveling upwards from the earth toward the cloud through the channel established by the stepped leader. This is called the *return stroke*. The average velocity of propagation is 5×10^9 cm sec^{-1}.

Subsequent to this first discharge there may be other discharges. These are also initiated by a leader, but of a different type, called *dart leader* or *continuous leader*, with a velocity of 2×10^8 cm sec^{-1}. As in the case of the first discharge, return strokes result on contact of the continuous leader with the earth. Occasionally leaders on discharges subsequent to the first have been observed to have a few steps. Data on leader and return-stroke characteristics are given in Table I.

Branching

Frequently the first discharge shows branching produced by a stepped-leader process. Branching is always in the direction of propagation of the leader. In general, subsequent leaders do not show branching, choosing the path where ground previously has been reached, resulting in a return stroke. In many cases more than one branch may reach ground simultaneously. In other cases ground is reached at a different point on subsequent discharges, following and completing a branch established on the first discharge. Upward branching has also been observed at the cloud end of the stroke. Photographs show that branching is the result either of discharges between portions of the cloud or of discharges from a different charge center in the cloud through part of the previously established channel. There are indications that branching is more profuse in hilly, wooded country than in flat, bare country.

Theories have been developed to explain the leader mechanism [8, 14]. These theories consider the presence of a pilot streamer which progresses more or less continuously, connecting the individual bright tips of the original leader. As the pilot streamer progresses, the ionization in the upper part of the streamer slows up and recombination of ions occurs. The impedance of the path therefore increases, and hence the potential difference across the established channel is also increased. As the potential is raised, reionization occurs down the channel. The speed and intensity of ionization increase as ionization reaches the tip of the pilot streamer. This increases the energy at the tip and results in greater illumination. The pilot streamer then proceeds for another 50 m and the process is repeated.

The breakdown or ionization process begins in a part of the cloud characterized by a high field gradient. At atmospheric pressure, 30,000 v cm^{-1} are required to begin ionization. At the reduced pressure in the clouds

and due to the presence of water droplets, it is estimated that a gradient of 10,000 v cm^{-1} may be sufficient. The process is started by the acceleration of one or more free electrons in the air. By collision with air molecules, these electrons liberate more and more electrons as they advance in the field, the number increasing very rapidly in the form of an avalanche. Large numbers of positive ions are left behind in the field. The resulting positive space charge increases the field gradient sufficiently for the attraction of photoelectrons. These in turn produce greater ionization and rapidly complete the breakdown process.

ten to several hundred feet. However, the evidence is insufficient to determine whether ground streamers occur on every lightning discharge.

If light intensity is considered a measure of the current amplitude in the return stroke, then in the majority of the cases photographed the first in a series of multiple strokes appears to carry current of the highest amplitude. This is not always the case. Oscillographic evidence also indicates that the first current peak does not always have the highest amplitude.

In many photographs taken in South Africa [9], the light intensity of the channel decreases as the

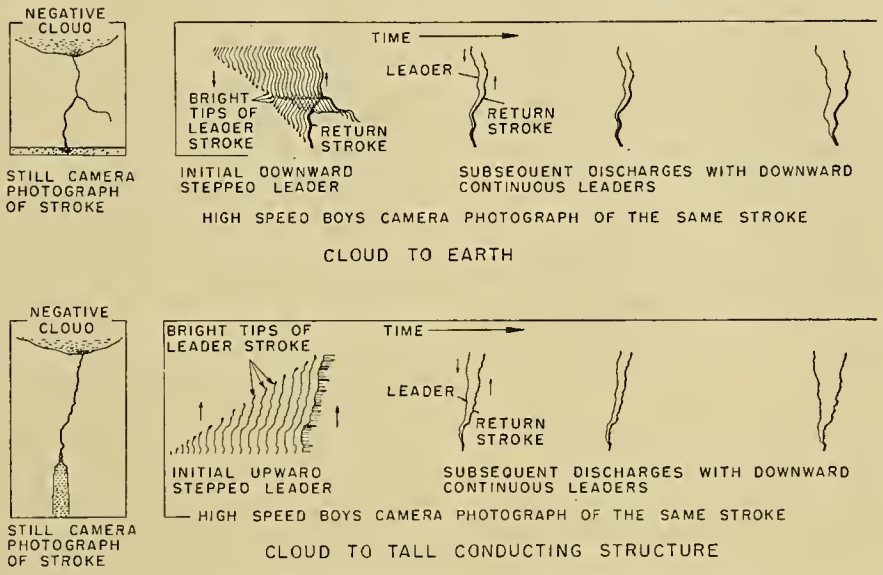

FIG 1.—Schematic diagram showing the mechanism of the lightning discharge from cloud to ground.

Laboratory experiments on long sparks have confirmed the stepped-leader process from negative point to plane, but not from positive point to plane. More sensitive measuring methods are needed to record the complete development of the streamers or leaders. There is considerable doubt as to the existence of the pilot streamer. The theory of the long discharge is not yet sufficiently developed, however, to provide a better answer to the formation of the lightning stroke by means of the stepped leader.

The Return Stroke

As the leader approaches the ground, the charges in the ground begin to move in the direction of the approaching leader. As the leader touches the ground, the charges in the channel and the ground charges can neutralize each other, resulting in the return stroke. Since the channel is partly ionized, further ionization can result at a more rapid rate. The current in the channel increases rapidly and the velocity of propagation upward becomes of the order of ten times that of the continuous downward leader.

There is some evidence that streamers from the ground start up toward the approaching leader, thus producing contact between leader and charges in the air [11]. The length of such streamers may vary from

return stroke progresses toward the cloud. Points of discontinuity are observed, particularly at the junctions of the main channel and the branches. There is a question of whether current surges proceed from the branch to ground or from the ground to the branch. The velocity in most cases exceeds 10^{10} cm sec^{-1}, and therefore cannot be accurately measured from the photographs. Measurements in other parts of the world do not seem to indicate such drastic changes in intensity in the channel as the return stroke progresses toward the cloud. This difference may be due to ground conditions. In those cases where charges are readily available, the current in the return stroke can be maintained up to higher altitudes at higher amplitudes than in ground with high resistivity.

Data are not available on current amplitudes in the leader strokes, the relation between currents and charges in the leader stroke, the charges available in the ground, and the wave shape and amplitude of the return stroke. The mechanism involved in the wave shape of the current in the return stroke is not too clear. It is thought by some that the front is formed shortly before the leader touches the ground and completed on contact [12]. Other theories indicate that maximum peak current is reached at the ground end after the current wave has traveled a short distance upwards in the channel.

Stroke Mechanism for High Buildings

Observations at the Empire State Building in New York [11] have shown that the starting mechanism of the stepped leader is quite different (bottom part of Fig. 1). In most cases the stroke starts as a stepped leader at the building rather than at the cloud. The length of the steps, the time interval between steps, and the velocity of propagation of the steps fall within the range of leaders from cloud to ground. Another significant difference is the absence of a return stroke after the leader has reached the cloud. Instead, a continuous flow of current of the order of magnitude of a few hundred amperes is observed. Frequently the stroke current stops without any further manifestation. In many cases, however, the initial discharge is followed by subsequent continuous downward leaders from the cloud to the building, followed by a return stroke upward from the building, as in the case of strokes reaching the ground in open country.

This sequence leads to the conclusion that charges in the cloud are not sufficiently concentrated to provide a return stroke. In spite of the large drainage of charges (as much as 80 coulombs) in the preliminary continuous-current period and a rather well-ionized channel, the cloud can precipitate a continuous leader to the building. This may be due to a more rapid increase of potential gradients within the cloud or to rapid interchange of charges from other charge centers within the cloud. The reason for establishing a continuous leader in a channel, quite well ionized by the preceding continuing current, is not clear. Photographs and oscillograms show that the return stroke, coupled with a heavy current discharge or peak current, is governed principally by conditions in the ground.

Continuous Current

Oscillographic and photographic evidence from the Empire State Building investigation seems to indicate that successive discharges are always connected by continuing current flow. Other investigators have made measurements which indicate that the current between successive discharges may drop to zero. The fact that successive lightning discharges in a stroke have the same shape is an indication that sufficient ionization remains in the channel for subsequent leaders to choose the same path. In some cases the time interval between such successive discharges is 0.5 sec. In the laboratory it was found that on establishing a long, sixty-cycle arc, a series of multiple discharges take place within a few hundreds of microseconds. The shape of these discharges differs greatly, indicating that ionization has ceased. The currents available in this case are of the order of a few amperes.

To solve this question it is necessary to greatly enlarge our knowledge on deionization time of the air and to determine more accurately whether current flow exists during deionization.

The Channel of the Lightning Stroke

The channel of the lightning stroke almost invariably follows an irregular path. This path and its branches are probably determined by the conditions in the atmosphere surrounding the tips of the stepped leaders as they progress downward. Space charges produced by the leader mechanism, and perhaps charge distributions involved in the thunderstorm process itself, may be largely responsible for the field distortion resulting in the irregular pattern of the lightning channel. The diameter of the channel is apparently a function of the rate of rise of current flowing in the channel and the amplitude of current flow. Experiments have shown that the channel diameter experiences equilibrium when the density of the current flowing reaches 1000 amp cm^{-2}. Much greater current densities, as high as 30,000 amp cm^{-2}, are reached when current flowing in the channel has a rate of rise of a few thousand amperes per μsec. As the result of such measurements, the probable maximum diameter of the channel was deduced as of the order of 5 cm. Other computations and experiments indicate diameters as high as 23 cm.

The change in current density and consequent enlargement of the channel as a result of ionization, heating, and disassociation along the path of the lightning discharge, results in pressure effects. For continuous discharges involving only low currents, the pressure effects are so negligible that thunder cannot be heard. Such observations permit the deduction that pressure effects will be greater the higher the rate of rise of current flowing in the channel and the greater the amplitude of the current. This is confirmed by laboratory experiments where the pressure effects are associated with high surge currents, while low-current discharges produce negligible pressure.

At times the path of the lightning channel is affected by wind. In such cases a stationary camera film and lens will record the multiplicity of the discharge. In some such cases the stroke path changes its shape considerably, indicating perhaps the disruption of current flow. However, it is quite possible that differences in wind velocity at various heights are responsible for distortion of the pre-established channel. In other cases the channel retains its precise form to the end of the stroke.

The Multiple Stroke

The formation of multiple strokes [6, 11] has been explained as the extension of the stroke channel to new charge centers in other portions of the cloud. Alternatively, it has been suggested that new charge centers develop toward the original channel by means of the leader process. In some strokes the regularity of the time interval between successive discharges has been suggested to be due to repeated charging of the original stroke center. Statistical data on the number of multiple discharges in a stroke are given in Table II.

Potential Involved in the Stroke Formation

Based on potential gradients measured at the earth and within clouds, it now appears that a lightning discharge can be initiated and completed with average gradients of the order of 100 v cm^{-1}. On this basis the total voltage required to initiate a stroke of 10,000-ft

length has been estimated at twenty to thirty million volts. Considering the formation of the channel by means of the stepped-leader process, it is reasonable to assume that the average gradient for the lightning stroke may be considerably less than that required to break down a gap in the laboratory (30,000 v cm^{-1}, uniform field; 5000 v cm^{-1}, nonuniform field—large gaps).

It is not known what gradients exist at the point where the leader is initiated in the cloud. The lower density of the air, and the presence of waterdrops with their associated charges, may greatly alter the gradient requirements initiating a discharge.

Cloud-to-Cloud Discharges

While the occurrence of cloud-to-cloud discharges is relatively much greater than that of cloud-to-ground discharges—estimates range between 50:1 and 0.7:1—the mechanism involved is not as well known because these strokes are frequently obscured by the cloud masses. However, the available photographs seem to indicate that cloud-to-cloud discharges are initiated by stepped leaders in the same manner as that of the first discharge in a cloud-to-ground stroke. Return strokes are not known to occur.

Measurements of field changes associated with cloud-to-cloud strokes also indicate the absence of return strokes. The measurement of the wave form of atmospherics, however, has disclosed that some types of cloud-to-cloud strokes result in wave forms similar to cloud-to-ground strokes, but of smaller amplitude and separated by short, quiet intervals. These probably arise from multiple discharges within the clouds. Photographic evidence indicates that discharges within clouds can take place from the tip to the bottom of the cloud, as well as in a horizontal direction within clouds.

The importance of cloud strokes lies in their effects on radio reception and on the safety of airplanes. It has been suggested that airplanes may trigger off cloud-to-cloud discharges, and evidence is accumulating that the susceptibility of planes to lightning strokes increases as the size and speed of the planes become greater.

Phenomena on Ground End of Cloud-to-Ground Discharges

To safeguard electrical installations against damage from lightning strokes, a large number of measurements have been made to determine the characteristics of lightning strokes at the ground end. Such measurements have involved the determination of voltages on transmission lines (maximum measured—5,000,000 v), but have dealt principally with the statistical evaluation of the current in the stroke, the charges involved in the stroke, the wave shapes of currents, and other data needed to provide reliable protective systems.

Figure 2 shows a composite oscillogram of a lightning stroke current to the Empire State Building. In this case an upward leader, followed by a long period of continuing current flow, initiated the stroke and terminated at 0.25 sec. At this moment a continuous downward leader to the building resulted in a return stroke or current peak of approximately 15,000 amp in which the time to half value of the crest current was roughly 40 μsec. A short period of continuing current was followed by a second current peak of 4000 amp. A total of four current peaks were measured in this stroke, the third one having the highest amplitude, 23,000 amp. The total duration of the stroke was approximately 0.46 sec.

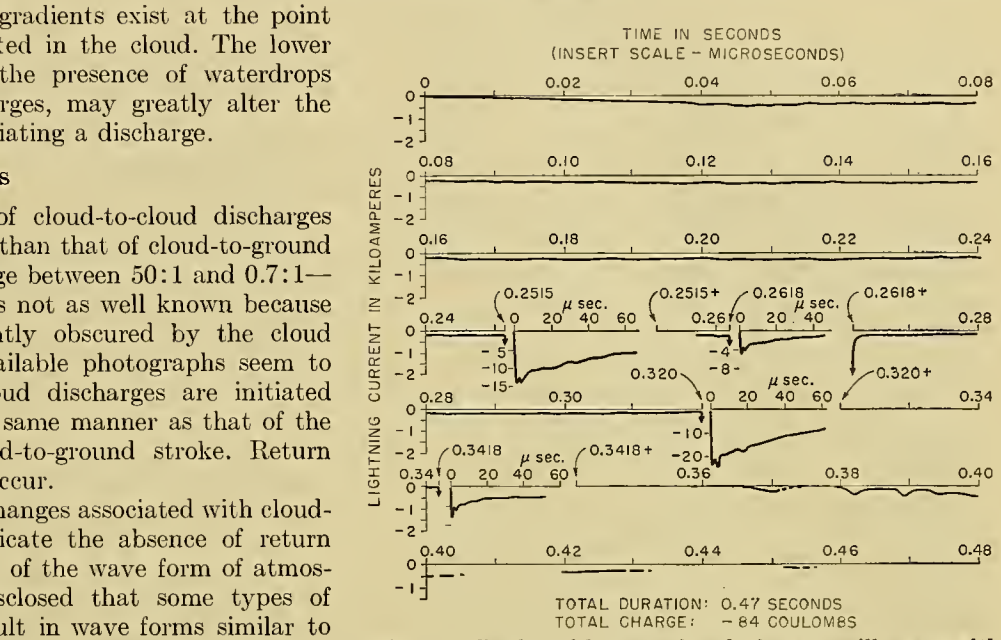

Fig 2.—Replot of low-speed cathode-ray oscillogram with inserts of high-speed cathode-ray oscillograms showing current peaks, Empire State Building, New York City, 1940.

In strokes to open country, the stroke starts at the cloud rather than at the ground, and consequently a current peak would be the first measurement made. The value of continuing current between current peaks is expected to vary greatly and may even be zero. Nevertheless, this oscillogram shows all the principal components of a cloud-to-ground stroke and the relative relations between amplitudes and wave shapes of the two principal components—current peaks and continuing currents—as well as the multiple character of the stroke.

From the available measurements, it has been possible to derive statistical data which are shown in Table II. These statistics in all cases give the minimum and maximum curves obtained from published data for 90, 50, and 10 per cent of the strokes, as well as the maximum available values. The great spread in some of the data is due to the various methods of observations used.

Stroke Current

Item 1 of Table II shows the amplitudes of current peaks measured in the path of the lightning stroke, with an average peak current of 7000 amp. A much greater number of records, which show a surprising agreement, have been obtained on transmission line towers (Item 2). Fifty per cent of the lower currents are in excess of 10,000 amp, while the maximum meas-

ured was 130,000 amp. By making various assumptions, the lightning stroke currents responsible for tower currents measured were deduced as shown in Item 3. The correctness of some of these assumptions is questionable, and the values shown in the table are probably

TABLE II. CHARACTERISTICS OF LIGHTNING STROKES

Item		Per cent of strokes with values in excess of those shown in Table I			Maximum
		90%	50%	10%	
1. Current peaks measured in stroke path, *kiloamperes*	Min.	2.2	6.0	20.0	—
	Max.	5.0	8.6	27.5	160
2. Current amplitudes in steel towers, *kiloamperes*	Min.	1.0	8.8	28.4	—
	Max.	5.3	12.2	35.8	130
3. Lightning stroke currents computed from Item 2, *kiloamperes*	Min.	2.4	13.3	50.0	—
	Max.	10.3	40.0	101.0	220
4. Rate of rise of stroke currents, *kiloamperes per μsec*	Min.	1.8	8.5	27.5	—
	Max.	2.4	14.5	35.0	45
5. Wave front of stroke currents, *μsec*	Min.	0.2	1.0	5.2	—
	Max.	0.9	2.51	5.5	10
6. Wave tail of current peaks—time to half value, *μsec*	Min.	11.6	30.3	78.0	—
	Max.	26.0	45.5	80.0	120
7. Charges in current peaks, *coulombs*	Min.	—	—	—	—
	Max.	0.04	0.23	1.03	5.6
8. Total stroke charges, *coulombs*	Min.	2.3	10.4	86.0	—
	Max.	4.2	22.2	100.0	165
9. Total duration of strokes, *sec*	Min.	—	0.0006	0.2	—
	Max.	0.1	0.37	0.68	1.6
10. Number of current peaks in lightning strokes	Min.	1.0	1.8	4.0	—
	Max.	1.3	3.0	11.0	42
11. Time interval between current peaks, *sec*	Min.	—	0.02	0.1	—
	Max.	0.03	0.088	0.18	0.5

too high. The statistical evidence indicates, however, that only very few lightning strokes will have current peaks in excess of 60,000 amp.

Wave Shape of Current Peaks

Of great importance for evaluating the effect of lead length in lightning protective systems is the knowledge of the length of the front and the rate of rise of current of the current peaks. The number of records available is relatively small. However, the data taken by different investigators with different means of recording are in sufficient agreement to allow confidence in the results. The limits of wave fronts and rates of rise measured indicate that inductive drops are a serious consideration. In 50 per cent of the cases the rate of rise was 12,000 amp per μsec or greater, which would result in approximately a 6000-v drop per foot of conductor.

The duration of the current peaks is of importance in estimating or determining the strength of insulation subjected to lightning strokes. For practical reasons this is usually expressed in terms of microsecond duration of the current wave while it rises from zero to crest and decays to half value. The statistical evidence shows that 50 per cent of the waves have a time to half value of approximately 38 μsec or more.

The charges in the current peak are related by an unknown factor to the charges laid down by the leader. The charges measured at the ground end of the stroke are expected to be lower than those in the leader because of losses during the formation of the leader. The charges given in the table are based on the integrated product of current in amperes and time in seconds, using only the portion of the current peak between its start and its decrease to half value. In all cases but one, the charges thus determined were less than one coulomb and resulted from lowering a negative charge from the cloud. The maximum value of 5.6 coulombs resulted from lowering a positive charge from the cloud.

The Composite Stroke

The lightning stroke may consist of a number of current peaks and continuing current flow. The total duration of the stroke measured by different investigators varies between 0.0006 sec and 0.35 sec for the 50 per cent level. The longest duration measured is about 1.5 sec. Fifty per cent of the strokes have two or more current peaks, while a maximum of 42 current peaks has been measured. The time interval between successive current peaks at the 50 per cent level varies between 0.02 sec and 0.09 sec, with a maximum of 0.5 sec between successive discharges.

Of considerable interest is the total charge in the lightning stroke. This is principally the charge conducted by the continuous currents. The average charge measured is approximately 18 coulombs, while a maximum of 165 coulombs has been recorded. Many of these measurements were obtained from strokes to tall buildings, and in all cases they represent the charges at the ground end of the stroke. They represent the total charges conducted in the channel through the point of measurement. There should be some difference in the total charges conducted when the stroke is initiated at the cloud and when it is initiated at a tall structure. In the latter case, the total charge in the channel can be measured, while for strokes initiated at the cloud, charges laid down from the cloud are not necessarily included in the measurement.

Measurement at the ground end of the stroke will not necessarily record all charges involved in a lightning stroke, particularly in the not-too-rare cases where the stroke changes its path at the ground end or at both ends. It is obvious that in such cases the total charges involved in the stroke mechanism can be considerably greater.

Charge determination by means of electric field measurements of thunderstorms has indicated a maximum charge of 200 coulombs, a value about 25 per cent higher than at the Empire State Building. A further indication of total charges involved in lightning strokes has been obtained from damage produced by lightning strokes on metal parts, particularly of airplanes. Comparison of such damage with similar effects produced in the laboratory has indicated charges at least as high as 300 coulombs, and possibly in excess of 500 coulombs. In some of these high total charges, strokes to ground were also involved, but since the total stroke mecha-

nism is not known, it cannot be determined whether all of the charges were conducted to ground or to what extent they occurred within the cloud only.

Polarity

The polarity of lightning strokes, in the great majority of cases measured, is negative; that is, negative charges are lowered from the cloud. The relation for grounded structures is approximately 15:1 in favor of negative charges. Since most measurements have been made on transmission line towers and other rather well-grounded structures, it has been pointed out that this would be conducive to a higher number of negative strokes on account of the possibility of guiding a negative leader to the structure by means of streamers produced at the positive grounded object. In the case of a positive stroke, a negative streamer would not be as likely to occur. From this reasoning it is expected that strokes to open ground may include a lower percentage with negative polarity. Measurements of field changes seem to favor this view because in many of these cases the ratio of negative to positive polarity cloud-to-ground strokes is of the order of 6:1 or less.

In cases where direct strokes to ground have been measured by means of oscillographs or other devices which permit detailed examination of the stroke current throughout its duration, it was found that the majority of the strokes were entirely of negative polarity. In some cases, however, the polarity of the continuing current flow changed, usually toward the end of the stroke. In other cases one of the current peaks was of positive polarity, while the remaining current peaks resulted from a negative cloud charge. The polarity relations throughout the length of the stroke are probably governed by the mechanism of multiple discharges which was discussed previously. The process must be governed by the means of charge exchange within the cloud during and following the first leader stroke to ground, as well as by the rate of production of charges within the original stroke center in the cloud.

The fact that charges of negative polarity are lowered to the ground in the majority of the cases seems to indicate that negative charges predominate in the bottom of the cloud. The fact that some of the highest current peaks measured were of positive polarity might be accepted as proof that centers of positive polarity can exist in the lower portions of some storm clouds.

Stroke Density

It is extremely difficult to obtain information on stroke density. Analysis has shown that the density per square mile is approximately one-half of the number of storm days from the isokeraunic map. This was partially confirmed by a two-year count in a region with 27 storm days per year where the average stroke density was approximately 15 strokes per square mile per year. Observed figures depend on the size of the area under observation and rapidly decrease with increased area. Accurate data would be of value to determine lightning risks.

Forms of Lightning

Names like *streak*, *bead*, *ribbon*, *fork*, *heat*, *sheet*, and *ball lightning* have been used to describe various observed forms of lightning discharges. Streak lightning is the normally observed type as described in the foregoing discussion. Bead, ribbon, fork, and heat lightning probably have the same characteristics as streak lightning. Bead lightning is assumed to be a form of streak lightning. The appearance of the beads may be caused by variations in the luminosity along the channel, perhaps caused by brush discharges. Ribbon lightning is probably a streak lightning stroke with multiple discharges where the channel is blown along by the wind. Fork lightning is the term used for strokes with several apparently simultaneous paths to ground. As explained, these ground termini may be formed simultaneously or during successive discharges of multiple strokes. Heat lightning is a form of streak lightning at a distance sufficiently far away so that thunder is not heard. Sheet lightning usually occurs in clouds between the lower and upper atmosphere over a considerable area. This areal distribution of sheet lightning, and its long persistence, constitute the principal difference between it and streak lightning.

Ball lightning is described as a luminous ball of reddish color, with an average diameter of 20 cm. When seen emerging from the cloud, its velocity has been estimated as high as 100 m sec^{-1}; while on the ground it travels at 1 to 2 m sec^{-1}. Usually the ball explodes after an average life of 3 to 5 sec. There is much controversy regarding this form of lightning. It has been described as an optical illusion caused by retention of vision of a heavy lightning discharge in the retina of the eye. However, the testimony of a few apparently well-qualified observers seems to indicate that such phenomena may exist. No reliable explanation for the existence of ball lightning has been offered. However, several theories exist explaining the phenomenon on the basis of chemical and physical reactions. Some photographic evidence submitted as possibly caused by ball lightning has been proved to have had an erroneous interpretation.

Measurements of Lightning Characteristics

The most exact measurements can be made at the ground end of a stroke. For this purpose a variety of instruments have been developed.

The Lichtenberg figure on photographic film [7, 13] placed between two electrodes is a corona discharge. The size of the figure is a measure of the voltage applied and the polarity of the discharge. By suitable shunts, currents can be measured. The accuracy of such devices has been estimated at 25 to 50 per cent.

A very simple method of measuring the peak value and polarity of surge or lightning currents is the magnetic link [4]. It consists of a number of steel strips of high retentivity. The magnetic flux associated with a lightning stroke magnetizes the link. The magnetization measured after exposure gives a very accurate indication of current crest. Two links at different spacing from

the conductor carrying the lightning surge are used to increase the accuracy, particularly where currents of opposite polarity may flow. These links will measure only the maximum peak in a multiple stroke.

Fulchronographs [17], devices where a number of links are mounted on a rotating wheel, permit determination of the variation of current with time. The resolution for continuing currents is good. The high-speed wheels used permit separation of amplitudes of successive high current peaks, but the speed is insufficient to determine the wave shapes of current peaks.

Magnetic links applied in circuits in which inductances or capacitances are used in combination with resistance permit determination of the maximum rate of current change of a current peak.

The photographic surge-current recorder [10] measures the intensity of light produced by a surge current across a short spark gap. A range of 0.1 amp to 150,000 amp is claimed for this device.

The cathode-ray oscillograph [3] is the most versatile, but also the most elaborate device for measuring surges. Several types of oscillograph must be used to record the high-speed (current peaks) and slow-speed (continuing currents) components of a complete lightning stroke. The development of the sealed-in cathode-ray tube has made this instrument simpler and subject to automatic operation.

Of considerable value for determining the mechanism of the discharge are the so-called *Boys cameras* [5, 15]. With high-speed rotating film, or high-speed rotating lenses, the speed of propagation of the leaders and return strokes can be analyzed. The low-speed cameras give valuable information on the time sequence of current peaks and the continuing-current flow between multiple discharges. It has been possible to obtain fairly good correlation between density of the film exposed to a stroke and the current flow causing the illumination, principally for the continuing components. A microphotometer has been used to correlate these quantities. For accuracy it is necessary to avoid overexposure of the film, as well as to have highest sensitivity for the weaker illumination. For this purpose multiple-lens cameras are used with apertures varied to cover the complete range of exposure expected in a straight-line relation.

Electric field measurements permit investigation of lightning-stroke phenomena from the point of view of the charges involved. Some of the measurements made differentiate the leader, the return stroke, and the continuing-discharge portions of strokes. The wave shapes of atmospherics and correlation with various forms of lightning discharges have been investigated. Such measurements have been extended to cover distances of hundreds of miles. By using two or more instruments, the distance of the source of atmospherics can be determined with good accuracy.

A rather useful means of determining lightning characteristics is the examination of damage produced by lightning. By reproducing similar effects in the laboratory it is possible to determine approximately the type of stroke responsible for the damage, as well as the amplitude of current peaks and the charge conducted in the stroke. Damage produced on metal parts of airplanes is in many respects the only means by which lightning currents occurring in the clouds can be determined.

Lightning Protection

The statistical knowledge gained over the past fifteen to twenty years has largely confirmed the effectiveness of a properly installed lightning-rod system (advocated by Benjamin Franklin more than 150 years ago) to protect ordinary buildings and houses against direct strokes. Such systems consist of interconnected air terminals mounted on the highest points of the structure, and connected to the ground at several points. The "Code for Protection Against Lightning" issued by the National Bureau of Standards and designated as *Handbook H40*, and the *British Code of Practice C. P. 1:1943* published by the British Standard Institution, contain the essential rules to follow for installation, materials, size, and other factors essential for an effective durable installation.

For continuity of electrical service to homes, farms, and factories, many practices have evolved, based directly on the many lightning studies and their results. For protection of electrical apparatus, the lightning arrester is a commonly accepted device. Such arresters have the property of conducting surge currents to ground at a reduced voltage. Any system power current (follow current) which may flow through the arrester immediately following the lightning discharge is interrupted, and the line is restored to its original condition. Many different types of arresters are in use. In some cases plain gaps are used for protection. These cannot limit the voltage applied to the apparatus to voltages as low as arresters. After sparkover of the gap occurs, circuit power current usually follows and must be interrupted by opening a breaker.

Transmission lines of higher voltage ratings can be effectively protected by the use of ground wires properly suspended above the transmission wires to intercept the direct strokes. The lightning currents contacting the ground wire and the towers to which they are connected will raise the tower potential by virtue of the resistance of the tower to ground and the current in the stroke. To this is added the inductive voltage drop caused by the inductance of wire and tower and the rate of rise of current on the current front. By reducing the ground resistance to less than one ohm per 12 kv of circuit voltage, it has been possible to reduce outages on circuits of 66 kv and above to an extremely low value. Ground resistance can be reduced by the use of buried wires—counterpoise—or deeply driven ground rods.

Lower voltage circuits have been made lightning-resistant in many cases by the use of wood as insulation in addition to the normal porcelain or glass insulators. Reclosing circuit breakers are another tool for preventing circuit outages. These breakers are able to open a circuit and reclose it in as little as one-fifth of a second by means of suitable relaying. Proper balance between

circuit breaker duty and protective means for reducing the number of flashovers must be considered.

Conclusions

The physical phenomena of the lightning discharge are not entirely understood. Photographic evidence indicates a stepped-leader initiation of the stroke followed by a return stroke from its ground terminal. Theoretical stipulation of a pilot streamer has not been proven.

To complete the understanding of the physical phenomena involved in lightning discharges, more information is required on these principal questions:

1. The gradient at the point of origin of the stroke.
2. Gradient distribution within clouds, as well as beneath clouds.
3. Gradients at the ground end of a stroke.
4. Existence and character of ground streamers prior to stroke contact with the ground.
5. Ionization processes within the stepped leader, continuous leader, and the return stroke.
6. Ionization and deionization of the stroke channel with special reference to continuing current discharges.
7. Influence of ground conditions on the return-stroke process.

For further progress on the protection problem, statistical evidence is desirable on:

1. The wave shape of lightning stroke currents of both current peaks and continuing currents.
2. The distribution of such currents in the ground network of protective installations, as well as in the earth.
3. The lightning stroke density in various regions of the earth.
4. The incidence of lightning to various structures as determined by height and physical location with regard to other structures and natural terrain.

From the numerous investigations of lightning undertaken during the last twenty-five years, it has been possible to devise protective systems and practices which reduce damage due to lightning to a negligible factor on electrical installations as well as on buildings.

REFERENCES

The sources of information are extensive. References to 750 papers are found in [1] and [2] below. To keep the number of references at a reasonable figure, only a few additional references are listed.

INSTRUMENTS AND METHODS FOR THE MEASUREMENT OF ATMOSPHERIC ELECTRICITY*

By H. ISRAËL

Institute for Atmospheric Electric Research of Buchau a. F.

System of Units

Various systems of units are used in electricity. Each of these is an entity in itself and is built up on a definite fundamental physical relationship:

1. The "electrostatic cgs system" is based on Coulomb's law of the force effects of interacting electrical charges and arbitrarily takes the proportionality factor to be nondimensional and equal to unity.

2. The "electromagnetic cgs system" is based on the Biot-Savart law of the forces between an electric current and a magnetic pole, and again the proportionality factor is set equal to unity.

3. Giorgi's "natural m-sec-v-amp system" assumes voltage and amperage as fundamental quantities, with the second (sec) as the time unit and the meter (m) as the length unit.

In the first two systems the electrical quantities are reduced to the mechanical units, cm, g, and sec (cgs), which appear in complicated, nonvisualizable combinations. The third system of units is more suitable to the scope of physics in general; therefore, its adoption for consistent use in the field of atmospheric electricity is recommended. In this system, the international standards for volt, ampere, etc., are employed.

Auxiliary Equipment and Practical Suggestions

The atmospheric electrical problems of measurement consist predominantly of the measurement of potential differences of medium magnitude and of minute electrostatic charges. They belong, therefore, to the domain of electrometry proper. Although increasing use is being made of "vacuum tube electrometers" (d-c current amplifiers or d-c voltage amplifiers), thorough familiarity with the electrometer is a prerequisite for work in atmospheric electricity.

All electrometers are based on the principle of electrostatic attraction or repulsion. An exception is the capillary electrometer which utilizes the change in the surface tension of mercury when traversed by an electric current. Therefore, strictly speaking, the capillary electrometer represents a type of galvanometer [103]. Quadrant electrometers have long oscillation periods and are therefore suited chiefly for the measurement of constant potential differences, whereas filament electrometers adjust themselves aperiodically and almost instantaneously at sensitivities that are not excessively high. The highest sensitivities are attained with the modern modifications of the quadrant electrometer.

Figure 1 shows schematically the well-known principle of the quadrant electrometer. Special electrometer types are: the model developed by Elster and Geitel [37], particularly suited to photographic recording; the Dolezalek electrometer [30, 31] for high sensitivities; a special design by Schultze [119]; the "Binanten" electrometer [49] and the "Duanten" electrometer of Hoffmann [48, 50, 51]; the Benndorf electrometer [11, 12], the familiar, low sensitivity quadrant electrometer for mechanical recording of potential gradients.

Figures 2 and 3 are sectional drawings of the bifilar electrometer without auxiliary potential and of the unifilar electrometer with auxiliary potential according to Wulf's design [152]. More modern designs for attaining the highest sensitivites include those of Lindemann and Keeley [85], Compton [26, 27], Shimizu [127], Swann [139] and Perucca [104, 105].

The development of the so-called electrometer tubes with their characteristically high insulation of the control grid and very low grid current (10^{-13} amp and less) has resulted in the substitution of vacuum-tube electrometers for the ordinary electrometers. Many types of electrometer tubes are now commercially available. During continuous operation, maintenance of a constant zero point is sometimes difficult; some amelioration can be provided by using oversized filament batteries and by the use of selected pairs of tubes in a bridge circuit (for further details see, for example, [22, 28, 36, 46, 47, 69, 77, 82, 106, 109, 114]).

There are several types of circuits available for use with quadrant and filament electrometers provided with auxiliary potentials: In the *idiostatic circuit* the needle (lemniscate or electrometer filament) and one pair of quadrants (knife edge) are grounded; the unknown voltage is applied to the other pair of quadrants (knife edge). The deflection is proportional to the square of the unknown voltage, thus making possible a-c measurement. In the *quadrant circuit* the needle is at a fixed high voltage; one pair of quadrants is grounded, and the unknown voltage applied to the other. Deflection is proportional to the unknown voltage. The *heterostatic* or *needle circuit* has both pairs of quadrants connected to a fixed auxiliary voltage of opposite sign and the unknown voltage applied to the needle. This is the most frequently used and most sensitive circuit, and has the lowest capacitance. In the *current circuit* the voltage measurement is made at the terminals of a resistor which is usually of the high-ohmic type.

Measurements of atmospheric electricity are almost exclusively electrostatic measurements and therefore call for high quality of the dielectric materials. The best insulating materials are the natural products, amber and sulfur. Good substitutes include high quality plastic dielectric materials such as hard rubber (ebonite), plexiglass, and Trolitul. Meticulous surface treat-

* Translated from the original German.

ment is particularly important. Such treatment includes high polish, drying, dust removal, paraffin coating in some cases, and protection against direct sunlight. When working in the open air, careful maintenance of the dryness of the dielectric surfaces by drying with hot air or by electrical heating is essential. The relative humidity on the insulator must not exceed approxi-

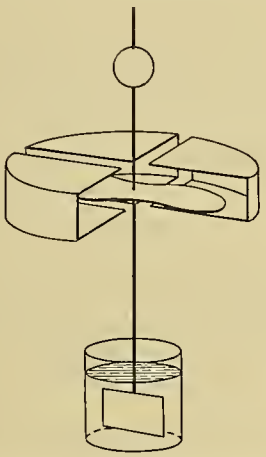

FIG. 1.—Schematic diagram of a quadrant electrometer.

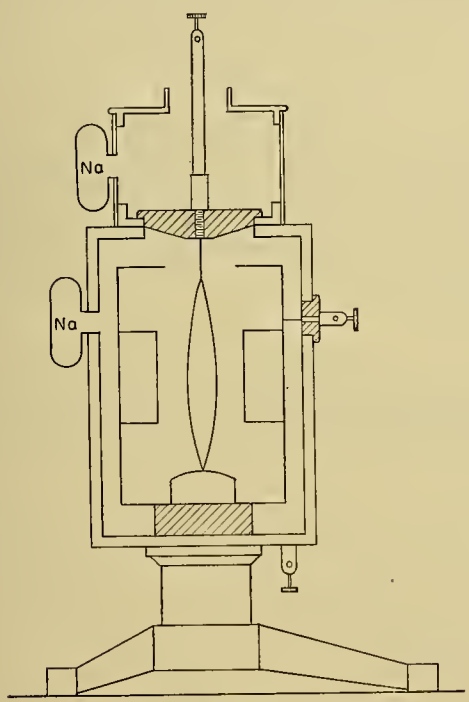

FIG. 2.—Wulf's bifilar electrometer.

mately 80 per cent. Figure 4 gives one example of a suitable form of open-air insulator which has held up well in practice.

To combat insects and spiders it is helpful to paint the metal parts about the air gap with an adhesive substance (fly-paper glue) and also with aromatic insect repellants. To eliminate air-borne spider threads in summer and fall, mechanical methods must be applied.

In all electrostatic measurements it is essential to maintain good grounding of all parts to be maintained at zero potential. In general, grounding to a water pipe is satisfactory. It is particularly important that all parts to be grounded are connected to the same ground

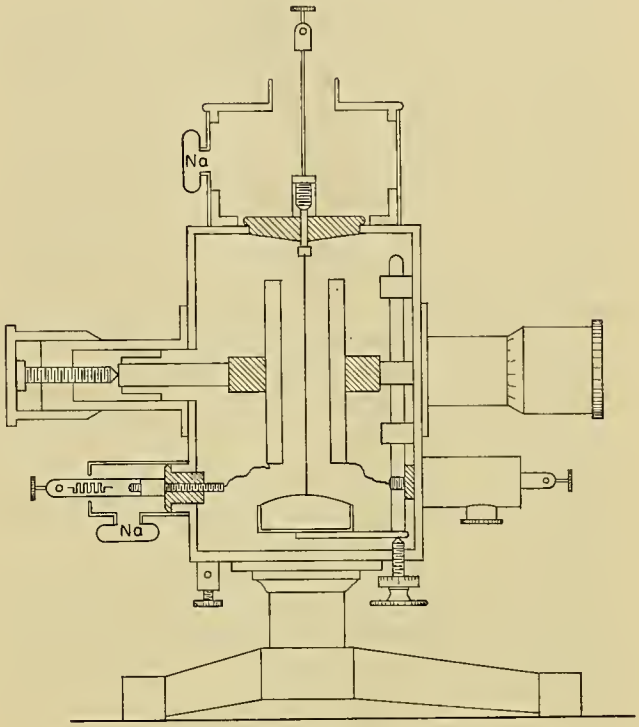

FIG. 3.—Wulf's unifilar electrometer.

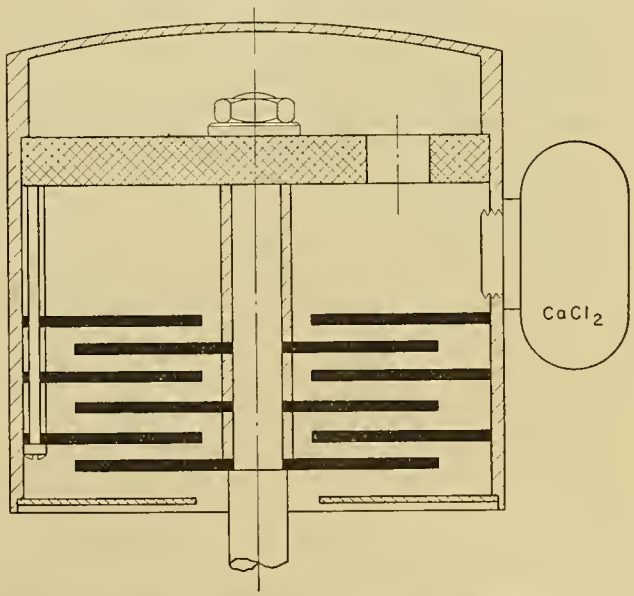

FIG. 4.—Open-air insulator for large mechanical load (antennas and the like).

connection. All other leads must be protected from induction by shielded cables.

With high electrometer sensitivities undesirable disturbances may appear as a result of certain unforeseeable phenomena in the insulating dielectric material, such as the formation of deposits and polarization phenomena. Direct creep of charges across an insulator

can be prevented by double insulation separated by a grounded metal plate. In all cases, when working with maximal sensitivities, it is judicious to protect the insulators against either direct or indirect influence of electric fields by shielding them.

On many occasions, especially when working with movable parts such as rotary collectors, unwelcome concomitant phenomena are possible as a result of the Volta effect. The latter must be determined and corrected for by check tests.

In electrostatic work, the almost universal contamination of rooms by a-c fields produced by the electric light network is a source of serious disturbance. Its effect can, in general, be easily recognized and eliminated when working with electrometers. When amplifiers are used such a-c fields may easily lead to errors of measurement and misinterpretation (apparent atmospheric electrical potential gradient in rooms) because of unintended and undetectable rectifier action.

Batteries are preferable to rectified a-c lines as sources of constant potential, especially in electrometric work. Portable high-voltage sources for counting-tube measurements in open country are described elsewhere [133, 136].

High ohmic resistors up to about 10^{13} ohms are fabricated commercially by evaporation of thin platinum films on quartz or amber. For homemade high ohmic fluid resistors, radioactive (Bronson) resistors, and other possibilities, see von Angerer [3].

Ions and Other Atmospheric Suspensions

Ionizers of the Atmosphere. The ionization of the lower atmospheric layers, aside from occasional local ionizers of subordinate significance (waterfall effect, combustion gases), is caused by the α, β, and γ radiation of radioactive substances and by cosmic radiation. The special methods for measuring radioactive substances and cosmic radiation are treated elsewhere in this Compendium.[1]

The ionization in a sealed chamber is due to radiation from the chamber walls (mathematical determination according to von Schweidler [120], experimental determination in mines [17]), radiation from the earth, radiation from the atmosphere, and cosmic radiation. The mathematical estimation of the radiation from the earth and the atmosphere is made as follows:

If ρ_{earth} and ρ_{air} are the concentrations of radium, or of its *RaC*-equivalent, in a cubic centimeter of earth or of air, μ_{earth} and μ_{air} the absorption coefficients of the corresponding γ-radiation in earth or in air, and if K is the "Eve number" (4.0×10^9 in the absence of secondary radiation, approximately 5 to 6×10^9 in thick-walled ionization chambers), the ion production q (*i.e.*, number of ion pairs formed per cubic centimeter per second) is given by

$$q_{\text{earth}}(0) = 2\pi\rho_{\text{earth}}K/\mu_{\text{earth}}, \quad \text{Radiation instrument directly on the earth's surface} \quad (1)$$

$$q_{\text{earth}} = 4\pi\rho_{\text{earth}}K/\mu_{\text{earth}}, \quad \text{Radiation instrument in the ground (caves, tunnels, etc.)} \quad (2)$$

$$q_{\text{earth}}(h) = q_{\text{earth}}(0)\phi(h\mu_{\text{air}}), \quad \text{Radiation instrument at an altitude } h \text{ above the earth's surface} \quad (3)$$

wherein

$$\phi(x) = e^{-x} - x\int_x^\infty \frac{e^{-u}}{u}\,du,$$[2]

$$q_{\text{air}}(0) = 2\pi\rho_{\text{air}}K/\mu_{\text{air}}, \quad \text{Radiation instrument on the surface of the earth} \quad (4)$$

$$q_{\text{air}} = 4\pi\rho_{\text{air}}K/\mu_{\text{air}}. \quad \text{For great altitudes} \quad (5)$$

Portable radiation devices, which are convenient to manipulate, have been described elsewhere [78, 79, 151], as have counting-tube instruments for field work [133, 136].

Conductivity, Concentration of Ions, and Ion Mobility. If an electric potential is applied to two electrodes in an ionized gas, a weak current begins to flow. Corresponding to the two oppositely flowing ionic currents, the current density is the combination of two terms:

$$i = \epsilon(k_1 n_1 + k_2 n_2)E = \Lambda E, \quad (6)$$

where ϵ is the charge of the ion and equal to 1.6×10^{-19} amp sec, E is the field intensity, n_1 and n_2 denote the number of positive and negative ions, and k_1 and k_2 represent the mobility of the positive and negative ions, respectively. The expression $\epsilon(k_1 n_1 + k_2 n_2) = \Lambda$ is designated as the (total) conductivity of the gas. The terms

$$\lambda_1 = k_1 n_1 \epsilon \text{ and } \lambda_2 = k_2 n_2 \epsilon$$

are the positive and negative polar conductivities of the ionic conductor.

FIG. 5.—Schematic curve of the current-potential relationship (characteristic) in an ionized gas at rest.

If the voltage is increased starting from zero, a gradual decrease in ion content results; the current does not rise in proportion to the voltage and remains constant after a given value of voltage has been attained. Accordingly a distinction is made between *ohmic*

1. Consult "Radioactivity in the Atmosphere" by H. Israël, pp. 155–161.

2. For a tabulation of this function, see [86].

current (I), *semi-saturation current* (II), and *saturation current* (III); see Fig. 5.

To attain clearer experimental conditions, it is now a general practice to employ the aspiration condenser in connection with the so-called *method of perpendicular velocities* as follows: When air containing ions flows through a condenser to which an electric field has been applied, the trajectory of an ion is found to be the resultant of the two mutually perpendicular forces, namely, that of the air current and that of the field. If M is the aspirated quantity of air in cubic centimeters per second, C is the condenser capacitance ($C = L/[2 \ln (R/r)]$ for cylindrical condensers having radii R and r and length L), and V is the potential in volts, the expression

$$k_g = M/4\pi CV \qquad (7)$$

represents the *limiting mobility* of the condenser and states that all ions whose mobility is greater than, or

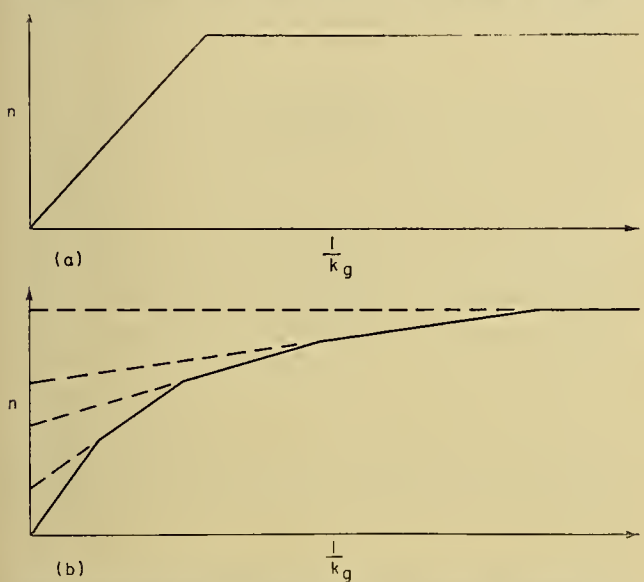

FIG. 6.—Schematic diagram of the current-potential characteristic in the aspiration condenser (*a*) in the presence of one type of ion, (*b*) in the presence of several types of ions.

at least equal to, this mobility are deposited. Of those ions, whose mobility k is smaller, only the percentage k/k_g is deposited.

It is evident that, in the foregoing, the characteristic relationship between current and potential in the condenser will be a broken linear curve. This curve will resemble Fig. 6*a* when but one type of ion is present, and assume the form of Fig. 6*b* when several types of ions occur. From the preceding statement, the following conditions are found for the measurement of ions:

Conductivity: M must be chosen so great or V so small that operations take place in the first segment of the curve that rises from the origin of the coordinate system.

Ion Counts: Determined from the saturation current.

Ion Mobility: Each break in the curve yields, according to equation (7), the mobility of a corresponding type of ion.

Ion Spectrum (numerical distribution on the basis of the individual mobilities): The number pertaining to a given mobility results from the magnitude of the change in slope of the characteristic; expressed in terms of differentials, the ion spectrum is determined by the second differential quotient of the characteristic.

Additional methodological details are given elsewhere [54, 56, 57]. With respect to "edge disturbances" (effect of the inhomogeneity of the field at the edge of the condenser), see Itiwara [73], Israël [56], and others. For special designs, that homogenize the field of cylindrical condensers, refer to Becker [8], Swann [137], and Scholz [115].

Well-known instruments that are easy to manipulate include the Gerdien aspirator [39, 40] for measurements of conductivity; the Ebert ion counter [32, 33, 35] and the Weger aspirator [58, 142] for measurements of the concentration and mobility of small ions (see references [6, 41, 42, 142] for errors of the Ebert instrument), and the Israël ion counter [55] for counts of medium and larger ions.

Mobility measurements by means of divided condensers are described in the literature [18; 19; 29; 54, pp. 179 ff.]; a differential method of very great resolving power had been proposed by Benndorf (*e.g.*, see [54, 56, 57]). Recording devices for conductivity measurements are also described in the literature [82, 108, 115, 116, 138]; recording instruments for counting ions have been devised by Nordmann [94–96], Leckie [82], Langevin [81], Hogg [52, 53], and others.

Schering's method [110, 111] for recording conductivity, which is still used occasionally, is somewhat different. A wire from 10 to 20 m long is freely suspended and surrounded by a cylindrical wire net having a radius of approximately 1 m. The wire is charged at certain time intervals and its voltage drop is recorded, for instance, by a Benndorf electrometer.

Rates of Ion Formation and Recombination; Mean Life of Ions. Under conditions of equilibrium, the rate of ion production q and the numbers n, N, and N_0 of the small ions, large ions, and uncharged suspensions, respectively, have the following relationship:

$$q = \alpha n^2 + \eta_1 nN + \eta_2 nN_0 + \eta_3 NN_0 + \eta_4 N^2 \qquad (8)$$

where

α = recombination coefficient between small ions,

η_1 = recombination coefficient between small and large ions,

η_2 = recombination coefficient between small ions and uncharged particles,

η_3 = recombination coefficient between large ions and uncharged particles,

η_4 = recombination coefficient between large ions.

The last two terms of equation (8) are insignificant as compared to the others, because η_3 and η_4 are smaller than the other coefficients by several orders of magnitude.

In order to determine the individual recombination coefficients, synchronous measurements of all participating constituents are necessary [92, 93]. Owing to the prerequisite of ionization equilibrium, such meas-

urements are very difficult [60, 63]. However, according to von Schweidler [121–123], the following visualizable approximation can be made: Under natural conditions near the ground where moderate to high values of N and N_0 prevail, we can write instead of equation (8)

$$q = \alpha n^2 + \beta n = \beta' n, \tag{9}$$

since the quadratic term becomes less important in comparison to the linear one, as the concentration of large ions in the air becomes greater. The coefficient β', which has the unit of sec^{-1}, is designated as the *vanishing constant*. Its reciprocal then is the *mean life of small ions*, in analogy to radioactive phenomena.

In practice, the air is introduced into an ionization chamber (condenser, sealed on all sides). By applying a high voltage, the value of n present is determined, and then the characteristic current-potential relationship is recorded. The values for q and n are determined by means of Method I (ohmic current), or q and β are found by Method II (semisaturation current); for more details, see the references previously cited.

Condensation Nuclei and Dust Particles. Aside from the hydrometeors (fog, clouds, and precipitation), the atmospheric content of suspended particles is somewhat arbitrarily divided into condensation nuclei and dust particles. Condensation nuclei, hygroscopic particles whose radius is approximately 10^{-5} cm or less, are counted by producing condensation upon them in supersaturated air and determining the number of resulting droplets. Two types of such nuclei counters are well known. One was developed by Aitken [1] and the other by Scholz [117, 118]. For details, see these papers as well as others [23, 71, 80].

The measurement of dust particles is made by means of the Owens counter [9] and the Konimeter.[3]

The Electric Field of the Atmosphere

If an uncharged conductor of any given shape is introduced into the earth's field, a separation of electric charges is found on this conductor, due to electrostatic induction. The conductor assumes the potential V_L, which is the potential of a given equipotential layer in the earth's field. This layer intersects orthogonally the electrically neutral line nn of the conductor's surface. It is the potential of the reference point B (see Fig. 7). The following possibilities exist for measurements of the electric field.

1. The body is temporarily grounded in the position shown in Fig. 7. Under such conditions it assumes the zero potential of the earth and takes on a charge $Q = -CV_L$ (where C = capacitance) from which, when it is introduced into a field-free space ("shielding"), the difference in potential of V_L with respect to the ground can be determined (electrostatic induction method). Variations of the method illustrated in Fig. 7 include:

a. The body is grounded, then insulated, and transferred to another point in the field. In this way its electrostatic induction is changed. Measurement of this "free induction charge" furnishes a measure of the difference in potential of the reference points of both positions. (For the principle of the movable conductor see [2; 7; 108; 137, p. 182]).

b. If after temporary grounding the body remains in position, its changes in electrostatic induction give a measure of the variation of the field; by means of high-ohmic leaks, the arrangement is converted into a field variometer [59].

c. If a metal plate is mounted flush with the earth's surface, grounded and exposed to the field, and thereupon shielded against the latter in an insulated state, it furnishes the surface density of the electrostatic inductance charge and thus the field intensity at the ground level (Wilson test-plate [146–149]). Rhythmical exposure to and shielding from the field produces an a-c current [87, 89–91, 124].

2. If provisions are made for the removal of the induction charge at a point P not situated on the neutral line of the conductor, a new neutral line is produced to which a different equipotential surface V_R

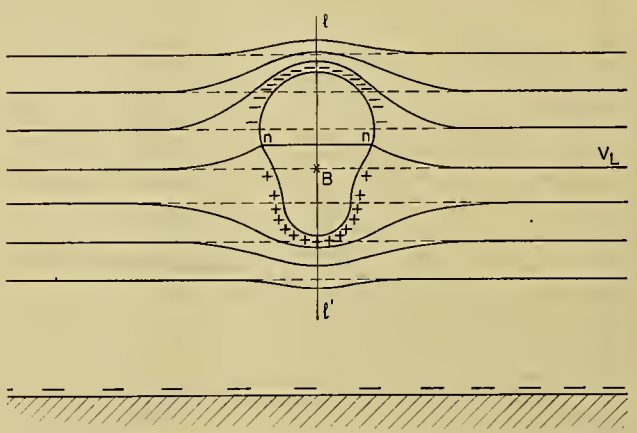

FIG. 7.—Electric field conditions produced by an uncharged conductor.

orthogonally connects (see Fig. 8). A connected measuring instrument indicates the potential of the reference point R with respect to the ground. Discharge of the electrostatic induction is attained by so-called *collectors* as enumerated herewith:

a. Point collector, based on the point discharge flow (no longer in use).

b. Flame collector, utilizing the ionization of the gases of combustion to conduct the charge away; a variant is the glow collector.

c. Water-dropper collector, operating by capacitive charge separation and discharge.

d. Radioactive collector, which provides for discharge by ionization of its environment.

The discharge proceeds according to an exponential law:

$$U_t = U_0 e^{-\kappa t/C}, \tag{10}$$

where U_t is the potential difference at the time t, U_0 the potential difference at the time zero, C the capacitance, and κ the discharge constant. The discharge constant κ or its reciprocal, the "apparent" or "transition"

3. Described in the Zeiss catalogue, Jena.

resistance, serves as an index of the efficiency of a collector. The value of κ fluctuates from approximately

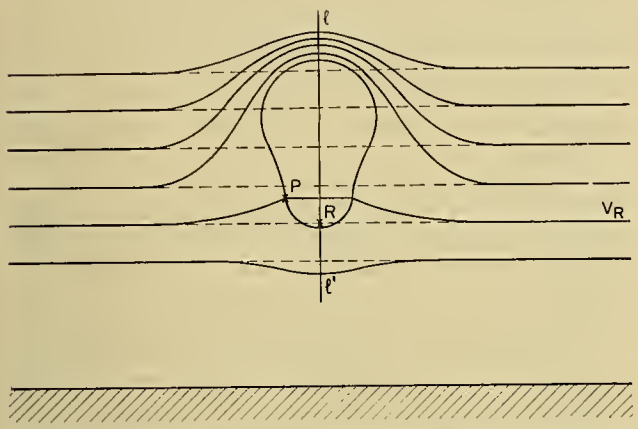

FIG. 8.—Electric field conditions produced by a collector.

unity for glow collectors to 50–100 $\times$ 10^{-12} for highly radioactive collectors.

The "external resistance," in other words, the resistance of the insulation of the collector from the ground, must be great compared to the transition resistance of the collector, as otherwise its readings become inaccurate. Attempts to operate the collector "short-circuited" were found to be subject to disturbances, for example, by the wind, and should therefore be avoided [77].

Exact field measurements can only be performed by means of the Wilson test-plate on completely level terrain. Any other type of arrangement disturbs the field and yields only more or less acceptable approximations. The so-called technique of *reduction to the free plane* can only be used as an approximation [16]. For this reason a comparison of "absolute values" of the field will always remain somewhat problematical. Therefore, consideration of the relative periodic and aperiodic variabilities of the electric field is fundamentally more important.

With respect to the selection of "undisturbed days" in the treatment of recorded data, see, among other sources, Israël and Lahmeyer [72].

The Vertical Current

The difficulties involved in measuring and recording the vertical electric current stem from the generally minute current density of about 10^{-12} amp m^{-2} and the disturbing effects of the electrostatic inductance of the field or of its changes on the receiver system. Galvanometric methods are applicable only to measurements of vertical currents intensified by thunderstorms. Therefore, accumulation methods (accumulation of inflow of charges over a given time) are used in most cases (Ebert [34], Simpson [128], and Wilson [146–149]). The disadvantage of these methods is that in the accumulation period the potential of the collecting body changes somewhat. Simpson circumvents this disadvantage by continuous draining of the charges by means of a water-dropper collector, whereas Wilson obviates the difficulty by a compensation method (see Fig. 9). Methods for continuous recording are described by Scrase [125] (accumulation method, quadrant electrometer) as shown in Fig. 10, and by Kasemir [77] (direct recording by use of a d-c amplifier). Scrase compensates for the effects of field fluctuation by using a supplementary field collector connected to alternate quadrants in the quadrant electrometer, whereas Kasemir largely suppresses these effects by increasing the capacitance. The vertical current can also be computed from the potential gradient and the conductivity, according to equation (6).

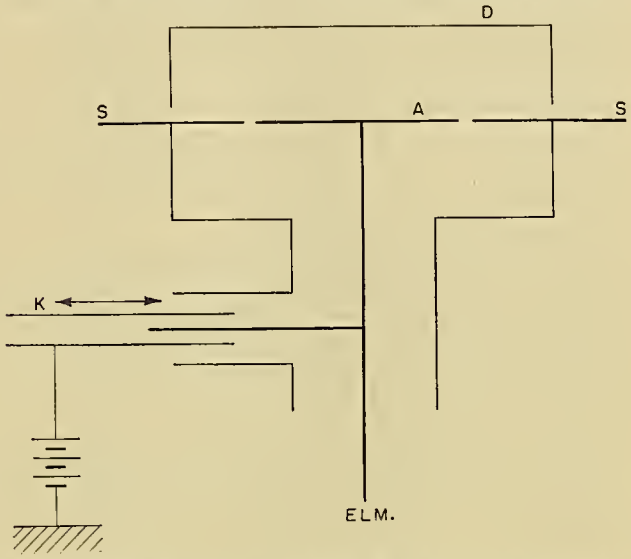

FIG. 9.—Diagram of the Wilson test-plate method (*K* is a variable condenser and *ELM* is the electrometer).

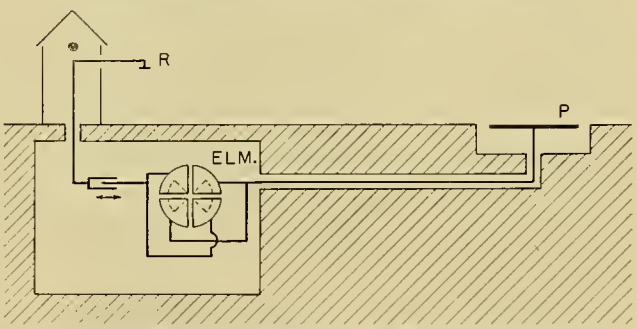

FIG. 10. Schematic diagram of the vertical-current recorder after Scrase (*R* is the radioactive collector, *P* is the test plate, and *ELM* is the quadrant electrometer).

The Space Charge

Measurement or recording of the space charge is made by means of the following methods: The *cage method* consisting of the measurement of the potential difference between the wall surface and the center of a wire cage whose volume ranges from approximately one to several cubic meters [75, 76]; the method of the *change of the potential gradient with altitude* according to Poisson's equation [13, 97, 145]; Obolenski's *filter method* [102]; or the method of *synchronous counts of positive and negative ions* [53, 82]. The cage method is disturbed in most cases by Volta effects [15].

Investigations of Thunderstorm Electricity

Field. Measurements of atmospheric electricity in conjunction with electrical storms require a very rapid response of the equipment. This requirement eliminates collector measurements. The measurements are based on the application of electrostatic induction techniques of field measurement (Wilson test-plate, Wilson elevated sphere, mechanical collectors, antennas) in combination with high-speed recording instruments including cathode-ray oscillographs.

Current. The vertical current can be determined with the aid of the Wilson test-plate in connection with a galvanometer or a capillary electrometer [148] or by recording the current through a point collector mounted in an exposed position [143, 150].

Precipitation Charge. Precipitation is collected in an insulated vessel. Splashing of the drops is prevented by lining the bottom with velvet, brushes, etc. Records are obtained either by the accumulation technique or by the "current-circuit method." For charge measurements on individual drops see Chalmers and Pasquill [25], Gschwend [43], and Gunn [44].

Investigations of Lightning Discharges.[4] The following methods can be employed: The optical method involves photography, using, for example, the Boys camera [20, 21].

In the electrical method the Klydonograph is used for the direct measurement of peak voltages in the lightning discharge by means of Lichtenberg figures; the measuring range is approximately 2–18 kv [83].

The magnetic method is based on the magnetization of small steel rods by currents flowing through lightning rods of various types [38] as, for example, the Fulchronograph [140, 141], or on the measurement of the magnetic field of the lightning discharge channel, and on numerous other special methods some of which are used in combination with high-tension lines [84, 99, 100, 144].

Radio Interferences. The electromagnetic pulses (atmospheric) originating from electric discharges in the atmosphere are investigated with respect to their number, direction of incidence, place of origin, and pattern. Excitation of an oscillating circuit coupled to a nondirectional antenna gives the number; use of rotating loop antennas gives the directional distribution; ranging with cathode-ray direction finders furnishes a bearing on the point of origin; finally, the pattern of the disturbance is established by use of aperiodic d-c amplifiers. For literature of the foregoing see: Appleton and collaborators [4, 5], Bureau [24], Lugeon [88], Norinder [98, 101], Schindelhauer [112, 113], and numerous others.

Measurements in the Free Atmosphere

The methods used for determination of the individual factors of electricity in the free atmosphere are fundamentally the same as those used at ground level. They must, however, be properly modified to allow for the special operational conditions obtaining in either the free-flying or captive carriers of the measuring instruments, such as manned free balloons, gliders, motor-driven aircraft, dirigibles and blimps, automatic recording balloons, captive balloons, and kites. For a summary of older and more recent aerological methods of atmospheric electricity see Israël [65].

Problems of Present-Day Research in Atmospheric Electricity

In concluding this discussion of equipment and methods, a few ideas may be presented on the most urgent problems of modern research in atmospheric electricity.

Although measurements have been made for almost two hundred years, the phenomena of atmospheric electricity have been considered a discrete part of the physics of the atmosphere; it is only recently that certain fundamental relationships to other atmospheric phenomena have been uncovered. Through the gradual detection of the inner relationships between atmospheric-electric and meteorological processes, new light is being shed on many of the electric phenomena that hitherto have been unexplained. Moreover, the possibility arises of immediate application of the knowledge gained in atmospheric electricity to meteorology and aerology.

As has recently been pointed out [68], the fundamental concepts of atmospheric-electric phenomena have undergone a mutation in that the tendency for segregation of electric from meteorological processes is slowly disappearing and is giving way to a trend toward correlating them. The stimulus for this development has been primarily the knowledge gained through the ocean expeditions sponsored by the Carnegie Institution. These cruises have revealed the world-wide synchronous component of the electric field, the coupling of this field with the world-wide weather, and the increasingly clear relationships between the local variations and the vertical mass exchange.

This last correlation, in particular, may furnish the key to the major portion of the relationship between atmospheric-electric and meteorological phenomena and, thus, simultaneously indicate the direction in which further research should proceed.

A primary requirement is the extension of the measurements to more than a single atmospheric-electric element, because the prevalent practice of recording the potential gradient alone permits only very limited conclusions. The three fundamental quantities of field intensity (potential gradient) E, conductivity Λ, and vertical current density i, are interrelated in Ohm's law:

$$E\Lambda = i.$$

Any statements regarding processes taking place in the atmospheric-electric circuit under equilibrium conditions require that two of these fundamental quantities be known. If we are to include the nonstationary ("switching-on") processes, all three quantities must be measured. It would be most desirable if this practice, now followed by the large atmospheric-electric

4. Consult "The Lightning Discharge" by J. H. Hagenguth, pp. 136–143 in this Compendium.

observatories, were introduced everywhere. (For details see [62, 72].)

For investigations of the effect of austausch on atmospheric-electric conditions, a simplified case must first be attacked by means of recordings made at altitudes as high as possible. Such investigations, conducted at high mountain observatories, promise freedom from changes in the aerosol that, in the lower atmospheric layers, are the result of the diurnal variation of the vertical mass exchange. We may expect that the atmospheric-electric processes in their entirety are composed of the interaction of low-level phenomena, which proceed according to local time and are caused by austausch variations, and of the world-wide synchronous processes at higher levels. We may also expect the transition to occur at an altitude of a few kilometers [61, 68]. For preliminary results of pertinent investigations see [70].

The following experiment appears to be an additional promising step in this direction. A program could be set up to obtain simultaneous records of atmospheric-electric elements at neighboring stations located at different altitudes. This would offer the possibility of observing the gradual upward penetration of the austausch effect [67].

In this connection, further investigation of the diurnal variations of atmospheric-electric elements in various air masses [64, 66] can be expected to furnish criteria of the degree of stability or instability of atmospheric stratification.

Research in the vicinity of "generators," that is, in the region of thunderstorms, precipitation, and clouds, offers special problems; see, for example, the work by Simpson [129, 130].

Without doubt, the greatest problem of atmospheric electricity is its systematic extension into the third dimension, that is, the development of an atmospheric-electric aerology with *regular* determinations of the conditions existing in the free atmosphere [65]. Recent developments of special methods of measurement suitable for this purpose, such as those by Simpson [131, 132], Rossmann [107], Gunn [44, 45], and Belin [10], furnish the practical means for this extension.

The exploration of the origin and propagation of high-frequency disturbances in the atmosphere (sferics) can materially aid weather reconnaissance and analysis [4, 5, 88, 113] and can be developed into an integrating component of meteorological practice.

RADIOACTIVITY OF THE ATMOSPHERE*

By H. ISRAËL

Buchau Observatory and University of Tübingen

Introduction

The conductivity of the air is a characteristic of the entire atmosphere at all times. It is the result of the most varied ionizing radiation of a corpuscular and electromagnetic nature. In the lower layers of the atmosphere the radiation of the radioactive substances that are contained in the air and in the uppermost strata of the earth's crust is the principal source of this ion formation.

Table I gives a summary of the three decay series of radioactive substances and the physical qualities of the respective types of atoms. As far as the atmosphere is concerned, our interest begins only with the gaseous intermediate transformation products (*i.e.*, the emanations) and therefore a consideration of all preceding elements has been omitted.

The discovery of radioactive substances in the atmosphere was made by Elster and Geitel [19], who thus gave a physical explanation for the weak conductivity of the air, already known to Coulomb in 1785.

Methods of Measurement

There are two possible methods of measuring the radioactive elements of the atmosphere. One method consists of removing the emanations from the air by adsorption or condensation and measuring them in an ionization chamber (emanometry). In the second method, the property of so-called "inductions" is utilized, that is, the property of some radioactive decay products of carrying a positive electrical charge; these products are deposited on negatively charged collectors where their ionizing effect can be examined. This technique is termed the "induction method." The experimental technique of the induction method is simpler than that of emanometry, but quantitatively less reliable. Therefore, emanometry is to be preferred for analysis of the relatively long-lived *Rn*. However, direct emanometry does not work for *Th*- and *Ac*-products because of the short life of *Tn* and *An*, and only the indirect induction method is possible.

Table I. Radioactive Substances in the Atmosphere

Element	Symbol	Rays	Half-life	Disintegration constant (sec^{-1})
Radon	*Rn*	α	3.825 day	2.097×10^{-6}
Radium A	*RaA*	α	3.05 min	3.78×10^{-3}
Radium B	*RaB*	$\beta + \gamma$	26.8 min	4.31×10^{-4}
Radium C	*RaC*	$\alpha + \beta + \gamma$	19.7 min	5.86×10^{-4}
Radium D	*RaD*	$\beta + \gamma$	22 yr	1.00×10^{-9}
Radium E	*RaE*	$\beta + \gamma$	5.0 day	1.61×10^{-6}
Radium F*	*RaF*	$\alpha(+\beta)$†	140 day	5.73×10^{-8}
Thoron	*Tn*	α	54.5 sec	1.71×10^{-2}
Thorium A	*ThA*	α	0.14 sec	4.95
Thorium B	*ThB*	$\beta + \gamma$	10.6 hr	1.82×10^{-5}
Thorium C	*ThC*	$\alpha + \beta + \gamma$	60.5 min	1.91×10^{-4}
Actinon	*An*	α	3.92 sec	0.177
Actinium A	*AcA*	α	2×10^{-3} sec	347
Actinium B	*AcB*	$\beta + \gamma$	36.0 min	3.21×10^{-4}
Actinium C	*AcC*	$\alpha + \beta + \gamma$	2.16 min	5.35×10^{-3}

* Polonium (*Po*) † uncertain

The gaseous emanations radon (*Rn*), thoron (*Tn*), and actinon (*An*) are emitted from the rocks and the soil into the air entrapped in the ground capillaries or directly into the air at the earth's surface and are transported to higher levels by the apparent diffusion of the vertical atmospheric mass exchange (austausch). Because of the interaction between this exchange and the disintegration rate of the emanations and their by-products, a certain characteristic vertical distribution for each element can be expected which, in the mean, can be proven experimentally (see below). The contribution made by these radioactive elements to the formation of ions in the atmosphere decreases rapidly with altitude and ceases approximately at the height of the tropopause.

Emanometry. The international unit of *Rn* is the *curie* (C). The curie is the quantity of radon which is in radioactive equilibrium with one gram of radium and thus emits as many alpha particles per unit time as does one gram of radium. The current which 1 C can maintain at saturation and with complete utilization of its radiation is 9.22×10^{-4} amp. In the course of approximately 3 hr, equilibrium is reached between

* Translated from the original German.

Rn and its three short-lived decay products, *RaA*, *RaB*, and *RaC*. The current is thereby increased to 20.0×10^{-4} amp.[1] These two "current equivalents" are the basis for emanometry.

A closed cylindrical vessel containing an insulated electrode is generally used as an ionization chamber. Between the walls of the vessel and the electrode, a potential of a few hundred volts is applied which causes the ions produced to deposit before their number changes appreciably by recombination (saturation current). As the ion concentration in the air is small, the measurement is usually made electrometrically by the charge or discharge method shown in Fig. 1.

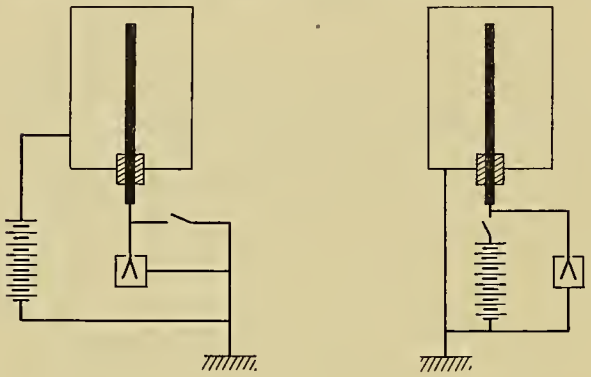

Fig. 1.—Circuit diagram for emanometrical measurements by the charge method (*a*) and by the discharge method (*b*).

Conversion of the measured data into radon units requires various corrections:

1. The "time correction" considers the change of the current equivalent due to formation of *RaA*, *RaB*, and *RaC*. Formerly, measurements were not begun until radioactive equilibrium had been attained between *Rn* and *RaA*, *RaB*, and *RaC*, at the earliest about 3 hr after pure *Rn* had been put into the measuring vessel. This method can now be shortened by using the intermediate values of the current equivalent (Table II).

2. Because of the limitation of the ionization space, not all alpha rays can become fully effective. Great difficulties are encountered in the numerical computation of the correction factor [14, 21, 54]. Therefore, the following empirical corrections developed by Duane and Laborde [16, 17] are used in most cases:

$$J = K\,(1 - 0.517\,O/V)$$
$$J' = K'\,(1 - 0.572\,O/V),$$

where J and J' represent the measured current values for pure *Rn* or for radon in equilibrium with *RaA*, *RaB*, and *RaC*; K and K' are the corrected current values; O is the surface, and V the volume of the ionization vessel.

3. It is difficult to attain saturation in ionization by alpha radiation, because a very strong initial recombination becomes effective in the closely packed ion columns concomitant to their formation. In this case, also, theoretical determination of a satisfactory correction factor is impossible. A generally valid empirical correction cannot be found either, since the saturation deficit is a function of the shape and size of the vessel and of the total quantity of ionizing substances. Therefore, this correction must be determined individually for each type of emanometer for varying quantities of radon. Suggestions for its practical evaluation have been made by Israël [31].

4. The effect of the atmospheric pressure and temperature on emanometrical measurements can be considered according to Lester [36]. In general, however, it remains a minor error compared with the other errors present [6].

Table II. Current Equivalents S_T for Emanometrical Measurements*

t (min)	S_T (10^{-4} amp)	t (min)	S_T (10^{-4} amp)
0	9.22	60	17.25
2	11.03	80	18.24
4	12.21	100	18.91
6	12.97	150	19.78
8	13.48	200	19.98
10	13.80	250	20.00
20	14.69	300	19.95
30	15.34	400	19.80
40	16.00	500	19.61

* Values of S_T are for t minutes after the introduction of pure *Rn* into an ionization chamber, taking into account the disintegration of *Rn*.

These corrections may be avoided if the measurements are compared with those of known quantities of radon. In order to obtain such small, but well-defined *Rn* quantities, the so-called radium standards are used, aqueous solutions of $RaCl_2$ which can be produced easily [8] or which can be obtained commercially. The precautions to be taken when working with such test solutions are discussed elsewhere [8, 29].

Various types of emanometers, especially useful for atmospheric *Rn* measurements, have been developed, for example, by Becker [7], Messerschmidt [42, 43], Janitzky [33], and Israël [28, 31]. Moreover, such devices for measurements in an air stream were developed by Israël [32] and Deij (see [16, 17]). Since the *Rn* concentration in the air is extremely small, a method of enriching it is often used to increase the accuracy. This method utilizes the very great solubility of *Rn* in some organic substances, its ability to condense at the temperature of liquid air, or, most conveniently, its property of being adsorbed by coconut-shell charcoal or activated carbon. By heating the adsorbent to incandescence, the *Rn* will again be given off completely. When large ionization chambers are used at high sensitivity, the "enrichment method" need not be used

1. In this case only 50 per cent of the ionization effect of the alpha rays from *RaA*, *RaB*, and *RaC* is considered, since these inductions deposit on the walls. The beta and gamma radiations from *RaB* and *RaC* constitute less than 1 per cent of the current and are usually not considered. Furthermore, the contribution of *RaD*, *RaE*, and *RaF* is far below the range of accuracy of measurement and may be disregarded. The only manifestation of these substances is the slowly increasing "pollution" of the measuring chamber which can usually be eliminated mechanically.

(lower limit of measurement approximately 2×10^{-17} C cm^{-3}). For further details see Israël [29].

Induction Method. If a charged body is exposed to air containing *Rn*, its surface acquires a certain activity, which becomes greatest with a negative charge. Because of this, it is apparent that the resultant products, principally *RaA*, must be positively charged. According to Eckmann [18], the *RaA* atoms are in fact positively charged immediately after their formation. Hence, they would be useful for an indirect quantitative *Rn* measurement, if they did not soon lose part of their charge by interaction with the ions in the atmosphere. Furthermore, the other by-products also carry, at least in part, electric charges. Finally, it must be considered that these charged inductions move under the influence of the electric field of the atmosphere.

All these possibilities of error greatly reduce the reliability of the indirect method of measurement. This method supplies only relative values which, when obtained under similar working conditions, are more or less comparable with one another. However, the relative values can be correlated with the direct-emission measurements only with very great uncertainty. Even the various attempts at applying corrections, made by Salpeter [49] and Curie [13] did not succeed in eliminating this uncertainty. Only Eve's and Aliverti's modification of the procedure (see below) leads to reliable quantitative results.

The oldest type of a practical technique for carrying out such measurements is that in which a wire is kept at a high negative potential, exposed for several hours, and then wound on a spool and examined in an ionization chamber. The resultant rate of discharge, expressed in volts per hour divided by the length of the wire (in meters), is known as the "activation number." An extensive improvement of this technique has been introduced by Swann [56], who segregated the contributions of various types of inductions by observing the decrease in wire activity with time. Gerdien [22] and Bauer and Swann [4, 5] use an aspiration process for collection. Eve [20] exposes the collecting wire in a large closed vessel, 16 m^3 in volume, and compares the resultant activity with that obtained under otherwise identical conditions, but with a known quantity of *Rn* in the vessel. In Aliverti's method [1, 2], all inductions contained in the atmosphere are deposited in a manner similar to that of electrostatic precipitators. The quantitative values for *Rn* and *Tn* can be obtained from the discharge curves.

Results

From the foregoing discussion, it is apparent that the activation numbers can give only an approximate picture of actual conditions. The values given in Table III represent averages derived from a large number of individual tests.

If we disregard the uncertainties involved, it is apparent from the values given in Table III that the lowest values are found over the oceans, increasing toward the shore, and the highest values in high mountains with strongly emanating igneous rocks. They give clear evidence that the radioactive admixtures get into the atmosphere exclusively from the continents.

The right-hand column of Table III gives mean values of the *Rn* content after improved induction measurements (aspiration method); they probably are much too small, particularly over the continents.

Table III. Average Values Resulting from Measurements of Inductions

Location	Activation number	*Rn* content after induction measurement (C cm$^{-3} \times 10^{-18}$)
Oceans	approx. 10	1.9
Continents	approx. 40	35
High Mountains		
Alps	approx. 100	—
High Cordilleras	450–500	—

Direct *Rn* measurements from various parts of the world are available in large number; a summary of such measurements is presented in Table IV. It will be seen from Table IV that the mean *Rn* content of the atmosphere near the surface over continents amounts to about $100–120 \times 10^{-18}$ C cm^{-3} (omitting the larger values for the high mountains (Innsbruck) and the smaller ones for high altitudes), and over oceans to about $1–2 \times 10^{-18}$ C cm^{-3}. Accordingly, one liter of air over the continent contains about 2000 atoms of *Rn*, over the oceans about 30 atoms. Thus, there can no longer be any doubt that the atmospheric *Rn* content is of purely continental origin; Bongards' assumption [12] that the atmospheric *Rn* is of cosmic origin can therefore be discarded. The same conclusion follows from the decrease of the *Rn* content with height (see below).

As far as the *Th*- and *Ac*-products of the atmosphere are concerned, data are more scarce. On the whole, it can be stated that (1) even over the continents, *Tn*, together with its disintegration products, contributes to the entire ionization probably less than, or at best just as much as, *Rn* with its inductions [44], and (2) *An* with its derivatives contributes hardly more than 3 per cent towards the formation of atmospheric ions.

The exhalation of *Rn* (*Rn* emission of the ground), according to the results obtained so far, is of the order of approximately 40×10^{-18} C cm^{-2} sec^{-1} (Table V).

The exhalation seems to have a single diurnal period with a maximum in the early forenoon [39], but its variation is strongly modified by meteorological factors [35, 61, 63]. The seasonal variation has a maximum in late summer [61]. Precipitation reduces the exhalation considerably, and solar radiation and an increase in temperature raise it; falling atmospheric pressure causes an increase of exhalation, rising pressure a decrease. Frost decreases it very sharply [63] and can stop it entirely [11].

Variations of the Atmospheric Radon Content. Over flat country and valleys the diurnal curves show unequivocally a single period with a maximum during the night (toward morning) and a minimum during the afternoon [9, 39]. In mountainous country the

diurnal curves are much less pronounced and apparently decisively influenced by austausch phenomena [47], inasmuch as for mountain stations well-developed regular diurnal variations appear only when there is a strong convective exchange of air with lower layers.

The seasonal variation seems to run parallel to the temperature curve, as is shown by the increase of the monthly mean from spring to summer [39, 42, 43, 47]; however, in the valley at Innsbruck, the cold season (January) shows the highest *Rn* values. This apparent contradiction can probably be explained by the fact that the temperature influence upon the exhalation is opposed by the effect of the temperature lapse rate on the vertical transport of *Rn*. In other words, during the cold season the *Rn* content of the valley air may increase in spite of reduced exhalation because of very little vertical transport, whereas in summer the effect of the austausch exceeds that of strong exhalation. Annual variations on mountaintops have not been measured as yet.

* Approximate.

There is a close relationship with meteorological influences: Falling pressure increases the *Rn* content, rising pressure decreases it [35, 39, 47], as is to be expected from the atmospheric influence upon the exhalation. The influence of the wind is twofold: With increasing wind velocity there appears first an increase in *Rn* content (because of increased exhalation), then a decrease (because of predominance of upward transport over increased exhalation). The direction of the wind is also important inasmuch as air masses of maritime origin show a smaller *Rn* content than those of continental origin [9]. Precipitation, particularly that of long duration, decreases the *Rn* content; this can easily be explained by a decrease of exhalation due to the clogging of the ground capillaries (*e.g.*, [39]). Precipitation particles themselves show a measurable content of radioactive inductions [23] which they apparently acquire while falling; on the high seas they are practically inactive, as is to be expected [48].

Table V. Radon Exhalation of the Ground

Place	Author	Exhalation ($C\ cm^{-2}\ sec^{-1} \times 10^{-18}$)

Liebenau/Graz	Kosmath [35]	40
Innsbruck	Zupancic [63]	23
Innsbruck	Zeilinger [61]	50
		Mean: 40

The fact that temperature inversion layers with a high aerosol content appear to be especially rich in *Rn* [9] would seem to indicate an austausch effect. On the other hand, this fact may also point to a causal relationship such that, because of selective adsorption by the aerosol particles, the vertical distribution of *Rn* is essentially caused by the distribution of the aerosol [27].

Radon Balance of the Atmosphere. As has been mentioned in the beginning, the gaseous emanations are the connecting links between the primary radioactivity of the ground and that of the atmosphere. By diffusion and the suction effect of the wind upon the ground capillaries, these emanations are brought into the atmosphere where they are distributed to greater heights under the influence of vertical convection. Since, together with their disintegration products, they have only a limited life-span, a height distribution, characteristic for each of the radioactive substances, must develop.

The measurements undertaken so far (see Table IV) show the expected decrease with height, but are not sufficient for the quantitative examination of this relationship. However, there is another possibility of de-

termining the balance (we restrict our examination to *Rn*).

In the mean, the supply from the ground has to maintain an equilibrium with the rate of disintegration of *Rn* in the entire atmosphere. Let us disregard the variations in a horizontal direction and consider a vertical column of air of one square centimeter cross section reaching to the top of the atmosphere; the following equation must then be fulfilled:

$$S\lambda = E,$$

where S is the entire *Rn* content of the column, λ is the disintegration constant of *Rn*, and E is the exhalation. The total content S of the air column can be computed as

$$S = \int_0^\infty s(h)\, dh,$$

where $s(h)$ represents the vertical distribution of *Rn*. For this function $s(h)$ we may write the following differential equation:

$$A\frac{d^2s}{dh^2} + \frac{dA}{dh}\frac{ds}{dh} - \rho\lambda s = 0,$$

in which ρ expresses the density of the air and A the austausch coefficient.

Integrations of this equation have been carried out by Hess and Schmidt [25] for an austausch that is constant with height ($dA/dh = 0$), and by Schmidt [51] with corrections by Priebsch [46], and by Lettau [37] for various assumed values of an austausch coefficient variable with height. Values for S and E as calculated by these various authors are presented in Table VI. The agreement between these values and the observed exhalation of 40×10^{-18} C cm^{-2} sec^{-1} (Table V) can be considered entirely satisfactory. In summary it can be said that the emanation content of the atmosphere over land and water can be completely understood if one considers the solid earth's crust as the almost exclusive source of emanation.

Table VI. Total Radon Content and Rate of Disintegration of a Vertical Column of Unit Cross Section and of Atmospheric Height, after Various Authors

Author	S (C $\times 10^{-12}$)	E (C sec$^{-1} \times 10^{-18}$)
Hess and Schmidt [25]

A = 100 g cm^{-1} sec^{-1}	18	38
Schmidt [51] (Priebsch [46])	8	20
Lettau [37]	27	57

Problems

Our knowledge of radioactive substances in the atmosphere is fairly complete as far as their identity, measurability, and origin are concerned. Less clear is the mechanism of the horizontal and vertical distribution of these substances in the atmosphere. As admixtures to the air, they take part in its movement and thus enable us to reach important conclusions regarding air-mass displacements. Therefore, if one considers the question of a suitable continuation of research, the use of radioactive air admixtures as tracers for special meteorological problems opens new possibilities. One experiment in particular suggests itself: the use of radioactive emanations as an indicator of austausch movements on the one hand, and for the determination of the life history of air masses on the other hand. Several of the above-mentioned investigations point in this direction; only a few will be mentioned.

1. The vertical distribution of the individual radioactive component can be considered as the result of austausch [9, 25, 27, 37, 39, 46, 47, 51]; therefore, with proper measurements, it ought to yield, in turn, information about its efficacy and vertical extent on the average as well as in single cases.

2. Air that stagnates in the same climatic region for some time acquires, by contact with the ground, certain characteristics which allow us to define it as an air mass of a given type. One must expect that the air mass also adopts different radioactive properties, according to the exhalation of the ground beneath. Thus, for instance, an air mass located over the ocean for a long time, will show a considerably smaller *Rn* content than air from the continent, as has been shown by measurements of the author on the Dutch coast [30] (see Table IV). Furthermore, the pronounced activity differences which Becker [9] has found above and below an inversion point to the effects of austausch or air-mass characteristics.

3. The radioactivity of precipitation gives an indication of the radioactive character of the air mass from which it falls. The pronounced increase in ionization near the ground during thundershowers [15, 57] is probably due to an especially strong upward transport of low-level (and therefore more strongly radioactive) air in the formation of a thunderstorm and the return of the radioactive admixtures through precipitation.

It is obvious that a more thorough investigation of these relationships from a meteorological and thus atmospheric-electrical and bioclimatological point of view can become of great importance.

The methodological problems, for example, consist of the following:

1. The over-all substitution of measurement by automatic recording.

2. A simultaneous survey of diurnal variations of the radioactive elements in the air at several stations at various altitudes.

3. Attempts at an air-mass classification according to origin and age on the basis of the *Rn* content and the proportion of *Ra*- to *Th*-derivatives.

4. Vertical cross sections of the atmospheric radioactivity, perhaps by means of airplane measurements or by testing the active deposits on the mooring cable of a captive balloon when bringing it in (using Geiger counters).

5. Determination of the radioactivity of precipitation.

ON THE PHYSICS OF CLOUDS AND PRECIPITATION

By HENRY G. HOUGHTON

Massachusetts Institute of Technology

INTRODUCTION

The entire science of meteorology is concerned with the physics of the atmosphere, but the term *physical meteorology* has been accepted as the designation for only one portion of the science. This division of the field includes topics such as atmospheric optics, atmospheric electricity, solar and long-wave radiation, and the physical processes of condensation and precipitation. The latter is the subject of the present contribution. The discussion will start with a consideration of condensation nuclei and will then proceed in turn to treat the initiation of condensation, the growth of the condensation products, and the formation of precipitation elements. A distinction must be made between condensation in the liquid phase and in the solid phase. There are also differences between the formation of solid and liquid precipitation elements. A brief discussion of the artificial dissipation of fog will also be included.

Some of these topics are discussed by other contributors to this volume.[1] The purpose of the present contribution is to review the entire subject. For this reason no attempt will be made to avoid the topics covered by the other authors. Such duplication is not only essential to a complete discussion of the subject but may also serve to emphasize more clearly some of the different points of view held by various workers in the field. Continuity does not require a discussion of the artificial modification of clouds, and this topic has been omitted in view of the complete treatments in this volume by Coons and Gunn and by Schaefer.

The subject of cloud physics has received much attention in recent years. This is due in large measure to the recent experimental work on the artificial modification of supercooled clouds. Other stimuli have been the problems of aircraft icing, artificial fog dispersal, the propagation of microwave radio energy, and the detection of precipitation areas by radar. In sharp distinction to many other areas of meteorology, the problems of cloud physics are amenable to the techniques of the experimental physicist both in the laboratory and in the free atmosphere.

NUCLEI OF CONDENSATION

The discovery of nuclei of condensation is generally attributed to Coulier who reported on them in 1875. The pioneer in this field was John Aitken [2] whose work on nuclei of condensation extended from about 1880 to 1916. C. T. R. Wilson's name is usually coupled with Aitken's, but his work has proven to be of more value to particle physicists than to meteorologists.

Once it was established that all natural condensation requires the presence of condensation nuclei, attention was focused on their source, nature, and size and on their distribution in time and space. Many of these questions are still in debate. Aitken studied the subject both in the laboratory and in the open air. His insight into the problem and his experimental techniques stand unrivaled as monuments to his name in this field. He developed the expansion type of nucleus counter which has been used in one form or another by all subsequent workers in the field. The careful reading of Aitken's many papers [2] is an absolute requirement for any serious student of condensation nuclei.

Source and Nature of Nuclei. Aitken [2] always referred to nuclei of condensation as "dust particles" although he stated clearly that they were distinct from the type of dust raised, for example, by high winds. He felt that there were two types of nuclei, those with an affinity for water vapor on which condensation begins below saturation, and nonhygroscopic nuclei which require an appreciable degree of supersaturation for the initiation of condensation. In his opinion the first type is the true fog-former while the second type usually produces only haze. Using an Aitken "dust counter," Wigand [56] found that an artificial increase in the dust content of air, such as was produced by beating a carpet in a room, had no effect on the nucleus count. He concluded that such nonhygroscopic dust was inactive as condensation nuclei and proposed that the Aitken dust counter be renamed the *kern counter*, a suggestion that has been generally adopted. Wigand's conclusions were apparently supported by kern counts in the presence of sand and dust storms and by Boylan's laboratory studies [5]. Boylan's results indicated that the introduction of dust such as coal dust and carbon black slightly decreased the kern count. He suggested that this was due to the sweeping action of the dust particles on the kerns. Later Junge [26] experimented with a wide variety of dusts, including some which are not wetted by water, and found that all dusts with a large number of particles smaller than about 10-μ radius increased the kern count. He concluded that particles of any substance can act as nuclei of condensation. He argued that larger particles would fall out in the chamber of the kern counter before the expansion could be made. Junge felt that earlier investigators did not produce dusts with a sufficient number of small particles to increase the kern count significantly. As he pointed out, a dust cloud of several hundred large particles in a cubic centimeter looks much denser than so-called "dust-free" air, which may contain several hundred thousand ultramicroscopic condensation nuclei per cubic centimeter. Junge's results are very convincing and it seems reasonable to accept his conclusions. On the other hand, the evidence still

1. In particular, reference should be made to the papers by Coons and Gunn, Junge, Ludlam, Möller, Nakaya, and Schaefer.

supports Aitken's conclusion that the hygroscopic nuclei are the important cloud producers and that neutral dust is of lesser importance. Boylan [5] found in Dublin that the number of kerns determined with the Aitken instrument averaged fifteen times the number of dust particles determined with the Owens impact dust counter.

Aitken and many others have established that flames and burning materials form tremendous numbers of nuclei and also that heat alone, as from a heated platinum filament, will form nuclei in natural air. Aitken and also Coste and Wright [6] showed that nuclei could be formed by spraying sea water. The latter authors also found that fuming sulfuric acid was an active kern producer. Although flames produce a variety of products it has been established that substances containing sulfur are the most effective fuels. This is significant because of the sulfur content of coal. When sulfur is burned the nonhygroscopic dioxide is formed. This does not easily oxidize to the hygroscopic trioxide in air at normal temperatures. Aitken found that both ozone and hydrogen peroxide are effective oxidizers of sulfur dioxide. He also claimed that ultraviolet solar radiation oxidized the sulfur dioxide. Coste and Wright [6] suggested that at temperatures above 620C, and in the presence of water vapor, hygroscopic nitrous acid is formed. This would explain the production of nuclei by hot filaments. They also suggested that the nitrous acid is the oxidizing agent for sulfur dioxide.

There is general agreement that sea salts are effective as condensation nuclei. Sea-salt crystals have been observed in the atmosphere by Owens [43], Dessens [8, 9], and Woodcock and Gifford [57]. Köhler [27, 28] and others have demonstrated the presence of chloride ion and of other sea-salt anions in water from clouds, fogs, and rain. If the amount of chloride ion, for example, as measured in a bulk sample is divided by the number of drops, it yields a nucleus of reasonable size. Any object which has not been carefully cleaned exhibits the ubiquitous sodium flame when it is heated. On the other hand there is evidence which suggests that the sea is not the principal source of condensation nuclei. The number of nuclei is much smaller over the oceans than over the land. A minimum kern count of nearly zero has been observed over the ocean and the usual count is from several hundred to several thousand per cubic centimeter. Typical values over land range up to 100,000 in rural, and a million or more in urban areas. Simpson [49] shows that if all active nuclei come from the sea surface, the rate of nucleus production must be about 1250 sec^{-1} cm^{-2}. This appears to be unreasonably large if the nuclei are formed by the evaporation of the spray resulting from wave action. A large proportion of the spray drops will be so large that they will fall back to the surface. Findeisen [12] holds that the sea salt indubitably present in the atmosphere is in the form of say 10–20 large particles of about 10^{-10} grams mass per liter of air. Although these are probably all active nuclei, their number is small compared to the total number of nuclei. Their presence would serve to explain the observed chloride content of cloud and rain water. There are isolated observations that the evaporation of sea water (without visible spray) produces kerns, and Aitken found that nuclei were formed by the action of the sun on the foreshore at ebb tide. Attempts to identify the nucleus in an evaporating cloud drop under the microscope have failed. Dessens [8] has caught nuclei from the air on spider webs and caused them to grow into drops or to form crystals by varying the humidity. These are probably the relatively large sea-salt particles referred to by Findeisen [12]. Wright [58] has shown that visibility near the seacoast is a function of the relative humidity, which can be explained by assuming that the nuclei are hygroscopic. Wright felt that he had shown in this way that the nuclei in question were sea salts but Simpson [49] argued that his procedure did not permit the identification of the hygroscopic agent.

It is generally concluded that most active condensation nuclei are hygroscopic particles and that the nonhygroscopic nuclei are unimportant. More information is required to explain this strong preference for hygroscopic nuclei. The hygroscopic and nonhygroscopic kerns are presumably of about the same size; if anything, the hygroscopic nuclei are somewhat smaller. It can be shown that the lowering of the vapor pressure by the salt is not of major importance, since a slightly larger nonhygroscopic particle will support condensation at the same degree of supersaturation. It appears from Volmer's work [52] that the wettability of the substance plays an important role. On a surface which is not wetted by water, condensation occurs in the form of small lens-shaped drops. The work required is greater than when the surface is wetted and increases with the contact angle between the water and the surface. Greater work for the phase change implies a higher supersaturation. Hygroscopic nuclei are liquid drops before cloudy condensation occurs and are therefore perfectly wetted. All other nonhygroscopic surfaces are less easily wetted and it may be that the nonhygroscopic atmospheric dust is largely hydrophobic. Junge's finding [26] that paraffin spheres will serve as condensation nuclei does not contradict this explanation since Volmer shows only that hydrophobic nuclei require a greater supersaturation than hydrophilic nuclei. Junge did not report on the supersaturations used, but since he employed an Aitken instrument it may be assumed that they were from 200 to 300 per cent. An extension of Junge's work with provisions for varying the supersaturation would probably shed some light on this problem.

The available evidence suggests that the hygroscopic nuclei are formed of sea salts and nitrous and sulfuric acids. Other hygroscopic materials may also be important but it has yet to be shown that other such substances regularly exist in the atmosphere in sufficient quantity and in finely divided form. If it be assumed that sea-salt nuclei are formed only by the evaporation of spray, it must be conceded that the source is insufficient to supply a major fraction of atmospheric kerns. Further study on other possible mechanisms for the formation of sea-salt nuclei is

desirable. Perhaps rapid evaporation of sea water in the absence of spray forms nuclei. Aitken's observation that nuclei are formed by the action of sunlight on salt-water beaches should be followed up. Dessens [9] found that salt droplets become supersaturated when the relative humidity is decreased and finally crystallize explosively, occasionally resulting in rupture. He tentatively offered this as a possible mechanism for the production of small condensation nuclei from the relatively large crystals formed when sea spray evaporates, but later expressed the opinion that the fracture mechanism is too rare to be of major importance.

The sulfuric acid in the atmosphere must come primarily from the sulfur in coal, although volcanic activity may contribute a small amount. Much of the research on nuclei has been done in industrial areas such as the British Isles and Germany, so that the importance of sulfuric acid nuclei may have been overemphasized. Although the high concentrations of nuclei in industrial areas is almost certainly due to the products of man-made combustion, no one believes that the cloud and precipitation regimes of the world have been greatly altered by industrialization. It appears that nitrous acid nuclei are also produced by combustion but here it is the high temperature which acts as a catalyst to form the nuclei from the natural constituents of the air. Forest fires are as effective for this as man's furnaces. It is also known that nitrous acid is formed by the action of lightning discharges. It may be that nitrous acid is the principal kern material and that the high kern-concentrations in urban areas are due to the products of combustion and are of only local importance. Adel [1] and Shaw and collaborators [48] have obtained spectroscopic evidence of the presence of about 1 cm of nitrous oxide at NTP in the atmosphere. There is no information on the vertical distribution of the nitrous oxide but these observations suggest that it is a universal constituent of the atmosphere. There may well be other substances, even nonhygroscopic ones, obscured by the abundance of other nuclei in industrial areas, which are the really important nuclei of the free atmosphere.

Size and Size Distribution of Nuclei. The upper limit of nucleus size is set by the settling rate and also in some cases by the method of formation. As an example, the largest sea-salt nucleus probably has a diameter of the order of 5×10^{-3} cm. Because the work of subdivision of a solid or a liquid increases rapidly with the amount of new surface formed, the diameter of the smallest sea-spray nucleus or dust particle produced by erosion or grinding is of the order of 10^{-5} cm. Diameters of nuclei formed from gases such as sulfuric and nitrous acids probably range from 10^{-5} to 10^{-6} cm. Such nuclei are not apt to be as large as sea-salt nuclei because of the small concentration of the gases from which they are formed. All sizes within these rather wide limits are to be expected. (For completeness it may be mentioned that small ions with dimensions of the order of 10^{-7} cm will serve as nuclei only at four to five fold supersaturations and cannot play any role in natural atmospheric condensation.)

Only the larger nuclei can be measured with the visual microscope. The electron microscope opens the way for the measurement of smaller nuclei if a means can be found for the collection of the nuclei on the stage of this instrument. Most measurements of the size of nuclei have been made by indirect means. The large or Langevin ions of the atmosphere are generally believed to be condensation nuclei which have captured a small ion or an electron. Boylan [5] states that about 60 per cent of the nuclei carry a single electronic charge and are identical with the large ions. The mobility (velocity in unit electric field) of such ions may be measured and their size computed from Stokes' law. Such measurements yield diameters in the neighborhood of 10^{-5} cm.

As already mentioned, the size of the nucleus may be determined by assaying a bulk sample of cloud or fog water for the assumed constituent and dividing by the number of drops represented in the sample. This was done first by Köhler [27], who collected rime at a mountain observatory and determined the chloride content by titration. The mean drop size was measured by the corona method. By assuming that the other anions of sea salt were present in the same proportion as in the sea, he computed the average mass of the nuclei to be 1.847×10^{-14} g, equivalent to a diameter of about 5×10^{-5} cm. This procedure is open to the criticism of Findeisen [12] that the salt might be in the form of a few relatively large particles.

Direct measurements of the size of nuclei have been made by Dessens [9] and by Woodcock and Gifford [57]. Dessens caught the nuclei on spider threads and examined them with a visual microscope. He reported radii of nuclei ranging from 0.3 to 0.5 μ. The nuclei were in the form of drops at a relative humidity of 60 per cent. There were others too small to measure, and also some larger ones. Woodcock and Gifford collected nuclei on glass slides 1 mm by 15 mm in size from an airplane flying over the ocean. The counts were corrected for the collection efficiency of the slides. They identified the nuclei as sea salts by determining the relative humidity at the transition between crystal and solution. They present their data in form of the mass distribution of the nuclei. The largest nuclei had a mass of about 2×10^{-9} g and the smallest a mass of near 5×10^{-14} g. These weights correspond to diameters of 24 and 0.7 μ respectively at a relative humidity of 80 per cent. When plotted on logarithmic paper, Woodcock and Gifford's distribution curves of nucleus mass versus number are nearly linear with negative slopes. Their method did not permit the collection of nuclei of mass less than 5×10^{-14} g. The total number of nuclei in a cubic centimeter of air was found to range from less than one to about thirty and to decrease rapidly with elevation in the first 300 m above sea level. Although no simultaneous measurements with an Aitken counter are reported, it is probable that the Aitken count would be large compared with that of Woodcock and Gifford. There is no evidence that these unmeasured nuclei are composed of sea salts.

The methods outlined above of determining the size

of nuclei yield the actual geometric diameter or mass. With the sole exception of the application of mobility measurements to large ion-nuclei, none of these methods can be used in the size range which includes the majority of the natural condensation nuclei of the atmosphere. An indirect measure of the effective size of condensation nuclei may be obtained by causing condensation to occur on them under controlled conditions. To discuss this procedure it is necessary to review briefly the theory of condensation on nuclei as first presented by Thomson [50] for neutral nuclei and Köhler [29] for hygroscopic nuclei. Thomson showed that the vapor pressure in equilibrium with a curved surface is greater than the vapor pressure in equilibrium with a plane surface at the same temperature. The supersaturation required to initiate condensation on the surface of a small sphere, which is wetted by water, is nearly inversely proportional to the radius. This effect is illustrated by the upper curve in Fig. 1. The vapor

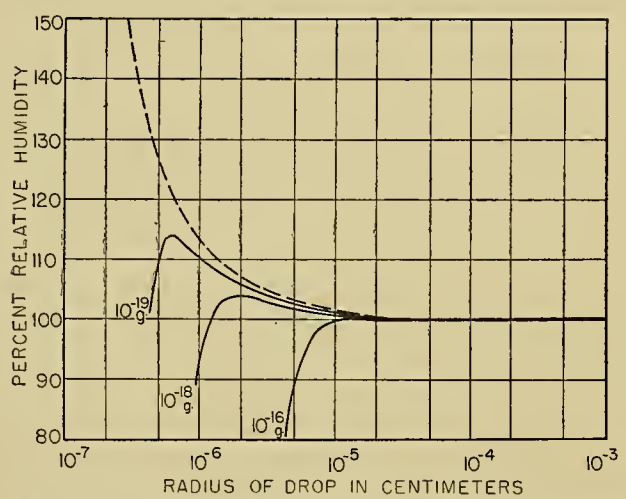

Fig. 1.—Growth curves of sodium chloride nuclei of masses as indicated at 0C. The dashed line is for pure water drops.

pressure over a solution of a hygroscopic salt is lower than that over pure water. In the case of a hygroscopic nucleus, both effects are in evidence and act in opposition. The net result is indicated by the lower curves of Fig. 1. The effect of the dissolved salt is dependent upon its concentration and thus is a function of the mass of the hygroscopic material and of the radius of the droplet. The Thomson effect is a function only of the radius of curvature. The three lower curves of Fig. 1 are for nuclei of sodium chloride of different masses as indicated on the curves. It is readily apparent that hygroscopic nuclei grow more slowly as the relative humidity increases toward saturation. In all cases, the growth curves reach a maximum in excess of 100 per cent relative humidity. This peak relative humidity must be exceeded if the nucleus is to become a cloud drop. The general behavior of these curves has been verified experimentally by Junge [25] who determined the size of hygroscopic nuclei at various relative humidities from the mobility of the nuclei as large ions. Wright [58] has obtained data on the variation of visibility with humidity which seem to confirm the general shape of the curves of Fig. 1 below saturation.

The supersaturation corresponding to the maximum of the curves of Fig. 1 is a measure of the effective size of the nucleus. The geometric size can be determined only if the nature of the hygroscopic salt is known. An adaptation of the Aitken nucleus counter can be used to determine the effective size of the nuclei, as was shown by Junge [25]. He produced expansions of known and increasing amounts in a chamber and determined the number of drops after each expansion. In this way he obtained a nucleus spectrum. Earlier, Aitken [2] performed a similar experiment with his apparatus. The principal difference in the two techniques was that Junge used a large chamber and applied his successive expansions rapidly so that none of the previously activated nuclei would evaporate. Aitken first produced a small expansion and counted the number of drops which fell out in the usual manner. He then proceeded to an increased expansion, waiting each time until the activated nuclei had fallen out of the air. Aitken's procedure is open to the objection that some of the drops might evaporate before falling out and thus leave nuclei to be counted again in subsequent expansions. Junge's method involves the errors of counting the number of drops while they are suspended in the air. Most of Junge's experiments were carried out with artificially produced nuclei, whereas Aitken used natural air. Qualitatively their results were very similar. The evidence is that a large number of nuclei are activated at the lowest expansion used, with smaller numbers requiring greater expansions or supersaturations. Aitken found that all of the ordinary nuclei in the samples of natural air were activated by a relative humidity of 150 per cent. Further increases in the expansion ratio had no effect until the supersaturation required to produce condensation on small ions was reached. Junge found that 110 per cent relative humidity was sufficient to activate all of the nuclei in a sample of outdoor air.

Number and Distribution of Nuclei. Literally thousands of measurements of the number of nuclei in the air have been made with the aid of the Aitken instrument. As ordinarily used, this instrument produces a supersaturation of from 200 to 300 per cent and therefore activates all natural nuclei but not small ions. As will be pointed out below, only a small fraction of the total number of nuclei are activated in natural condensation processes. For this reason the total number of nuclei as determined by the Aitken counter is of limited value since no information regarding the size or the size distribution of the nuclei is obtained. A very complete summary of the measurements which have been made has been given by Landsberg [33], and no attempt will be made here to give any of the detailed results. The maximum concentration was found in cities, with an average of 150,000 per cubic centimeter and a maximum of some four million. In the country, the average is of the order of 50,000 and the maximum near 400,000. Much lower concentrations are found over the oceans with an average of about 1000 and a maximum of about 40,000. At a given

location, the concentration of nuclei has a diurnal and annual variation, the nature of which is largely dependent upon the local conditions. Correlations have been made of nuclei concentration with visibility, air mass, wind direction and force, and so forth. The important question of the variation of the concentration of nuclei with elevation has not been thoroughly studied because of the difficulties in the way of such measurements. Most of these measurements have been made in mountainous regions at various elevations. These show a rapid decrease in concentration with elevation. A few determinations have been made from free balloons. These show a more rapid decrease of concentration of nuclei with increasing elevation than the mountain observations. The average vertical distribution of nuclei from the balloon ascents shows a count of 22,300 per cubic centimeter in the layer from 0 to 500 m decreasing to 80 above 5000 m. Of necessity the balloon flights were made in anticyclonic weather, and the results cannot be considered typical of stormy conditions. In any event, the rapid decrease in concentration with increased elevation indicates that the source of condensation nuclei is at or near the surface. The nuclei are presumably carried aloft by turbulence and convection. This reasoning would suggest that the decrease in concentration with elevation would be smaller in cyclonic than in anticyclonic conditions. No information is available on the change in size of the nuclei with elevation. It would be highly desirable to obtain more information regarding both the number and the size distribution of condensation nuclei in the free atmosphere.

THE INITIAL PHASE OF CONDENSATION

Reference has been made above to the factors which control condensation on both hygroscopic and nonhygroscopic condensation nuclei. Referring again to Fig. 1, it is evident that condensation nuclei will not attain cloud drop size unless the supersaturation corresponding to the maximum of the curves for hygroscopic particles is exceeded. The magnitude of the supersaturation required is dependent on the mass of the hygroscopic material in the nucleus. The supersaturation required in the case of nonhygroscopic nuclei is dependent on the radius of curvature of the nucleus as indicated by the upper curve in Fig. 1. As was pointed out earlier, the critical supersaturation is probably also dependent on how easily the surface of the nucleus is wetted. If the nucleus is composed of a microporous substance, condensation will occur at a lower relative humidity, the exact value depending on the size of the pores. Even in this case the nucleus cannot grow to cloud drop size unless some initial supersaturation occurs. It is therefore generally true that cloudy condensation cannot occur without a small degree of supersaturation. Such data as are available on the size and size distribution of nuclei indicate that the supersaturation required is usually less than one per cent. This is confirmed by the observation that the cloud base corresponds to the saturation level within the precision of the measurements.

As the relative humidity exceeds 100 per cent, condensation occurs first on the largest nuclei, that is, on those requiring the smallest amount of supersaturation to become active. Nuclei are said to be active when they have exceeded their critical supersaturations and are free to grow to cloud drop size. If the condensation is extremely slow, only the very largest nuclei will become active. As the rate of condensation is increased, the rate of condensation on the larger nuclei will not be sufficient to hold the supersaturation down and additional nuclei will be activated. This shows that the concentration of cloud drops is dependent primarily on the initial rate of condensation.

The process which has just been described qualitatively has been investigated theoretically and numerically by Köhler [29] and by Howell [24]. Köhler combined the radius of curvature effect and the effect of the hygroscopic solute with the thermodynamic equations of the condensation process. He did not introduce numerical values and did not consider the effect of a distribution of nuclear sizes. Howell assumed a broad spectrum of nuclear sizes and several different rates of condensation. He was able to show that only a very small fraction of the nuclei were activated and that under reasonable conditions the initial supersaturation was less than one per cent. He places the maximum probable supersaturation at about three per cent. By using different size distributions of the nuclei, Howell found that the concentration of cloud drops was much more dependent on the initial rate of condensation than on the size distribution of the nuclei. As soon as the initial stages of condensation are over, the supersaturation rapidly declines so that it is extremely unlikely that any additional nuclei will be activated. Because of the rapid decrease in supersaturation it is possible that a few of the smaller nuclei which were activated may evaporate. Howell contends that although this presumably occurs, the number of drops which start to form and then evaporate is very small compared to the total. It is reasonably safe to state that the concentration of cloud particles immediately after the initial condensation is very nearly equal to the concentration of activated nuclei and that there is little likelihood of an increase in the concentration of the cloud particles thereafter.

GROWTH OF CLOUD DROPS

When the initial phase of the condensation process is completed, the dissolved hygroscopic material and the radius of curvature have a relatively small effect on the further growth of the drop. The steady-state diffusion equation for the growth of drops as given by Houghton [21] is

$$\Delta(a^2) = 8k(\rho_w - \rho_{0w})\,\Delta t, \tag{1}$$

where $\Delta(a^2)$ is the increment of the square of the drop diameter in the time Δt, ρ_w is the water vapor density at a distance from the drop, and ρ_{0w} is the density of water vapor in equilibrium with the drop. As pointed out by Howell [24], this equation is not valid during the initial condensation phase nor for very small drops

but it may be used to determine the effects of continued condensation on the size and size distribution of the cloud drops. The latent heat of condensation is released at the drop surface and transferred to the air by conduction. As a result the equilibrium temperature of the drop is greater than the air temperature and ρ_{0w} is therefore greater than the saturation water vapor density at the temperature of the air. Since $(\rho_w - \rho_{0w})$ is always positive, supersaturation must exist throughout the condensation process. Computations show that the supersaturation can hardly exceed a few tenths of one per cent for any reasonable rate of lift. As a result of the parabolic relation between the drop diameter and the time in equation (1) the drop diameters will become more uniform as the condensation proceeds. This conclusion has been verified by Howell [24].

Howell [24] attempted to find the conditions most favorable to a broad distribution of cloud drop sizes but was unable to delineate them in a clear-cut fashion. Slow cooling was expected to allow the initial effects of the solute and radius of curvature to exercise a maximum effect in broadening the size of the distribution. The small number of nuclei activated largely compensated for any such broadening. Rapid cooling had the opposite effect and it appears that some intermediate rate of cooling will yield the broadest drop-size distribution. The computed drop-size distributions are of the same general form as those observed in natural clouds, but are quite narrow, corresponding to the more homogeneous half of the clouds measured at Mount Washington, New Hampshire. It does not seem possible to explain the broader size distributions often observed by a uniform lift process of the type treated by Howell. This conclusion appears to be definite, in spite of incomplete knowledge of the condensation nucleus size spectrum, because of the controlling effect of the initial rate of condensation.

Some other mechanism must be sought to explain broader size distributions than those which result from uniform lift. Arenberg [3] suggested that turbulence would bring condensation products of different histories into the same region, thus resulting in a broad size distribution. Arenberg also suggested that the alternate up and down excursions of the drops in a turbulent atmosphere might lead to a broadening of the size distribution. However, excluding the evaporation during the descending branches of the motion, turbulence tends to narrow the size distribution and its net effect is apt to be small.

In nature the uniform lift process adopted by Howell [24] for his computations is subject to important modifications. The rate of lift of different samples of the air at the condensation level will not be the same. Because of the controlling influence of the rate of lift on the concentration and size of the cloud drops it is to be expected that the mean drop sizes of the samples will show a rather wide range. Subsequent mixing of these samples by turbulence will result in a size distribution broader than that produced by a uniform lift. It is to be noted that fine-grain turbulence is required for the final intimate mixing essential to the broadening of the local drop-size distribution. It seems probable that any observed drop-size distribution can be explained on the basis of a suitable variation in the rates of condensation of separate air parcels and their subsequent mixing. No data are available on the distribution of vertical velocities at the condensation level, so that a quantitative verification of this theory is not possible. Advective marine fogs also have broader drop-size distributions than might be expected from uniform cooling at the initiation of condensation. Such fog is formed at a much slower rate of cooling than any type of cloud. One anticipated result is that the drop concentration in advective marine fogs is much smaller than in clouds. The cooling is produced at the underlying surface and even in the usual stable stratification the mechanical turbulence is apparently sufficient to produce a range of cooling rates at the initiation of condensation. Such data as are available suggest that the drop-size distribution of radiation fog is quite narrow, presumably as a consequence of the more stagnant conditions of formation.

The breadth of the drop-size distribution in clouds has an important bearing on the stability of the clouds and on the release of precipitation in clouds which do not reach the freezing level. It is important that further studies of the factors which determine the breadth of the distribution be undertaken. It appears that knowledge of the growth of the drops from condensation nuclei to large cloud drops is now well understood from the physical point of view. The missing information is concerned with those details of the air motion which determine the initial rate of cooling and the mixing of condensation products with diverse histories.

Equation (1) shows that the time required for a drop to grow by condensation increases with the square of the drop diameter if the supersaturation is constant. This suggests that the maximum size of a condensation drop can be estimated by selecting a maximum time and a suitable supersaturation. An analysis of the drop growth process shows that the supersaturation reaches its maximum at the activation of the nucleus and thereafter rapidly declines, adjusting itself so that water will be condensed at the rate called for by the rate of lift. It is thus impossible to select an appropriate supersaturation for the computation of the maximum drop size. The factors that truly determine the maximum drop size are the drop concentration and the amount of water vapor available for condensation. The former is dependent on the initial rate of condensation, the latter on the water-vapor content of the air and the total lift. It is now known that a considerable amount of unsaturated air from the environment is entrained by the rising column in cumulus convection. This desiccates the rising air and thus reduces the maximum drop size. Large drops are favored by slow initial lift, large water-vapor content, and large total lift. These factors are not all mutually compatible, so that the actual maximum drop size is considerably smaller than that computed for optimum values of each of the separate factors. It is generally believed

that the practical maximum diameter reached by condensation is about 100 to 200 μ.

OBSERVATIONS OF DROP SIZE AND LIQUID WATER

Methods of Measurement. Although a complete discussion of methods of measuring cloud drop size and liquid-water content is beyond the scope of this article, some understanding of the measuring techniques is essential to a proper evaluation of the data. The most frequently used method of measuring cloud drop size has been the corona method. The angular diameter of the first- and higher-order diffraction rings observed around a light source is a measure of the average drop size. The method is theoretically unsound for drop diameters less than about 10 μ. Although the possibility of determining the drop-size distribution by the corona method exists, no satisfactory technique has been developed. The method is most applicable to the measurement of the drop size in homogeneous clouds; the coronas become diffuse and difficult to measure when the drop-size distribution is broad.

Mean drop size and some indication of drop-size distribution can be obtained from the rotating multicylinder. This instrument consists of a series (often five) of cylinders of different diameter arranged to be slowly rotated with the axes of the cylinders normal to the wind. The collection efficiency of a cylinder is dependent on the air speed, the cylinder diameter, and the drop diameter. The numerical relations between these quantities and the collection efficiency have been determined by Langmuir and Blodgett [35]. From a comparison of the relative collections of the several cylinders the mean drop size and a measure of the drop-size distribution may be obtained. The liquid-water content (mass of liquid water in a unit volume of air) also may be determined from the measurements. This technique has been used at Mount Washington, New Hampshire (where it was developed by Arenberg), and on aircraft. It was first used only in supercooled clouds where the deposit is in the form of rime but absorbent cylinders are now used at temperatures above freezing. In order to obtain measurable collections the cylinders must be exposed to a few miles of cloud. For this reason the method yields only average values and cannot indicate rapid changes in drop size. In order to obtain a drop-size distribution it is necessary to assume the general form of the distribution curve.

The most direct means for the measurement of drop size and drop-size distribution is the collection and photomicrography of a sample of the drops. Direct photography of the drops in the air has so many inherent difficulties that it cannot be considered to be a practicable method. The usual technique is to expose a suitably coated slide to the windstream and take photomicrographs of the collected drops. Each drop image must be measured individually, and from one hundred to several hundred drops must be so measured to secure a representative distribution curve. The slide surface is covered with a hydrophobic surface, with an oil layer, or it is smoked. If the oil film is used, the drops are immersed thus retarding evaporation and preserving their spherical shape. On the smoked slides the drops leave clear areas which are related to the drop size. The drops on the hydrophobic surface are semiflattened and are subject to evaporation. Because of the finite size of the slides there is discrimination against the smaller drops. In addition, large drops tend to fracture on impact at high air speeds. In spite of these difficulties this general method is the only one which permits the nearly instantaneous determination of the drop-size distribution.

It is clear, even from this brief discussion, that none of the present techniques is entirely satisfactory. It is not believed that improvements in any of the existing techniques will remedy this situation. A new approach to the measurement of drop size and size distribution is badly needed.

Drop-Size Measurements. Köhler [30] has reported on the results of a large number of corona measurements of drop size made at a mountain observatory in northern Norway. Similar measurements have been made by others but Köhler's work may be taken as representative. Köhler made several thousand individual measurements in mountain fog, stratus, stratocumulus, and altocumulus. The absolute range of mean drop diameter was about 5 to 70 μ. The most frequent diameter was found to be about 17.6 μ. He found that the range of the most frequent diameter was smaller for altocumulus and stratocumulus than for fog and stratus. Köhler's measurements yield no information on the size distribution, although he notes that some of the coronas were sharper than others; the sharper coronas corresponded to the narrower size distributions.

Köhler has claimed that his data show what he calls a "mass grouping" such that the sizes in a group represented by $d = d_0(2)^{n/3}$, $n = \pm 1, 2, 3$, etc., are predominant. Here d_0 is the constant modal diameter of the group and d represents the diameters of the drops composing the group. Other investigators have reported similar groupings. If this result were accepted, it would imply that there is a rather fixed drop size resulting from condensation and that other sizes are formed by the combination of drops of this initial size. This does not seem reasonable on physical grounds. No such grouping has been found in the multicylinder or microscopic data. It seems that Köhler's results must be due to some peculiarity of the corona technique and it is no longer believed that such a mass grouping exists.

A large amount of data on drop size, size distribution, and liquid-water content in clouds has been collected at Mount Washington, New Hampshire [51]. All three of the methods described above have been utilized but the bulk of the data has come from the rotating multicylinder. The mean drop diameter was found to be 13 μ, which is somewhat smaller than Köhler's 17.6 μ. The observed range of median diameter was about 5 to 40 μ. It should be noted that the multicylinder mean diameter is a volume median such that one-half of the water is in smaller drops and one-half is in larger drops. The diameter obtained from the corona method probably corresponds to the most frequent size. With the

usual type of size-distribution curve the volume-median diameter is larger than the most-frequent diameter.

As already stated, an indication of the breadth of the drop-size distribution can be obtained from the multicylinder data. The general form of the distribution curve must be assumed. The evidence available suggests that the majority of drop-size-distribution curves are of the general form assumed although there are occasional curves with multiple maxima. For convenience, nine standard volume-distribution curves have been adopted, identified by the letters A through J (I is omitted). The A distribution corresponds to complete uniformity and the succeeding letters to distributions of increasing breadth as shown in Table I.

Table I. Standard Volume-Distribution Curves Used in the Multicylinder Method

Per cent of liquid water in each group	Ratio of diameter of group to volume-median diameter for each distribution								
	A	*B*	*C*	*D*	*E*	*F*	*G*	*H*	*J*
5	1.0	.56	.42	.31	.23	.18	.13	.10	.06
10	1.0	.72	.61	.52	.44	.37	.31	.27	.19
20	1.0	.84	.77	.71	.65	.59	.54	.50	.42
30	1.0	1.00	1.00	1.00	1.00	1.00	1.00	1.00	1.00
20	1.0	1.17	1.26	1.37	1.48	1.60	1.73	1.91	2.22
10	1.0	1.32	1.51	1.74	2.00	2.30	2.64	3.04	4.01
5	1.0	1.49	1.81	2.22	2.71	3.30	4.02	4.93	7.34

As will be seen from Table I, each distribution is made up of seven different drop diameters each representing the percentage of the total water indicated in the first column. The drop sizes are represented as the ratios of the drop diameter to the volume-median diameter so that the distributions may be applied to any volume-median diameter. The frequency of occurrence of the nine drop-size-distribution types at Mount Washington for the months November 1946 through May 1947 is indicated in Table II.

Table II. Occurrence of Drop-Size-Distribution Curves by Type at Mount Washington, N. H.

Distribution curve type	*A*	*B*	*C*	*D*	*E*	*F*	*G*	*H*	*J*
Number of occurrences	241	96	47	21	13	5	2	4	7

The predominance of narrow size distributions is striking. This is probably due in part to the high frequency of cloud-cap conditions which do not favor the nonuniform rates of lift apparently required to produce broad size distributions. For this reason Table II cannot be taken as typical of the clouds of the free atmosphere. It is also apparent from Table II that a significant number of broad distributions occur (E through J) which certainly cannot be explained on the basis of uniform lift.

Multicylinder observations were also used to compute the liquid-water content. For the winter season 1945–46 the mean liquid-water content was 0.472 g m^{-3}. The most frequent value was 0.24 g m^{-3} and the range was 0 to 1.44 g m^{-3}. There is a tendency for the higher liquid-water contents to be associated with higher temperatures. There is a similar tendency for the drop size to increase with the temperature.

An extensive series of in-flight measurements of the liquid-water content and drop size of supercooled clouds has been made by the National Advisory Committee for Aeronautics and reported by Lewis and collaborators [37, 38, 39]. The principal instruments used were the rotating multicylinder, a rotating disc icing-rate meter, and a fixed cylinder which gives a measure of the maximum drop size. The measurements were made during three winter seasons and in both the eastern and the western portions of the United States. Although identification of the cloud type was made in each case it was found that, in general, the data did not warrant a more detailed classification than the distinction between cumuliform and stratiform clouds. For three winter seasons the average volume-median drop diameter was found to be 20.5 μ for cumuliform clouds and 14.7 μ for stratiform clouds. The range of volume-median diameters was 3 to 56 μ for cumulus clouds and 3 to 50 μ for stratiform clouds. Nearly 50 per cent of the size distributions as determined from the rotating multicylinder were type A. Evidence is presented that the size-distribution data are unreliable and the authors feel that this technique is not applicable to in-flight measurements. By comparison of the simultaneous observations of volume-median diameter and maximum diameter they concluded that the clouds are more homogeneous than is indicated by the rotating multicylinder.

The liquid-water contents reported by Lewis and collaborators [37, 38, 39] ranged from 0.02 to 2.0 g m^{-3} for cumuliform clouds and from 0.01 to 0.7 g m^{-3} for stratiform clouds. The average values for the three winter seasons were found to be 0.51 g m^{-3} for cumuliform clouds and 0.134 g m^{-3} for stratiform clouds.

In considering these data it must be remembered that they are winter values and that the temperatures were always below freezing and usually markedly below. The data presented show that both the drop size and the liquid-water content tend to increase with the temperature. The mean drop diameter obtained from these in-flight measurements is significantly larger than the Mount Washington mean. Again, this is probably due to the prevalence on the mountain of cloud caps which are presumed to contain smaller drops as a result of the rapid lifting. There is no significant difference in the liquid-water observations in flight and on Mount Washington.

Diem [10] has reported the most extensive set of drop-size-distribution data from the free atmosphere. His measurements were made from aircraft by exposing a small oil-covered slide to the air stream for about $\frac{1}{50}$ sec. The slides were photomicrographed within a minute of collection. The slides undoubtedly discriminated against the smaller drops. Diem states that the collection was satisfactory down to a diameter of 3 μ but there is reason to believe that the discriminatory effect started at a somewhat larger diameter. Diem gives the most frequent drop diameters for six cloud types (Table III). Fair weather cumulus, altostratus

and stratocumulus show the sharpest distributions. The other three cloud types exhibit broad size distributions. It is interesting to note that, in general, the cloud types

Table III. Data from Composite Drop-Size-Distribution Curves
(*After Diem* [10])

Cloud type	Peak diameter (μ)	Range of curve (μ)
Dense cumulus	14.5	3–40
Fair-weather cumulus	8.5	2–20
Stratocumulus	7.9	2–24
Nimbostratus	13.2	2–42
Stratus	12.9	2–42
Altostratus	10.6	2–30

associated with precipitation have broad distributions. Very few of Diem's size distributions would fall in types *A* and *B* of Table I. The difference between Diem's data and the Mount Washington data in this respect is doubtless due in part to the different methods of measurement, but the writer feels that much of the difference is real. As pointed out above, there is good reason to believe that the conditions of formation of the Mount Washington cloud cap favor a narrow drop-size distribution. Until more data from the free atmosphere are available it seems reasonable to accept Diem's data as typical rather than that from Mount Washington.

Drop-size measurements were made in sea fog by Houghton and Radford [22] on the northeast coast of the United States. The fog drops were collected on slides with a hydrophobic surface and then photomicrographed. Sampling errors occurred for drops smaller than about 20 μ but this did not greatly affect the results in view of the relatively large drop size. The volume-median drop diameters ranged from 25 to 75 μ with an average of 45 μ. The drop-size distributions appear rather broad because of the large drop size but most of them correspond to the *C* distribution of Table I, while a few *B* and *D* distributions also occurred. The largest drop measured was 120 μ in diameter. The mean liquid-water content was found to be 0.13 g m^{-3} with a range of from 0.01 to 0.30 g m^{-3}.

The most striking feature of these results is the large size of fog drops as compared to cloud drops and the relatively small variation in the volume-median diameter and in the breadth of the size distribution. Coupled with the large drop size the relatively low liquid-water content shows that the drop concentration is very small. This suggests that the fogs observed formed on a few relatively large nuclei of condensation which quite possibly were sea-salt particles. Chemical analyses of the fog water tended to confirm this conclusion. The chloride content of the water averaged 70 parts per million and ranged from 8 to 480 parts per million. In fog water there appeared to be more sulfate ion in proportion to chloride than there was in sea water. This suggests the presence of some nuclei of industrial origin but does not prove that such products served as nuclei.

Hagemann [18] obtained drop-size distributions in fog in Germany using an adaptation of the oil-covered slide technique. He found that the most frequent size ranged from 9- to 34-μ diameter with an average of 15.6 μ. As pointed out earlier, the volume-median diameter is always greater than the most-frequent diameter, so that Hagemann's data do not differ greatly from those of Houghton and Radford [22]. Although data are not available it is to be expected that the drop size in urban fogs would be smaller than in fogs formed in relatively clean air.

Although more data on the drop-size distribution in clouds of the free atmosphere are badly needed, the information at hand is sufficient to give a good general idea of the end results of natural condensation processes. The most important conclusion is that most clouds of the free atmosphere, especially those associated with precipitation, have drop-size distributions broader than is explicable by a uniform lifting process at the condensation level. As already indicated, the most promising explanation for such a broad distribution is non-uniform rates of lift at the condensation level combined with later turbulent mixing.

THE ICE PHASE

Supercooled Water. The regular existence of supercooled water clouds in the atmosphere is now a matter of common knowledge. Water clouds are much more common than ice clouds at temperatures down to −10C and they have been observed down to −35C and possibly below. Dorsey [11] and others have shown that water in bulk may be supercooled from a few degrees to as much as 20 degrees. The temperature at which water freezes spontaneously is not known with certainty, but theoretical considerations suggest that it is in the neighborhood of −70C. Dorsey found that sealed samples of water had characteristic and reproducible freezing temperatures. The freezing temperature was found to be lower for the cleaner samples such as conductivity water than for natural water from ponds and puddles. Prolonged ageing, or heating to 97C, was found to lower the freezing temperature. Samples maintained a few degrees below their characteristic freezing temperature remained unfrozen indefinitely. Dorsey concluded that his results were best explained by the assumption that freezing is initiated by "motes" of submicroscopic size.

Rau [45] and Heverly [19] have investigated the freezing of supercooled water drops. Heverly reported that the freezing temperature was constant at −16C for drops larger than 400-μ diameter and decreased rapidly with the diameter for smaller drops with a suggestion of a minimum near −40C for very small drops. Rau repeatedly froze a group of 24 drops and found a distribution of freezing temperatures which was apparently independent of drop size. The first two or three freezings lowered the average freezing temperature which thereafter remained constant. Other unpublished investigations have yielded results similar to Rau's and it must be concluded that Heverly's findings were in some way influenced by the experi-

mental technique. Schaefer [46] has found that a supercooled fog may be converted to an ice-crystal fog by cooling a portion of it to −39C. Hollstein, quoted by Weickmann [55], studied the freezing of drops of sodium chloride solution of various concentrations. She found that the freezing point of the solution was equal to the freezing point of the water solvent minus the computed lowering of the freezing point due to the solute. There was some suggestion that the lowest possible freezing point of a sodium chloride solution lies in the neighborhood of −35C at which point the salt may act as a freezing nucleus.

Condensation and Sublimation Below 0C. The ice phase may appear in the atmosphere either by the freezing of the liquid or by the direct sublimation of the vapor to the solid phase. Wegener [54] first suggested that the atmosphere contained sublimation nuclei which would act in a fashion analogous to condensation nuclei to promote sublimation in the vicinity of ice saturation. Findeisen [13] expanded on this concept and based his precipitation theories, in part, on the existence of such nuclei. It was assumed that sublimation nuclei were small solid particles of a shape similar to an ice crystal. Sublimation should occur on a nucleus truly isomorphic with ice at ice-saturation.

The search for sublimation nuclei has been conducted by two experimental techniques. The first of these employs the expansion chamber and the second the dew-method in which the processes are observed on a chilled surface. Cwilong [7] used an expansion chamber of the Wilson-type which could be refrigerated. After the air was cleaned by repeated expansions, he found that a cloud of ice crystals was formed when the minimum temperature during the expansion fell below −41.2C. He felt that small ions were acting as sublimation nuclei below this temperature since the ice cloud formed at smaller expansions than those used to clean the air. In uncleaned outdoor air the transition temperature rose to −32.2C and to −27C when tobacco smoke was added. Cwilong also reported that at −70C there was a distinct change, in that a small shower of quite large grains of ice accompanied the cloud of crystalline dust. Fournier d'Albe [17] repeated and extended Cwilong's experiments with similar apparatus. He was unable to get the dense ice cloud in cleaned air below −41C reported by Cwilong but confirmed the latter's conclusion that only liquid drops are formed above this temperature. Fournier d'Albe also found that no ice crystals were formed until water-saturation was reached or exceeded. He concluded that the ice phase was attained via the liquid phase and suggested that the particles be called *freezing nuclei* rather than *sublimation nuclei*. He also investigated the action of several types of artificial nuclei, including silver iodide, which Vonnegut [53] had reported as causing the crystallization of supercooled clouds. Fournier d'Albe found that silver iodide nuclei caused ice crystals to appear at −7C, but only at water-saturation. Other artificial nuclei such as sodium chloride, sodium nitrate, caesium iodide, and cadmium iodide were found to have no effect on the water-ice transition temperature. It is to be noted that the latter two substances form crystals with lattice constants similar to ice. It was on this basis that Vonnegut selected silver iodide. On the other hand a water-drop cloud formed on cadmium iodide and then evaporated left nuclei on which ice formed at ice-saturation. This suggests that the nuclei of silver, caesium, and cadmium iodides used by Fournier d'Albe may not have been in crystalline form.

Findeisen and Schulz [16] used a much larger expansion chamber with a volume of 2 m^3, which was arranged to permit expansions at rates comparable to those in nature. Their results were similar to those of Cwilong and Fournier d'Albe in that the clouds formed by steady expansions were invariably water or mixed water-ice clouds even at a temperature of −40C. On some occasions when the expansion was interrupted just prior to the attainment of water-saturation, ice crystals were formed in the absence of a water cloud. At an expansion equivalent to a vertical velocity of 5 m sec^{-1} ice crystals were first observed at about −7C and their number increased with decreasing temperature. In the neighborhood of −35C a very large increase occurred. At more rapid expansions the first ice crystals appeared at lower temperatures but the sudden increase occurred at a temperature somewhat higher than −35C. All of these experiments were performed in uncleaned surface air. Very similar results were obtained by Palmer [44], who observed the formation of a few ice crystals at −22C and at a relative humidity of 97 per cent with respect to water. He also observed a rapid increase in ice crystals at −32C in natural surface air. In airplane flights, with a smaller expansion chamber, Palmer found the −32C nuclei only below the haze inversion; at higher altitudes the first crystals appeared at from −41C to −44C.

The most extensive investigations of condensation, freezing, and sublimation on a chilled surface have been made by Weickmann [55]. The advantages of this technique are that the individual particles may be viewed with a high-power microscope, that the temperature and rate of cooling may be controlled precisely, and that the supersaturation with respect to ice is known at all times. The disadvantage is that the condensation occurs on a surface rather than in the air. Weickmann showed rather conclusively that the effect of a properly cleaned surface was small. Weickmann worked mostly at or near −40C. He found that ice crystals formed only when water-saturation was approached. In one series of ten tests, using nuclei from a heated room, ice crystals formed at an average water relative humidity of 97 per cent, the range being from 93 to 104 per cent. Using the residue from evaporated drops as nuclei, a few crystals formed after 33 minutes at relative humidities of from 85 to 90 per cent with respect to water or from 120 to 130 per cent with respect to ice. At or above 100 per cent water relative humidity thousands of ice crystals formed at once. A few substances were found which favored the formation of ice at higher temperatures or lower ice-supersaturations, but in no case were crystals formed near ice-saturation.

No ice formed on soluble nuclei even at low temperatures; it appeared that solid nuclei were required.

Weickmann and others [55, 31, 32] also considered the problem from the theoretical side and showed that the structure of the ice crystal is so unique that it is extremely unlikely that any substances exist in the atmosphere which are truly isomorphic with ice. Weickman concluded that the atmospheric ice phase is formed by the freezing of the liquid on solid freezing nuclei. He felt that the freezing nuclei were often condensation nuclei with a microporous or fissured surface which promoted condensation. He conceded that sodium chloride nuclei might act as freezing nuclei at temperatures below −35C. Although he observed a few nuclei on which ice formed below water-saturation, he preferred to call all of the nuclei *freezing nuclei* rather than *sublimation nuclei.*

There are still many unanswered questions regarding the formation of ice crystals in the atmosphere, but some tentative conclusions can be formed. It seems clear that at all temperatures down to about −40C liquid condensate is more common than ice. Almost all investigators found a critical or transition temperature near −40C although mixed water-ice clouds have been reported both in the free atmosphere and in the laboratory down to at least −50C. The latter measurements may be in error and should be checked. It should not be concluded without further information that −40C is a spontaneous freezing temperature. Since all drops or crystals probably form on some type of nucleus this may be the temperature at which the small soluble condensation nuclei act as freezing nuclei. The computed spontaneous freezing temperature of −70C is based on physical constants, the values of which are not accurately known.

It is probably true that there are no atmospheric nuclei on which sublimation occurs at or below ice-saturation. It has been concluded from this that there are no true sublimation nuclei in the atmosphere except ice itself. On the other hand, ice crystals have been formed below water-saturation, although at considerable supersaturations with respect to ice. In the opinion of the writer it is not proper to require that a sublimation nucleus be active at ice-saturation. Many solid condensation nuclei do not become active until a considerable water-supersaturation is attained but they are still classed as condensation nuclei. Until more information is available it would seem preferable to call all nuclei on which ice forms below water-saturation *sublimation nuclei.* It is conceded that the deposition of the first few molecular layers on such a nucleus may not be in the form of ice, but little is known about this. There is certainly a clear physical difference between ice crystals formed in this way and those which are formed by the freezing of a liquid drop which has already attained cloud drop size. In the latter case it is evident that a freezing nucleus is involved.

On the basis of the definitions given above, it appears that a few sublimation nuclei which are active at temperatures as high as say −10C exist in the atmosphere. The failure to find these nuclei in the small expansion chambers may be attributed to their low concentration. Such low concentrations are adequate and even requisite for the release of precipitation by the ice-crystal mechanism. The evidence is that the large number of ice crystals found in surface air at −32C and in cleaned air at −41C are formed on freezing nuclei rather than on sublimation nuclei. There may also be freezing nuclei in the atmosphere which are active at much higher temperatures than −32C. In some cases these may be solid condensation nuclei, or they may be picked up by collision after the drops are formed.

PRECIPITATION PROCESSES

It has been realized for some time that precipitation elements cannot be formed by a continuation of the processes of cloudy condensation, but that other physical processes are necessary. In general, cloudy condensation leads to the formation of a high concentration of small particles. The precipitation process must convert this multitude of small particles into a smaller number of much larger elements. Since the mass of a raindrop of 1-mm diameter is one million times that of a cloud drop of 10-μ diameter, any proposed precipitation mechanism must be capable of causing the rapid combination of large numbers of cloud elements.

In a classic paper, Bergeron [4] reviewed the possible precipitation mechanisms and concluded that the only one of importance was the colloidal instability of a mixed water-ice cloud at temperatures below 0C. As is well known, the vapor pressure over water is greater than that over ice, at temperatures below freezing. The introduction of a few ice crystals into a supercooled water cloud will result in the relatively rapid growth of the ice crystals at the expense of the supercooled waterdrops. This idea was expanded and extended by others, particularly by Findeisen [13]. Various theories were offered to explain the appearance of the necessary ice crystals in the supercooled cloud. Findeisen's proposal of sublimation nuclei was once accepted as best explaining the observed phenomena but is now questioned for the reasons already discussed. The substitution of freezing nuclei would not alter Findeisen's theory in any important respect.

The ice-crystal theory of precipitation was widely accepted, since it seemed to be in accord with observational evidence. The proponents of the theory categorically stated that all moderate-to-heavy precipitation was initiated in this fashion and that, at most, only drizzle-type precipitation could fall from clouds which did not contain ice crystals. This conclusion was based largely on the observations that the precipitating clouds of middle latitudes extend above the freezing level and that much of the precipitation reaching the ground as rain is melted snow. The most common and apparently conclusive evidence is the glaciation of cumulonimbus prior to the release of precipitation.

It has now been established that many low-latitude clouds which release moderate to heavy precipitation are entirely below the freezing level. This shows that there is another mechanism for the release of precipitation but does not invalidate the ice-crystal theory of

precipitation for those clouds which extend above the freezing level. In the past the extension of a precipitating cloud above the freezing level has been taken as evidence for the operation of the ice-crystal process. In view of the existence of nonsupercooled precipitating clouds a more rigorous criterion must be adopted. It cannot be assumed that the ice-crystal process is operating unless it can be established that ice crystals and supercooled drops are coexistent.

The only other precipitation process worthy of serious consideration is the coalescence of drops in the gravitational field. If the drops are of nonuniform size, collisions will result because of their different terminal velocities of fall. The rate of growth by this process is dependent on the size and size distribution of the drops and on their concentration. Findeisen [14] studied this process in a cloud chamber and found that the resultant growth corresponded closely to what would be expected if each drop coalesced with all drops in its path. Findeisen's measurements were relatively crude and could not reveal the collection efficiency of one drop for slightly smaller drops. More recently, Langmuir [34] has computed the efficiency of collection of small drops by larger drops. The details of these computations are not presented in the reference but it is believed that the results are not completely reliable when the collecting and collected drops are of nearly the same size. In these computations it was assumed that the drops will coalesce if brought into physical contact; the collection efficiency is determined by the aerodynamic forces which tend to cause the smaller drops to follow the air streamlines around the larger drop.

An intelligent appraisal of the two precipitation processes outlined above must be predicated on a quantitative analysis. Unfortunately, few such analyses have been made, and indeed many of the requisite data are lacking. The ice-crystal theory involves a molecular diffusion process. An expression similar to equation (1), derived for the geometric shape of the ice crystal rather than of a sphere, is required to permit a quantitative discussion of this process. The solution of the diffusion equation for geometric forms approximating ice crystals has not been given. In an unpublished study, the writer has obtained a solution for a thin circular disc which might be a useful approximation to some ice-crystal forms. Under the rather severe limitations imposed by the lack of a suitable equation, only approximate results can be obtained. The time required for an ice crystal of mass equivalent to a sphere of 20-μ diameter to grow to an equivalent sphere diameter of 200 μ is of the order of 5 to 10 minutes. It was assumed that the vapor was saturated with respect to water at the optimum temperature of about -15C. To a fair degree of approximation the time required for the growth of the crystal increases with the square of the equivalent sphere diameter. Thus the time required for a crystal to grow to a mass equivalent to that of a raindrop of 1 mm diameter would be of the order of several hours. These numerical values are only approximate and are for the most favorable conditions of supersaturation with respect to ice. The ice-crystal effect is capable of producing crystals of mass comparable to drizzle elements in a few minutes but an excessive time is apparently required to form crystals of mass comparable to raindrops.

With the aid of Langmuir's computed collection efficiencies of drops by larger drops [34] it is a relatively straightforward task to compute the growth of drops by accretion in the gravitational field. Langmuir's paper is so recent that no such calculations have yet appeared in the literature. The writer has made a few preliminary calculations which will have to serve as the basis for the present discussion.[2] The problem was simplified by considering the growth of an initially somewhat larger drop falling through a homogeneous cloud. It will suffice to consider one example in which the diameter of the homogeneous cloud drops was assumed to be 20 μ, the liquid-water content 1 g m^{-3}, and the diameter of the larger drop 30 μ. The growth of the drop under these conditions is presented in Table IV. The relatively long

Table IV. Growth of a Drop of Initial Diameter 30 μ Falling through a Cloud of 20-μ Drops Containing 1 g m^{-3} Liquid Water

Drop diameter (μ)	Time (cumulative) (minutes)	Distance fallen (cumulative) (meters)
30	0	0
40	45	65
60	74	163
100	92	322
200	105	650
500	116	1475
1000	123	2675

time required for the drop to grow to 100 μ, compared with the time required for it to grow from 100 to 200 μ, is striking. The larger the falling drop is in relation to the smaller cloud drops, the more rapid the accretion process. Thus, this process is favored by a broad cloud drop-size distribution. The data in Table IV should be considered as examples and not as definitive numerical values. More refined computations, based on a typical drop-size distribution, should be made.

The two precipitation mechanisms can now be compared on the basis of the approximate numerical results presented above. The ice-crystal effect is more rapid than the collision process in the initial stages and is independent of the drop-size distribution. In the latter stages of growth the collision mechanism is more rapid than the ice-crystal effect, and may also initiate precipitation in clouds which do not contain ice crystals if the drop-size distribution is sufficiently broad. The two precipitation mechanisms taken together appear to be sufficient to explain the formation of precipitation. The writer's concept of the roles of the two processes is as follows: In all cases in which ice crystals are present, the ice-crystal process is dominant in the initiation of precipitation and in causing growth to an equivalent sphere diameter of the order of a few hun-

2. Subsequent to the preparation of this article the writer has extended these calculations. They will be found in "A Preliminary Quantitative Analysis of Precipitation Mechanisms," by H. G. Houghton, *J. Meteor.*, 7: 363–369 (1950).

dred microns. In the absence of ice crystals, the collision mechanism may initiate the precipitation process if the drop-size distribution is broad. Regardless of the process of initiation, the further growth of the precipitation elements is primarily by collision. This includes collisions of the precipitation elements with themselves as well as with cloud elements. In the case of snow, collisions between crystals are common, as is evidenced by even a casual examination of snowflakes. No process depending on the diffusion of water vapor seems to be capable of forming raindrops of 1-mm diameter and larger in the time available. Such precipitation elements must be formed by a collision mechanism. In middle latitudes, it is probable that the collisions are primarily between ice crystals, forming snowflakes which later melt into raindrops. In low latitudes, or in any situation in which a water-drop cloud of large vertical extent exists, once drops of, for example, 100-μ diameter appear, collision with the cloud drops is sufficient to explain the growth of the precipitation elements. More quantitative information on collision processes is badly needed, particularly on collisions between ice crystals and between cloud drops of nearly the same size.

The question naturally arises as to why all clouds do not ultimately release precipitation as a result of collisions between drops of unequal size. It is well known that many clouds produce precipitation which evaporates before reaching the ground, but this is not the complete answer. Langmuir's computations [34] show that for each drop size there is a minimum size of the larger drop below which no collisions will occur. For example, no drop of less than 45-μ diameter will collide with drops of 12-μ diameter. As the smaller drop diameter increases, the minimum diameter of the larger drop approaches that of the smaller drop. These results unfortunately lie in the region where the computations are least reliable. If correct, these results show that clouds composed of small drops are stable even when the drop-size distribution is broad. Diem's data [10] show that clouds such as fair-weather cumulus and stratocumulus contain smaller drops than clouds such as nimbostratus and heavy cumulus. Stratus also contains large drops but is not deep enough to yield more than drizzle. Houghton [20] and others have also suggested that a unipolar electric charge on the cloud drops might serve to inhibit collisions.

Snow. For the most part the discussion above has assumed the initial presence of a water-drop cloud. It may be that snow is often initiated in this way, but it is probable that snow also occurs in the absence of a water cloud. Also, a water cloud will not ordinarily exist for more than a short time in the presence of snow. It has been stated earlier that ice crystals do not form until saturation with respect to water is approached. Apparently few freezing or sublimation nuclei are active at temperatures above -10C, and lower temperatures are generally required. On the other hand, there is evidence that the top of a snow cloud may be warmer than -10C. This suggests that once snow is initiated, nuclei are produced which are active at higher temperatures. An important contribution to this problem was made by Findeisen [15], who found that the more delicate forms of crystals (stellar or dendritic) shed tiny splinters of ice as they fall. These splinters would serve as sublimation nuclei for new crystals at any temperature below freezing.

Approximate computations of the rate of growth of ice crystals suggest that the vapor pressure must be nearer saturation with respect to water than to ice if the observed sizes are to be attained. In this respect the process is quite different from condensation on liquid drops, where the vapor is only very slightly supersaturated with respect to the condensed phase. This difference is due to the much smaller number of ice crystals. The supersaturation increases as required to cause sublimation to proceed at the rate prescribed by the lifting, saturation with respect to water setting the upper limit.

Nakaya and collaborators in Japan [40, 41, 42] have made outstanding contributions to our knowledge of the formation of snow crystals. In one paper Nakaya and Terada [42] have presented useful data on the mass, physical dimensions, and velocity of fall of several types of natural snow crystals. In general, the maximum masses of the crystals are equivalent to a solid sphere of several hundred microns diameter while the velocities of fall are much smaller than those of solid spheres of equivalent mass. Nakaya and collaborators [40, 41] have succeeded in producing in the laboratory all of the types of crystals observed in nature. The two fundamental parameters determining the crystal type are temperature and degree of supersaturation. In general, the more compact crystal forms such as columns, prisms, and plates are formed at low supersaturations and the more open types such as needles and stellar or dendritic crystals are formed at the higher supersaturations. The dependence on temperature was not clearly established in the references, all of which were published before World War II. Dr. Nakaya was able to continue his researches during and after the war, but these results have been published only in Japanese. However, he has prepared all of his material in book form in English, and early publication is anticipated.

Weickmann [55] collected and photographed ice crystals in the free atmosphere. He summarized his observations as follows: In the lower troposphere, the nimbostratus region, there is slight ice supersaturation, the temperature ranges from 0 to -15C, and the crystals are in the form of thin plates and stars; in the middle troposphere or the altocumulus and altostratus region, there is moderate ice supersaturation, the temperature ranges from -15 to -30C, and the crystals are mainly thick plates and prisms; in the cirrus region or the upper troposphere, the temperature ranges from -30 to -60C, and the ice crystals are principally hollow prisms often combined as twins or clusters.

Size of Raindrops. All of the published data on raindrop size were obtained at the surface. A considerable number of such measurements have been published but it will suffice to refer to the rather recent measurements of Laws and Parsons [36]. They used the flour-pellet technique and found that the volume-median diameter

increased with rainfall intensity. For a rainfall rate of 0.05 in. hr^{-1} they give a volume-median diameter of 1.1 mm with a maximum diameter of 4 mm; for 0.5 in. hr^{-1} the volume-median diameter was 1.9 mm and the maximum diameter was 5.5 mm; for 4.0 in. hr^{-1} the volume-median diameter was 2.8 mm and the maximum diameter was 6.7 mm. The size and size distribution of raindrops can be expected to change from the cloud base to the ground because of evaporation, coalescence of drops, the variation of time of fall with drop size, and the fracture of large drops. For studies of the precipitation process it would be necessary to measure the raindrop size in and immediately below the cloud.

Hail. Hail is a special type of frozen precipitation associated with thunderstorms and characterized by extreme sizes much in excess of those of any other precipitation elements. A typical hailstone exhibits an onionlike structure when dissected, which has given rise to the belief that hailstones are formed by repeated excursions above and below the freezing level whereby successive layers of water are frozen onto it. A natural consequence of this theory was the inference that vertical velocities equalling the free-fall velocities of the hailstones exist in the atmosphere (over 100 mph in some cases).

It is now generally accepted that the major growth of the hailstone is by the collection of supercooled water as the stone falls relative to the cloud. In the earlier stages the stone may well travel in a very irregular fashion, up as well as down, but the largest hailstones can hardly be supported by updrafts. The growth of the hailstone is essentially the same as the accretion of ice on aircraft. The layer structure is due to inhomogeneities in the turbulent cloud. A similar layer structure is commonly observed in ice deposits on aircraft. Large hailstones are favored by high vertical velocities, a large vertical extent of the supercooled portion of the cloud, and high liquid-water content. Schumann [47] has shown that the extreme values of these parameters associated with cumulonimbus can lead to hailstones of the observed sizes. Hailstones large enough to damage aircraft have been reported in the clear air surrounding a thunderstorm, suggesting that stones for example, of one or two centimeters diameter may be discharged from the tops of thunderclouds. The terminal velocities of hailstones of 1 and 2 cm diameter are about 12 and 16 m sec^{-1} respectively. Extreme thunderstorm updrafts may readily exceed these velocities. Regardless of their direction of travel with respect to the earth, the hailstones are moving downward through the supercooled water drops at their terminal velocities. The thunderstorm updraft serves primarily to increase the length of the hailstone's path through the cloud and thereby to increase its collection of ice.

ARTIFICAL DISSIPATION OF FOG

Although fog hampers all types of transportation, its effects on air transportation are most serious. Much of the impetus for the development of methods for artificial dissipation of fog has come from aviation interests. Many unsuccessful attempts have been made to dissipate fog, failure being due in most cases to a lack of understanding of the problem. Some successful experiments were not followed up because it was believed that instrument-landing systems would make fog dissipation unnecessary. With the advent of World War II the problem became acute, and the British developed a thermal method now called "Fido." This system has been developed further, since the war, both in England and in the United States where an operational installation has recently been made at a commercial air field. In spite of continued advances in instrument-landing systems, most operators still feel that a cleared region for the final touchdown would greatly increase the safety of the landing. It seems evident that instrument-landing techniques will eventually be developed to the point where fog dissipation is completely unnecessary, but the writer would not care to speculate as to when this will come to pass.

In general, fog can be dispelled by the evaporation of the drops or by the physical removal of the drops from the air. Most of the methods for accomplishing this have been discussed critically by Houghton and Radford [23]. Those methods which were considered reasonably feasible were (1) the direct application of heat, (2) the use of hygroscopic materials to "dry" the air, and (3) the dropping of electrically-charged particles through the fog. The first method is exemplified by "Fido," in which heat is released by the burning of oil in long lines of burners on either side of the runway. The second method was used successfully by Houghton and Radford. The third method was experimented with by Warren, who dropped charged sand on clouds with occasional success.

There is now no doubt that fog can be dispelled by artificial means. Further experimentation with methods already proved practicable is desirable and there is still room for new ideas in both methods and equipment. The basic problem lies in the economics of fog dispersal. The mass of suspended water to be dealt with in even a relatively small volume is large, and it is inevitable that relatively large expenditures of energy will be required to remove it. As an example, the mass of water over an airport runway 6000 ft long and 300 ft wide to a height of 200 ft is about one to two tons, depending on the liquid-water content of the fog. In order to dissipate the fog by evaporation it is necessary both to supply the latent heat of vaporization and to lower the relative humidity of the air to cause the drops to evaporate rapidly. It is generally necessary to reduce the relative humidity to 90–95 per cent to meet the latter requirement. The heat energy required to evaporate the waterdrops and to reduce the relative humidity to 90 per cent in a fog at 10C, containing 0.1 g m^{-3} of liquid water, is about 559 cal m^{-3}. Of this amount, nearly 500 cal m^{-3} are required to reduce the relative humidity of the air.

If we use the figures above, a total of some 5.7×10^9 cal would be required to clear the fog in the volume assumed above. This rather impressive number of calories can be supplied by burning the modest amount of 250 gal of oil at a combustion efficiency of about 70

per cent. The computed energy requirement is for optimum conditions which cannot be realized in practice. Even a light wind steadily brings in more fog, so that the heating must be continuous. It is not practicable to apply the heat uniformly, and in practice much of the heat is wasted in raising the temperature of some of the air much higher than is necessary. The concentrated heat sources produce convection currents which may carry the heat to unwanted heights and suck in additional fog from the sides. For these reasons the practical energy requirements are many times the computed minimum. Working installations are designed to burn on the order of 100,000 gal of oil per hour.

Methods utilizing hygroscopic materials to dissipate fog are also evaporative processes and the basic energy requirements are the same as for the heating methods. Experiments reported by Houghton and Radford [23] indicate that operating systems require from five to ten times the theoretical minimum quantities of hygroscopic material.

Methods of physical removal of the fog drops, such as the charged-sand process, have smaller theoretical energy requirements than the evaporation methods. No basic energy requirement comparable to that given for the evaporative methods can be set and no experimental values are available.

The two evaporative methods which have been subjected to full-scale tests, namely the burning oil and hygroscopic material methods, are demonstrably capable of producing clearings of useful size. In both cases the costs of operation are relatively high and extensive installations are required. The use of hygroscopic materials involves the hazards of corrosion and damage to electrical equipment, although these may be nearly eliminated by proper design. The existence of large oil burners along the sides of the runway is a potential hazard which can also be minimized by proper design. Because of cost and other practical considerations only limited clearings are feasible, so that auxiliary instrumental methods must be available to guide the aircraft into the clearing. Neither method can deal with other conditions of poor visibility, such as dense snow, smoke, and dust. It must be concluded that fog dissipation by these methods is economically marginal and that installations are justifiable only in locations of extreme fog frequency or for urgent military purposes.

The fact that all proved methods of fog dissipation require much more energy than the theoretical minimum offers some hope that more efficient methods can be found. There is certainly room for further work on methods such as the electrified-sand technique where there is reason to believe that the energy requirements are more modest. The ever-recurrent hope that a method will be found which will clear large areas of fog with the expenditure of small amounts of energy is incompatible with physical reality.

CONCLUSIONS AND RECOMMENDATIONS

Our present understanding of the physics of condensation and precipitation is incomplete in many important areas. The writer has attempted to point out deficiencies in each phase of the subject during the detailed discussion. It is hoped that this will be of value to the reader, but it is felt that a more general appraisal of the situation is in order. In particular, an attempt will be made to present the writer's views as to the relative importance of those phases of the subject which need further study. This requires a decision as to the most important contribution to meteorology as a whole which can be expected from the study of cloud physics. The author feels that the complete explanation of precipitation should be the dominant aim of the cloud physicist. Of the elements forecast, precipitation is probably the most important to the majority of people. Further, the complete explanation of the precipitation process involves a knowledge of most of the topics in cloud physics. In making this decision the writer is acutely aware of the possibility that some new discovery will necessitate a refocusing of the entire cloud physics program.

Knowledge of condensation nuclei and of condensation in the liquid phase is incomplete in detail but is relatively satisfactory as compared to other parts of the field. The most important problem in this area is the investigation of the factors determining the breadth of the drop-size distribution. Knowledge of the ice phase in the atmosphere is inadequate. It is imperative that the nature and mode of action of freezing nuclei and sublimation nuclei be determined. This information is essential to an evaluation of and practical utilization of the ice-crystal theory of precipitation. It is equally imperative that a complete study be made of the growth of drops by collision in the gravitational field.

It is the writer's opinion that these problems should be attacked experimentally both in the laboratory and in the free atmosphere. The mechanisms of phase changes can be studied only in the laboratory, and the collision process is also a proper subject for laboratory investigation. However, the most complete laboratory study will not tell us what is happening in the atmosphere. It is therefore essential that flight measurements be made to determine which precipitation process operates under various conditions and to obtain a quantitative verification of the operation of the assumed processes. No adequate instrumentation is available for flight observations, and instrument development is therefore an essential part of the program. Flight measurements are extremely costly and time-consuming and should not be embarked on without careful planning and adequate instrumentation.

NUCLEI OF ATMOSPHERIC CONDENSATION*

By CHRISTIAN JUNGE

Meteorological Institute for Northwestern Germany

The Condensation Effect of the Nuclei

According to Wall [38], the condensation effect of a nucleus can be compared to that of a droplet of pure water on which, because of the surface curvature, condensation will take place only when there is a definite amount of supersaturation (Thomson's equation). The following distinctions between different types of nuclei can then be made:

1. Particles insoluble in water and *unwettable*. These may serve, as tests have shown [20], as nuclei of condensation. They require (when spherical) a larger amount of supersaturation than do droplets of pure water. Their importance for the natural aerosol is slight.

2. Particles insoluble in water, but *wettable*. According to the existing humidity and to their degree of wettability, these particles are surrounded by one or more molecular layers [40] of adsorbed water. They begin to condense at, or somewhat below, the value given by Thomson's equation. If these particles are of irregular or flaky structure, condensation begins before saturation, either in cavities (as capillary condensation) or in porous nuclear substances (as absorption of water).

3. Droplets of solutions. These form an important group of nuclei. Owing to the dissolved substance, the degree of supersaturation necessary for condensation falls to as low a value as ⅓ of that indicated by Thomson's formula [25].

Between particles of types 2 and 3 there are many intermediate types, because, as a result of coagulation, many nuclei will contain both soluble and insoluble matter (mixed nuclei). Figure 1 shows the relationship between the radius of the nuclei and the amount of supersaturation necessary for condensation to occur. It is evident that, in the presence of condensation nuclei, the range of supersaturation necessary for the formation of clouds extends from 0 to about 20 per cent.

The processes of condensation on nuclei at temperatures below 0C, which have recently been the object of thorough research, will be mentioned only briefly here, because they represent a transition into the field of cloud physics [27]. Weickmann [41] found that the nuclei act fundamentally as condensation nuclei for the *liquid* phase even at temperatures below freezing, that is, only at saturation with respect to *water* does condensation take place in the form of droplets, some of which may subsequently freeze. Sublimation nuclei, in the sense of Bergeron-Findeisen, which may form ice particles already at supersaturation with respect to ice, seem to exist only in negligible quantities, if at all.

According to Lafargue [22], the droplets initially formed freeze at about −41C in the size range between 1 μ and 20 μ, rather independently of the presence of dissolved substances. Heverly [13] found that this spontaneous freezing point rises to −16C for drops of 0.4 mm diameter and then remains constant for drops up to about one mm diameter, likewise largely independently of the source of the water. However, according to Weickmann, the presence of certain solid particles, so-called freezing nuclei, appears to modify these processes by raising the freezing point. This modification depends on the size and nature of the freezing nuclei.

Size, Number of Nuclei, and Methods of Measurement

If we disregard the small ions (radius $r \approx 10^{-7}$ cm), which are not of interest here, the size range of condensation nuclei extends approximately from $r = 4 \times 10^{-7}$ to 10^{-4} cm (Fig. 1). Although all types of particles may be active as condensation nuclei in a nuclei counter (see next paragraph and [20]), only those nuclei which require the lowest degree of supersaturation (*i.e.*, haze droplets and large nuclei droplets) are active in the actual atmosphere. It is within this group of particles —recently re-examined by Dessens [8, 9] and Woodcock and Gifford [43]—that we find the real meteorological condensation nuclei. By what method, now, can we measure these particles which range in size over three orders of magnitude?

All nuclei, whether hygroscopic or even unwettable, with radii ranging from about 4×10^{-7} to 2×10^{-5} cm, are counted in *nuclei counters*, so called after Aitken [3, 23]. The lower limit of this range is determined by the ratio of expansion; however, it appears that the values of supersaturation computed from this ratio are substantially too high [17]. The upper limit—which is highly uncertain—can be established with a certain degree of probability by assuming that larger nuclei droplets grow so rapidly in the saturated air of the counting chamber that they are probably precipitated before the actual measurement (Fig. 3). This seems to be corroborated by the photographs of condensation nuclei taken with an electron microscope, as described by Linke [26]. For these photographs, the nuclei were precipitated on an object screen by condensation in the nuclei counter and show an upper limit at $r = 10^{-5}$ cm, which corresponds to droplets of solution of $r \approx 2 \times 10^{-5}$ cm (Fig. 1). However, the aerosol, which was taken from a room, undoubtedly contained larger particles. It is possible that these limits are subject to variations when different types of counters, or even different instruments of the same type are used; this would explain the discrepancies recently found by Israël and Krestan [17] when they made comparative measurements with different nuclei counters.

While the nuclei counter gives only the number of nuclei, the method developed mainly by Israël [18]

* Translated from the original German.

permits the measurement of the size distribution of these particles. However, such an "ion spectrum" is not equivalent to the "nuclei spectrum," because:

1. The proportion of nuclei with an electrical charge depends upon their size.

2. Ions have multiple charges when the number of nuclei is small and their size large (see pp. 187 f.).

It is therefore not permissible to infer the number of particles from the number of electrical unit charges. Figure 1 gives examples of such ion spectra with the terminology introduced by Israël. The influence of a counter is correctly computed from the expansion [17]. Observations of the fall velocity of the nuclei [23] as well as of the optical properties of haze [35, 46, 48] establish only mean nuclei sizes. Photographs taken with the electron microscope appear to be most promising. Here, however, it must be considered that during the exposure all the water and, to some extent, also the solid substances evaporate because of the high vacuum in the microscope and the heat generated by the electron beam. For this reason, the residues that are photographed represent only minimal sizes.

10. Predominant sizes of the dust particles in winter (W) and summer (S) [33].
11. Size of haze droplets (H) and dust particles (D) of preferential optical effectiveness, according to Siedentopf [35].
12. Supersaturation values necessary for the condensation on pure water droplets (above) and droplets of solutions (below) in per cent relative humidity.

large city is clearly shown by the high content of large ions. The upper limit of resolution of the ion spectra is at $r \approx 10^{-5}$ cm.

There have been other attempts to determine the size distribution of nuclei. For example, by measuring the supersaturation necessary for condensation [19], it is possible to infer the "size spectrum of the nuclei" from the "supersaturation spectrum," under the assumption that, as with droplets of solution, there is an unequivocal relationship between nuclei size and supersaturation and that the supersaturation in the nuclei

The range of particles up to about $r = 2 \times 10^{-5}$ cm may be designated here as *Aitken-nuclei*. For the time being there is no method available for determining the proportion of nuclei droplets and solid nuclei in this size range. However, from the growth of these particles with increasing humidity (see pp. 184 f.) we may infer that there is a preponderance of nuclei droplets.

For reports on the results of nuclei counts we may refer to the excellent monographs by Landsberg [23] and Burckhardt and Flohn [3]. The nuclei concentrations vary within a wide range; absence of nuclei, how-

ever, has seldom been found. Tables I and II may serve as a guide.

The large nuclei (those with radii greater than about 1 to 2 $\times$ 10^{-5} cm) are above the resolution limits of the optical microscope. In this category only solid particles have been measured so far, in the well-known dust counters of Owens and Zeiss. It was only recently that Dessens, and Woodcock and Gifford succeeded in observing the haze droplets, thus closing a gap in our methods of observation. Dessens [9] moved fine spider threads through the air, thus capturing the haze droplets quantitatively. It is uncertain whether or not solid particles can be collected in this way. Woodcock and Gifford [43] deposited haze droplets on small glass plates and showed that over the ocean practically all these droplets consist of *NaCl*-solutions. Dust and haze-droplet counters enable us to determine both the total number of suspensions and their size distribution (Fig. 1).

Table I. Horizontal Distribution of Aitken-Nuclei [23]

Location	Number of		Nuclei per cc				
	localities	observations	Average	Mean maximum	Mean minimum	Absolute maximum	Absolute minimum
Large city	28	2500	147,000	379,000	49,100	4,000,000	3,500
Town	15	4700	34,300	114,000	5,900	400,000	620
Open country	25	3500	9,500	66,500	1,050	336,000	180
Ocean	21	600	940	4,680	840	39,800	2

Table II. Mean Vertical Distribution of Aitken-Nuclei (Data from 28 Balloon Ascensions [23])

Altitude (km)	0–0.5	0.5–1	1–2	2–3	3–4	4–5	5
Nuclei per cc	22,300	11,000	2,500	780	340	170	80

The dust concentrations show—particularly in industrial areas—a close correlation with the Aitken-nuclei concentrations [44], which is not surprising since both types of particle often have the same source. The concentration of the dust particles and haze droplets over land amounts to about 10–200 cm^{-3}, that of the haze droplets over the ocean to about 1–10 cm^{-3} [43].

From the foregoing discussion we can conclude that it is not yet possible to measure the nuclei spectrum in its entirety; so far there is only the substitute of counting nuclei, ions, dust, and haze droplets simultaneously.

Form and Physical State of Nuclei

Photographs of Aitken-nuclei taken on the stage of an electron microscope show irregular clusters of molecules interspersed with a few hexagonal crystal outlines [26] that can be attributed to hexagonal or cubic crystals. Soot, for example, consists of loosely connected platelets; cigarette smoke, of small crystals [41]. It is likely, however, that these are essentially the boiled-down residues of nuclei droplets.

Previous examinations of samples collected with dust counters have revealed a similar picture. These samples showed, in addition to various crystalline shapes (*e.g.*, cubic forms) and some organic substances, a preponderance of irregular particles. However, according to recent investigations by the author, these dust particles, when deposited on suitable surfaces, consist to a considerable extent of droplets. This is to be expected from Dessens' observations. The proportion of droplets varies greatly and increases with humidity. Many of these droplets contain both soluble and insoluble substances. It is conceivable that the Aitken-nuclei have a similar composition, since the mixed nuclei among them constitute an even larger portion owing to the greater coagulation, and all intermediate types between pure water droplets and solid particles covered with a hygroscopic film probably exist.

Important clues to the physical state of nuclei may be deduced from the study of their growth with increasing humidity. Figure 2 shows a few typical results

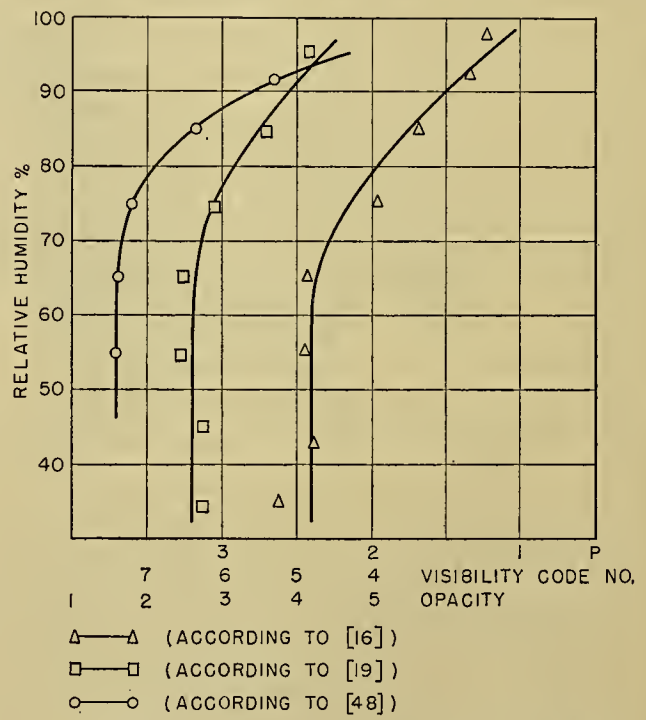

Fig. 2.—Effect of the growth of nuclei with increasing relative humidity on the opacity (circles), on the visibility (squares), and on the ratio $P = \frac{\text{total number of nuclei}}{\text{total number of large ions}}$ (triangles).

of observations of various quantities related to natural aerosols. The dependence of visibility on relative humidity (see pp. 187 f.) reflects primarily the growth of the large nuclei ($r > 10^{-5}$ cm) with humidity, whereas the dependence of P on humidity (see pp. 187 f.) chiefly illustrates the growth of nuclei in the size range below $r = 10^{-5}$ cm. A few isolated, direct size measurements lead to the same conclusions (Fig. 3, curve 1). From these results we see that as a general rule, the

growth of the nuclei, regardless of their size and origin, starts only after a relative humidity of approximately 70 per cent has been attained, and that this growth accelerates as the humidity approaches saturation value.

The interpretation of this principle of growth is not devoid of difficulties. A comparison of the curves of growth of different-sized solution droplets, computed in the usual way [25], shows reasonably good agreement above a relative humidity of 70 per cent. Wright [48] attributes the deviation at humidities below this value to the crystallization of *NaCl* which he believes to be predominant. However, Simpson [37] and Wall [39] correctly point out that in the case of crystallization the size of the droplets (Fig. 3, curve 8*a*) is bound to decrease in a discontinuous manner until all the water is evaporated. Dessens [8] has been able to observe this process directly; he noted that the solution droplets may show a supersaturation which is greater the smaller the droplets, and that the ensuing violent condensation sometimes results even in a shattering of the crystal. The renewed dissolution of these crystals will then take place at higher degrees of humidity. There is, however, no evidence for such abrupt size changes of the nuclei at intermediate humidities.

On the other hand, there is a fairly close approximation to the observations with mixed nuclei, that is, droplets of solution with a more or less large content of insoluble substances. Figure 3 gives a few computed curves of growth with hatched markings indicating the radii of the solid portions of the nuclei. Below a relative humidity of 70 per cent, the solid nucleus is covered by only a thin solution film, with the radius remaining almost constant.

Wall [40] pointed out that insoluble but wettable surfaces may adsorb multimolecular layers of water at relatively high humidities, a process that may become significant considering the original smallness of the nuclei. An example of such a growth of a solid particle having $r = 10^{-6}$ cm and the surface properties of glass, is given by curve 3 in Fig. 3. Comparison with the solution droplets of curve 2 shows that growth by adsorption becomes decisive for sizes below that value. Evidently at these dimensions the borderline between solution and adsorption becomes confused [39]. This is in accord with the observation [19] that insoluble but flaky nuclei require a higher degree of humidity for their first condensation than for their second; thus they seem to disintegrate at the first condensation, and the finely divided substance goes, so to speak, "into solution."

As yet, no attention has been paid to the influence of

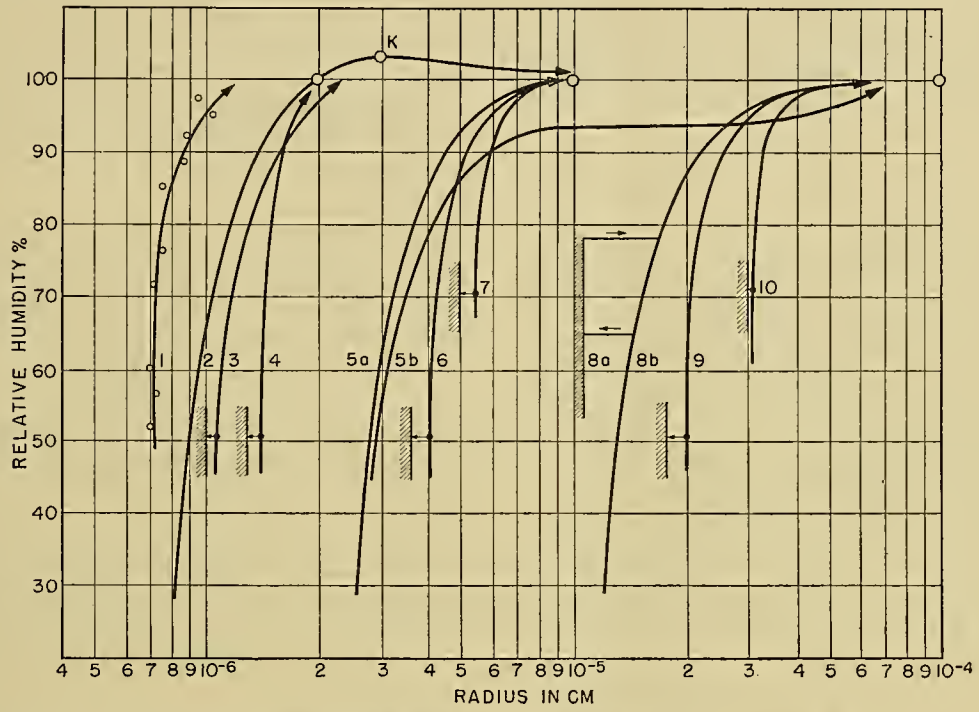

FIG. 3.—Curves relating the growth of various nuclei to humidity.

1. Measured values of the growth of newly formed gas-flame ions [19].
2, 5*a*, 8*b*. Calculated curves of the growth of pure droplets of solutions whose radii at 100 per cent relative humidity have values of 2×10^{-6}, 10^{-5}, and 10^{-4} cm, respectively.
3. Growth by adsorption of a solid nucleus with the surface properties of glass and $r = 10^{-6}$ cm [40].
4, 6, 7, 9 and 10. Curves for the growth of mixed nuclei whose radii at 100 per cent relative humidity are successively 2×10^{-6}, 10^{-5}, and 10^{-4} cm and whose solid portions have the radii indicated by the hatched lines.
5*b*. Modification of the growth curve 5*a* in the presence of 250×10^{-6} g m^{-3} of *HCl* and a nuclear count of 10^4 cm^{-3}. *HCl* was chosen, since we have precise physical-chemical data for it.
8*a*. Crystallization (with decreasing humidity) and solution (with increasing humidity) of a *NaCl* nucleus (schematic).

stable compounds, such as HCl, HNO_3, and H_2SO_4, on the growth of nuclei. In the presence of traces of such compounds there is equilibrium between the phase dissolved in the nuclei and the gaseous phase. If gases, such as SO_2 and NH_3, that form less stable solutions are involved, the dissolved part is minute (because of the smallness of the nuclei) so that practically everything goes into the gaseous phase. With increasing humidity a point will be reached (depending on the quantity and type of the substance) at which there is a sudden growth of nuclei. This growth will continue until the vapor pressure of the gas traces decreases perceptibly (Fig. 3, curve 5*b*). This process is likely to be of importance in the formation of dry fogs in industrial areas.

Formation of Nuclei in Smoke and During Gas Reactions

The formation of nuclei in smoke is engendered by the growth of the smallest molecular particles by sublimation, and by condensation of matter having a very high boiling point. Because of the high original nuclei concentrations, these particles continue to grow by coagulation, causing the formation of mixed nuclei. Among the important examples of this type of nuclei are soot particles and the tarry and hygroscopic particles present in most combustion effluents.

Gas reactions are likewise significant as a source of nuclei. Often they may become effective only at a great distance from the point where the gas traces originate, after mixing with other gas traces or through photochemical processes. According to Rothmund [32], nuclei are always produced if the products of such reactions are water-soluble and if the humidity of the air is sufficiently high. During the most varied reactions, he noted the formation of haze droplets of $r \approx 5 \times 10^{-5}$ cm. Details of the formation mechanism of these nuclei, particularly with reference to the significance of humidity, as well as the establishment of an equilibrium between the gaseous participants in the reaction and the reaction product (nuclei number, size), are not yet known.

The concept of such equilibriums between the gaseous phase and the "nuclei phase" permits these two conclusions:

1. Many traces of matter will be found in the gaseous phase and also as condensation nuclei. This is corroborated by the fact that in many instances the amount of matter appears to be too high to be explained by plausible numbers and sizes of nuclei. For example, Cauer [5] was unable to establish a relationship between the concentration of Aitken-nuclei and traces of matter (NH_4^+, NO_2^-, SO_4^{--}, and Cl^--contents). It must be pointed out, however, that *quantitatively* the *large* nuclei, that is, the haze droplets and dust particles, may (in spite of their small number) prevail over the Aitken-nuclei, so that a more exact statement will have to wait until the entire nuclei spectrum is known.

2. The change in external conditions (*e.g.*, in the humidity or the concentration of the gaseous phase) may cause the number of nuclei to change; the nuclei concentration in a given mass of air would thus not represent a constant quantity. It is, for example, not unlikely that nuclei whose substances are only faintly volatile (such as oils and tars as well as the acids HNO_3, H_2SO_4, and HCl) slowly evaporate if mixed with pure air. In areas which are far removed from human settlements and industry (*e.g.*, mountains, oceans), one may not expect to find aerosols other than those consisting of solutions of nonvolatile salts or solid matter. In this connection mention should be made of an observation by Schlarb [34], according to which pressure changes in a climatic chamber between ½ and 1½ atmospheres were found to result in a fluctuation of the number of nuclei in a proportion of about 1:50!

In the following paragraphs a few meteorologically important gas reactions will be mentioned briefly [4, 23, 29, 32].

Ozone, O_3, while not in itself nucleogenic, enters into reaction with many other traces of matter, such as nitric oxides or SO_2, thereby producing nuclei [31]; H_2O_2, which, however, according to Cauer [4], is found only close to flames, shows a similar behavior.

Oxides of nitrogen, NO and NO_2, originate simultaneously with O_3 during electric discharges (thunderstorms) and as a result of the ultraviolet solar radiation [29], as well as in all incandescent processes and in flames, according to Coste and Wright [7]. These oxides are very effective in creating nuclei.

Sulfur dioxide, SO_2, which develops in all combustion processes, forms nuclei in combination with O_3 or, according to Aitken [2], through photochemical processes in combination with gas traces (formation of dry fogs *after* sunrise). These nuclei are probably composed of H_2SO_3 and H_2SO_4.

Chlorine ions, Cl^-, according to Cauer [6], escape from the surface of the sea as well as from droplets of ocean spray, and form HCl-nuclei photochemically. This explains why a separate determination of the magnesium and chlorine contents of the air gives mass proportions which are entirely different from those found in sea water. Part of the chlorine content exists in the form of salts.

Ammonium ions, NH_4^+, result from all processes of combustion and from the decomposition of organic substances and, when reacting with the acids mentioned above, lead to the formation of nuclei.

Iodine, I_2, is dispersed into the air along the Atlantic Coast of Europe mainly by industrial charring of seaweed for the extraction of iodine [4].

Some typical values, indicated by Cauer [4], will stress the significance of these traces (values are in 10^{-6} g m^{-3}).

Ozone:	Tatra 30, Jungfraujoch 10;
Nitrite:	Tatra and Silesia 0.2;
Sulfite:	Berlin 200, Silesia occasionally 3, Tatra, faint traces, but very rarely;
Chloride:	Brittany 7, on the sea near Kiel 149, Silesia 32, Tatra 70;
Ammonia:	Silesia 17, Brittany 21;
Iodine:	Average for Central Europe before November 1, 1933, 0.6; thereafter 0.05 (be-

cause of the crisis in the iodine industries).

Mechanical Sources of Nuclei

In contrast to the particles treated in the foregoing section, which grow from molecular dimensions, the dust particles and the droplets of sea spray are produced by mechanical separation. Simpson [36] points out that, according to Gibbs, the limit of these separations is of the order of $r = 5 \times 10^{-6}$ cm as a result of the action of cohesion- and surface-forces; usually, however, the particles are found to be substantially greater. Thus Köhler [21] found in his spray experiments with sea water that the greatest number of droplets had dimensions ranging between $r = 1.5$ and 3.5×10^{-5} cm, that is, the same size as the haze droplets obtained by Dessens.

As a result of the thorough investigations by Woodcock and Gifford [43] it appears certain that over the ocean the large nuclei largely consist of sea water sprayed by storms and surf and are transported by austausch to great heights in maritime air masses. The chloride content of hoarfrost and precipitation [47], the observed cubic crystals sublimated from haze droplets over the continent [1, 8], and the observation by Cauer [4, 6] of considerable traces of *Mg* and *Cl* ions during influx of maritime air masses into the Tatra mountains lead to the conclusion that, far into the continents, the haze droplets among the large nuclei represent a more or less significant portion of maritime aerosol. Although it is certain that these nuclei are often numerically insignificant as compared to the nuclei concentrations over densely populated continents, they nevertheless play a role in the analysis of traces of substances because of their size.

It is still uncertain to what extent the Aitken-nuclei over the oceans consist also of seawater spray [11, 37, 46, 47, 48]; it is certain only that the oceans are not very productive sources of nuclei in point of numbers [3, 23] (Table I), so that the numerical proportion of *NaCl*-Aitken-nuclei is probably small over land.

One important source of nuclei is the particles that, together with dust, are raised by storms over land. Substantial amounts of matter can thus be carried considerable distances, as is indicated by the Sahara-dust falls occasionally observed in Europe [12].

In conclusion of the discussion on the sources of atmospheric nuclei, the estimates of the relative contributions by various sources to the total nuclei content of the air, first given by Lettau [24], may be reproduced. If the total production of the nuclei is set to equal unity, the proportions indicated below are obtained, attributable as follows:

Steppe and forest fires	0.4
Detachment from the soil surface	0.3
Combustion products from man-made fires	0.2
Volcanic activity	0.1
Detachment from the sea surface and from extra-terrestrial sources	negligible amounts

The indicated values can be taken only as very rough approximations.

Electrostatic Charges of Nuclei

The electrical state of an aerosol is conveniently characterized by the ratio

$$P = \frac{\text{total number of nuclei}}{\text{sum of positive and negative ions}}.$$

The combination of small ions and *uncharged* nuclei, which is, among other things, considered as proportional to the surface area of the nuclei, is increased in the case of *charged* nuclei as a result of the attraction of the electric charges which is independent of the size of the nuclei. It follows that a greater percentage of the larger nuclei must be charged. Wright [45] derived the values

Table III. Relationship between P and the Size of Nuclei (*after Wright* [45])

Radius of nucleus (cm $\times 10^{-6}$)	0.0	1.0	2.0	4.0	6.0	∞
P	∞	10.0	3.3	2.0	1.7	1.5

given in Table III. The quantity P can be measured by the following two methods:

1. Through the determination of the total nuclei count and the nuclei count after the elimination of the large ions (both found with a nuclei counter).

2. Through the determination of the total nuclei count and of the number of elementary charges (with an ion counter).

From the difference of the two measurements [14, 15], we obtain the number of multiple charges on the nuclei

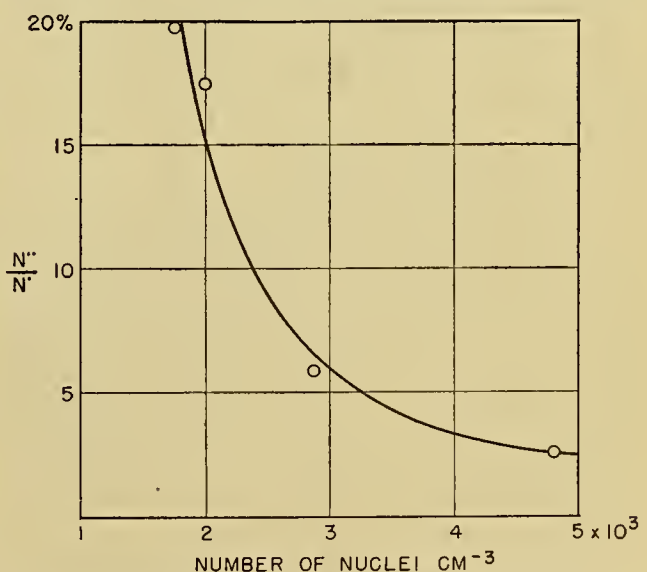

Fig. 4.—Percentage of doubly charged ions as a function of the number of nuclei [14, 15].

(Fig. 4). With nuclei counts below 5000 cm^{-3} a considerable proportion of nuclei are doubly charged.

From extensive observations by Israël [16] and others the following relationships involving P are obtained:

1. There is an increase of P with increasing nuclei count, varying locally; this increase becomes more pro-

nounced when the second method is used because of the multiple charges on the nuclei. Thus in a larger nuclei count, a smaller fraction of the nuclei are charged, because only a limited number of small ions are available. As yet, there has been no quantitative explanation of this.

2. There is a decrease of P with increasing humidity (Fig. 2). The nuclei, whose growth with humidity has a marked influence on P, have, according to Table III, radii of less than about 6×10^{-6} cm. Thus the behavior of P reflects the growth of particles of this size.

The quantity P gives us a good example of how careful we must be when we want to interpret statistically determined relationships between the properties of natural aerosols and meteorological quantities. If, for example, we arrange measurements of the nuclei concentrations and P values according to visibility, as Israël did in Frankfort, we obtain an increase in P values and a decrease of nuclei count with an increase of visibility. According to the relationship (1) described above we would have expected a decrease in P. However, it is probable that, on the average, with increasing visibility, both the number and size of the nuclei decrease, and the size appears, according to Table III, to have a dominant influence on P.

Israël further points out that individual measurements of P show considerable fluctuations which are especially large in the vicinity of cities, that is, of the sources of nuclei [16]. He attributes this phenomenon to the slow establishment of the ionization equilibrium.

From the preceding survey it is apparent that the study of the ionization equilibrium permits us to reach important conclusions concerning the aerosol. However, this possibility will be most fully realized only when we can take into account in the investigations the influence on P of the size distribution in the nuclei spectrum.

The Optical Effects of Nuclei

Primarily effective for the scattering of light, and consequently the turbidity of the atmosphere, are the particles of the order of magnitude of the wave lengths of light or larger, that is, those with radii of approximately $r \geqslant 4 \times 10^{-5}$ cm. If the radius of the particle decreases, the optical effects diminish very rapidly. Thus, according to our method of notation, only the large nuclei, and not the Aitken-nuclei, are significant for the turbidity, unless the Aitken-nuclei are particularly numerous, or the atmosphere is extremely clear.

Wright [46] used these facts in order to reach conclusions concerning the composition of the aerosol, through extensive investigation of the visibility conditions at some English stations. He found that there were approximately 1000 table-salt nuclei with a radius of 2×10^{-5} cm in a cubic centimeter. This nuclei concentration varies relatively little with time and location and constitutes the maritime portion of the aerosol. Over land we have additional solid particles (such as soot) which can be detected with a dust counter. These can become so numerous, especially during wintertime and in densely populated areas, that their optical effects are dominant. The many small nuclei of combustion (Aitken–nuclei) have hardly any effect on visibility.

Dessens [8] found good proof for these conclusions. He measured the attenuation coefficients for various wave lengths and also calculated them from the simultaneous determinations of the size distribution of the haze droplets, according to the formulas of Stratton and Houghton. The agreement between observed and computed values is good and at the same time shows that his method of measurement yields a quantitatively correct sample of the haze droplets.

Recently, and independently, Siedentopf [35] and others have deduced the optical effects of the aerosol from Mie's theory on a much more inclusive and exact basis. Siedentopf bases his calculations on an atmosphere in which the visibility is 20 km, and attempts to find the composition of the aerosol which would correspond most closely to the dependence of the absorption on the wave length, as well as to the scattering function (dependence of the scattered light on the angle of the incident ray). With pure dust aerosols (completely opaque, index of refraction $n = \infty$) or with pure droplet aerosols ($n = 4/3$), no agreement could be reached. This was possible only with "mixed aerosol," composed of particles of both types in the proportion of 20 dust particles per cubic centimeter to 500 haze droplets per cubic centimeter, with an average radius from 2 to 3×10^{-5} cm. The addition of several thousand Aitken–nuclei with $r = 5 \times 10^{-6}$ cm has no effect on the results. These findings are in good agreement with the results of both Dessens and Wright, a fact which seems to indicate that these haze droplets, found far inland, are essentially of maritime origin.

It is therefore clear why previous investigations yielded no definite relationship between the Aitken–nuclei count and visibility (according to [23]). The situation is different, however, for dust particles, as was shown by Rötschke [33].

The effect on visibility of the growth of haze droplets with humidity has already been discussed. Wright [46, 47] has established a similar relationship between humidity and visibility when the optical effect of the dust particles predominated. This can be explained by postulating either a considerable accumulation of such particles during very humid weather conditions or a coagulative effect of humidity.

Processes of Nuclei Destruction

Aside from condensation itself, the following processes essentially diminish the number of nuclei:

1. Sedimentation.
2. Diffusion (adhesion to surfaces of all kinds).
3. Coagulation.

In all these processes, the mobility of the particles plays a role. The mobility of particles that are smaller than, or comparable to, the length of the mean free path of the air molecules (approximately 10^{-5} cm), is

$$B = \frac{1 + Al/r}{6\pi\eta r},$$

where B = mobility (sec g^{-1}),
l = free path length (cm),
r = radius of particle (cm),
A = numerical factor of 0.9,
η = viscosity of air (g cm^{-1} sec^{-1}).
The viscosity η is practically independent of the atmospheric pressure, so that with decreasing pressure, B increases with l.

1. The fall velocity of the particles is

$$V = BMg,$$

where M = mass of the particles (g),
g = gravitational acceleration (cm sec^{-2}).
Despite the small fall velocity, the sedimentation process that takes place continuously and everywhere in the immediate vicinity of the earth's surface is probably important for the nuclei balance [24]. The same holds true for the charged particles settling in the electric field of the earth.

2. The diffusion coefficient that is valid for the adhesion of particles to surfaces of all kinds is

$$D = \frac{RT}{N} \cdot B,$$

where R = gas constant (erg deg^{-1} mol^{-1}),
T = absolute temperature (deg),
N = Loschmidt number.
The diffusion coefficient D greatly increases with decreasing radius of the particle and has been used for the determination of the average particle size [28]. In contrast to sedimentation, adhesion affects especially the small particles. In closed spaces or vessels, the influence o diffusion increases with increasing ratio of surface to volume [30].

Diffusion is effectual in forests and grassland with their very large surface areas (filter effect) and in the clouds, in which the decreased nuclei concentration [23] is probably caused not so much by consumption during condensation as by adhesion to the droplets. For this reason, analyses of traces of substances in hoarfrost and other condensation products in combination with measurements of droplet number and size do not permit any conclusions regarding the mass of the individual nuclei.

3. As regards coagulation, reference is made to the exemplary investigations of Whytlaw-Gray and Patterson [42]. The decrease in the number of particles n per unit time and volume in homogeneous aerosols is

$$\frac{dn}{dt} = -\frac{8\pi RT}{N} Brn^2 = -\frac{4RT}{3\eta N}\left(1 + A\frac{l}{r}\right) n^2,$$

that is, the small particles coagulate more rapidly. The numerical results given in Table IV clearly show that coagulation is much more effective for the originally very small combustion nuclei that are highly concentrated in city air, etc., than for the coarser and less concentrated dust and ocean spray aerosols. Mixed nuclei are, therefore, to be expected especially from industrial and similar nuclei sources. The laws of coagulation, experimentally confirmed by Whytlaw-Gray, become more complicated in natural aerosols because of the broad distribution of sizes and occasional electrostatic charges. For example, if two particle sizes are present, the greater coagulation rate of the smaller nuclei is further increased by adhesion to the larger nuclei. Therefore, aged aerosols contain only a small percentage of small nuclei.

Table IV. The Decrease in the Number of Particles per Hour in Homogeneous Aerosols

Nuclei number (cm^{-3})	Radius (cm)		
	10^{-6}	10^{-5}	10^{-4}
10^3	6.86×10^0	1.66×10^{-1}	1.13×10^{-1}
10^4	6.86×10^2	1.66×10^1	1.13×10^1
10^5	6.86×10^4	1.66×10^3	1.13×10^3

Since the large particles grow more rapidly with increased humidity than do the small ones, a slight increase in coagulation rate with humidity is to be expected. This was confirmed by Landsberg [23] who found a decrease in the number of nuclei in rooms when the humidity was increased. Effenberger [10] also found by simultaneous nuclei and dust counts in the open air that, with increasing humidity, the nuclei concentration decreases while the dust content increases. However, in this case it must be noted that there is a possible selective effect of the synoptic situation. Moreover, the sedimentation rate in the dust counters is greater with higher humidity because of the growth of the dust particles.

Concluding Remarks

Because of lack of space it has been impossible to include a compilation of the results of the many works dealing with nuclei counts. However, such a compilation is not really necessary, since the reader can refer to exhaustive monographs [3, 23], and no new information has been obtained on the subject. In the various sections we have touched upon those relationships, determined by such investigations, of the nuclei count, etc., to other meteorological elements that were of interest from the point of view of the physics of nuclei. In many cases these relationships have only a limited value in explaining physical processes, since the correlations generally overlap. For this reason, it has been suggested by various investigators that stress should be put on additional laboratory research work. A number of open questions touched upon in the sections above could thereby be clarified.

In conclusion some of the areas of study that seem especially important to the author are summarized:

1. The growth of nuclei, especially at humidities of less than 70 per cent, and the associated problem concerning the physical structure of nuclei (mixed nuclei, supersaturation of solution, and crystallization).

2. The chemical composition of the aerosol. Parallel measurements of the traces of substances and of the number of nuclei, dust particles, and haze droplets

should be made. The proportion of traces of gaseous materials should be determined.

3. The performance of haze-droplet counts on a larger basis to determine the contribution of maritime aerosol (sea-salt nuclei).

4. The behavior of substances of low volatility, and the influence of equilibrium and humidity in gas reactions on the concentration and size of nuclei.

5. Effect of humidity on coagulation.

However, the success of pertinent research projects is contingent upon the development of a new method for the measurement of the entire spectrum of nuclei. At the present time this measurement is possible only approximately through simultaneous counts of the nuclei, ions, dust particles, and haze droplets. We should, however, investigate exactly how the individual ranges of measurement overlap. Here, the electron microscope probably offers new possibilities.

THE PHYSICS OF ICE CLOUDS AND MIXED CLOUDS

By F. H. LUDLAM

Imperial College of Science and Technology and Meteorological Office, London

THE APPEARANCE OF ICE CLOUDS

It has long been recognised that clouds of ice particles have a characteristically fibrous appearance very different from that of droplet clouds, which look "solid" and have more sharply defined edges, even when dissipating. Small, isolated trails of snow or soft hail, known as *Fallstreifen* (fall-streaks) or *virga*, which fall from medium-level clouds, also possess this fibrous structure, and when they become separated from their parent clouds and are seen in a favourable light exactly resemble forms of true cirrus. A fibrous structure on a coarser scale can also be seen in rain beneath shower clouds.

It is therefore natural to interpret the fibrous appearance as the result of the high falling-speed of unusually large particles falling in trails from small condensation-regions, and to consider typical isolated cirrus clouds as a form of precipitation. Wegener [21] regarded cirrus uncinus as *Fallstreifen*, and attributed their development to the absence of efficient ice nuclei, those available acting only at a high supersaturation so that the ice particles then formed grow quickly and acquire a large falling-speed. There have been other attempts to explain the form of these clouds, but careful observation supports the *Fallstreifen* theory, and in recent years investigations concerning the properties of ice-particle nuclei have completely explained why ice clouds so often contain much larger particles than droplet clouds, and have led to a better understanding of the processes attending the formation and decay of both pure *ice-clouds* and *mixed clouds* (containing both ice and liquid water).

THE BEHAVIOUR OF ICE NUCLEI

For some time it has been thought that the nuclei effective in producing ice crystals are probably solid, water-insoluble particles, distinct from the hygroscopic nuclei which readily allow the formation of droplets. Wegener [21] and Findeisen [5] suggested that quartz dusts, carried up from the ground, might be the atmospheric ice nuclei. The prevalence of clouds of liquid water at temperatures down to about −10C was ascribed to the inefficiency of the ice nuclei or to their absence. The nuclei were called *sublimation nuclei*, and it was generally believed that the ice crystals were formed by the direct transition of water vapour into the solid state.

This conception has been altered by recent researches. The first important contributions to the subject were by Krastanow [10, 11], who outlined the theory of condensation according to the principles of statistical physics, and showed that the direct deposition of vapour into ice upon such solid nuclei as occur in the atmosphere is to be expected very rarely and only at temperatures approaching −70C.[1] He suggested that ice particles are usually produced secondarily by the thermodynamically easier path through the freezing of droplets containing these nuclei, and claimed that such infected droplets exist because condensation can also proceed upon solid, insoluble (but "wettable") particles as well as upon hygroscopic nuclei. Accordingly, it appeared that crystals usually arise as a result of the freezing of supercooled drops (and perhaps also by the freezing of the microscopic film of adsorbed water which grows on solid "wettable" particles at vapour pressures approaching the saturated vapour pressure over liquid water, followed by direct condensation from the vapour). For any such particle there are successively lower ranges of temperature in which it may act as a nucleus for a supercooled drop, for a supercooled drop which freezes, and for an ice crystal formed by direct condensation. Krastanow was concerned primarily with estimating these ranges, but his work contained the important implication that atmospheric crystal nuclei would become active only at approximate saturation over liquid water—formerly it was believed that they would allow direct condensation at small ice-supersaturations. At the temperatures of the cirrus levels, however, water-saturation corresponds to relative humidities of 150 per cent or more over ice.

Some support for this view was provided by the expansion-chamber experiments of Regener [16] in which droplet fogs were formed at temperatures down to at least −50C, crystals also appearing when high expansion ratios were used. Weickmann [22], observing the condensation products upon nuclei supported on a metal face chilled to about −40C, gave a complete confirmation, finding that no crystals could be produced at low ice-supersaturations, that a few formed under prolonged high ice-supersaturations, and that relatively abundant formation occurred in the neighbourhood of water-saturation. He also showed that particles of the common minerals (including quartz) are not especially active as ice nuclei, but concluded that atmospheric ice nuclei are small insoluble solids about 1 μ or less in size, which, from their mode of action, he calls *freezing nuclei*.

It is interesting that by careful search particles have now been found which appear to act as true sublimation nuclei (allowing the formation of ice crystals direct from the vapour at temperatures below −10C and at

1. A more detailed account of these references and some subsequent ones has already been given by the present writer [12].

small ice-supersaturations). Fournier d'Albe [9] produced these particles by evaporating crystals which had been grown at −41C in the presence of solution droplets of cadmium iodide. It seems likely that the particles remaining consisted of cadmium iodide bearing microfilms of water which retained an icelike structure such as cannot be imposed upon films adsorbed from the vapour, even by cooling to temperatures in the neighbourhood of −70C. This suggests that the only sublimation nuclei are in fact particles of ice, and raises the possibility that after the evaporation of ice clouds at low temperatures some freezing nuclei may be left in a condition which enables them to act as sublimation nuclei in a future cloud formation. However, nuclei having the efficiency of those made by Fournier d'Albe cannot be expected to occur naturally in the atmosphere, where even the poor ice nuclei available are greatly outnumbered by nuclei capable of aiding the formation of liquid droplets. This scarcity of ice nuclei, which may be even more marked in the high troposphere than near the ground, is an important factor which in association with the speed of atmospheric condensation processes results in the frequent appearance of droplets during cloud formation at temperatures down to −50C or even lower. If the humidity is increased very slowly some ice particles will form some time before water-saturation is reached; their subsequent growth may then remove enough vapour to prevent a further increase in humidity, or the process responsible for the rise of humidity may cease. In this way very thin pure ice clouds may arise without any droplet formation. Their occurrence must be very infrequent in view of the great scarcity of ice nuclei which act before water-saturation is almost reached, and the slowness and duration of the condensation mechanism which would be necessary, but the structureless veils of cirro-nebula and the "diamond-dust" ice-mists probably are such clouds.

Evidently, in experiments designed to discover the critical temperatures at which droplet formation is entirely replaced by crystal formation in the presence of foreign nuclei, particular attention must be paid to the speed of the condensation process. It is clear that the violent expansions commonly used in cloud chambers may produce predominantly droplet clouds at temperatures down to −40C and even lower, and it is also clear why different workers, using various rates of expansion, have found different values for the critical temperatures.

The expansion-chamber experiments which most faithfully reproduced natural conditions are those of Findeisen and Schulz [8], who used an unusually large chamber (volume 2 m^3) to increase the sensitivity to the rare but still meteorologically important ice nuclei, and who controlled the rate of expansion to values corresponding to vigorous atmospheric convection processes. Their apparatus was not portable, and so only the surface air (at Prague) was examined for ice nuclei. The number of such nuclei in this polluted air may have been much larger than is usual in the air of the upper troposphere, but even so in the chamber-clouds the droplets still outnumbered the crystals at temperatures around −40C. Down to this temperature the clouds formed in the chamber by uninterrupted expansions were initially pure water-clouds or mixed clouds, but some pure ice-clouds were produced with great difficulty by ceasing the expansion just before droplet-formation was expected. The numbers of nuclei active at various temperatures composed an ice-nucleus "spectrum," which changed somewhat from day to day and with the rate of expansion, but which possessed the general form shown in Fig. 1. With another apparatus, in which the speed of the condensation process was much less, Schulz [17] has recorded results which do not differ materially from those given in this figure. As the temperature falls below about −32C there is a sudden great increase in the number of active nuclei, which Findeisen and Schulz consider due to the introduction of a second class of nuclei. These appear to be the nuclei responsible for the first appearance of crystals (in droplet fogs) in the smaller chamber used by Fournier d'Albe [9], and which are now referred to as the *32-nuclei*. Findeisen and Schulz apparently did not continue their experiments to temperatures below −40C, and so did not find a second critical temperature of about −41C below which Fournier d'Albe observed relatively dense ice-fogs in which the presence of any droplets could not certainly be established. Fournier d'Albe, however, was able to confirm that these ice fogs formed only when the air was cooled near to, if not below, the dew point (at saturation with respect to liquid water). The reason for this critical temperature of −41C and the part it plays in more moderate expansions remain unknown. More detailed examination may show this critical temperature to be no more sharply defined than the threshold temperature at which the 32-nuclei become active.

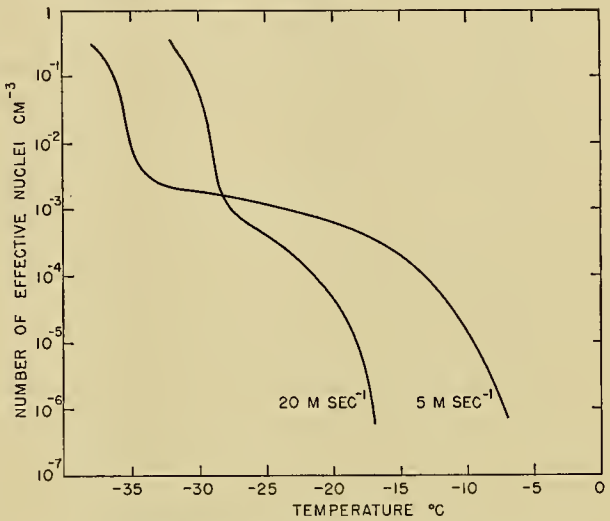

FIG. 1.—Average ice-nucleus "spectrum" for samples of surface air at Prague, showing the numbers of nuclei active at various temperatures during the expansion of the air at rates corresponding to vertical speeds in the atmosphere of 5 m sec^{-1} and 20 m sec^{-1}. (*After Findeisen and Schulz.*)

Very little is known about the number of ice nuclei occurring in the upper troposphere. Palmer [14] has

used an expansion chamber in an aircraft on four occasions and found that the 32-nuclei were absent (or very scarce) above the lowest inversion or haze-top. This suggests that these nuclei at least are derived from the earth's surface, and that at the cirrus levels the ice-nuclei count is likely to be far smaller than that observed at the surface by Findeisen and Schulz [8]. It is therefore to be expected that, in the atmosphere, clouds formed by the more vigorous ascending motions will initially contain liquid water even at very low temperatures, and indeed this has been observed in several ways. For example, R.A.F. aircraft have reported serious icing at temperatures down to below −40C [13], Weickmann [24] has photographed droplets (with crystals) at −50C over the Alps in the lenticular Moazagotl cloud, and aircraft wing-icing has been observed at −58C in a condensation trail formed at the airscrew [1]. The limit of supercooling, at which crystals grow spontaneously in liquid water without the aid of foreign nuclei, is not known. It has been roughly estimated theoretically at about −70C or below, and Rau [15] appeared to have found it experimentally at −72C, but Cwilong [4] has since thrown doubt on this result. It would certainly seem that at all temperatures likely to occur in the troposphere ice crystals always require special nuclei for their formation, and that these nuclei are always actively available at low enough temperatures, since stable supercooled clouds have apparently not been observed at temperatures below about −35C [24] and are rarely observed at temperatures below about −15C.

Before leaving the discussion of nuclei it may be said that further information is needed on the behaviour of hygroscopic nuclei at low temperatures, both when they are pure and when they are contaminated by freezing nuclei. Wall [20] has considered the matter theoretically, and some experiments on the freezing of droplets of common-salt solution are described by Weickmann [24]. From these latter experiments it appears that salt crystals can act as ice nuclei at temperatures below about −30C, but in spite of the decreasing solubility of salt with falling temperature it is unlikely that solid salt crystals can occur at high humidities unless they arise in contaminated solution-nuclei. It also seems that freezing nuclei may have their efficiency considerably reduced in the presence of a concentrated salt solution, so that such nuclei might begin to act only when the solution becomes sufficiently diluted by condensation. Mason, at the Imperial College of Science and Technology (in work unpublished), has attributed the critical temperature of −41C mentioned above to the freezing of solution droplets in which the ions formed by the dissociation of the electrolyte act as nuclei.

Meteorologically, the most important features of the recent studies on ice nuclei are the recognition of the rarity of ice nuclei and the establishment of the fact that ordinarily they allow the formation of ice crystals only near water-saturation, and therefore in the presence of high ice-supersaturations. Present problems concerning ice nuclei may be divided into two classes.

1. Problems related to individual nuclei: What is the mechanism of nucleation? and, What are the properties which determine the efficiency of an ice nucleus? Such questions may be answered by examining the behaviour of small numbers of artificial nuclei, or perhaps even a single nucleus, under humidities increased at carefully controlled rates. Dew-plate techniques are likely to be more convenient than those using expansion chambers, in which the control of temperature and humidity is very difficult, but investigations must first be made to determine whether the presence of a supporting surface interferes with the behaviour of the nuclei. If it can be established that certain unwettable surfaces are sufficiently indifferent, this method could readily be used to examine the efficiency of particular nuclei when they are covered by films of adsorbed vapour, and when they are immersed in droplets of both pure water and salt solutions. It should be possible to determine whether solutions of salts or of gases (*e.g.*, NO, SO_2, and NH_3) are in any circumstances able to act as ice nuclei when not contaminated with insoluble solid particles.

2. Problems of a more meteorological nature: What are the effective ice nuclei in the atmosphere? and, What are their numbers at different levels in various air masses? To observe the numbers of ice nuclei occurring naturally a very sensitive counter is required, capable of indicating ice-nucleus concentrations as low as 1 m^{-3}. The high-pressure expansion apparatus described by Schulz [17] was designed (but never used) as a portable nucleus counter; in this apparatus the air was first compressed to a pressure of about twelve atmospheres so that, on controlled expansion to about one atmosphere, low temperatures could be reached without the necessity of a preliminary cooling of the expansion chamber, while the concentration of ice nuclei was not reduced below that occurring in the atmosphere. However, elaborate precautions are needed to prevent the introduction of artificial nuclei during the compression process, and it is to be hoped that some much simpler counting apparatus may be practicable.

THE DEVELOPMENT OF THE ICE PHASE IN NATURAL CLOUDS

Cumulus and Cumulonimbus. Cumulus clouds are composed of air which has risen from near the ground, and conditions within them are likely to resemble closely those produced in the expansion chamber of Findeisen and Schulz [8]. Accordingly, ice-crystal formation does not begin in these clouds until the temperature has fallen several degrees below 0C, depending to some extent on the rate of ascent of air into the cloud base (see Fig. 1). Since the crystals are in a considerable supersaturation they grow more rapidly than the droplets and after a period of perhaps a few minutes reach a size and falling-speed such that growth by coagulation with droplets in their path begins to exceed that due to the condensation of vapour. Rough calculations show that this stage is reached when the ice particles have reached diameters of about 100 μ and falling-speeds of about $\frac{1}{4}$ m sec^{-1} and when (relative to the surrounding air) they will have fallen rather less than 30 m. Beyond this stage growth by coagulation rapidly accelerates,

both the volume swept by a particle and its rate of fall quickly increasing, and the particle becomes a precipitation element. However, it is important to note that it takes an appreciable time for the growth to reach the critical stage: if the cloud begins to dissolve in the meantime the ice particles will not develop into precipitation elements, but will disappear with the droplets. Observation shows that the summits of cumulus clouds are constantly and rapidly replaced from below, fresh cloud masses rising only to diverge, sink, and evaporate, so that the life of each particle near the cloud tops is very brief. It can therefore readily be imagined that cumulus, rising some distance above the level at which the ice nuclei first act in significant numbers, have summits containing ice crystals which fail to reach the critical size which would enable them to sink into the bulk of the cloud and continue their growth, thus eventually becoming hail or rain. The magnitude of this effect is difficult to estimate, but it is likely to be most marked in clouds of low liquid-water content, in which the rate of growth of the ice particles is least. In general the liquid-water content of cumulus varies directly with the temperature of the cloud base. This may account for the failure of cold-weather cumulus, with summit temperatures as low as −20C, to produce showers. Such clouds may be wholly below the temperature at which the ice nuclei first act, and yet show no external trace of the presence of ice particles. Valuable data for this problem could easily be obtained by observing the base- and summit-level temperatures of convection clouds (noting those clouds which produce precipitation) and by attempting to detect the presence of small ice particles during flight through the supercooled tops of cumulus.

When the critical stage is passed and the ice particles have begun their growth as precipitation elements, the cumulus becomes transformed into the cumulonimbus. If the cloud ceases to grow soon after the critical stage is reached, the total number of ice particles formed remains very small, and slowly dissipating patches of water cloud may persist for a time near the summits, all the ice particles having fallen out. Usually, however, the top of the cumulonimbus becomes an ice cloud of considerable density, and it seems that the number of crystals finally formed must be substantially increased by a mechanism which Findeisen has begun to investigate [6, 7]. During the growth or evaporation of an ice particle, air flowing past it carries away minute charged fragments of ice (radius about 20 μ). These ice "splinters" are produced only by particles which are aggregates of small crystals, and are not formed at the surfaces of simple crystals or at glassy layers of ice. Little is known about the manner in which these splinters and their electrical charges arise, but Findeisen regards this process as the predominant source of thunderstorm electricity, and it must be of great importance in all ice clouds and mixed clouds as a means of ice-crystal reproduction without the aid of special ice nuclei. According to Findeisen's experiments [7], the rate of formation of ice splinters during the direct condensation of vapour into ice amounts to about 5 sec^{-1} from an ice surface of area 50 cm^2. At temperatures down to about −30C the number of ice particles growing upon ice nuclei is not likely to exceed 10^3 m^{-3}. If one-tenth of these have reached a radius of 10^{-1} cm, after about twelve minutes they alone will have produced as many ice crystals by the splintering process as were formed on the ice nuclei. During the growth of ice particles by coagulation with supercooled droplets, however, the rate of splinter formation is increased perhaps a thousand fold, and it therefore becomes clear that this process is of dominating importance in the ice-nucleus economy of all mixed clouds. The large numbers of crystals of insignificant falling-speed, and therefore of small size, which compose the extensive anvils of mature cumulonimbus are probably almost all produced without the aid of special nuclei. The splinter formation may be essential to the development of cumulonimbus over the oceans in polar air masses whose content of ice nuclei is likely to be extremely small.

Here it may be remarked that as yet little attempt has been made to work out in detail the growth conditions of cumuliform clouds and the modifications introduced by the appearance of the ice phase and the development of precipitation. Again it will be necessary to consider the speed of the condensation and coagulation processes. The rate of ascent of air in vigorous cumulus is of the order of 10 to 20 m sec^{-1}, greatly in excess of the speeds assumed by recent writers (*e.g.* Austin [2]), who have developed the concept of entrainment of air from the environment into the rising currents. The present writer doubts whether this materially affects the growth of large clouds, and believes that the simple parcel method of representing convection may still prove the most useful, but that it needs modification in the light of important factors which have been ignored so far, such as (1) the short life of individual clouds and the effect of their continual dissipation on the condition of the environment, (2) the effect of evaporation and mixing at the edges of small clouds, and (3) the effect of the rate of heating at the bottom of the convective layer. It is doubtful, in view of the predominant condensation of liquid water in rapidly ascending air, whether the latent heat of fusion plays any part in the development of cumulonimbus. The writer has shown (in work not yet published) that in dense clouds the larger ice particles pick up supercooled water at a rate which prevents its complete freezing, so that the precipitation elements have wet surfaces and a temperature not much below 0C. A proportion of the latent heat of fusion is thus used in warming the precipitation and is lost to the cloud. On the other hand, the accumulation of precipitation elements in the upper part of the cloud leads to the mechanical destruction of the updraught, and with the release of the precipitation a powerful downcurrent is initiated [3]. There is therefore reason to believe that in aerological work the development of cumulonimbus may best be followed on thermodynamic diagrams constructed wholly with respect to liquid water. Such diagrams are also appropriate in considering the formation of high ice-clouds, but it is advisable also to include lines showing the saturation

mixing-ratios over ice when the subsequent growth of these clouds is to be examined.

Medium- and High-Level Clouds. Medium- and high-level clouds are formed in air which has not recently been near the ground and in which the ice nuclei are likely to be especially rare. Nevertheless it appears that the number of active nuclei always increases as the temperature falls. In general, apparently stable supercooled clouds are encountered at temperatures between 0C and about −10C. At somewhat lower temperatures supercooled clouds commonly survive the appearance of ice particles, which quickly grow and fall out as *Fallstreifen*, while at temperatures below about −30C droplet clouds become increasingly rare. Usually they appear only fleetingly before becoming rapidly transformed into pure ice-clouds.

Clouds of the altocumulus type are often very shallow and have very small liquid-water contents, and since the air in the cloudlets is constantly replaced, any ice crystals present will grow slowly and may for some time produce no effect which would reveal their existence to an observer on the ground. However, the ice crystals will be slower to evaporate than the droplets, and it is conceivable that in a shallow layer of convective circulations they may be drawn back into cloudlets a number of times, increasing in size and number all the while (because of splinter formation). It may be in this way that parts of altocumulus sheets are transformed into thin ice clouds some time after their formation; the ice particles frequently fall out of the damp layer in which the cloud had formed and evaporate in the drier air beneath, so that the final effect of the action of the ice nuclei is the dissipation of the cloud. This is the typical result of the introduction of crystal nuclei into shallow, slightly supercooled clouds. On some occasions altocumulus appear to become infected with ice particles over a very limited area, a hole developing in the cloud layer over a patch of *Fallstreifen* [18]. This may be due to the irregular distribution of the ice nuclei, or may be the result of splinter formation following the action of a very few ice nuclei in a particularly large cloudlet with lower summit-temperatures than are reached in the other cloudlets. It is common for some cloudlets of a high altocumulus to produce *Fallstreifen*, and it is characteristically the larger cloudlets which are so affected, not only because of the lower summit-temperatures at which more ice nuclei act, but also because in the larger cloudlets the growth of ice particles is favoured by the higher water content, the greater depth of cloud, and the stronger upcurrent, which prevents early precipitation.

While falling through the ice-supersaturated layer beneath the base of the parent cloud, *Fallstreifen* particles continue their growth. In general, the depth of this layer and the degree of supersaturation in its upper part increase with fall of temperature. High, delicate altocumulus clouds may disappear in producing faint short trails of ice particles, which then continue to grow while descending some thousands of feet, finally becoming dense ice clouds.

Clearly no fundamental distinction need be made between ice clouds originating in this way and cirrus forming from a condensation region at lower temperatures with no trace at all of a parent cloud containing liquid water. At temperatures below about −40C the ice nuclei seem to be significantly more abundant; water droplets have a very short life and are produced only in clouds of convective or lenticular type in which updraughts of the order of a few meters per second occur. Nevertheless, the number of ice particles found in cirrus clouds by Weickmann [24] was on the average only about $\frac{1}{6}$ cm^{-3} (droplet clouds usually contain several hundreds of droplets per cubic centimetre), and it is evident that the crystals are so few that most may reach a size at which they have an appreciable falling-speed (about $\frac{1}{2}$ m sec^{-1}). Weickmann [23] photographed the particles of high clouds and obtained striking evidence of the large size of cirrus particles, which typically consisted of radiating tufts of long prisms containing hollows and air-enclosures. This crystal form is an indication of rapid growth at high supersaturation, although the cause of the grouping into tufts is unknown. The crystals of cirrostratus were smaller and had simpler "complete" shapes. For this reason cirrostratus clouds produce halos much more readily than cirrus, in which halo details are rather rare.

In the initial stages of their formation cirrus clouds are not typically fibrous. Frequently the first details to appear have a patterned or granulated structure resembling that of cirrocumulus, which slowly coarsens and fuses while thin *Fallstreifen* develop, or they may contain waves and ripples. With steep lapse rates, shreds of clouds very much like fractocumulus occur; these sometimes develop into true cumuliform clouds several thousands of feet deep, but more often they spread out and become less dense, gradually becoming transformed into patches of *Fallstreifen*. Bright, iridescent colours may be seen in such newly formed clouds when they are very near the sun, and there seems no reason to doubt that initially they contain at least some water droplets. On the other hand, the typical *Fallstreifen* forms of cirrus, although they often occur with shreds of cloud near their summits which are not truly fibrous and look like the vestiges of a parent cloud, do not always develop from such shallow initial forms. It is likely that these clouds often arise when especially suitable ice nuclei just forestall a more general condensation, so that a very few crystals are able to reach an unusual size and falling-speed. Weickmann [24] has remarked on the extraordinarily small number of large particles (diameter up to about 400 μ) which are found in the trails of cirrus uncinus.

The shape of *Fallstreifen* trails is determined by the wind shear at their level and the falling-speed of their particles. At first the trails are usually almost vertical, but near their lower ends they become almost horizontal as the falling-speed of the evaporating particles dwindles and a decrease of wind causes them to lag more and more behind the condensation region. A simple hook-shape (uncinus) can thus arise with only a gradual wind-shear, but some cirrus trails indicate a very rapid

change of wind with height, suggesting that frontal surfaces at these heights may be more sharply defined than is usually supposed.

There is a noticeable tendency for the lowermost parts of *Fallstreifen*, even in the cirrus levels, to become mammillated, presumably owing to the chilling of the air in the trail by the evaporation of the ice particles. The *Fallstreifen* path probably marks a stream of descending air whose motion is initiated by the drag of the particles and is sustained by this chilling. The downdraughts in precipitation are very pronounced in cumulonimbus and they play an important part in the development of these clouds by spreading out near the ground and acting like scoops to help fresh cloud growth near the shower borders [3]. A similar process on a smaller scale, may occur near *Fallstreifen* trails and lead to lines of cloud arranged along the direction of the wind shear.

THE RELATION OF ICE CLOUDS TO CONDENSATION MECHANISMS

High-level clouds are produced by the large-scale lifting of air masses, especially at frontal surfaces, but it is unusual for the clouds to appear as uniform sheets. Thus the first clouds to appear ahead of a warm front are characteristically isolated cirrus containing uncinus forms, and the overcast of cirrostratus which follows often contains *Fallstreifen* or is of very irregular density. Schwerdtfeger [19] attempted to show that isolated cirrus are the result of cooling in the high troposphere with the production of a convective layer, whereas cirrostratus is produced by the lifting of stable air masses over frontal surfaces. It would be possible to examine this view more critically now that frequent upper-air soundings are available. Isolated cirrus clouds could arise in uniformly lifted air because of the irregular distribution of especially suitable ice nuclei or as the result of small disturbances in the general air flow. Waved or rippled detail and lenticular-like patches of cloud are often seen in cirrus systems, and it is likely that orographic disturbances frequently reach the cirrus levels and trigger the formation of clouds. Whereas lenticular clouds consisting largely of droplets remain stationary at the crests of standing waves, similar clouds containing many crystals could survive descent in the troughs and continue their growth in ice-supersaturated layers.

The growth of individual ice clouds in deep supersaturated layers may extend over a few hours before general decay sets in, and during this time the clouds may be carried hundreds of miles from their birthplace. The air may remain supersaturated and the growth be maintained even though the mechanism which lifted the air has ceased. Thus, the mere presence of ice clouds, whose decay is correspondingly protracted, by no means indicates an active condensation mechanism, and in this respect they differ from droplet clouds, which evaporate within a few minutes of the cessation of the condensation mechanism. *Only young ice clouds accompany active condensation mechanisms; they may always be recognised by the presence of cirrocumulus (droplet cloud) or patches of granular and flocciform cloudlets.* Beautifully arranged delicate *Fallstreifen* forms are also young ice clouds—as they age they degenerate into diffuse streaks or fibres of lifeless appearance, usually described as cirrus filosus.

As far as the writer knows, no methods of forecasting the extent and thickness of ice clouds are in use other than the making of estimates based on recent measurements or the relating of the clouds to frontal systems in accordance with textbook models. It is unlikely that much more can be done at present, as forecasting high cloud formation is essentially a matter of forecasting the vertical displacement of air at high levels, about which very little is known. More accurate measurements of humidity than are now made at these heights would probably also be required. A further difficulty is that abundant cirrus clouds often occur far from fronts and appear to have their origin in disturbances existing entirely above the surface layers. Thus cirrus systems may be seen to move with shallow cold "pools" and troughs which are clearly shown on 300-mb charts (but not on 500-mb charts). The occurrence of cirrus well ahead of cold fronts is also unexplained, but its presence seems related to the movement of the front, and its disappearance is symptomatic of the retardation of the front. However, there are few cirrus systems which are not highly organised, perhaps containing great parallel bands of cloud or long sharply defined clearing-edges and with *Fallstreifen* indicating systematically changing wind shears, so that it is certain that the mechanisms producing the systems have coherent structures which may be forecast once they are understood. It is unfortunate that the sharpness of the boundaries of cirrus systems is so often masked on synoptic charts by the reporting of clouds near the horizon which are at a great distance—these reports might profitably be made only by isolated stations.

CONCLUSION

It is hoped that many important problems of cloud physics will have been sufficiently indicated in the paragraphs above. It may be remarked that one class of problems concerns the microphysics of cloud particles, and another the macrophysics of the occurrence and growth of clouds, and that usually the two are very intimately related, especially at temperatures below 0C. Recently, substantial progress has been made with the microphysics, but careful attention must now also be directed to the study of the formation and growth of clouds in relation to air movements. Here valuable information may be expected from the researches on atmospheric dynamics which are being pursued so vigorously.

THERMODYNAMICS OF CLOUDS*

By FRITZ MÖLLER

Gutenberg University at Mainz

OBSERVATIONAL BASIS

The radiosonde epoch, in which—from an aerological point of view—we are now living, is not favorable to a thermodynamical examination of clouds. The great age for thermodynamics and aerology was about twenty or twenty-five years ago, when Shaw [37], Stüve [40], Robitzsch [31, 32], Rossby [33], and others after them [47] computed and used their thermodynamic diagrams to make a careful examination of each sounding of the free atmosphere. Today it is still customary to plot each ascent on such diagrams, but only in rare cases is there a thorough analysis of the stability, the available energy, etc. There are several reasons for this:

1. The observational data are incomparably more numerous. Where formerly one had five ascents a day, one now has one or two hundred. Therefore, each sounding cannot be studied with as much attention and care. The analysis is made for synoptic purposes in most cases and is therefore exclusively dynamic in character. In consequence of this:

2. The information which is transmitted is arranged to permit a quick, dynamic-synoptic representation, in other words, the drawing of isobaric surfaces. In the German weather service, thermodynamic measures of energy have been calculated and transmitted for every ascent for about ten years. These measures have not been adopted internationally, but their use would facilitate synoptic-thermodynamic investigations.

3. We have reason to assume that the instruments now in use, the radiosondes as well as the instruments designed for use with aircraft, do not represent the temperature distribution properly. Twenty years ago, Lautner [19] used sensitive resistance thermometers and found, in flying through a subsidence inversion, a discontinuous temperature increase upward, in other words, a really ideal inversion. It is very likely that most inversions have the same form, but that, because of the lag of the instruments, this can never be established. In the writer's opinion, an examination of the tropopause by a trained meteorological observer, who would test it with thermoelements or resistance thermometers, would yield many surprises.

4. The most important obstacle to the successful development of cloud physics is related to this problem of inadequate instrumentation: The radiosonde furnishes only an inflexible, unmodifiable cross section of the atmosphere; the observer in an airplane is much more efficacious for cloud investigations. He can supplement the vertical pressure, temperature, and humidity curves by what he sees: the form and character of the clouds, vertical stratification, horizontal extent, spatial density, changes in the course of time, etc. He can circle or penetrate an interesting cloud, taking along various special instruments or even an entire laboratory; this cannot be done with radiosondes except with tremendous difficulty. For this reason, airplane ascents and weather reconnaissance flights with meteorologically well-trained observers furnish invaluable observational material. Furthermore, such flights are of indirect value, because, in the process of observing, striking new problems always occur which are much harder to detect when one is merely working at one's desk. Observation flights will always be necessary for special problems; soundings alone will never suffice.

PREREQUISITES FOR THE IDEAL MOIST-ADIABATIC PROCESS

The basic problem around which the thermodynamic investigation of clouds must be centered is the moist-adiabatic process. This holds true for stratus as well as for cumulus clouds. Besides this macrophysical problem, there are microphysical processes whose effect is by no means restricted to invisibly small elements. This group of processes will be treated in a later section of this article. The classical theory of the moist-adiabatic process has recently been supplemented by various considerations which take into account the influence of the environment of the vertically moving particle. In this connection the slice method and the concept of lateral entrainment may be mentioned here. Further additions to the theory will be required in order to describe fully the basic process of the thermal reaction of a cloud. Nevertheless, the simpler method still furnishes some interesting viewpoints which are worthy of consideration.

The prerequisites for the ideal moist-adiabatic process are (1) the heat of condensation is exchanged so rapidly between condensing water vapor or evaporating water and the air that no temperature differences will develop; (2) there is no transfer of heat between the parcel and the environment; and (3) there is no transfer of mass, either water or air, between the parcel and the environment.

Heat Exchange between the Cloud Elements and the Air. Findeisen [10] has carried out a numerical investigation of the heat exchange between droplets and the air. He has come to the conclusion that under normal cloud conditions the temperature difference between the air and the droplets is not much greater than 0.2C. However, for clouds of low density, that is, those with a very small number of droplets or crystals per unit volume (as in the upper parts of altostratus or cirrus), the distances along which heat is transferred through diffusion or conduction are so large that temperature differences may reach several degrees. The vertical movement of the air can then proceed almost

* Translated from the original German.

dry-adiabatically, or the parcel may even be cooled by radiational heat loss (see below, also p. 203).

Heat Conduction in the Interior of the Cloud. Cloud elements can be heated either by conduction or by radiation. Conduction inside a cloud can be neglected entirely if the cloud has a homogeneous horizontal temperature distribution and a moist-adiabatic or at least a uniform lapse rate of temperature. It is known through the investigations of Peppler [27] that nimbostratus clouds frequently have a "laminated" structure, in other words, they are characterized by numerous small superimposed inversions and isothermal layers. If this observation holds true for a closed nimbostratus mass and not for the dissolving region to the rear of it (as seen from the ground these two conditions cannot be distinguished), then the turbulent heat conduction in the vertical can lead to deviations from the moist-adiabatic process in the interior of the cloud. However, no deviation from a smooth temperature distribution is to be expected in the interior of a cumulus cloud.

Evaporation and Heat Conduction in the Environment. The edge of the cloud is a mixing zone between the cloud itself and the environment, where, no doubt, there are considerable deviations from the ideal moist-adiabatic process as a result of the turbulent heat conduction across the horizontal and vertical cloud boundaries. Evaporation of the droplets into the neighboring dry air and the increased water-vapor content of the air lead to a loss of heat from the border zones of the cloud, which then become colder than the environment. This process can be of importance on the edges of cumulus clouds and on stratus cloud surfaces which lie under inversions. This fact was pointed out by von Bezold [4] and later by Robitzsch.

Radiation Processes. The heat transfer by radiation from and to the cloud is just as important as is heat conduction. In general, the clouds absorb only a small part of the sun's radiation. About 50 to 70 per cent of the incoming radiation is reflected from the upper cloud surfaces [14]; most of the remaining 30 to 50 per cent is transmitted and only a very small portion is absorbed. This absorption is unimportant in comparison with the other thermal processes. However, it is the only process which shows only a minor decrease from the edge to the interior of the cloud; although insignificant, the absorption is rather uniformly distributed throughout the entire cloud mass [1].

The long-wave radiation, however, acts in an entirely different way. The surface of a cloud can be considered as a black body for the wave-length region from 4 to 100 μ. Even very thin layers of water vapor and carbon dioxide in the surrounding air absorb almost totally at most of these wave lengths; however, between 8 and 13 μ, even very thick air layers with an abundance of water vapor and carbon dioxide have almost no absorption. Therefore, the clouds can produce strong surface emissions in this spectral range and lose much heat. On the undersurface of the cloud layer where the radiation of droplets is opposed by that of the usually warmer earth's surface acting as a black body, the clouds receive more heat than they radiate and therefore become heated. Numerical values for this process can be found in the article on long-wave radiation in this Compendium.[1] In any case, these processes do not penetrate very deeply into the cloud mass; they influence only a very thin surface layer, whose thickness can be estimated as about 10 m in the case of a cloud with high water content. Although these processes are characteristic of the surfaces of stratocumulus or cumulus clouds, the processes in thin altostratus or cirrus are entirely different. Here, the individual heat-radiating particles, the ice crystals or water droplets, are so far apart from each other that radiation exchange with the environment can take place even through thick cloud layers. The heat loss upward and the heat gain from below therefore take place rather uniformly in the entire mass of thin, veil-like clouds. Here, a clear-cut, moist-adiabatic process that can be defined thermodynamically is no longer possible, because the heat balance of the cloud is considerably influenced by radiation. In the lower layers of the troposphere, where the clouds have a relatively high water content, the rule holds true that the moist-adiabatic process is undisturbed by radiation into some distance from the cloud's edge. In the same way, other surface processes (such as evaporation and "outer" heat conduction on clouds) cannot have any effect within extensive cloud masses or in smaller clouds characterized by large vertical velocities. Thin and scattered clouds depart even further from the moist-adiabatic process. The effect of radiation upon various cloud types will be treated below.

Mixing Processes. It seems to be obvious that an air parcel which is lifted moist-adiabatically does not undergo any mixing with the surroundings, and one is easily inclined to take this for granted. However, there is no proof of this. In cumulus, the entire cloud mass is not uniformly lifted; the parcels in the upper portion of the cloud are retarded, whereas in the lower portion new masses move up and penetrate the higher layer. It is not at all certain in this process that the subsequent parcels from below move along the same moist-adiabatics. Probably, their equivalent potential temperature is higher, and the mixing of the masses disturbs the thermodynamics.

Furthermore, it must be considered that the requirement of the absence of mixing also concerns the liquid and the solid constituents of a cloud. In the normal pseudo-adiabatic process we assume that all liquid water drops out as soon as it is produced. This, however, would mean a loss of mass; the ejected mass of liquid water takes its part of the entropy with it, that is, the process is no longer isentropic. Similarly, one must also consider that in a precipitating cloud the crystals and the growing water droplets are falling relative to the air in the cloud. Relatively speaking, they thus enter the individual ascending parcels of moist air from above, collect some cloud droplets, and then leave the air parcel. All in all, the process is by no means isentropic.

THE MOIST-ADIABATIC PROCESSES

Ascending Motions. Despite the influence of the processes just mentioned, the classical theory of the moist-adiabatic still represents the basic process upon which all refinements must be made. The fundamental concept has been checked by Schnaidt [36] and Bleeker [6] in careful theoretical investigations. Schnaidt no longer distinguishes between the obsolete rain, snow, and hail stages. He defines, according to Dinkelacker's suggestion [9], (1) the cloud-adiabatic, in which all condensed water is retained in the ascending mass and is carried along, (2) the general pseudo-adiabatic, in which part of the water drops out, and part is carried along, and (3) the special pseudo-adiabatic, in which all the water drops out. All three stages can take place with condensation or sublimation. The first and third processes do not occur in nature. The normal process is the second one which, however, cannot be theoretically evaluated, since no numerical estimate can be made of the amount of precipitation elements which drop out or are carried along. The temperature curve for the three cases is different. For the same pressure decrease, the temperature decrease is smaller for the cloud-adiabatic than for the pseudo-adiabatic. The case which can be handled most easily from a numerical standpoint does not permit a physical interpretation: In the pertinent equation, the specific heat of the mixture of air, water, and water vapor contains a term cM (where c is the specific heat of the water, and M is the entire content of water plus water vapor); this term is set equal to zero. The resulting equation can be integrated as a whole and is the basis for the diagrams of Rossby and Shaw; however, the trend of the curve yields a still more rapid temperature decrease with decreasing pressure than do the cloud- and pseudo-adiabatics. Dinkelacker has called this the "main-adiabatic." Distinguishing these cases and their computation should not be considered mathematical sophistry; the selection of the proper adiabatic as the basis for a graphical determination of instability criteria or for the precise computation of the lateral entrainment can become very important.

Descending Motions. It must be noted that the moist-adiabatic is also being followed by air parcels that contain liquid water and have a vertical, *descending* motion [26]. One example of this process is the descending motion which the falling precipitation establishes below a thundercloud. As the air descends moist-adiabatically to the ground, it loses part of its charge of water droplets by evaporation; the temperature difference between this air and the dry-adiabatically stratified air surrounding the thunderstorm becomes increasingly negative toward the ground. The instability thus released is, to a large extent, responsible for the kinetic energy of the squall that is, so to speak, squeezed out from the region of falling precipitation. Suckstorff [41, 42] has studied these processes very thoroughly.

Wagner [43], in a careful study, has recently drawn attention to a second phenomenon, the formation of mammatus clouds. If the top of a thundercloud takes the form of an anvil, then this part of the cloud air is in thermal equilibrium with the dry air underneath it; it is therefore neither heavier nor lighter than the latter. Through a renewed swelling of neighboring cumulus tops, the anvil is quite often forced to descend, particularly in the rear of the thunderstorm. The layers of dry air below the anvil, and the cloud's air, are descending simultaneously, the former dry-adiabatically, the latter moist-adiabatically. Therefore, a temperature discontinuity develops, with cold air above warm air, in other words, a region of instability with an almost horizontal boundary surface. The mammatus pouches form either through horizontal differences of temperature or water content or through dynamic perturbations of the boundary surface. As they penetrate deeper into the dry air underneath, they become increasingly colder than their environment. Under certain conditions they can even detach themselves from the upper anvil clouds. Similar extended layers of altostratus mammatus are frequently observed on the north side of low-pressure areas (in central Europe, for instance, to the west of *Vb*-lows which are moving from south to north), where the warm air masses have ascended above the lower air and where divergence in the horizontal flow may cause a subsidence of the entire stratified mass of air.

EXTENSION OF THE THEORY OF CONVECTIVE CLOUDS

In the last decade, two fundamental lines of investigation have been followed with the purpose of widening the theory of the dynamics of convective clouds. On the one hand, we have the theories of Bjerknes [5] and Petterssen [28] dealing with the descent and dynamic heating of the air masses surrounding cumulus clouds; on the other hand, we have investigations into the entrainment of the surrounding air in the rising movement of cumulus, an approach developed particularly by Austin [2]. Both ideas may be based on the observation that an indication of marked "moist-instability" from the sounding is not always accompanied by a strong formation of convective clouds. On the contrary, even with large temperature lapse rates convection is often missing or only very feebly developed. Both theories, therefore, lead to a higher instability lapse rate than does the parcel method.

The Slice Method. The simple theory of moist-adiabatic change does not take into account the fact that an ascending air parcel is surrounded by air which must descend in order to preserve continuity of mass. This becomes quite clear when we consider that the exact theory does not describe the temperature change with respect to height, but with respect to pressure; in other words, it may also hold true for air in the chamber of an air pump. Actually, the descending air masses in the environment of a convective cloud are warmed so that the temperature excess, which the ascending air will take on because of the released heat of condensation, becomes smaller. This decrease in temperature difference is insignificant because the temperature excess is so large when the ascending cloud columns are small, and a slow descent takes place over the large spaces between the columns. However, the

temperature excess becomes considerably smaller with an increase in the downward displacement of air or an increase in the quotient M'/M where the ascending and descending masses of air are M' and M, respectively. These ideas of Bjerknes and Petterssen have already been adopted in a number of textbooks, therefore a detailed derivation is unnecessary here. It ought to be borne in mind, however, that the smaller the quotient M'/M, the more valid are the instability criteria of the parcel method according to Shaw, Normand, or Stüve. Furthermore, in this case the "moist–instability" is much greater with the same lapse rates, and a much smaller lapse rate in the surrounding air can still be considered as an unstable stratification. As the ratio M'/M becomes larger, it becomes increasingly imperative to take into account Petterssen's slice method, since the energy associated with the instability, which is decisive for the possible vertical velocities, becomes so much smaller, and a greater lapse rate corresponds to neutral equilibrium.

Petterssen and collaborators [29] have been able to demonstrate the usefulness of the slice method by an excellent statistical investigation; according to this new method the maximum possible height of convective clouds is much smaller than it is according to the parcel method. In fact, the heights attained by the tops of cumulus clouds have been found to be in good agreement with the heights predicted by the slice method. The parcel method yields no clues concerning the amount of cloudiness, whereas the slice method provides some information which corresponds to the actual cloudiness, although the correspondence displays considerable scattering. Nevertheless, it should not be overlooked that in other respects the parcel method yields useful information. For instance, it answers questions such as how high the condensation level is, and whether or not cumulus clouds are to be expected at all. However, the degree of instability is less important here than is the stability of the stratification which has to be overcome initially.

Here, too, there seems to be a minor defect in the slice method. In establishing the criteria, it is assumed that the mass of air ascending per unit time equals the descending mass of air. This means that on the average no vertical component of motion will result over a sufficiently large horizontal area. It has already been proved, through the valuable investigations of Calwagen [7], that the most favorable condition for the occurrence of local summer showers is the existence of an old front, believed dissipated, which sometimes will be steered back into the region under observation. Such old fronts are simply minor convergence zones in the horizontal air flow; their presence requires the simultaneous existence of weak vertical motion over the given region according to the continuity of mass. Petterssen [29] implicitly comes to the same conclusion when he shows that 50 per cent of the cases of weak convection are coupled with cyclonic curvature or wind shear, whereas this holds true in 85–95 per cent of the cases of stronger convection. This, however, means convergence, although it may be only weakly developed. Then, however, the consideration of a resultant upward component (in other words, the prevalence of ascending masses M' over the descending masses M) leads, in turn, to an increase in the instability lapse rate, so that the parcel method yields a more accurate measure than does the slice method.

A further point should be taken into account when considering an isolated convective cloud. In the derivation of the slice method, the assumption must be made that a cloud tower has already penetrated the whole layer, and that the ascent and descent of the air masses take place uniformly throughout the entire layer. However, a growing cumulus cloud pierces vertically into the layer, so that the downward displacement and heating of the air around the intruding head are relatively slight, while around the lower portions of the cloud these processes are intensified. The parcel method is therefore more applicable to the conditions at the cloud top than to the conditions in the cloud column beneath. Perhaps this effect is the explanation of the detachment frequently observed in rapidly developing castellatus towers which ascend without a supply of air from below —much in the manner of free balloons.

The slice method makes the following particularly valuable contribution: When the ascending and descending particles are subject to the same changes of state, it predicts a released energy of instability that is significantly *larger* than would be indicated by the parcel method. This is the case in the dry convection below the condensation level, the violence of which can thus be explained. It is likewise true for the rapidly ascending masses in the interior of a cumulonimbus which give rise to vertical squalls. The theory of the formation of waterspouts and tornadoes (for which Koschmieder [17] considered the unstable spouting up of cloud particles within the cumulonimbus to be necessary) thus finds a welcome support. The difference between the two types of instability can be seen directly from cloud observations. In time-lapse motion pictures, taken by Mügge [24], one can recognize that the growth of cumulonimbus does not occur in the form of a symmetrical and uniform ascent. A cloud tower shoots up quickly and calms down; immediately a second one shoots up by its side, partly piercing the old one which, in turn, descends and may evaporate in its thinner portions. The vertical motion of the new tower ceases only when it has reached the height of the top of the old tower and finally comes to rest, whereupon another tower builds up. This rapid ascent and quick succession of the individual protuberances (which has also been demonstrated in the Thunderstorm Project) is caused by moist-adiabatic ascent within an environment that descends moist-adiabatically. The slow lifting of the top levels of the entire multiple cloud structure manifests the restricted energy of moist-adiabatic ascents in a dry environment.

The Lateral Entrainment of Air. A second and older assumption by Calwagen [7] would indicate that cumulus convection becomes more difficult when the air to be penetrated is particularly dry. The synoptic investigator who is familiar with this explains it as the result of

subsidence causing the dry air and the divergence of the horizontal flow. The statistics of Petterssen and his collaborators, mentioned above, also confirm this. It is, therefore, surprising to note that, according to the most recent investigations, this hindrance to convection is explained by a lateral entrainment of dry air masses in the ascending cloud. This theory is already well developed [2] and is treated in a separate article in this Compendium.[2] However, neither the ordinary observations of a cumulus cloud nor the processes visible in time-lapse motion pictures lead to the conclusion that a cumulus cloud is fed in any other way than by the entrance of air masses through its base. Indeed the cauliflower-like forms of cumulus have been considered as proof that no mixing with the surrounding air takes place. At best, only the barrier layers that are pierced by cumulonimbus clouds and surround the cloud towers like collars as, for example, a wreath of stratocumulus cumulogenitus, can be considered as locations of substantial feeding of the cloud by lateral entrainment. This takes place only at discrete heights, and not continuously at all heights.

Theoretical computations based on observational material show the lateral supply of mass and the liquid water content as a function of height. The second quantity, which can be measured from an airplane, should serve as a criterion for testing this theory [39]. However, another point must also be considered: The theory has taken into account only the parcel method of the moist-adiabatic and has supplemented it by the consideration of the lateral entrainment. This leads to a temperature lapse rate within the cloud which is greater than the moist-adiabatic and which approaches the dry-adiabatic. We come to the result already presented above by the slice method of convection. Perhaps a combination of the two methods would lead to different ideas about lateral entrainment in cumulus clouds. However, a simultaneous test of the two theories would require a very extensive observational program.

Cellular Convection. Perhaps an entirely different method of studying the instability conditions of cumulus humilis may be necessary. The time-lapse motion pictures by Mügge [24] mentioned above indicate that a cumulus humilis is not a single swelling structure. The individual parts of a cumulus are in constant motion. In the vertical wind shear the cloud mass, which appears calm to the eye, is, in fact, rolling; condensing cloud masses ascend continuously in the rear, pass the summit of the cumulus, and then dissolve while descending in front. The cumulus is not to be considered as the top cover of a chimney of ascending warm air, but rather as the upper portion of a rolling ball or cylinder. If this picture is correct, then the laws of cellular convection [20] must control the formation of such convective structures [38]. In this case, the existence of convection currents or cells depends not only on the lapse rate's exceeding a certain value, but also on the vertical thickness of the layer in which the convection takes place. Furthermore, it depends on the viscosity and heat conductivity of the air (thus on the austausch coefficient) and, finally, on the horizontal dimensions of the various convection cells. The theoretical concepts of cellular convection, which have been successfully applied to the explanation of stratocumulus and altocumulus structure [21, 44], must then also be valid for cumulus humilis [45]. A complicated picture would result: The laws of cellular convection apply to the distribution of clouds, the parcel method is applicable to the condensation level, and the slice method applies to the vertical extent of the clouds. In fact, clouds of vertical development are formed in layers characterized by uniform convection, because Petterssen and his collaborators [29] found that in a region of cumulus the vertical wind shear and shift are particularly small while directly above the summit of a cumulus cloud the wind shear is four times larger than at lower levels. This fact seems to justify the use of the cellular method. However, as is quite often the case in meteorology, it is problematic whether the small wind shear is the cause of cumulus formation, or whether, inversely, the existence of strong convective mixing is responsible for the absence of a large variation of wind with height.

Radiational Influences on Certain Cloud Forms. The influence of long-wave radiation upon cloud surfaces has already been mentioned above. This influence is most important for stratocumulus and altocumulus. As a consequence of the heat supplied at the cloud base and the heat lost at the top, parcels of air in the lower portion of the cloud are heated, evaporate their liquid water, and rise, while particles near the top cool and descend. Thus the heating and cooling establishes an internally driven convection cell [22], which, according to Bénard, operates in conjunction with the cellular convection to break up the cloud layers into individual globules. This internal convection transports heat from the bottom to the top of the cloud; for this reason, Raethjen has called stratocumulus clouds "the thermodynamic singularity in the vertical flux of radiation" [30].

In the tropics, the effect of radiation on high cloud layers (when there are no low or middle clouds below) becomes so great that above approximately 14 km clouds can no longer exist. Even a broken cloud cover would receive so much energy from the warm surface of the earth that it would be subject to evaporation and dissolution in a short time [23]. The fact that the upper limit of cirrus clouds in the tropics is found 3–4 km below the tropopause can probably be explained by this process alone.

The effect of radiation on thunderclouds has not been so clearly determined. The summit of a high-towered cumulonimbus loses much heat by radiation. In daytime this cooling is probably cancelled in part by radiation from the sun, but toward evening or during the night the emission from the cloud tops prevails. It is possible that because of this emission a kind of cold convection from above will be initiated in the remnants of thunderclouds, which might lead to a revival of earlier thunderstorm activity in the late evening or

2. Consult "Cumulus Convection and Entrainment" by J. M. Austin, pp. 694–701.

during the night. In addition to this process there may be still other causes for the formation of the nocturnal thunderstorm maximum.

It is much more difficult to try to explain in this manner the nocturnal shower maximum over the oceans. In this case, no thunderclouds that could be reactivated are left over from the daytime. On the contrary, synoptic investigations and weather-reconnaissance flights made during World War II revealed that, during the day, there were no clouds over the ocean, whereas at night the region was densely covered with severe thunderstorms. This condition recurred for several days in succession. The synoptic situation, that is, the presence of a cold air dome, was favorable for convective clouds in these cases, but the initiation of the cloud formation is hardly attributable to long-wave radiation. One is much more inclined to ascribe it to a remnant of the diurnal temperature variation which, over the thermally passive ocean surface, would produce a diurnal instability variation that is opposite to that observed over the thermally active surface of the continent.

THERMAL PROCESSES ON CLOUD ELEMENTS

The cloud elements are the actual vehicles of thermal changes. As the droplets or crystals fall in the gravitational field or mix with neighboring air parcels containing a different concentration of cloud elements, they do not remain in the volume of air in which they formed. Thus, they are no longer in equilibrium with their environment; evaporation will occur if the new environment is drier, condensation if the environment is supersaturated; likewise, freezing or melting of the cloud elements may take place.

Evaporation of Cloud Droplets. Evaporation of cloud elements takes place on the surface of clouds. It has already been pointed out in the papers by von Bezold [4] and later by Robitzsch that the lower temperatures which are frequently observed when flying into cumulus clouds [16] may be caused by evaporation of cloud droplets into the drier environment. This process was studied quantitatively by Findeisen [12], who found that cloud droplets in an environment of 90 per cent relative humidity have a lifetime of only 2½ seconds before they evaporate. The conditions for evaporation seem to be especially favorable at the edges of cumulus clouds. In the strong wind shear that exists between the ascending cloud and the descending environment, violent turbulence and mixing of cloud air with the environment takes place. It has been observed quite frequently from gliders and airplanes that the turbulence is much stronger in the peripheral than in the interior parts of the cloud. However, photographic measurements of the ascending velocity of cumulus clouds [35] seem to show that the ascending motion in the outer portions is only slightly retarded, and that the air directly adjacent to the cloud is also lifted. The sinking occurs only some distance away from the cloud. The model proposed by Christians [8] concerning motion in cumulus clouds and comparison with the hydrodynamic jet stream according to Schmidt [34] support this assumption. Then, however, the relative humidity in the immediate vicinity of the ascending cloud tower cannot be very low, and the evaporation as well as the resultant cooling will therefore be insignificant.

Still less significant is the evaporation over the dome of an ascending cumulus cloud, for here the surrounding air is strongly lifted, and its relative humidity is increased. This can even lead to the well-known phenomenon of caps (*pileus*) which stay for a short while over the swelling cumulus head separated from it by a thin, cloud-free region, until fusion takes place. However, there may be a positive temperature difference between the moist-adiabatically ascending cloud top and the dry-adiabatically lifted air above it, a difference which favors evaporation. This, however, is opposed to the results of Petterssen and his collaborators [29] concerning the heights of cumulus tops. These heights are given approximately by the height at which the moist-adiabatic lapse rate becomes equal to the vertical temperature gradient of the surrounding air. Therefore, no large temperature differences and, in turn, no significant evaporation can be expected. On a non-swelling cloud, these temperature differences would be equalized by austausch processes or even reversed by radiation.

Condensation and Sublimation on Cloud Elements. The opposite process, the condensation of water vapor on cloud elements that fall from their original air volume, occurs everywhere in the cloud. However, until now, this process has been given little attention in theoretical studies of the structure of clouds and the lapse rate within them. According to the computation by Findeisen [11], condensation contributes very little to the formation of precipitation, particularly in comparison with the essentially much more effective "chain reaction" process of Langmuir's theory [18]; nevertheless, it cannot be neglected in the thermodynamics of clouds. Condensation can only occur when the falling cloud elements are colder than their new environment. This causes the saturated water vapor to become supersaturated with respect to the cooler droplets. The amount of this supersaturation and its dependence on the temperature difference has been given, for example, by Harrison [15]. The temperature difference itself, however, depends on the heat transfer between the air and the falling water droplets; this transfer is, in turn, influenced by the condensation process. It is probably for this reason that condensation is rather ineffective in the growth of cloud elements.

The sublimation of water vapor on ice crystals or small graupel pellets is much more intense, since cloud air which is saturated with respect to water is considerably supersaturated with respect to the falling solid particle, depending on the temperature. In this case, the supersaturation is so great that the difference in temperature of the crystals with respect to their surroundings can be neglected. The thermal reactions have been discussed by Harrison [15]. The downward increase of the fall velocity and diameter of the droplets and the increase in vapor content of the air cause more heat of condensation or sublimation to be released in the

lower parts of the clouds than in the higher parts. For the numerical computation of these processes on falling snow crystals it would be valuable to consider the investigations of Wall [46] and the indices of crystal growth introduced by him. The greater heat release in the lower cloud portions increases the vertical temperature gradient and augments the instability in all clouds which already contain falling particles of precipitation. Now, the slice method shows that when air ascends or descends moist-adiabatically within the cloud, the released instabilities and vertical motions are considerably larger than would be expected according to the parcel method. Therefore, these comparatively minor amounts of released heat have a certain importance for the thermodynamics and mechanics of the cumulonimbus as well as for the upgliding nimbostratus. A numerical calculation of all these processes would be very desirable.

Droplet Accretion and Graupel Formation. A quantitative evaluation of the thermal effects of accretion of small cloud droplets on falling ice crystals and hail grains has not been made. Only the accretion on falling rain droplets has been computed in the theory of "chain reaction" processes in convective clouds by Langmuir [18]. We will not go into any further details here. However, the thermal consequences will be stressed again. It is evident that the heat of condensation does not play a role in this accretion. In the formation of precipitation, accretion on falling droplets is more important than condensation, but it is of no significance in the thermal processes. This is similarly true of the accretion of supercooled droplets on ice crystals (formation of graupel). In this process only the heat of fusion is released, whereas the amount of heat released in the sublimation of water vapor on ice crystals is 8½ times greater per unit mass. The accreted masses, however, are considerably larger in the process of graupel formation than in sublimation or the formation of rime; therefore the quantities of heat involved may be comparable. Here, too, the effects of the growth and the increasing fall velocity of the droplets, etc., are such that larger amounts of the heat of fusion are released in the lower portions of the cloud, thus causing an additional instability [15].

This becomes particularly important for the intermittent formation of a thundercloud. It has already been emphasized that a cumulonimbus does not form all at once, but that only one cloud tower at a time builds upward, spreads to an anvil (*incus*), glaciates, and stops growing; immediately following and quite close to the old tower, a new one rises. At first this contains only supercooled droplets, but soon it mushrooms into the existing anvil consisting of ice crystals, thus providing the best possible natural seeding of the ascending cloud. Consequently, conditions are favorable for the precipitation of large drops, graupel, and hail; for whenever one cloud tower or cell has fulfilled its task of producing precipitation, the next one swells up, ready to catch the falling ice particles and carry them upward again. Thus the processes of graupel formation and the release of heat of fusion causes additional instability in each subsequent tower which enables it to ascend higher than the preceding one. Also noteworthy is the interaction between the upper glaciated part of a nimbostratus cloud, which effects the seeding, and the lower part, which contains a large supply of liquid water [25]. A separation of the two cloud parts from each other may, under certain conditions, occur at mountain barriers when the lower current (and thus the cloud) is held back, while the upper current passes over the top of the mountain (Bergeron [3]). This can also happen with warm fronts, where the rain areas will be either very narrow or very wide, depending on the variation of wind with height.

Melting Processes. Somewhat more complicated processes exist in or directly below the freezing level. If the cloud reaches below this level, melting of the falling ice particles will not immediately occur, but rather, intensified condensation and sublimation will take place. Thus, the instability will spread below the freezing level. Only at some lower level will the melting of the falling ice affect the thermal processes. This melting will consume so much heat that the air is considerably cooled and its temperature kept constant at 0C. In this layer an isothermal lapse rate and thus marked stability will develop. This isothermalcy has nothing to do with the hail stage of the old classification of the moist-adiabatic processes (rain, hail, and snow stages), for here we do not deal with temperature changes of an individual quantity of moist air moving either upward or downward vertically, but with air that can remain at rest while precipitation falls through it. A strong instability will develop below this stable layer if the lapse rate was previously adiabatic or less. Findeisen [13] has called attention to this instability and has shown that it frequently causes the formation of scud clouds below the rain cloud proper. At this level, there are squalls and strong vertical turbulence, which permit formation only of fractocumulus clouds, but not of a closed cloud layer [15].

PROBLEMS FOR FUTURE RESEARCH

The discussion in this article has been presented with the principal idea that, fundamentally, we are concerned with disturbances or modifications of the simple moist-adiabatic process. It should be the aim of further scientific investigations to combine all the separate stones of our mosaic into a coherent picture of the heat balance of the clouds, in particular, (1) the heat balance of clouds in general, (2) the heat balance of the individual types of clouds, and (3) the role of the individual cloud types in the heat balance of the entire atmosphere.

THE FORMATION OF ICE CRYSTALS

By UKICHIRO NAKAYA

Hokkaido University, Sapporo, Japan

When pure liquid water suspended in the air is cooled, it keeps the liquid state till about −35C. Liquid water at temperatures below the freezing point is called supercooled water. The supercooled water is transformed spontaneously into ice at about −35C. The rate of freezing is determined by the rate at which the latent heat liberated by freezing is removed. In the case of freezing of the water supercooled to s degrees centigrade, $s/80$ parts of the volume are transformed instantaneously into ice at the moment when freezing starts, because the latent heat liberated is 80 cal g^{-1}. The whole system, $s/80$ parts of ice plus $(1-s/80)$ parts of water, is warmed up to 0C, and the speed of later freezing is a function of the rate of removal of the latent heat liberated by the subsequent freezing. Altberg [1] studied the freezing of the rapids in Siberia, and found that most of them are supercooled to the order of −0.05C just before freezing commences.

The freezing of still water in nature starts from the surface, as the maximum density of water is at 4C. X-ray studies show that the thin ice plate obtained at the surface of still water is a single crystal, the orientation being such that the principal axis is perpendicular to the water surface. Under favorable conditions very large single crystals are obtained in lake ice. McConnel [10] observed single crystals as large as about one foot in diameter at Lake Davos.

In the case of water in turbulent flow or in a refrigerated vessel, crystallization starts at numerous points in the water and the crystals develop in random directions. The bulk ice thus obtained is composed of a mosaic of ice crystals oriented at random. Thus ordinary ice has a microcrystalline structure and is not a crystal in the usual meaning of the word.

Single crystals of ice are obtained in the most beautiful and complicated manner by the sublimation of water vapor. In nature they are observed as crystalline frost, window hoar, and snow crystals. In this article the descriptions are confined to the ice crystals obtained by the sublimation of water vapor, with special emphasis on the snow crystal.

THE FORMATION OF ICE CRYSTALS BY SUBLIMATION

Crystalline Frost. It is well known that frost has two structural forms: amorphous and crystalline. Amorphous frost is produced when the temperature is only slightly below 0C, or by the deposition of supercooled water droplets. Crystalline frost is formed at lower temperatures by the condensation of water vapor by sublimation on a solid body. The solid body may be a particle of ground snow or other substance. The crystalline frost produced on a new snow surface usually develops in a fern-like shape and is called surface hoar. It is often observed on cold winter mornings after a calm, clear night. Crystalline frosts are frequently observed also on the walls of snow cavities. Cup crystals and feather-like forms are typical of these crystals. They are called depth hoar. Detailed descriptions of these surface and depth hoars have been given by Seligman [13, pp. 46–77].

The crystalline frosts can be classified into five forms: (1) needle, (2) feather-like, (3) plate, (4) cup, and (5) dendritic. From the crystallographic point of view, each of these frost crystals has its corresponding type in the crystals of snow.

1. Needle form. This crystal often grows out from a wall of snow in the form of needles 0.2–0.5 mm in diameter and about 1 cm in length. Microscopic examination shows that it is an assemblage of parallel hexagonal columns. It corresponds to the columnar crystal of snow.

2. Feather-like form. This type is frequently observed. Sometimes it develops to 5–6 cm in length. Under a microscope it is seen to be composed of small hexagonal columns, some columns being attached at right angles to the sides of others. The corresponding snow crystal is also known.

3. Plate crystal. This type is sometimes observed hanging down from the snow ceiling of a cavity and also growing out in the air from an exposed object such as the wall of a wooden box. The form and structure are quite similar to those of one branch of the snow crystal called sector form.

4. Cup crystal. When completely developed this type takes the shape of a whisky glass of hexagonal form. But usually one side is not completed and appears to be rolled up. This is the most common type of depth hoar. The corresponding snow crystal is very rarely observed.

5. Dendritic crystal. Dendritic crystals are often observed, in addition to the surface hoar, among the crystalline frosts developed on the branches of trees when the weather is calm and the temperature is low. This type corresponds to the fern-like crystal of snow, the only difference being that snow lacks the minute internal structure resulting from sublimation. When the temperature is very low, it is sometimes possible to observe a remarkable frost crystal that is very similar both in form and in structure to one branch of a hexagonal crystal of snow.

The correspondence of the habits of snow and frost crystals makes it possible to infer the conditions for the formation of various types of snow crystals. Before the artificial production of snow crystals, this was the only way to study the mechanism of snow-crystal formation.

Window Frost. On crisp winter mornings, in northern countries, various crystals of ice are observed on the

window panes of houses. These ice flowers are of two kinds: window frost and window ice. The former is a product of the sublimation or freezing of minute supercooled droplets; the latter results from the freezing of a water film. Window ice is likely to be formed in a kitchen or bathroom, where the moisture is abundant and the indoor temperature is just below freezing. The excessive water vapor condenses on the pane as a thin water film, and the mosaic of ice crystals obtained by the freezing of this thin film gives window ice.

Window frost is quite different from window ice in its appearance. The most familiar type is shown in Fig. 1. It must be again classified into two kinds: the detached hoar crystal *H* and the sheet frost *S* in Fig. 1. The hoar crystal is a product of sublimation, and is formed by a mechanism similar to that which produces the snow crystals. The sheet frost, which always extends over some area of the glass pane, is a two-dimensional assemblage of minute ice granules that are formed by the freezing of supercooled droplets scattered over the pane.

The mechanism responsible for the formation of hoar crystals can readily be studied by observing the initial stage of artificial hoar formation. Experiments have been performed in a cold chamber laboratory. Several minutes after exposing the plate to supersaturated air, numerous infinitesimal droplets condense on the surface, and the glass plate takes on a blurred appearance. After a little while, many germs[1] of hoar crystals appear at diverse points and begin to grow. As soon as growth starts, the blurred surface around the crystal begins to clear, that is, the minute droplets in that region evaporate. The vapor pressure of supercooled water is higher than that of ice at the same temperature, so the water is evaporated from the droplets and condenses on the hoar crystal, resulting in the growth of the latter at the expense of the former. The process is shown remarkably well by slow-motion pictures, one frame of which is reproduced in Fig. 2.

When water droplets are frozen into ice granules without evaporating, they form sheet frost. Supercooled water itself does not freeze easily, but once it touches ice, it becomes solid almost instantaneously. Thus, if one of the series of droplets freezes for some reason or other, the action is relayed to all the rest of the droplets, which also freeze. This relaying action can be seen under a microscope of high magnification. From one frozen droplet, a thin streamer of ice extends, and the moment it touches the next droplet, the one thus

Fig. 1—Detached hoar crystals and sheet frost (×0.73).

1. The term "germ" is used in this article to designate the primitive ice crystal.

touched freezes, while the streamer disappears; the behavior of this streamer which relays the freezing action is beautifully demonstrated by slow-motion pictures, one frame of which is shown in Fig. 3. This frame shows the instant when the droplet marked *A* becomes frozen by a streamer from the already frozen droplet *B*.

There are innumerable variations in the shape of window hoars observable in nature, for example, spiral patterns, odd arabesque designs, snow-like forms, etc. The ordinary glass plate is always covered with an invisible film of some organic substance. It is found that the combination of the effect of this invisible film and the atomic nature of ice gives rise to the variation observed in the patterns. When the glass surface is chemically clean, crystallization takes place very slowly. Even when the crystallization is almost complete, the hoar crystal is very thin and greatly distorted. The effect of an adsorbed film is very well demonstrated by exposing the glass plate to alcohol vapor for a short time, so that the surface is covered with an invisible film of alcohol molecules. Alcohol has a strong affinity with water, and the growth of the ice crystal may be expected to suffer a marked deformation. The results of such an experiment are as might be expected. One example is shown in Fig. 4.

The opposite effect can be observed on a glass plate covered with a thin, invisible film of paraffin wax. Since the water is repelled by the paraffin film, crystallization must be free from the effect of the surface. The glass plate is well cleaned and desiccated, and then exposed to paraffin vapor by being kept in a horizontal position 5 cm above the surface of molten (not boiling) paraffin wax. Under favorable conditions hoar crystals very much like snow crystals can be obtained on the plate. The best example is seen in Fig. 5. The three stages of development of a hoar crystal thus obtained are shown. It is apparent that the window hoar crystal also develops hexagonal symmetry if the effect of the base surface is eliminated.

Snow Crystals. The snow crystal is a solid product of precipitation formed in the atmosphere by sublimation of water vapor on minute solid nuclei. The symmetry of a snow crystal is due to its free development in a suspended state in air. The theory of crystal lattices can explain the symmetry of the angle between the faces, but it cannot touch upon the question of the symmetry of the macroscopic form of a crystal. The extraordinarily symmetrical pattern, sometimes observable in the hexagonal plane crystals of snow, is favored by the rotational motion around the vertical axis, while it is falling in a nearly horizontal position according to hydrodynamic theory.

The formation of a snow crystal is best classified as taking place in two stages: (1) the formation of the germ or initial stage of the crystal, and (2) its subsequent growth into a snow crystal proper. The snow crystal proper is that which we observe on the ground, being several millimeters in dimension. The many varieties in the shape of a crystal are usually discussed with respect to the snow crystal proper, although some varieties are also observable among the germs. The latter are usually very tiny, being a few hundredths of a millimeter in dimension. The well-known experiments on cloud modification by I. Langmuir and V. J. Schaefer are those of transforming the supercooled cloud droplets into the germs. The nature of germs and the conditions for their formation will be found in the article by Schaefer.[2] In this article the description is confined to the snow crystal proper, which henceforth is simply called the snow crystal.

Dobrowolski's book [5] is the most comprehensive study of snow crystals thus far published. The book by Bentley and Humphreys [3] is famous for the vast collection of over three thousand photomicrographs of snow crystals. The crystal appears quite different if the mode of illumination is changed. Transmitted light is usually used. Photography using transmitted light is advantageous in obtaining a clear picture of the boundary and internal structure of the crystal. However, ordinary transmitted light does not show clearly the topography of the surface. An illumination by reflected light increases the beauty of the photograph, outlining the white image clearly against the dark background, but the delicate structure inside the crystal is not revealed. Recently M. Hanajima improved the technique of photomicrography to a remarkable extent by using oblique illumination. He succeeded in taking photomicrographs showing both the internal structure and the slight ruggedness of the crystal surface. The method is shown in Fig. 6.

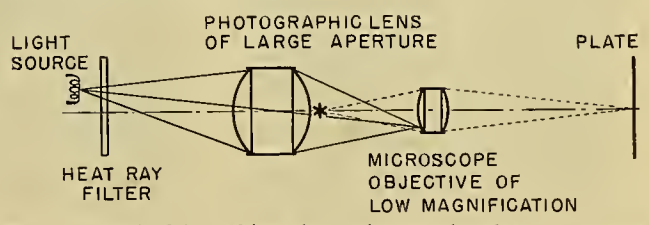

Fig. 6.—Method for taking photomicrographs of snow crystals (*after M. Hanajima*).

Snow crystals of various types photographed by this method of illumination are illustrated in Figs. 7–14.

CLASSIFICATION OF SNOW CRYSTALS

Principles of Classification of Snow Crystals. The famous astronomer Kepler was reputedly the first to point out the hexagonal symmetry of snow crystals. Descartes [4, p. 298] left the first scientific record of snow crystals. He made observations of snow crystals in 1635 at Amsterdam. Hooke, the discoverer of plant cells, gave the first sketches of snow and frost crystals observed through a microscope in his *Micrographia*. Hellmann [9, p. 37] in Berlin and Nordenskjöld [12] in Stockholm independently classified snow crystals into three kinds: planar, columnar, and a combination of the two. The basic idea of this system is retained in the general classification of snow crystals today.

VII	*I*	Irregular snow particle	*1.* Ice particle *2.* Rimed particle *3.* Miscellaneous	

The development of photomicrography gave rise to a tendency to attach particular importance to the regular hexagonal crystals of planar type, although in reality spatial and irregular types occur in greater quantity. Before the method of photomicrography was fully developed, crystals with spatial structure were often reported in the literature, but they have been more or less neglected by workers using photomicrography. In

this sense we could say after A. Wegener that the development of photomicrography hindered the study of snow crystals. The author, therefore, has always tried to attach equal importance to every type of crystal actually observed in nature.

General Classification for Scientific Purposes. The general classification presented in Table I is more or less similar to that of Hellmann and Nordenskjöld, but the special feature is the addition of new types and the various forms and structures are observed only slightly less rarely than regular hexagonal ones. They are caused by asymetrical growth of branches, malformation by attachment of nuclei, overlapping of several planes, V-shaped notch in the plate, etc.

5. Spatial hexagonal type, *P5a*. This is composed of a base crystal of dendritic form with many branches attached at various points of the base crystal and extending upwards.

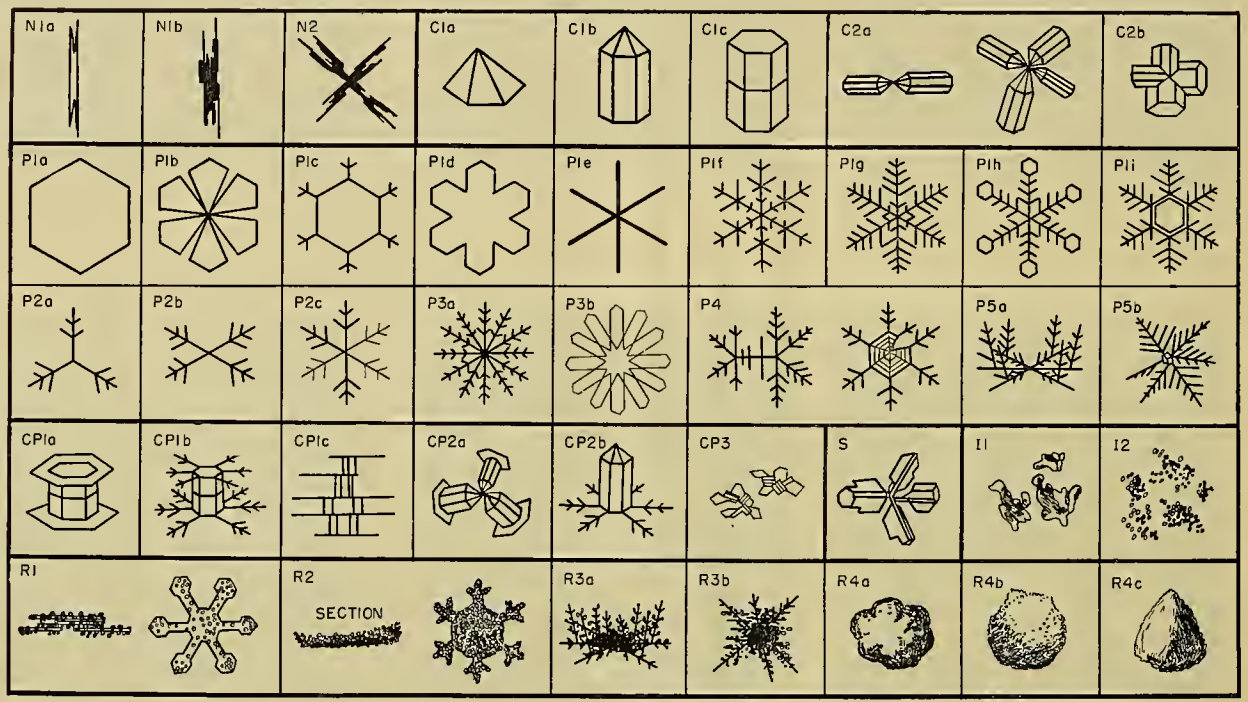

FIG. 15.—Sketches of all types of crystals in the general classification.

alteration in some items of the classification on the basis of crystalline structure. The graupel (snow pellet) is included, because it is an extreme case of the rimed crystal of spatial structure.

The sketches of all types of crystals in the general classification are shown in Fig. 15. A brief explanation will be given for some items in the general classification.

1. Needle crystals, *N*. Considering the results of the experiments on the artificial production of needle crystals, this should be taken as a kind distinct from the elongated column.

2. Crystals with an irregular number of branches, *P2*. Crystals which look as if they had developed from two nuclei or in parallel growth are observed in fairly large numbers. They have the appearance of a twin crystal. This twin crystal can easily be separated by a slight external force, giving the three-branched, four-branched, and other types. Seven pairs of components can be expected, as shown in Fig. 16. All of these component crystals have been actually observed in appreciable quantities.

3. Crystals with twelve branches, *P3*. This type is composed of two overlapping component crystals, and can be separated into ordinary hexagonal crystals.

4. Malformed crystals, *P4*. Malformed crystals of

6. Spatial assemblage of radiating type, *P5b*. This type has dendritic branches radiating in space from the center. The central part is a combination of small sectors or columns. The heavy snowfall in Japan is composed mostly of the spatial crystals, *P5a* and *P5b*.

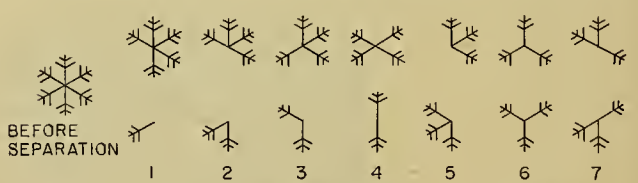

FIG. 16.—Seven modes of separation of a twin crystal.

7. Capped column, *CP1*. This is a crystal composed of a hexagonal column with plane crystals at both ends. We can find some examples of this crystal in the sketches by Descartes.

8. Irregular assemblage of columns and plates, *CP3*. The "flour snow" frequently observed in the Alpine regions is an agglomeration of minute crystals of this type.

9. Columnar crystals with extended side planes, *S*. The structure of this type has not yet been completely clarified, but experiments with artificial snow show that

the plane parts observable in this crystal are the extensions of the side planes of the columns, which form the skeleton of this crystal.

10. Rimed crystal, *R*. Supercooled cloud droplets are sometimes frozen to a snow crystal, and thus a rimed crystal is obtained. When many droplets become attached to a plane crystal, it turns into a thick plate (*R2*), sometimes half a millimeter in thickness. The graupel bearing a trace of hexagonal symmetry (*R4a*) is composed of a spatial hexagonal crystal *P5a* with numerous droplets attached, the graupel-like snow of hexagonal type *R3a* being the intermediate stage. The lump graupel *R4b* is made in a similar manner from the spatial assemblage of radiating type *P5b*, through the stage of graupel-like snow *R3b*. The cone-like form *R4c* is considered to be due to the rotational motion around the vertical axis during its fall.

11. Irregular snow particles, *I*. Snow particles are sometimes observed which do not show any regular crystalline form. There are many varieties: one type looks like an assemblage of pieces of ice (*I1*); another type has many water droplets attached (*I2*), etc.

Practical Classification of Snow Crystals. The general classification described in the preceding paragraph is not adequate for practical purposes. At the Oslo meeting of the International Commission on Snow and Ice in 1948, a committee was appointed to prepare a practical classification of snow, acceptable not only to scientists but also to others interested in snow. The aim was to promote uniformity in the method of describing snow and to simplify the correlation of data obtained by different groups. In 1949, this Committee on Snow Classification proposed a tentative snow classification covering solid precipitation and the deposited snow.

This tentative classification for solid precipitation is considered to be more convenient and adequate for practical purposes than similar ones so far proposed. It is shown in Table II.

In Table II, each class and basic feature of snow is designated by a code symbol with a view toward making the classification international (*i.e.*, independent of language). The description is made very simple. For example, *F1rD1.5* or ⬡ 1.5 means plate crystals with water droplets attached, the average size being 1.5 mm. *F2fwDd* or ❀ *d* means a cluster of stellar crystals partially melted, the average size of the crystals composing the flake being large, or between 2.0 and 3.9 mm.

Table II. Practical Classification of Solid Precipitation

	Code	Graphic symbol	Term	Remarks
Type of particle (*F*)	*1*	⬡	Plates	*P1a, P1b, P1c, P4.*
	2	✳	Stellar crystals	*P1d, P1e, P1f, P1g, P1h, P1i, P2a, P2b, P2c, P3a, P3b, P4.*
	3	▭	Columns	*C1a, C1b, C1c, C2a, C2b.*

	9	△	Sleet (ice pellet)	United States Weather Bureau definition; frozen raindrops, fairly small and transparent.
	0	▲	Hail	Solid precipitation formed by the successive freezing of water layers.
Additional characteristics	*m*	✳	Broken	Broken crystals of type *1*, *2*, etc.
	r	✳	Rimed	*R1*, *R2*, *R3*.
	f	❀	Flake	Clusters of crystals of type *1*, *2*, etc.
	w	✳	Wet	Wet or partially melted crystals of type *1*, *2*, etc.
Size of particle (*D*)	*a*	0 –0.49 mm	Very small	The size of particle means the greatest extension of a particle (or average when many are considered) in millimeters. For a cluster of crystals it refers to the average size of the crystals composing the flake.
	b	0.5–0.99	Small	
	c	1.0–1.99	Medium	
	d	2.0–3.99	Large	
	e	4.0 or larger	Very large	

ARTIFICIAL PRODUCTION OF SNOW CRYSTALS

Method for Making Snow Crystals in the Laboratory [11]. The artificial production of snow crystals means the production of frost crystals freely suspended in the air in a cold chamber laboratory. It takes at least from one-half to one hour for the complete development of a snow crystal. A thin filament was used to keep the crystal suspended in air for such a time.

In order to obtain nearly steady convection of water vapor, the apparatus shown in Fig. 17 was designed. Two concentric glass cylinders are held vertically, so that warm water vapor is driven upward inside the inner tube, while the cooled air comes down through the space between the two cylinders. The water in the

reservoir R is warmed electrically. The cover C is a metal sheet and D is a plate of wood. After examining five kinds of filaments, a thin rabbit hair was chosen because it was the most suitable filament to which a few

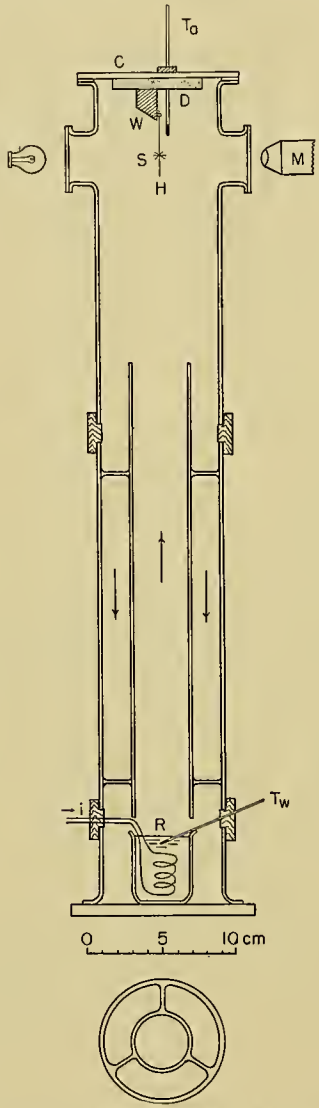

FIG. 17.—Apparatus for making artificial snow.

isolated germs of snow crystals could be attached. The structure of rabbit hair was examined under a microscope of high magnification, and it was found that a few knobs occur at suitable intervals. These knobs seem to serve as the nuclei for snow formation. The whole apparatus is set in a thermostat placed in the cold chamber which is kept below −30C by a refrigerating machine.

The temperature of the water in the reservoir (T_w) is measured. This is a measure of the degree of supersaturation and can be controlled. The temperature of the air (T_a) where the crystal is formed is a function of T_w and the temperature of the thermostat T_t. For a given T_w the air temperature T_a is regulated by changing T_t. Snow crystals have been produced for various combinations of T_a and T_w, and the relationship between the crystal form and the external conditions has been studied. It was found that T_a and T_w are the two elements controlling the form of the crystals.

The mode of air convection in the apparatus was studied by measuring the temperature distribution under operating conditions; one example is shown in Fig. 18. In this figure it is evident that the warm vapor

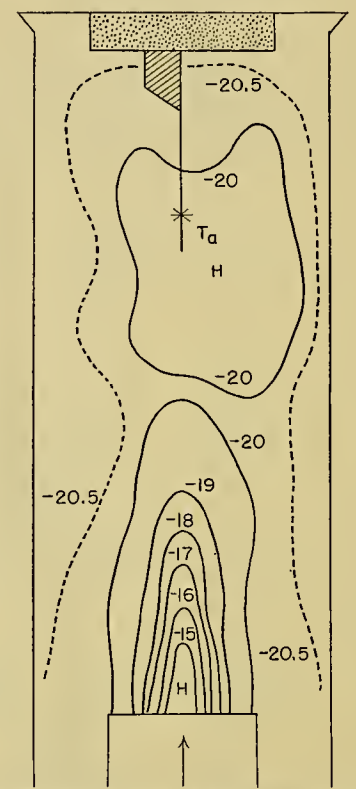

FIG. 18.—Convection of air in the apparatus (temperatures in degrees centigrade); $T_a = -23$C, $T_w = +15$C.

rises through the inner cylinder and is cooled gradually as it ascends from the outlet. The accumulation of warm air in the upper part of the apparatus is shown by the existence of a high temperature region H.

Three values of T_a, T_w, and T_t were recorded during the course of formation of a snow crystal. They were plotted as a function of time and the resulting graph was taken to represent the history of the conditions leading to the production of the crystal in its final form.

The Relation between the Crystal Form and the External Conditions. Inasmuch as T_a and T_w are the factors controlling the crystal form, a given type must be indicated by a point on the (T_a, T_w)-diagram. In fact, it was proved experimentally that a certain type of crystal occupies a certain region in the (T_a, T_w)-diagram. A crystal of complicated form which has been developed through successive stages of various conditions is represented by a succession of arrows in the (T_a, T_w)-diagram.

The relation between the crystal form and T_a and T_w has been examined for 700 crystals by Hanajima [7]. The results are plotted in the (T_a, T_w)-diagram shown in Fig. 19. Crystals are classified into eight types: den-

dritic, sector, plate, spatial assemblage of plates, cup or scroll, needle, irregular needle, and column. Region I in Fig. 19 is the condition for dendritic growth. It means that the necessary condition for dendritic development is that T_a is between −14C and −17C and the supersaturation is above a certain lower limit. Contrary to what has hitherto been believed, the air temperature is an important factor controlling the crystal form.

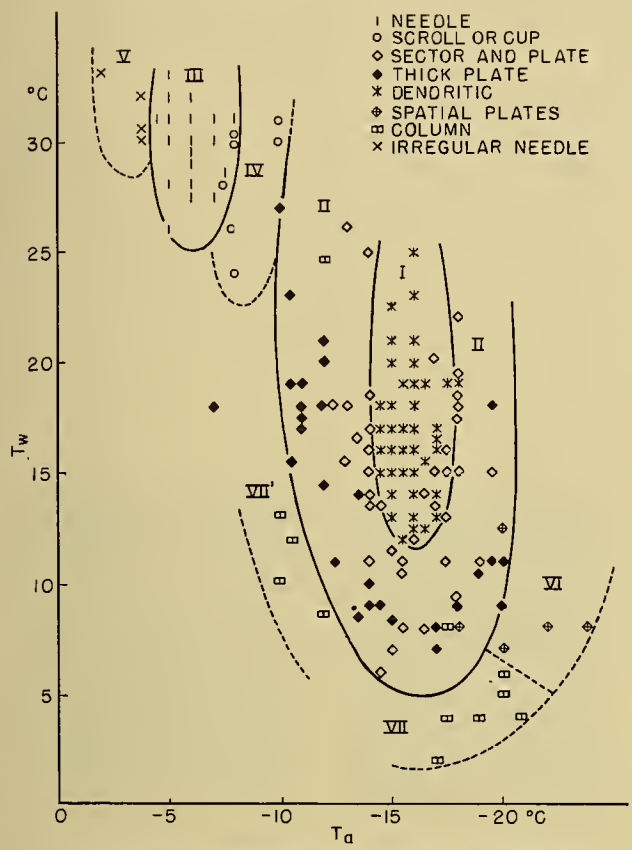

Fig. 19.—Relation between the crystal form and T_a and T_w.

The degree of supersaturation s is taken as the ratio of the amount of vapor and droplets per unit volume (measured) and the amount of saturated vapor at T_a per unit volume (calculated). In other words s is a relative humidity in the range of supersaturation, where humidity is taken to mean the total water content in the atmosphere. The ratio s was measured by a gravimetric method using P_2O_5, and Fig. 19 was transformed into Fig. 20, which represents the crystal form as a function of T_a and s [8].

Figure 20 tells us more clearly that the chief factor controlling the form of the crystal is the air temperature, and that a given type of crystal can be obtained for a wide range of supersaturation. It has generally been believed that the degree of supersaturation determines the form of the crystal, but Fig. 20 shows that this is not the case, except within a certain range of temperature. The transition of the plate form into the dendritic form occurs when the supersaturation exceeds about 110 per cent, provided the temperature lies between −14C and −17C. Above a supersaturation of 140 per cent the crystal is attached with numerous water droplets and becomes a rimed crystal.

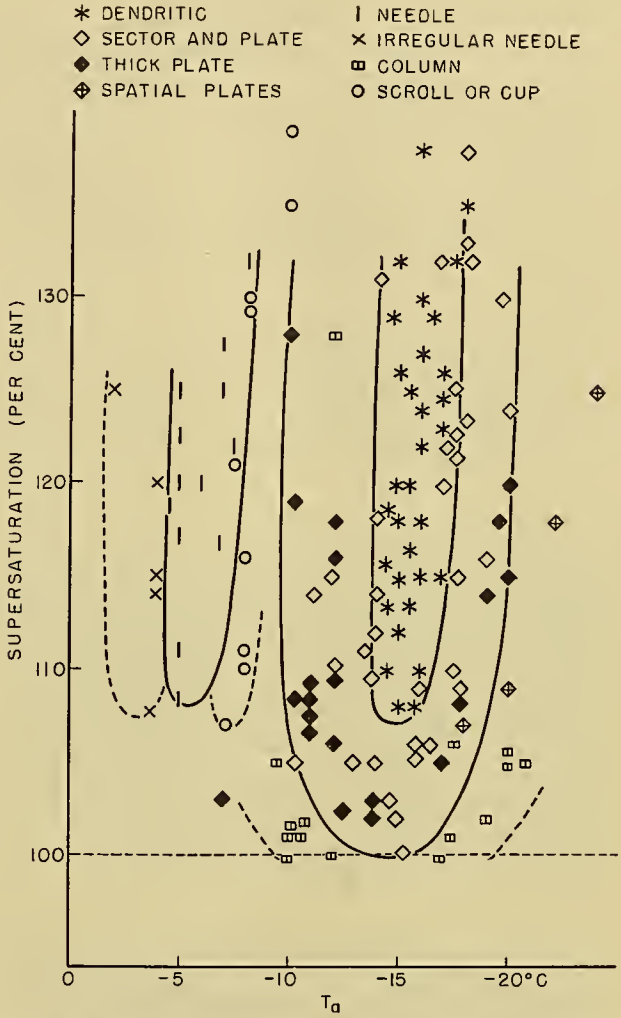

Fig. 20.—Relation between the crystal form and T_a and s.

The Growth of Snow Crystals. The acquisition of a detailed technique made it possible to produce all types of snow crystals almost at will. In the case of natural snow, the germ is first formed in the upper atmosphere as a result of the sublimation of water vapor on a nucleus or by the spontaneous transformation of a supercooled droplet. While falling through the atmospheric layers of various temperatures and degrees of supersaturation, this germ gradually grows into a snow crystal of complicated structure and eventually reaches the ground. In the case of artificial snow, this development can be observed in the course of time since the primitive crystal is recognized at a spot on the rabbit hair.

The course of formation is studied by taking photomicrographs of the growing crystal from outside the apparatus at regular time intervals while keeping the crystal in the apparatus. In order to maintain the crystal at rest against the convection current, the rabbit hair is stretched on a frame of thin glass rods.

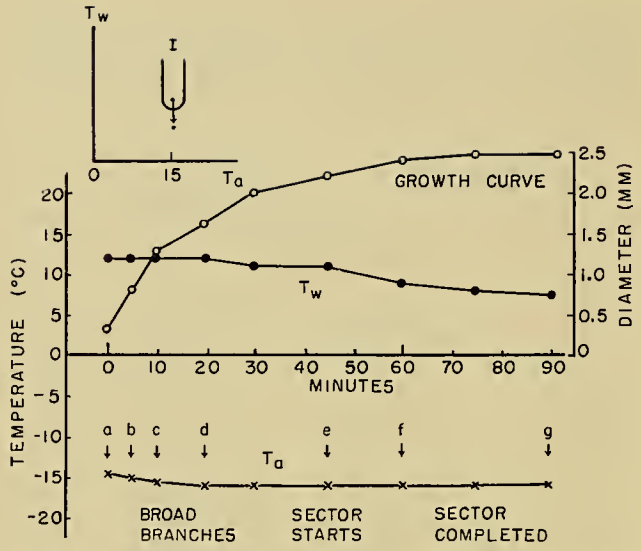

FIG. 21.—Condition of formation of the crystal in Fig. 22.

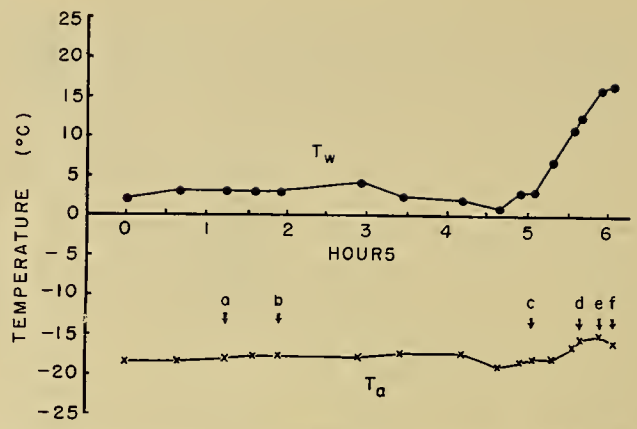

FIG. 23.—Condition of formation of the crystal in Fig. 24.

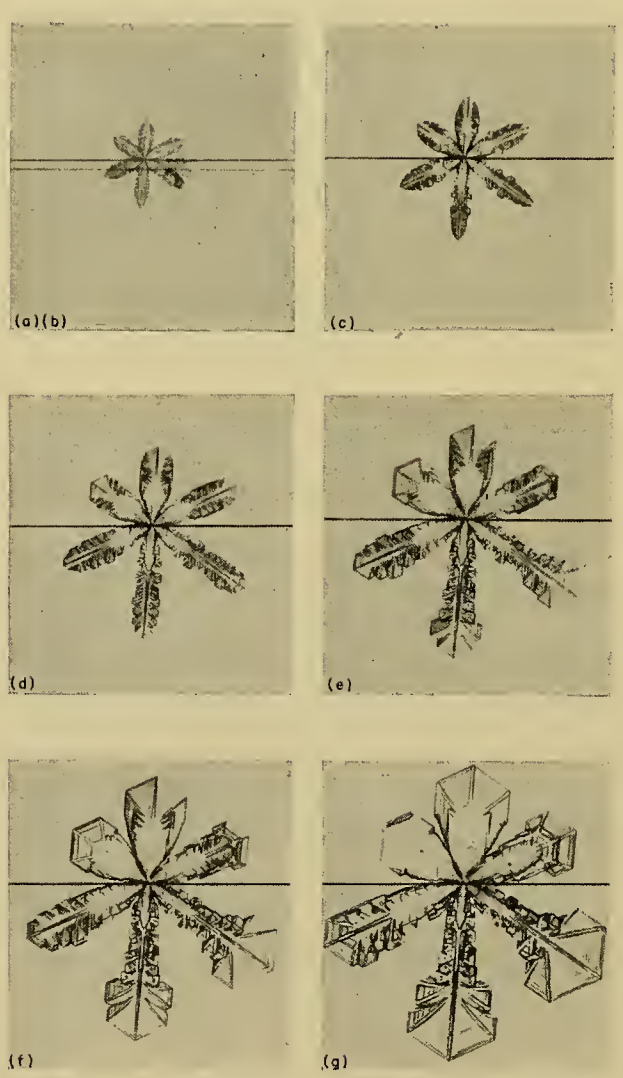

FIG. 22.—Course of formation of a stellar crystal with plates (×14).

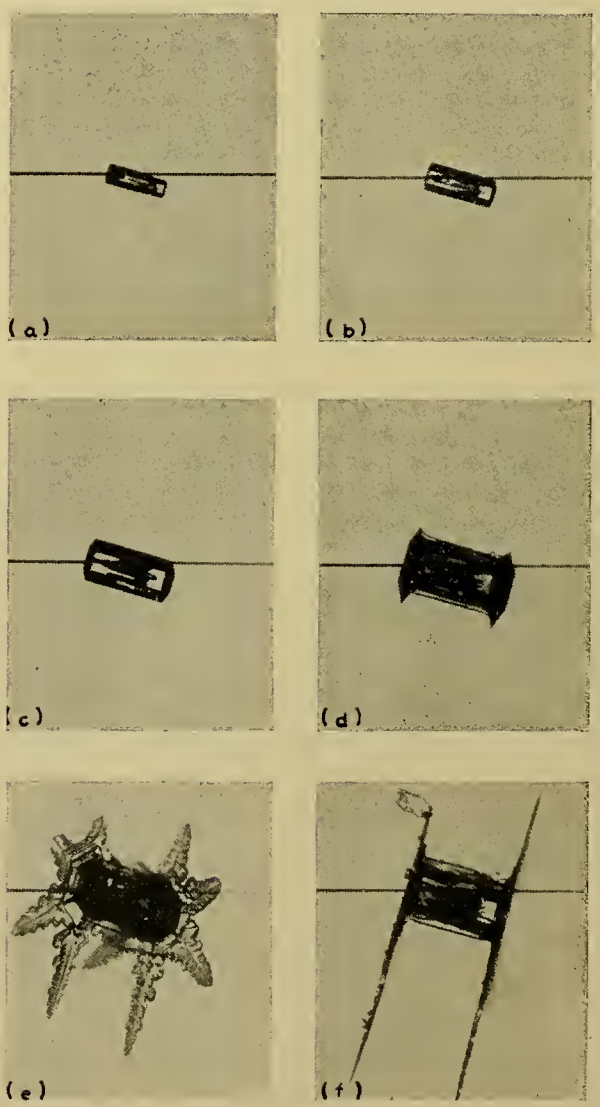

FIG. 24.—Successive stages in the formation of a capped column (×37).

Two examples showing the process of formation are illustrated, together with the condition of formation, in Figs. 21–24. Figure 22 shows the mode of formation of a stellar crystal with plates at the ends of the branches (*P1h* in the general classification). The conditions of formation are given in Fig. 21. The lettered arrows on the T_a curve show the moments at which the photomicrographs of Fig. 22 were taken. During the stages between *a* and *d* the air temperature T_a was kept at nearly −15C and T_w at about +12C; that is, the condition was within the region for dendritic development, although the degree of supersaturation was comparatively low. The crystal became a broad-branched type *P1d*, owing to the small amount of supersaturation. After this stage had been reached, T_w was gradually lowered, while T_a was kept at −16C. This change in condition made the rate of growth gradually smaller. The condition changed to that for plate development, as shown in Fig. 21. Accordingly, the tips of the branches began to widen (*e*), and finally the expected crystal was obtained as shown in *f*.

Figures 23 and 24 show the course of formation of a capped column. This crystal was obtained by first making a column under the condition of low temperature and humidity, and then changing the condition rapidly to that favorable for dendritic development. In the initial stage the column was slender in form. This column thickened without marked longitudinal elongation. In this example it took nearly five hours to attain the dimension observable in the central part of the natural capped column (Fig. 24*c*). Then the temperature of the water in the reservoir was raised rather quickly in order to increase the degree of supersaturation. In this condition a plate began to develop at each end of the column (*d*). The crystal finally developed into a completed, capped column as shown in *f*, through the stage *e*.

These two examples show that any crystal belonging to a certain type or a combination of several types can easily be produced artificially. The method is simple, the only thing to do is to establish the required conditions one after another.

APPLICATION OF SNOW CRYSTAL STUDIES TO METEOROLOGY

Upper-Air Conditions and Snow Crystal Forms. As described in the preceding paragraph, a snow-crystal germ is born in the upper atmosphere and develops to a snow crystal of complicated shape as it is subjected to different conditions while falling through the various layers of the atmosphere. The final form of the snow crystal observed at the earth's surface is an accumulation of the elements produced in the various strata.

Shedd [14], Wegener [15, p. 284], Findeisen [6], and others inferred the mechanism of snow crystal formation by comparing many photographs of snow crystals. Of these theories, Wegener's will be chosen as representative. According to Wegener, a primitive hexagonal crystal is first formed in a sufficiently supersaturated zone of the atmosphere and then the space between the branches is filled with ice while the crystal is falling through a less supersaturated layer, transforming the dendritic crystal into plate form. The next stratum of sufficient supersaturation will add other dendritic appendages. When the crystal comes down through a subjacent layer of less supersaturation, it becomes a larger plate. By the repetition of processes similar to these, many variations occur in the form of the snow crystals.

Wegener's theory was examined in an artificial snow experiment, and the transformation of a dendritic crystal into a plate in a less supersaturated atmosphere was found not to be the actual case, as described in the experiment of Fig. 22. However, the general idea of his theory is correct. Our experiments show that a complicated form of snow crystal is made by adding the characteristic features, corresponding to variations in the external conditions. The simplest example is a plate with dendritic extensions. It is produced when a plate is made in the upper atmosphere and the dendritic branches grow from the corners of the plate while the crystal is falling through lower layers suitable for dendritic development.

By examining the natural snow crystals from this point of view, we can infer to some extent the structure of the upper atmosphere, because the external conditions controlling the form of snow crystals are now made clear.

Comparison of Natural and Artificial Snow Crystals. By comparing natural and artificial snow crystals, the upper-air conditions can be estimated for each of various types of crystals, using the (T_a, T_w)-diagram. Four examples will be described.

Fern-Like Hexagonal Crystal. Natural and artificial crystals of fern-like type are reproduced in Fig. 25*a–b*. The form and structure of the branches are very similar in both cases, although the central part is somewhat different. The course of formation of this fern-like crystal is shown in Fig. 25*c*. During the primitive stage the temperature is lower and the supersaturation is less than the critical value for dendritic formation. Then the initial stage of this crystal is the irregular assemblage of small sectors. From this stage both T_a and T_w are increased so that the condition is most favorable for dendritic development. The crystal rapidly grows in a fern-like form and reaches the stage shown in Fig. 25*b* in about 15 min. The rate of growth is very large in this case. The rate of fall is about 1 km hr^{-1} for crystals of this type. Thus we can infer that there must be an atmospheric layer with ample moisture and a temperature of about −15C near the earth's surface, when the crystal of the type shown in Fig. 25*a* is observed at the earth's surface. The thickness of this layer will be about ¼ km.

Stellar Crystal with Plates at the Ends of the Branches. The crystal shown in Fig. 26*a* is frequently observed in nature, and is designated as *P1h* in the general classification. The artificially produced crystal shown in Fig. 26*b* certainly belongs in this group. The fine strips in the plate portion are less marked in the case of natural snow, which is probably due to sublimation in the

FIG. 25.—(*a*) Natural, and (*b*) artificial crystals of fern-like type; (*c*) physical conditions during course of formation.

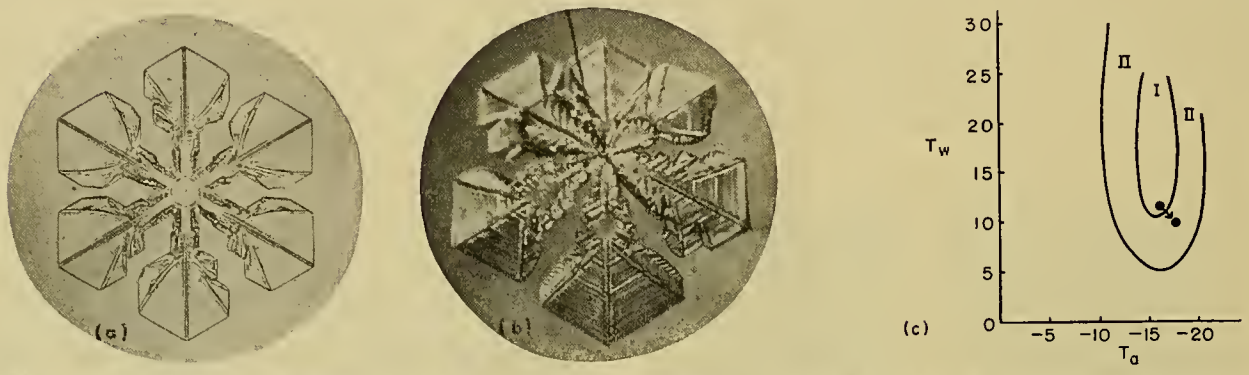

FIG. 26.—(*a*) Natural, and (*b*) artificial crystals of stellar type with plates; (*c*) physical conditions during course of formation.

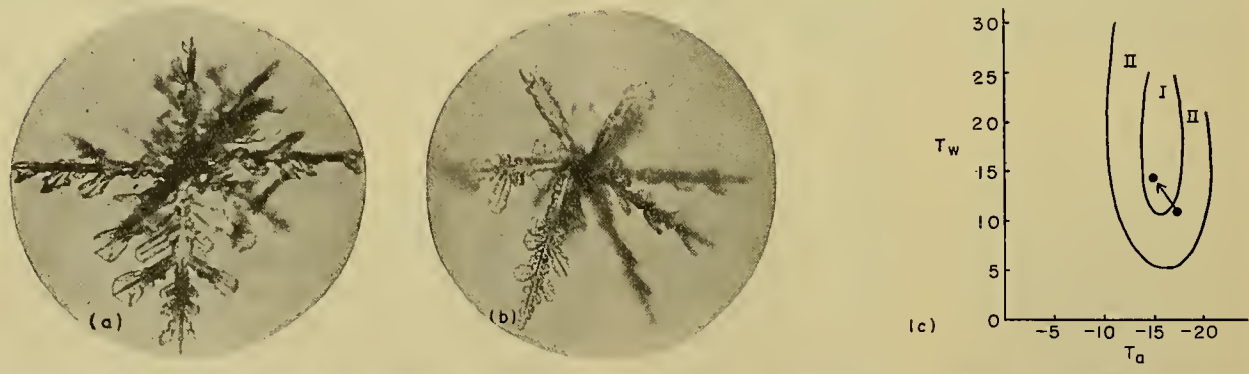

FIG. 27.—(*a*) Natural, and (*b*) artificial crystals of spatial radiating type; (*c*) physical conditions during course of formation.

FIG. 28.—(*a*) Natural, and (*b*) artificial crystals of dendritic type with small plates attached; (*c*) physical conditions during course of formation.

atmospheric layer near the earth's surface. The course of formation is shown in Fig. 26*c*. In the early stage the condition is favorable for stellar development, then both T_a and T_w decrease to just outside Region I, and the crystal is kept under this condition for a considerable time. In general, when a crystal is kept under a nearly constant condition at a point near the lower border of Region I, the ends of branches show the tendency to develop into plate or sector form. This can be explained as the result of a decrease in the vapor supplied per unit area to the crystal surface. The crystal of the form shown in Fig. 26*a* seems to show that a slightly supersaturated, homogeneous layer exists near the earth's surface with a thin layer suitable for dendritic development above it.

Spatial Assemblage of Radiating Type. The conditions favorable to formations of this type are also clear. The early stage is obtained at lower T_a and T_w. In the case of the crystal in Fig. 27*b*, T_a is approximately -20C and T_w is about $+12$C. After the formation of this primitive stage, T_a and T_w are increased to the condition of dendritic development, that is, $T_a = -16$C and $T_w = +15$C. Dendritic branches grow rapidly in space, giving the crystal of Fig. 27*b* in about twenty minutes. We may interpret the natural crystal of Fig. 27*a* as follows: In the upper atmosphere there exists a layer, at a temperature of -20C or lower, in which the crystal is born; this minute crystal falls through a layer characterized by ample moisture and a temperature of nearly -15C. The lower layer will be a few hundred meters in thickness.

Dendritic Crystal with Small Plates Attached. The natural snow reproduced in Fig. 28*a* is a good example of this type. Many small plates are attached in a spatial manner to the base crystal of hexagonal type. An artificial crystal similar to this is shown in Fig. 28*b*. This crystal is produced by a condition just the opposite of that for the preceding case. The base crystal is formed in Region I in about fifteen minutes. Then T_a is gradually decreased to -24C in two hours. The supply of water vapor is also reduced. In this second step many small plates extend out in space from various points of the base crystal. As the rate of growth of these small plates is very small, the development takes nearly two hours in this example. When this type of natural snow is observed, we may expect a thick layer of temperature inversion. The layer near the earth's surface must be at a temperature of nearly -20C and less supersaturated. The thickness of this layer is estimated from the data of falling velocity to be about 2 km, and above this cold layer there exists a warm, well-supersaturated layer at a temperature of nearly -15C. The warm layer may not be as thick as the cold layer, say, only several hundred meters.

The foregoing descriptions demonstrate the possibility of inferring the structure of the lower atmosphere by a synthesis of the examination of crystal forms and a knowledge of artificial snow. In this article we did not consider the question of wind. The horizontal component of wind velocity has no sensible influence upon our argument, but the vertical component and the turbulence will have a strong effect.

CONCLUDING REMARKS

In discussing the phenomenon of ice crystal formation in the atmosphere, the most important factor is the problem of supersaturation. As Bennett said in 1934 [2], "the evidence is merely negative as to whether supersaturation does or does not exist, and positive evidence is urgently required." This question is still left unanswered. It is very unlikely that more water vapor than the critical value of saturation exists in a purely gaseous state in the natural atmosphere. Strictly speaking, the existence of ample supersaturation of water vapor in air cannot be expected, except in some special cases such as at the instant of adiabatic expansion in a Wilson cloud chamber. Furthermore, in this special case the duration of the supersaturation is extremely short, say, 10^{-3} or 10^{-4} sec. Supersaturation observable in the natural atmosphere is considered to mean the existence of minute droplets in saturated air.

In our artificial snow experiment, the supersaturation was defined as the excessive water content in the atmosphere, including both water vapor and minute droplets. Values of supersaturation as high as 120 per cent or 130 per cent, referred to in this article, can thus be understood. We learned that in a rising air current which appeared to be transparent by ordinary illumination, a strong beam of light showed a Tyndall phenomenon. If a glass plate covered with oil film is exposed to the ascending air current for a short time, and then examined under a microscope of high magnification, a great many minute droplets can be observed in the oil film, many of them about 2 μ in diameter, the smaller ones about 1 μ. These minute droplets are not frozen to a snow crystal in the form of droplets, but appear to spread on the crystal surface at the moment when they are brought in contact with the crystal. In helping the growth of crystals, they act as if they were in a gaseous state. The larger droplets, 20–30 μ in diameter, behave in a manner quite different from that of the minute ones. They freeze to the snow crystal as droplets, and give rise to a rimed crystal. High values of supersaturation can be expected in the natural atmosphere, if by the supersaturation is meant an excessive water content, including water vapor and minute droplets of the order of 1–2 μ in diameter. This is not unreasonable, since in the process of condensation these minute droplets act as if they were in a gaseous state. Larger droplets such as ordinary fog particles do not behave in the same manner as do these minute droplets.

Another point is the relation between the air temperature and the crystal form. The apparently new result described in this article may be interpreted as follows: T_a is a factor controlling the rate of heat transfer liberated by the formation of the crystal and this rate of heat transfer determines the form of the crystal. Another explanation is that the vapor pressure difference between ice and supercooled water at the same temperature is a function of temperature, and that this

vapor pressure difference determines the mode of crystal development, that is, the crystal form. Further studies along this line, which is an attempt to introduce the methods of experimental physics into meteorology, may contribute something to this new field of meteorology.

SNOW AND ITS RELATIONSHIP TO EXPERIMENTAL METEOROLOGY

By VINCENT J. SCHAEFER

General Electric Research Laboratory, Schenectady, New York

Snow in its many forms has been the subject of observation, conjecture, and scientific discussion for many centuries. It has long been recognized that a better understanding of the formation of snow in the atmosphere would eventually explain some of the little-known but important meteorological processes related to the development of precipitation.

The occurrence of supercooled clouds in the free atmosphere is one of the most common of meteorological phenomena, even in many parts of the tropics. The importance of such clouds as the source of much heavy precipitation has been pointed out by Bergeron [2]. The differential in vapor pressure between water and ice at all temperatures below 0C permits the rapid growth of snow particles at the expense of the liquid cloud droplets. This process is of basic importance in the formation of snow and is a primary mechanism in the science of experimental meteorology.

Types of Solid Precipitation

Over the years, many attempts [25] have been made to devise a classification system for describing the observed forms of solid precipitation. Most of these have been either too elaborate for easy use or have failed to include important forms.

During the course of snowstorm studies in 1944, an effort was made to devise a simple system which might be used in the field under adverse weather conditions. Revisions of this system were made as extensive field experience demonstrated the need. In the fall of 1949, an effort was made to pool the experience of workers concerned with this problem in Switzerland, Japan, Canada, and the United States. The chart shown in Fig. 1 illustrates the classification decided upon and the code and types proposed for international use. Although subject to further revision, it is believed that the types shown on this chart include most of the basic forms which occur in the atmosphere throughout the world.

As may be expected, there is an almost infinite variation in the forms of the basic types of this solid precipitation. These differences may be so minor as to be visible only under high-power magnification or great enough to be easily seen by the unaided eye. Typical variations in structure and relative size of the plate-type crystal are illustrated in Fig. 2.

Nakaya [16], in his ice-crystal experiments, showed that the crystal habit of snow may be due entirely to the temperature of the environment and the moisture supply available. It is quite likely that most crystals in the free atmosphere grow as they do because of these environmental conditions.

It should be pointed out, however, that the habit of crystals may also be modified by an entirely different mechanism—the blocking of the growth on certain crystal faces by the adsorption of surface-active chemicals [27]. Figure 3 illustrates the effects which may be induced by traces of an impurity in the air where crystals grow. Further research to understand these effects better is under way in the General Electric Research Laboratory.

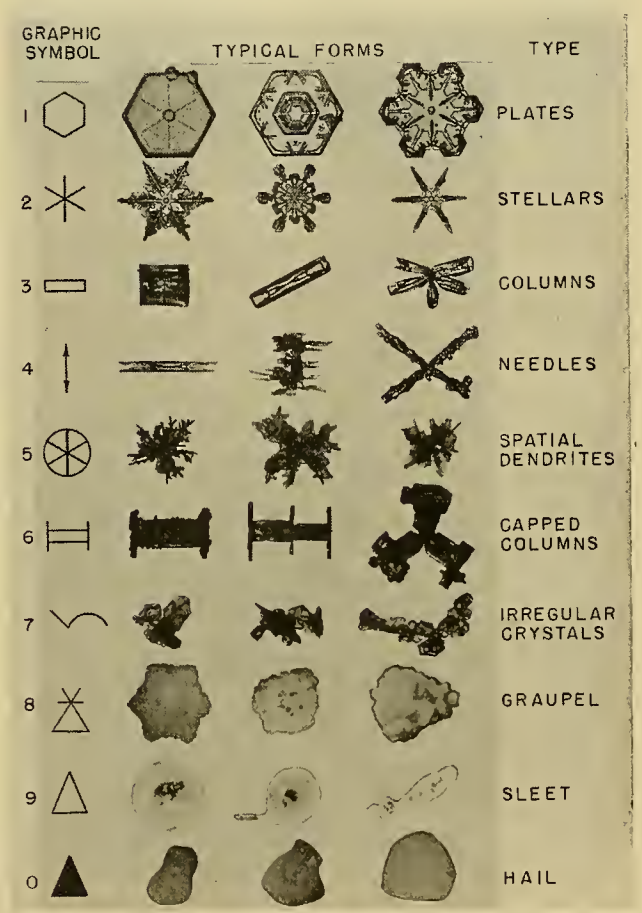

Fig. 1.—Types of solid precipitation.

The Use of Replica Techniques for Studying Snow. In 1941 a method was devised by the writer [18, 19] for making permanent replicas of snow crystals. The technique encases a snow or frost crystal within a thin plastic film which, as it forms, makes an exact three-dimensional impression of the surface features of the crystal. The replica solution, consisting of one to three parts of the synthetic plastic polyvinyl formal dissolved in 100 parts of ethylene dichloride, readily wets an ice surface. By capillarity and surface activity it rapidly covers any ice crystal which comes in contact with it.

The solvent evaporates in five to ten minutes, after which the slide (glass, cardboard, etc.) bearing the samples may be warmed above freezing. Upon melting, the water molecules evaporate through the thin film, leaving a hollow shell which refracts and scatters light

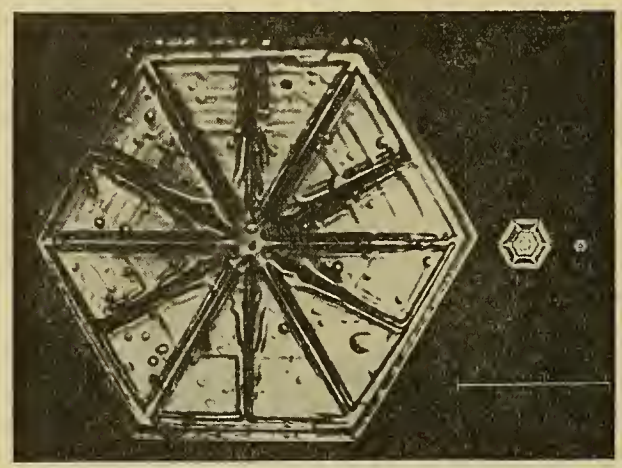

FIG. 2.—Variation in size and structure of hexagonal plates (*a*) from low and middle type clouds, (*b*) from high cirrus type clouds, and (*c*) from very low altitudes, forming in clear air.

in a manner quite similar to the optical properties of the original crystals. Figure 4 shows a typical replica of a stellar crystal.

This technique is also very useful in making surveys of snowstorms since it permits the accumulation during the course of a storm of many samples of crystals for

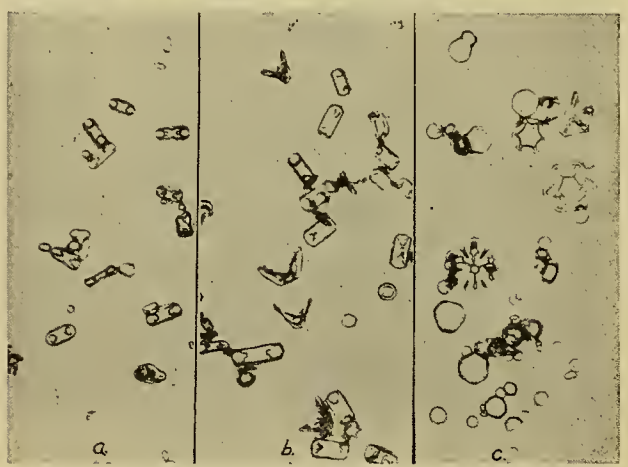

FIG. 3.—The effect of acetone vapor on the crystal habit of snow. (*a*) Effect of 1 molecule of acetone to 10 molecules of water. (*b*) Effect of 1 molecule of acetone to 100 molecules of water. (*c*) Effect of 1 molecule of acetone to 1000 molecules of water.

subsequent study. Samples have now been obtained by this method in most parts of the world as well as at high altitudes in the atmosphere during flight studies with Project Cirrus airplanes. Figure 5 shows some of these replicas.

A more recent technique for making replicas utilizes a plastic spray.[1] Although the solvent used in this spray would not work under normal conditions, since it would tend to dissolve the ice structure, its evaporation is so rapid that satisfactory replicas are obtainable if brief applications are made. This technique works best if the spray container is cooled below 0C. However, if the spraying is carried out in air at temperatures below freezing, enough entrainment of cold air takes place so that good replicas have been made at −10C with the dispenser temperature at 25C.

moisture content of the air in which such precipitation may form at temperatures below 0C range from more than 3 g m^{-3} in supercooled water-droplet clouds to such small amounts that the air contains no visible cloud, although it is supersaturated with respect to ice.

Ice Crystals in Cirrus Clouds. The highest clouds commonly found throughout the world are the cirrus types. Evidence is accumulating suggesting that most clouds of this type form at temperatures below −39C. At this temperature, spontaneous nucleation occurs, that is, foreign particles are not required to initiate the formation of ice crystals.

The simple 22° halo and the more complex optical phenomena of cirrus clouds are generally produced by snow crystals of special form floating with a particular orientation in the air. Since the initial formation of such crystals may take place in clear air having a very low total water content, it is obvious that they must be very small and their growth quite slow. The crystal types common to these high-level clouds are the hex-

agonal plate and column and the irregular or asymmetric crystal.

The "false cirrus" streaming from the tops of very high cumulonimbus clouds, the condensation trails of

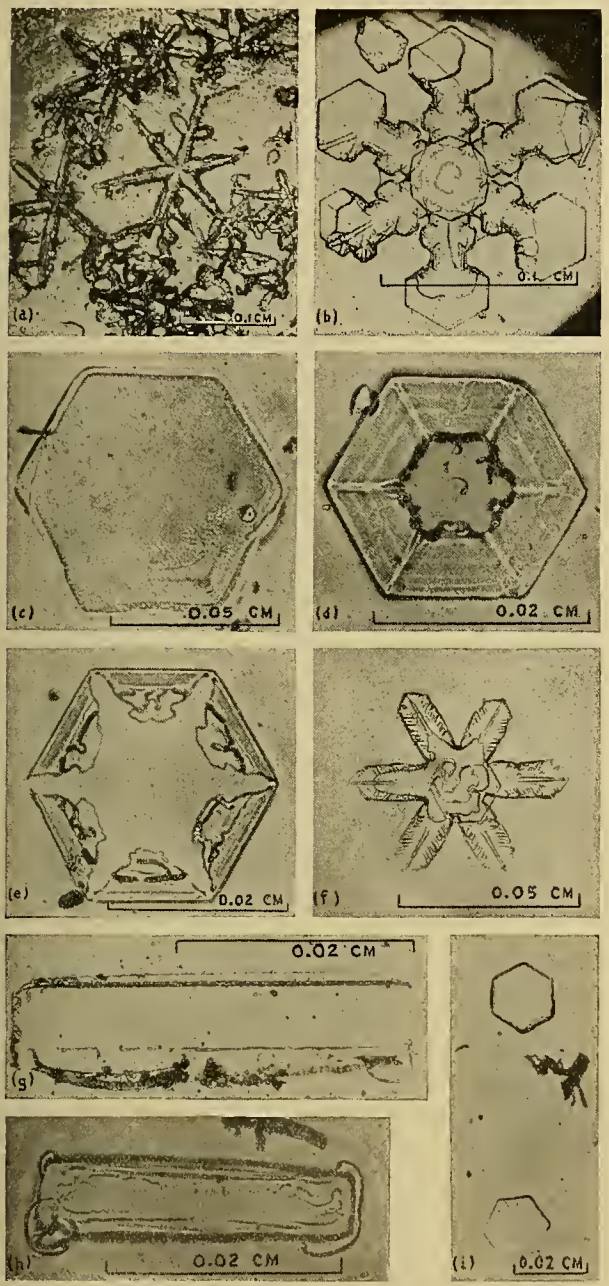

FIG. 5.—Replicas of snow crystals from seeded clouds. (*a*) Stellar forms from cloud seeded with silver iodide. (*b*) Stellar crystal from overseeded cloud after 51 min. (*i*) Plates found in stratus cloud 15 sec after dry-ice seeding.

ice crystals from airplanes, and the ice fogs occurring in polar regions have features similar to cirrus clouds. Their formation is due, apparently, to the fact that the air in which they form is colder than −39C. In the case of condensation trails, this temperature occurs momentarily in the vortices streaming from the wings and propeller tips. When supercooled cloud droplets are present, they become frozen when contacted by the innumerable crystals spontaneously generated in their vicinity.

A snowstorm developing from cirrus clouds often requires from two to six hours for the crystals to reach the ground. A thin ice crystal haze producing a 22° halo thickens until the sun or moon finally appears as though covered by a ground-glass screen. Before reaching the ground, cirrus-type crystals may fall into lower supercooled clouds and become coated with cloud droplets. They sometimes serve as crystallization centers for the formation of stellars, spatial dendrites, or needles.

Solid Precipitation in Stratus Clouds. When air is stabilized by the presence of an inversion, the clouds which form contain considerably smaller quantities of liquid water than do cumulus clouds. Supercooled stratus clouds rarely have a liquid-water content higher than 1 g m^{-3}, while the average content ranges between 0.2 and 0.4 g m^{-3}. Ground fogs may be considered as a special type of stratus cloud, since they have similar properties.

Depending on the properties of supercooled clouds previously mentioned, the precipitation types from stratus clouds may vary from capped columns and stellar crystals to sleet. A deficiency of ice nuclei in stratus clouds is likely to produce a fairly heavy coating of rime on the crystals. When a layer of warmer air overruns a colder stratum, light rain may form in these upper clouds, becoming supercooled as it falls into the lower clouds and reaching the earth as rain or sleet. As sleet forms, an icy shell first coats the raindrop and freezing proceeds toward the center. As the last of the water freezes, the expansion causes the formation of many strange protuberances which modify the symmetry of the icy sphere.

Precipitation in Solid Form from Cumulus Clouds. High values of liquid water occur only in cumulus or thick orographic type clouds. Highest values of condensed cloud water occur when the vertical thickness of the cumulus exceeds 10,000 ft and the base of the clouds is in warm air, that is, warmer than 0C. Moist air forced upward by encounter with a mountain barrier and generally aided by convection induced by insolation often produces orographic clouds with features similar to cumulus. Such clouds may cover the upper slopes of a mountain or may have their bases considerably higher than the summit.

Many precipitation types form within the cold part of cumulus clouds. These include stellars, needles, spatial dendrites, and irregular crystals in addition to graupel and hail. The crystal forms may be expected when suitable ice nuclei occur in abundance, while graupel and hail types are products of a deficiency of such nuclei.

Factors Controlling the Formation of Snow

As suggested in previous sections, and demonstrated in the laboratory by the classic work of Nakaya [16],

solid precipitation types are a product of the variations in the physical nature of their environment. Let us consider the factors which initiate the formation of such particles in the atmosphere. At least five different mechanisms are of importance.

1. *Freezing Nuclei.* It has been shown experimentally [35] that bulk water may be cooled to at least −38.5C. Under carefully controlled laboratory conditions, which avoid seeding of the water by contact with frosted surfaces, water nearly always supercools to at least −5C to −10C [4]. In streams and ponds, however, there are always some freezing nuclei which initiate freezing in water at a temperature of only a few hundredths of a degree below 0C. However, the concentration of such particles seems to be relatively low, rarely exceeding 1×10^3 m^{-3}. The thin discs which form on such nuclei in flowing water are responsible for the formation of frazil ice [33].

Little evidence has been found in our studies to suggest that freezing nuclei are important in the formation of snow crystals in the atmosphere. The centers of snow crystals rarely show them to be formed on a frozen cloud droplet except when the crystals have apparently formed at very low temperatures. The size of cloud droplets, which on the average range between 8 and 25 μ, makes such observations quite feasible. However, the failure to find frozen droplets in the centers of snow crystals may be explained by some recent studies in my laboratory which show that cloud droplets condensed on silver iodide particles in warm air tend to assume the form of perfect hexagonal plates and columns as they freeze at a temperature of −4C.

2. *Sublimation Nuclei.* The most important mechanism responsible for the *initiation* of snow-crystal formation in the lower portion of the free atmosphere involves sublimation nuclei. These are very small air-borne particles upon which ice forms by the condensation of water molecules directly from the vapor phase.

Despite the claims of some workers [6, 40] who believe sublimation nuclei are extremely rare, experiments show that small particles of silicates and minerals common to desert and volcanic sources readily serve as active centers for snow-crystal formation. Figure 6 illustrates the temperature dependence of the effectiveness of different types of such particles when they are placed as an aerosol in cold air having sufficient moisture to be supersaturated with respect to ice.

Sublimation nuclei should not be confused with condensation nuclei. The latter are foreign particles, such as those produced by the evaporation of sea spray [9, 41], the burning of combustible waste, the particulate effluent from industrial processes, and the smoke of forest fires. Water molecules condense on such particles to form liquid droplets. Concentrations of condensation nuclei range from 2×10^8 salt particles per cubic meter in the air over the sea to concentrations of 1×10^{12} particles per cubic meter in the vicinity of industrial regions [11]. While the relative concentration of condensation nuclei is important when related to the stability and persistence of liquid-water clouds, since it is an important factor in determining the particle size, no evidence is known which relates the ordinary condensation nuclei to the formation of ice crystals.

A three-year study of the concentration of sublimation nuclei in air passing over the summit of Mount

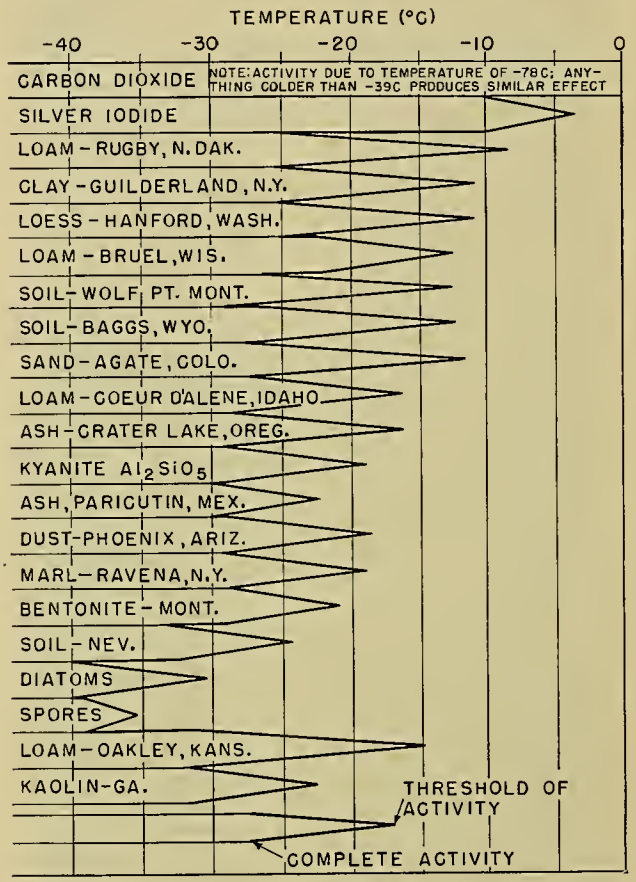

FIG. 6.—The temperature dependence of foreign-particle ice nuclei.

Washington (elevation 6288 ft) using the cold-chamber method [29] showed that the variation in concentration of such nuclei ranged from none observable to ten million per cubic meter [30]. Table I illustrates the range in concentration observed in the 8137 observations

TABLE I. RANGE IN CONCENTRATION OF ICE NUCLEI AT MOUNT WASHINGTON
JANUARY 1, 1948–JANUARY 1, 1950

Approximate number of nuclei per cubic meter of air	Number of observations
1×10^0–5×10^2	4062
5×10^2–5×10^5	3388
5×10^5–1×10^7	687

which were made up to January 1, 1951. Such studies are continuing at Mount Washington and are being supplemented by similar observations at Socorro, New Mexico. A study of the synoptic situation existing when the levels of nuclei were unusually high suggests that they might be dust particles from the Northwest and

the Great Plains which were carried aloft as the air passed over those regions.

The very important conclusion which may be inferred from the Mount Washington studies is that for extended periods the atmosphere contains very low concentrations of suitable nuclei for the formation of ice crystals. Thunderstorms, hail, heavy rain, and other storms which have part of their structure above the 0C isotherm are basically related in their developmental stage to the concentration of ice nuclei in the atmosphere where they form. It follows, therefore, that any modification in the natural concentration of such particles in the atmosphere should exert profound effects on the formation of such storms. This subject will be discussed in greater detail later under the section on experimental meteorology.

The most effective sublimation nucleus known at the present time is silver iodide. This fact was discovered during research activity in the General Electric Research Laboratory [37]. Since silver iodide does not normally occur in the free atmosphere, and since it is much more active than any known natural ice nucleus, far-reaching and anomalous effects may be expected to occur when large numbers of these particles are released in regions where supercooled clouds occur.

As Vonnegut [39] has shown, silver iodide is a very effective nucleus for ice formation because its atomic and crystalline characteristics, including the size of the unit cell, approach the structure of ice within 1 per cent.

While the temperature dependence of the effectiveness of sublimation nuclei is probably related to a number of such parameters, the nature of the surface layers of molecules seems to be of primary importance in determining whether a surface will be *kryophilic* or *kryophobic*.[2]

Typical effects illustrative of these properties are shown in Fig. 7. The kryophilic surface (Fig. 7*a*) consisting of clean glass, is coated with frost crystals whose major, or *c*-axis, is perpendicular to the glass surface. The kryophobic surface (Fig. 7*b*) is glass treated with a molecular layer of a dichlorosilane. Over the relatively small area contacted by frost crystals, the *c*-axis is parallel or inclined away from the treated surface at an acute angle. This surface is so strongly kryophobic that less than 1 per cent of the glass is contacted by the frost crystals.

It is my belief that such properties are inherently related to the effectiveness of, for example, a clay particle (active as an ice nucleus at −15C) and the spore of *Lycoperdon gemmatum* (which does not act as a crystal center until the temperature becomes −36C).

3. *Spontaneous Nuclei.* At high levels in the atmosphere where cirrus clouds form, or at lower levels when the temperature is below −39C, foreign particles are not required for the formation of ice crystals. Whenever moist air supersaturated with respect to ice is cooled below −39C tremendous numbers of ice crystals appear spontaneously. One of the easiest ways of demonstrating this effect is to use the cold-chamber method previously mentioned [29]. Tiny dry-ice fragments

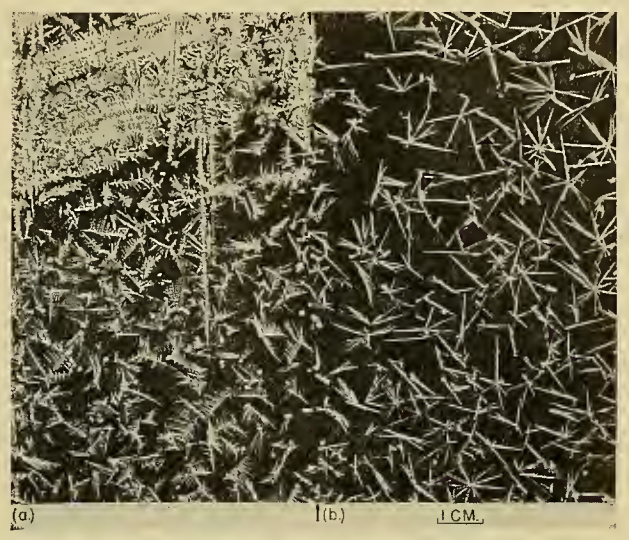

Fig. 7.—Frost crystal structure produced by surface property of a solid surface: (*a*) crystal forms on clean glass, and (*b*) crystal forms on glass coated with a very thin layer of a dichlorosilane.

dropped into cold air supersaturated with respect to ice produce many millions of ice crystals, as shown in Fig. 8. Photomicrographs of such crystals are shown in

Fig. 8.—Snow crystals forming in a cold chamber with air supersaturated with respect to ice.

Fig. 9. It can easily be shown that 1 g of dry ice may generate 10^{16} ice crystals under such conditions [26].

The critical temperature which produces this effect may be determined in a simple manner. By solidifying

2. These terms are suggested to designate the tendency of a surface to permit or to prevent, respectively, the formation of a frost layer.

a small drop of mercury with liquid air or dry ice and then passing it through saturated air at −15C, ice crystals are generated while the mercury is in the solid state. The instant it melts (melting point of *Hg* is −38.89C) ice crystals no longer are formed. Further

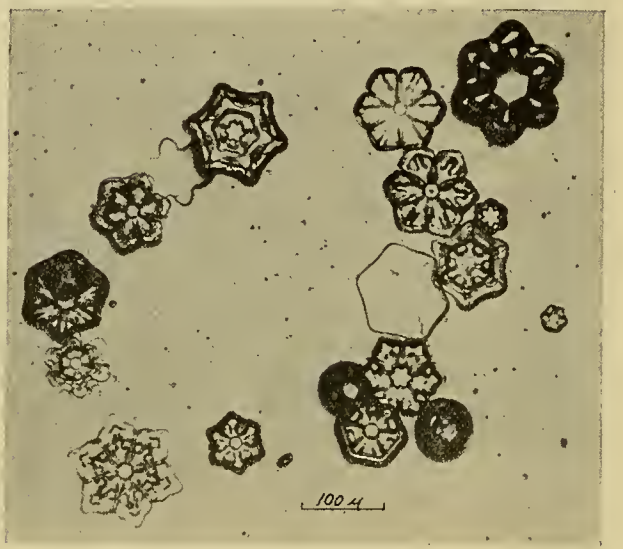

FIG. 9.—Typical hexagonal plates formed by dry-ice seeding of a supercooled cloud.

evidence that the critical transition temperature for the spontaneous nucleation of ice crystals is close to −38.9C may be demonstrated by using a sealed cold chamber with remote controls to add moisture to the air. As the air in the chamber is warmed and cooled between −37C and −41C, ice crystals suddenly appear at a temperature of −38.9C ± 0.1C. If the air remains colder than the critical temperature, snow forms and falls to the floor of the chamber continuously. This proves that foreign particles cannot be a factor in this process, since they would be quickly exhausted from the air by precipitation. A further interesting fact is that when the temperature passes from −38C to −39C many of the supercooled waterdrops present become frozen and serve as condensation centers for ice-crystal formation. Asymmetric crystals grow on such particles in such a manner as to suggest that the cirrus-type crystals shown in Fig. 10 probably grow on cloud droplets which freeze when they supercool to −39C and are seeded by several very small ice crystals spontaneously generated in their vicinity.

Another effect related to this critical transition temperature has been demonstrated by Vonnegut [38]. By suddenly expanding a cubic centimeter of air so that the rapid adiabatic expansion cools the air below −39C it is possible to form 10^{12} ice crystals within a small fraction of a second.

Since it is unusual for ordinary air to contain more than 1×10^6 cm^{-3} foreign particles of all kinds it is obvious that spontaneous nucleation occurs under these conditions.

4. *Fragmentation Nuclei.* A snow crystal formed by any of the preceding processes produces some interesting effects when in the presence of a supercooled cloud. Although the mechanism is not yet clearly understood, the effects may be produced experimentally [34]. They involve the formation of tiny ice particles in the immediate vicinity of the larger crystal, each of which subsequently grows to form new snow particles. It is believed at present that fragile dendritic growths in

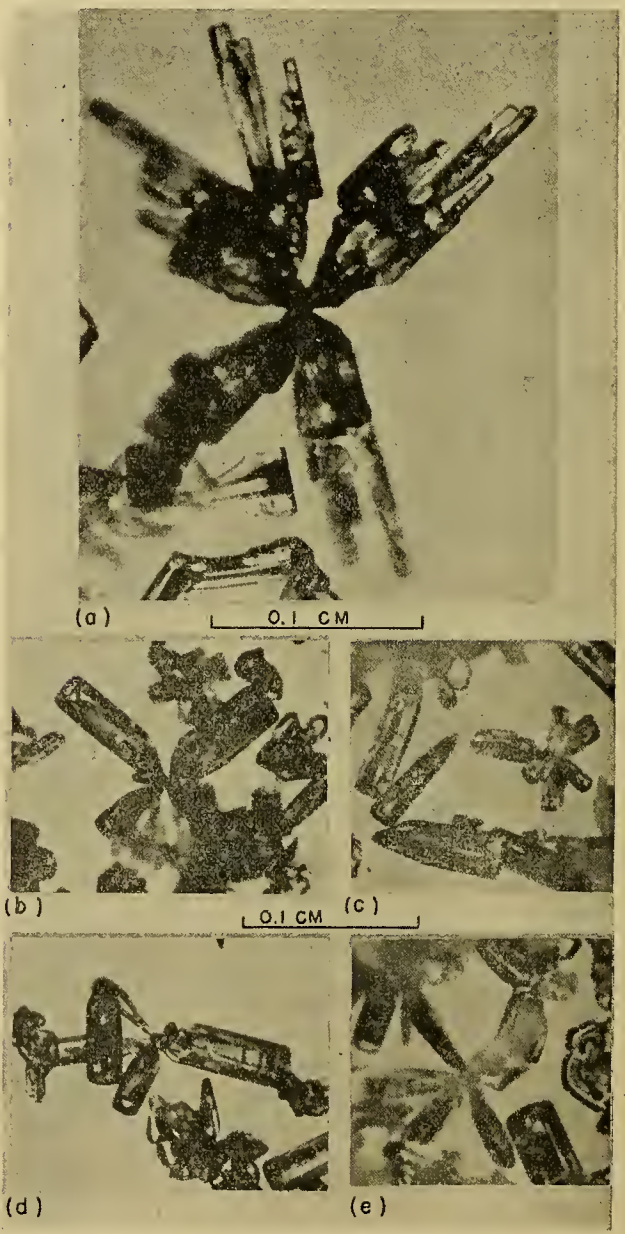

FIG. 10.—Compound columns from cirrus clouds probably growing on a frozen cloud droplet.

the form of fine needles, and frostlike structures of the type shown in Fig. 11 are required for the development of fragmentation nuclei.

Contact by liquid cloud droplets may produce thermal strains leading to the fracture of the delicate portions of such crystals. Collision with other particles could also lead to the formation of such fragments. In many snowstorms, especially those having convective activity, high winds, and supercooled clouds, broken

and irregular crystals (the latter probably formed on fragmentation nuclei) constitute the major portion of the snow reaching the ground. It is this chain reaction mechanism which must be responsible for most extensive snowstorms not seeded by high-level clouds.

5. *Electrification Ice Nuclei.* That some type of electrification may be an important producer of ice nuclei is suggested by laboratory experiments and field observation. If a field of several hundred volts per centimeter is established in a supercooled cloud, dendritic treelike growths may form if some ice crystals are present. These treelike forms seem to grow from a combination of crystals and supercooled cloud droplets. Subsequently they break and form many ice fragments, each of which becomes a potential ice crystal.

This effect has never been observed unless ice crystals were already present, and it may be associated with the Workman-Reynolds effect [42]. Although it has so far been impossible in the General Electric Research Laboratory to show any freezing effect or production of nuclei using either a-c or d-c fields up to 1 kv cm^{-1} in a supercooled cloud, a temporary coexistence of cloud droplets and ice crystals shows electrification phenomena which may be of great importance. These effects may be of primary importance in the establishment of the chain reaction which seems to be necessary to produce the many crystals required to form an extensive snowstorm. Certainly high fields are present in many snowstorms [22], particularly in those characterized by convective activity and supercooled clouds.

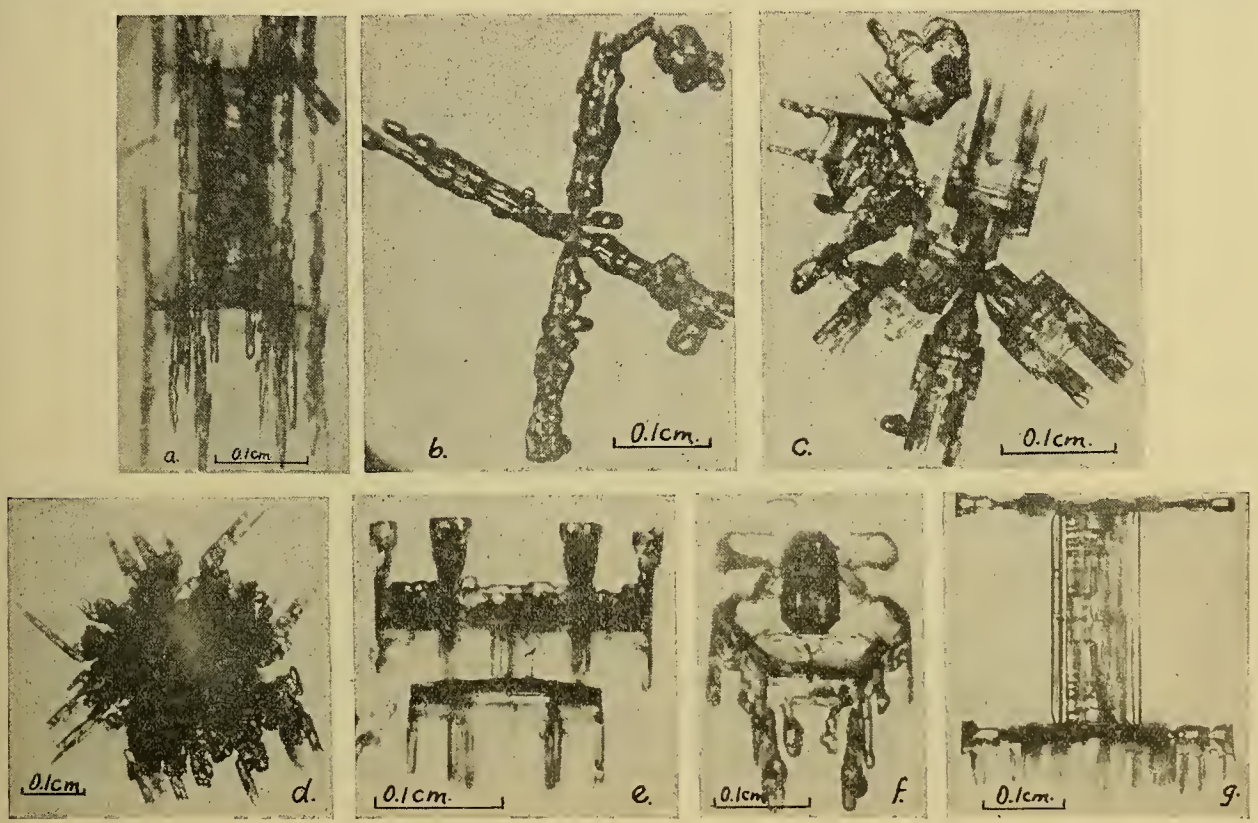

Fig. 11.—Types of snow crystals which are probably important in the formation of fragmentation nuclei.

Figure 12 illustrates the type of atmospheric electricity observed in snowstorms.

Electrical Properties of Snow

It is very likely that the chain reaction mechanisms suggested by the operation of fragmentation processes at temperatures from −12C to −20C and the interesting effects observed in electric fields are complementary mechanisms. Since snow crystals reaching the ground are often electrically charged, it seems obvious that they are indicators of mechanisms operating in the atmosphere where they were formed. The electrification may be a causative agent or an end result. The highest amounts of atmospheric electricity observed occur at temperatures not far below freezing and with broken stellars, needles, spatial dendrites, and sleet particles, all of which could be associated with fragmentation and electrification processes. Typical air-to-ground currents during a snowstorm are shown in Fig. 12.

The fact that the fragmentation of snow crystals causes a large increase in the charging potential of snow crystals shows the close interrelation which must exist between these two effects [22]. Further studies in this field should produce important results.

Factors Controlling the Life Cycle of Supercooled Clouds

The icing of aircraft, the formation of hail and graupel, and the electrical phenomena of thunderstorms are typical products of supercooled clouds. The growth,

persistence, or dissipation of such clouds is governed chiefly by evaporation and nucleation.

Evaporation may affect the life cycle of a supercooled cloud in two ways: (1) the cloud droplets may evaporate into air which is unsaturated with respect to water, or (2) they may evaporate and the water molecules condense on an ice nucleus. Either process is a very rapid one and for most purposes may be considered to be instantaneous. Nucleation under special conditions may cause a direct freezing of the supercooled cloud droplets when the concentration of ice nuclei is very high. It is unlikely that this latter process occurs very often in the atmosphere except at the spontaneous nucleation temperature of −39C. The tops of large cumulus clouds and the initial stages of some cirrus clouds show abundant evidence of this process. It is probably due to this mechanism that the optical properties of clouds at the −39C level remain unchanged. The freezing of cloud droplets does not alter the shape of the particle, and although high concentrations of small ice crystals probably form nearby they immediately disappear by evaporation since their vapor pressure is higher than that of the larger frozen cloud droplets. It is very likely that compound crystals like those in Fig. 10 form on cloud droplets frozen by this process.

When supercooled clouds are warmer than −39C and the air containing them is moist enough to prevent evaporation, several different processes control their persistence. If the cloud is of a stratiform type with few or no ice nuclei present, a freezing drizzle may develop and fall from the base of the cloud. If a few ice nuclei are present in the cloud, snow crystals form on them, grow rapidly, and fall out of the cloud as scattered snow particles. Initial growth develops from the vapor phase, but as soon as the crystals become sufficiently large to move faster than the surrounding supercooled cloud droplets, they sweep up cloud droplets which freeze as they touch the snow crystal. Graupel, hail, some forms of ice needles, and all other rimed crystals depend on supercooled cloud droplets for their formation. The presence of such crystals in the atmosphere is evidence of a low concentration of ice nuclei in the air mass and the absence of a chain reaction.

Most cumulus clouds supercool above the 0C isotherm and persist for unpredictable periods. If the moist air forming them carries with it certain types of air-borne dust which have the proper structure to serve as potential ice nuclei, they may rise only three or four thousand feet above the freezing level before shifting over to snow. At times, however, they may go nearly or all the way to the −39C level without enough snow crystals forming to initiate a chain reaction effect. It is this type of cloud which may develop into a storm producing lightning or hail, or both. At other times, the cloud may be completely dissipated into false cirrus at high altitudes without producing any precipitation.

Orographic clouds also have a strong tendency to become supercooled. Such places as the summit of Mount Washington have extensive icing storms during much of the year. Because of the very large vertical component of the wind caused by the mountain barrier, coexistence of supercooled cloud droplets and ice crystals is more likely than in most clouds in the free air, since condensation occurs faster than the evaporation-diffusion process can transport the moisture to the ice crystals. It is likely that orographic clouds in which

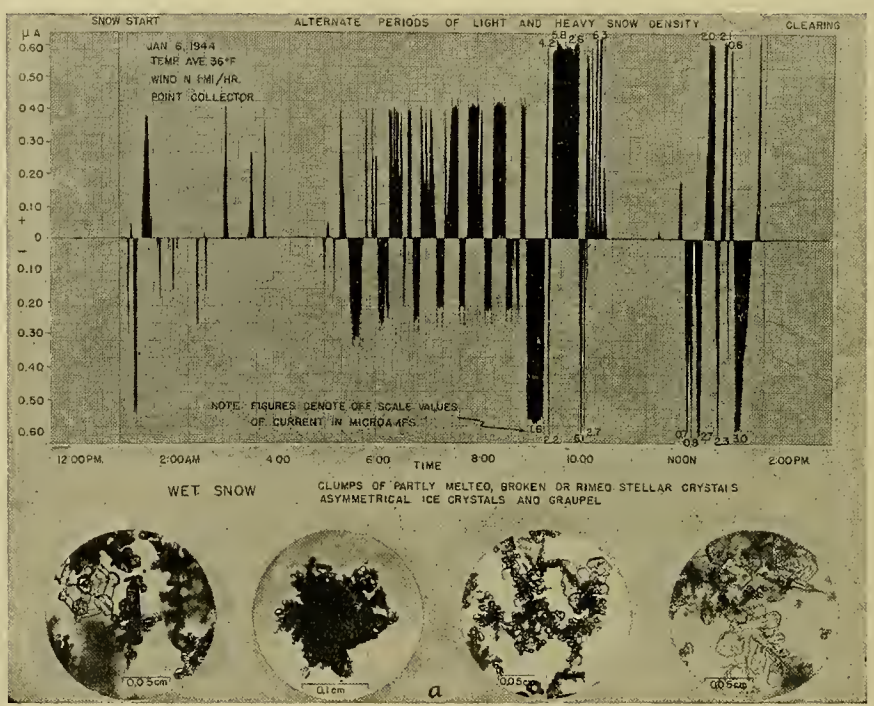

FIG. 12.—Typical air-to-ground electric currents which often occur during convective type snow storms.

the wind velocity is high have features in common with the more turbulent portions of large cumulus clouds.

The Development of Experimental Meteorology

Control of the Weather. For many years man has dreamed of the possibilities of exercising control over the weather. To a limited degree he has accomplished this by heating, air conditioning, and artificial illumination of homes, workshops, and places of culture and amusement, as well as by the use of flood-control techniques, irrigation systems, and similar technical improvements in limited areas of his countryside.

One of the first suggestions that scientific research would eventually lead to the modification of weather systems is contained in an important paper by Findeisen [5]. Others, such as Gathman [7], had previously proposed the use of dry ice to produce clouds and rain, a method subsequently tried by Veraart [36]. Their idea was to use dry ice to chill the air below its dew point to produce clouds and rain. Unfortunately, countless tons of dry ice would be required to produce even a small rainfall by this method. The insignificant results produced by this method and others, such as the formation of rain by dumping electrified sand into clouds (tried by Warren and Bancroft), led in 1926 to the conclusion (Humphreys [8]) that none of the proposed methods were of any consequence and that they had no scientific importance.

Recent Advances. In 1941 Langmuir [12] and Schaefer devised a method for producing an artificial fog which eventually was used to blanket sixty miles of the Rhine Valley as well as other large areas during the latter part of World War II. Subsequent research following the production of artificial fog involved basic studies of precipitation static on aircraft and of aircraft icing [20]. This latter study, which involved research with supercooled clouds, led the writer to discover a method of changing a supercooled cloud to ice crystals in a simple but highly effective manner [21].

When this discovery was made, it was immediately apparent that the time had arrived to attempt the modification of clouds on a large scale. Unlike all previous attempts, the methods proposed would utilize dry ice as a triggering device to release the energy stored within supercooled clouds by causing a change in phase of the unstable supercooled cloud. By utilizing the inherent instability of such clouds it was planned to introduce ice crystals in such numbers that large effects would be produced according to the Bergeron mechanism.

The first experiments designed to transform a supercooled cloud to snow crystals were carried out by Schaefer in the fall of 1946 [24] and the early months of 1947. In March 1947 cloud-seeding experiments using dry ice in supercooled clouds were undertaken on a larger scale with government support. This activity, called Project Cirrus, was sponsored by the Army Signal Corps and the Office of Naval Research, using planes and crews supplied by the Air Forces, with technical consultation provided by Langmuir and Schaefer of the General Electric Research Laboratory at Schenectady, New York.

The laboratory, field, and flight studies of this group have been described in more than a score of reports [15]. Flight studies up to July 1950 have included experimental investigations of clouds in the northeastern United States, New Mexico, Puerto Rico, and Florida. In addition, detailed observations of natural clouds have been undertaken in various parts of the country and many field and laboratory projects have been completed or are actively under way at the present time.

Cloud Modification Methods

The Use of Dry Ice to Modify Clouds. As mentioned earlier, whenever any object with a temperature less than −39C is introduced into air colder than 0C and supersaturated with respect to ice, tremendous numbers of ice crystals are generated. The simplest method for achieving this effect is to introduce small fragments of dry ice (solid carbon dioxide) into the air. This may be accomplished in the free atmosphere by using free balloons, projectiles, or airplanes, or by placing the dry ice or expanding liquid CO_2 in orographic clouds on mountains or in supercooled ground fogs.

Dry ice may be introduced into various parts of clouds with differing effects. The ice crystals it generates will immediately disappear unless the air is below freezing and supersaturated with respect to ice. Langmuir has summarized our general methods [14]. Briefly, the judicious use of dry ice may (1) dissipate clouds, (2) precipitate clouds, or (3) make existing clouds more persistent.

Clouds may be dissipated by seeding their tops from an airplane before they develop a deep supercooled layer or by seeding along a line from the side, using liquid carbon dioxide. It is much easier to dissipate clouds after they have passed their maximum vertical development than when they are actively growing, since seeding a growing cloud may trigger off a chain reaction.

Since it requires considerable experience and judgment to select a growing cumulus, experiments planned to cause precipitation may fail because of improper selection of the area to be seeded. If the larger of the towers in a cumulus system are selected for seeding while the airplane is in a position to see the general cloud system, the selected cloud will probably be in a subsiding state before seeding takes place. Under such conditions, dissipation is likely to result. The life cycle of such clouds is so short [43] that an intimate knowledge of their dynamic properties is essential if effective seeding is to be achieved.

The effects are generally spectacular when the seeding is done to release effectively the heat of sublimation stored in supercooled clouds. In unstable air, a tremendous upheaval may occur if the seeded cloud is actively growing and well supercooled. This increase in convection occurs because of the heat liberated by the shift from the water to the ice phase. In stratus clouds, this increase in temperature may amount to 0.5C, while in

large cumulus formations an increase in temperature of several degrees within the cloud is quite possible.

The Use of Silver Iodide as a Seeding Agent. An entirely different process for seeding the atmosphere with ice nuclei involves the use of submicroscopic silver iodide particles produced with a smoke generator. Since this substance is most effective at temperatures below −10C, techniques which are somewhat different from those used with dry ice are employed. Silver iodide lends itself particularly well to the use of ground generators and the modification of large cloud systems. By the use of the generators described by Vonnegut [39] it is possible to produce invisible smokes of silver iodide particles in such high concentrations as to infect many thousands of cubic miles of the atmosphere. Not only is it possible to exceed the highest concentrations found in the free atmosphere, but the silver iodide particle is a more effective ice-crystal nucleus than any which has thus far been found in nature.

The Seeding of Clouds with Water. Under certain conditions the precipitation cycle may be initiated in large cumulus clouds by introducing large water drops into actively convective portions of the cloud. This seeding initiates a chain reaction [13] involving the growth and breakup of water drops. Since this seeding mechanism is not related to snow, it will not be discussed here.

Cloud Seeding

Effects of Seeding Operations. Laboratory experiments show that a concentration of about 50 ice nuclei per cubic centimeter will exhaust all the moisture in a supercooled cloud in about 10 sec. Since supercooled clouds are sometimes invaded by ice crystals falling from cirrus clouds, it is interesting to determine their effect on a supercooled cloud. Such crystals have a falling velocity of about 1 m sec^{-1} and a concentration in the air of about 1×10^4 m^{-3}. Assuming typical atmospheric conditions with the invading crystals moving through the supercooled cloud at a rate of 1 m sec^{-1}, not more than 20 min would be required to use up the supercooled cloud droplets in a specific region of a cloud. This process may often be observed in the free atmosphere.

The Overseeding of Clouds. In most natural clouds the number of cloud droplets ranges from 100 to 500 cm^{-3}. This is about one hundred times more than the number of potential ice nuclei thus far observed under natural conditions. Supercooled droplets can be transformed to ice crystals without a decrease in the number of the individual particles when they reach the spontaneous nucleation temperature of −39C or when they are artificially seeded with dry ice or silver iodide. Concentrations of ice nuclei exceeding 10,000 cm^{-3} may be induced in natural supercooled clouds by proper seeding methods. This fact is most easily demonstrated in a supercooled ground fog [23]. Since one gram of dry ice may generate 1×10^{16} ice crystals, this minute quantity effectively distributed could fill 1×10^7 m^3 of air (a volume of fog 100 m thick, 100 m wide, and 1000 m long) with a concentration of 1000 cm^{-3}.

The optical effects produced by overseeding of clouds are very striking. Very beautiful halos, sun pillars, sun dogs, etc., of brilliant color and high intensity occur in overseeded clouds. Sometimes a peculiar bluish hue develops in an overseeded cloud because the particles are small with respect to the wave length of visible light.

As suggested by Bergeron [3] and Schaefer [31], overseeding may eventually be used to cause the transport of moisture from one region to another or may be utilized to form large reservoirs of ice nuclei. Such formations could affect clouds some distance from the seeding point or any clouds in the infected region which became large enough to form precipitation. It follows therefore that overseeding of supercooled clouds may become an effective method for preventing the formation of rain or snowstorms in specific areas.

Figure 13 illustrates the active formation of an ice-crystal cloud by dry-ice seeding in clear air. The early

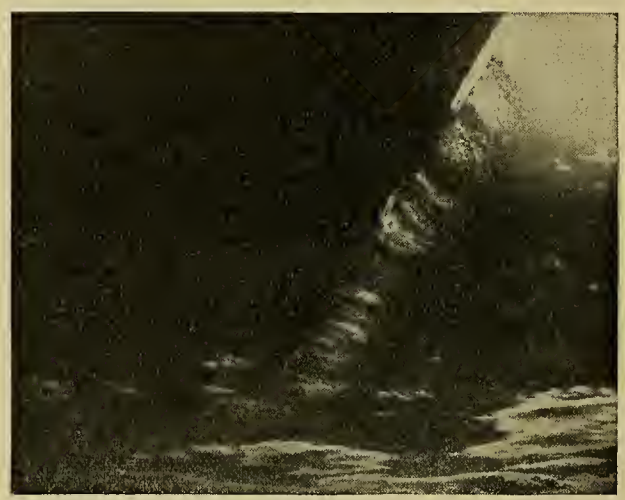

FIG. 13.—The formation of an ice-crystal cloud by dry-ice seeding of air supersaturated with respect to ice at a temperature of −18.5C.

stage of a stratus-cloud seeding, producing removal of cloud cover over a local region, is illustrated in Fig. 14. Not enough moisture was contained in these clouds to produce substantial amounts of precipitation.

The Effective Seeding of Clouds. To achieve maximum effectiveness in the form of energy release and precipitation, it is necessary to seed young, actively growing cumulus clouds in a region of the atmosphere which is potentially unstable. The clouds should be seeded when they have a vertical thickness above the freezing level of 3000–5000 ft. Care must be exercised that the dry-ice particles penetrate the entire supercooled region.

As mentioned earlier, the seeding of cumulus clouds with dry ice to effect a sudden release of the heat of sublimation should produce unusually intense convection in growing cumulus clouds. Such effects have been observed in experiments conducted in Australia [10], South Africa [1], Canada [17], and New Mexico [32]. Under optimum conditions, judicious seeding to produce this effect could lead to a local convergence by breaking through a limiting inversion layer or other restrictive atmospheric condition. At times it is conceivable that

this could develop into marked alterations of the general synoptic situation. Despite the skepticism of some meteorologists, it seems reasonable to presume that such end results are quite likely, since this would be in

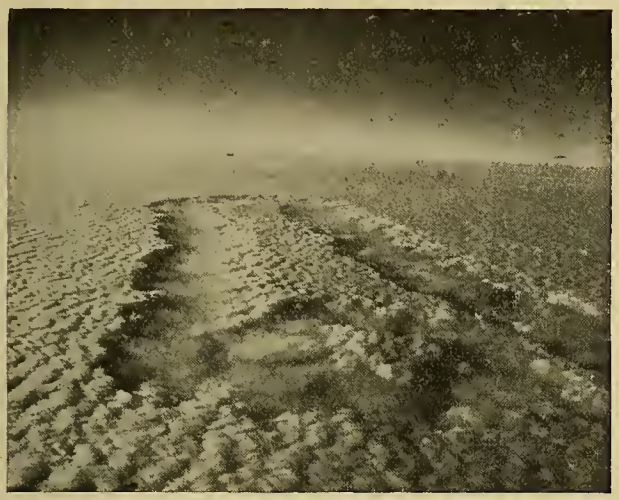

FIG. 14.—The effect produced in a supercooled stratus cloud with ½ pound per mile of dry ice. The straight legs of the pattern are 18 miles long.

accord with the physical processes which lead to the formation of certain types of widespread natural storms.

Figure 15 shows an area of cumulus clouds in New Mexico seeded with pellets of dry ice when the clouds were actively growing and had a vertical thickness above the supercooled layer of 5500 ft. The photograph illustrates the appearance of the clouds 33 min after four

FIG. 15.—A view of the cloud area in New Mexico seeded with dry ice. The towering cumulus to the right of center was seeded with one pound of dry ice 15 min earlier.

pounds of dry ice were placed in five local regions along the Monzano Mountains. Figure 16 shows the subsequent development of the rainstorm triggered off by the dry-ice seeding. This cloud system produced its initial precipitation 15 min after dry-ice seeding was completed. The development of this storm was followed in minute detail by radar, two ground stations, and two airplanes. No other precipitation could be detected by the radar within sixty miles, and the precipitation records show nothing within a hundred miles except from seeded clouds. An adjacent mountain range, the Sandia Mountains, to the northwest of the area used in these experiments, was employed as a control region. Although cumulus clouds similar to those which were seeded formed over the Sandias throughout the day, no

FIG. 16.—Rain showers falling from cumulus cloud 90 min after seeding with one pound of dry ice.

trace of precipitation occurred from them. A series of experimental studies in July 1950 produced similar results.

The Effects of Silver Iodide Seeding. Anomalous cloud effects were anticipated and have been observed in regions where experiments were conducted with silver iodide. Figure 17 shows a large precipitation area which

FIG. 17.—A rainstorm which originated in a region containing silver iodide produced by a ground generator.

began in air filled with silver iodide particles and formed rain several hours before any other clouds developed in the region on July 21, 1949 near Albuquerque, New Mexico. Further information on this subject may be obtained from Langmuir's and Vonnegut's papers [13, 38].

Possibilities and Limitations in Seeding of Clouds

In any science it is possible to establish the possibilities and limitations of certain physical phenomena.

In experimental meteorology, such factors as the stability of the atmosphere, the concentration of ice nuclei, the absolute humidity, the circulation of the air, and the heating by the sun are important.

The absence of clouds, the presence of strong temperature inversions, large variations in wind velocity with altitude, low absolute humidity, small lapse rate, weak circulation, large quantities of cirrus clouds, and other similar atmospheric situations present serious, if not absolute, limitations to cloud-seeding operations. Conversely, if large cumulus clouds occur without the formation of precipitation, if there is abundant moisture, large lapse rates, low concentrations of ice nuclei, an absence of wind shear, and few inversions, the possibilities of cloud modification are great and some unquestionable effects may follow the use of proper seeding techniques. However, even under ideal conditions, it is still possible to have poor or inconclusive results unless intelligent seeding techniques are followed.

With evidence now at hand it is possible to draw some fairly definite conclusions with regard to the possible effects of seeding methods under the following general conditions.

Thunderstorms. Thunderstorms generally occur in clouds of large vertical thickness containing large amounts of supercooled droplets and some ice crystals. By dissipating or overseeding all clouds in a thunderstorm "breeding area" [28] shortly after they pass above the freezing level, it should be possible to prevent the formation of a thunderstorm. This may be accomplished by local seeding with dry ice from an airplane or from projectiles from ground stations, but eventually it may be accomplished most effectively and over a larger area by the proper use of silver iodide generators at the ground. Initial success may be expected from orographic type thunderstorms rather than from the much more complex storms associated with frontal systems.

Hailstorms. Since it is believed that damaging hailstorms are due primarily to the presence of a deep supercooled layer and a relatively small number of ice nuclei, techniques similar to those employed in preventing thunderstorm development should be effective in preventing hail. Since such storms often possess special characteristics in regions where they are common, a careful study will suggest the best method of dealing with them. If certain features of the local topography favor their development, it may be possible to locate silver iodide generators so that their effluent will be carried into the most active part of the cloud system. It is important to provide so many ice nuclei that the competition for the available moisture is too great for individual particles to grow large. It would be more effective, however, to prevent the development of a deep supercooled layer and for this purpose a program of early seeding should be more effective.

Increased Precipitation from Cumulus Clouds. As suggested earlier, large cumulus clouds sometimes form without the development of a precipitation phase. High wind shear at upper levels in the atmosphere or a low concentration of ice nuclei are two of the factors responsible for such occurrences.

Proper seeding by artificial means may have economic value in several ways. Besides forming precipitation in the vicinity of such clouds, the process would prevent the formation of false cirrus streamers which sometimes reduce solar radiation to such an extent [30] that the formation of other convective clouds downwind is seriously affected. The formation of precipitation also may lead to increased air circulation which, if accomplished on a large enough scale, could change the weather pattern.

As suggested recently by Langmuir [14], the seeding of a given portion of the atmosphere with a sufficient concentration of ice nuclei to start a chain reaction serves primarily to increase the probability of precipitation coming from any given synoptic situation. Depending on the "triggering" nature of the seeding effect, the effectiveness of any particular seeding operation will involve many complex physical relationships in the atmosphere not yet understood in enough detail even to consider at this time.

The Prevention of Windstorms and Torrential Rains. Local windstorms of the type characterized by high gustiness and turbulence are often caused by downdrafts induced by heavy precipitation. By preventing the formation of thick cumulus clouds through judicious seeding techniques, this type of local storm damage may be prevented. Whether these techniques can be expanded to affect larger storm systems must await further experimental studies.

The Elimination of Ground Fogs. Under special conditions supercooled ground fogs may form by radiational cooling, contact of cold air with warm open water, or some similar condition. Seeding of such fogs may be effective in dispersal if care is exercised that they are not overseeded. An initial concentration not greater than 100 particles per cubic centimeter must be achieved. If the concentration is much greater, the fog will be overseeded and the visibility will become reduced from that existing in the supercooled fog.

No methods are known at present which would lend themselves to the effective dissipation of warm fogs.

The reduction of ice-crystal fogs which form at very low temperatures is also a difficult condition to overcome by seeding methods, since these fogs commonly form at temperatures below −39C. Under such conditions, any surplus of moisture exceeding the frost point comes out in the form of ice crystals. In the temperature range from 0C to −39C, the air may become supersaturated with respect to ice. Under such conditions, it may be possible to put out an optimum quantity of ice nuclei to precipitate the moisture as snow.

The Elimination of Supercooled Clouds in the Atmosphere. It is now feasible, using the mechanisms referred to in the preceding sections, to limit the formation of supercooled clouds in the atmosphere. This control over supercooled clouds is not necessarily limited to local regions; if desired it could be achieved throughout

the world. By using silver iodide in relatively insignificant quantities, a situation could be developed under which ice crystals would immediately form in *any* cloud which formed in air colder than −5C.

The anomalous effects which would follow from such an atmospheric condition are not predictable at the present time. It is obvious that important changes in storm patterns and climatic conditions could follow wherever these phenomena are governed by supercooled cloud structures.

The Use of Seeding Techniques for Studying the Atmosphere. By placing a known quantity of dry ice or silver iodide in a supercooled cloud it is possible to "mark" a cloud in such a way that subsequent changes in the physical nature of the cloud may be followed in great detail and with an accuracy hitherto impossible to achieve. By this method, the development of turbulence, the growth characteristics of snow crystals, the chain reaction mechanisms responsible for the development of widespread snowstorms, the change of insolation from cloudy sky to clear sky, the formation of new clouds, the development of precipitation, the occurrence of supersaturation, the properties of false cirrus, and many other atmospheric phenomena may be studied in great detail. Since it is possible to initiate many of these processes, it is possible for the first time to follow a particular meteorological process from beginning to end.

As experience is gained in this field, it is likely that these techniques will be most valuable in permitting us to reach a better understanding of that very complex but fascinating subject which we call *weather*. A careful scientific approach to these problems, using imagination, enthusiasm, and sound judgment, is of utmost importance if success is to be achieved in this new aspect of experimental meteorology.

RELATION OF ARTIFICIAL CLOUD-MODIFICATION TO THE PRODUCTION OF PRECIPITATION

By RICHARD D. COONS and ROSS GUNN

Physical Research Division, U. S. Weather Bureau

Introduction

With the important discovery in 1946 that supercooled cloud elements could be artificially converted to ice crystals by introducing pellets of carbon dioxide snow [11, 12], the possibility of human control of weather seemed imminent. Claims and speculation concerning the degree of possible weather control and the probable amount of artificially induced precipitation were rife, and meteorological opinion ranged from the one extreme "of academic value only" to the other "of great economic and military importance." The more favorable claims were supported in part by a few incompletely documented single experiments conducted in 1946 and 1947. These claims excited the interest of the public and stimulated demands for immediate weather control, drought relief, and storm diversion and dissipation, even though at the time there was no definite objective evidence that these were possible.

Alfred Wegener [15] was the first to suggest that the coexistence of ice and water in supercooled clouds led to colloidal instability resulting in rapid growth of ice particles. The possibility of modifying and producing rain from supercooled clouds by adding sublimation nuclei was foreseen by Bergeron [1, 2] and Findeisen [8]. Until 1946, however, no method was known of producing the necessary ice-crystal nuclei artificially. Earlier experiments by Veraart [13] in Holland in 1930 in which he dropped solid carbon dioxide, among other things, into supercooled clouds must have produced such nuclei, although Veraart at that time did not recognize this possibility. He was credited with producing slight amounts of rain on several occasions. However, because of his sweeping claims, even his positive results were discredited. Not until Schaefer and Langmuir [12] demonstrated (1) that a single solid carbon dioxide pellet could produce prodigious numbers (of the order of 10^{16}) of sublimation nuclei in its fall through a supercooled cloud, and (2) that, in actual field tests, a number of CO_2 pellets dropped into a supercooled cloud converted it largely into ice crystals, was it possible to investigate the importance of artificial nucleation in producing rain and modifying clouds as previously suggested by Bergeron and Findeisen. More stable sources of sublimation nuclei have also been found suitable. Silver iodide in particular has been used most successfully [14]. It should be noted that Heverly [9] has demonstrated in the laboratory that spontaneous freezing of water droplets in supercooled clouds may be a more important natural precipitation instrument than the sublimation of water vapor onto suitable active nuclei. According to Heverly's results, the effect of dry ice in producing colloidal instability could possibly be due either to the resulting spontaneous freezing of the supercooled droplets or to the production of myriads of ice-crystal germs from the water vapor in the cloud. In any case, whatever the effect of the dry ice, there is no question that it is capable of almost completely converting seeded portions of supercooled clouds into ice particles. The optical effects of such conversions are startling. In Fig. 1 the reflection of the sunlight from the ice-crystal cloud produced by seeding is seen to be brilliant when compared to the light reflected from the adjacent supercooled water-droplet clouds.

FIG. 1.—Reflection of sunlight on aluminum aircraft wing, ice-crystal cloud, and supercooled water-droplet cloud. Note that the reflection from the ice-crystal cloud is nearly as bright as that from the wing.

Bergeron [3] has fully discussed the suitability of the various types of rain-producing clouds for artificial release of precipitation. Briefly, the following conditions must be met in a cloud or cloud system in order for artificial nucleation to be effective in the modification of clouds and the production of precipitation: (1) The cloud must contain water droplets at a temperature below freezing, while there are still no ice crystals present in the immediate vicinity or falling through the cloud; (2) it must have some minimum thickness (arbitrarily about 1000 m) in order for the amount of moisture that could be converted into precipitation to be appreciable; (3) there probably should be some vertical instability in order to allow the growth, if any, of the cloud to spread the ice crystals as a result of the heat liberated by the freezing of the water (this would be accentuated in the presence of large-scale horizontal convergence that would provide a continuing source of moisture into the seeded area). Less important factors determining the possibility that precipitation will reach the

ground include (4) the height of the cloud base above the terrain, and (5) the humidity of the air below the cloud. In view of all the specialized conditions and factors involved, one of the objectives of conclusive tests of cloud-seeding potentialities must certainly be the determination of the frequency of such conditions and the importance of such factors. The question and importance of particular seeding rates, the one variable under control of the experimenter, are somewhat nebulous and will be discussed later in the light of some experimental results.

The Cloud Physics Project

In view of the divergent claims made by both qualified and unqualified experimenters in the rain-making field, the requirement for a long series of well-controlled objective tests became obvious. Such a program, the Cloud Physics Project, was initiated by the U. S. Weather Bureau, the U. S. Air Force, and the National Advisory Committee for Aeronautics in 1947. Since the 170 tests of that project are the only well-documented series yet reported [4, 5, 6, 7], the following discussion of seeding results will be based upon them.

The first requirement for an evaluation program is that it be able to separate results of seeding from natural effects. This is especially important in view of the fact that the necessary conditions for successful seeding operations approach those required for natural precipitation processes. The Cloud Physics Project experiments were designed to use the maximum number of controls and observational tools available for such an atmospheric investigation. Tests were first conducted for a period of about one year in the vicinity of Wilmington, Ohio, where ideal facilities were available [4, 5]. Further tests were then conducted from Sacramento, California [6] in the Sierra Nevada Range, and from Mobile, Alabama [7] along the Gulf Coast. At Wilmington, all of the project seeding operations were controlled from a central radar site. The high-powered 10-cm V-beam radar was of utmost importance in these tests. Not only was it capable of indicating and marking permanently on film the paths of each of the aircraft involved in the investigation, but also it indicated the presence of precipitation areas, whether they were formed naturally or as a result of seeding. This radar then was an invaluable tool which indicated if the cloud chosen visually for seeding, or for that matter other clouds in the vicinity, had precipitation echo sources before seeding, while, on the other hand, it indicated if echoes resulted exclusively from seeding. This radar, of course, was also of great help in keeping the observational aircraft properly positioned with respect to the cloud area being investigated.

Whenever possible, the project's operations were carried out over a 55-station surface network south of Wilmington. The rain gages at these stations, along with recording gages of the hydrometeorological service, were used to measure precipitation amounts. Also available in the Wilmington area were two rawinsonde stations which provided, as required, information regarding the temperature, pressure, moisture, and winds of the upper atmosphere.

A number of aircraft were used in most of the seeding flights. A B-17 usually performed the seeding operation in an area such that its effects would be noted and measured over the surface rain-gage network. Its seeding conveyor was carefully calibrated and indicators of the rates and periods of seeding were photographed continuously from remote-reading instruments installed in a photo panel along with indicators of other important parameters, such as temperature, pressure, altitude, and electric field. Also installed in the seeding aircraft was a low-powered X-band radar which would indicate the presence of light-precipitation areas. Photographs of the seeded cloud were taken from this aircraft both before and after seeding. Other aircraft which participated in the flights were high-altitude photo planes which took vertical and oblique photos of the seeded area, and observation planes which flew above, within, and beneath both the seeded cloud and neighboring clouds to determine their characteristics. Paths of all of the aircraft participating in the missions were recorded on the photographs of the ground radarscopes. From these photos, it was possible to determine the exact location of any of the planes at any instant, since each of them was identified by its own radar-triggered beacon code. All oral descriptions of seeding operations and results were recorded on continuous records, making it possible to determine easily the exact time of any observation. Since the position of the particular aircraft at the time of the observation was known from the radar data, the location of the observation was also known.

In summary, observations of the results of the seeding operations were made from several points of vantage: the radar, the aircraft flying above and below the seeded cloud, and on the ground (by visual observers). The quantities measured were the height of the base and top of the seeded cloud, the relative humidity above and below, the temperatures inside and outside the cloud, lapse rates, optical characteristics, and the extent and character of resulting precipitation. In the Sacramento and Mobile operations, not all of these quantities were available. However, the basic observational plan was followed with a high-powered 10-cm radar installed in a B-17 used to obtain the important radar information.

Experiments with Stratus Clouds

The first results to be discussed will be those obtained by the Cloud Physics Project in stratus clouds. Altogether 37 seedings in such clouds were conducted in the Wilmington area in 1948 and 15 seedings into orographic clouds were made in the Sacramento area in 1949. The objectives of these tests, as set forth in 1948, were to determine "the practical limits and general utility of cloud modification processes in producing or suppressing precipitation and increasing the visibility for flying aircraft."

On January 21, 1948, over one inch of snow fell in the vicinity of Wilmington, Ohio, within eighteen hours

of the completion of a cloud-seeding mission [4]. Since this snow fell in exactly the area where the seeding had been done and was somewhat local in character, it seemed that it had resulted from the artificial nucleation processes. However, a detailed analysis of the information secured during the mission, especially the radar pictures, indicated that this was definitely not the case. Actually, the measured winds carried the seeded clouds outside the precipitating area within a couple of hours. A layer of altostratus clouds, based at 4000 ft and extending to 8700 ft, where the temperature was −13C, was seeded with dry-ice pellets at the rate of four pounds per mile. The first task in analyzing the data was to determine the exact place of the seeding. Since the seeding run was made from 1443:45 to 1445:15 EST, its exact location could be found from the pictures of the radarscope during that period. The seeding aircraft's location was easily marked by its coded beacon signal during the run. Before the seeding, it had been determined that the cloud deck was composed wholly of supercooled water droplets, but ice crystals were observed to form immediately along the seeded line as the dry ice was dropped. Observers in an aircraft flying 12,000 ft above the cloud top reported that the seeding aircraft looked like a snowplow moving across the cloud deck. A trough about 300 ft deep resulted as the conversion to ice crystals took place while, along the perimeter of the affected area, clouds built up an estimated 100 ft. This trough, which widened to 2½ miles, was easily recognizable for about 45 min, after which mixing dissipated the lines of demarcation between the treated clouds and the rest of the deck. The first radar echo resulting from the seeding was observed about 30 min after the drop (see Fig. 2). The position of this echo

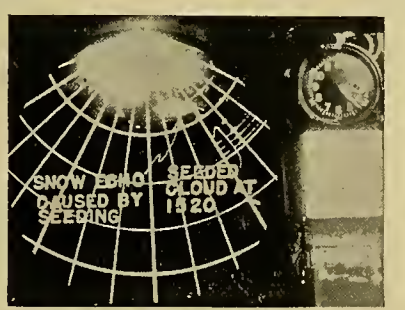

Fig. 2.—Radarscope photograph, January 21, 1948 (first seeding).

agreed exactly with the location of the seeded area as indicated by the observing aircraft and also with its position computed from the winds aloft. This seeding echo was approximately three miles wide by about eight miles long and never grew any larger. By 1540, about one hour after the seeding, it had almost completely disappeared. It can be concluded, then, that the seeding resulted in the production of a precipitation area from which a limited radar echo was observed for about 30 min. This echo, however, was not unique at the time of seeding, since other echoes of similar size and natural origin were also indicated. This seeded area was observed to move with the prevailing winds at the cloud altitude and, by the time it disappeared, it was some twenty miles to the east of the rain-gage-network area. At 1540, a new echo directly over the rain-gage area was observed to form, completely independent of the seeded echo. Snow continued to fall for some time from the unseeded cloud deck as it passed over the network, but it was not until approximately 1800 that enough had fallen to affect the rain gages. A complete series of photographs like Fig. 2 is given for this test in Weather Bureau Research Paper No. 30 [4].

In summary, to quote from this paper:

> A definite change in texture of the supercooled cloud deck was caused by the first seeding. Shortly thereafter, a radar echo was noted to be associated with the seeded area and snow was observed underneath it. However, at the same time in the immediate vicinity, snow echoes were existing or were forming. Within one hour after the seeding, the area could no longer be distinguished by the observers flying in the aircraft above the cloud. The snow echo as indicated on the radar scope had disappeared also. At no time was there a definite hole broken through the cloud as a result of the seeding, although there were large breaks in the clouds nearby.

A study of the pictures presented in that report indicates that some few ice crystals remained in the seeded area and acted as an obstruction to visibility even when the snow was reported to be falling from beneath the seeded line. Whether or not the seeding resulted in a hole in the cloud deck does not seem to be a meaningful question in this case, since the same pictures indicate very large natural breaks immediately bordering the seeded area.

Another seeding conducted in the Wilmington area, that of October 5, 1948, was also successful in producing a radar echo in the exact pattern of the seeding. On this particular day, the cloud deck extended from 8000 ft to 11,600 ft, where the temperature was −5C. Dry-ice pellets were dropped at the rate of five pounds per mile in an L pattern. Immediately after the seeding run, a texture change and the horizontal diffusion of ice crystals were observed. The area continued to spread slowly and a slight boiling effect was observed along the extremities of the pattern. At 1445, almost exactly 30 min after the dry ice was dropped, a small radar echo was observed from the seeded area. Within 5 min this echo assumed the shape of the L pattern (Fig. 3) but within 5 min thereafter completely disappeared. Observers flying underneath the seeded pattern reported that light rain fell at about the time of the maximum radar echo. They indicated that the rain was of short duration and possibly did not reach the ground.

On this day, project pilots indicated that a visual descent would have been possible in the seeded area at about the time of maximum dissipation, which was also the time of maximum radar echo. However, this dissipation was not considered particularly significant in view of the fact that much larger natural openings existed within a few miles of the seeded area. (See Fig. 4, which shows the seeded L in the upper middle

of the picture with large natural openings in the foreground.) These two examples illustrate that even the most favorable seeding missions in the Ohio tests resulted in only slight precipitation amounts and in dissipation only when the clouds were breaking up due to natural conditions. A study of the data presented in the Ohio report indicates without exception that such large-scale seeding effects, as illustrated above, were possible only when the cloud deck treated was undergoing natural dissipative action. On the "unfavorable" days, seeding resulted in the production of narrow lines of ice crystals which did not diffuse through the supercooled cloud deck.

FIG. 3.—Radarscope photograph of seeding, October 5, 1948, showing L-shaped area of light rain.

FIG. 4.—First seeded area as seen from 10,000 ft above cloud deck, photographed thirty minutes after seeding (October 5, 1948). Note natural breaks in clouds.

The Sierra Nevada tests were conducted for the purpose of evaluating the importance of dry-ice seeding in orographic type stratus clouds. It was felt that the clouds formed along the Sierra Nevada Range by the mechanical lifting of moist Pacific air would offer the most favorable conditions for seeding. The report for the Project's operations near Sacramento [6] indicates that its seeding results were no more successful than those in Ohio [4]. First of all, it was found that nonfrontal orographic clouds existed only a fraction of the time, and that the majority of cloud systems over the Sierra Nevada Range were of frontal origin and contained natural ice-crystal clouds before lower supercooled decks were formed. On only three days during a two-month operational period was it possible to find nonfrontal clouds and, on each of these days, the lack of large-scale horizontal convergence in the general area resulted in somewhat broken cloud decks. A discussion of the seeding of February 15, 1949, is included here since on this particular day fairly large-scale dissipation results were observed. An altocumulus deck extending from 9800 ft to 10,650 ft where the temperature was −7C was seeded in the shape of an L along the base of the Sierras near Auburn, California. Dry ice was used as the seeding agent and was dropped at the rate of four pounds per mile. Immediately after seeding an ice-crystal pattern conforming to the dry-ice pattern was observed and within some 20 min the ice-crystal area had spread about 1½ miles. Within one hour after the seeding, definite holes through to the ground, especially along the borders of the seeded pattern, were observed and at the apex of the L a large opening some three to four miles across was observed. However, the significance of this dissipation becomes questionable in view of the natural dissipation occurring simultaneously. The natural openings could easily be seen, and within a half-hour after the observation of the large seeded opening, the whole cloud deck began to break up rapidly and disappeared shortly thereafter. No precipitation of consequence could have fallen as a result of seeding, since its effects did not spread over a large area nor did it cause any large-scale convection. The only amount of moisture that could have fallen was that which could have been extracted from the 800-ft thick cloud.

Other experimenters in the field have indicated that they believed that the Cloud Physics Project was not successful in causing large-scale dissipation because of its use of excessive amounts of dry ice, usually two to five pounds per mile, and they recommended that rates of one pound per mile or less be used. They felt that overseeding had occurred in most of the cases studied by the Cloud Physics Project and that, as a result, the ice crystals which formed did not grow large enough to precipitate from the cloud deck in sufficient numbers actually to cause it to dissipate. As a matter of fact, they suggested the use of only one pellet of dry ice to open relatively large areas. Four such single pellet drops by the Cloud Physics Project during its California tests gave no results on a scale large enough to be recognized. There is no doubt that there exists some optimum ratio of the specific number of droplets to ice nuclei for most favorable seeding results. Bergeron [3] has discussed this in some detail in his paper and gives examples of the effects of the various ratios from underseeding to overseeding. It is readily apparent there is no one seeding rate which will give the

optimum ratio because of the variability of the water-droplet distribution in different stratus cloud systems and because of differing diffusion conditions. It is obvious, considering the tremendous number of nuclei created from the fall of one dry-ice pellet, that there will be gross overseeding in the cloud segment through which such a pellet falls while at some distance away, depending upon diffusion conditions, there will be underseeding. Somewhere, then, between where the pellet passes through the cloud segment and where its nucleation effects are just felt, there must exist the optimum ratio for the particular cloud. It is seen, then, that the problem of overseeding is not a consequence of excessive amounts of dry ice thrown out along a path, but rather is due to the lack of uniform dispersion by the diffusion of the tremendous numbers of nuclei produced by even one dry-ice pellet. To quote Langmuir [12] "The conclusion is obvious, however, that with a reasonable number of pellets dropped along a flight path into the top of a cloud, the limiting factor will not be the number of nuclei but the rate at which the nuclei can be distributed throughout the cloud." In cumulus clouds, the characteristic internal turbulence and mixing would spread the nuclei from even one pellet throughout a large portion of the cloud within a short period of time. However, in characteristically stable stratus clouds, only horizontal divergence or mixing would tend to distribute the nuclei through a large cloud volume. These factors are of course the same ones that result in natural dissipation of stratus clouds. Thus, the results of the Cloud Physics Project emphasize the importance of divergence and mixing by diffusion. In both the Ohio and California tests, spread of artificially induced nuclei and subsequent stratus dissipation were observed only when natural dissipation was occurring. The effect of heats of fusion and sublimation released as a result of seeding was never observed to be on a scale large enough to cause any important local circulation and resulting spread of artificial nucleation.

Experiments with Cumulus Clouds

It appears that the most suitable cloud for the artificial production of precipitation would be a cumulus congestus whose top, having reached above the freezing level, would contain supercooled water while still not containing ice crystals. If seeding resulted only in the conversion of the water in such a cloud into precipitation, it is possible that a maximum of 0.2 in. of rainfall might reach the ground under the most favorable circumstances. In addition, it has been suggested that the heat released in the conversion of the cloud top to ice crystals might be of sufficient value to set off additional convection within the treated cloud and thus to result eventually in the production of a heavy rain shower or thunderstorm.

The investigation of the results of seeding cumulus clouds is somewhat more difficult than the investigation of similar results in stratus clouds. In the latter, the untreated portion of the seeded deck can be used as a control or a standard, while the ever-changing configuration and often violent activity of cumuli make it impossible to use any one of them as a control. It has been suggested that the cloud to be seeded be chosen randomly from among those possessing the required characteristics and that, for each cloud seeded, a similar one, also chosen randomly, be observed in its natural course. However, the results of the Cloud Physics Project in seeding cumulus clouds indicate that the control exercised through the use of the several observational aircraft and, especially, of a rain-sensitive radar, made the scheme described above unnecessary. Altogether the project conducted 79 seedings in cumulus clouds in the Ohio area [5] and 44 in semi-tropical cumulus along the Gulf Coast [7]. A number of clouds seeded in the Ohio tests were not supercooled but were seeded with water droplets for the purpose of investigating the reality of "chain reaction processes" within warm clouds as envisaged by Langmuir in 1948 [10]. The results of seedings in such warm clouds appeared to be unfavorable from the relatively few tests conducted, and they were not continued in the Gulf Coast tests, but rather the more favorable supercooled cumulus clouds were investigated there.

As indicated in U. S. Weather Bureau Research Paper No. 31 [5], only trivial amounts of precipitation resulted from seeding the Ohio cumulus clouds and even in cases where these amounts were observed, there were nearby natural showers of the same or greater intensity. In none of the cases reported did the seeded cloud build extensively as a result of the dry-ice drop and it is thus obvious that no large amounts of precipitation could have been expected to fall. On the contrary, the most obvious effect of seeding dry ice into both supercooled and nonsupercooled cumulus clouds was the resulting rapid dissipation. There were very few cases in which the cloud built up after seeding, and in each of these the growth did not exceed a few thousand feet. On the other hand, dissipation was usual and often almost complete in its effect. The following is quoted from this report [5]:

> This dissipation appeared to be nearly independent of supercooling or of the particular agent employed. Its occurrence was consistent with the idea that convective clouds often have lapse rates steeper than the moist adiabatic as a result of mixing and entrainment between such clouds and the environment. A downward movement initiated by dry ice, large numbers of ice crystals, water or other means (aircraft flying vertically upward through the cloud have been employed successfully) might easily cause an appreciable mass of air to become colder than the surrounding clouds, and thus induce further downward motion. A similar explanation has been advanced by Byers and Braham for the formation of the thunderstorm downdraft.

Regarding the general results in the Ohio area, the following is also quoted from the same report:

> The experiments showed that the artificial modification of cumuliform clouds is of doubtful economic importance for the production of rain. Dissipation rather than new development was the general rule. There is no indication that seeding will initiate self-propagating storms, and therefore, the only precipitation that can be extracted from a cloud is that con-

tained within the cloud itself. The methods are certainly not promising for the relief of drought.

In the Weather Bureau report are included detailed examples of three different cases in which the radar, in particular, and other operational tools available to the Cloud Physics Project proved invaluable in assessing the results of seeding. One of the examples illustrates a case in which a small shower which resulted from the seeding was differentiated from other natural showers occurring almost simultaneously within five miles. In the second example, there is discussed a case in which a small radar echo and accompanying shower resulted from seeding when there were no other showers indicated by the radar within fifty miles. In the last example covered in the report, an untreated tower which was part of the seeded cloud showed an echo previous to the dry-ice drop, indicating that precipitation had already started in that portion. The tower that was seeded did not give any precipitation. However, observers underneath the cloud reported rain which, as a result of the detailed analysis procedure, was definitely attributed to the tower that showed an echo previous to the seeding. These cases show that the use of all available controls, such as radar, is most important in properly evaluating the results. Without a radar in the first example, the adjacent natural showers might either have been overlooked or, on the other hand, attributed to the seeding operation. In the last example, the rain which was already falling from the seeded cloud might easily have been attributed to the effect of the dry ice. This third example illustrates a real difficulty in the seeding of cumuliform clouds. In the Ohio area many of these clouds reached the spontaneous freezing level soon after surpassing the 0C isotherm, thus occasionally making it impossible to find clouds extending above the freezing level which did not have ice crystals in them before seeding. The following results of the tests conducted at Mobile, Alabama, indicate this to be a particularly important difficulty in the seedings conducted in that area.

In clouds over the Gulf States [7], ice crystals would usually form naturally just a few thousand feet above the freezing level, often when the temperature at the tops of the clouds was not below −6C. Such clouds would appear to be composed of only water droplets when observed visually from outside, but the occurrence of radar echoes and subsequent visual observation of ice crystals within these clouds proved external visual observation to be unsatisfactory and somewhat misleading. Thus, there was only a short period of time during cloud development in which seeding was likely to be effective; that is, between the time the cloud reached the freezing level and the time it reached the natural crystallization level, from 3000 to 6000 ft higher. As in the Ohio tests, there was no appreciable building as a result of seeding, but rather dissipation of the cloud top was the rule. Occasionally, clouds containing only ice crystals were seeded because of the unavailability of strictly supercooled ones. The report of the Cloud Physics Project indicates that even in these cases seeding hastened the process of dissipation, possibly by increasing the number of nuclei available within the cloud.

Three specific examples of the Mobile seeding operation seem of interest. On June 5, 1949 the cloud under study had its base at around 5600 ft with the top at 18,000 ft where the temperature was −6C. It was seeded twice with dry ice at the rate of five pounds per mile. On the first run, only supercooled water was observed to freeze on the aircraft. This seeding resulted in the dissipation of the pinnacle traversed during the run. On the second seeding run, 13 min later, both supercooled water and ice crystals were observed. Shortly after the dry-ice drop, a faint radar echo appeared in the seeded area, while at the same time another echo formed in a cloud four miles away. This natural echo grew to a much larger size than that in the seeded cloud. Figures 5 and 6 show the cloud before and after the second seeding and illustrate its rapid dissipation into a small stratified cloud. The second picture shows a rainbow from the light precipitation which fell from the cloud. It is interesting to note in Fig. 5 the concurrent thunderstorms in the near background.

FIG. 5.—Second seeding, June 5, 1949 (before seeding). Altitude, 18,000 ft; time, 1452; azimuth, 300°.

A very favorable situation for seeding is illustrated in the third seeding of June 7, 1949. A cloud whose base was near 5000 ft and whose top was estimated to

FIG. 6.—Second seeding, June 5, 1949 (after seeding). Note rainbow under cloud. Altitude, 18,000 ft; time, 1503.

be at 24,000 ft where the temperature was −25C was seeded with dry ice at the rate of five pounds per mile. This cloud contained only supercooled water at the 20,000-ft seeding altitude and no radar echo was observed from it prior to the seeding. Within 10 min after the seeding, a small rain echo was observed from the cloud and light virga was observed by the low observation aircraft. It was estimated that within about one-half hour after the seeding this cloud had dissipated approximately 75 per cent. Figures 7 and 8 are

FIG. 7.—Third seeding, June 7, 1949 (before seeding). Altitude, 20,000 ft; time, 1430; azimuth, 360°.

pictures of the cloud immediately before and 14 min after seeding. They show its rapid conversion into ice crystals.

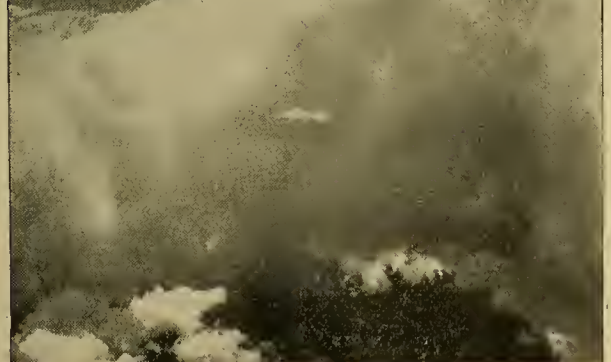

FIG. 8.—Third seeding, June 7, 1949 (after seeding). Altitude, 21,000 ft; time, 1444; azimuth, 360°.

Considering the result obtained in the Ohio tests, and especially in the Gulf tests, the project report [7] concludes in part that

> . . . it seems a logical conclusion that seeding, by usually stopping the development of cumulus soon after they reach the freezing level, possibly interferes with the growth of some few of them to full-scale thunderstorms. All of our observations seem consistent with this conclusion. Seeding then might actually be a deterrent to the production of precipitation over any particular area. It apparently inhibits the growth of cumulus clouds by initiating premature downdrafts of ice crystals which subsequently choke off the necessary moisture inflow at lower altitudes and at lesser stages of development than those decreed by nature.

The large number of independent experiments conducted by the Cloud Physics Project have been generally disappointing in terms of the practical and economic results hoped for. However, the treatment of natural clouds by large numbers of artificially dispersed sublimation nuclei has frequently induced weather perturbations whose study has added notably to our scientific understanding of precipitation processes. The objective analysis of detailed changes occurring in the tremendous spaces of the atmosphere is extremely difficult even with all the instruments and facilities available. Future progress will depend, in no small measure, upon the invention and development of better airborne instruments suitable for making rapid determinations of the detailed characteristics of each cloud to be explored.

GENERAL ASPECTS OF UPPER ATMOSPHERIC PHYSICS

By S. K. MITRA

University of Calcutta

INTRODUCTION

The present article is intended as an introduction to the articles on the different aspects of the upper atmosphere which follow. The main topics of this contribution will be a discussion of the physical origin of the upper atmosphere, methods of investigation and a general survey of the contemporary state of our knowledge of the upper atmosphere, and an account of the problems which still remain unsolved. There will, of necessity, be references to many subjects which are dealt with in the articles that follow. These references will be included at the risk of a certain amount of repetition, as the aim of the present article is to give a general idea of the physical aspects of the upper atmosphere. The reader who desires detailed knowledge in any particular subject should seek it in the specialised articles that follow. It should also be mentioned that the treatment of some of the topics in the present article will follow closely that given in the author's recent book [72].

The region of the earth's atmosphere denoted by the term *upper atmosphere* is not yet well defined. To the meteorologist, upper atmosphere may mean the regions investigated by the conventional sounding balloons; to the geophysicist studying the aurora or the ionosphere, upper atmosphere may mean the high regions near and above 100 km. In the present article, the words *upper atmosphere* will generally refer to the regions above the troposphere. However, for purposes of reference the whole atmosphere may sometimes be divided into three regions: the lower atmosphere (troposphere); the middle atmosphere (stratosphere); and the upper atmosphere, extending above 100 km. The lower stratosphere, as reached by sounding balloons, will be generally left out of consideration in the present discussion.

In studying the upper atmospheric region it is helpful to bear in mind its high tenuity. At 15 km, near the base of the stratosphere, the atmospheric density is about one-eighth of that at sea level. Above this the density falls off rapidly, and at 100 km it is only a millionth of that at sea level. The pressure is thus about 10^{-3} mm, which is of the same order as in the so-called "vacuum" of ordinary electric bulbs. At 300 km the pressure is of the order 10^{-6} mm. This is the pressure attained by only high quality modern vacuum pumps. If we consider the mean free path of a molecule, we note that its value near sea level is 10^{-5} cm, at 15 km it is 10^{-4} cm, at 100 km it is 10^{2} cm, and at 300 km it is 10^{6} cm.

It may seem surprising that regions of such extreme tenuity in the upper atmosphere could be the seat of any phenomenon of geophysical importance or of interest for any aspect of our daily life. Nevertheless such is the case. But for the presence of the ionospheric regions at heights of 200 km and above, long distance radio communication at night would be impossible. Auroral displays which illuminate the long winter nights in the polar regions occur with greatest frequency near a height of 100 km, and auroral streamers sometimes extend up to heights of 1000 km and beyond. The common phenomenon of shooting stars appears most frequently in the region 50 to 150 km. During World Wars I and II the sound of cannon fire in France could be heard in England because the wave of explosion was bent downward by refraction at heights of about 35 km.

Many upper atmospheric phenomena are also of great scientific interest because they occur under conditions and on a scale which cannot be reproduced in laboratories. As a matter of fact the upper atmospheric regions may be regarded as constituting a vast physical laboratory where Nature carries out experiments on a gigantic scale on such phenomena as bombardment of air masses by charged and uncharged particles, electric discharge, magnetic double refraction, ionization by collision, photochemical reaction, and recombination of ions and electrons. In laboratory experiments the ionization track of a charged particle in a Wilson cloud chamber may be only a few centimetres long; in the upper atmosphere it may be hundreds of kilometres long. In a laboratory, rarefied gas for study of discharge phenomena has of necessity to be confined within a glass vessel. The walls of the vessel are responsible for the quick disappearance of electrons and ions and the consequent extinction of the discharge glow. In the rarefied upper atmosphere there are no glass walls. Unhindered by the wall effect, the ions and the electrons and the luminescence persist for a long time.

One further point of interest in connection with upper atmospheric phenomena may be mentioned. Unexpected associations (some still unexplained) have been found to exist between physical conditions in the upper atmosphere, tens or hundreds of kilometres above the surface of the earth, and weather conditions in the tropospheric regions.

Finally, accurate knowledge of the physical properties of the high regions of the atmosphere is of utmost importance to those engaged in the development of the many new types of high-flying aircraft.

THE UPPER ATMOSPHERE

We may now consider the origin of the observed structure of the upper atmosphere. If the earth's atmosphere were at rest, undisturbed by any external agency, conduction of heat from one part to another—slow as it is—would, after a sufficient length of time, produce uniform temperature throughout the mass. Further, if the atmosphere consisted of more gases than

one, the pressure and density of each gas would be distributed according to the well-known exponential law of Dalton. Thus if, for a gas, m is the molecular mass, P the partial pressure at a height h, and P_0 that at the ground, then

$$P = P_0 \exp\left(-\frac{mg}{kT}h\right).$$

Such an atmosphere is said to be in isothermal equilibrium.

The terrestrial atmosphere is, however, subject to turbulence due to heating and other causes and is characterized by convective motions. There is therefore a tendency for adiabatic equilibrium to be set up, since conduction in gases is very slow. In the ideal case of adiabatic equilibrium an element of gas transferred from one place to another does not lose or gain any heat by conduction and takes up the requisite temperature and pressure in its new position. The density (ρ) distribution with height in this case is given by

$$\rho = \left[\rho_0^{\gamma-1} - \frac{\gamma-1}{A\gamma}gh\right]^{\frac{1}{\gamma-1}},$$

where A is equal to P_0/ρ_0^{γ} and γ is the ratio of the specific heats of air at constant pressure and at constant volume.

If the troposphere were in ideal adiabatic equilibrium, then the lapse rate—the fall of temperature with height—would have been 9.8C km^{-1}. Also, theoretically, an atmosphere in ideal adiabatic equilibrium has a natural limit. From the expression for ρ it is easily seen that ρ is equal to zero at $h = \gamma P_0/[\rho_0 g(\gamma-1)]$. For the terrestrial atmosphere in ideal adiabatic equilibrium, this limit would be 27.5 km. However, owing to various factors, the troposphere is not in perfect adiabatic equilibrium. The actual lapse rate is only 5C km^{-1}. Also, the height of the troposphere varies between 8 km over polar regions to about 18 km over equatorial regions, instead of averaging 27.5 km. The limit of the adiabatic atmosphere, under actual conditions, cannot be a surface separating a region of perfect vacuum above from a region containing gas molecules below. Because of thermal agitation, molecules from the atmosphere below will constantly be evaporating, as it were, across the separating surface in much the same manner as molecules evaporate from the body of a liquid to the space above it. The region above the natural limit will therefore contain molecules. The atmosphere in adiabatic equilibrium may thus be considered to be capped by a region which we call the *outer atmosphere*. The outer atmosphere is necessarily in isothermal equilibrium.

According to the simple consideration given above, the outer atmosphere need be only a few metres thick. However, account has to be taken of the fact that radiation from the relatively hot gases below is continually reaching and heating this isothermal layer and that in order for the atmospheric gases to be in equilibrium the radiation and the absorption of heat by each element must balance. These considerations lead to the conclusion that the isothermal layer above the adiabatic layer, instead of being a few metres thick, extends to great heights.

Assuming that the atmosphere consists of two layers, the lower in adiabatic and the upper in isothermal equilibrium, and working out the condition for radiative equilibrium, it has been shown that for an atmosphere of uniform constitution, the adiabatic state cannot extend to a height greater than that given by $P = P_0/2$, where P_0 is the pressure at the surface of the earth. For an atmosphere of nonuniform constitution, the adiabatic layer may extend to greater heights. Under certain assumptions concerning the amounts of radiation absorbed by water vapour at different heights, it has been shown that the height of the adiabatic layer cannot exceed that given by $P = P_0/4$ which, for the case of the terrestrial atmosphere, is 10.5 km. This, as indicated above, is roughly the height of the troposphere.

Limit of the Outer Atmosphere. The outer atmosphere, being more or less in isothermal equilibrium, has no natural limit, though the point of minimum density resulting from the balance of the centrifugal and the gravitational forces is sometimes spoken of as the limit of the outer atmosphere. But long before this height is attained (distance 6.6 earth-radii in the equatorial plane) a limit of the outer atmosphere is reached due to the rarity of collisions and the escape of molecules.

We are thus led to enquire into the limit of the outer atmosphere or, more popularly, to ask, Where does the atmosphere end? The question is of considerable importance, since it is closely related to the question of the escape of the atmospheric gases from the gravitational field of the earth.

A limit of the outer atmosphere may be understood from the following considerations. In any region above the surface of the earth, the atmosphere in the ordinary sense of the term can exist only if the molecules in the region are prevented from escaping by collisions with the molecules above. Now, as one goes up, the atmosphere becomes increasingly rarefied and the frequency of collisions between the gas particles becomes smaller and smaller. Ultimately a height is reached where the collisions are so few and far between that a molecule from the denser atmosphere below has little chance of returning to earth by collision with molecules above. The height at which this state of affairs prevails may be said to be the limit of the atmosphere. There is, of course, a transition region of considerable thickness from which a particle, projected upwards, *may* escape without collisions. The mean height of this transition region is variously estimated to lie between 500 and 1000 km [98].

Escape of Atmospheric Gases—The Problem of Helium. This leads to the question of atmospheric gases overcoming the gravitational field and escaping from the earth. The process of escape may best be understood as follows (after Milne [66] and Jones [51]). Let us suppose that an observer ascends upwards from a layer where molecular density is small but appreciable. If the molecules were opaque, the hemispherical sky

above the observer would appear to him absolutely opaque; a line drawn from the observer towards any direction would pass through many molecules one behind another. If the observer continues his ascent, the molecules overhead will gradually thin away and he will reach a level where the molecules overhead will just fill the sky, that is, a line drawn vertically upwards will pass through only one molecule, whereas a line drawn in any other direction will pass through more than one molecule. Mounting still higher, the observer will find his sky overhead gradually clearing up and he will "see" a cone with its axis vertical within which his sky will be clear. It is obvious that this cone will open out with height and the observer will finally "see" the whole sky clear. This cone is called by Milne the *cone of escape* of the molecules. A molecule moving within the solid angle of this cone will have some chance of escaping without a collision. The escape velocity v is given by $v^2 > 2ga^2/r$, where v is the velocity of the molecule, g is the acceleration due to gravity at the level from which the molecule escapes, a is the earth's radius, and r is the distance of the level of escape from the centre of the earth.

Since the mean velocity of the molecules depends upon temperature it may be expected that a considerable quantity of gas, particularly of the light variety, will escape from the upper atmosphere if a high temperature is assumed [49]. The problem of helium in this connection is particularly interesting. Measurements show that the atmosphere near the surface of the earth contains 5×10^{-4} per cent helium by volume. If, however, account is taken of the helium discharge from the earth's crust during the geological ages, the amount of the helium in the atmosphere should be very much more than this. The reason for the scarcity of helium is believed to be that it is continually diffusing upwards and escaping. In order that the escape may be possible a temperature of the order of 1000K has to be assumed near the limit of the atmosphere. We shall see later that considerations of a number of other atmospheric phenomena lead to a similar conclusion.

The Fringe Region or the Exosphere. Beyond the limit of the atmosphere as discussed above, the molecules move freely with the velocity acquired at their last collision in the lower region and, being subject only to the force of gravity, describe elliptic, parabolic, or hyperbolic paths according to the magnitude of their velocities. Escaped molecules whose velocity is not enough to overcome the gravitational pull, will fall back to the atmosphere after describing elliptic paths. These high-flying particles constitute the *fringe region* or the *exosphere* of the atmosphere. The exosphere obviously commences at the level where the semivertical angle of the cone of escape approaches 90°. In the exosphere the particles move without collision in enormous orbits. The heights to which these particles will rise depend on the magnitude and direction of velocity acquired at the last collision and also on g at the point of collision. A few tracks of such particles are shown in Fig. 1. The merging of the atmosphere with interstellar space (average density of matter one particle per cc) is estimated to take place in the region about 2500 km above the surface of the earth [73].

If the atmospheric particles are ionized, the phenomenon of escape becomes complicated. This is because the

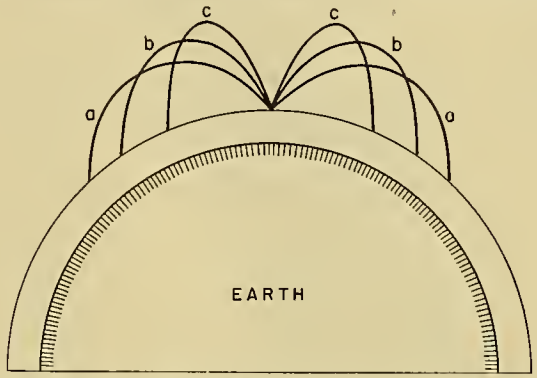

FIG. 1.—Trajectories of a particle projected from 1000-km level and moving freely without collision. Velocity 3.5 km sec^{-1}; initial angle with the vertical—(a) 60°, (b) 45°, (c) 30°.

motion of an ionized particle is profoundly influenced by the terrestrial magnetic field. Thus, although for a neutral particle the critical velocity of escape is independent of latitude, it is not so for an ionized particle [73].

According to Vegard [103], the topmost layer of the atmosphere is an electric double layer formed by electrons, ions, and neutral molecules, the sun being supposed to emit radiation corresponding to soft X rays. The particles in the double layer are disposed of by the earth's magnetic field in a manner similar to that of matter in the solar corona, which is also known to be highly ionized. The terrestrial atmosphere is thus supposed to be topped by a corona—a cloud of particles—similar to the solar corona [103].

According to Hulburt, the particles in the exosphere may be the scattering matter of the zodiacal pyramid which is seen in the evening (or early morning) to rise above the horizon as a faintly luminous cone after the disappearance (or before the appearance) of twilight [48].

In connection with the above two hypotheses of Vegard and of Hulburt it should be mentioned, however, that according to some authors, the particles spend such short time in the transition layer or in the exosphere that they have not much chance of being ionized [98].

SOLAR CONTROL OF THE UPPER ATMOSPHERE

The upper atmospheric regions are under strong solar control due, firstly, to absorption of the whole of the ultraviolet radiation below 2900 A and, secondly, to bombardment by charged particles emitted by the sun. The ultraviolet absorption produces dissociation, allotropic modification, and ionization of the upper atmospheric gases. The bombardment by charged particles—which is concentrated round the magnetic axis poles—produces auroral displays associated with optical excitation and ionization of the upper atmospheric gases. The effects of the different parts of the ultraviolet solar spectrum are presented in Table I.

It is to be noted that if the sun is assumed to be radiating like a black body, then the number of emitted quanta decreases rapidly with the decrease of wave length. As such, the available number of quanta may not be sufficient to produce the observed effects in the region of extreme ultraviolet. It is therefore believed that the sun must be sending out continuously (with occasional outbursts) line radiations in the extreme ultraviolet, for example, principal series of H, He and He^+. Besides, there may also be ultraviolet radiation

Illumination of the Upper Atmosphere by Solar Rays. In connection with the solar control of the upper atmosphere it is important to remember that the hours at which the sun's rays first strike in the morning or disappear in the evening from the high atmospheric regions are quite different from those at the surface of the earth. For example, the high atmosphere above 100 km as far from polar regions as lat. 55°, is illuminated at midnight by solar rays during high summer. The method of calculating the hours of sunrise and sunset at

Table I. Effects of Solar Ultraviolet Radiation on Upper Atmospheric Gases

Spectral region	Reaction	Remarks
3000–2100 A (Hartley absorption bands of O_3)	$O_3 + h\nu \rightarrow O_2 + O^*$ (excited)	Very strong absorption by ozone (50–60 km).
1925–1760 A (Runge-Schumann absorption bands)	$O_2 + h\nu \rightarrow O_2$ (excited) $O_2^* + O_2 \rightarrow O + O_3$ $O + O_2 + M \rightarrow O_3 + M$ (Note: The last reaction is a three-body collision process, in which M is the so-called *third body* which takes away the excess of momentum and energy.)	Comparatively weak absorption. Production of ozone.
1751–1200 A (Runge-Schumann continuum)	$O_2 + h\nu \rightarrow O + O^*$ (excited)	Very strong absorption. Dissociation of O_2 above 80 km.
1012–910 A	$O_2 + h\nu \rightarrow O_2^+$ (normal) $+ e$	Weak absorption. First ionization potential of O_2. Production of D-region (?) (50–80 km).
910–795 A	$O + h\nu \rightarrow O^+ + e$	Very strong absorption. Ionization of O. Production of F_1- and F_2-regions (?) (200 km upwards).
795–755 A	$N_2 + h\nu \rightarrow N_2^+$ (normal) $+ e$	Comparatively weak absorption. First ionization potential of N_2. Production of E_2-region (?) (140–160 km).
744–661 A	$O_2 + h\nu \rightarrow O_2^+$ (excited) $+ e$	Strong absorption. Second ionization potential of O_2. Production of E_1-region in the transition region $O_2 \rightarrow O + O$ (90–120 km).
661–585 A	$N_2 + h\nu \rightarrow N_2^+$ (excited) $+ e$	Very strong absorption. Second ionization potential of N_2.

and soft X rays coming out of the corona which is regarded as having a very high temperature of the order of some million degrees.

The phenomenon of radio fade-out strikingly illustrates the solar control of the upper atmosphere. During an intense solar flare, when bright spots of hydrogen light appear on the sun, the magnetic disturbances and the ionization in the absorbing D-region of the ionosphere both show an abnormal and simultaneous increase. This causes total stoppage of radio traffic over the sunlit portion of the earth [64].

different atmospheric levels and the results obtained for a few typical cases are given below.

The shadow cast by the earth in space is of cylindrical shape. We have from Fig. 2,

$$H = a\left(\frac{1}{\cos\theta} - 1\right),$$

where H is the height at which the cylinder cuts the zenith, a is the radius of the earth, and θ is the depression of the sun below the horizon.

The hour angle h of the sun at its rising at any height H may be obtained as follows. We have

$$\cos Z = \sin \phi \sin \delta + \cos \phi \cos \delta \cos h,$$

where Z = zenith distance of the sun, δ = declination of the sun, and ϕ = latitude of the place of observation. From Fig. 2, $Z = 90^\circ + \theta$.

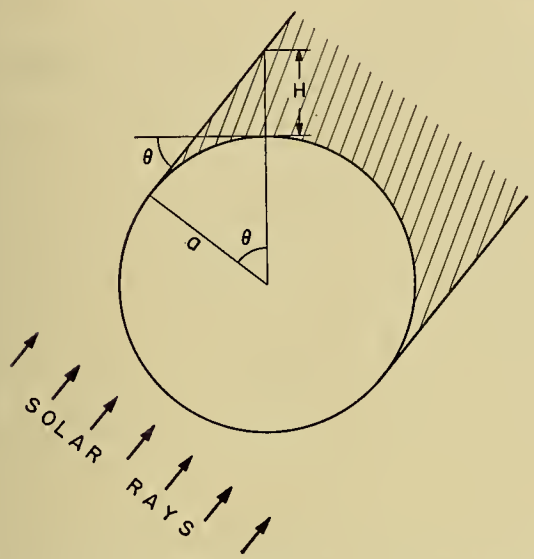

FIG. 2.—The height H at which the cylindrical shadow cast by the earth cuts the zenith is given by $H = a\left(\frac{1}{\cos\theta} - 1\right)$.

The effect of refraction—which accelerates the time of rising—has not been taken into account in the equation above. The true zenith distance of the sun's centre when it rises at height H above the ground is given by

$$Z = 90^\circ + \theta + 50'.$$

Here $34'$ has been allowed for horizontal refraction and $16'$ for the semidiameter of the sun.

Now, at actual noon the apparent time is 12^h and the mean time is $12^h + \epsilon$, where ϵ is the equation of time. Hence the mean time t of sunrise at height H above the ground is given by

$$t = 12^h + \epsilon - h.$$

Similarly, the hour of sunset at H is given by

$$t = 12^h + \epsilon + h.$$

The values of ϵ and δ may be obtained from the *Nautical Almanac*. Hence the hours of sunrise and sunset at different atmospheric levels may be calculated with the help of these equations.

Curves in Figs. 3*a* and 3*b* delineate (after Ghosh [40]) the variation of the hour of sunrise with height for the whole year at intervals of about a fortnight for the latitude of Calcutta (22° 32′ 48″ N). Figure 4 depicts (after Bartels [10]) the height above which the atmosphere is illuminated by solar rays at midnight during the course of the year in the latitudes 40° to 90°.

Useful curves depicting the hours of sunrise at different latitudes on the surface of the earth and also at a given set of heights (*e.g.*, 50 km, 180 km, 250 km, and 500 km) are also given by Bartels [10].

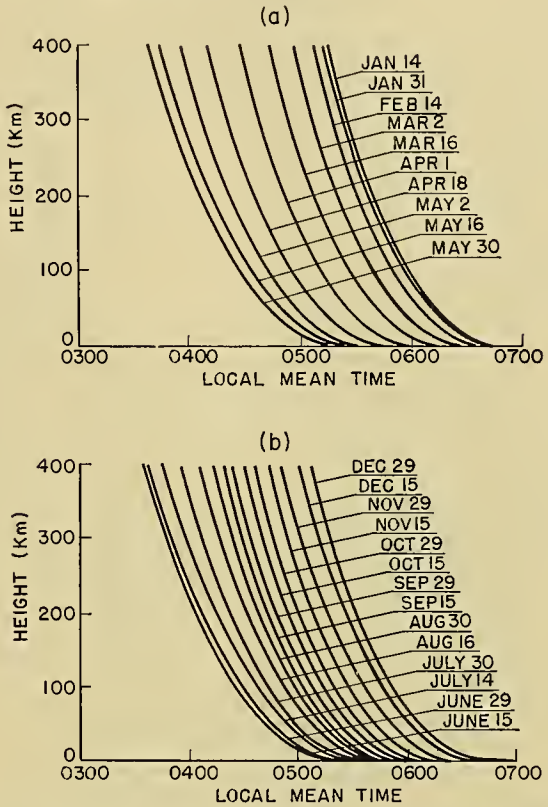

FIG. 3.—Illustrating how the hour of sunrise at different heights in the upper atmosphere changes in the course of the year at the latitude of Calcutta. (*After Ghosh.*)

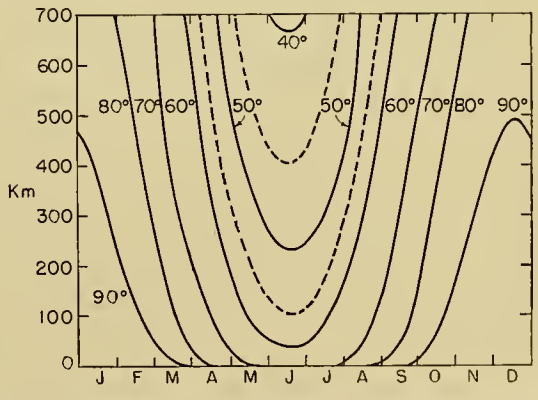

FIG. 4.—Illustrating the heights above which the atmosphere is illuminated at midnight in the course of the year at different latitudes. (*After Bartels.*)

A PICTORIAL REPRESENTATION OF THE PHYSICAL FEATURES OF THE UPPER ATMOSPHERE

In Fig. 5 an attempt has been made to depict the physical features of the upper atmosphere and some of the phenomena occurring there.

Starting from the tropopause we note that the region

from 20 km to 40 km is rich in atmospheric ozone. The total quantity of ozone is small—only about 0.25 cm thick if reduced to standard temperature and pressure—but it suffices to cut off all solar radiation in the near ultraviolet below 2800 A. In the region round 80 km noctilucent clouds occur. Meteors appear and disappear most frequently in the region from 50 to 150 km.

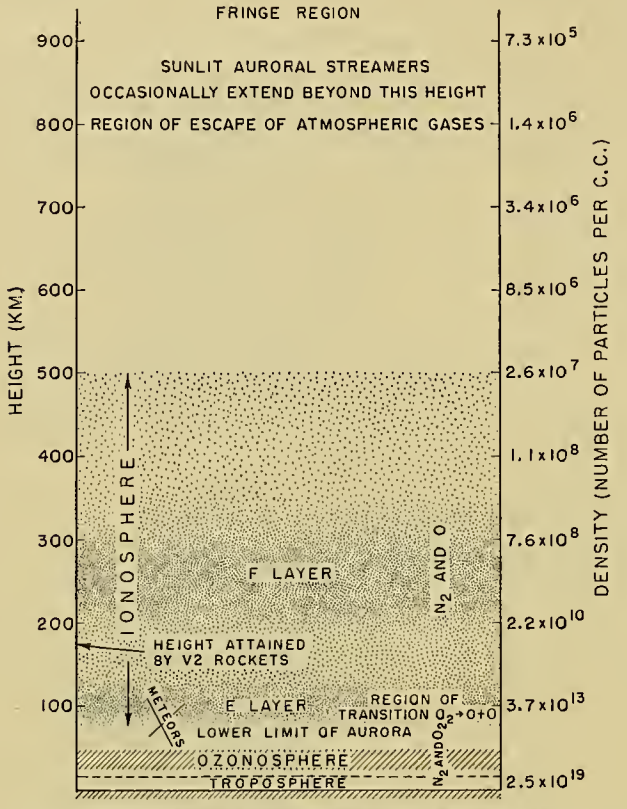

Fig. 5.—Illustrating some of the physical features of the upper atmospheric regions. The ionospheric regions are shown by shading with dots, the depth of shading roughly indicating the relative intensity of ionization.

The regions above 70 km are ionized by the solar extreme-ultraviolet rays and are collectively called the *ionosphere*. The region from 80 to 130 km is the region of transition from an atmosphere consisting of N_2 and O_2 to one of N_2 and O, due to the dissociative action of solar ultraviolet rays. The region from 80 to 120 km is the region of the most frequent occurrence of aurorae. But auroral rays are sometimes known to extend up to a height of 1000 km and beyond.

Atmospheric gas particles which are not ionized by solar ultraviolet rays escape from the region estimated to lie between 500 and 1000 km. Such particles as escape from the atmosphere but are unable to overcome the gravitational pull travel in closed orbits and form the exosphere or the fringe region of the atmosphere.

The physical features depicted in Fig. 5 are, of course, only illustrative and should not be taken too literally. This remark is particularly applicable to the density distribution above 100 km. Here, because of the uncertainty of the temperature distribution and of the mean molecular mass, the density distribution is uncertain. For example, if it is assumed that the region above 100 km is in diffusive equilibrium, the higher regions would consist almost entirely of oxygen atoms. But the spectrum of auroral rays shows that, up to the highest limits, the intensity of the negative bands due to ionized nitrogen molecules vies with that of the lines of atomic oxygen.

METHODS OF EXPLORING THE UPPER ATMOSPHERIC REGIONS

The methods of exploring the upper atmospheric regions may be classified under two heads—direct methods and indirect methods.

Direct Methods. Under this caption we include those methods in which the physical agency employed for exploration is under the control of the investigator. A straightforward direct method is to send up craft carrying recording apparatus which may register temperature, pressure, humidity, wind, and any other measurable physical quantities. A variation of this method is the so-called *radiosonde method* in which the craft carries a small radio transmitter which automatically sends out signals of the recorded data. The great advantage of radiosondes is that instantaneous knowledge of the data is gained and it is not necessary to wait until the craft comes down and the registering apparatus is collected.

Until recently the craft used for this purpose were generally sounding balloons filled with hydrogen gas. (Aircraft are also used for regions up to about 14 km.) The height reached by such balloons seldom exceeds 30 km. But a new departure was made in 1946 by utilising the V-2 rockets devised during the war. These reach enormous heights (up to 180 km) and even the very first trial flights have yielded many important results.

A few words may be said here of the technique of this latest method of sounding the upper atmosphere. (General accounts of it are to be found in articles by Krause [52] and by Newell [80]; an excellent summary is also given by Sheppard [96].) The war head which contains the recording instruments bursts towards the end of the flight and the instruments are landed by means of a parachute. The height and the velocity of the rocket are tracked by radar throughout its flight. For the flight at White Sands, New Mexico, on March 7, 1947, the highest velocity, 1600 m sec^{-1}, was attained at the height of 127 km, 80 seconds after launching the rocket. The highest altitude attained was nearly 180 km. Measurement of the velocity is important because it is necessary for evaluation of the temperature. Much of the recorded data was also telemetered to the ground during the flight. By various instruments and devices pressure down to 10^{-5} mm was measured. The temperature was derived from the pressure-height curve and/or from the ratio of the ram pressure (the pressure at the stagnation point on the nose of the rocket) to the static pressure. The probable errors of measurement are still

rather large, averaging ± 20C. The recorded data will be discussed in the next section.

Another agency for direct study is pressure waves produced by explosion. These waves proceeding upwards may be bent down if they meet a region of high temperature where the phase velocity is greater. Records of the downcoming wave yield information regarding the density and temperature distribution.

An analogous method is to use radio waves instead of sound waves. These waves penetrate beyond the highest limits attained by V-2 rockets and when they come down, "reflected" by the ionized regions of the upper atmosphere, they carry with them indelible messages regarding the physical conditions of such regions, which are no less useful than those recorded by instruments carried by sounding balloons or rockets.

Indirect Methods. These consist in studying critically such of the geophysical phenomena occurring near the surface of the earth or in the upper atmosphere as are known to have bearings on the physical state of the upper atmosphere. These phenomena include aurorae, lights from the night sky, meteoric flashes, noctilucent clouds, oscillations of barometric pressure, terrestrial magnetic variations, and spectra of direct or scattered sunlight.

The various direct and indirect methods that have been employed in the study of the upper atmospheric regions and the main results obtained therefrom are shown in Tables II and III. Short accounts of the methods together with a brief survey of the contemporary state of ourknowledge of the physical state of the upper atmosphere will be given in the next section.

TABLE II. DIRECT METHODS OF STUDYING THE UPPER ATMOSPHERE

Method	Region explored	Atmospheric conditions inferred from the study
Sounding balloon	Up to 30 km	Troposphere is in quasi-adiabatic equilibrium; in the stratosphere the temperature distribution is nearly constant with height; information about composition and wind systems.
Smoke shell	Up to 30 km	Existence of seasonal wind systems.
V-2 rocket	Up to 120 km	Generally confirms results on temperature and density distribution as inferred from the indirect methods of study; the chemical composition of the atmosphere at 70-km level is practically the same as that in the troposphere; solar spectrum is extended beyond the ozone absorption limit; Mg^+ doublet (2802 A) obtained in emission.
Sound explosion	35–60 km	Rise of temperature in the middle atmosphere; existence of wind systems.
Radio-wave exploration	70–500 km	Atmospheric constituents from 70 km upwards are ionized; measurements of scale height H, intensity of magnetic field, recombination coefficient. High temperature (approx. 1000K) in the region 250 km. "Bursts" of ionization are produced along meteor trails.

TABLE III. INDIRECT METHODS OF STUDYING THE UPPER ATMOSPHERE

Phenomena studied	Region explored	Atmospheric conditions inferred from the study
Meteoric phenomena	40–150 km	Rise of temperature in the middle atmosphere and correspondingly greater density; drop in temperature at 80-km level; existence of seasonal winds.
Ultraviolet spectrum of direct or scattered sunlight	20–60 km	Contains ozone with maximum concentration at about 25-km level; thickness of the ozone layer reduced to S.T.P. is only about 0.25 mm.
Noctilucent clouds	70–90 km	High-velocity wind and low temperature (approx. 200K).
Barometric oscillations	50–400 km	Tidal motions in the upper atmosphere; temperature rise in the middle atmosphere with a cold top.
Terrestrial magnetic variations	70–100 km	High electrical conductivity and world-wide electric current systems.
Night-sky luminescence	60–500 km	Sodium atoms in the middle atmosphere (60–80 km); atomic oxygen in the higher regions above 100 km; nitrogen molecules are ionized by solar rays.
Aurorae	80–1000 km	Entry of high-speed charged particles; atomic oxygen and atomic nitrogen present.

A SURVEY OF THE CONTEMPORARY STATE OF OUR KNOWLEDGE OF THE UPPER ATMOSPHERE

Composition. Near the surface of the earth the atmosphere consists of nearly 99 per cent by volume of the gases nitrogen and oxygen. Next in importance are argon 0.93, carbon dioxide 0.03, neon 1.8×10^{-3}, and helium 0.5×10^{-3} per cents by volume [26].

Chemical analysis by laboratory methods of samples of air collected in stratosphere flights and by pilot balloons has shown that this composition is maintained up to a height of about 29 km [84]. Contemporary experiments made with samples of air collected by V-2 rockets show that practically speaking the same composition is maintained up to 70 km [23]. This is very satisfactory, because from various considerations the same conclusion had been arrived at long before the observations with V-2 rockets. (Ozone is present in the middle atmosphere in appreciable quantities. This will be discussed later.)

The atmosphere above 80 km begins to change in composition because of the dissociative action of solar ultraviolet rays on molecular oxygen ($\lambda < 1751$ A). The region 80–130 km is the region of transition from

an atmosphere consisting of N_2 and O_2 below, to one of N_2 and O above [25, 57, 88, 90, 108]. Since low pressure is conducive to diffusive separation, it might be expected that atomic oxygen would predominate in the highest regions of the atmosphere [75]. There is, however, no evidence of it. Spectra of auroral streamers extending up to 1000 km and beyond show lines due to atomic oxygen and bands due to N_2^+ with almost equal intensity. Presence of atomic nitrogen has also been reported in low-latitude aurorae [32, 41], but whether atomic nitrogen is as generally distributed as atomic oxygen is not yet known (see section on aurorae below).

Temperature Distribution. The temperature distribution in the troposphere and the lower stratospheric regions is now well known from direct observations with the help of sounding balloons and smoke shells [50]. There is a falling temperature (lapse rate about 5C km^{-1}) in the troposphere, the depth of which varies between 8 and 18 km. Above the troposphere the temperature is nearly constant. For the higher regions up to 120 km, we now have results of direct observation thanks to successful V-2 rocket flights. These observations are now confined only to isolated places (in the United States) but it is hoped that in the near future reliable data based on rocket observations will also be available for the different latitudes at different hours of the day and night and in different seasons. A complete picture of the world distribution of temperature, at least up to Region E of the ionosphere, will thus be available. In Fig. 6 the temperature distribution obtained from the rocket flight at White Sands, New Mexico, on March 7, 1947 is depicted [15]. For comparison, the distributions obtained from results of indirect observations (abnormal sound propagation, meteoric flashes, and noctilucent clouds), are also given.

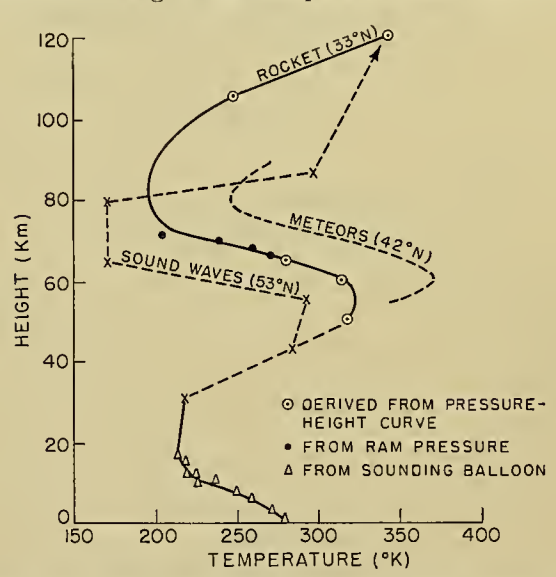

FIG. 6.—Temperature distribution with height. The rocket data are from the flight on March 7, 1947 at White Sands, New Mexico. The sounding balloon data were obtained within an hour of the rocket flight. For comparison, temperature distributions as deduced from abnormal sound propagation experiments and from meteoric data are also given after Sheppard [96].

It will be seen that the trend of the rocket-observation curve is the same as the general trend of the results from indirect observations.

Some remarks about the origin of this peculiar temperature distribution in the middle and in the upper atmosphere and the indirect methods of investigation by which it had been surmised long before may be made here. The rise of temperature in the middle atmospheric region (30–50 km) is due to absorption by ozone [43, 87]. The existence of any marked temperature variation in the stratosphere was, however, not suspected until the famous work of Lindemann and Dobson on meteors [54]. These authors developed a theory of the appearance and disappearance of meteors and applied it to determine the density distribution in the middle atmosphere. Their findings could be reconciled with observed meteoric data only if it was assumed that an isothermal region of high temperature (about 100C) existed above 55 km.

A later interpretation of meteoric data by F. L. Whipple [106] based on a different theory of meteors (first suggested by Sparrow [97] and subsequently developed by Öpik [83]) also confirms these results. The meteoric data, according to Whipple, can best be reconciled if it is assumed that there is a flat temperature maximum of about 375K near the 60-km level (as in the case of the Lindemann-Dobson theory), a rapid drop to 250K near 80 km (as in the Taylor-Pekeris theory, see below), and a constant or slowly rising temperature up to about 110 km. A seasonal variation is also indicated. The upper atmosphere, under average midsummer temperatures, is raised 5.3 ± 1 km above its height under average midwinter temperatures.

Existence of high temperature in the middle atmosphere, as indicated by the study of meteors, is also confirmed by the study of abnormal propagation of sound waves. The sound of an explosion or the firing of a cannon can be heard not only in the neighbourhood of the source of sound but also at a greater distance, in an area separated from the audible zone by a silent zone. The phenomenon is caused by refraction of the sound waves by the region of high temperature in the middle atmosphere. Since the trajectory followed by the sound ray in the region of high temperature depends upon the temperature gradient of the region, it is possible, from a systematic study of the abnormally propagated waves (the source being an artificial explosion), to deduce the gradient as well as the temperature. Such studies have been made in Germany, in England, in the United States, and recently in India [62].

In the region from 60 to 80 km there is no strong absorption of solar radiation. (Below 60 km there is absorption by ozone; above 80 km there are absorptions leading to dissociation of molecular oxygen and ionization of the atmospheric gases.) Hence, a falling temperature is to be expected in this region. The rocket curve shows this clearly, the temperature dropping to about 180K near the 80-km level. A drop was also inferred from indirect evidence long before rocket experiments. For example, the so-called noctilucent clouds which are observed in the region around 80 km are

believed to be composed of ice crystals. According to some authorities the presence of the ice crystals indicates a temperature of 160K in this region [60]. Again, radio measurements show that the scale height (kT/mg) for this region has a value which corresponds to a temperature of about 200K [19]. Meteor observations by Whipple, however, indicate a drop to only 250K near 80 km (see above). Work on atmospheric tides [104] also confirms the general trend of the drop in temperature in this region.

Above 80 km a rise in temperature would be expected because of strong absorption by O_2 molecules (1751 A). This is fully supported by the rocket observations. A rise from 180K to 335K is found between the levels 80–120 km.

Beyond 120 km there are several indirect evidences indicating that the rising gradient is maintained and a temperature near 1000K to 1200K is attained at the height of Region F_2. These evidences are (1) increased scale height in Region F_2 as compared to that in Region E [3], (2) escape of helium from the outer atmosphere, which demands a temperature of above 1000K [49, 98], and (3) large width of the green line of atomic oxygen in the spectrum of night-sky emission [8]. (It should be mentioned, however, that in regard to the last-named evidence more recent measurements of the green oxygen line [102] show that the previous estimation of temperature was too large.)

It appears that there is considerable variation, both spatial and temporal, in the value of this high temperature within the ionospheric Regions E, F_1, and F_2, 80 to 400 km [95]. In the F_2-layer the temperature is found to vary (both spatially and temporally) from 100K to 1000K. In lower levels the range is smaller. In the stratum from 200 to 300 km, in the noon meridian, two centres of high temperature are found, one from 30°N to 50°N and the other at 35°S. The former is less peaked than the latter. It should be mentioned that these temperatures have been derived by Seaton [95] from the values of the recombination coefficient computed from ionospheric data for January 1947, collected at eighteen stations situated between 71°N and 43°S. Existence of such thermal patterns implies the existence of quite strong wind systems in the ionospheric regions (see below).

The existence of a high temperature in the uppermost regions of the atmosphere can also be inferred on strong theoretical grounds. The primary effect of the absorption of solar radiation might be dissociation, ionization, or excitation of the constituent gases of the atmosphere; but, like all other forms of energy, the absorbed energy must ultimately degrade into thermal energy of molecular agitation, causing a rise of temperature. (The applicability of the concept of temperature for the very high regions of the atmosphere has been discussed by the author [72, pp. 507–510].)

Study of Meteors. It has already been mentioned that the existence of a region of high temperature in the middle atmosphere was first inferred from a study of the heights of appearance and disappearance of meteors. Winds in the upper atmosphere have also been studied from measurements of the drift and distortion of long-lived meteor trails [47, 82, 99]. Study of meteors, in fact, provides a valuable means of investigating the physical characteristics of upper atmospheric regions. It is, therefore, very satisfactory that a new technique—the radar technique—has been adapted for this study, and developed in the research laboratories of different countries [46, 55, 58, 63]. Not only is the ionization produced by meteoric impacts being systematically studied, but methods have also been developed for measuring the velocity [34] and other characteristics of meteors (*e.g.*, height, range, and radiant point). Accurate determination of the meteor velocity is very important in the application of the theory of meteors in deducing various upper atmospheric data.

Ozonosphere—Origin of High Temperature in the Middle Atmosphere. The high temperature of the middle atmosphere mentioned above is a consequence of absorption of solar radiation by atmospheric ozone. Because of this absorption the solar spectrum ends abruptly at about 2900 A. The absorption bands responsible for this are known as Hartley absorption bands.

The ozone content of the atmosphere may be determined by the measurement of the variation of the intensity of solar radiation near the ultraviolet end of the spectrum as the zenith distance of the sun changes [20]. A more accurate method is spectrophotometric study of sunlight scattered from the zenith sky. The intensities of two spectral regions near the absorption edge, one of which is rather strongly and the other weakly absorbed, are compared when the sun is setting [41]. This makes possible, with the help of the so-called Umkehr effect, an approximate estimate of the distribution of ozone with height. Contemporary improvements in the technique of ozone measurement, utilising photoelectric multiplier tubes should be mentioned. At the 1948 Oslo meeting of the Union of Geodesy and Geophysics it was claimed that with the improved technique, the scattered light from the moon and the stars sufficed for making measurements of the ozone content at night.

It has been found that the proportion of ozone to air by volume is a maximum at a height of about 35 km. The atmospheric ozone near the region of 50 km acts as an enormous reservoir of heat. This height is much above the centre of gravity of ozone because the solar ultraviolet radiation responsible for heating is almost completely absorbed in the top layer [87].

The ozone content shows a diurnal variation, being greater at night or at least never less than that during the day. There is also a seasonal variation; the maximum occurs in spring and the minimum in autumn in both hemispheres. This annual variation is greatest in the high latitudes and least near the equator.

It is to be noted that solar radiation is responsible for both production and destruction of ozone. It is produced by absorption by molecular oxygen in the range of the so-called Runge-Schumann absorption bands (1760–1925 A) when excited O_2 molecules are

produced. It is destroyed by absorption in the near ultraviolet in the Hartley bands (2100–3000 A).

Observations show that the variation of the atmospheric ozone content has little if any association with the 11-year solar cycle. It appears, however, that there are 27- and 15.5-day periods of variation with small amplitudes.

Ionization in the Upper Atmosphere—Radio Exploration. Atmospheric constituents from 70 km upwards are more or less ionized by the action of the extreme solar ultraviolet rays. Under certain ideal conditions each atmospheric constituent ionized may be supposed to produce a distinct layer or region of ionization. Such a region of ionization is called a *Chapman region* [24]. There are several ionized regions and these are known collectively as the ionosphere. The two main regions of maximum ionization, Region E and Region F, are at average heights of 100 km and 275 km respectively. The average maximum ionization densities of these two regions, in the epoch midway between the maximum and minimum of solar activity, are of the orders 10^5 and 10^6 electrons cm^{-3}, respectively. During daytime, Region F splits up into two regions, F_1 and F_2. A subsidiary Region E_2 (above E, which is sometimes called E_1) also appears during the daytime. The average heights of the maximum ionization of F_1 and E_2 are 200 km and 140 km, respectively. The ionization below 80 km (Region D), present during the daytime, causes absorption of radio waves of medium length.

As may be expected, the ionization densities of the various regions vary with the hour of the day, the season of the year, and also with the solar cycle. It should be noticed, however, that while Regions E and F_1 follow, in the main, the simple $\sqrt{\cos \chi}$ law (*i.e.*, intensity of ionization is proportional to $\sqrt{\cos \chi}$, where χ is the zenith angle of the sun), Region F_2 refuses to do so. Region F_2 is, in fact, notorious for its erratic behaviour.

Besides the regions mentioned above, which are more or less permanent features of the ionosphere, mention should also be made of what is known as *sporadic E*. Part, at least, of sporadic E is ascribed to ionization produced by meteoric impacts [55].

The knowledge of upper atmospheric ionization summarized above has been gained mainly through exploration by radio waves. The radio wave is now the most powerful experimental tool for studying upper atmospheric ionization. The most important method of radio exploration is as follows: Packets or "pulses" of radio waves are sent upwards. These are generally scattered if they meet a region of ionized atmosphere. If the ionized region is extensive—of dimensions much larger than the wave length—then, depending upon the frequency, the wave packet may be totally or partially reflected. Or it may penetrate through, or be absorbed by, the ionized region.

The technique of the method has now been greatly perfected. Records of ionosphere characteristics are now kept in many stations of the world as regularly as weather and magnetic data. Predictions of ionospheric conditions, well in advance, for determining the maximum usable frequencies for communication over given distances, are also made regularly by many ionosphere stations.

The other physical properties of the upper atmospheric regions which have been determined from the ionospheric studies are the following:

1. The absorption phenomena of radio waves enable us to estimate the collisional frequencies and the molecular densities in the different regions. Thus, it is found that for Region E, the pressure is of the order 10^{-3} mm and for Region F 10^{-5} mm.

2. Analysis of the records of diurnal variations of the heights and the maximum ionization densities of the Regions E and F_2 has confirmed the existence of tidal motions in the high atmosphere. Observations on absorption in the lowermost ionospheric region—the D-region—has revealed the existence of lunar tidal oscillation effects in this region also [5].

3. The study of the magnetic splitting of the radio waves in the ionosphere affords a means of estimating the intensity of the earth's magnetic field at great heights above the surface of the earth.

It has now been established that the different ionospheric regions are produced by the ionization of the different atmospheric constituents at different levels. According to one hypothesis [16], Region F_2 is produced by ionization of atomic oxygen, Region F_1 by ionization of N_2, Region E by ionization of O_2 at second ionization potential, and Region D by the ionization of the same molecule at its first ionization potential [74]. According to another hypothesis, Region F_1 is produced by ionization of atomic oxygen in the normal manner and Region F_2 by splitting up of this region into two regions [78]. According to still another hypothesis, some of the ionized regions may be produced by radiation from the solar corona [107]. In regard to Region E it may be noted that for a long time it had been difficult to explain theoretically the location of its height of maximum ionization, because the height at which it was expected was much above the observed height. The difficulty has been reconciled by the hypothesis that the E-layer is located in the region (90–110 km) where the density of O_2 molecules diminishes rapidly with height on account of the dissociative action of solar ultraviolet rays [67]. Further, it is believed that in this region the O_2 molecules are pre-ionized, rather than directly ionized, by solar radiation of appropriate wave length [81].

Luminescence of Upper Atmospheric Regions. On dark moonless nights, the portions of the sky devoid of stars are found to emit a faint light. Part of this light is due to starlight scattered by the atmosphere and part due to other sources. But a certain proportion, about 40 per cent, has been found to be due to the self-luminescence of the upper atmospheric gases. Spectroscopic study of the night-sky radiation shows the presence in the upper atmosphere, besides O_2 and N_2, of O and Na atoms and of H_2O and OH.

The most prominent lines and bands in the night-sky spectrum in the visible region are lines due to O atoms and bands due to N_2 molecules. The luminescent region emitting these lines and bands may possibly be identified with Region F of the ionosphere (200–400 km). It

has been found that the night-sky brightness due to these lines and bands fluctuates erratically when the ionospheric conditions in Region F do so [69]. The reaction which excites these spectra is most probably due to the mutual neutralization of N_2^+ and O^- ions [67], thus,

$$N_2^+ + O^- \rightarrow N_2 \text{ (excited)} + O \text{ (excited)}.$$

In the infrared region there are strong emissions due to *OH* bands [65]. The region from which these are emitted is still uncertain.

There is a luminescent layer (60–80 km) emitting sodium *D* lines [12] and also possibly one emitting O_2 bands at the height of Region E.

The intensity of the night-sky radiations varies with the season of the year and with the solar cycle and shows how upper atmospheric conditions are controlled by solar radiation and by the corpuscular emission from the sun.

Winds in the Upper Atmosphere—Atmospheric Tides. There is evidence that up to the height of Region F the atmosphere is subject to winds, caused partly by temperature gradient and partly by tidal effects. Tentative curves depicting the variation of wind with height, for summer and winter in the middle latitudes, are drawn after Sheppard in Fig. 7 [96]. The data for the region

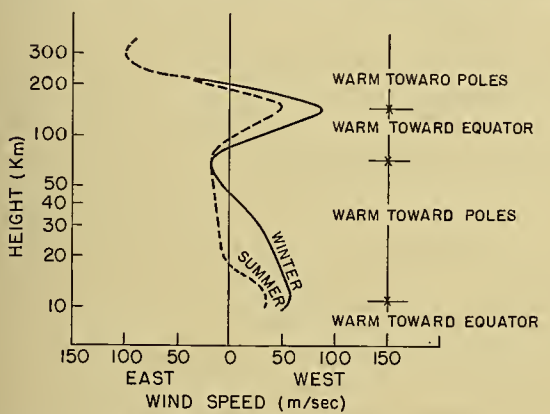

FIG. 7.—Probable variation of wind (east and west components) with height in middle latitudes for summer and winter. The height is given in logarithmic scale as this enables one to infer directly the approximate mass flow. The meridional temperature gradient for quasi-geostrophic winds is shown on the right. (*After Sheppard* [96].)

around 30 km are from sounding-balloon [44] and smoke-shell observations [50]. For higher regions, the evidence is from observations on noctilucent clouds and from meteor trails. For the latter (in the region of 120 km) an optical technique has been developed for measurement of wind from the drift and distortion of long-lived meteor trails by Störmer in Norway [99], Olivier in the United States [82], and Hoffmeister in Germany and Southwest Africa [47]. Radio observations on the movements of what are called *ion clouds* also confirm the existence of winds in this and in still higher regions [14, 36, 77, 79].

Regarding the tidal effect it is to be mentioned that there exist in the atmosphere, just as in the ocean, tidal motions due to the pulls of the sun and the moon. These tidal effects have been observed up to the highest regions of the ionosphere—the F-region (250–400 km). A direct effect of the tidal oscillations is seen in the rhythmic variation of the barometric pressure. An indirect effect is the rhythmic variation of the terrestrial magnetic elements on a magnetically quiet day. The amplitudes of these variations are small—only about a few thousandths of the total value—but they are singularly persistent.

The tide-raising force of the moon is about 2.5 times as strong as that of the sun. But, contrary to expectation, it is found that the solar tidal effect is very much more prominent than the lunar one. The origin of this anomaly is traced to a resonance effect. It was first pointed out by Taylor and Pekeris that, because of the peculiar temperature distribution in the middle atmosphere (a temperature rise in the neighbourhood of 50 km followed by a cold top), the atmosphere has a mode of oscillation with a 12-hour period [86, 100]. Hence the solar tidal effects are greatly enhanced by resonance.

The ionized regions of the upper atmosphere are also necessarily subject to the tidal oscillations. The oscillations of the lowest of these regions are responsible for the quiet-day magnetic variations as follows: As the conducting ionized region, in its horizontal tidal motions, cuts the magnetic lines of the earth, emf's are developed in these regions. These emf's produce world-wide electric current systems in the upper atmosphere. The magnetic field of these current systems produces the quiet-day variations of the terrestrial magnetic elements. It is believed that the most probable location of these current systems is the lower regions of the ionosphere (D- and E-regions) where the mean free paths of electrons and ions are small [64].

Aurorae—Entry of Fast Charged Particles into the Upper Atmospheric Regions. The luminescence of the aurora is due to the excitation of air molecules by collision with the fast charged particles emanated from the sun and incident on the upper atmosphere. Besides the lines and bands observed in the night-sky light (with different intensity distribution) a special feature of the auroral spectrum is the great intensity of the so-called negative bands of nitrogen due to N_2^+ ions. It also appears that nitrogen atoms are present in the aurora. Identification of forbidden lines of atomic nitrogen in the auroral spectrum has been reported by more than one worker. Bernard [13] claims to have identified the forbidden ultraviolet doublet of N, $^2P \rightarrow {}^4S$ (3466 A) while Dufay, Gauzit, and Tcheng Mao-lin [33] announce that they have observed the forbidden green doublet, $^2D \rightarrow {}^4S$ (5199 A) in low-latitude aurorae. It should be mentioned that according to quantum-mechanical calculation by Pasternack [85], the lifetime of the excited state for 5199 A is 10 hours. According to Götz [42], the strength of this radiation in the case of low-latitude aurorae (which generally lie at greater heights) may continue undiminished for hours after the aurora ends. From the intensity measurement made on a particular aurora, the concentration of excited N atoms, at an altitude somewhat above 200 km, was estimated to be of the order 10^6 cm^{-3}.

As is to be expected, auroral activity and magnetic disturbances are closely associated with solar phenomena. For instance, both auroral and magnetic activity show remarkable correlation with sunspot numbers [28]. Also both have seasonal variation—maxima in March and October and minima in June and January [27].

Weather and the Upper Atmosphere. It may seem surprising that weather conditions in the tropospheric regions should have any association with the physical conditions of the atmosphere tens or even hundreds of kilometres above the surface of the earth. Nevertheless, evidence of such associations (some of them yet unexplained) has been obtained.

It has been found that the ozone content in the middle atmosphere is markedly related to weather conditions in the troposphere [31, 32]. Almost without exception the ozone value is found to be high with cyclonic systems (low pressure) and low with anticyclonic systems (high pressure). Periods of fine and settled weather have been observed to be associated with relatively low ozone value [101].

Atmospheric densities at heights of 75 km (as deduced from observations on meteors) show a marked seasonal variation, and this variation is correlated with the mean ground temperature [105], a maximum density being indicated at the time of maximum ground temperature.

Association between Region E ionization and thunderstorms has been reported by some observers [6, 17, 92, 93]. Evidence has also been obtained of association of weather conditions in the tropospheric regions with variations of ionization densities in the ionospheric regions [60]. For instance, it has been observed that the variations of the minimum heights of Region F and of the Region E tend to follow the variations of the barometric height. Again, day-to-day variations of noon ionization of Region E seem to correspond to the day-to-day variations of barometric height. Some remarkable correlations of the variation of Region F_2 ionization and cyclonic conditions near the ground have also been reported from Australia [9]. Other similar correlations, scarcely less remarkable, have been reported from Shanghai, China [38]. It has been found that there is close relationship between the occurrences of the E, F_1, and F_2 echoes (when the ionosphere apparatus is set to the fixed frequency, 6 mc sec^{-1}, the mean E-critical frequency of the place) and the movements of the three main air masses—polar, maritime, and equatorial—which cause weather all over the world. It is claimed that these observations can be very successfully used for weather prediction.

Extension of the Atmosphere to Great Heights. Streamers of aurorae of the ray type extend to great heights (800 to 1100 km) into the sunlit portion of the upper atmosphere. Spectroscopic study of the auroral light shows that even up to such heights the atmosphere consists of atomic oxygen and molecular nitrogen.

SOME UNSOLVED PROBLEMS

The brief account of the contemporary state of our knowledge of the upper atmosphere given above shows that in spite of the many difficulties, a considerable amount of information has already been gained. However, there are still gaps in our knowledge. This is due not only to the inaccessibility of the regions concerned, but also to the lack of many fundamental laboratory data of the atmospheric constituents. But perhaps the greatest obstacle has been our imperfect knowledge regarding the nature of extreme ultraviolet radiation from the sun. Let us hope that this gap will soon be filled up by observations made with the help of V-2 rockets.

Let us attempt a survey of the upper atmospheric problems which need further investigation or are still awaiting solution. It is very satisfactory that direct observations with V-2 rockets have confirmed the surmise made long ago that the main atmospheric constituents up to about 70 km occur in the same proportion as near the ground [23]. It is very probable that not far above this level the dissociation of O_2 molecules begins. But the relative distributions of O_2 and O with height are not known with certainty. Several possible distributions have been obtained by different authors under different assumptions [25, 57, 88, 90, 108]. But the distribution which best represents the actual state of affairs has still to be found. Accurate determination of this distribution is very necessary because, according to more than one author, the electron-density distribution in Region E depends upon the distribution of molecular oxygen in this transition layer [16, 67].

The question at what height above 70 km diffusive separation becomes important is of considerable interest because on it will depend the relative abundance of N_2 and O in the highest regions of the atmosphere [75]. With diffusive separation the highest regions should consist almost entirely of O atoms. But, as mentioned earlier, the spectrum of auroral streamers up to 1000 km contains atomic oxygen lines and molecular nitrogen bands with comparable intensities. It is still not clear how nitrogen molecules which are nearly twice as massive as oxygen atoms reach such great heights.

In the ozonosphere the modes of production and destruction of ozone and the ozone equilibrium resulting therefrom are in need of further elucidation. Interesting relations have been found between the ozone content of the atmosphere and weather conditions. But the ozone observations are still confined to a few stations. It is extremely desirable that a world-wide network of stations be established for simultaneous and systematic studies of atmospheric ozone, of temperature distribution in the middle atmosphere (by abnormal sound propagation method), and of meteors (by radar technique [34, 46]). Such studies will be helpful in understanding the correlations that have been observed between weather conditions in the troposphere and temperature variations in the middle atmosphere and may also be of help in long-range weather forecasting.

The temperature distribution in the region 70–90 km needs more accurate determination. Rocket observations confirm the results of studies by various indirect methods indicating that there is a rapid drop in temperature in this region. But the magnitude of the

drop is still not known with any reasonable degree of certainty.

Thanks to the work of Taylor [100] and of Pekeris [86], the long-standing problem of semidiurnal barometric oscillations and, along with it, the difficulty of the dynamo theory of quiet-day (solar) magnetic variations appears to have been solved. But the lunar semidiurnal barometric oscillations and the corresponding magnetic variations still have their puzzles. The barometric oscillations have unaccounted-for variations both in regard to amplitude and phase.

Our knowledge of upper atmospheric ionization has been extended remarkably by radio exploration utilising the powerful pulse technique. Notable additions to our knowledge have also been made by the adaptation of radar technique for this purpose. The ionosphere, however, is still full of mystery. Very plausible hypotheses have been put forward regarding the production of the different ionospheric regions, but it is safe to say that the last words on the subject have not yet been spoken.

Part, at least, of what is known as sporadic E is now known certainly to be due to meteoric ionization. The sudden bursts of ionization that had been noticed by many ionospheric workers have been traced to ionization produced by individual meteor trails [55]. It may be recalled, in this connection, that 450 kg of meteoric material burn up every day in the atmosphere near the level of Region E. Still, there is clear evidence that meteors cannot be assumed to be responsible for all sporadic E [91]. Also the increase of meteoric echo frequency, when the wave length is increased from 6 to 8 m (the large background rate), is still not quite explained [55, 89, 105].

An interesting observation on radio echoes from meteoric trails requires further clarification. Echoes of long duration show, besides a regular decay, a periodic fluctuation in intensity. It has been suggested that such a fluctuation may be caused by variations of wind with height [45]. These winds deform the straight column left by the meteor. Further observations in different latitudes are needed to test this suggestion and also to find out how far the magnetic field of the earth influences the cross section of the ionized column. But perhaps the central problem in the study of radio echoes from meteors is to find the mechanism by which sufficient electron density, for periods of more than a minute, could be maintained against the forces of diffusion [18, 45, 56].

The reason for the bifurcation of the F-layer into F_1 and F_2 during daytime is not yet understood. Associations between F_2 ionization and tropospheric conditions have been observed. But what is the origin of such association?

It is now suspected that many of the anomalous behaviours of Region F_2 may be traced to the effect of the terrestrial magnetic field, because ions and electrons in Region F, unlike those in Region E, have long mean free paths. For example, a geomagnetic control of Region F, in the form of a belt of low ionization round the geomagnetic equator, has been observed [4]. A plausible explanation of this has also been given [71] but the phenomenon needs much fuller investigation [53].

An attempt has also been made to explain some of the F_2-region anomalies by action of atmospheric tidal movements [59]. For example, the variations of h' (minimum height) and h_{max} (height of the region of maximum ionization) have been explained as due to simple rising and falling of isobaric surfaces, caused by tides. Variation of N_{max} (maximum electron density) cannot, however, be so simply explained. For this a theory has been developed in which it is shown that horizontal tidal motion of ionized masses gives rise to electrodynamic forces which produce a vertical component everywhere except near the magnetic equator. Many of the observed anomalous behaviours of Region F_2 have been explained by this theory. However, a complete theory of the F_2-region is still lacking.

An ionospheric region is by no means smooth in its ionization. Patches or clouds of more intense ionization, against a general background of uniform ionization, have been detected by workers in different countries [91]. As a matter of fact, the existence of winds in the high regions of the ionosphere has been established by systematic study of the movements of these clouds. The clouds are generally believed to be produced by meteor ionization. But their exact nature and life history are still little known. More observational data in different latitudes are needed.

The coefficient of recombination of electrons and ions in the high ionized regions, as deduced from observations, is found to be several orders higher than the theoretical value. This discrepancy appeared to have been removed by the hypothesis of effective recombination coefficient [7, 61]. Further, the identification of the nocturnal Region F with the luminescent layer of the upper atmosphere emitting the O lines and N_2 bands has helped to unify the effective recombination hypothesis with the emission process of these lines and bands [39, 69]. Contemporary work, however, questions the soundness of the effective recombination hypothesis. It has been pointed out by Martyn [59] that if account is taken of the electrodynamic forces developed as a result of the tidal motions, a term appears in the expression of the recombination equation which becomes important in Region F. The computed result, taking into account the contribution of this term, agrees with the observed value of the recombination coefficient. A closer comparative study of the effective recombination hypothesis and Martyn's hypothesis is needed to estimate the relative importance of the two in bringing agreement between observed and theoretically computed values.

Evidence of association between weather conditions near the ground and ionization density in Region F_2 has been obtained. No theoretical explanation of such association has yet been given.

It is highly desirable that more systematic observations on ionospheric data, particularly in regard to ionospheric absorption and ionospheric tides, be made in different parts of the world. With regard to the tidal

effect, it is very necessary to know how the phase of the tide varies with latitude. It appears that there are more observational stations in the Northern than in the Southern Hemisphere. Consequent lack of data is a great handicap in obtaining a complete world picture of the ionosphere. More ionosphere stations, particularly in the southern latitudes, are therefore very necessary. It has been suggested that a sea expedition be sent out to secure observations at different latitudes and longitudes which are scientifically important but for which data are lacking.

In the night-sky spectrum there are still lines and bands the origin of which is uncertain. Special interest lies in the identification of 3471 A. If this be due to atomic nitrogen, then photo-dissociation of N_2 like that of O_2 will have to be assumed, though laboratory experiments do not show any such dissociation effect.

It is satisfactory to note that the strong radiations 6580 A in the red and 10,444 A in the infrared, the origins of which had long been matters of controversy, have now been identified as bands due to the radical OH [65]. Bands of O_2 are reported to have been identified in the night-sky spectrum. If this is confirmed, then there must be another luminescent layer—perhaps at the level of the E-layer. The presence of sodium D-lines has been established and the location of the luminescent sodium layer has been studied. But the presence of sodium in the high atmosphere has raised many questions which are still unanswered. The continuous spectrum which forms the background of the lines and bands of the night-sky light appears to have received inadequate attention and awaits further study regarding its intensity variations and origin [30].

The intensity variation of night-sky light has a regular part (diurnal and seasonal) and an irregular part. Some investigators have sought to associate the irregular part with the magnetic disturbances. Some correlation has been found, but the whole subject is still in a speculative state and requires more intensive study.

A very plausible hypothesis regarding the excitation of the atomic oxygen lines and of the observed N_2 bands (first positive and Vegard-Kaplan bands) has been given [68], but the subject is still controversial [11].

Several attempts have been made to determine the heights at which night-sky luminescence originates. The values obtained vary from 60 km to a few hundred kilometres [21, 22, 35]. It is very likely that, like the several ionospheric regions, there are several layers of maximum luminescence. It is highly desirable that the many ionospheric stations which are being established in different parts of the world have attached to them observatories for study of night-sky luminescence. There are reasons to believe that some at least of the luminescent layers may be identified with some of the ionospheric layers [39, 69]. Close comparison of the variations of the night-sky intensity with those of ionized regions will help in the determination of the existence of such association.

Of the other lights from the night sky, the mystery of zodiacal light is still far from solved. There is little doubt that the light is due to scattering by some sort of dust cloud in extraterrestrial space. But the location of the cloud is still a matter of controversy; whether it belongs to the earth or to the sun is not known definitely. Many theories as to the origin of this cloud have been put forward, but none of them can be considered fully satisfactory [37, 48, 103].

The problems of the aurorae and of the incidence of the magnetic disturbances, so closely related to each other, are only partially solved. There is little doubt that the primary cause of these phenomena is emission of fast charged particles from the sun. It may be noted that direct evidence has been obtained of the existence of Ca^+ ions and protons between the earth and the sun during magnetic storms [1, 25, 65a]. That these may be at least one of the kinds of charged particles emitted from the sun had long been suspected, but the mechanism of the emission of such particles is still only guesswork. Further, the fundamental dilemma still remains: The charged particles, to produce the observed effects, must arrive in bundles, whereas they are bound to be dispersed on their way by electrostatic repulsion. Attempts at solving this problem by imagining that the particles constitute a neutral beam have met with only partial success [2, 29]. (See, however, [59a].)

The lines and bands of the auroral spectrum may be classified under two heads: first, spectra excited by direct bombardment of charged particles—first negative bands of N_2^+; and second, spectra excited as a result of reactions amongst neutral and charged particles produced by the bombardment (second positive, first positive, and the Vegard-Kaplan bands of N_2, as well as the forbidden lines of O [70]). Of these, the excitation processes of the first positive and the Vegard-Kaplan bands may be the same as those of the night-sky light spectrum. But there remains the problem that whilst the Vegard-Kaplan bands are strong in the night sky they are comparatively faint in the auroral spectrum. It has been suggested that this might be due to the fact that the auroral spectrum originates at much lower heights than the night-sky luminescent layer and as such the metastable $N_2(A)$ molecules from which these bands originate are de-excited by collision. However, objection to this has been raised on the ground that the strength of the Vegard-Kaplan bands does not increase with height in the spectra of auroral streamers. The excitation of second positive bands has been suggested as due to radiative recombination of N_2^+ ions and electrons. But here again it may be objected that the calculated intensity of such radiation is very small compared to the observed intensity.

In regard to the insufficiency of laboratory data which is still standing in the way of upper atmospheric study, mention might be made of the electronic spectra and of the absorption coefficients of N_2, O_2, and O in the extreme ultraviolet region. More complete knowledge is very necessary because the ionization densities of the ionospheric regions are controlled by the photo-ionization of these particles by absorption in the extreme ultraviolet. A more detailed study by the quantum-

mechanical method of the collisional cross sections of these molecules and atoms is also necessary. It may be recalled that ionospheric studies yield collisional frequencies of electrons with atmospheric particles, and one is tempted to infer from this the molecular densities in the respective regions. However, this is not justifiable since the cross sections of the atoms and molecules for low-velocity colliding electrons (corresponding to a temperature, for instance, of 1000K—a few tenths of an electron volt) may be widely different from the gas kinetic cross section [76, 94]. More theoretical and experimental data on the collisional processes between meteor atoms and air molecules are also needed. This will be helpful in improving the theoretical calculations on meteors.

It is a pleasure to record my thanks to Dr. S. N. Ghosh, Imperial Chemical Industries Research Fellow of the National Institute of Sciences of India, now working in my laboratory, for the help he has given me in the preparation of this article by collecting data, checking references, and suggesting improvements.

PHOTOCHEMICAL PROCESSES IN THE UPPER ATMOSPHERE AND RESULTANT COMPOSITION

By SYDNEY CHAPMAN

Queen's College, Oxford, England

INTRODUCTION

1. Chemistry and the Troposphere. The meteorology of the lower atmosphere, the region of weather, is essentially a *physical* science, in which chemistry plays practically no part; chemists may become good meteorologists, but meteorologists need not know much chemistry. Their work is concerned with fluid dynamics, with heat interchanges by radiation and conduction and convection, with mixing and changes of state of water vapor—evaporation, condensation, sublimation, and precipitation.

Chemists are indeed interested in the composition of air,[1] but their work has generally been supposed to end with the chemical analysis. This shows that air is a *mixture* of several gases, merely coexisting and not reacting chemically with each other to any significant degree in the lower atmosphere.[2] This is true for the main permanent constituents, nitrogen N_2 (78 per cent of dry air, by volume) and oxygen O_2 (21 per cent); for the chief variable constituent, water vapor H_2O; and also for carbon dioxide CO_2 and the rare gas constituents, helium, neon, argon, krypton, xenon, and radon.

In the lower atmosphere the only changes in the composition of dry air are minor and local, such as the *withdrawal* of a small amount of oxygen (and ozone) by plants or by oxidation of iron and organic matter; or the *emission* of carbon dioxide by plants, of organic and other gases by decaying matter and by factories and chimneys, and of helium and radon from radioactive matter below ground. Among the few constituents of the lower atmosphere that undergo appreciable chemical change are ozone and radon; the latter disintegrates radioactively, so that its concentration decreases upwards. This is a process of *nuclear* chemistry, outside the realm of ordinary chemistry, which is concerned with reactions affecting only the outer structures of atoms and molecules. The incidence of cosmic rays must also produce nuclear chemical transformations, relatively very rare, but worthy of study. However, the main fact of tropospheric chemistry is the uniformity of the composition of dry air all over the globe, near the ground, as shown by Paneth.[1]

Thus ozone is almost the only chemically active constituent of the tropospheric air, though it may be that there are other very rare but chemically active gases present, whose changes have not yet been considered. Ozone is always present in the air near the ground,[3] though it is reduced in concentration over industrial areas and to windward of them by oxidation processes. For a long time, however, little attention was paid to the chemical problems raised by the continued presence in the air of a somewhat unstable gas like ozone.

2. Atmospheric Chemistry. A more active interest in the chemical processes of the atmosphere was aroused when it was found that the ozone density is less in the air near the ground than in the air well up in the stratosphere—the height of maximum density being 20 to 25 km, though early estimates were 40 to 50 km. Such a distribution differs from that of all the other known constituents of the lower atmosphere, which decrease upwards in density, maintaining the same relative concentrations at least up to 20-km height, except in the cases of radon, whose relative concentration decreases upwards, and water vapor, whose distribution is irregular and variable.

This peculiar height distribution of ozone may be explained by attributing the formation of ozone to the dissociation of oxygen molecules into atoms O by sunlight; the O atoms then combine with O_2 molecules to form ozone ($O + O_2 \rightarrow O_3$), which is itself dissociated by sunlight ($O_3 \rightarrow O_2 + O$). The consequent reactions between the three forms of oxygen (O, O_2, O_3), which achieve a slowly changing equilibrium mixture, are very complicated, and the relative importance of these reactions varies with the height. Above about 80 km the ozone concentration sinks to insignificance and the atomic oxygen concentration increases to importance, and at levels probably of 100 to 120 km O becomes predominant over molecular oxygen. Its presence is indicated by the emission spectra of the atmosphere, namely those of the night sky and of the aurora. Similar spectral evidence reveals the presence of atomic sodium Na and also of atomic nitrogen N in the upper atmosphere, and the terrestrial part of the absorption spectrum of sunlight indicates that some oxides of nitrogen also exist in the atmosphere. The presence of such chemically active gases as atomic oxygen and sodium raises very interesting chemical problems, on which there is now a growing literature.

The chemical reactions and their energy mainly originate from the absorption of *light* from the sun, so that meteorological chemistry is in the main a branch of *photo*chemistry. It includes also some *impact*-chemistry, as it may be called, concerned with reactions initiated by the entry of fast-moving particles into the atmosphere from outside—a process somewhat analogous to the chemistry of reactions inside discharge tubes, in which fast-moving ions and electrons produce chemical changes in the gas. In the atmosphere the impacts are mainly those of the solar particles that cause aurorae and magnetic storms.

1. Consult "The Composition of Atmospheric Air" by E. Glueckauf, pp. 3–10 in this Compendium.

2. Consult "Some Problems of Atmospheric Chemistry" by H. Cauer, pp. 1126–1136 in this Compendium.

3. Consult "Ozone in the Atmosphere" by F. W. P. Götz, pp. 275–291 in this Compendium.

The chemistry of the atmosphere differs from laboratory chemistry because the atmosphere is without any material boundary except the ground, which exerts an appreciable chemical influence only on the air at the lowest levels. Above these levels, the wall-reactions, so important in laboratory chemistry of gases, play no part in meteorological chemistry.

The chemistry of the upper atmosphere is a borderline subject between the main fields of chemistry and meteorology, and naturally involves many aspects and conceptions that may be unfamiliar to meteorologists. The chief aim of this article is to assist them to read past and future papers on the subject by outlining its principles and some of its technicalities. The present primitive state of the subject is also briefly described, and some of its main problems are indicated. In so doing it is necessary to pay some attention to atmospheric spectroscopy and ionization.

SOME GENERAL PRINCIPLES OF GAS CHEMISTRY

3. Atomic and Molecular Particles. Atomic particles consist of a positively charged nucleus surrounded by (negative) electrons; molecular particles comprise more than one such nucleus, with electrons around and between them. If the number of electrons is equal to the number of positive electronic charges (each of magnitude ϵ) in the nucleus or nuclei, the particle is electrically neutral, and is called a (neutral) atom or molecule respectively; otherwise the particle is called an ion, atomic or molecular. In general, ions are positive, the number of electrons being less than that necessary for electrical neutrality; but certain gases, notably (in the atmosphere) atomic and molecular oxygen (but not nitrogen or the rare gases) form negative ions, taking on an extra electron beyond their normal number in the neutral state. Negative ions are indicated thus: O^-, O_2^-. Positive ions may be similarly indicated, for example, O^+, N_2^+ or, if doubly ionized, N_2^{++}. Otherwise I, II, III, are added to the chemical symbol to signify respectively the neutral state, the first positively ionized state, the second, and so on: for example, N_2 I, N_2 II, N_2 III instead of N_2, N_2^+, N_2^{++}.

The charge on an atomic nucleus is $Z\epsilon$, where Z is an integer, called the *atomic number;* it determines the chemical nature of the atomic particle. For hydrogen H, carbon C, nitrogen N, oxygen O, and sodium Na, Z is 1, 6, 7, 8, and 11 respectively.

The unit of atomic mass m_0 is one-sixteenth of the mass of the chief type of oxygen atom, the isotope O^{16}; $m_0 = 1823\ m_e$, where m_e denotes the mass of an electron [32]; hence the electrons make a very minor contribution to the masses of atoms. The mass of an atom or molecule is expressed respectively as Am_0 or Mm_0; A or M is called the atomic or molecular *weight.* Atoms may have the same Z (and therefore the same chemical nature) but different atomic weights A; the different forms are called *isotopes.* They usually differ greatly in their relative abundance; for example, in the case of oxygen the isotope for which $A = 16$ far predominates over the isotopes for which A (always nearly an integer number) is approximately 15 or 17, so that the average atomic weight of oxygen (including all isotopes) differs very little from 16. The isotopic constitution of the chemical elements in the atmosphere forms an interesting subject of study, as yet little developed. It will not be further mentioned here.

Chemists call M grams of a substance whose molecular weight is M a *gram-molecule* or mole or gram molecular weight (and, similarly, A grams of an element whose atomic weight is A, a *gram-atom*). The number N of molecules (or atoms) in a gram-molecule (or gram-atom) is M grams divided by the mass of one molecule, namely Mm_0, that is, $N = 1/m_0$ if m_0 is measured in grams; likewise for the number of atoms in a gram-atom. This number N is called *Loschmidt's* (or, less appropriately, *Avogadro's*) *number:*

$$m_0 = 1.660 \times 10^{-24} \text{ gram}; \quad N = 6.023 \times 10^{23}.$$

4. Energy Levels. Atomic and molecular particles, neutral or ionized—hereafter for brevity often referred to simply as particles—may exist in more than one state, and each state has a definite amount of internal energy (as distinguished from the kinetic energy of translatory motion). These states form a discrete (not continuous) series.

In an atomic particle the internal energy is determined solely by the *electronic configuration* (including the electron spins). In a molecular particle it may also include energy of internal vibration and of rotation. These latter energies mainly depend on the disposition and motion of the nuclei, because of their preponderant share of the molecular mass. Each type of energy has a discrete series of values, associated with *quantum numbers,* electronic, vibrational, and rotational. There is consequently a series of electronic *energy levels,* and in the case of molecular particles these levels (for states without vibration and rotation) are supplemented by many neighbouring levels of higher energy, for states in which there is also vibration or rotation or both.

The state of lowest energy is called the *ground state;* the others are called *excited states.* The energies of the latter are reckoned as differences from the energy of the ground state, and are called *excitation energies* or *excitation potentials.* The minimum energy needed to remove an electron altogether from a particle in its ground state is called the *ionization energy* or *ionization potential;* in atmospheric chemistry one mostly considers only the first ionization potential, for the removal of only one electron from the neutral particle. The energy required to detach the excess electron from a negative ion such as O^- or O_2^- is called the *attachment energy* or *electron affinity.* The energy necessary to divide a molecular particle (neutral or ionized) into two atomic (or molecular) particles is called the *dissociation energy* or *dissociation potential.*

In a molecule the distances between its atomic nuclei are in general different in different electronic configurations. A molecule may be raised to a state in which its energy, including vibrational energy, is greater than that required for dissociation, yet the internuclear distances may not be such that the molecule will divide, without some rearrangement of the nuclei and electrons. If the molecule is such that this redistribution can take

place, it is said to be, before the change occurs, in a state of *pre-dissociation* [12]; a similar definition applies to *pre-ionization*.

Symbols are assigned to the various states of particles; the details of the electronic configuration may be specified; for example, by $(1s)^2(2s)^2(2p)^4$ for the lowest levels of the O atom [16, p. 45], but these symbols will not be explained here. For this configuration there are three main energy levels associated with the *term* symbols. ^3P (ground term) and $^1D_2$, $^1S_0$, the two latter being *metastable* terms (§ 12). The ground term itself has three closely spaced levels, $^3P_2$, $^3P_1$, and $^3P_0$, the first being the lowest. Often the suffixes in these term symbols are omitted.

For atomic sodium the ground state has the symbol ^2S, and the first excited state has two closely spaced levels $^2P^0_{\frac{3}{2}}$ and $^2P^0_{1\frac{1}{2}}$. The symbols for the states of molecules are, as might be expected, more complicated than those for atoms. For example, the ground state and the next succeeding energy states for neutral molecular nitrogen have the symbols $X^1\Sigma_g$, $A^3\Sigma_u$, and $B^3\Pi_g$ [12].

5. Energy Units. The cgs unit of energy is the erg, and a larger unit is the joule (1 joule = 10^7 ergs). Another unit much used by chemists is the calorie (or gram-calorie—the terms have identical meanings), which is the energy required to raise the temperature of 1 cc of water at 15C by 1C (1 calorie = 4.185 joules). Chemists often quote energies in kilocalories (or large calories); 1 kilocalorie = 1000 calories.

Physicists often use another unit called the *electron volt* (ev). An energy of V ev is equal to that acquired by an electron in traversing a fall of potential of V volts; this is ϵV joules, if ϵ (the electronic charge) is measured in coulombs:

$$\epsilon = 4.802 \times 10^{-10} \text{ electrostatic cgs units}$$
$$\epsilon = 1.602 \times 10^{-20} \text{ electromagnetic units}$$
$$\epsilon = 1.602 \times 10^{-19} \text{ coulombs.}$$

Hence, as a volt is 10^8 electromagnetic units,

$$1 \text{ electron volt} = 1.602 \times 10^{-12} \text{ ergs.}$$

Hence also for a change of energy of V ev per particle, the change expressed in gram-calories per mole (N particles) is $1.602 \times 10^{-12}\, NV/4.185 \times 10^7$, so that 1 ev per particle is equivalent to 23,053 calories per mole.

Yet another form of energy-reckoning by physicists, the *wave number*, is explained in the next section in connection with the quantum relation.

6. Light Absorption and Emission; the Quantum Relation. An atomic or molecular particle may gain energy of amount W ergs by absorption of light of frequency ν (the frequency is the number of light-vibrations per second), or it may emit the energy W as light of this frequency: in either case W and ν are connected by the *quantum relation*

$$W = h\nu,$$

where h denotes *Planck's constant:*

$$h = 6.624 \times 10^{-27} \text{ erg sec,}$$

according to the latest estimate by R. T. Birge [5].

This relation can also be expressed in other forms, in terms of the wave length λ of the light, or in terms of its wave number n, which is the number of waves per centimetre: so that if λ is expressed in centimetres (denoted by λ_{cm}),

$$n = 1/\lambda_{cm} ;$$

ν and λ_{cm} are connected by the relation

$$\lambda_{cm}\nu = c,$$

where c denotes the speed of light, which *in vacuo* is

$$c = 2.998 \times 10^{10} \text{ cm sec}^{-1} .$$

Hence the relation $W = h\nu$ can be expressed as $\lambda_{cm}W = hc$ or $W = hcn$; energies and energy differences can therefore be expressed in terms of wave numbers, where

$$1 \text{ wave number} = hc \text{ ergs} = 1.986 \times 10^{-16} \text{ erg.}$$

Hence an energy expressed as V ev has a wave number n given by

$$n = 8068V, \text{ or } V = 1.2395 \times 10^{-4}n.$$

Wave lengths are generally expressed in angstrom units (A) or in microns (μ):

$$1 \text{ A} = 10^{-8} \text{ cm}, \ 1\ \mu = 10^{-4} \text{ cm} = 10^4 \text{ A}.$$

Thus λ expressed in A is $10^8\ \lambda_{cm}$. The relation $\lambda W = hc$, when W is expressed in electron volts V and λ in angstrom units, takes the form

$$\lambda V = 12395 \qquad (\lambda \text{ in A}).$$

Similarly if W is expressed in calories per mole,

$$\lambda W = 2.858 \times 10^5 \quad (\lambda \text{ in A}).$$

7. Spectra Associated with Atomic and Molecular Transitions. When an atomic or molecular particle undergoes a transition from a state of higher energy to one of lower energy, one way in which it can dispose of the energy difference W thus released is by radiation in light of frequency $\nu = W/h$. The spectrum of the light emitted by a gas whose particles are undergoing one or more such transitions is called an *emission* spectrum.

If, however, the particles are undergoing transitions from lower to higher energy levels, one way in which the necessary energy W may be acquired is by absorption of light, which must be of frequency W/h. The spectrum of the beam of light will be darkened at this frequency, because of the absorption and the consequent reduction of the transmitted intensity. This darkening, at as many frequencies as are concerned in the transitions taking place in the gas, gives what is called an *absorption* spectrum.

The spectrum of sunlight shows absorption of two kinds: one (the Fraunhofer spectrum) due to absorption by gases of the sun's own atmosphere, and another due to absorption in the terrestrial atmosphere (§18).

From our knowledge of spectra for various substances, either studied experimentally in the laboratory, or in simple cases obtained from theoretical calculation of the energy levels of particles, it is often (though as yet not always) possible to infer the nature of the

emitting or absorbing particles responsible for given emission or absorption spectra, and also, from the intensity of the spectrum, to infer how many transitions of any such kind are taking place, per unit cross section of the beam of light per second. (See §§18, 19.)

8. Line, Band, and Continuous Spectra. Atomic particles have definite configurations and energy levels, and definite energy differences and associated frequencies, corresponding to definite *lines* in their emission or absorption spectrum. Their spectra are therefore called *line* spectra.

Molecular particles have far more energy levels and energy differences and associated frequencies than atomic particles have, because of their additional energy of vibration and/or rotation. Any "line" in their spectrum, associated with a change purely of electron configuration, may be accompanied by many lines of rather different frequencies, corresponding to the same electronic change accompanied by any one of many possible changes of vibratory or rotational energy. In spectra of moderate dispersion some of these lines may be so crowded together as to appear like a continuous band; hence the name *band spectra* for molecular spectra.

A definite minimum energy (see § 4) is required to ionize or dissociate a particle. Corresponding minimum frequencies are associated with these processes when they are induced by light absorption; but light of any greater frequency may also induce the process, the excess energy going into the kinetic energy of separation of the resulting two particles. Hence the absorption spectrum can be *continuous* on the high frequency (or short-wave) side of the frequency corresponding to the ionization or dissociation potential. Similarly for the emission spectrum resulting from the *recombination* (with radiation) of ions and electrons or combining particles; for example, in the combinations

$$O^- + O^+ \rightarrow O_2 \text{ , or } O + O_2 \rightarrow O_3,$$

the energy released may exceed the ionization or dissociation energy, because of the kinetic energy of approach of the combining particles. Such continuous spectra are an indication of the occurrence of ionization or dissociation, or of their converse, recombination. Certain bands in molecular spectra indicate pre-dissociation or pre-ionization (§4) leading to dissociation or ionization with certain probabilities.

9. Atomic and Molecular Spectra: Different Ranges of Wave Length. The range of the visible spectrum extends from about 4000 A (violet) to 7600 A (red); for $\lambda < 4000$ A the spectrum is called *ultraviolet*, and for $\lambda > 7600$ A, *infrared*. The energy differences between the lower electronic levels of atoms and molecules are often as much as 1 to 10 ev, corresponding to light of wave lengths from 12395 A to 1239 A, extending from the infrared to the ultraviolet. The energy differences between different vibrational states of a molecule in the same electronic configuration are of order 0.1 ev to 1 ev, corresponding to wave lengths from 12395 A to 123950 A (or from 1.2 μ to 12 μ) in the "near" infrared. Purely rotational transitions involve energy differences about one-tenth as great, corresponding to wave lengths from 12 μ to 120 μ in the "far" infrared. Light of a single wave length is called *monochromatic*.

Numerous bands are named after their discoverers or interpreters, working either in the laboratory or with natural light in emission or absorption. Examples are the Hartley and Huggins bands of ozone, extending respectively from about 2000 to 3200 A and from 3200 to 3500 A, and the Chappuis band in the visible region (maximum absorption, in air, at about 6100 A); ozone also has infrared bands. Oxygen (O_2) has Schumann-Runge and Herzberg bands with ranges from about 1750 to 1930 A and 3100 to 3800 A, respectively, and others in the near infrared. Nitrogen (N_2) has the "first positive" system (about 6000 to 6500 A) in the red, as well as the Vegard-Kaplan system (3100 to 4500 A), and ionized nitrogen (N_2^+) has the "first negative" system (3800 to 4700 A). Hydroxyl (OH) has strong infrared (Meinel) bands ($\lambda > 7200$ A). The ranges of wave length here specified are somewhat rough and depend upon conditions which may be different in the laboratory from those in "natural" emission or absorption in the atmosphere.

10. Absorption Coefficients. When light of frequency ν passes through a gas which contains particles that can absorb it, it is weakened proportionately to its own intensity and to the number n of the absorbing particles per cubic centimetre. This is expressed by

$$dI = -k_\nu n I dl,$$

where dI is the reduction of the intensity I in traversing a path length dl; hence k_ν has the same dimensions as $1/ndl$, which is length squared or area. The factor k_ν is called the *atomic (or molecular) absorption coefficient*, or alternatively the *absorption cross section*. In the case of some processes in which light is absorbed k_ν can be calculated theoretically; for example [30], for the ionization of neutral atomic oxygen by radiation whose quanta have energy between 13.55 and 16.86 ev, k_ν is of the order 3×10^{-18} cm^2 . In other cases k_ν must be determined experimentally by observing the decrease of intensity in passing through a known amount of the gas.

If $n = n_0$, where n_0 is the number of molecules per cubic centimetre of gas at normal temperature and pressure, and $\alpha = k_\nu n_0$, the absorption in a gas of uniform density with this value of n is given by $dI = -\alpha I dl$, where α is constant. This leads to the relation

$$I = I_0 e^{-\alpha l} = I_0 10^{-0.4343\alpha l}.$$

Here α is called the *absorption coefficient;* 0.4343α is sometimes called the *decimal absorption coefficient* and denoted by α_{10}, the suffix bearing reference to the replacement of e by 10 in the formula above. For ozone at about $\lambda = 2500$ A, α_{10} is of order 100, and it has the same order of magnitude for molecular oxygen at about 1500 A.

The value of k_ν or α depends greatly on the wave length. For example, for ozone, α_{10} sinks to 10^{-3} for λ somewhat greater than 3000 A.

11. Monochromatic Absorption in an Exponential Atmosphere. The term *exponential atmosphere* is used to

refer to an atmosphere in which the density ρ varies with height h above the ground according to the relation

$$\rho = \rho_0 e^{-h/H}, \; n = n_0 e^{-h/H},$$

where H is a constant (called the scale height), and ρ_0 denotes the density at the ground ($h = 0$). The alternative form $n = n_0 e^{-h/H}$ refers to the number of particles per cubic centimetre, n at height h, n_0 at the ground. Such formulas do not apply to the actual atmosphere unless H is itself regarded as a function of h, but they are useful approximations over a range of height in which H does not vary greatly. The value of H is $kT/\bar{m}g$, where k is Boltzmann's constant (1.380×10^{-16} ergs per degree C); T denotes the absolute temperature, g the acceleration of gravity (981 cm sec^{-2}), and $\bar{m}$ the mean mass of the particles composing the atmosphere. Also $H = RT/\bar{M}g$, where $\bar{M}$ ($= N\bar{m}$) is the mean molecular *weight*, and R ($= kN$) is called the gas constant; $R = 8.314 \times 10^7$ ergs per degree C per mole.

It is of special interest to consider the absorption of light in such an atmosphere, because of the simplicity of the relations involved, and their approximation to the actual conditions in our atmosphere.

It will be supposed that outside the atmosphere the intensity of the light considered is I_∞, and that at height h it is I. The absorption will be supposed to take place with a definite absorption coefficient k_ν, so that in effect the light must be monochromatic, of a definite frequency ν (or rather, within a narrow band of frequency ν to $\nu + d\nu$). Instead of I and I_∞ one might therefore alternatively consider the flux of photons of this frequency, Q per square centimetre per second at height h, and Q_∞ at $h = \infty$ (outside the atmosphere): $Q \propto I$ or $Q/Q_\infty = I/I_\infty$.

The absorption may be due to a particular atmospheric constituent, and if so, n and ρ will refer not to the whole air but to this particular constituent only. If the atmosphere is so static that the different constituents are each distributed in accordance with their molecular weight, each will have its own value of H; for example, for O_2 at 273° absolute (0C), H is about 7.2 km, and for O it is twice as great; the only assumption here made, however, is that H can be regarded as independent of h.

Let χ denote the zenith angle of the sun, which is also the angle made by the beam of light with the vertical (the curvature of the level layers of the atmosphere being neglected). The equation of absorption is $dI = -k_\nu n I \sec\chi \, dh$, of which the integral is

$$I = I_\infty \exp(-k_\nu n_0 H e^{-h/H} \sec\chi).$$

The rate of absorption q per cubic centimetre at height h is $-dI \cos\chi/dh$, which has the value $k_\nu n I$. This has its maximum at the level

$$h_{\max} = H \ln (k_\nu n_0 H \sec\chi) = h_0 + H \ln \sec\chi,$$

where ln denotes the logarithm to the Napierian base e ($= 2.718$), and h_0 is the value of $h_{\max}$ for $\chi = 0$ (vertical sunlight); at this level n has the value $n_{\max}$ given by

$$n_{\max} = (1/k_\nu H) \cos\chi,$$

and q has the value $q_{\max}$ given by

$$q_{\max} = (I_\infty \cos\chi)/H \exp 1,$$

where $\exp 1 = 2.718$.

Let $z = (h - h_{\max})/H$, and $q' = q/q_{\max}$; then the relations above lead to

$$q' = e^{1-z-e^{-z}}.$$

A graph of this function is shown in Fig. 1. It represents the proportionate distribution of absorption per unit volume as a function of height z, reckoned upwards or downwards from the level of maximum, in terms of H as the unit of height. The form of the curve is independent of the particular value of H and of the initial light-intensity I_∞, as well as of the absorption coefficient k_ν. Though the actual *level* of maximum absorption depends on k_ν, n_0, H, and χ, the *value* of the maximum absorption depends on I_∞, H, and χ, but not on k_ν or n_0.

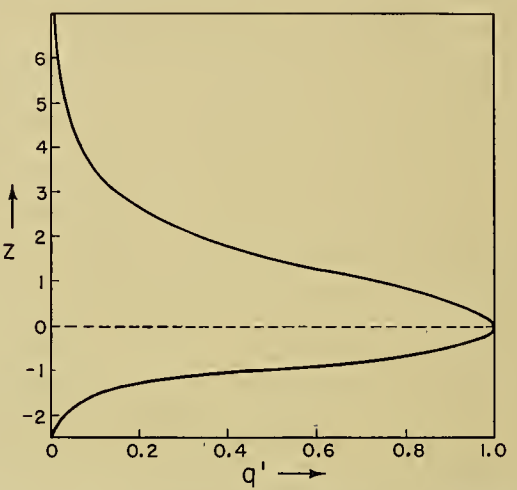

FIG. 1.—The proportionate distribution of absorption of monochromatic radiation per unit volume of gas in an exponentially distributed atmosphere, given as a ratio (q') of the absorption at any level, to that at the level of maximum absorption; the level is indicated by z, reckoned from the height of maximum absorption, in units of the scale-height of the atmosphere.

Below the level $h_{\max}$ the beam intensity and the absorption fall away very rapidly, the beam being quickly attenuated by the increasingly dense air. The decrease of q' upwards is slower; at great heights q' varies approximately as e^{1-z}. The main part of the absorption lies in a layer of thickness about $3H$ (from $z = -1$ to $z = 2$). Throughout the day, $q_{\max}$ varies as $\cos\chi$, and $h_{\max}$ is ln sec χ above h_0. When $\chi = 60°$, sec $\chi = 2$, ln sec $\chi = 0.7$, and so $h_{\max} = h_0 + 0.7H$.

The height h_0 ($= H \ln k_\nu n_0 H$) may be negative for sufficiently small values of k_ν and n_0, that is, if the absorption is weak; q then increases downwards to the ground, and much of the radiation penetrates to ground level. For oxygen (O_2), for which n_0 is of order 10^{19}, and H of order 10^6 cm (7.2 km), the minimum value of k_ν for which h_0 will not be below ground, namely

$1/n_0H$, is 10^{-25} cm^2. For maximum absorption at about the height of the ozone layer ($h = 3H$, for example), $k_\nu n_0 H = e^3 = 20.1$. These formulas for h_0 and $n_{\max}$ or $q_{\max}$ are very useful in the study of atmospheric dissociation and ionization.

If the absorption of the light quanta produces dissociation or ionization, this will partly exhaust the absorbing gas, which will not be distributed exponentially at great heights, where the separation products will become predominant. (See § 22.)

If the absorbing gas is not distributed exponentially (and the ozone layer is such a case) the above formulas will not apply to it, but even so they may give some help towards estimating the nature of the distribution of absorption. If the light absorbed is not monochromatic, but includes radiation of widely differing atomic or molecular absorption coefficients, the resultant distribution of the rate of absorption will be a superposition of layers of the type discussed above, with differing values of $h_{\max}$ and $q_{\max}$ for each small interval of frequency. In the case of the regions of absorption by molecular oxygen or ozone, for which the values of k_ν vary at least 10^5 fold, much of the radiation will be filtered out at levels far above those to which the less absorbable frequencies penetrate.

The light considered here is unidirectional, but a parallel beam of sunlight will be *scattered* as well as absorbed, and the scattered light, relatively more intense for the higher frequencies ν, will itself be scattered and absorbed. The rate of absorption at any level will thus depend on contributions from light of all directions —a complication to which little attention has yet been given in the field of atmospheric photochemistry.

If we knew k_ν and I_∞ for each frequency, and the distribution of each absorbing constituent, the distribution and amount of the absorption would be calculable. In many cases, however, some of these data are unknown, especially I_∞ at frequencies for which the radiation is completely absorbed at high levels. But this gap in our knowledge is now becoming partly closed by information concerning the spectra of sunlight obtained at different heights in the atmosphere by rocket-borne instruments.

12. Reversibility. De-excitation with Radiation. Atomic and molecular processes are reversible. The converse of excitation by radiation is de-excitation (a fall from a higher to a lower energy level) with emission of radiation. The fall need not, however, be made in one stage only; there may be two or more falls through intermediate states. The emission occurs spontaneously, and not at one definite interval after attaining the higher energy level. For each type of transition there is a constant T, called the *half-life* (or more loosely the *lifetime*), such that the probability of the transition occurring during any given short interval from time t to time $t + dt$, after attaining the higher level, is $e^{-t/T}dt$. The transition probability is briefly expressed as $1/T$.

There are certain *selection rules* concerning the permissible changes of the various quantum numbers, from the initial to the final state of the particle; these determine whether or not any particular transition is *allowed* or *forbidden*. In the case of allowed transitions, T is generally very small (*e.g.*, 10^{-8} sec).

Among the various states of a particle there may be some from which there is no allowed transition to a lower level. Such states are called *metastable* states. Even in such cases, however, there may be possible transitions (not of the normal type to which the selection rules apply) with finite though small probability, and such states consequently have a finite lifetime, much longer than that of ordinary excited states.

Neutral atomic oxygen is such a case, of great interest for upper-atmospheric chemistry. Its terms $^1D_2$ and $^1S_0$ of its first electronic configuration (see § 4) are both metastable. Their energy levels (or excitation energies) are approximately 1.96 and 4.17 ev above the ground term ^3P. There is a finite probability 2.0 sec^{-1} for the transition $^1S_0$ to $^1D_2$, involving a change of energy by 2.21 ev and giving rise to the light of the famous "green auroral line" 5577 A. The transition probabilities for fall from $^1D_2$ to the ground levels $^3P_2$, $^3P_1$, and $^3P_0$ are 0, 2.5×10^{-3}, and 7.5×10^{-3} sec^{-1}, giving rise (in the last two cases) to the two "red auroral" lines of atomic oxygen, 6364 A and 6300 A, of which the latter, because of its threefold greater probability, is three times the more intense. Thus the lifetimes of the $^1S_0$ and $^1D_2$ states are of the order ½ sec and 100 sec respectively.

The first excited states of neutral atomic sodium are not metastable; transitions occur with probability 0.62×10^8 sec^{-1} from $^2P^0_{\frac{3}{2}}$ and $^2P^0_{1\frac{1}{2}}$ to the ground state ^2S, giving rise to the sodium yellow line 5893 A (really a close doublet or pair of lines, with wave lengths 5890 A and 5896 A, of which the former is twice as intense as the latter, because the number of atoms in the $^2P_{1\frac{1}{2}}$ state is twice that in the $^2P_{\frac{1}{2}}$ state). The lifetime of the ^2P state is 1.6×10^{-8} sec.

13. Excitation and De-excitation by Collision. Atomic and molecular particles can be excited by impact as well as by absorption of radiation, and the process is reversible, that is, such particles can be de-excited by collision. In the first case the kinetic (and possibly also other) energy of the impinging particle (which may be atomic, molecular, or an electron) is reduced by the energy required for excitation; in the second, it is increased by this amount. Such collisions are called collisions of the *second kind*, or *inelastic* or *superelastic*, in contrast to the elastic collisions considered in the kinetic theory of gases. In these, the speed of separation of the particles after collision equals that of their approach, so that the translatory kinetic energy of their motion relative to their mass-centre is unaltered. A collision between two uncharged unexcited particles is elastic if this kinetic energy is too small to raise either to its first excited state. For such elastic collisions the particles, though without definite boundaries, have a certain joint collisional *cross section* (which in the case of rigid elastic spheres would be πR^2, where R denotes the sum of the radii of the two particles). Similarly there is a collisional cross section for any given type of excitation, depending on the nature of the particles and on their relative speed of approach; it is one mode of ex-

pressing the probability of such excitation occurring in such a collision.

The *mean free path* l_{12} of a particle of type 1, between collisions with particles of type 2, is of the order $1/n_2S_{12}$, where S_{12} is the cross section for the type of collision (elastic or otherwise), and n_2 is the number of particles of type 2 per cubic centimetre of the gas. If V_1 is the mean speed of the particles of type 1, the corresponding *collision-interval* t_{12} is l_{12}/V_1, and the mean collision-frequency ν_{12} is $1/t_{12}$. The number of the collisions per cubic centimetre per second is $n_1\nu_{12}$, which equals $V_1n_1n_2S_{12}$ or $\alpha_{12}n_1n_2$, where $\alpha_{12} = V_1S_{12}$; α_{12} depends on T, the absolute temperature, through V_1 (both directly and in S_{12}), which is proportional to $(T/m_1)^{1/2}$.

Whether, in a gas containing excited particles, de-excitation occurs mainly by collision or by radiation depends on whether the lifetime T of the excited state is greater or less than the collision interval t_{12}. The greater the height in the atmosphere, and therefore the smaller the values of n_1 and n_2, the more likely are the excited particles to emit their excess energy spontaneously, with radiation. For example, the collision frequency of electrons in the D-layer of the ionosphere has lately been estimated to be 1.5×10^6 at 91.7 km height and 2.8×10^6 at 86.3 km (giving a scale height H_1, at this level, of 8.5 km). The collision frequency of atomic particles in the same region is likely to be smaller by perhaps two powers of ten, so that de-excitation by allowed transitions (such as those that give the yellow lines of sodium) would be little reduced by collisions, whereas atoms of oxygen in their metastable states ^1D and ^1S would not radiate appreciably at this level.

14. Kinetic Energy of Particles of a Gas at Absolute Temperature *T*. In a gas in thermal equilibrium at the absolute temperature T, the distribution of velocities for each type of particle (mass m, number n per cubic centimetre) is given by Maxwell's formula,

$$dn = n\left(\frac{m}{2\pi kT}\right)^{3/2} e^{-m(U^2+V^2+W^2)/2kT}\, dUdVdW;$$

dn is the number of these particles, per cubic centimetre, whose velocity components U, V, and W (relative to the mean motion, if any, of the gas) lie within the ranges

$$U \text{ to } U + dU, \qquad V \text{ to } V + dV, \qquad W \text{ to } W + dW.$$

Hence in terms of the speed v of a particle (where $v^2 = U^2 + V^2 + W^2$), and its translatory kinetic energy E $(= \frac{1}{2}mv^2)$,

$$dn = 4\pi n\left(\frac{m}{2\pi kT}\right)^{3/2} e^{-mv^2/2kT}\, v^2dv$$

$$= n\frac{2}{\sqrt{\pi}}\left(\frac{1}{kT}\right)^{3/2} e^{-E/kT}\, E^{1/2}dE,$$

giving the number of particles dn per cubic centimetre with speed between v and $v + dv$, or energy between E and $E + dE$. The last formula does not contain m, whence it appears that the mean E for particles of any mass is the same, and equal to $(\frac{3}{2})kT$ ergs, where k denotes Boltzmann's constant; the energy per mole is NE_T or $(\frac{3}{2})RT$ calories, if the gas constant R is expressed in calories per degree per mole (its value then being 1.986); see § 11.

Table I gives the energy E_T in ergs and electron volts, and also, in the last column, its value per mole (NE_T)

Table I. Mean Translatory Kinetic Energy At Various Temperatures

T deg K	$10^{14}\,E_T$ ergs per particle	E_T ev per particle	NE_T cal per mole
200	4.1	0.026	596
300	6.2	0.039	894
400	8.3	0.052	1192
500	10.4	0.065	1490
750	15.5	0.097	2235
1000	20.7	0.129	2980
1500	31.1	0.194	4470

expressed in calories, for T from 200K to 1500K (the range which is of interest for the upper atmosphere). For particles of mass m, the mean square $\overline{v^2}$ of the speed $(2E_T/m)$, and the mean speed $\bar{v}$, are given by

$$\overline{v^2} = 3kT/m, \qquad \bar{v} = (8\overline{v^2}/3\pi)^{1/2} = 0.921\sqrt{\overline{v^2}}.$$

The fraction of particles (of whatever mass) whose energy is fE_T or more is

$$\frac{2}{\sqrt{\pi}}\left(x_0\, e^{-x_0^2} + \int_{x_0}^{\infty} e^{-x^2}\, dx\right),$$

where $x_0^2 = (\frac{3}{2})f$. This fraction is tabulated. For $f = 5$ the fraction is 0.00182.

Even at the highest temperature given in Table I, E_T is too small to produce appreciable excitation (and still less dissociation or ionization) by impact; and the fraction of the particles that have an energy of 1 ev is likewise very small, even at 1500K. It is not an entirely negligible fraction, however, and the few particles of high energy may have some small influence in determining the state of the upper atmosphere. In particular, they will excite rotation,[4] detectable in absorption spectra, which if obtained from high rockets may give some information concerning the temperature of the upper atmosphere.

15. Dissociation and Ionization in the Upper Atmosphere. A particle can be divided into two (thus being dissociated or ionized) either by radiation or by impact. Each quantum of radiation absorbed, of appropriate frequency ν and energy $h\nu$, divides one particle, so that the rate of production of the separate component particles per cubic centimetre per second is equal to the rate of absorption q of quanta, and is a function of the height, as illustrated for monochromatic absorption in an exponential atmosphere in § 11. The process of division by absorption of radiation is called *photolysis*.

The energy necessary for ionization from the neutral state is rather high for most of the gases of the atmos-

4. A molecular particle without rotational energy is not set in gentle rotation by the impact of another particle, however well directed, unless the transferable kinetic energy (allowing for conservation of momentum as well as of energy) at least equals the minimum rotational excitation energy. (See §4)

phere (sodium is an exception), as shown in Table II; the electron detachment energies for O^- and O_2^- are also given. Table III gives various dissociation potentials of interest in connection with the upper atmosphere.

Table II. Ionization Potentials V ev

Gas	N	O	O^-	Na	N_2	O_2	O_2^-	N_2O
V ev	14.5	13.6	2.2	5.1	15.5	12.2	1	12.7

Table III. Dissociation Potentials V ev

Gas	N_2	O_2	O_3	NaO	H_2	OH
V ev	7.4, 9.8?	5.09	1.1	3?	4.5	4.3

The fraction of particles with thermal kinetic energies of the amounts shown in the two tables above is very small in the upper atmosphere (see § 14), and division by impact is produced mainly by fast-moving particles coming in from outside—meteors, cosmic rays, and (of most importance) the streams or clouds of gas emitted by the sun, which produce aurorae and magnetic storms—and by atmospheric particles to which these external particles communicate sufficient of their energy. They dissociate N_2 and O_2, ionize them and the atoms N, O, and excite N_2, N, O_2, O, and their ions. The influence of such transient (though frequent) impact processes on the average composition of the air in auroral latitudes has received little attention as yet. But there can be little doubt that over most of the earth the chemistry of the upper atmosphere is mainly determined by the effect of sunlight.

Among the chief of these effects is the ionization of the various layers of the ionosphere—D, E, F_1, and F_2, in ascending order of height (respectively about 90, 120, 220, and 300 km). Their detailed explanation still presents difficulties [29]. It is uncertain whether the main ionized particles in the E- and F-layers are O_2 and O respectively, or O and N. The high degree of F-layer N_2-dissociation implied in the latter case seems to conflict with the evidence of the sunlit auroral spectrum indicating that there is undissociated nitrogen 200 km and more *above* the F-layer. There seems to be little N_2^+ in the F-layer. The D-layer has been ascribed to atomic sodium. The formation of these layers filters out all or most of the sunlight of highest frequency, whose quanta exceed 12 ev.

The light whose quanta have energy between about 5 and 10 ev dissociates molecular oxygen, being absorbed at levels between about 15 or 20 km and 120 km height. It is still uncertain to what extent molecular nitrogen is dissociated by part of this radiation, or radiation of somewhat greater frequency; the nitrogen molecule seems to be more readily ionized than dissociated by radiation.

Other constituents of the upper atmosphere that are partly dissociated by absorption of sunlight are ozone ($O_3 \rightarrow O_2 + O$), water vapor ($H_2O \rightarrow OH + H$), and sodium oxide ($NaO \rightarrow Na + O$).

16. Combination of Particles; Conservation of Energy and Momentum; Two- and Three-Body Collisions. The reverse of the division of one particle into two (dissociation or ionization) is the combination of two into one. This is called *recombination* in the case of ions and electrons, and *attachment* in the case of a neutral particle and an electron (for example, $O + e \rightarrow O^-$). The act of combination essentially involves juxtaposition, that is, a collision. The mean interval after division, before the two particles collide and may recombine, depends upon the density (see § 13), and therefore may have any value. Thus it differs essentially from the mean interval between an excitation and a subsequent de-excitation with radiation, the *lifetime*, which depends solely on the nature of the particle itself and on its spontaneous processes.

The results of separation can consequently persist for hours or even days in air of sufficiently low density; during this period the energy of dissociation or ionization is stored up in the gas as a kind of potential energy. In the upper atmosphere some of the energy absorbed from the sunlight during the day hours, causing dissociation and ionization, remains in this potential form after sunset, and during the night it is partly transformed slowly into radiation, which is observed as a faint luminosity of the night sky—the *airglow*.

In general the two particles resulting from the division of any one particle do not recombine with each other. The parent particle gives birth to its progeny among a host of jostling neighbours, and the "new-born infants" at once lose each other in the crowd. Each may combine in due course with some other particle of the same kind as its lost brother, or it may enter into a new partnership of a different kind.

The division of a particle can take place in either of two ways: by absorption of light or by impact. The process that is the reverse of division by absorption of light is combination with emission of light, in a *two-body collision*. The process that is the reverse of the division of a parent particle AB into components A and B, by the impact of a particle X—a transformation symbolized by

$$AB + X \rightarrow A + B + X$$

—is the combination

$$A + B + X \rightarrow AB + X$$

produced by the *three-body* or *triple* collision of A and B and X, to form the two bodies AB and X. The two-body radiative combination is symbolized by

$$A + B \rightarrow AB + h\nu.$$

In all types of collision there is conservation of both energy and momentum. In a radiative combination, by two-body collision, the initial velocities of the two combining particles determine the initial total momentum, which after the collision is divided between the single combined particle and the emitted photon; as

the momentum of the photon is insignificant, the initial momentum determines the velocity of the combined particle, and therefore also its kinetic energy. The energy released in the photon is the energy of the division of AB into A and B, that is, the dissociation or ionization potential, less the change (a reduction) of the kinetic energy of translation resulting from the combination; the amount of this change is not governed by the intrinsic nature of A, B, and AB, but depends on whatever particular velocities A and B may happen to have just before the collision. The chance that in the process of combination it will be possible to emit a photon of just the right energy thus determined is in general small; if the circumstances permit its emission, the combination occurs, otherwise the particles A and B part again without combining, the collision being an elastic one (see § 13). The probability of a radiative combination is expressed by means of its effective collisional cross section.

In a combination by three-body collision, the existence of two particles after the collision permits the ready fulfilment of the two conditions of conservation of momentum and of energy, and the chance that combination will result from the collision is consequently higher. But the chance of the *occurrence* of a triple collision is much less, in a rare gas, than that for a two-body collision; when particles are sparsely scattered, the simultaneous concourse of three particles in one small vicinity is naturally much rarer than that of two particles. The number of two-body collisions of A and B in a gas, per cubic centimetre per second, is $\alpha n_A n_B$ (see § 13); the corresponding number of three-body collisions is $\alpha' n_A n_B n_X$; here the n's denote the numbers of particles per cubic centimetre, of the three kinds. With increasing height all the n's will in general decrease, but the triple product will decrease faster than the double one. Hence the radiative combinations must increase upwards relative to the three-body combinations; at the confines of the atmosphere the combinations are predominantly radiative.

17. Reactions in General; Transference; Activation Energy; Resonance. A *combination* of A and B to form AB (whether by two-body or three-body collision) is a simple special case of chemical transformation or reaction; another general type of reaction involves a *transfer* of part of one of the colliding particles to the other particle, breaking only one molecular bond, as in

$$O + O_3 \rightarrow O_2 + O_2\,, \qquad O + OH \rightarrow O_2 + H\,, \quad (1)$$

or a division of both particles and subsequent interchanged unions, as in

$$OH + OH \rightarrow H_2 + O_2\,. \quad (2)$$

Both of these result from a two-body collision, and as there are two bodies also after the collision, energy and momentum can readily be conserved. It would be expected, therefore, that the *efficiency* of the processes would be greater than that for *radiative* combination, provided of course that they are *exothermic* (*i.e.*, give out heat) and not *endothermic* (*i.e.*, absorb heat). While this is indeed generally true, it is found that transfer does not occur unless the relative kinetic energy in the collision is above a certain limit E_A called the *activation energy*. For endothermic reactions it must at least equal the difference between the internal energies of the initial and final particles. For exothermic reactions, although (by definition) they give out heat, the activation energy is *not*, in general, zero; its value, expressed in calories per N collisions [31], is generally as much as a few kilocalories for reactions of type (1), and some tens of kilocalories for reactions of type (2). It can easily be seen that this means that at moderate temperatures the former are far more important than the latter. Thus at room temperature the fraction of collisions of energy 5 kilocalories or above is about 10^{-4}, whereas the fraction of energy 50 kilocalories or above is only 10^{-39}.

Besides *chemical* transfer reactions there are reactions in which what is transferred is energy of excitation, as in

$$N_2' + O_2 \rightarrow N_2 + O_2'\,, \quad (3)$$

(where the primes denote excitation), or charge, as in

$$O^- + O^+ \rightarrow O' + O''\,, \qquad O^+ + XY \rightarrow O + XY^+\,. \quad (4)$$

The efficiency of transfer of *excitation* is not high unless the change of kinetic energy of relative motion is small; when this is so there is said to be *resonance*, and the effective cross section for the collision may exceed the gas-kinetic cross section. In contrast, transfer of *charge* can occur most readily when the reaction is exothermic by a few tens of calories.

Yet another type of two-body reaction is *dissociative recombination*, as in

$$O_2^+ + e \rightarrow O' + O''\,, \qquad XY^+ + e \rightarrow X' + Y'\,, \quad (5)$$

in which the ionization energy released is taken up in some form by the fragments of the original molecular ion. Quantal arguments have recently been advanced which indicate that the mechanism may be extremely rapid. Bates and Massey [29] have indeed suggested that (5) may be responsible for the observed high (and pressure-independent) coefficient of recombination α for electrons in the E-layer of the ionosphere. The pressure-independence of α in this layer implies that the recombination occurs by two-body collisions; if the rate of combination or reaction between particles of types (a) and (b) is expressed by $\alpha n_a n_b$, and the process took place predominantly by three-body collisions, α would be proportional to the total number of particles per unit volume, and therefore to the pressure (and inversely proportional to the temperature). If both two- and three-body collisions were of importance, α would have a constant part and a part proportional to the pressure. It may be noted that the theory of the rate of recombination observed in discharge tubes, where the conditions are subject to control, still involves unexplained difficulties.

CONSTITUENTS AND REACTIONS IN THE UPPER ATMOSPHERE

18. Absorption-Spectral Evidence Regarding Atmospheric Composition. The absorption spectrum of sun-

light has a part which is of terrestrial origin and includes bands due to N_2, O_2, O_3, CO_2, and H_2O. Except for O_3, the major part of all these gases lies in the lowest and densest part of the atmosphere, but the absorption in the ultraviolet region by N_2, O_2, and O_3 occurs at higher levels.

The amount of ozone present varies with the latitude, season and weather, but is of the order 3 atmo-millimetres. (It is convenient to express the amount of the rarer gases of the atmosphere by the thickness of the layers they would form if all of each such gas were separated out from each vertical column of atmosphere, and collected at ground level at normal temperature (0C) and pressure (760 mm of mercury); the amount may then be named as being in atmo-centimetres or atmo-millimetres.)

There is also good evidence for the presence of about 1 atmo-cm of nitrous oxide (N_2O); it seems likely that it is mainly in the lower atmosphere. This gas is very transparent for radiation of wave lengths greater than 2000 A, and must therefore be very stable photochemically. Study of its ultraviolet spectrum indicates an ionization potential of 12.66 ev, but its dissociation potential and products are still uncertain. Other oxides of nitrogen may also be present; it appears to be possible to set upper limits of 0.1 atmo-mm for the amounts of NO_2 and NO_3; there is some evidence for the presence of less than 1 atmo-mm of N_2O_5. If formaldehyde (CH_2O) is present (presumably in the troposphere and lower stratosphere), its amount must be less than 1 atmo-mm [26].

The sun's absorption spectrum gives information concerning atmospheric composition by day; similar information about the atmosphere at night could be obtained from the spectrum of moonlight or starlight, but the practical difficulties are much greater than with sunlight, owing to the much lower intensity of such light.

19. Emission-Spectral Evidence Regarding Upper Atmospheric Composition. The spectrum of the night sky shows prominently the green and red lines of atomic oxygen and the yellow line of atomic sodium (§ 12). In the infrared there are strong hydroxyl (OH) bands [33] (probably including bands at 10,400 A originally ascribed to N_2' by a process depending on recombination of N atoms) and also Kaplan-Meinel bands of O_2 (1.7 ev). These are the parts of the spectrum as yet most certainly identified. There is also a continuous background throughout the visible region, fading in the ultraviolet at λ 3900; somewhat lost in the blue and violet part of this continuum ($\lambda > 3900$) there are very many lines and bands, and there are others, very distinct, in the ultraviolet ($\lambda < 3900$). Of the latter, the strongest have been ascribed to the Herzberg bands of O_2 (excitation energy 4.7 ev), and others, weaker, as the Schumann-Runge bands of O_2 (6.2 ev). In the visible region many bands are ascribed to the Vegard-Kaplan bands of N_2 (>7.0 ev). Barbier has ascribed some of the visible bands to CO. Not all these ascriptions are certain.

The OH emission may be due to the reaction

$$H + O_3 \rightarrow OH' + O_2 \ (+76 \text{ kilocalories}),$$

the H atoms being produced by dissociation of water vapor by sunlight.

The excitation energies indicated for the oxygen green and red lines respectively are 4.2 ev and 2.0 ev, and 2.1 ev for the sodium yellow (or D) line.

It is likely that the spectrum is mainly what is called a *recombination spectrum*, the energy being provided by the recombination of atomic O to form O_2, and (less probably) of atomic nitrogen to form N_2. One argument for the latter hypothesis is that the recombination of oxygen provides no more than 5.09 ev, whereas that of nitrogen can provide at least 7.38 and possibly 9.76 ev. (The dissociation energy of N_2 is still doubtful.) The energy provided by the recombination of ions and electrons will also contribute to the night-sky spectrum to a smaller degree.

At twilight (dawn and sunset), part of the emission spectrum is enhanced: chiefly the red oxygen line and the sodium yellow line. At these times there also appears emission of light in the band spectrum of ionized nitrogen (N_2^+), in the region 3914 A, correlated with the enhanced emission of the red oxygen line. This betokens higher energy absorption from sunlight in the high atmosphere then irradiated, and consequent emission, some of which is visible from places on the ground where the sun has already set or not yet risen.

The auroral spectrum shows chiefly the green and red lines of atomic oxygen, bands of N_2 and N_2^+; it seems also to indicate the presence of atomic nitrogen, hydrogen, helium, and perhaps He^+. The energy of excitation is much greater than for the night-sky spectrum, and can reasonably be attributed to impacts caused by fast-moving particles coming from the sun and entering the atmosphere from above; they will "knock on" many atmospheric particles, which will thus be secondarily responsible for the impacts causing most of the observed excitation effects. Auroral emission caused by weak corpuscular streams impinging on the upper atmosphere may at times be mingled with the true night-sky recombination spectrum, even when there is no obvious visual sign of the presence of an aurora.

Recently it has been found that the atomic hydrogen lines in the auroral spectrum, when their light is received at a small inclination to the auroral rays, may show much broadening and large Doppler displacements towards the ultraviolet. This indicates that the emitting H atoms are travelling downwards through the atmosphere with speeds up to some thousands of kilometres per second.

20. The Heights of the Absorbing and Emitting Layers. By observing the intensity of absorption or emission of any particular kind along paths of different inclination to the vertical, or (by day) of different zenith distances of the sun, it is possible to estimate the level of absorption or emission, and in some cases to infer also the height-distribution of the atmospheric constituent concerned. In this way it has been possible to determine the height-distribution of atmospheric ozone,[5]

5. Consult "Ozone in the Atmosphere" by F. W. P. Götz, pp. 275–291 in this Compendium.

and the results have been substantially confirmed by more direct measurements, namely, by obtaining the solar spectrum at different altitudes, in and above the maximum ozone level, using instruments carried in balloons or rockets.

The height of the auroral emission has been much studied, chiefly by Störmer; and the spectrum has shown the presence of atomic oxygen and molecular nitrogen (neutral and ionized) between heights of 100 and 1000 km, the greater heights being associated with sunlit aurorae. The determination of the levels of emission of the various spectral components of night-sky light is much more difficult, because of the faintness of the light. The level of the sodium emission is estimated as mainly between 70 and 100 km, though part of the emission has been acribed to greater heights. The red oxygen light is ascribed to a level extending upwards from 100 km. A. and E. Vassy conclude that there is a second layer of emission at 800 to 1000 km. The green oxygen light is estimated to proceed partly from 75 to 100 km, and partly from a much higher level. These results must be considered as still provisional.

21. The Amounts of the Absorbing and Emitting Constituents. The amount of a gas which contributes to the terrestrial part of the absorption spectrum of sunlight can be estimated therefrom in cases in which the absorption coefficient is known through laboratory or other studies. It is in this way that the number of atmo-millimetres of ozone in the atmosphere is determined daily at several places.

In the case of emission it is possible to infer from the intensity the number of quanta received per second from within a vertical column of atmosphere of, say, an area of one square centimetre at the ground. This was first done by Rayleigh for the light of the green oxygen line in the night sky. He found that 2×10^8 photons of this light are radiated per square centimetre per second, and later studies have confirmed this. The corresponding number for the D line of Na is 8×10^7. There is a very strong infrared emission band of OH at about 10,400 A, for which the number of photons may be 10^{10} or even more. Studies of this kind are still in their infancy: they do not indicate the total amount of the emitting gas, but they give very valuable information to be fitted into our total conception of the state and phenomena of the upper atmosphere [24].

As an example of the type of argument that can be based on such data, consider the green oxygen emission; as it continues all night long with no very great change of intensity, the number of quanta emitted from a column one centimetre square per night (about 40,000 sec) is of order 10^{13}. It is not difficult to show that this exceeds the number that might be derived from ion-electron recombination in the ionized layers of the ionosphere, but that the number of the $O + O \rightarrow O_2$ recombinations is more than adequate. Hence this green light may draw its energy from the daily dissociation of oxygen by sunlight during the daytime, a reservoir of energy steadily drawn upon without apparent serious depletion throughout the night. The process suggested is a three-body collision, in which the third body is the oxygen atom which is thereby excited so as to emit the green light.

22. Ozone and Atomic Oxygen [26]. The ozone layer is produced by photolysis of O_2 into atomic oxygen. The O_2 absorption of the dissociating radiation occurs at different wave lengths and extends from more than 100 km down to 20 km or so. Let Q_2 and Q_3 denote the respective numbers of O_2 and O_3 molecules dissociated per cubic centimetre per second. Let n, n_1, n_2, n_3 denote the number per cubic centimetre of air molecules in general, and of O, O_2, and O_3 respectively, per cubic centimetre. The ozone is formed by attachment (in three-body collisions $O_2 + O + X \rightarrow O_3 + X$), and is destroyed by the reactions $2O_3 \rightarrow 3O_2$ (probably negligible in the atmosphere) and $O + O_3 \rightarrow 2O_2$, as well as by photodissociation. The atomic oxygen is removed by attachment and also by combination ($2O + X \rightarrow O_2 + X$). These various processes lead to the equations

$$dn_1/dt = 2Q_2 + Q_3 - k_{12}n_1n_2n - k_{13}n_1n_3 ,$$
$$dn_3/dt = k_{12}n_1n_2 - Q_3 - k_{13}n_1n_3 ,$$
$$dn_2/dt = -Q_2 - k_{12}n_1n_2n + k_{11}n_1^2n + 2k_{13}n_1n_3 ,$$

where the k's denote coefficients of combination or reaction. One difficulty in using these equations to determine n_1 and n_3 as functions of height and time is that Q_3 is known only when n_3 is known.

It is possible to explain the seasonal variation and latitudinal distribution of ozone on the basis of these formulas, using the known type of seasonal variation and latitude distribution of Q_2 and Q_3, depending merely on the changing zenith distance of the sun. The constants k are not directly known, but may be chosen (with values reasonable from a photochemical standpoint) consistent with the attempted explanation.

The primary process in ozone formation is O_2 dissociation, with the formation of atomic oxygen. With increasing height above the region of maximum ozone, the rate of attachment of O atoms to O_2 molecules, which will be mainly by three-body collisions, will decrease upwards as $e^{-2h/H}$ (see § 11). As the rate of ozone formation thus decreases rapidly upwards, the life of the free oxygen atoms will increase upwards. By simple quantitative arguments it may be inferred that at about 100 or 120 km the value of n_3 will have decreased to less than 10^5 (from over 10^{12} at the maximum level, about 25 km), whereas n_1 will be of the order 10^{12}, comparable with n_2; and that not far above this level n_1 will exceed n_2, the ratio n_1/n_2 increasing upwards.

Thus from the observed presence of the ozone layer, and from the theory of the associated reactions, the increasingly complete dissociation of oxygen as we ascend to high levels can be inferred independently of, though in accordance with, the spectral evidence for the presence of atomic oxygen as a permanent constituent of the upper atmosphere.

23. Atmospheric Sodium. Our knowledge of the presence of atomic sodium in the high atmosphere comes solely from the emission spectra, night-sky, twilight-

sky, and auroral. Intensity measurements at different altitudes have led to widely different estimates of the heights of emission of the sodium light. Bricard and Kastler have shown that for the twilight emission the spectral line is very narrow, whereas it is much wider in the night-sky emission.

The problems connected with the sodium light concern not only the levels and processes of emission; they concern also the amount of invisible sodium that may be present in the upper atmosphere, that is, the amount of sodium not in a state to emit the yellow (or other observable) light. Sodium is easily ionized by sunlight in the Hartley band, and must intercept some of this light, though most of it is absorbed lower down, in the ozone layer. The presence of some ionized sodium atoms must be expected in the high atmosphere, though their presence is not likely to make an important contribution to any of the ionized layers except possibly to the D-layer. Further, sodium forms oxides, NaO and NaO_2, and these also would not be likely to give direct spectral indication of their presence.

The proportions of Na, Na^+, NaO, NaO_2 and any other forms in which sodium may exist in the upper atmosphere will differ with differing height, and the distribution and reaction processes of the sodium present a fascinating problem of atmospheric photochemistry, on which some speculation has been exercised, though as yet without any clear and definite conclusions being established. The oxides of nitrogen (as well as oxygen itself) may play a significant part in the reactions associated with sodium. The discussion of these oxides, as well as of the sodium itself, demands much knowledge that is still lacking, concerning, for example, energy data and reaction coefficients. As an illustration, one process suggested for the excitation of sodium atoms to the state $^2P_0$ from which they can emit the D light is $Na + O + X \rightarrow NaO + X$, $NaO + O \rightarrow Na' + O_2$; for the excited sodium atom Na' in the latter equation to be in the $^2P_0$ state, the energy 2.1 ev must be derivable from the oxygen dissociation energy gained (5.1 ev) less the energy needed to dissociate NaO; this is about 3 ev, but it is not yet certain that it is not slightly too great for this process to provide the excitation energy, unless the colliding particles NaO and O have kinetic energies substantially greater than their average thermal energy (see § 14). This suggested process is based on the dissociation energy of oxygen stored up in the daytime from absorbed sunlight. Another possible process, involving only two-body collisions, is $Na + O_3 \rightarrow NaO + O_2$, $NaO + O \rightarrow Na' + O_2$; it involves the same doubt as to the latter reaction.

The photochemical problems briefly discussed here have an intrinsic interest and also some practical importance in that their solution is likely to aid in a full understanding of the phenomena of the ionosphere. At present the formation of the various ionized layers, themselves so vital to radio communication, is far from being properly understood, and every additional clue or sidelight concerning the electrical and chemical processes in those regions is likely to prove valuable.

SUGGESTIONS FOR FUTURE WORK

On the observational side the study of the photochemical processes in the upper atmosphere has vast scope. A basic necessity is the determination of the composition of the upper atmosphere as well as the height-distribution of temperature and density. Rocket investigations may aid greatly in this field, particularly with regard to the composition, which indicates the extent to which diffusive separation occurs. Such investigations will also provide basic knowledge as to the solar radiation received at high levels in the atmosphere.

Spectroscopic studies, from the ground and *in situ* (by means of balloons and rockets), have much to add concerning the nature and distribution of the constituents of the upper atmosphere, including water vapor, carbon dioxide, ozone, atomic oxygen and nitrogen, the oxides of nitrogen, hydroxyl (OH), and sodium. The study of the absorption and emission by these and other gases in the high atmosphere, by night, at twilight, and during the day will enhance our understanding of the nature and processes of chemical, electrical, and energetic change there. For this work it is necessary to develop instruments of enhanced light-gathering power, spectral range, and dispersion, in particular for the auroral and night-sky luminosity.

Radio investigations will greatly extend our knowledge of the energy absorption, photoelectric processes, and motions in the ionosphere, both at normal times and during magnetic disturbances, when corpuscular energy as well as wave energy is operative.

Such observations need to be made not only at one or two places on the earth, but at a network of stations, so that the world distribution of the phenomena may be known—for its own interest, and also to aid in understanding the processes occurring in any one place. Continued observations to determine seasonal changes and changes throughout the sunspot cycle are desirable in many cases.

On the theoretical side the subject is still young. Many additional purely chemical and physical data are required as a basis for atmospheric theories, namely data on the rates of various types of atomic and molecular processes, and in some cases on the temperature dependence of these rates. These data must be obtained partly by laboratory measurements, and partly by theoretical calculations in atomic and molecular physics. Such data are needed to elucidate the main processes of photochemical and photoelectrical change in the upper atmosphere, and to determine their height-distribution, distinguishing, among the vast number of possible reactions and processes, those whose rate and number give them real significance.

OZONE IN THE ATMOSPHERE*

By F. W. PAUL GÖTZ

Lichtklimatisches Observatorium Arosa and University of Zürich

INTRODUCTION

As early as 1845 the chemist Schönbein, discoverer of ozone, attempted to prove that traces of this gas are a constant constituent of the atmosphere. However the ozone problem in its entire scope was revealed only when Fabry and Buisson [32] recognized by spectrographic methods that the principal quantities of ozone are present in the upper strata of the atmosphere. Although the ozone amount, that is, the total quantity of ozone present when reduced to standard conditions, amounts to but a few millimeters of the 8-km height to which the homogeneous ocean of air rises, this small trace is nevertheless sufficient (because of the enormous absorption in the ultraviolet) for intercepting the entire extraterrestrial radiation below 2900 A, for heating the "warm layer" at a height of 50 km, and for protecting the biosphere against an excess of short-wave radiation. Only during recent years has it been possible to pass through the high ozone layer with the aid of V-2 rockets, a feat which opened an entirely new spectral range of solar radiation to astrophysical investigations. But how is it possible for such a relatively heavy component of air to maintain itself high in the atmosphere? Only if it is constantly being regenerated, if short-wave radiation from the sun is capable of transforming oxygen to ozone. The opposing effect of long-wave ultraviolet which is again absorbed by ozone thereby destroying it (E. Regener), produces a spontaneous chemical ozone equilibrium in the upper layers of the atmosphere; below 35 km, however, this latter process is so slow that ozone which, by some meteorological processes, has been transported to these altitudes is largely "protected." In lower layers ozone becomes an important conservative property of the air until the stream from the high altitude ozone source is finally destroyed near ground level due to photochemical, chemical, and catalytic decomposition. In view of its intimate connection with weather processes (Dobson), the study of ozone provides methods of indirect aerology; there is an ever-increasing tendency to supplement a mere observation of total ozone amount with a detailed measurement of its vertical distribution and changes thereof. Only by investigation of this latter type will it be possible to understand the effect of ozone on the flux of radiation.

An intriguing aspect of the ozone problem is that the most diverse scientific fields converge at it. Two international conferences [16, 31] and several national conferences [71] have so far been devoted to this problem. The Meteorological Association of the International Union for Geodesy and Geophysics has a special commission on ozone.

* Translated from the original German.

METHODS OF OBSERVATION

Absorption Coefficients. *Ozone* has its principal absorption in the Hartley band [68] extending from 3200 to 2000 A. At $\lambda = 2553$ A the decadic absorption coefficient is 145, that is, a layer as thin as $\frac{1}{145}$ cm reduces the intensity of radiation to one tenth. On the short-wave side, in the region of the ozone-oxygen gap which is so important for the theory, Mme. A. Vassy [96] satisfactorily verified the older measurements of Edgar Meyer. The long-wave side of the Hartley band connects with the Huggins bands which extend up to 3690 A, and these bands are temperature dependent. However, new determinations [4] yielded the opposite finding that the absorption maxima too are influenced by temperature. The Chappuis bands, although relatively weak, coincide with the region of maximal solar energy; because of the superposition of the vapor bands in the solar spectrum, they are not suitable for ozone determination, according to Mme. Vassy. Absorption in the long-wave region is important for the problem of heat balance; the absorption band between 9.0 and 9.7 μ seems particularly significant because it lies in the otherwise very transparent atmospheric window between 9 and 13.5 μ. According to Strong [92], and Adel and Lampland [1], absorption in the 9.6-μ band exceeds all previous assumptions by a factor of about ten and is very dependent on pressure, approximately proportional to the fourth root of pressure, a fact which Strong uses for determining the average height of the ozone layer by simultaneous determination of the ozone absorption in the ultraviolet and the infrared.

Oxygen has absorption properties which form the basis for the theory of the ozone layer. In this connection, the region of maximal absorption between 1300 and 1750 A [56] is of less interest than the wave lengths around 2000 A [96] which overlap the ozone absorption. Deviations from Beer's law are significant. I am indebted to W. Heilpern and E. Meyer [51] for information regarding the current state of this question. If the absorption of light is given by $J = J_0 \times 10^{-\epsilon l}$, where ϵ denotes the extinction coefficient for a pressure P in kilograms per square centimeter, and if the thickness of the layer $l = 1$ cm, then ϵ for pure oxygen is given by

$$\epsilon(O_2) = \epsilon_1 P + \epsilon_2 P^2. \qquad (1)$$

For an arbitrary mixture of O_2 and N_2, where c_1 denotes the volume concentration of O_2 and c_2 that of N_2, ϵ is given by

$$\epsilon(G) = \epsilon_1 P c_1 + \epsilon_2 P^2 c_1^2 + \epsilon_3 P^2 c_1 c_2 , \qquad (2)$$

where P denotes the total pressure. The third term represents the effect of the "extraneous gas." In the region investigated, the constants ϵ_1, ϵ_2, and ϵ_3 have

the following values:

λ(A)	$\epsilon_1 \times 10^5$	$\epsilon_2 \times 10^{-5}$	$\epsilon_3 \times 10^{-5}$
2100	12.82	10.50	4.07
2144	6.17	9.30	4.01
2150	6.70	8.81	3.70
2200	5.49	7.21	3.25
2250	4.10	5.73	2.86
2300	2.63	4.31	2.57
2350	2.69	3.10	1.87
2400	1.47	2.10	1.37

The formulas given above agree surprisingly well with observed data and are valid in the large pressure interval between $P = 0.20$ and 130 kg cm^{-2}, in which ϵ varies by four orders of magnitude.

Determination of the Ozone Amount. At first, we are interested in the total atmospheric ozone amount, which is customarily expressed in terms of the thickness x of a layer under standard conditions of temperature and pressure. The decadic extinction coefficient of the total, pure atmosphere above the observer, according to Rayleigh, may be denoted by β; the decadic extinction coefficient of the total turbid atmosphere may be denoted by δ, and that of ozone by αx; correspondingly, let the total path of the sun's rays, having a zenith distance z be m according to Bemporad (for the turbid layer, $m = \sec z$ because the turbid layer generally lies on the ground), and let $\mu = \sec \zeta$ for the ozone layer, with

$$\sin \zeta = \frac{\sin z}{1 + h/R}, \tag{3}$$

where h is the height of the ozone layer and R the radius of the earth. For radiation of the extraterrestrial intensity I_0 subject to ozone absorption in the Hartley band, we obtain

$$\log I = \log I_0 - \beta m - \delta \sec z - \alpha x \mu; \tag{4}$$

for a neighboring wave length ($\lambda' > \lambda$) subject to lesser absorption by ozone, we find

$$\log I' = \log I_0' - \beta' m - \delta' \sec z - \alpha' x \mu. \tag{5}$$

From equations (4) and (5), we obtain the amount of ozone as

$$x = \frac{\log I_0/I_0' - \log I/I'}{(\alpha - \alpha')\mu} - \frac{(\beta - \beta')m}{(\alpha - \alpha')\mu} - \frac{(\delta - \delta')\sec z}{(\alpha - \alpha')\mu}. \tag{6}$$

The quantity $(\delta - \delta')$ may be neglected except in the case of dense haze [42, 79]. The constant $\log (I_0/I_0')$ is then obtained by plotting diurnal measurements of $\log (I/I') - (\beta - \beta')\, m$ as ordinate versus μ as abscissa and extrapolating to $\mu = 0$.

The experimental apparatus must be of such construction that scattering within the spectrograph is avoided since this would be a serious disturbance, particularly in view of the pronounced intensity drop at the end of the spectrum. Dobson's spectrophotometer [22] is particularly designed to avoid such errors. By means of a rotating sector, I and I' are made to fall, in rapid alternation, upon a photoelectric cell connected to an amplifying device. By a measured attenuation with an optical wedge, I' can be made equal to I, a condition indicated by a zero amplifier output; in this manner, the ratio I/I' is measured. As calibration runs in Arosa and on the Jungfraujoch have indicated, the wave-length adjustment of the instrument depends not only on temperature but also on altitude, since the refractive index of quartz with respect to air changes with air pressure. Values obtained with the old photographic Dobson instrument [24] must be reduced to 88 per cent of the indicated value [40]. For the purpose of increasing the sensitivity of the Dobson spectrophotometer, it has recently been the practice to replace the photoelectric cell by a photo-multiplier. Figure 1 shows the latest model of the instrument according to the catalog of its manufacturer, Beck of London [70].

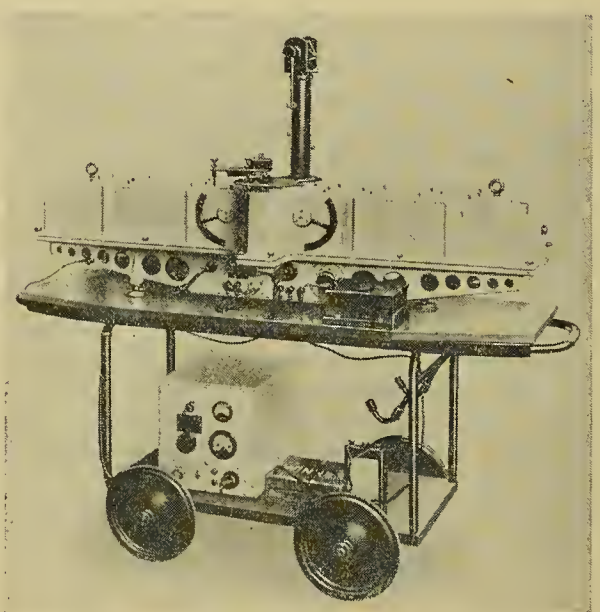

FIG. 1.—The Dobson Spectrophotometer.

The ozone near ground level is determined by essentially the same method, employing in place of the sun, moon, or stars [13] an artificial light source [44] rich in ultraviolet and located at a distance of several kilometers. Improved chemical ozone determinations have recently gained extensive use [12, 20, 29, 73, 87, 91].

Determination of the Vertical Distribution. Two methods are available for determining the vertical distribution of ozone.

1. *The Umkehr Effect.* In the case of solar radiation, ozone absorption as well as scattering is responsible for the fact that with increasing zenith distance z, the intensity I of a shorter wave length (for instance $\lambda = 3110$ A) decreases more strongly than the intensity I' of a longer wave length (for instance $\lambda' = 3290$ A); the composition of light I/I' which we may also designate as light quality, decreases continuously as the zenith distance of the sun increases. For zenith radiation i, the ratio i/i' shows a similar behavior at first, as long as the zenith distance of the sun is relatively small;

as z continues to increase, however, the function i/i' reaches a minimum at about $z = 85°$, and shows an inversion (Umkehr) [36] at $z > 85°$, that is, i/i' increases again at very low elevations of the sun. This experimental result (Fig. 2) is explained on the basis of

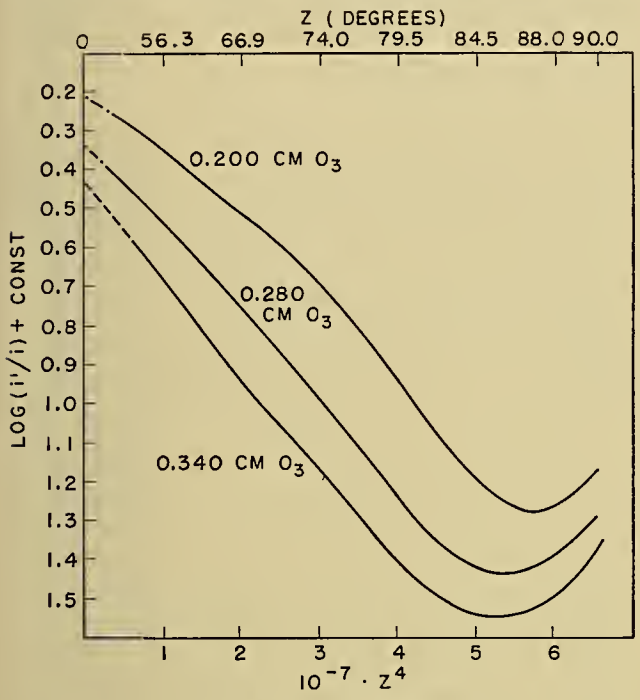

Fig. 2.—Umkehr curves.

the distribution of ozone in the scattering atmosphere. Zenith light is the sum of the components scattered at various altitudes corresponding to the prevailing air density. Because of its smaller density, the atmosphere above the ozone layer scatters to a lesser extent than the atmosphere below this layer. However, the short-wave radiation scattered vertically downward traverses the attenuating ozone layer by the shortest path and, as the zenith distance increases, it attains ever more significance in comparison with the radiation scattered below the ozone layer; in this case scattering power would indeed be greater, but the sunlight which is to be scattered has been considerably weakened by traversing the ozone layer by the long, oblique path. The stronger the absorption, the greater the tendency for the sky radiation of the shortest wave length to find the shortest path directly from above through the ozone layer. The variation of the Umkehr function i/i' with z depends on the type of stratification, that is, the vertical distribution of ozone. It thus provides a means for measuring the vertical distribution.

We divide the atmosphere into a number of shells within each of which we assume the ozone content (expressed in centimeters of ozone per kilometer) to be constant. We might assume the following shells [39, 45]:

Altitude	Ozone amount
65–50 km	0, but scattering not zero
50–35 km	x_1
35–20 km	x_2
20– 5 km	$x - (x_1 + x_2 + u)$ since x is known.
5– 0 km	u, where u is assumed to be known.

Thus the characterization of the vertical distribution involves only two unknowns, x_1 and x_2, which is desirable in order that the numerical solution of the equations may not be too difficult. The unknowns x_1 and x_2 enter into the expression for the thickness l cm of an ozone layer which is traversed by a sun ray incident at a zenith distance z. The ray is scattered at point A where the barometric pressure is b and reaches the instrument at the point B. The path length in each ozone shell is determined trigonometrically; it suffices to tabulate the distance s of Fig. 3 as a function of the

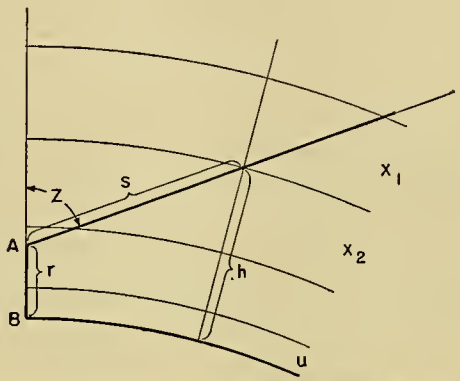

Fig. 3.—Subdivision of the atmosphere into layers.

quantity $h - r$ (*i.e.*, independently of r). Of significance for the Rayleigh scattering is the air mass L traversed by the ray, which is easily found to be

$$L = 1 + (b/760)\,(m - 1). \tag{7}$$

We sum the light scattered by each kilometer A from the ground to an altitude of 65 km and find the intensity of zenith radiation i to be

$$i = \Sigma 10^{-\beta L} b 10^{-\alpha l} \text{const} \tag{8}$$

and similarly for i' and i/i' or i'/i. The corresponding expression for i'/i is the same as the result of observations (Fig. 2). It is to be noted that the undetermined constant in the observed curve may be determined by calculating i'/i for $z = 0$, since the vertical distribution of ozone has no effect for $z = 0$. The two unknowns x_1 and x_2 require two equations, such as an equation for $z = 90°$ and one for $z = 80°$. The solution is obtained graphically by plotting x_2 as a function of x_1 for both cases and determining the intersection of the two curves. Choice of a third value of z, such as $z = 86.5°$, provides a convenient check. The values of x_1 and x_2 then characterize the vertical distribution stepwise.

In addition to this analytical method A, use has also been made of a more synthetic method B, which consists of starting with an assumed vertical ozone distribution and varying it until calculated and measured Umkehr curves are in agreement. In both methods secondary scattering should be further considered.

In order to obtain a more detailed ozone distribution curve it is, of course, desirable to choose our shells as thin as possible. It has been verified that essentially no ozone is present above 50 km. Between 50 and 35 km the ozone may be assumed constant as will be seen

later. From the ground upwards, the region of known ozone concentration could today easily be extended from 5 to 10 km above ground by modern aerological methods (chemical measurements by airplane). A subdivision of the region between 10 and 35 km into three shells would then remain for the Umkehr measurement. Day-to-day measurement of these three layers would be of the most important meteorological interest.

2. *Techniques Using Recording Balloons, Stratospheric Balloons, and V-2 Rockets.* In addition to the rather indirect method involving the Umkehr effect, there is of course the challenge of sending spectrographs to ever higher altitudes until finally the ozone layer is penetrated. The first great success in this respect was achieved by E. and V. H. Regener on July 31, 1934 when they sent a recording spectrograph to an altitude of 31 km by means of a balloon [85]. The lightweight spectrograph was pointed downward against a horizontal magnesium oxide disk exposed to sunlight; magnesium oxide effectively reflects ultraviolet. The apparatus is installed in a light wooden frame, the lower half of which is covered with aluminum foil, the upper half with cellophane, an arrangement which affords excellent protection against cold. The photographic plate Fig. 4) is rotated through a small angle every ten

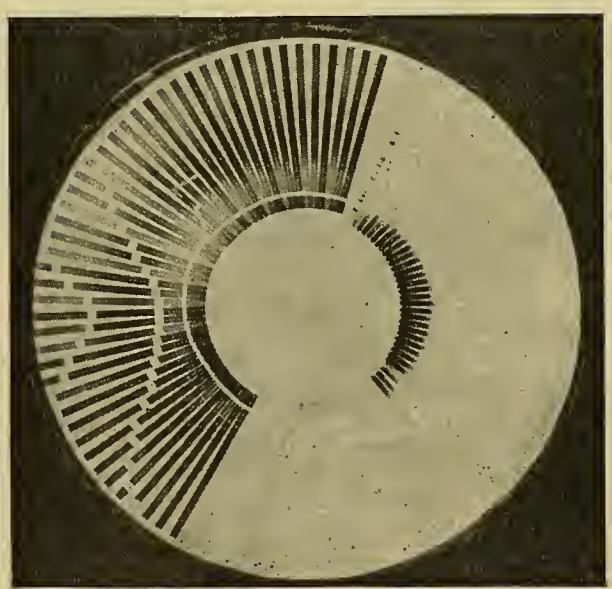

Fig. 4.—Regener-photographs of the ultraviolet spectrum taken in the stratosphere.

minutes, being continuously exposed in the meantime. At the instant the plate is advanced, a small light bulb is turned on by which the readings of two aneroid gauges (standard barograph and low-pressure barograph) as well as of a bimetallic strip to indicate the temperature of the instrument are recorded. On the plate which has a diameter of 10 cm the step-shaped interruptions of the long rays are the shadows of the two indicators connected to the aneroids; they represent lower pressures the closer they approach the center. The clear ultraviolet spectra are located diametrically opposite the pressure indications and they are seen to extend to shorter wave lengths the greater the altitude and the smaller the quantity of ozone traversed by the solar radiation. In addition, the plate also bears a mercury calibration spectrum. The entire device, including a protective frame, weighs 2.7 kg. If λ_n represents the shortest wave length of the solar spectrum at an altitude h_n and zenith distance z_n, and if x_n represents the total quantity of ozone located above the instrument, then, approximately,

$$x_2\alpha_2 \sec z_2 = x_1\alpha_1 \sec z_1 . \qquad (9)$$

Further improvements are obtained with an accurate intensity measurement at the end of the spectrum and elimination of diffuse sky light, for instance with the aid of a magnetically oriented hemispherical stop [86].

Coblentz and Stair [15] and Stranz [91] attempted to simplify the methods by replacing the spectrograph by a cadmium cell and filter as was done in the first ozone measurements in 1921 at Arosa. The intensity values are transmitted radiotelegraphically as in the radiosondes.

With the aid of a free balloon, A. Wigand as early as 1913 measured the ultraviolet end of the solar spectrum up to a height of 9 km. Shortly after the Regener experiments, the stratosphere balloon, which is capable of carrying aloft high quality instruments, was employed for this purpose. Under the leadership of Stevens and Anderson, *Explorer II* reached an altitude of 22 km in November 1935; ozone at even higher altitudes was determined indirectly from the sky radiation [39, 69]. Ozone determination by means of captured V-2 rockets [95] represents the climax of this brilliant development. It was the fulfillment of a dream when on October 10, 1946 in White Sands the ozone layer was penetrated and a large unknown range of the solar spectrum became accessible (Fig. 5).

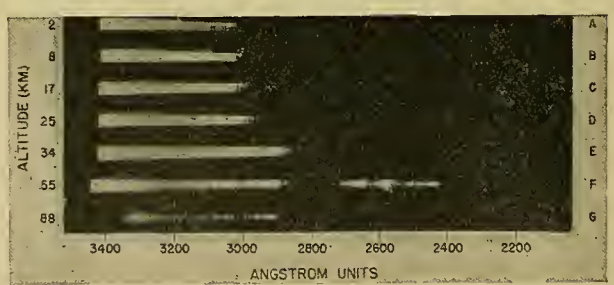

Fig. 5.—Short-wave end of the solar spectrum taken from V-2 rocket.

RESULTS OF OBSERVATIONS

The Ozone Amount. The first ozone determinations made in Marseille [32], as well as the measurements made at Arosa with filtered cadmium cells since 1921, revealed irregular ozone fluctuations from *day to day.* Dobson [24] discovered their connection with the general distribution of air pressure so that they may be designated as *meteorological* fluctuations. The interdiurnal variability of the ozone amount at Arosa was found to be:

	cm		cm		cm
January	0.017	May	0.011	September	0.008
February	0.017	June	0.010	October	0.009
March	0.015	July	0.010	November	0.010
April	0.015	August	0.009	December	0.013

During the summer season there are no great meridional differences in the interdiurnal variability. In July and August, in India it is 0.005 cm, at Tromsö 0.010 cm, at Spitsbergen 0.007 cm; in December it rises to 0.056 cm at Tromsö. The fluctuations frequently become manifest even during a single measuring day, in the form of an "ozone cloud" [55]. In one case in which ozone was determined by sighting on stars in various directions of the sky, it was possible to delineate such

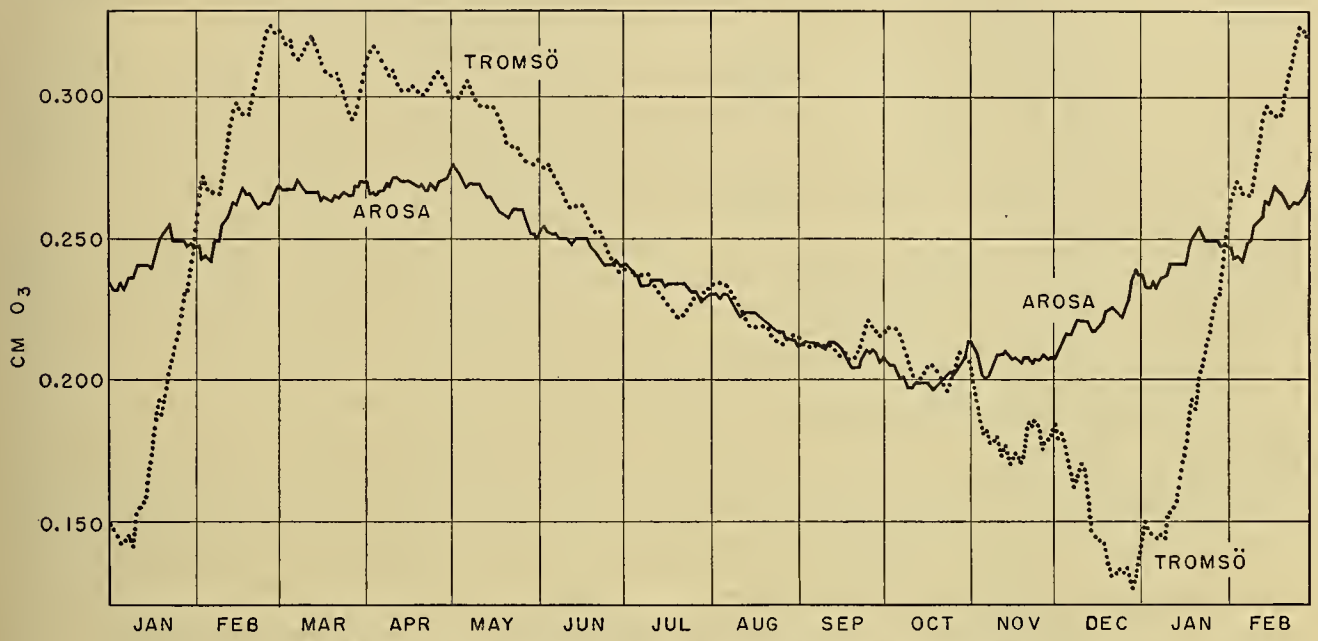

Fig. 6.—Annual variation of the ozone amount at Arosa and Tromsö.

an ozone cloud in space [3] as a forerunner of a considerable increase in ozone. A regular, slight *daily* variation of ozone has so far been reported only from Delhi [53]; at Arosa, a change in the temperature correction of the Dobson spectrophotometer simulated a diurnal variation for some time. Differences between day and night have not yet been confirmed. Frequently ozone fluctuations are of periodic nature [43] with periods up to 36 days, as has been found for the barometric pressure at the ground.

Concerning the *annual* variation of ozone amount, we are quite well informed by the extensive observational network of Dobson [21]. The representation as a yearly sine curve, with an amplitude which increases with latitude from a value of zero at the equator, is a considerable simplification even at middle latitudes. Figure 6 represents the overlapping five-day averages of the extensive measurements at Arosa (1926–1946) and Tromsö (1939–1948). At Tromsö an almost sudden linear increase in January and February is followed by a gradual decrease terminating in an "ozone gap" at the end of December. It seems doubtful that all the peaks in the Arosa curve, such as those found at the end of April or the end of October, will be smoothed out by averaging more extensive observational material [43].

The latitudinal dependence of the annual averages of ozone amount is revealed by an increase from 0.17 cm at the equator to an "ozone belt" (Götz) of 0.26 cm at latitude 60°N; the ozone amount again decreases toward higher latitudes. In the Southern Hemisphere, the gradient is more pronounced, and here again it is the maxima rather than the minima that are significant. The variation is best described by an isoplethic representation (Fig. 7), in which the ozone belt is shown by means of a dot-dash line.

As regards the *secular* variation, that is, ozone variation from year to year, Fowle's hypothesis concerning the correlation with the relative sunspot number was

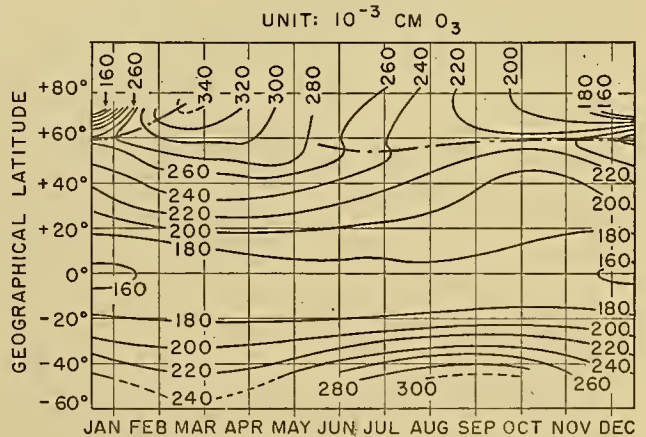

Fig. 7.—Isopleths of the average ozone amount. The ozone belt is indicated by dot-dash lines.

untenable. Figure 8 shows the secular variation for the twenty-year series at Arosa, which reveals waves of several years' length. For our further conclusions we might wish to have such figures back to ice ages! The mean monthly fluctuation about the over-all monthly

average is given below:

	cm		cm		cm
January	±0.014	May	±0.008	September	±0.007
February	±0.014	June	±0.006	October	±0.007
March	±0.012	July	±0.005	November	±0.005
April	±0.012	August	±0.006	December	±0.008

It is apparent that the fluctuation is twice as great in winter as it is in summer and fall; in winter, as well as in spring, it is considerably greater at Tromsö than it

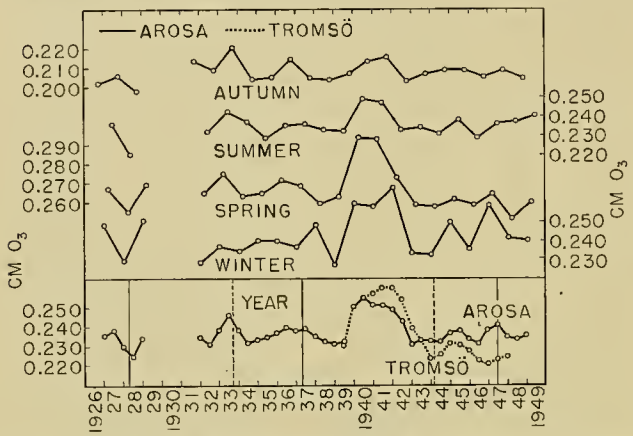

FIG. 8.—Secular fluctuation of the ozone amount. Vertical broken lines represent sunspot minima; vertical solid lines, sunspot maxima.

is at Arosa; the series is thus subject to the same influence which also causes the meteorological (interdiurnal) variability. If one were to seek a direct correlation between ozone and solar activity, then the double fluctuations of the Eurasian large-scale weather within the sunspot cycle according to Baur [7] would be of interest. In the lower yearly average curve of Fig. 8, the vertical solid lines represent sunspot maxima, the vertical broken lines represent sunspot minima. For the yearly averages the following correlation coefficients are obtained.

	Correlation coefficient
Ozone and relative sunspot number	+0.01
Ozone and air pressure	−0.43
Ozone and solar constant	+0.48

As regards the analysis of other long series of observations, there exists only the attempt [11, 93] to determine ozone by means of the Chappuis band from the Smithsonian measurements. Even though wide scattering of these values makes them seem rather unreliable, it is nevertheless interesting to note the very slight ozone amount during the year 1912 since it has been ascribed to an effect of the eruption of the Katmai Volcano [37]. Such a possibility has also been discussed by E. Regener [84].

The Vertical Distribution of Ozone. The vertical distribution of ozone, first of all shows a high primary layer of maximum ozone content at an altitude of 20 to 25 km. Its stratified character is more pronounced the smaller the total ozone amount. The layer thickens as the ozone amount increases, owing to meteorological

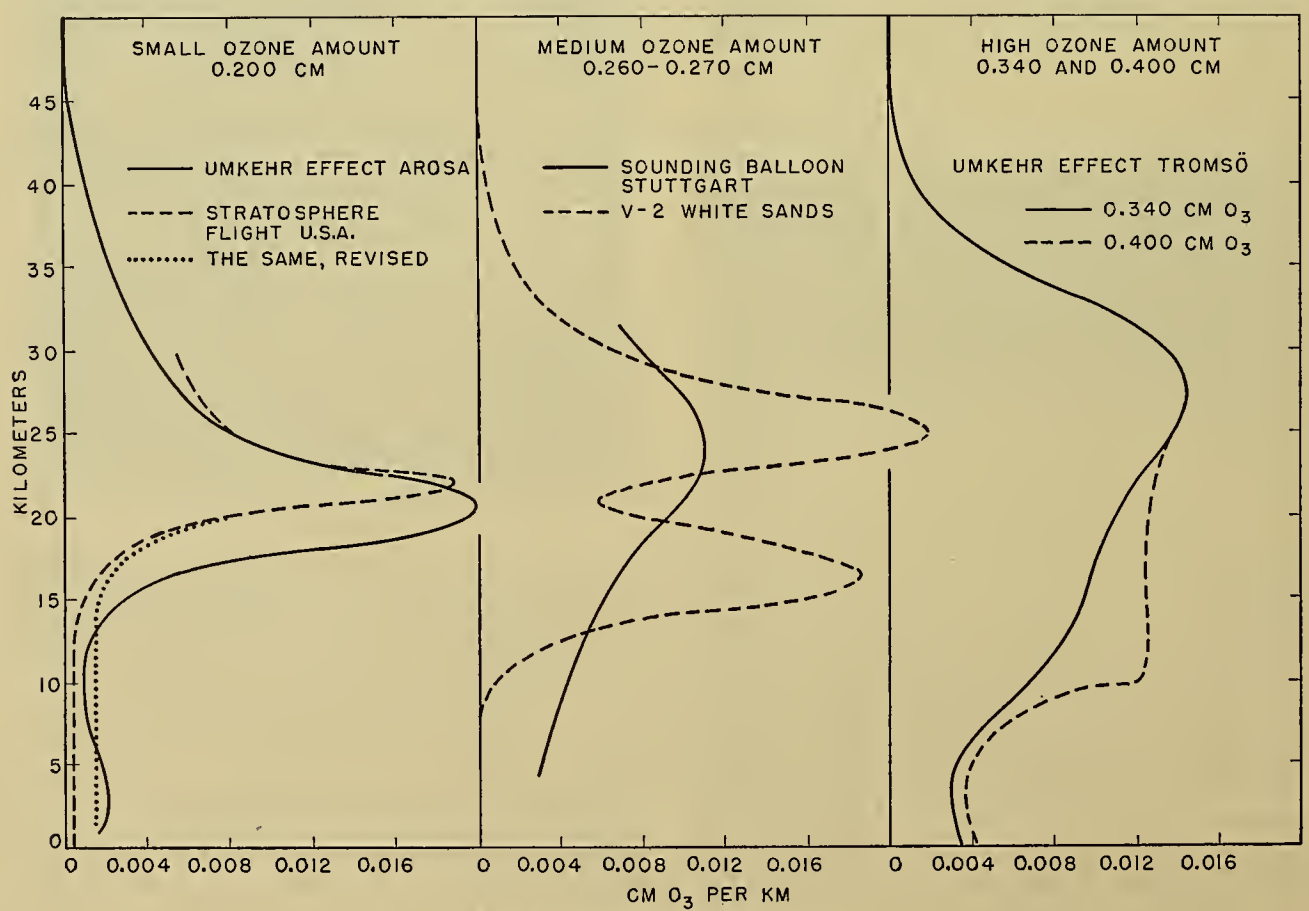

FIG. 9.—Vertical ozone distribution.

processes. It is not impossible that, on the one hand, the primary layer moves to slightly higher altitudes; on the other hand, it is principally of meteorological significance that a lower secondary layer [39] appears which swells with increasing ozone amount, so that the original separation of the two layers becomes more and more indefinite. Representation by the direct stepwise distribution according to the Umkehr method may be most instructive in this connection [39]. Figure 9 shows smoothed curves for several examples, including the result of the first vertical ozone determination with V-2 rockets in which the lower secondary layer was also found.[1] Table I summarizes in customary manner

TABLE I. ALTITUDE OF THE MASS CENTER OF OZONE (in km)

Station	Lat.	Method	Ref.	Ozone amount (cm O_3)				
				0.160	0.220	0.280	0.340	0.400
Poona	18°	*B*	[54]	28.1				
Delhi	29°	*B*	[54]	26.2	25.1			
White Sands	35°	*V*-2	[66]			22.5		
Arosa	47°	*A*	[45]		23.4	21.5	21.3	
Arosa	47°	*B*	[45]		22.6	21.4		
Tromsö	70°	*B*	[62]		21	21		
Tromsö	70°	*A*	[94]	26.7	25.7	24.7	23.0	20.8

the mass center of ozone; there *A* denotes the analytical, *B* the synthetic evaluation of the Umkehr curve. The variation of the center of mass of ozone with latitude evidently requires additional measurements.

The lowest portion of the vertical ozone distribution may be determined by direct measurement of the ozone content near ground level. Whereas in the lowlands the ozone near ground level is subject to considerable

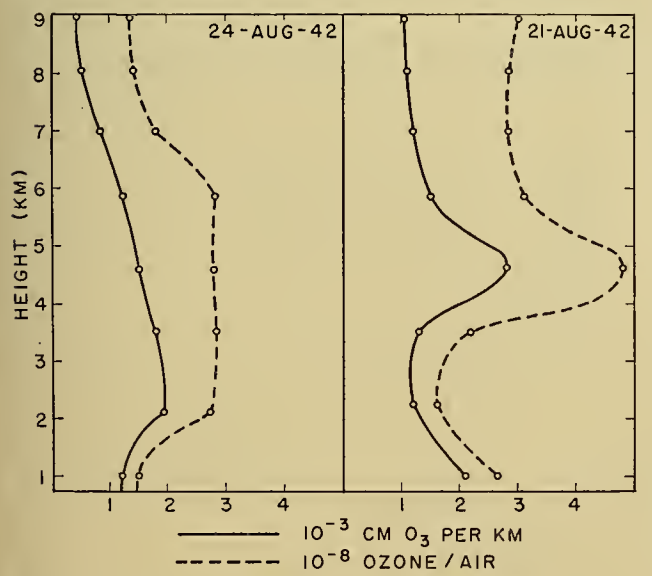

FIG. 10.—Tropospheric ozone distribution.

fluctuation [2], it shows considerable constancy at Arosa which is situated at an altitude of 2 km; thus there appears to be a weak tertiary ozone layer at this altitude. As shown by aircraft measurements by Ehmert [28] the altitude of this tertiary tropospheric layer may vary in individual cases, depending on meteorological conditions (Fig. 10).

THE THEORY OF ATMOSPHERIC OZONE

The Ozone in Undisturbed Photochemical Equilibrium. The existence of a layer of a heavy gas in the upper atmosphere necessitates the assumption of continuous regeneration and destruction with consequent equilibrium. As early as 1906, E. Regener demonstrated by means of laboratory experiments the photochemical equilibrium of ozone under the influence of the short-wave ultraviolet radiation which, when absorbed by oxygen, generates ozone, and also under the influence of a radiation that is then again absorbed by the ozone. This clearly provides a basis for a photochemical equilibrium in the atmosphere under the action of solar radiation. No other theory provides an equally adequate explanation even though it cannot be denied that occasionally electrical storms and cosmic radiation might contribute some ozone. At the altitude of the equilibrium layer, radiation in the wave length region between the Schumann-Runge and Herzberg bands produces ozone, whereas the wave length of the Hartley band particularly, but also those of the Chappuis band, destroy ozone. The various wave lengths involved are absorbed very differently and therefore penetrate the atmosphere to different depths.

We are indebted to S. Chapman for the first theory of atmospheric ozone based on these considerations. Wulf and Deming, to whom more extensive data were available [103], worked on the basis of Chapman's fundamental reactions. There are two primary photochemical reactions, namely,

$$O_2 + h\nu(\lambda < 2420) \rightarrow O + O, \tag{10}$$

involving the number Q_2 of oxygen-dissociating quanta $h\nu$, and

$$O_3 + h\nu(\lambda < 11540) \rightarrow O_2 + O, \tag{11}$$

involving the corresponding number Q_3 of ozone-destroying quanta. The quantities Q_2 and Q_3 are the numbers of quanta absorbed by oxygen and ozone, respectively, in a given unit volume of air. For example, Q_2 is given by

$$Q_2 = \int_\lambda \alpha_{2\lambda} I_\lambda [O_2]\, d\lambda,$$

where $\alpha_{2\lambda}$ is the absorption coefficient of oxygen, I_λ is the number of quanta incident on the volume, and the brackets about O_2 indicate (here and in subsequent discussion) the concentration of oxygen. In addition to (10) and (11) there are the secondary reactions.

$$O_2 + O + M \rightarrow O_3 + M, \tag{12}$$

which requires a triple collision with an arbitrary collision partner M for conserving energy and momentum, and for which k_2 represents the coefficient of the reaction rate, and finally,

$$O_3 + O \rightarrow 2O_2^*, \tag{13}$$

1. The reality of this lower-altitude maximum has been questioned in a recent paper: "Upper Air Research by Rockets," by H. E. Newell, Jr., in *Trans. Amer. geophys. Un.*, 31: 25-34 (1950). (See p. 31)

with k_3 as the constant of the rate of reaction (O_2^* is an excited molecule). The constants k_2 and k_3 enter only in the form of the ratio $k_2/k_3 = k$; the data for k are as yet somewhat variable. If the concentration [ ] is referred to the number of molecules per cubic centimeter, the extrapolated measurements by Eucken and Patat [30] yield the values of k shown in Table II.

TABLE II. VALUES OF k

deg C	k	deg C	k
100	1.95×10^{-21}	0	4.00×10^{-20}
80	3.16×10^{-21}	−20	9.95×10^{-20}
60	5.27×10^{-21}	−40	2.79×10^{-19}
40	9.51×10^{-21}	−60	9.85×10^{-19}
20	1.88×10^{-20}	−80	4.35×10^{-18}

From the equations (10) to (13) and the reaction constants we obtain the changes in concentration per second:

$$\frac{d[O_3]}{dt} = k_2\,[O_2]\,[O]\,[M] - k_3\,[O_3]\,[O] - Q_3 \qquad (14)$$

and

$$\frac{d[O]}{dt} = 2Q_2 + Q_3 - k_2\,[O_2]\,[O]\,[M] - k_3\,[O_3]\,[O]. \qquad (15)$$

If we calculate $[O]$ from the condition of equilibrium $\frac{d[O]}{dt} = 0$, we obtain

$$\frac{d[O_3]}{dt} = \frac{2Q_2\,k_2\,[O_2]\,[M] - 2Q_2\,k_3\,[O_3] - 2Q_3\,k_3\,[O_3]}{k_2\,[O_2]\,[M] + k_3\,[O_3]}, \qquad (16)$$

whence, under equilibrium conditions, $\frac{d[O_3]}{dt} = 0$, it follows that

$$[O_3] = \frac{k_2}{k_3}\frac{[O_2]\,[M]}{1 + Q_3/Q_2} = k\,[O_2]\,[M]\,\frac{1}{1 + Q_3/Q_2}. \qquad (17)$$

Wulf and Deming base their numerical calculations of the vertical ozone distribution upon this equation, in which Q_3 itself is a function of $[O_3]$, so that one can only proceed by a method of successive approximations.

In addition to oxygen, the third collision partner M is primarily nitrogen which, however, is only about one-half as effective as oxygen so that

$$[M] = [O_2] + \tfrac{1}{2}[N_2] \sim 3[O_2]. \qquad (18)$$

We may replace Q_3, the number of quanta absorbed per second per cubic centimeter (which is also proportional to $[O_3]$), by

$$Q_3 = [O_3]f_3\,, \qquad (19)$$

where f_3 is the number of quanta absorbed per molecule, and correspondingly

$$Q_2 = [O_2]f_2\,. \qquad (20)$$

Dütsch [27], using this resolved form (which facilitates subsequent treatment of nonequilibrium conditions), obtains a quadratic equation for $[O_3]$:

$$[O_3]^2 f_3 + [O_3][O_2]f_2 - 3k[O_2]^3 f_2 = 0. \qquad (21)$$

with the solution

$$[O_3] = [O_2]\,\frac{-f_2 + \sqrt{f_2^2 + 12\,f_3\,f_2\,[O_2]k}}{2f_3} \qquad (22)$$

and, with the justified approximation $f_2 \ll 12\,f_3 f_2 [O_2]k$,

$$[O_3] = [O_2]\sqrt{3kf_2[O_2]/f_3}. \qquad (23)$$

This equation does not differ much from the form

$$[O_3] = [O_2]^2\sqrt{Cf_2/f_3}, \qquad (24)$$

which served as basis for Mecke's theory [60] as early as 1931. Mecke replaced the numerical integrals f_2 and f_3 by $\alpha_2 I_2$ and $\alpha_3 I_3$, thus taking not only average radiation intensities but also average constant mean values for α_2 and α_3. This enabled him to integrate over limited intervals, resulting in the following ozone distribution:

$$[O_3] = [O_3]_{\max}\left(\frac{p}{p_{\max}}\,e^{1-(p/p_{\max})}\right)^2. \qquad (25)$$

In this equation, according to recent analyses, the power 2 is to be replaced by the power $3/2$ which furnishes a somewhat broader maximum (Fig. 11). The symbol $p_{\max}$ denotes the pressure p at the altitude of maximum ozone concentration $[O_3]_{\max}$. When Mecke introduced the total amount x of ozone (instead of the maximum ozone content) he obtained for an altitude H of the homogeneous atmosphere the ozone content

$$\epsilon 10^{-5} = \frac{x}{1.85H}\left(\frac{p}{p_{\max}}\,e^{1-(p/p_{\max})}\right)^2. \qquad (26)$$

We might mention one conclusion [39] derived from Mecke's theory. If we start with the altitude of maximum oxygen absorption Q_2 (which, incidentally, is still dependent upon the zenith distance z of the incident solar radiation), then we find the altitude of maximum ozone content to be lower by the constant amount $H \ln 3 = 7$ km, independently of z. Figure 11 gives

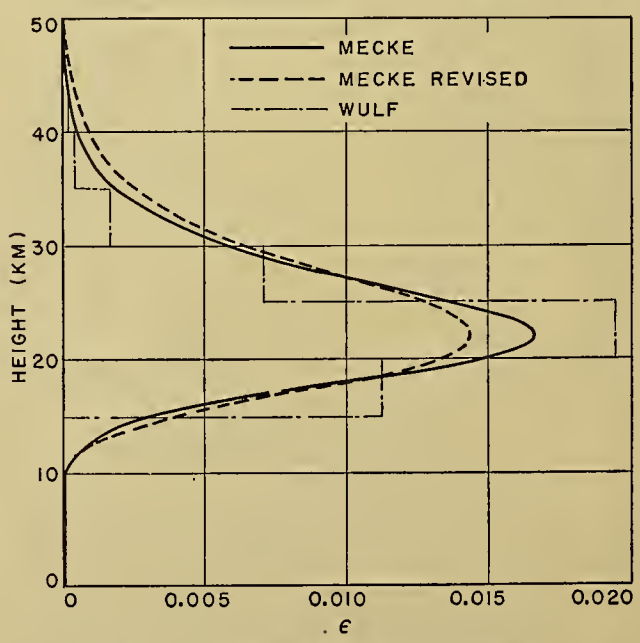

FIG. 11.—Theoretical ozone distribution.

Mecke's result, for which the total ozone amount and altitude of the maximum content are given, according to the original and to the revised formula, as well as according to Wulf and Deming's result, valid only for the sun at the zenith. Below 10 km the ozone content approaches zero because at lower altitudes the deozonizing effect of light becomes prevalent. Above 50 km the ozone content again approaches zero because the frequency of ozone-forming collisions decreases much more rapidly with altitude than does the oxygen concentration. The highly gratifying results from the analytic integration should not lead us to forget that Mecke's theory cannot be developed further in view of its inherent simplifications.

Wulf's treatments have been independently expanded by Schröer [89] and Dütsch on the basis of more modern theories. These make allowance first of all for the sun's elevation, that is, the effect of season and latitude. The ozone calculation is again performed layerwise, from the top downward with the aid of equation (23). New data are used for the seasonal and zonal vertical temperature variation in the stratosphere, for the ozone absorption coefficients in the vicinity of 2100 A, for the deviations of oxygen absorption from Beer's law, and for extraterrestrial solar radiation. Whereas the results concerning vertical ozone distribution and total ozone amount are satisfactory, one finds a decrease of ozone from equator to pole and from summer to winter. Even if the effect of the daily variation of the sun's position as well as of Rayleigh scattering is considered, it is not possible to reverse this erroneous trend completely. It follows that the observed ozone distribution cannot be explained by assuming pure radiation equilibrium at every point of the atmosphere. Recently, Craig [17] has reached the same conclusion.

An explanation for the seasonal variation of ozone solely on the basis of temperature variation [49, 98] is not convincing.

Ozone under Conditions of Disequilibrium. The period of time required for photochemical equilibrium to be established was investigated quantitatively by Wulf [104]. Dütsch [27] gives the temporal trend of ozone concentration in the case of a disturbance; during the time $t_R = \frac{1}{4}\,(f_2 f_3/k[M])^{-\frac{1}{2}}$, the ozone concentration is reduced to approximately $1/e$ of its original value, corresponding to the "time of half restoration" used by Wulf. Within high altitude layers ($\geqslant$ 35 km) correction of the disturbed equilibrium takes place almost immediately; between 30 and 25 km from several days to several months are required; at low altitudes ("protected regions") equilibrium is practically never regained. At high elevation of the sun, equilibrium is established more rapidly than in the case of low sun. Schröer, too, emphasizes the conclusion that (in middle latitudes) photoequilibrium occurs only down to about 33 km, and that the ozone distribution below this altitude is determined by transport processes (turbulence).

The Effect of Air Motion on Ozone. Dütsch lets the subscript s denote the effect of disturbances, R represent the absolute gas constant, takes the molecular weight of air as 28.9, and finds the effect of air currents on ozone concentration to be

$$\left(\frac{\partial[O_3]}{\partial t}\right)_s = -\,v_z\left(\frac{28.9g}{RT}\,[O_3] + \frac{\partial[O_3]}{\partial z}\right) - \left(v_x\frac{\partial[O_3]}{\partial x} + v_y\frac{\partial[O_3]}{\partial y}\right). \tag{27}$$

This derivation is based on the simplifying assumptions that the air density varies only with altitude and that the vertical temperature gradient is zero, an assumption that is justified only as applied to the lower stratosphere. Reed [80] therefore took the vertical temperature gradient into account and obtained the expression

$$\left(\frac{\partial[O_3]}{\partial t}\right)_s = -\,v_z\left\{[O_3]\left(\frac{28.9g}{RT} + \frac{\partial \ln T}{\partial z}\right) + \frac{\partial[O_3]}{\partial z}\right\}. \tag{28}$$

He uses this equation primarily in treating the diurnal meteorological ozone fluctuations and in establishing a theory concerning seasonal and zonal ozone fluctuations. Dütsch, moreover, finds the effect of turbulent exchange (austausch) to be

$$\left(\frac{\partial[O_3]}{\partial t}\right)_a = \frac{[O_2]}{\rho}\,\frac{\partial}{\partial z}\left\{A\,\frac{\partial}{\partial z}\,\frac{[O_3]}{[O_2]}\right\}, \tag{29}$$

where the subscript a denotes the effect of the austausch and A represents the austausch coefficient. Diffusion may be neglected. Because of the long time required for establishment of photochemical equilibrium at lower altitudes, changes in the concentration owing to flow and turbulence play an essential role. If B is the change in ozone concentration per second caused only by air motion (flow and austausch) then equation (23) becomes

$$[O_3] = [O_2]\sqrt{\frac{f_2 + \dfrac{B}{2[O_2]}}{f_3}\,k\,[M]}, \tag{30}$$

and the equation for disequilibrium becomes

$$[O_3](t) = \frac{[O_3]\,(t_0)\sqrt{\dfrac{4\left(f_2 + \dfrac{B}{2[O_2]}\right)f_3}{K[M]}} + 2\left(f_2 + \dfrac{B}{2[O_2]}\right)[O_2]\tanh\left(\sqrt{\dfrac{4\left(f_2 + \dfrac{B}{2[O_2]}\right)f_3}{K[M]}}\,(t - t_0)\right)}{\sqrt{\dfrac{4\left(f_2 + \dfrac{B}{2[O_2]}\right)f_3}{K[M]}} + \dfrac{2f_3[O_3](t_0)}{K[O_2][M]}\tanh\left(\sqrt{\dfrac{4\left(f_2 + \dfrac{B}{2[O_2]}\right)f_3}{K[M]}}\,(t - t_0)\right)}. \tag{31}$$

Thus, equilibrium can be established only if $f_2 > B/(2[O_2])$; equation (31) is always valid.

Dütsch used this expression to recompute the seasonal variation of ozone at various latitudes. For the layers above 16 km, the austausch coefficient is calculated on the basis of experimental results of Paneth and

E. Regener concerning separation in the atmosphere; for the equatorial zone it is assumed that the turbulence extends to higher altitudes corresponding to the greater altitude of the tropopause. The result of this calculation indicates a constant downward stream of ozone caused by turbulence. It follows that ozone must constantly be destroyed in the layers near ground level. The mean ozone distribution in the lowermost 15 to 20 km is determined essentially by the austausch. The small amount of total ozone in the tropical zone (O_3 = 0.185 cm) is due to high-reaching turbulence combined with a rapid destruction of the downward transported ozone in the layers near the ground level, which seems plausible for tropical conditions. Disregarding the possibility of achieving a better agreement between theory (as indicated in Table III) and observation by making

Table III. Amount of Ozone According to Equation (31) (mm O_3)

ϕ	I	II	III	IV	V	VI	VII	VIII	IX	X	XI	XII

60°	2.28	2.53	2.69	2.68	2.53	2.18	1.88	1.75	1.68	1.69	1.78	2.02

different assumptions concerning several as yet uncertain quantities entering the calculations, it is possible to improve agreement by assuming a meridional circulation. The last line of Table III is calculated under the assumption of an ascending flow in the higher latitudes of the summer hemisphere, and a descending flow in the higher latitudes of the winter hemisphere, the seasonal variations occurring primarily in the lower layers.

Another circulation hypothesis by Craig [17] has not yet been calculated. Reed [80], on the other hand, suggests an explanation of the seasonal and zonal ozone fluctuations based on the variable large-scale atmospheric turbulence with a maximum in winter and at a latitude of 60°. Between fall and spring, this is supposed to cause more ozone to be transported down into the protected regions than can be destroyed at ground level. During this period an increase in the total amount of ozone would consequently occur since the ozone transported to low altitudes is replaced at high altitudes. Between spring and fall, on the other hand, decomposition at ground level presumably predominates so that there is a drop in the total ozone content. The discussion by Schröer and Moser [71] will be dealt with in the following section.

OZONE AND WEATHER

Ozone in the Stratosphere. According to Dobson, the amount of ozone varies with the atmospheric pressure distribution, that is, the synoptic situation. In western Europe a maximum in the ozone amount is found on the rear side of a cyclone, a minimum of ozone is found above the southwest side of a high [25]. More recent studies concerning the connections between ozone amount and the surface weather map and fronts have supported this observation [23, 94] and have shown that the center of high ozone amount on the rear side of a cyclone is particularly the property of a newly developing depression (Fig. 12). Since its axis is inclined back-

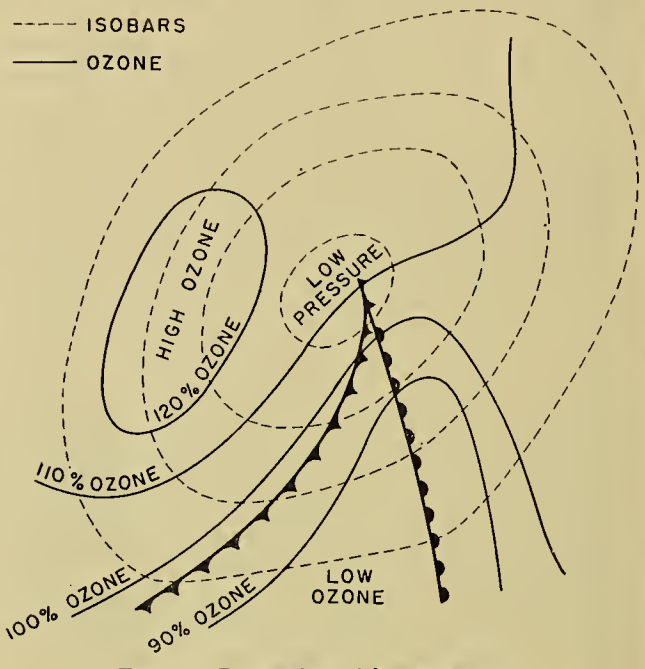

Fig. 12.—Depression with warm sector.

wards, Palmén [72] was able to point out that the region of maximum ozone coincides with the tropopause vortex, that is, the trough at the tropopause, and that the ozone amount is symmetrical to the pressure distribution at that height. Tropopause topography as well as ozone is explained as a common consequence of the three-dimensional air flow within a deepening cyclone. Thus, at the time at which one was still dependent upon statistical studies between ozone amount and the other atmospheric elements, Meetham [61] found the best correlations when referring all elements (variables) to a "pseudo-center" 300 to 350 km to the southwest of the center of the surface pressure system; this pseudo-center corresponds to the tropopause vortex. According to Meetham, a 0.01-cm increase in the amount of ozone is accompanied by a 3C rise of the potential temperature at an altitude of 18 km and by a lowering of the tropopause by 1 km. The correlation coefficient between the ozone amount and potential temperature at an altitude of 18 km has the high value of 0.8, a fact which however should not induce us to seek the seat of ozone fluctuations at this altitude. Johansen [52], who conveniently groups the ozone measurements according to rise and fall regions of atmospheric pressure at ground level, also finds high ozone amounts with a low tropopause over Tromsö.

According to the preceding section, these conditions must be explained by the fact that meteorological transport processes displace the ozone from its source. Two main possibilities exist; the decision between them requires modern upper-air weather maps on the one

hand, and continuous measurements of the vertical ozone distribution on the other hand.

As a first possibility, one considers the meteorological ozone distribution as a result of horizontal advection. Every veteran observer of ozone has long been familiar with the fact that invasions of arctic air extending to high altitudes are accompanied by an increase in ozone amount, whereas the ozone amount is slight in the case of European anticyclones composed of air of southern origin. The increased ozone amount accompanying invasions of cold air has been particularly noted by various expeditions [5, 97]. Lejay [58] points out that in the Siberian anticyclone in which the ozone amount is high, cold northern air masses advance so that the "transportation theory" removes the apparent contradiction with European findings. Penndorf [76] finds the 96-mb surface as suitable for indicating the flow conditions. Moser [65], in examining drawings of the trajectories at 5, 11, and 16 km, finds the best correlation between the trajectories at 11-km height and the ozone amount; he therefore assumes the main location of ozone fluctuations to be in the stratosphere near the tropopause where the maximum in wind velocity is located. This ozone maximum coincides with the lower secondary ozone layer which was first suggested, at least intermittently, by the investigations at Arosa [39]. This lower secondary layer is generally separated from the very constant high-altitude layer of ozone by a minimum in wind velocity between 15 and 22 km. The trajectories of Moser (Fig. 13) illustrate well the

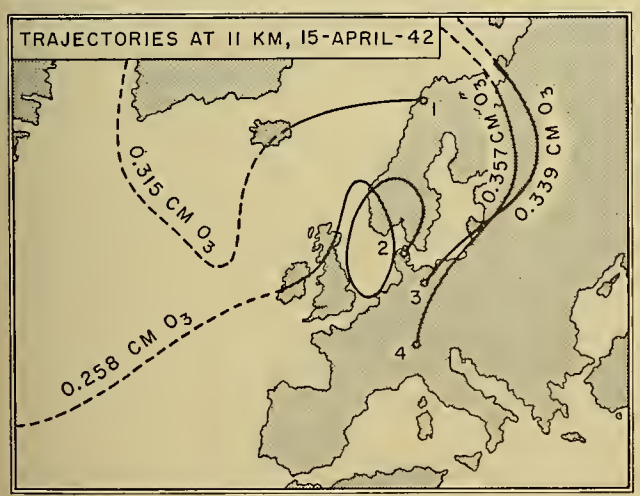

Fig. 13.—Air trajectories at 11 km.

temporal constancy of ozone amount at various points situated in the same air current, indicating that ozone is a conservative property of the air and may thus serve as an important indicator for air-mass determinations. On the other hand, in Fig. 14, Moser shows that at Arosa the ozone amount is higher the more northerly the latitudes from which the air current comes. The source of ozone, in this case, is the ozone belt located by us (Fig. 7). But how is this secondary source of low-altitude ozone supplied? Moser and Schröer suggest that the great temperature gradient at the shadow boundary between polar night and the sun-illuminated

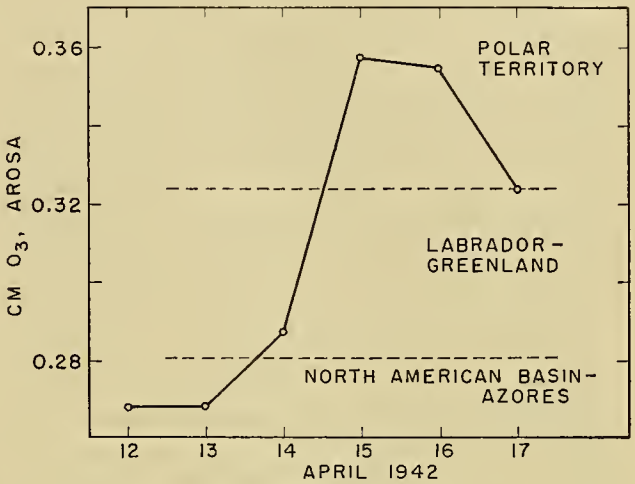

Fig. 14.—Ozone amount and origin of air at 11 km.

atmosphere leads to increased shear-turbulence between the layer of photochemical equilibrium and the lower ozone layer at an altitude of 23 km. They also suggest that a further connection with the lower stratosphere is provided by high-reaching cold-core lows within which the barrier by the minimum in wind velocity is lacking. This theory needs corroboration by additional measurements. Flohn [33] sees a possible source of the winter singularities in the 30.5-day oscillations of the winter circumpolar vortex of the warm layer [43]. Craig also suggests continuous subsidence of ozone in the polar cap during the cold months.

This leads us to the second possibility for ozone distribution, that of transport by vertical flow. A sinking column of air, such as exists in low-pressure regions at least at the height of the tropopause, is lengthened (stretched) in its upper ozone-containing portion and this is accompanied by a horizontal convergence or contraction. This is equivalent to an increase in ozone amount. An ascending current has the opposite effect. Thus, the explanation of the day-to-day changes does not even require the assumption that sinking air comes directly from the layer of photochemical equilibrium and is there replenished with ozone. Dobson [25] pointed out long ago "that the air immediately in the rear of a cyclone often has a higher ozone value than in the same general air stream further to the north or northwest." Haurwitz [50] emphasizes that horizontal advection cannot explain closed lines of equal ozone deviation such as those in Fig. 12. Moreover, the ozone content at the rear of a cyclone is sometimes higher than it is during the same season in the northern ozone source. Reed [81] emphasizes:

> Particularly noteworthy is the fact that closed isopleths of positive and negative ozone deviations bear the same relationship to surface cyclone centers as the closed isotherms which are invariably observed on the 200 mb chart (approximately

12 km), the warm pocket at this level coinciding with the positive deviations, the cold with the negative. Since these warm and cold areas are unquestionably due to subsidence and lifting respectively, it seems reasonable to suspect that the vertical displacements also in some fashion affect the ozone concentration.

Reed, moreover, recently calculated the change in ozone content during vertical displacements on the basis of the fact, already emphasized by Regener, that in strong vertical mixing the ozone mixing ratio (grams of ozone per gram of air) is independent of altitude. To begin with, the curve of ozone content versus altitude is transformed into a curve of ozone mixing ratio versus altitude. The curve is thereupon raised or lowered and finally reconverted back to an ozone content curve. In Fig. 15 it is assumed, at first, that the vertical displacement extends through the entire column of air [80]. More recently [81] the assumption was made that, in the closed region of high ozone amount to the west and southwest of an intense surface cyclone, the air subsides most markedly near the tropopause and that the sinking motion becomes unnoticeable above the tropopause between 16 and 18 km and below it at 7 to 8 km. Thus, the vertical displacements take place only within the secondary advection layer. Figure 16 is based on an Arosa curve for an ozone amount of 0.131 cm between altitudes of 5 and 20 km and an assumed maximum downward displacement of 1.4 km and shows an ozone increase of 0.025 cm. A corresponding example for lifting motion would yield a decrease of 0.017 cm. According to this new estimate, the contribution of the vertical motion in the interplay between advection and vertical motion is less significant than in previous assumptions, for instance that of Nicolet [67]. According to Reed, vertical motions account for, at most, about ⅓ of the total range. In summer and in fall, when the ozone content of the lower stratosphere is considerably less and vertical motion much weaker, the vertical motion effect will be almost negligible.

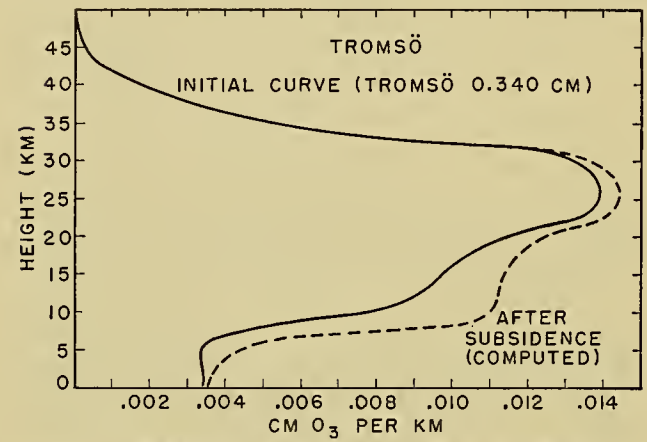

Fig. 15.—The effect of subsidence on the ozone distribution.

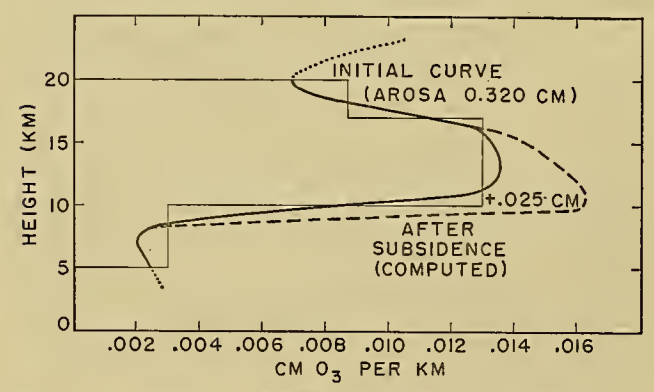

Fig. 16.—The effect of subsidence on the ozone distribution.

According to the upper-level weather maps, on which isobars generally have sinusoidal shape, advection and vertical motion always affect ozone changes in the same sense. In an influx of air from a ridge to a trough, the air comes predominantly from northern latitudes, and the consequent higher ozone amount is further increased by subsidence. In the example studied by Reed, the higher ozone content of 0.320 cm in an advectively transported air mass increases to 0.345 cm owing to subsidence; by contrast, the ozone content of 0.260 cm is decreased to 0.243 cm in an air mass that is lifted in the northeast quadrant of a surface cyclone.

Ozone Conditions in the Troposphere. Ozone conditions in the troposphere are evidently quite variable (Fig. 10), depending on the interplay of advection, which makes ozone suitable for air-mass analysis, with the turbulent ozone supply from the secondary tropopause layer ("flux d'ozone" according to Jaumotte, "Ozonstrom" according to V. H. Regener [86]). Whereas mixing produces an increase of ozone content at lower altitudes, it may happen in layers near ground level, in which ozone is consumed at a rapid rate by dust and oxidizable organic substances, that the ozone flow completely disappears in the case of stagnant air [83]. As a result, a weak tertiary layer of ozone develops at an altitude of several kilometers which is of climatic significance in high mountain regions. Starting from ozone near ground level, the significance of turbulence has been successfully demonstrated by E. Regener [82, 83] and his collaborators. The ozone stream treated theoretically by Lettau [59] has only on the average a downward direction in the troposphere because of advective superposition of air masses and shows relatively pronounced irregularities in space and time. Glueckauf [35] explains the region of diminished ground-level ozone ahead of a warm front on the basis of an interruption of the turbulent air exchange by the barrier layer of the front.

Ozone and Radiation Flux. A direct physical influence of ozone on meteorological processes through the medium of radiation flux has not been ascertained. As Lord Cherwell (Lindemann) suggested as early as 1919, ozone is as important for radiation balance in the lower stratosphere as are water vapor and carbon dioxide. However, any temperature rise due to increased ozone evidently takes place so slowly that it cannot be detected in meteorological circulation processes. However, in the case of a prolonged influence, the effect of ozone on incident and emitted radiation can

hardly be denied. Möller [64] explains the stratospheric temperature differences between tropics and temperate latitudes on the basis of the variable protective action of the ozone located above the emitting carbon dioxide; Dobson [23] arrives at an identical result even more directly. For the lower stratosphere he estimates the temperature of radiative equilibrium of H_2O to be 200C, that of CO_2 to be 200C, and that of O_3 to be 260C, which, for equal portions of these three absorbers, would lead to the plausible mean value of 220C. In comparison with higher latitudes, the lower secondary advection layer is absent in the vicinity of the equator, and ozone has correspondingly less effect on temperature. But even considering only the indirect action due to advection of air masses of different temperature, ozone has a significant effect on our weather.

ADDITIONAL REMARKS CONCERNING THE SIGNIFICANCE OF ATMOSPHERIC OZONE

Ozone and the Constitution of the Upper Atmosphere. *The Warm Layer.* Absorption of the short-wave radiation from the sun at the upper boundary of the ozone layer results in a temperature of +50 to +80C at an altitude of 55 km. This region is known as the warm layer [34]. This warm layer was first encountered in 1922 by Lindemann and Dobson in connection with the determination of the altitude at which meteors become incandescent. The anomalous propagation of sound, which results when sound encounters the warm layer and is refracted back to the earth [101], leads to good temperature data for this high layer; taking an average of the values given by Duckert [26], Gutenberg [48], and Whipple [26], the temperature in summer is −50C at an altitude of 30 km, +28C at 40 km, and +70C at 50 km. If a gas, such as ozone at its upper boundary, absorbs mainly in the ultraviolet part of the spectrum but emits according to the laws of temperature radiation, then its temperature must rise to a rather high value before incident and emitted radiation will attain equilibrium. This is even more applicable, incidentally, to the case of oxygen absorption in the ionosphere [38]. On the other hand, water vapor with its absorption in the infrared tends to lower the equilibrium temperature. Considering the fact that the sun's temperature is lower in the short-wave continuum, Gowan [46] finds that his calculations show satisfactory agreement between ozonosphere temperature and the data on record. According to his calculations [47], the warm layer persists even during the night. Barbier and Chalonge, E. Vassy and Déjardin (for references see [19]) attempted to calculate the mean temperature of the ozone layer on the basis of the temperature dependence of absorption in the Huggins bands by methods of indirect aerology; they also attempted to calculate the mean temperature of ozone above 30 km on the basis of the temperature distribution up to 30 km. In order to analyze the warm layer proper, Götz suggests that, instead of measuring the ozone bands in sunlight as customary, the Umkehr effect should be used in zenith light at low elevation of the sun. Indirect conclusions concerning the vertical temperature distribution have recently been verified [66] quite satisfactorily by means of V-2 rockets.[2]

Pekeris [74] has shown that on the basis of the warm layer it is possible to calculate a free oscillation of the atmosphere with a period of very nearly 12 hours, such as is necessary for the resonance theory of the migratory pressure wave of a half day's duration. As a heat source at high altitudes, the warm layer is capable of damping the circulation currents in the troposphere and is thus of climatic significance [8]. Many years ago, Wegener [100] deduced the existence of a high altitude troposphere (*Hochtroposphäre*) above 60 km from the existence of noctilucent clouds at an altitude of 82 km; we now know that the heat source for this phenomenon is the warm layer caused by ozone.

The Screening Effect of the Ozone Layer. The atmosphere of the earth forms an opaque screen for short-wave ultraviolet, so that the shadow cone for this radiation is not tangent to the earth's surface but rather to a sphere of enlarged radius. Götz [37] has therefore suggested that the upper boundary of the ozone layer be determined from ultraviolet observations during lunar eclipses. Barbier, Chalonge, and Vigroux [6] have accomplished this up to an altitude of 16 km [71*a*]. According to Götz this screening effect is of particular significance if the altitude of atmospheric dissociation, excitation, and ionization processes is to be calculated from the time of onset of these processes at dawn or the time at which they cease in the evening. When the altitude of sodium luminescence was given as 60 km on the basis of the dawn effect, it was pointed out [39] that the altitude of the ozone layer would have to be added to this figure if photoluminescence were assumed. And indeed, Vegard and Tønsberg [99], by simultaneous measurement of the intensity drop of the sodium line at the zenith and at the horizon, found the upper sodium boundary to be at 116 km and the altitude of the screening layer at 56 km. Penndorf [75], rigorously defining the ozone shadow boundary, has carefully calculated the conditions in an effort to determine accurately the upper boundary of the ozone layer from such observations. The ozone shadow boundary seems also to be significant in connection with certain delay processes observed in the E-layer by Lugeon and Mitra [39]. Störmer [90] found that noctilucent clouds always appear only when the sunlight striking them is no closer to the earth's surface than 30 to 45 km. It does not follow, of course, that it is the ozone shadow which is significant in all similar cases. In the case of the photoluminescent effect of the red twilight line at 6300 A, it is the shadow of the oxygen sphere which is opaque up to an altitude of about 100 km [41].

Ozone and Bioclimatology. The biological significance of the ozone layer can be touched upon but briefly within the scope of the present article. The ozone layer is of the greatest importance in controlling the ultra-

2. Consult Fig. 8 in "Temperatures and Pressures in the Upper Atmosphere" by H. E. Newell, Jr., pp. 303 to 310 in this Compendium.

violet radiation climate [10, 37, 57, 84] in a spectral range distinguished by a number of biological effects such as the formation of erythema, the formation of vitamin D, and bactericidal effects. Radiation intensities in the ultraviolet range of the solar spectrum are highly variable from wave length to wave length; however, the ozone measurements can entirely account for these variations in intensity. Our present-day knowledge concerning ozone amount is sufficient to allow us to estimate the incidence of ultraviolet over the entire earth. Without the ozone layer, sunburn would easily be fifty times as effective as it is during the highest sun's elevation during summer in high mountains. On the other hand, an increase in the ozone screen would completely eliminate the stimulating radiation, that, in proper dosage, is essential to life, and would leave us in biological darkness. Therefore it is probably significant if, as Fig. 8 would indicate, the ozone amount increases over a period of years while the ultraviolet radiation decreases. The zoologist Rowan [88] has recently raised the question as to whether such fluctuations may not provide an explanation for the ten-year cycle in the abundance of certain species among the Canadian fauna. Equally stimulating from the bioclimatological viewpoint are speculations as to whether the protective effect of the ozone layer has undergone changes during the development of the earth. For a mature oxygen planet such as Mars, the photochemical equilibrium layer must rest on the ground, a fact which would substantiate the explanation of the red discoloration of extended portions of the surface of Mars [102].

This oxidizing effect leads us, finally, to the ground-level ozone of the earth's biosphere. Götz and Ladenburg [44] have emphasized the desirability of investigating any possible direct influences of ozone on the human body. As E. Regener has pointed out, ozone bioclimatologically plays the important role of an air purifier [82]. It may even be said that it is ozone which characterizes "living air." The physician Curry [18] draws very extensive conclusions concerning the effect of ozone, and in general, of active forms of atmospheric oxygen on the human body. Even though these assertions have aroused much interest in this problem, they have not yet been substantiated by the use of rigorous statistical methods.

CONCLUSION

If we consider the results obtained thus far, the data concerning ozone amount appear the most reliable. Of course, the observation network is still not sufficiently dense, particularly in the region of large vortices. It has justly been pointed out that the present state of synoptic meteorology would leave much to be desired if it were dependent on a dozen barometers distributed over the entire earth! The continuous series of observations which were started at several locations must be carried on for prolonged periods of time because secular fluctuations reflect long-term changes in atmospheric circulation. The most interesting annual curve of ozone amount was observed in Tromsö, a fact which urgently suggests that the observation network be extended to the polar regions proper, such as Spitsbergen, for example.[3]

Since the ozone problem is fundamentally a flow problem, ozone amount must also be observed continuously in the third dimension. Information now available concerning the vertical distribution of ozone is far from adequate and, above all, much too disconnected. Vertical ozone distribution, together with information concerning water vapor, could be exploited directly in connection with forecasting and would provide the material necessary for approaching the problem of radiation flow. Perhaps it is a desire for more simple and less expensive apparatus which is discouraging meteorologists from attempting large-scale experiments? Stratosphere flights and V-2 rockets are rare opportunities. The Umkehr-effect method could be refined considerably if it were supplemented by ozone determinations in the lower ten kilometers by flight measurements —if one does not expect to measure the Umkehr effect continuously from meteorological aircraft at cloud-free altitudes. Perfection of the radiosonde should meet with no further fundamental difficulties.

It is fascinating to observe how ozone pulsates through the atmosphere like blood circulating in an organism. Ozone is created by radiation in high-altitude layers. Primarily at the shadow boundary of the polar night, and at the altitude of the warm layer, it produces the temperature contrasts and resulting polar vortices which enable it to sink as a secondary layer down to the theater of meteorological activity. And finally, diffusing to the vicinity of ground level, the ozone re-enters the oxygen metabolism. Much work remains to be done before this sketchy picture is completed and verified by observation.

This task requires ever-increasing international cooperation. It would be appropriate to pool all available tools (apparatus as well as observers, including other aerological methods) during international ozone weeks and to distribute them over suitable regions. International cooperation has indeed always been exemplary in the ozone field. Typical single cases could then be treated in a united effort which would help us in a decisive manner to push forward to the last meteorological consequences.

RADIATIVE TEMPERATURE CHANGES IN THE OZONE LAYER

By RICHARD A. CRAIG

Harvard College Observatory

THE OZONE LAYER

The term "ozone layer" as used here refers to that part of the atmosphere that lies above the tropopause and below about 60 km. The bulk of the atmospheric ozone lies in this region. The physical characteristics of the ozone layer have been studied, principally from the surface of the earth, by various indirect methods. Some of the conclusions reached by these methods, however, have been verified by a few direct measurements obtained by means of manned and unmanned sounding balloons and rockets.

The present state of knowledge with regard to the ozone layer is outlined elsewhere in this volume by Götz.[1] Götz has also presented a very complete summary of ozone work as of the year 1938 [20] and in a more recent paper has brought this summary up to the year 1944 [21]. Even more recently Craig [10] has given a somewhat less comprehensive summary. Nevertheless, in order that this contribution may be more or less self-contained, certain basic facts about the ozone layer, particularly those that are necessary to an understanding of the remainder of this paper, are outlined briefly in this section.

Ozone Distribution. The total amount of ozone in a vertical column above the earth's surface is small compared to that of other atmospheric constituents, namely, about 0.3 cm at NTP.[2] Nevertheless, because of its absorbing qualities, ozone is an extremely important constituent of the atmosphere.

A large number of measurements at the earth's surface have determined the variations with season and geographical position of this total amount of ozone.[3] At a given place on the earth, the ozone amount is a maximum in the early spring and a minimum in the late fall. The total ozone amount is a minimum at the equator and increases toward higher latitudes. At least in the Northern Hemisphere, it apparently reaches a maximum near 60°N and decreases poleward from there. A further interesting feature of ozone distribution in middle and high latitudes is that the total amount of ozone above a given place may vary markedly from day to day. The amplitude of this variation of daily values in any given month may be as large as the amplitude of the annual variation of the monthly means. Moreover, the day-to-day ozone variations reveal marked correspondence to weather conditions at the surface, as shown by Dobson [12], Lejay [37], and Tønsberg and Olsen [55].

The vertical distribution of ozone has been most generally studied by means of the Umkehr effect. This effect, first noted by Götz at Arosa and applied by Götz, Meetham, and Dobson [22], refers to the observations of scattered zenith light when the sun is near the horizon. The ratio of the intensities of two wave lengths, both absorbed by ozone but to different degrees, decreases as the sun nears the horizon, reaches a minimum, and then increases. This phenomenon results from the fact that the effective height of scattering increases as the sun nears the horizon and finally lies above the ozone layer. The shape of the Umkehr curve may be used to deduce the vertical distribution of ozone, as has been shown by Götz, Meetham, and Dobson [22] for Arosa observations. Meetham and Dobson at Tromsö [40], Tønsberg and Olsen at Tromsö [55], and Karandikar and Ramanathan at Delhi and Poona [33] have also applied the method. The Umkehr method is only approximate, but its results have been verified by various direct measurements [8, 9, 43, 47, 51]. The measurements show that the maximum density of ozone occurs between 20 and 30 km and that it decreases rapidly above the level of maximum. The density of ozone below the maximum level is quite variable. In fact, the observations show that most of the variability in the total amount of ozone (latitudinal, seasonal, and day-to-day) reflects variability between the tropopause and the level of maximum ozone.

Temperature Distribution. The temperature distribution in the ozone layer, at least above 30 km, is less well known. In the vertical, the temperature between the tropopause and about 30 km is nearly isothermal. This region has been studied directly by radiosonde. Above 30 km, mainly indirect evidence points to a rapid increase of temperature with height, reaching a maximum at 50–60 km. This evidence is based on observations of the anomalous propagation of sound [58] and of the characteristics of meteor trails [38, 59, 60]. Recently, measurements from a V-2 rocket have verified this qualitative picture [31].

In the lower, isothermal region, where direct measurements are available, seasonal and latitudinal variations of temperature are known. In the summer, the temperature is lowest over the equator and increases toward the poles. In the winter, the poleward increase of temperature also occurs in lower latitudes, but a maximum of temperature occurs in middle latitudes and the temperature is again lower at higher latitudes [29]. At a given point in middle latitudes the maximum temperature in the lower part of the ozone layer occurs just before the summer solstice, the minimum just before the winter solstice. This contrasts with the behavior of the upper troposphere, where the maximum and

1. See "Ozone in the Atmosphere" pp. 275–291 of this Compendium.

2. Ozone amounts are generally expressed in terms of the height of the resulting volume of ozone if all the ozone in the column were brought to normal temperature and pressure at the earth's surface.

3. For references to published series of ozone observations, see [10].

minimum follow the solstices. Dobson, Brewer, and Cwilong [11] and Goody [19] explain this behavior as a balance between two conflicting factors. They point out that the temperature of the lower stratosphere is primarily controlled by radiative processes, and is heated at least in part by ozone absorption of infrared radiation from the troposphere. The flux of this radiation reaches a maximum (or minimum) after the solstices. On the other hand, the amount of ozone reaches a maximum (or minimum) much earlier, just after the equinoxes. Therefore the temperature extremes occur at intermediate times.

The temperature variations in the upper, warm, region of the ozone layer are not known. Direct measurements on a routine basis are not as yet obtainable there.[4] Indirect evidence, however, indicates that the seasonal variations, at least, may be very large. Whipple, Jacchia, and Kopal [60] have shown from their meteor studies that the density of the atmosphere at 70 km is approximately 2–3 times greater in summer than in winter in middle latitudes. This astonishing fact can be explained only in terms of a summertime expansion of the ozone layer above 30 km, corresponding to a mean temperature some 50C higher than in winter. Furthermore, Gowan's calculations of radiative equilibrium temperature at 50°N [26], discussed more fully below, indicate a summer-winter temperature difference of the same magnitude.

Ozone Absorption. The explanation for the warming of the upper part of the ozone layer lies in the absorbing qualities of ozone. Laboratory measurements of ozone absorption reveal intense absorption bands in the ultraviolet and less intense bands in the visible. The Hartley bands of ozone, the most intense of all, lie between 2000 and 3200 A, with a strong maximum near 2500 A. The Huggins bands occur in the 3200–3600 A region. In the visible are the Chappuis bands at 4800–7800 A. The most detailed and homogeneous set of laboratory-derived absorption coefficients stem from the work of Ny Tsi-zé and Choong Shin-piaw [45, 46] and of Vassy [56]. Many other investigators [16, 34, 36, 41] have obtained results in agreement with theirs.

Photochemistry of Ozone. The existence of ozone in the upper atmosphere may be explained on the basis of photochemical principles. The photochemistry of atmospheric oxygen has been discussed by many investigators, for example, Chapman [7], Bamford [1], and Wulf [61].

The primary reaction leading to the formation of ozone is the dissociation of the oxygen molecule by solar energy at wave lengths less than 2400 A:[5]

$$O_2 + h\nu\ (\lambda < 2400\ A) \rightarrow O + O, \qquad (1)$$

where ν is the frequency of the incident light and h is Planck's constant. Ozone is then formed by the collision of an oxygen atom, an oxygen molecule, and any third body:

$$O_2 + O + M \rightarrow O_3 + M. \qquad (2)$$

Ozone in turn can be dissociated by absorption of solar energy or by collision with an oxygen atom:

$$O_3 + h\nu\ (\lambda < 11{,}000\ A) \rightarrow O_2 + O, \qquad (3)$$

$$O_3 + O \rightarrow 2O_2. \qquad (4)$$

From these four reactions, the rates of change of the amounts of ozone and atomic oxygen per unit volume are

$$dn_1/dt = 2Q_2 + Q_3 - k_{12}n_1n_2n_m - k_{13}n_1n_3, \qquad (5)$$

$$dn_3/dt = \quad - Q_3 + k_{12}n_1n_2n_m - k_{13}n_1n_3. \qquad (6)$$

The symbols n_1, n_2, and n_3 represent the numbers of molecules per unit volume of atomic oxygen, molecular oxygen, and ozone, respectively; n_m represents the total number of molecules per unit volume in the air. The numbers of quanta absorbed from the solar beam per unit volume and unit time are given by Q_2 (for O_2) and Q_3 (for O_3). The rate of production or destruction of molecules from collisions is proportional to the numbers of colliding molecules in the unit volume, the photochemical reaction factors k_{12} and k_{13} being the constants of proportionality for the collisions represented by (2) and (4), respectively.

Under equilibrium conditions, $dn_1/dt = dn_3/dt = 0$. From (5) and (6), then,

$$n_3 = \left(\frac{k_{12}}{k_{13}}\right) n_2 n_m \left(\frac{Q_2}{Q_2 + Q_3}\right). \qquad (7)$$

This equation was derived and numerically integrated by Wulf and Deming [61, 62, 63]. More recently Dütsch [13], Nicolet [44], and Craig [10] have repeated the calculations, making use of more recent and detailed information about the parameters entering into the calculation. All these computations give the equilibrium amounts of ozone to be expected at various levels in the atmosphere. Despite some uncertainties in the computations, the results are generally compatible with observation.

Among the most interesting information derived from computations of equilibrium ozone amounts is that concerning the degree to which actual ozone amounts may be expected to correspond to equilibrium amounts. At and above the level of maximum ozone, any deviations from equilibrium conditions could last only a few hours. However, below the level of maximum ozone density this time interval rapidly increases until, in the lower part of the layer, it is extremely large. Thus, below perhaps 25 km, the ozone is never necessarily in equilibrium with the sun. It is in just this region that the large variations in ozone amount are observed to occur.

Possible Solar Effects on the Ozone Layer. One interesting aspect of the question of radiative changes in the ozone layer is the suggestion, made most recently

4. Recent work at the Evans Signal Laboratory [3] gives hope that observations from improved radiosondes may soon become available up to 40–50 km.

5. Not all absorption below this wave length produces direct dissociation, but it all at least excites the molecule to the point where it is easily dissociated.

by Haurwitz [28], that solar variability may affect the ozone layer directly and our weather indirectly. Solar variability in the visible is at best very small, while in the ultraviolet it appears, from various phenomena in the upper atmosphere, to be large. The ozone layer is a strong absorber of solar ultraviolet radiation and is situated at a level in the atmosphere where there is still appreciable mass. This interesting question, then, lends added importance to the whole problem of the size and distribution of radiative changes in the ozone layer.

HEATING OF THE OZONE LAYER

Several different radiative processes serve to heat the ozone layer. Most of these processes involve the absorption, by some constituent of the atmosphere, of energy from the direct solar beam. The lower part of the ozone layer, however, is also heated by absorption of infrared radiation from the earth's surface and from the troposphere and by ozone absorption of solar energy reflected and scattered from the troposphere.

The next section, on cooling of the ozone layer, deals with the absorption characteristics of atmospheric gases in the infrared. The general information pertinent to the question of heating due to infrared absorption is available there. In this section, only general considerations relative to the question of absorption in the ultraviolet and visible are included. In a later section some numerical results from computations will be presented.

Ozone Absorption. Ozone is the most important constituent of the ozone layer from the point of view of absorption of solar energy. Particularly, the Hartley bands (2000–3200 A) absorb strongly and are responsible for the sharp cut-off of the solar spectrum near 3000 A.

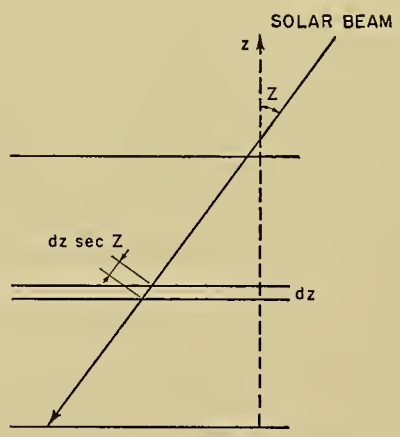

FIG. 1.—Solar beam passing through the ozone layer when the sun is at the zenith angle Z.

In Fig. 1, let a parallel beam of radiation from the sun be incident at the top of the ozone layer at an angle Z from the vertical. In the spectral interval $d\lambda$ let the intensity of the incident solar radiation be $I_{0\lambda}$, and call the ozone absorption coefficient α_λ. Consider a column of air that is parallel to the solar beam and that has unit cross section. While passing through a vertical distance dz, the solar intensity in $d\lambda$ is decreased by the amount

$$dI_\lambda = I_\lambda \alpha_\lambda n \sec Z \, dz, \tag{8}$$

where n is the amount of ozone per unit volume and I_λ is the intensity at the level z. The sign in (8) is positive because z is taken positive upward. Equation (8) can be integrated to give

$$I_\lambda = I_{0\lambda} \exp\left(-\int_z^\infty \alpha_\lambda n \sec Z \, dz\right). \tag{9}$$

The energy absorbed per unit volume in the spectral interval $d\lambda$ is

$$\frac{dI_\lambda}{\sec Z \, dz} d\lambda = I_{0\lambda} \alpha_\lambda n \exp(-\alpha_\lambda N) \, d\lambda, \tag{10}$$

where

$$N \equiv \int_z^\infty n \sec Z \, dz \tag{11}$$

is the total amount of ozone the solar energy has traversed in its oblique path above the level z. The total energy absorbed per unit volume at the level z is

$$E_z = \int_0^\infty \frac{dI_\lambda}{\sec Z \, dz} d\lambda = n \int_0^\infty I_{0\lambda} \alpha_\lambda \exp(-\alpha_\lambda N) \, d\lambda. \tag{12}$$

In practice, the integration in (12) needs to be taken only over the spectral interval of appreciable ozone absorption; namely, the Hartley bands (2000–3200 A), the Huggins bands (3200–3600 A), and the Chappuis bands (4500–6500 A). The spectrum can be divided into several finite intervals characterized by appropriate mean values of $I_{0\lambda}$ and α_λ. Then (12) is a function only of N. Later in this section (Fig. 2) E_z/n is shown graphically as a function of N for specific spectral distributions of $I_{0\lambda}$ and α_λ.

The rate of heating of the unit volume is then

$$\frac{\partial T}{\partial t} = \frac{E_z}{c_p \rho}, \tag{13}$$

where c_p is the specific heat of air at constant pressure, which has the value 0.239 cal g^{-1} deg^{-1}, and ρ is the air density, which of course varies with elevation.

In the Huggins and Chappuis bands, a large part of the extraterrestrial solar radiation penetrates the ozone layer and is later scattered and reflected back from the troposphere to be absorbed by the ozone. The treatment of this phase of the problem is quite similar to the discussion above, except that the radiation is diffuse rather than parallel. The equation corresponding to (12) is

$$E_z' = \frac{2\pi n \int I_{t\lambda} \alpha_\lambda Ei_2(\alpha_\lambda N) \, d\lambda}{3 \sec Z}, \tag{14}$$

where $I_{t\lambda}$ is the intensity reaching the troposphere in the spectral interval $d\lambda$. The exponential transmission

function in (12) gives way to the function $2\pi Ei_2(\alpha_\lambda N)$, where $Ei_2(\alpha_\lambda N)$ is an exponential integral, because the returning radiation is diffuse. The path length N is, of course, now measured vertically upward from the tropopause. The factor 3 in the denominator indicates that only about one-third of the incident radiation is reflected upward from the troposphere, while the factor sec Z takes care of the fact that the radiation is incident at the angle Z from the vertical.

Oxygen Absorption. The absorption spectrum of oxygen in the ultraviolet includes the weak Herzberg bands which converge near 2400 A; the much stronger Schumann band system which begins near 2000 A, converges at about 1750 A, and reaches its maximum intensity at about 1450 A; and, finally, the Hopfield bands between 1000 and 600 A. Absorption by oxygen in the infrared and visible regions of the spectrum is very weak.

The absorption coefficients of air in the Hopfield bands have been estimated by Schneider [53]. These results are only approximate, but leave no doubt that the solar energy in this spectral interval is already absorbed far above the ozone layer. Between 1000 and 1300 A the atmosphere has some strong bands and some transparent regions. Particularly, near the wave length of the Lyman-α emission line of hydrogen (1216 A), the atmosphere seems to be relatively transparent. Here, however, Preston [49] has made careful measurements of absorption coefficients of air and its constituents and finds that solar radiation could hardly penetrate below 60 km in important amounts. Similarly Ladenburg and Van Voorhis [35] have measured oxygen absorption in the Schumann region (1300–1750 A) and their results show that the solar energy here also is depleted above the ozone layer.

The only solar radiation, then, that can heat the ozone layer lies above 1800 A. Above about 2200 A, on the other hand, oxygen is comparatively unimportant as a heating agent because ozone absorbs the bulk of the available energy. For the intermediate region, 1800–2200 A, Granath [27] has measured the oxygen absorption in the 1900–2100 A region. The absorption of air has been determined by Buisson, Jausseran, and Rouard [6] in the interval 1855–2653 A. Because the measurements were made in surface air relatively free from ozone, one can determine the absorption of oxygen from these measurements with some degree of precision. The absorption coefficients so derived agree well with Granath's measurements in the region where they overlap.

The oxygen absorption spectrum is complicated by a pressure dependence of the absorption in the Herzberg region. Heilpern [30] discussed oxygen absorption at 2144 A for pressures varying between 148 and 663 mm Hg at a temperature of 18C and found a rather strong pressure dependence.

In any case, heating caused by oxygen absorption is generally negligible compared to that caused by ozone absorption in the ozone layer. Only in the upper part of the layer (above 40 km), where it may approach 10 per cent of the ozone absorption, does oxygen absorption need to be considered by the careful investigator. At the present stage of this type of study, the figure of 10 per cent is considerably less than the uncertainties introduced by other doubtful factors.

Solar Energy in the Ultraviolet. Until recent V-2 rocket flights were consummated, the spectral distribution of solar energy to the violet of 3000 A was unknown. This factor is, of course, necessary for the calculation of heating in the ozone layer. Nearly all calculations of this heating have been based on the assumption that the sun radiates as a black body at a temperature of 6000K. The rocket measurement has shown that the radiation is actually considerably less intense.

The first source of information about the solar spectrum in the region under consideration (1800–3500 A) is that of measurements made at the earth's surface and corrected for absorption in the atmosphere. Such information can, of course, extend down to only about 3000 A, but even this shows that the radiated energy is considerably less than would be expected from the black-body assumption mentioned above. Several series of such measurements have been summarized by Moon [42]. Below 4000 A, the measurements indicate a steady decrease of emission relative to black-body emission at 6000K until at 3000 A the ratio is only about 40 per cent.

The rocket flight of October 10, 1946 obtained a spectrum at 55 km (already above all but about one per cent of the ozone) extending down to 2200 A [31]. The ratio of observed intensity to black-body intensity for a temperature of 6000K was observed to decrease irregularly from about 70 per cent at 3300–3400 A to about 6 per cent at 2200 A. The agreement with surface observations in the overlapping region (3000–3400 A) is satisfactory. An approximate spectrum based on these two types of information has been given by Craig [10, Fig. 10]. The graph of E_z/n against N in Fig. 2 is based on this distribution.

Ozone Distribution. The vertical distribution of ozone is, of course, an important parameter in the determination of rate of heating of the ozone layer at various levels. Unfortunately, Umkehr measurements give little more than the order of magnitude of the amount of ozone present above 30 km. Neither do these measurements give any reliable information about the seasonal and latitudinal variations of ozone amount above 30 km.

In this connection, the calculations of equilibrium ozone amounts may be useful. There are many uncertainties in the calculations that make them only approximate. However, particularly above 30 km, they agree as to order of magnitude with the Umkehr results. The calculations have the advantage over the observations that they are capable of showing, at least approximately, the variations of ozone amount with zenith angle. The photochemical theory also indicates a substantial variation of equilibrium ozone amount with temperature, because the photochemical factor k_{12}/k_{13} in (7) varies markedly with temperature [15]. Thus calculations of the photochemical-equilibrium amounts of ozone above 35 km, applied to the problem of computing the rates of radiative heating of the ozone layer, give

the same order of accuracy as the Umkehr observations and can show, at least qualitatively, the variations of rate of heating with latitude and season.

Calculation of Heating of the Ozone Layer. To calculate the heating of the ozone layer resulting from ozone absorption of direct solar radiation, one needs to know (1) the absorption spectrum of ozone, (2) the spectral distribution of solar energy, 2000–3500 A and 4500–6500 A, and (3) the vertical ozone distribution.

With regard to the absorption spectrum of ozone and the solar spectrum, Craig [10] has given estimates based on the most recent and reliable data. Figure 2 gives

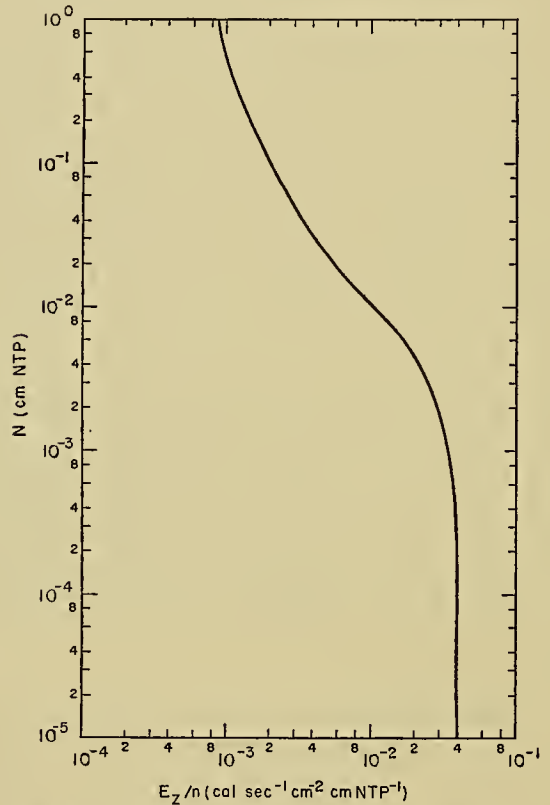

FIG. 2.—Variation of E_z/n as a function of N.

E_z/n as a function of N, from (12), for these estimates. For very small values of N the exponent in (12) is small, so the exponential term is close to unity; hence E_z/n is nearly independent of N. The curve then shows a strong variation of E_z/n with N in the range of path lengths that includes most of the Hartley absorption. When the solar energy in the Hartley region is exhausted, the integration in (12) effectively extends only over the Huggins and Chappuis bands. Here the absorption coefficients are small and, for values of N encountered in the atmosphere, the exponential term in (12) again approaches unity. From this graph the reader can easily find E_z, and hence the heating from (13) at any desired level in the ozone layer and for any assumed solar zenith angle and vertical ozone distribution.

COOLING OF THE OZONE LAYER

Cooling of the ozone layer results from radiative transfer in the infrared. The atmospheric gases responsible for this cooling are water vapor, carbon dioxide, and ozone. Several factors make calculations of the rate of cooling inherently more complex than calculations of the rate of heating. In the first place, the infrared radiation that affects a given level originates at all other levels of the atmosphere and is *diffuse* radiation. In the second place, the absorption bands in the infrared consist of sharp lines with little continuous background absorption, so that the absorption coefficient varies rapidly with wave length. In the third place, the absolute amounts of the gases in the ozone layer are very small, smaller than those used heretofore in most laboratory experiments. Finally, the range of variation of pressure in the region under consideration is two to three orders of magnitude, and pressure effects on the infrared absorption are marked and not completely understood.

Infrared Spectra of Water Vapor, Carbon Dioxide, and Ozone. Water vapor contains two principal absorption bands in the infrared. The most intense, the *rotational* band, is located at the long-wave end of the spectrum, beyond about 20 μ, and has been studied spectroscopically by Randall, Dennison, Ginsburg, and Weber [50]. The band at 6 μ has not been studied as exhaustively, but Fowle [17, 18] has made absorption measurements.

Carbon dioxide has three bands in the infrared, intense ones at about 4 μ and 15 μ and a weak band near 10 μ. The band at 4 μ, while intense, is located in a region of comparatively small radiation for black bodies at atmospheric temperatures. However, the 15-μ band is exceedingly important in the radiative processes of the atmosphere, lying as it does near the peak of the black-body radiation at atmospheric temperatures. Martin and Barker [39] have studied this band spectroscopically.

Ozone has two bands, one near 10 μ and a second that nearly overlaps the 15-μ carbon dioxide band. Strong [54] has studied the absorption of the former band.

Methods of Calculating Cooling. To compute the flux of infrared radiation arriving at a given level in the atmosphere, one needs to consider the radiation originating at all other levels and also the absorption of radiation during its passage from its origin to the reference level. In Fig. 3, let the unit area P, through which the downward flux is to be computed, lie on the horizontal plane $u = 0$, where the symbol u represents the mass of the radiating substance in a vertical column of unit area. Consider an infinitesimal volume element in the plane $u = u$, with vertical thickness du. The line from this element to P makes an angle θ with the vertical and an angle φ with an arbitrary reference direction in the horizontal. The emission of monochromatic radiation from this element is

$$dI\, d\lambda = kI_b \sec\theta\, du \sin\theta\, d\theta\, d\varphi\, d\lambda, \qquad (15)$$

where k is the absorption coefficient and I_b is the black-body radiation of the element at the wave length λ in question. The vertical flux reaching P from this element is $\cos\theta\, dI\, d\lambda \exp(-ku \sec\theta)$. The total monochromatic flux reaching P from the plane $u = u$ is obtained by

integrating this expression over the plane,

$$f(u,\lambda) = du\,d\lambda \int_0^{2\pi} d\varphi \int_0^{\pi/2} kI_b e^{-ku\sec\theta} \sin\theta\, d\theta \qquad (16)$$
$$= 2\pi k I_b Ei_2(ku)\, du\, d\lambda,$$

where $Ei_2(ku)$ is an exponential integral.

The total vertical flux reaching P from all points above is thus

$$F = \int_0^{\infty} \int_0^{u} 2\pi k I_b Ei_2(ku)\, du\, d\lambda. \qquad (17)$$

The integration of (17) solves the computational problem. In practice, however, this integration is very difficult. In the first place, the black-body radiation I_b depends on the temperature, which in turn depends on the path length u in an irregular manner that varies from time to time in the atmosphere. Secondly, the absorption coefficient k depends on the wave length λ in a rapid and irregular manner. Indeed, this variation in the infrared bands is so rapid as to prevent the direct application of methods of numerical integration.

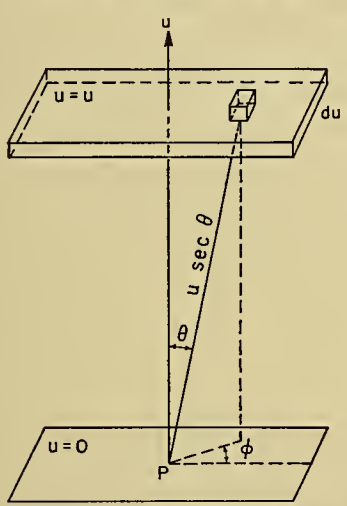

FIG. 3.—Radiation to P from a volume element above P.

Elsasser [14] and Schnaidt [52] have introduced a simplification that makes the integration over wave length practicable. They divide the spectrum into small intervals, each interval containing a number of absorption lines. Under the assumptions that these lines are broadened by pressure effects and that the lines in any one spectral interval are all equal in intensity and equidistant, they derive expressions for the average absorption in the spectral interval. The absorption coefficient, which may vary greatly in the interval, can then be replaced by a "generalized" absorption coefficient which is constant in the interval.

The *transmission function* $\tau_I(u)$ is defined as the ratio I/I_0 of the radiation penetrating a layer of thickness u to the radiation incident at the top of the layer. For diffuse radiation, the transmission function $\tau_f(u)$ is similarly defined in terms of fluxes rather than intensities. The relation between τ_f and τ_I is

$$\tau_f(u) = \int_0^1 \tau_I(u \sec\theta)\, d \sin^2\theta. \qquad (18)$$

Thus for exponential absorption of a beam of monochromatic radiation, $\tau_I = e^{-ku}$ and $\tau_f = 2Ei_3(ku)$. In these more general terms, (17) may be written in the form

$$F = -\int_0^{\infty} d\lambda \int_0^{u} f_b \frac{d}{du} \tau_f[lu]\, du, \qquad (19)$$

where f_b is the black-body flux, given by πI_b and l is the generalized absorption coefficient.

The transmission functions given by Elsasser [14] and Schnaidt [52] apply strictly only to spectral intervals that contain equal and equidistant lines, each line broadened by pressure effects only. Experiment, however, has shown that the formulas apply to a good approximation to the actual behavior of the infrared absorption bands of the atmospheric gases. With the aid of these developments one can integrate (19) over wave length. The integration over path length must be accomplished numerically or graphically in a separate calculation for each atmosphere that has a distinctive relationship between path length and temperature. The cooling at any level in the atmosphere is then proportional to the vertical divergence of the net flux at that level.

A more direct method of computing cooling in the atmosphere has been given by Bruinenberg [5] and Brooks [4]. It gives the divergence of the flux, and hence the cooling, directly. This method is to be preferred for the ozone layer where the fluxes are small in any case.

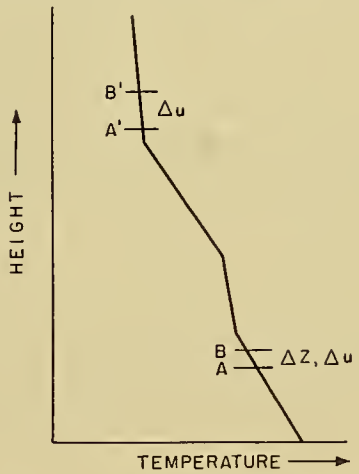

FIG. 4.—Schematic representation of temperature-height sounding of the atmosphere. The path length of absorbent, u, between A and A' is the same as that between B and B'.

Figure 4 gives a schematic representation of the variation of temperature with height. Let the total amount of absorbent above A be u_A, and that above B be u_B, where $u_A - u_B = \Delta u$. Define the flux from an *isothermal* column as

$$\mathcal{F}(u, T) = \epsilon_f(u, T)\, \sigma T^4. \qquad (20)$$

The total emissivity of the isothermal column, ϵ_f, is defined as the ratio of the flux emitted from the column to the black-body flux at the temperature of the column. Thus,

$$\epsilon_f = \frac{1}{\sigma T^4} \int_0^{\infty} f_b(1 - \tau_f)\, d\lambda. \qquad (21)$$

The downward fluxes at A and B can be written as

$$F_A = \int_0^{u_A} \frac{\partial \mathcal{F}_A}{\partial u}\, du, \qquad F_B = \int_0^{u_B} \frac{\partial \mathcal{F}_B}{\partial u}\, du. \tag{22}$$

Equations (20) and (22) are consistent with (19). Therefore,

$$F_A - F_B = \int_0^{u_B} \left(\frac{\partial \mathcal{F}_A}{\partial u} - \frac{\partial \mathcal{F}_B}{\partial u}\right) du + \int_{u_B}^{u_A} \frac{\partial \mathcal{F}_A}{\partial u}\, du. \tag{23}$$

Consider a level A' at a path length u above A and a level B' at the same path length u above B. (The linear distances $A - A'$ and $B - B'$ are not necessarily the same.) The flux from B' through B and the flux from A' through A would be identical except that A' and B' may be at different temperatures.
One can write

$$\left(\frac{\partial \mathcal{F}_A}{\partial u} - \frac{\partial \mathcal{F}_B}{\partial u}\right)_{\text{from } u} = \frac{\partial^2 \mathcal{F}}{\partial u\, \partial T}\,(dT)_u = \frac{\partial^2 \mathcal{F}}{\partial u\, \partial T}\frac{dT}{du}\,\Delta u. \tag{24}$$

The second integral in (23) represents the additional flux at A because $u_A > u_B$ so that

$$\int_{u_A}^{u_B} \left(\frac{\partial \mathcal{F}_A}{\partial u}\right) du = \left(\frac{\partial \mathcal{F}}{\partial u}\right)_t \Delta u, \tag{25}$$

where $(\partial \mathcal{F}/\partial u)_t$ is the value of $(\partial \mathcal{F}/\partial u)$ at the top of the atmosphere. With these values inserted (23) becomes

$$\Delta F = \int_0^{u_B} \left(\frac{\partial^2 \mathcal{F}}{\partial u\, \partial T}\right)_u \left(\frac{dT}{du}\right)_u \Delta u\, du + \left(\frac{\partial \mathcal{F}}{\partial u}\right)_t \Delta u. \tag{26}$$

The cooling is proportional to the divergence of the flux. Divide both sides of (26) by Δz and let both sides approach the limit $\Delta z = 0$. Then

$$\frac{\partial F}{\partial z} = \frac{\partial u}{\partial z}\left[\int_0^{u_B} \left(\frac{\partial^2 \mathcal{F}}{\partial u\, \partial T}\right) dT + \left(\frac{\partial \mathcal{F}}{\partial u}\right)_t\right]. \tag{27}$$

The divergence of the upward flux can be derived in the same manner. However, because the ground acts as a black body, the expression for the upward flux has no term comparable to the second term in (27). Thus, finally,

$$\begin{aligned}\frac{\partial T}{\partial t} &= +\frac{1}{\rho c_p}\left(\frac{\partial F^{\downarrow}}{\partial z} - \frac{\partial F^{\uparrow}}{\partial z}\right) \\ &= +\frac{1}{\rho c_p}\frac{\partial u}{\partial z}\left[\int_0^{u_B} \left(\frac{\partial^2 \mathcal{F}^{\downarrow}}{\partial u\, \partial T}\right)_{u,T} dT \right. \\ &\qquad \left. + \left(\frac{\partial \mathcal{F}^{\downarrow}}{\partial u}\right)_t - \int_0^{\infty} \left(\frac{\partial^2 \mathcal{F}^{\uparrow}}{\partial u\, \partial T}\right)_{u,T} dT\right].\end{aligned} \tag{28}$$

Data for Calculating Cooling. According to (28), the cooling at any level in the ozone layer can be determined by numerical or graphical integration if $\mathcal{F}$ is known as a function of u and T. From (20)

$$\frac{\partial^2 \mathcal{F}}{\partial u\, \partial T} = 4\sigma T^3 \frac{\partial \epsilon_f}{\partial u} + \sigma T^4 \frac{\partial^2 \epsilon_f}{\partial u\, \partial T}. \tag{29}$$

The emissivity ϵ_f can be determined either from laboratory measurements or from the theoretical transmission functions according to (21).

Elsasser [14] has summarized measured values of the emissivities of water vapor and carbon dioxide. Summerfield[6] has given data on the 10-μ band of ozone. Unfortunately, in none of these cases do the measurements extend to values of u as small as those met in the ozone layer. Some radiation computations have made use of extrapolations of these emissivity curves.

An alternative procedure is to make use of the transmission functions for the infrared bands. The functions can first be tested against and fitted to the observation in the range of u where measurements are available. In general, it is possible to get a good agreement between theory and observations. The transmission functions can then be used to extrapolate the available information to small values of u. Even this type of extrapolation, however, is risky. The transmission functions, as stated above, were derived on the basis of idealized bands. That they describe the behavior of the actual infrared bands in a certain range is no guarantee that they will serve equally well in another range. A further difficulty stems from the overlapping of the ozone and carbon dioxide bands at 15 μ. Very little is known about the former band. How much its presence may affect the carbon dioxide emissivities as measured in the laboratory is not known.

Pressure Effects on Infrared Absorption. Still another difficult and unsolved problem is the question of pressure effects on absorption in the infrared. It is certain that the half-width of the absorption lines in the infrared varies with pressure. Elsasser [14] gives a rather complete discussion of the experimental facts about this dependence.

For water vapor, the half-widths of the absorption lines seem to vary as the square root of the pressure. Strong [54] has shown a similar square-root dependence for the 10-μ ozone band. In the case of carbon dioxide evidence is conflicting, and various investigators have assumed that the half-width varies as the pressure according to laws ranging from square-root dependence to direct dependence. This is a question, particularly in the case of carbon dioxide, that should be cleared up before accurate calculations can be made.

RESULTS OF CALCULATIONS

Despite the difficulties discussed above, some investigators have made calculations based on the available knowledge. These calculations correspond qualitatively to the observational information available about the temperature distribution in the ozone layer. It is the purpose of this section to outline the results so far achieved.

Gowan's Calculations of Equilibrium Temperature. E. H. Gowan has pioneered the work in this field. In a pair of early papers [23, 24], he made some preliminary calculations which showed that the suspected

6. In an unpublished doctoral dissertation at the California Institute of Technology in 1941.

temperature maximum near 55 km was reasonable. In 1936 [25], he revised these calculations on the basis of later determinations of the vertical distribution of ozone. Finally, in 1947 [26] he published revised results based on further information about absorption in the infrared. Only the last results are included here.

Gowan gives his results in the form of radiative-equilibrium temperatures at various levels in the ozone layer. These are the temperatures that would exist according to his calculations if the radiative gains of the layer were just balanced by the radiative losses, with no effects of atmospheric circulations. The assumptions made by Gowan are:

1. *Solar Energy.* For all calculations except one, Gowan assumes that the sun radiates as a black body at 6000K in the ultraviolet. In this one case, the emission is taken as that of a black body at 4000K.

2. *Vertical Distribution of Absorbing Gases. Ozone* is assumed to vary vertically according to the Umkehr measurements of Götz, Meetham, and Dobson at Arosa for a total amount of ozone of either 0.20 cm NTP or 0.28 cm NTP. *Water vapor* is assumed to be either 10 per cent or 40 per cent saturated at the tropopause with constant mixing ratio in the ozone layer. *Carbon dioxide* is assumed to be present throughout the ozone layer in a concentration of 0.03 per cent by volume (corresponding to tropospheric conditions).

Table I. Radiative-Equilibrium Temperatures at 50°N (*After Gowan* [26])*

	Summer								Winter	
Amount O_3 (cm NTP)	.280		.280		.280		.200		.280	.280
Amount H_2O (%)	0		10		40		10		10	10
Solar temperature (°K)	6000		6000		6000		6000		4000	6000
Height (km)	Temperature (°K)									
50–55	452	415	*448*	344	*441*	410	*445*	323	*347*	406 *439*
45–50	429	410	*424*	361	*421*	409	*422*	321	*333*	364 *375*
40–45	399	385	*397*	350	*394*	382	*390*	311	*319*	305 *314*
35–40	335	324	*332*	295	*327*	320	*330*	291	*301*	278 *285*
30–35	296	285	*295*	262	*291*	281	*292*	272	*283*	262 *273*
25–30	275	258	*272*	244	*265*	257	*269*	252	*266*	246 *256*
20–25	254	241	*249*	240	*239*	239	*247*	236	*245*	230 *238*
15–20	239	232	*232*	232	*221*	229	*225*	229	*229*	221 *221*
11–15	228	218	*217*	211	*209*	215	*208*	217	*215*	208 *209*

* The two columns under each group of assumptions represent the alternative results if water vapor absorption is (right column) or is not (left column) corrected for a pressure dependence.

3. *Absorption Spectra* In the ultraviolet, absorption coefficients of oxygen are taken from the measurements of Granath [27], those of ozone from the measurements of various investigators [16, 36]. In the infrared, the emissivity of carbon dioxide is taken from laboratory measurements, as summarized by Elsasser [14], and extrapolated on log-log paper to smaller values of path length. Similarly the absorption coefficients of Fowle and Hettner [17] for water vapor are extrapolated on log-log paper. Summerfield's measurements at the 10-μ hand of ozone are utilized. The water vapor coefficients are corrected according to the square-root pressure law in some cases. The calculations apply to a latitude of 50°N in summer or winter according to various combinations of the assumptions listed above. Table I gives the results.

These results show reasonable agreement with observations. The temperature increases with height to the top of the ozone layer, although the maximum is not usually reached in these calculations. The temperatures are considerably higher than those that actually occur in the ozone layer; this is due in part to the assumption of solar black-body radiation at 6000K. Recent rocket measurements show much less energy.

Penndorf's Calculations of Rate of Heating and Cooling because of Ozone Alone. Penndorf [48] has computed the rates of heating and cooling of the ozone layer that would result from the effects of ozone alone. He takes the solar emission curve in the ultraviolet as that of a black body at 5910K and assumes the vertical distribution of ozone to be that measured by the Umkehr effect at Arosa. He integrates the temperature changes over the period of a day.

Penndorf's results show maximum heating resulting from ozone absorption of solar ultraviolet radiation to lie between 45 and 50 km. The cooling effect of long-wave radiation is a maximum at 50 km. The absolute value of the rate of heating is 10–50 times greater than that of the rate of cooling, at least from 30 to 50 km. This discrepancy is probably at least partially due to two factors: (1) smaller solar emission in the ultraviolet than the assumed amount; and (2) the cooling effects of carbon dioxide and water vapor are not included.

Karandikar's Calculation of Heating of the Ozone Layer. Karandikar [32] has given a rather complete discussion of the rate of heating of the ozone layer. He considers not only heating caused by ozone absorption of ultraviolet solar radiation, but also the heating caused by absorption of solar radiation in the infrared bands of ozone, carbon dioxide, and water vapor. He assumes the sun to radiate as a black body at 6000K. The vertical distribution of ozone is based on available Umkehr measurements, that of carbon dioxide on a constant proportion by volume (0.03 per cent) throughout the ozone layer. Several alternative assumptions are made about the total amount of water vapor present, the vertical distribution of the water vapor being taken to follow Dalton's law.

The results show a maximum of absorbed energy between 40 and 50 km. For a solar zenith angle of 0°, the maximum absorption occurs at 40–45 km. For a solar zenith angle of 75°, the maximum absorption occurs at 45–50 km and is only about half as intense as for the smaller zenith angle. Karandikar's computations show that the heating produced by infrared absorption of solar energy can be safely neglected above 30 km in comparison with the heating produced by ultraviolet absorption of ozone. Below 30 km, on the other hand, the former process becomes predominant, water vapor playing the most important role.

Craig's Calculations of Heating and Cooling. The writer has carried through some unpublished calculations of heating and cooling of the ozone layer. They are mentioned here to show the results that have been

obtained with somewhat different assumptions than the ones on which the published calculations are based. The assumptions that differ markedly from those outlined above are:

1. *Solar Energy.* The solar emission curve in the ultraviolet corresponds to the results of the rocket measurements. As mentioned previously, these show considerably less solar energy than a black body at 6000K would radiate.

2. *Vertical Distribution of Absorbing Gases.* The vertical distribution of ozone above 35 km is computed from photochemical-equilibrium theory [10]. This gives the same magnitude as Umkehr measurements and shows to a first approximation variations with solar zenith angle and temperature.

3. *Absorption Spectra.* The emissivities of carbon dioxide and ozone for small path lengths are obtained from the theoretical transmission functions rather than from straight extrapolation of existing measurements. Cooling is evaluated directly by graphical integration of (28).

For the temperatures generally assumed to occur in the ozone layer [57], the calculated rates of heating and cooling are of the same order of magnitude at all levels. This contrasts with Gowan's results; since his equilibrium temperatures are considerably higher than those that actually occur, his assumptions would give greater heating than cooling at the lower temperatures. It also contrasts with Penndorf's results. In both cases, the difference in assumed solar energy is the principal reason for the discrepancy. The level of maximum heating is at 40–45 km, lower than that found by Karandikar. This difference is probably also a result of the different assumed-energy curves. The ratio of the measured solar intensity to the black-body intensity is relatively smaller near the maximum of the Hartley bands of ozone, which heat the upper part of the ozone layer, than at longer wave lengths.

The infrared cooling due to the carbon dioxide band at 15 μ is more intense than that due to ozone or water vapor, at least above 35 km. This result must be considered somewhat doubtful until further light is shed on the problems of pressure effects on this band, and of the overlapping of the 15-μ ozone band. The absolute values of the rates of heating and cooling are relatively low, of the order of magnitude of 0.1C per three hours below 30 km and of 1C per three hours at 35–50 km. These are no larger than might be expected from normal atmospheric circulation processes.

SUBJECTS FOR FURTHER RESEARCH

It has become evident throughout this discussion that several fruitful avenues of research lie open to the interested investigator. In this concluding section, these are summarized and briefly discussed.

Solar Energy in the Ultraviolet. Even though rocket measurements of the solar spectrum down to 2200 A have thus far been of great help, many more are needed. For the present problem, only a slight further extension into the ultraviolet is necessary, perhaps to 1800 A. However, many more measurements should be made to check the accuracy of the information now available and to show whether there are any significant variations of the spectrum with time.

Vertical Distribution of Absorbing Gases. The vertical distributions of all of the absorbing gases in the ozone layer are in doubt. In the case of ozone, the vertical distributions above 30 km at various latitudes and times of year are urgently needed. For carbon dioxide, some direct measurements should attempt to test the usual assumption that the concentration in the ozone layer is the same as in the troposphere. Particularly above 30 km this is desirable. Water vapor is probably not important to the present problem at levels above 30 km (unless it is present in much greater concentration than now assumed). However, in the lower isothermal part of the layer its concentration should be measured carefully under a variety of conditions. Recent developments in England [11] and the United States [2] give encouragement in this direction.

Absorption Spectra. The absorption spectra of oxygen and ozone in the pertinent part of the ultraviolet seem to be satisfactorily known. For the problem of calculation of photochemical-equilibrium amounts of ozone, however, further study of the pressure dependence of oxygen absorption should be made in the laboratory. The spectral region where information is vitally needed is 1800–2200 A and the pressures range from 10 to 0.1 mb.

Absorption data in the infrared are urgently needed. Perhaps the most practical type of laboratory measurements for the present problem would give the isothermal emissivities of carbon dioxide and ozone as a function of path length, pressure, and temperature, particularly the first two. The range of path lengths of carbon dioxide that needs further study is from 0.01 to 1 cm NTP at pressures ranging from 0.1 to 10 mb. Ozone path lengths from 10^{-4} to 10^{-2} cm NTP at pressures of 1 to 10 mb need further study. Furthermore, emissivity measurements should be made on various mixtures of ozone and carbon dioxide within these limits to determine the effect of the former on the latter at 15 μ.

Calculations with Existing Data. Further calculations with existing data are possible, and indeed desirable, unless some of the above experimental information is forthcoming in the immediate future. The calculations made up to now show that useful results can be obtained. Particularly, calculations for various latitudes and seasons may begin to show the extent of temperature variations in the ozone layer, a matter about which we now have no information.

TEMPERATURES AND PRESSURES IN THE UPPER ATMOSPHERE

By HOMER E. NEWELL, Jr.

Naval Research Laboratory

Introduction

The stratosphere was discovered in the pioneering days of high-altitude balloon research. Between 1899 and 1902 experiments performed by Assmann and Teisserenc de Bort revealed a cold isothermal layer extending upwards from the top of the troposphere. The initial height of the layer appeared to vary from about 6 km in the polar regions to 18 km above the equator. As a result of such balloon measurements, it was long supposed that beyond the troposphere the temperature ceased to change with altitude. In the presence of the earth's gravitational field such an isothermal region would, of course, be characterized by a diffusive separation of its various constituents, with the heavier gases settling out and the lighter ones predominating at the higher altitudes. The name *stratosphere* aptly describes such an atmosphere.

In the course of time, however, evidence began to accumulate to show that the temperature of the atmosphere is not the same at all heights above the tropopause. On the basis of data now available from sound and meteor studies, from rocket measurements, and from a number of other sources, it is plain that atmospheric temperatures vary markedly with altitude. In higher latitudes and the polar regions an isothermal region does exist above the troposphere; but as one moves southward the purely isothermal stratosphere disappears to be supplanted by a rather flat temperature minimum somewhere between 10 and 20 km above the surface of the earth [16]. Above the (improperly named) stratosphere, in the region now referred to simply as the *upper atmosphere*, the air is definitely not isothermal. On the other hand, the total pressure difference between ground and 110 km is nearly that to be expected in an isothermal atmosphere of about 240K.[1] In this sense one may regard 240K as an average temperature for the entire region below 110 km. Above 110 km there are some indications of very high temperatures.

There are now numerous sources of data on which to base conclusions about temperatures and pressures in the upper atmosphere. Some of these are discussed in the sections below. No attempt is made, however, either to exhaust the literature or to furnish complete details of the temperature and pressure studies which are discussed.

Balloon Studies in the Upper Atmosphere

Until recently the highest-flying balloons could rise not much higher than 30 km. Measurements on such balloon flights indicated a small but definite rise in the temperature near the top of the stratosphere. Such a rise appeared consistent with temperatures deduced from studies of the anomalous propagation of sound, which suggested a sharp rise above 30 km, but which furnished only an indirect determination of temperature. Now, with improved balloons, it is possible to trace out by direct measurement an additional 10 km or more of the temperature curve.

The graph of Fig. 1 shows a curve of temperature variation from the ground up to 43 km. The measurements were made at Belmar, New Jersey, on September 28, 1948 at 1:20 P.M., using a new type of balloon especially developed for the Signal Corps [4]. It will be noted that a positive temperature gradient is observed from 15 km to the peak of the flight. The measured temperatures indicate an abrupt inversion in the neighborhood of 15 km, and show no isothermal region. They do not even appear consistent with any flat temperature minimum in the stratosphere. The measurements are

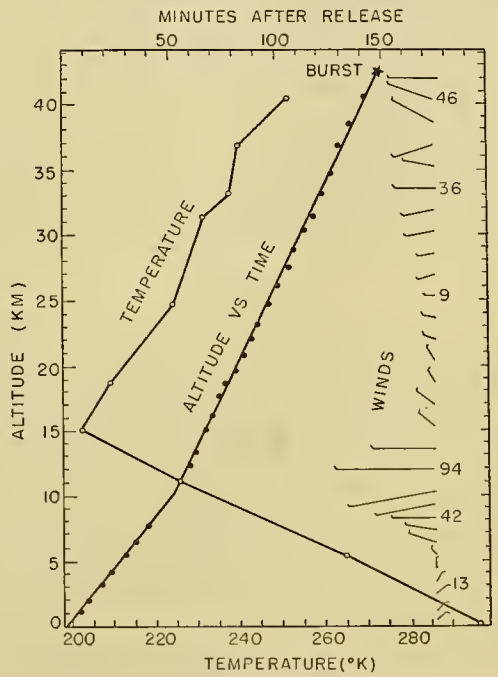

FIG. 1.—Results obtained from balloon flight at Evans Signal Laboratory, Belmar, New Jersey, on September 28, 1948, 1:20 P.M. The length of the wind vector is proportional to the wind speed (mph). The tail of the wind vector indicates the direction from which the wind was blowing. Thus, near the ground, the wind was northeasterly; at 15,000 feet, northerly; at 40,000 feet, westerly; and at 50,000 feet northwesterly (taken from [4] Brasefield: *Sci. Mon.*, 68:398 (1949), by permission of the publishers).

1. This statement is based on the pressure curve of Fig. 7 below.

in keeping with both balloon and rocket measurements at White Sands, New Mexico, which likewise fail to show any genuinely isothermal layer [9].

Propagation of Sound Through the Upper Atmosphere

Occasionally sound generated by an explosion can be heard distinctly at remote points, but not at all at points nearer to the source. The total region of audibility consists of a primary zone containing the source itself, plus one or more surrounding rings separated from each other and from the primary zone by regions of silence. Throughout the primary zone the sound is propagated at normal speeds. Within the secondary zones, however, the sound arrives much later than would be expected of waves propagated along the earth's surface.

Anomalous sound propagation was first noted in connection with gunfire at Queen Victoria's funeral. It was soon concluded that waves reaching the annuli of abnormal audibility had traveled into and through the upper atmosphere before returning to earth. An early explanation was that high-altitude winds caused the waves to bend back to the ground. The observed omnidirectionality of anomalous sound propagation, however, was not compatible with the wind theory.

Von dem Borne proposed an explanation based on refraction of sound waves [3]. If atmospheric properties vary only with height, the refraction law is

$$\frac{v}{\cos e} = V, \tag{1}$$

where for a given path V is constant. The quantities v and e are respectively the local speed of sound and the angle between the ray path and the horizontal plane. The ray paths are straight, curve upward, or bend downward according as v is constant, decreasing, or increasing with altitude. Assuming refraction as the cause of anomalous propagation, one concludes that sound returning to earth from the upper atmosphere passed through a region in which its speed increased with altitude. Moreover, at the apex of its path, the wave front was moving horizontally at the speed V.

The speed of sound through a gas is given by

$$v = \sqrt{\gamma \frac{R}{M} T}, \tag{2}$$

where γ is the ratio of the specific heat at constant pressure to that at constant volume, R is the universal gas constant, M the average molecular weight of the gas, and T its absolute temperature. To explain anomalous sound propagation, von dem Borne postulated a decreasing value of M with height caused by increasing proportions of the lighter gases above the troposphere [3]. Data available at present, however, show far too small a change in composition to vary either M or γ sufficiently to account for the observed refraction, which must accordingly be due to changes in the only remaining variable, namely temperature.

In 1923 F. J. W. Whipple first suggested an explanation of anomalous sound propagation based on a positive temperature gradient in the upper atmosphere [19]. Since then Whipple, Gutenberg, Duckert, and numerous other authors have written extensively on the subject [5, 6, 8]. Whipple's explanation is the one now generally accepted, and leads directly to a method for determining upper-air temperatures.

Referring to Fig. 2, suppose that within a zone of abnormal audibility P_1 and P_2 are neighboring points

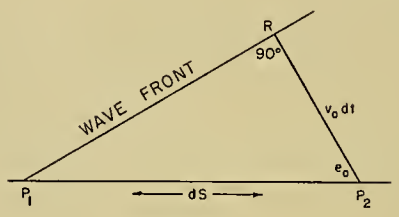

Fig. 2.

in line with the sound source. At the moment the wave front reaches P_1, it still has a distance RP_2 to travel before reaching P_2. If dt is the time interval between the arrival of the sound at P_1 and its arrival at P_2, and if v_0 is the speed of sound in the neighborhood of P_1 and P_2, then RP_2 is equal to $v_0\,dt$. Letting $dS = P_1P_2$, one has:

$$dS \cos e_0 = v_0\,dt;$$

or, using equation (1):

$$\frac{dS}{dt} = \frac{v_0}{\cos e_0} = V. \tag{3}$$

The quantity dS/dt is the apparent speed of sound along the earth between P_1 and P_2, and can be measured quite easily. Moreover, as shown by (3), the measured value of dS/dt is precisely the speed of sound V at the apex of its path through the upper atmosphere. The value of V can also be obtained by measuring the angle of arrival e_0 of the wave front.

Once determined, V can be used in equation (2) to compute the temperature at the apex of the sound path. To associate the temperature so calculated with a specific height, the ray path must be traced out in order to determine the altitude of the apex. This can be done quite accurately at lower altitudes, using data from balloon observations. Assuming a positive temperature gradient, the remainder of the path in the upper atmosphere is then constructed so as to fit the observed transit times for the sound and so as to join smoothly onto the lower segments.

Temperatures determined by Gutenberg, and more recently by Cox, are shown in Figs. 3 and 4 [8, 5]. Between 40 and 60 km the temperatures quoted by Cox are considerably below those obtained by Gutenberg. Cox's results are more in conformity with rocket findings at White Sands. A temperature maximum, such as that shown by Cox near 55 km, has always been observed in rocket flights.

Winds may have a large effect upon temperatures deduced from sound observations. With this in mind

Weekes and Wilkes have analyzed sound data obtained from more accurate controlled experiments carried out by the British Meteorological Office. They found that

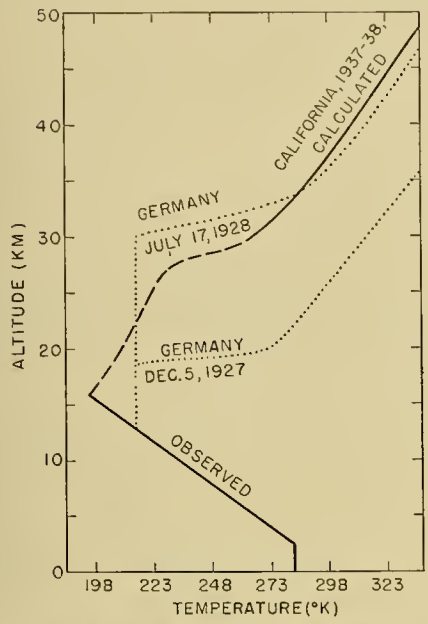

FIG. 3.—Temperatures derived from velocity of sound waves in Southern California, with results for Northern Germany plotted for comparison (taken from [8, p. 200]).

at night "the temperature starts to rise at about 35 km and rises at a rate of about 5C km^{-1} to at least 50 km, at which height the temperature lies between 290 and 350K, with the lower value more likely." [18, p. 87].

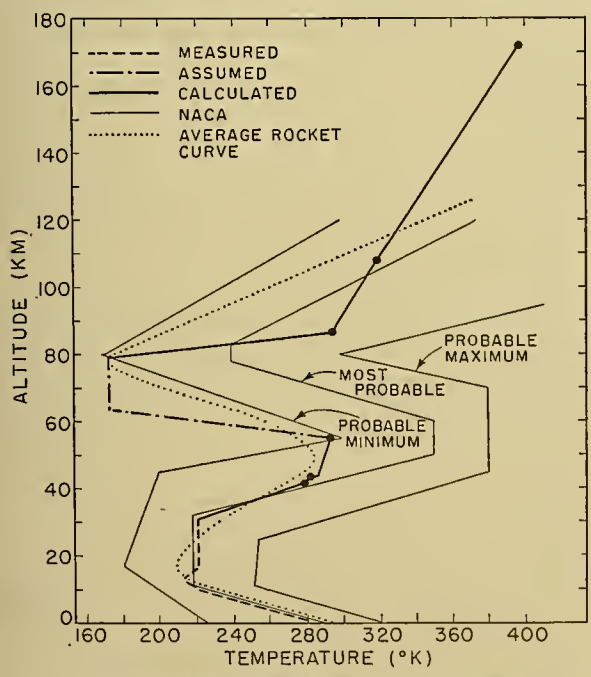

FIG. 4.—Comparison of measured upper-atmosphere temperatures (Helgoland blast), V-2 rocket results, and N.A.C.A. tentative standards (taken from [5] Cox: *Amer. J. Phys.*, 16: 473 (1948), by permission of the publishers). Rough rocket data appearing on Cox's published figure have been replaced by an average curve of temperatures calculated from Naval Research Laboratory rocket flights.

The lower values are more in keeping with Cox's results and those obtained from rockets.

Ozone Heating in the Upper Atmosphere

The high-temperature region deduced from sound-propagation experiments coincides with the upper portion of the ozonosphere, which lies between 15 and 55 km. The total amount of ozone in the atmosphere is at most a few millimeters at standard conditions. Nevertheless ozone absorption in the ultraviolet is strong, and the ozone content appears to be sufficient to account for observed atmospheric heating immediately above the stratosphere.

Gowan [7] and Penndorf [15] have made extensive calculations to show how much heating can be expected from atmospheric ozone. Gowan assumes the ozonosphere to be essentially nonconvective and in radiative

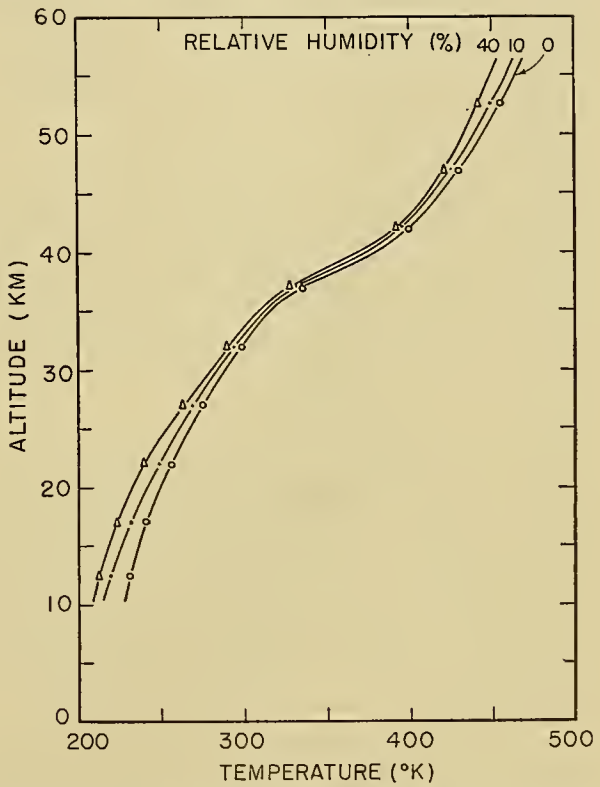

FIG. 5.—Atmospheric temperatures based on calculations of ultraviolet absorption in the ozonosphere (taken from [7] Gowan: *Proc. roy. Soc.*, (A) 190: 223 (1947), by permission of The Royal Society).

equilibrium. The validity of these assumptions, however, is open to question. Water vapor, ozone, and carbon dioxide are taken to be the principal gases involved, and the calculations are made for a number of different humidities. The assumed solar temperature is 6000K. Ozone content is taken from experiments of Götz, Meetham, and Dobson and applies to the atmosphere above Switzerland. A temperature-distribution curve is obtained by dividing the ozonosphere into nine layers and calculating the equilibrium temperatures for the various layers. Some of the results are set forth in Fig. 5. It will be noted that the temperature begins to

rise at somewhat below 30 km, and at 50 km is still rising. Above 42 km, however, the rate of rise falls off. The temperatures are very much higher than those given by Cox and by rocket soundings at White Sands.

Penndorf [15] does not assume radiative equilibrium and considers only ozone heating and cooling. He considers the effect of water vapor in the ozonosphere to be negligible. Above 3000 A the solar radiation is taken from Abbot's table; from 3000 A to 2000 A the radiation is assumed to be that of a black body at 5910K. Rates of heating and cooling in the ozonosphere are computed for different temperature distributions. Penndorf's results on daytime heating and nighttime cooling correspond to rather high equilibrium temperatures during the day, with little change during the night. According to Penndorf the maximum rate of heating and most of the ultraviolet absorption both occur near 50 km.

Gowan's and Penndorf's calculations agree qualitatively with sound propagation and rocket results in showing a temperature rise in the upper ozonosphere. The computed ozone heating, however, is much greater than Cox's measurements and rocket findings would indicate.

At present, calculations of ozone heating involve so many uncertainties that conclusions based upon them must be regarded with considerable caution. It appears highly desirable to perform a number of rocket experiments to measure the total energy absorbed at various atmospheric levels from the solar and terrestrial radiations. Such data would provide a firmer foundation for temperature calculations than is now available.

Free Oscillations in the Atmosphere

Observed amplitudes of solar tides produced in the earth's atmosphere are about one hundred times as great as one normally would expect. Kelvin suggested that this might be a resonance phenomenon, due to a free atmospheric oscillation period of 12 hr. Evidence also is available to show the existence of a second free period in the atmosphere. The speed of large explosion waves, such as those generated by the Krakatau eruption and the Great Siberian Meteor, corresponds to a period of 10.5 hr.

It is to be expected that the natural periods of the atmosphere are directly associated with its temperatures. Pekeris has, in fact, shown that an atmosphere with the temperature distribution set forth in curve 7 of Fig. 8 possesses both the 10.5- and the 12-hr periods [14]. His results are further substantiated and clarified by later work of Weekes and Wilkes [18]. The 10.5-hr period is a property of the lower atmosphere with the temperature distribution revealed by balloon measurements. The 12-hr period, on the other hand, is associated with the upper atmosphere, and requires the indicated temperature drop above the hot ozonosphere. Pekeris' conclusions, based upon analysis of a number of special cases, were that the atmosphere must become cold again at or above 80 km.

Meteors and Atmospheric Temperatures

A meteor striking the earth's atmosphere is heated by impact with the molecules of air. Depending upon the speed, size, and material of the meteor, the heating causes incandescence along some portion of the meteor path. The altitudes at which incandescence begins and ends depend also upon the density of the atmosphere.

In a pioneering work on meteor studies, Lindemann and Dobson [12] developed a theory which enabled them to calculate atmospheric densities at the heights of appearance and disappearance of a meteor from its speed, size, and composition. The theory applies to an isothermal atmosphere, whereas it now appears that the region in which meteors are observed visually is definitely not isothermal. Nevertheless, the theory can provide a curve of densities from which an average temperature can be estimated. The densities obtained by Lindemann and Dobson were not consistent with an average temperature of 220K in the neighborhood of stratospheric values, but were consistent with a much higher temperature, about 300K.

More recently F. L. Whipple [20] presented a theory relating the mass, shape, composition, speed, deceleration, and luminosity of a meteor to atmospheric densities. From a study of available photographic meteor data he obtained a curve of log-density versus altitude, with which a number of temperature distributions can reasonably be associated. In his paper Whipple states:

> The best solution appears to be one in which the height-log ρ curve corresponds to a flat temperature maximum of about 375K near the 60-km level, a rapid drop to 250K near 80 km, and a constant or slowly rising temperature at greater heights to about 110 km.

Rocket Measurements in the Upper Atmosphere

Since the spring of 1946 rockets have been employed at White Sands, New Mexico, for measuring pressures and temperatures in the upper atmosphere [1, 2, 10]. Initially the German V-2 was the only large rocket available, but at present the V-2 and the Navy's Aerobee and Viking are all being used. So far, pressure measurements extend only to 130 km, although some of the rockets have exceeded 100 miles in altitude. Instead of being measured directly, atmospheric temperatures are computed from the pressure data.

On each rocket there is an area, usually just ahead of the tail fins, where ambient pressures exist during flight. Gages are mounte in this area to measure atmospheric pressures directly. As a check on the accuracy of readings from gages so mounted, it is customary to compare measurements at low altitudes with balloon data acquired just before and just after the rocket flight. In the past there has been excellent agreement between rocket and balloon measurements.

Gages are also mounted at various points on the nose of the rocket. Measurements from such gages must be converted to ambient pressures by some method such as application of the Taylor-Maccoll theory. Stagnation pressures, recorded with gages at the nose tip, provide essentially a measure of density.

Temperatures are computed from the pressure versus altitude curve using the relation

$$\frac{1}{p}\frac{dp}{dh} = -\frac{Mg}{RT},$$

where M is the average molecular weight of the air, R is the universal gas constant, g the acceleration of gravity, T the absolute temperature of the air, h the altitude, and p the measured pressure. Temperatures can also be calculated from the stagnation pressure at the nose, using the following simplification of Rayleigh's formula for supersonic speeds:

$$\frac{\text{stagnation pressure}}{\text{ambient pressure}} = \cdots + .46 + 1.29 \left(\frac{\text{speed of rocket}}{\text{speed of sound}}\right)^2,$$

and using the known speed of the rocket to obtain the local speed of sound. Once the speed of sound is known, the temperature is quickly deduced.

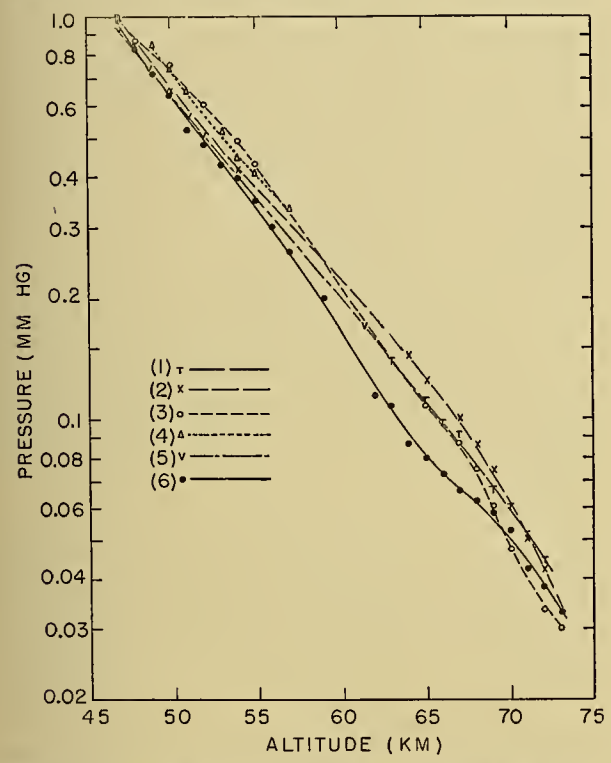

FIG. 6.—Pressures obtained from rocket flights above White Sands Proving Ground, New Mexico. Except for the point at 61.3 km which is 0.17 ± 0.03 mm of *Hg*, the data are probably correct to within 10 per cent of ambient. The flights are: (1) 10 October 1946, 1102 MST; (2) 7 March 1947, 1123 MST; (3) 22 January 1948, 1313 MST; (4) 5 August 1948, 1837 MST; (5) 28 January 1949, 1020 MST; (6) 3 May 1949, 0914 MST (taken from [10]).

Three types of gages were employed in making rocket pressure measurements. For pressures down to 50 mm of *Hg*, bellows gages were used. Pirani-type gages measured pressures in the interval from 2 mm to 7×10^{-3} mm of *Hg*. Philips gages were employed for the range from 10^{-3} down to 10^{-5} mm of *Hg*. Unfortunately there is a gap between the ranges covered by the bellows and Pirani gages, and this gap exists in the data obtained so far. Moreover, the Philips gage measurements were not too accurate in their range, partly because of peculiarities of the gage, and partly because of the behavior of the rocket. At altitudes above 80 km the rocket pressure measurements were influenced to varying extents by motions of the missile and by emission of gas from the interior and surface of the rocket. Because of differences in missile behavior, it was necessary to make separate estimates for each rocket of the errors introduced by pitching and yawing. In many cases emission of gas placed an upper limit on the altitude to which pressures could be measured.

Recently a new type gage invented by R. J. Havens [11] has been introduced into the rocket work. With this gage it should be possible in the future to cover the entire pressure range up to 150 km or more.

Pressure and temperature data accumulated by R. J. Havens and his colleagues at White Sands during the past several years are shown in Figs. 6, 7, and 8.

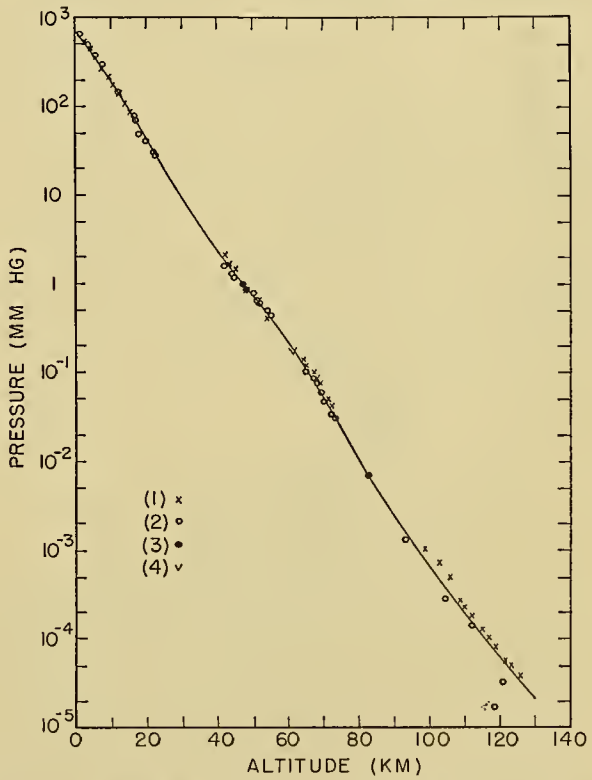

FIG. 7.—Pressures obtained from rocket flights above White Sands Proving Ground, New Mexico. The point at 82.4 km is 0.007 ± 0.002 mm of *Hg* and that at 61.3 km is 0.17 ± 0.03 mm of *Hg*. These were taken at the top of the rocket flight and pressure was therefore ambient within the error of the measurement. All other data up to 80 km are probably within 10 per cent of ambient. Data obtained above 90 km are not ambient due to the yaw of the rocket and the location of the gages. It is estimated that they are within a factor of two from ambient. (1) 7 March 1947, 1123 MST; (2) 22 January 1948, 1313 MST; (3) 3 May 1949, 0914 MST; (4) 28 January 1949, 1020 MST (taken from [10]).

The temperatures are based on the assumption of sea-level composition throughout.

Some of the differences in the pressure curves of Fig. 6 could be due to seasonal and diurnal changes, and possibly to variations in solar conditions. The same is true of the temperature curves of Fig. 8. In the latter case, however, the differences are harder to pin down

because of inaccuracies introduced in differentiating the pressure curves to obtain temperatures. Havens estimates that the pressure measurements permit the determination of an average temperature for a layer 20 km thick correct to within ±10K. The error for a 10-km layer would be on the order of ±20K. The curves of actual temperature variation with altitude must, therefore, be regarded as only indicative.

The double hump on curve (5), Fig. 8, appears to be real. Its presence was suspected in the reduction of data on other flights, and strongly suggests two distinct heating processes. The lower hump is due to ozone absorption in the ultraviolet above 2000 A. The upper hump may be due to oxygen absorption in the ultraviolet below 2000 A.

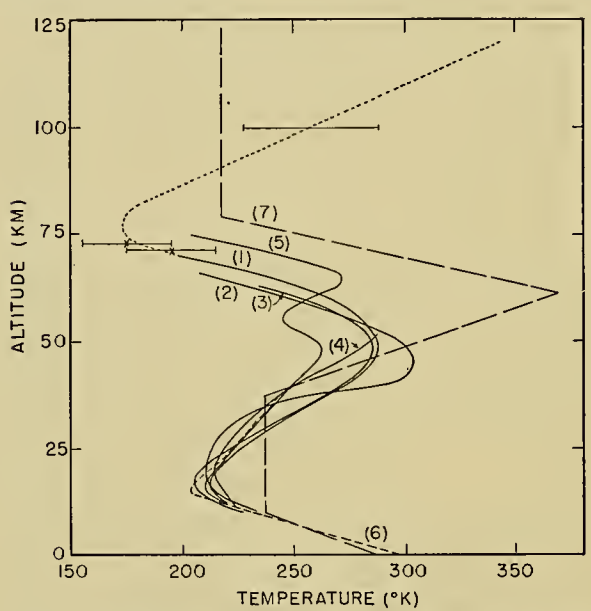

Fig. 8.—Temperatures calculated from pressures measured on rocket flights above White Sands Proving Ground, New Mexico. The points indicated by × with their probable errors are temperatures calculated from the ratio of stagnation pressure at the nose of the rocket to ambient pressure. Sea-level composition is assumed throughout. The curves in the drawing are: (1) 7 March 1947, 1123 MST; (2) 22 January 1948, 1313 MST; (3) 5 August 1948, 1837 MST; (4) 28 January 1949, 1020 MST; and (5) 3 May 1949, 0914 MST (taken from [10]). Also shown are: (6) Balloon flight shown in Fig. 1; and (7) Temperature distribution assumed by Pekeris for calculation of atmospheric oscillations (taken from [14] Pekeris: *Proc. roy. Soc.*,(A) 158: 653 (1937), by permission of The Royal Society).

The increase above 80 km indicated by the dotted extension of curve (1), Fig. 8, was drawn so as to have the average value of about 260K between 80 and 120 km. This average value, indicated at the 100-km level, is the sole calculated point on which the dotted portion of the curve is based. The heating of this atmospheric level is possibly due to absorption of solar X-radiation such as that recently discovered in V-2 flights by T. R. Burnight.

Temperatures and Pressures at Extreme Altitudes

Rocket measurements [1, 2, 10] and Cox's sound propagation studies [5] indicate a continually increasing temperature above the minimum near 80 km. The former measurements extend to about 130 km, and the latter to about 172 km, although Cox states that he places little faith in the highest point on his curve. According to Whipple a positive temperature gradient above 80 km is consistent with data from meteor studies. From the energy distribution in the nitrogen bands of the auroral spectrum Rosseland and Steensholt [17] report a temperature of 347K (at 110 km approximately), correcting a much lower value obtained earlier by Vegard.

It appears reasonable to assume a general temperature increase to great heights, with a corresponding lessening in the rate of decrease in pressure. For one thing, if the temperature were essentially constant above 100 km, the atmosphere at 400 km would be practically nonexistent, as a simple calculation will show, whereas observations of aurorae indicate appreciable densities at these heights. Secondly, helium appears to be escaping from the earth's atmosphere at a rate which requires temperatures on the order of 1000K between 600 and 800 km [13, pp. 21–24]. Thirdly, Babcock's measurements of the width of the night-sky line 5577 A indicate temperatures on the order of 1200K at several hundred km [13, p. 509].

In comparison with information available on the atmosphere below 100 km, data on temperatures and pressures at higher altitudes are meagre indeed. To be sure there is an appreciable amount of spectroscopic data; and ionospheric studies also indicate high temperatures in the ionospheric layers. Nevertheless, at present, conditions in the outer reaches of the earth's atmosphere are largely a matter of speculation.

Conclusion

Even a casual survey of the literature shows wide differences in the temperatures and pressures ascribed to the upper atmosphere. This is apparent in the limited selection of material presented above. Some of the differences can be traced to diurnal and seasonal effects and to geographical differences. Also atmospheric conditions are closely associated with conditions in the sun, which fluctuate continually. On the other hand, most of the methods of determining atmospheric temperatures and pressures cannot be proved free of systematic errors. The rather involved ozone calculations of Gowan and Penndorf, for example, and Whipple's meteor theory, contain many uncertainties which cannot be resolved without additional information. The most direct measurements are those made by balloons and rockets.

It would be worth while to compare critically the various methods of determining pressures and temperatures in the upper atmosphere, at least to point up systematic differences in the results. At present, accomplishment of such a comparison is hindered by lack of any single standard. To provide such a standard, data should be available from a single credible method covering different times and seasons and a wide range of geographical and solar conditions.

Because of their on-the-spot character, rocket meas-

urements appear to hold the greatest promise for determining conditions in the upper atmosphere. Recent improvements in technique and the lessons of past experience indicate that good results should be forthcoming in the next few years. With the mobility afforded by the Navy's *Norton Sound*, the measurements now being made at White Sands can be extended to widely separated parts of the world. The three branches of the Armed Forces are devoting considerable attention to this phase of rocket research in the upper atmosphere. Their efforts should aid materially in solving the temperature-pressure problem, at least for altitudes below 150 km. A critically comparative survey of the field is probably best left in abeyance until more work has been done both with rockets and with other methods.

A summary of current knowledge about atmospheric temperatures may be found from the N.A.C.A. Tentative Standard Atmosphere, drawn up in 1947. This curve was shown in Fig. 4 for comparison with Cox's sound propagation results. At the time it was constructed, the tentative standard was intended to be a rough average of data then available. The wide variation in temperature data was reflected in the upper and lower limits provided with the standard curve. Rocket results and Cox's sound propagation measurements, obtained since issuance of the standard, indicate that the temperatures should be lowered in the neighborhood of 55 km to less than 300K. The rocket measurements also reveal quite low temperatures near 80 km, perhaps as low as 180K. This is in keeping with temperatures required for formation of noctilucent clouds seen near 80 km in the higher latitudes. At present, however, the quantity of rocket data is too small, and the question of temporal, solar, and geographic influences too unsettled, to warrant changing the standard curve now.

Evidences of high temperatures, on the order of 1000K or more, at several hundred kilometers and above, were presented in the preceding section.

The best curves of pressure variation with altitude are probably those of Figs. 6 and 7, obtained from rocket soundings.

The rough sketch in the preceding paragraphs oversimplifies the true picture, as plainly it must, considering the large number of variables involved. None of the measurements to date are adequate to pin down small local phenomena which may exist. Mother-of-pearl clouds, for example, appearing at 22 to 30 km, indicate a region of cooling at the top of the stratosphere. It is not unlikely that such local temperature variations come and go with time. The double hump shown in the Viking temperature curve of Fig. 8 appears real. Hints of such a phenomenon were seen in the reduction of other rocket data. As pointed out above, the presence of the two maxima suggests the possibility of two types of atmospheric heating. Possibly the lower altitude maximum was due to ozone heating primarily, and the upper one to oxygen absorption of ultraviolet radiation below 2000 A. Then again, the phenomenon may be due simply to mass motions in the air. Certainly wind structure and temperature of the atmosphere are closely associated. In particular, the effect of mixing or lack of mixing upon composition of the air should influence atmospheric temperature-pressure relationships appreciably, although at present it appears that mixing below 80 km is adequate to prevent any significant diffusive separation of atmospheric constituents. Heating in the E-layer of the ionosphere may be caused by an influx of X-radiation from the sun.

Even a brief consideration of the complexity of the atmosphere serves to emphasize the need for an abundance of accurate data before a truly complete understanding of the atmosphere can be had. Specifically:

1.) Further flights with balloons to maximum attainable altitudes are highly desirable. Such flights should be made over as wide a range of time and geographical position as is possible.
2.) Extensive sound propagation studies in various parts of the world, with especial care to eliminate errors due to winds, should be made to obtain further temperature data.
3.) Rocket pressure-temperature measurements should be extended to reach different latitudes and to cover the various times of day and year.
4.) Whenever possible, the experiments listed above should be conducted at the same time and place, and the results from the three methods carefully compared.
5.) Absorption of terrestrial and solar radiations at the various altitudes should be measured in rocket flights to provide a basis for calculations of atmospheric heating. These measurements also should cover a wide temporal and geographical range.
6.) Rocket and balloon measurements of wind structure in the upper atmosphere are essential.
7.) Before the pressure-temperature problem in the upper atmosphere can be completely solved, atmospheric composition at the various altitudes must be determined. It is to be hoped that rocket soundings can aid in this.
8.) Eventually a careful, critical comparison of the various methods of determining atmospheric pressures, temperatures, and densities should be made to point up systematic differences, and to "calibrate" the different methods, so to speak. With the *Norton Sound* the Armed Forces may be able within the next several years to provide enough rocket data to form a standard for comparison. Needless to say, not only the methods discussed above, but also others, such as ionospheric and spectroscopic studies, should be included in the comparison.

WATER VAPOUR IN THE UPPER AIR

By G. M. B. DOBSON and A. W. BREWER

The Clarendon Laboratory, Oxford

INTRODUCTION

Water vapour in the upper air plays an important part in the dynamics of the atmosphere because (1) it is a source of atmospheric energy, (2) its presence affects the release of energy, (3) it is the origin of all hydrometeors, and (4) it is the main constituent of the lower atmosphere to absorb infrared radiation. In addition the water-vapour content of the air can be used in meteorological studies as a natural "tracer" element.

The importance of water vapour as a source of atmospheric energy has been discussed by Normand [12], but generally when the temperature is below about −20C the water vapour is not thermodynamically significant. All hydrometeors originate from the condensation of water vapour in the upper air, but the production of large amounts of rain or snow requires the larger vapour pressures, which occur only at temperatures above about −20C. Condensation at lower temperatures than this may be of importance in inaugurating the colloidal instability of a cloud whereby the liquid cloud droplets can fall as snow, but the quantities of water contributed by the regions of low temperatures will not usually be significant.

Measurements of the humidity of the free air have been made for many years using, for example, hair or goldbeater's skin hygrometers, or wet- and dry-bulb psychrometers, but these are useful only when the amount of water vapour in the air is large. We do not propose to discuss these phenomena, which are already well known.

For the remaining processes listed in the first paragraph, water vapour is important even if present in very small amounts, but since there has been no hygrometer capable of measuring very small water-vapour pressures, this field of study has received little attention. Since 1943 it has been possible, by a simple development of the well-known dew-point hygrometer, to obtain reliable measurements of the water content of the upper air at all levels which multiseated aircraft can reach, and a large number of measurements up to 12 or 13 km have been made by the Meteorological Research Flight of the British Meteorological Office.

No entirely reliable measurements of the distribution of water vapour at levels above about 13 km have yet been made, but the values obtained by Regener [14] appear to be very high.[1] The rare mother-of-pearl clouds which have been described by Störmer [17] are usually formed at about 25 km and appear to be very tenuous water clouds, which would indicate that at times the air may be saturated at these levels.

1. This was written before the results of Barrett, Herndon, and Carter [1] were available. Their results are discussed below.

THE MEASUREMENT OF WATER VAPOUR IN THE UPPER ATMOSPHERE

The difficulty of measuring the water-vapour content of the upper air lies in the extremely small amount of water vapour present, and sometimes even at moderate levels the air is too dry to permit measurement of its water content with ordinary hygrometers (see Fig. 9). One cubic metre of saturated air contains only 26 mg of water at a temperature of 220K, 1.6 mg at 200K, and 0.3 mg at 190K. Water-vapour densities of the order of 1 mg m^{-3} are found in the stratosphere over southern England. Since it is possible to deal with only a small fraction of a cubic metre of air, it will be realized how very small an amount of water or ice has to to be measured, and it is for this reason that most of the usual methods of measuring humidity fail when used in the upper air.

Glueckauf [8] showed that a very thin film of polyvinyl acetate containing a hygroscopic salt could be used as a very rapid hygrometer. The thickness of his films was about 0.1 μ; the films changed their thickness rapidly with changing relative humidity (with respect to *water*). If illuminated by monochromatic light, the thickness of the film could be estimated from the reflection coefficient. Unfortunately these films are very delicate, and the method has not come into general use Glueckauf [9] has also obtained humidity measurements at high levels by correcting the hair hygrometer of a Dines meteorograph for its lag.

Another possible hygrometer involves the use of a Wilson cloud chamber. Air with suitable nuclei is supplied to the chamber and expansions of increasing ratio are made until a fog is just formed. The first formation of a fog can be detected by the scattering from a strong beam of light passing through the cloud chamber. This method has not yet been fully developed, but tests made by Palmer [13] show that it should be effective down to a frost point of about 210K, below which the fog formed is too thin for convenient observation.

A method of measuring the water content of the high atmosphere which has some unique advantages is to measure the absorption of the sun's infrared energy by water vapour. Because of the very small amount of water vapour in the upper atmosphere it is necessary to use the 6.3-μ absorption band of water vapour since, except for the absorption band at 2.7 μ, the bands of shorter wave lengths have absorptions which are too small. The 2.7-μ band is confused with a CO_2 absorption band and cannot be used.

The absorption gives information about the total amount of water vapour above the height of observation, and the vapour pressure at various levels must be obtained by differences. If these differences can be com-

pared with frost-point hygrometer measurements made at the same time, they should provide a useful check on the infrared absorption data. The method is being developed by G. B. B. M. Sutherland and R. M. Goody at Cambridge, England.

Simon [16] has suggested that enough air to allow accurate analysis could be condensed in a small container cooled in liquid hydrogen and carried by a balloon to the height at which the sample is to be collected. This method is now being developed by F. E. Simon and A. J. Peckover at Oxford.

The dew- or frost-point hygrometer has been found satisfactory even at low temperatures. It has the great practical advantage that it needs only a very simple calibration, since all that is required is the temperature of the thimble when a thin deposit of hoarfrost is neither increasing nor decreasing. At −80C it is necessary to detect deposit changes of the order of 10^{-8} grams of ice, corresponding to a uniform deposit on the thimble surface of the order of thickness of one atomic diameter. This is not impossible because the ice is deposited as a large number of small crystals which scatter light very efficiently, so that changes in the deposit can be detected by changes in the light which it scatters. This will be understood, since only 10^{-10} grams is equivalent to 1000 crystals each 0.4 μ across. With proper instrument design the change in the deposit can be detected by eye, though the observations are difficult when the frost points to be measured are below about 200 to 210K. A photoelectric method of estimating the amount of light scattered by the deposit, though more complicated, is usually preferable.

DESIGN OF A FROST-POINT HYGROMETER

Three types of instruments have been employed in Great Britain: (1) an instrument in which the deposit is observed visually, and the cooling of the thimble performed manually, (2) an instrument in which the amount of deposit is indicated photoelectrically, and the cooling operated by hand, and (3) an automatic instrument in which the thimble is held constant at the frost point.

If the instrument is to measure the frost point of very dry air accurately (*e.g.*, frost points down to 190K), there are certain conditions which must be observed:

1. *Air Supply.* A constant source of trouble, when measuring very dry air, is the possibility that the air might pick up water vapour from the walls of piping leading to the hygrometer. In aircraft observations this error is guarded against by passing a large and rapid current of air through the tubing leading to the hygrometer. Most of this air passes out of the aircraft again and only a small fraction is used in the hygrometer. The branch pipe actually leading to the thimble is kept very short.

2. *Determination of the Amount of Deposit.* As stated above, the only way in which it has been found possible to observe the very small deposit which is obtained with very dry air is to illuminate the surface of the thimble strongly and measure the light scattered by the deposit. The surface of the thimble must be highly polished so that little light is scattered by it. If the deposit is detected by a photoelectric cell, the light scattered into the cell by the clean thimble must be kept as small as possible, so that the additional light scattered by a faint deposit is as large a fraction as possible of the total light entering the photocell.

3. *Temperature Control of the Thimble.* For the hand-operated hygrometer the thimble has been cooled by cold petrol (cooled in a surrounding bath of petrol and solid CO_2), or by liquid air, forced as a jet against the hollow underside of the thimble. With suitable design it is easy to control the temperature of the thimble by varying the rate of pumping. An alternative—which is always used in the automatic hygrometer—is to cool the thimble by conduction to liquid air and to warm it by an adjustable heating current.

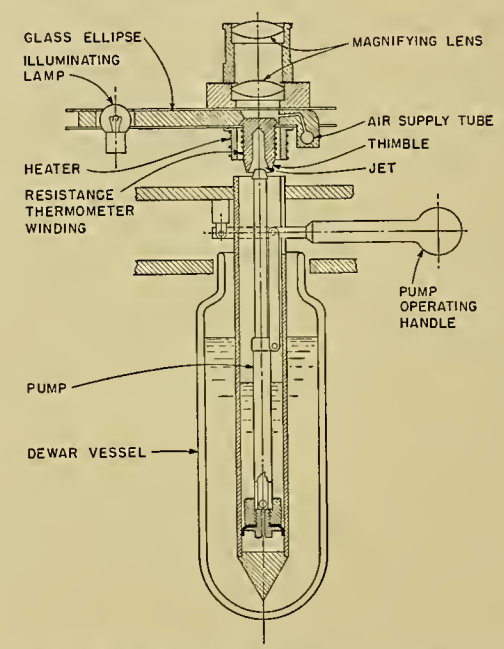

FIG. 1.—The frost-point hygrometer. A deposit of dew or hoarfrost on the top surface of the thimble is illuminated obliquely and observed by eye through a ×7 magnification. The thimble temperature is controlled by operation of the pump and measured by a platinum resistance wire wound on the thimble skirt. (*Reproduced by courtesy of the Royal Society, London.*)

In the automatic hygrometer the scattered light from the thimble is received by a photocell or photomultiplier. A second photocell or multiplier receives a constant small light from the same source which illuminates the deposit, and the difference of the photocurrents for the two multipliers is amplified. To avoid hunting, a differentiating circuit is usually necessary so that the final control of the heating current depends both on the amount of the deposit and on its rate of growth (or evaporation).

One of the difficulties with which an automatic hygrometer must contend is the very extended range of the absolute humidity of the air which it must measure. Also, the rate of growth of ice crystals decreases progressively at temperatures below about 218K, and for practical purposes crystals do not grow at temperatures

lower than 180K. Thus if the thimble should be cooled below this temperature, the ice will form as a glassy layer which scatters no light.

In using the eye-observation hygrometer it is essential that two thimble temperatures be found, one at which the deposit is slowly evaporating and the other at which it is growing equally slowly. The mean of the temperatures will be the frost point. Since a deposit will usually not form on a clean thimble until it is cooled to near the dew point, large errors will be made if the temperature at which the deposit is first seen is used. The temperature at which the deposit finally evaporates is also of no significance. With photoelectric indication of the amount of deposit, one can adjust the thimble temperature until the deposit indicator is steady and then read the thimble temperature, which gives the frost point directly.

Figures 1 and 2 show the general design of the types of hygrometer used in Great Britain [4, 6].

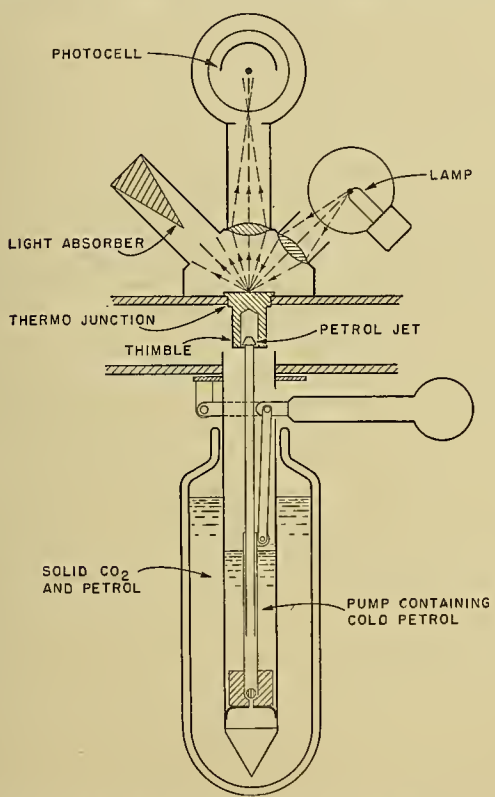

Fig. 2.—The frost-point hygrometer with photoelectric deposit indication. A deposit on the top surface of the thimble scatters light which is received by the phototube. The thimble is at frost point when a small deposit is neither growing nor evaporating. (*Reproduced by courtesy of the Royal Society, London.*)

THE RESULTS OF AIRCRAFT ASCENTS

The measurements which have so far been made show that wide variations of relative humidity occur in the atmosphere, and any relative humidity between 30 and 90 per cent, with respect to ice, is about equally common. Relative humidities of about 5 per cent are relatively frequent, and the lowest which has yet been observed is 0.65 per cent. This humidity was observed at an air temperature of 266K and a frost point of 219K. It is characteristic of the frost-point hygrometer that even low humidities of this kind can be measured precisely. If the relative humidity were, say, 0.75 per cent, this would correspond to an increase in the frost point by one degree centigrade to 220K, which could be measured quite readily. A similar relative humidity, 0.65 per cent, has also been observed in the stratosphere with an air temperature of 225K and a frost point of 189K, but this could not be measured so precisely. Supersaturation with respect to ice is a relatively frequent occurrence, but supersaturation with respect to supercooled water has not been observed.

Comparison with Radiosonde Measurements. The comparison of radiosonde humidity measurements with humidity measurements made by a dew-point hygrometer is difficult because the air is often patchy and any differences may not be instrumental unless the ascents are made at the same time and place. Two ascents have been made by Brewer and Harrison [5] in which the aircraft from which the dew-point measurements were made circled the ascending radiosonde which had a goldbeater's-skin hygrometer. The two ascents are shown plotted as relative humidity against height in Fig. 3.

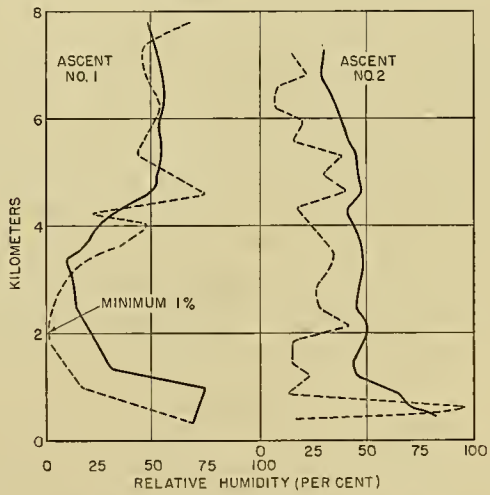

Fig. 3.—Comparison of humidities as measured by frost-point hygrometer (broken curve) and Kew pattern radiosonde (solid curve). The aircraft from which the frost-point hygrometer measurements were made circled the balloon, which was operated at reduced lift. (*Reproduced by courtesy of the Physical Society, London.*)

It will be seen that the radiosonde very greatly smooths the curves and in ascent No. 1 does not show the dry layer at 2 km where the lowest humidity is 1.0 per cent. Below 1 km the difference between the radiosonde and the aircraft hygrometer is due to the presence of broken cloud layers. The aircraft was flown through the dry air between the clouds, but a balloon tends to become entrained in clouds.

The Lower Stratosphere. In the ascents which have so far been made into the stratosphere (about seventy, all in southern England), the frost point generally falls with height in the region of the tropopause, but immediately above the tropopause there is an increase in the rate of fall, and one or two kilometres above the tropo-

pause the air normally has a frost point of about 190–200K and a humidity with respect to ice of 2 or 3 per cent. The effect is normally striking and consistent. An ascent is shown in Fig. 5, and a mean curve (due to Shellard [15]) of the results so far available (southern England) is shown in Fig. 4.

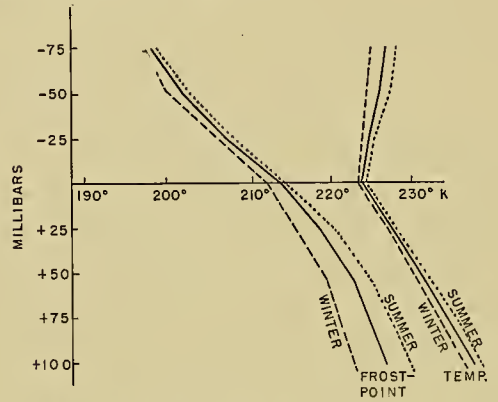

Fig. 4.—Mean variation of temperature and frost point with height above and below the tropopause, for southern England. All data so far available. (*Curve due to H. C. Shellard* [15].)

This effect had been predicted by Jaumotte [11], but other workers on the radiation balance of the lower stratosphere had assumed that the stratospheric air would be at or near saturation. The relative importance of water vapour in the radiation balance of the stratosphere is therefore much less than has usually been supposed. Dobson [6] has, for example, suggested that as a result of the small amount of water vapour present, the carbon dioxide and the ozone, which also take part in the radiation processes, may be equally important and that the radiative equilibrium may be determined by the relative amounts of these gases present.

If we consider the water vapour as a "tracer," it is difficult to give a satisfactory explanation of the presence and origin of the extremely dry air of the stratosphere. Since the dry air is consistently found with upper winds from all directions, it seems certain that the effect occurs in all temperate latitudes, and probably in polar regions also. Photolysis of the water vapour at these relatively low levels seems unlikely, for if it occurred, the reaction would be well known. If the photolysis occurs at high levels, it is difficult to see why the transition to dry air should be as low as 10 or 12 km.

The temperature at the equatorial tropopause, which is the lowest temperature found in the atmosphere, is about 190K and all the results so far obtained might be explained by assuming that the air is dried there, the excess water being condensed out at the low temperatures. Cwilong [6] has stated that at very low temperatures condensation occurs in the form of large ice crystals which would fall out easily.

Air which has been dried to a frost point of about 190K at the equatorial tropopause can then be brought to the polar or temperate stratosphere either (1) by ordinary advection parallel to the tropopause, or (2) by a zonal circulation in which air rises at the equator, enters the stratosphere, and moves to higher latitudes where it sinks into the troposphere. These processes may, of course, occur together in any proportion. Whatever the process, it must be considered in conjunction with the work of Glueckauf and Paneth [10], who found that up to 20 km the proportion of helium in the atmosphere was constant to within ½ per cent (the accuracy of their measurements). This suggests that turbulent mixing in the stratosphere is enough to maintain the composition of stratospheric air constant, at least up to 20 km, as otherwise the helium concentration would increase rapidly at high levels. The water-vapour results, on the other hand, suggest intense stratification.

It seems unlikely that the water-vapour distribution is maintained by the advection of dry air from the equator without the assistance of large-scale but slow zonal overturning, for it should be noted that the flow would have to be parallel to the tropopause, and there seems no obvious reason for this. Also, in the absence of large-scale vertical motions, turbulence is required to maintain the constancy of the helium content, and on these, and other grounds, the value of K (the diffusion coefficient) in the lower stratosphere would be expected to be at least 10^3. In this case, to maintain the shape of the observed vapour pressure versus height profile, it would be necessary for the air to be redried at the equator every twenty or thirty days. Since the potential temperature of the air at the equatorial tropopause is at least 20C higher than at the tropopause over England, it would be necessary for the air to be cooled by radiation at a rate of one or two degrees centigrade per day during its journey from the equator; this rate seems improbably high.

A mean zonal overturning in which air entered the stratosphere via the equatorial tropopause in a slow but roughly continuous motion would simultaneously maintain the dryness of the stratosphere and would prevent gravitational settling out of the helium. An extremely slow circulation would suffice to account for the observed distribution of helium, and the "water-vapour–height" curves would be maintained against the effects of diffusion ($K = 10^3$), with a circulation rate such that the mean time taken for the journey from the equator is about six months, and with a mean subsidence rate in the stratosphere over England of about 30 m per day. This would require radiative cooling of the air in temperate and polar latitudes of 0.3C per day. On the other hand, zonal overturning does not enjoy current favour and on dynamical grounds it is generally believed to be impossible, except in regions of zero or negative absolute vorticity. Thus the water-content observations raise the whole problem of the origin of the stratosphere, first because radiation conditions are drastically changed by reducing the available radiating water vapour, and second because it seems unlikely that the dryness of the air can be maintained without significant dynamic movements. If these dynamic movements occur, they will affect the temperature by adiabatic compression or expansion and the basic assumption of a stratosphere in radiative equilibrium may have to be abandoned. These points have been discussed by Brewer [2].

Results of a balloon ascent to 30 km, which included dew- or frost-point measurements, have been given by Barrett and others [1] and other successful ascents have since been made. They have observed an increase of humidity mixing ratio with height in the stratosphere in the summer and a decrease in the winter. A moist layer has also been observed, but only a single layer and not a double layer as reported in their note. This work will be watched with great interest.

On thermodynamic grounds, kinetic energy cannot be released in the atmosphere, except where low temperature is associated with low pressure. In the stratosphere, therefore, the complex dynamic movements which occur in the troposphere would not be expected as the energy for them is not available. The explanation of the shallow moist layer which Barrett found at 16 km will therefore be of special interest. The difference between summer and winter rather suggests that the low temperatures now known to occur in the stratosphere over the poles in winter may be a factor in maintaining the dryness of the stratosphere.

The Tropopause. It was first suggested by Gold that the air at and immediately below the tropopause would be substantially saturated. Observations now show that the actual humidity is highly variable. Its average value is about 50 per cent. The lowest relative humidity observed at the tropopause is 3 per cent. When high humidities, including supersaturation with respect to ice, occur, the temperature is usually low enough for dens- or persistent condensation trails to be formed by aire craft. A simple account of the relation between aircraft condensation trails and the humidity and temperature of the air has been given by Brewer [3]. When humidity observations are being made, the condensation trails formed by the aircraft should always be noted, as they are a most useful check on the observations.

Low relative humidities at or just below the tropopause could be due to a recent sinking movement of the tropopause, in which the air at the tropopause, and possibly in the stratosphere as well, moved downward. This process has often been suggested to explain the low tropopause heights which are found to the rear of depressions. The low humidities could also be caused by the incorporation of a substantial volume of stratospheric air into the upper troposphere.

It may be mentioned that the reverse process, the incorporation of moist tropospheric air into the stratosphere, must be quite rare over southern England. The stratosphere air is so very dry that a small admixture of air from the troposphere would raise its frost point markedly.

The Troposphere. In the troposphere the water-vapour distribution is extraordinarily complex. The atmosphere can be very moist, very dry, or very variable with intense stratification. The structure of the water-vapour distribution presumably arises from the complex dynamic movements which occur in the atmosphere, and these are too poorly understood at present to permit a clear explanation of any particular observed distribution. The purpose of this section will be to present a small selection of the ascents which have so far been made, to indicate the usefulness of dew-point observations as a technique for dynamic investigation, and to show how the dew-point curve shows features which are otherwise difficult to identify. At present only isolated ascents have been made, and no analysis on a synoptic basis is possible.

Subsiding Polar Air, May 3, 1944 (Figs. 5*a* and 5*b*). This ascent shows strongly subsiding polar air behind a vigorous depression. The surface synoptic situation is shown in Fig. 5*b*. The convective friction layer of moist air extends to about 820 mb, but at 800 mb the relative humidity is 5 per cent and cloud development is suppressed by the dryness of the air. The upper air is so dry that there is only about 0.2 mm of precipitable water in the whole atmosphere above 800 mb.

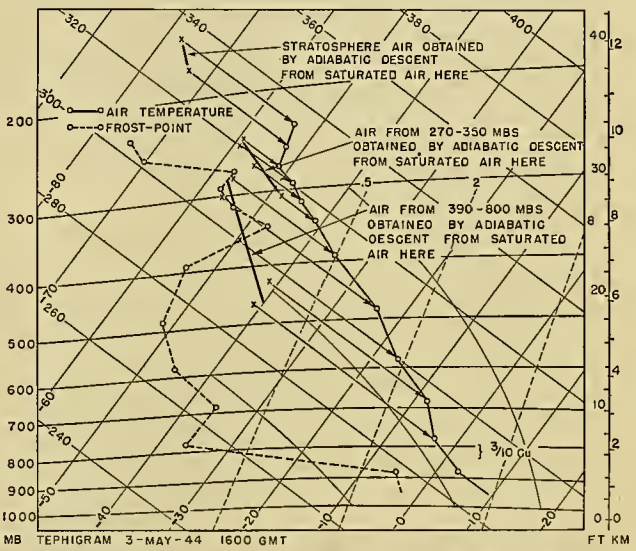

Fig. 5*a*.—Typical frost-point hygrometer ascent in strongly subsiding polar air (1600 GMT, May 3, 1944). Ascent made over northeast England, at approximately 54°N 0°W.

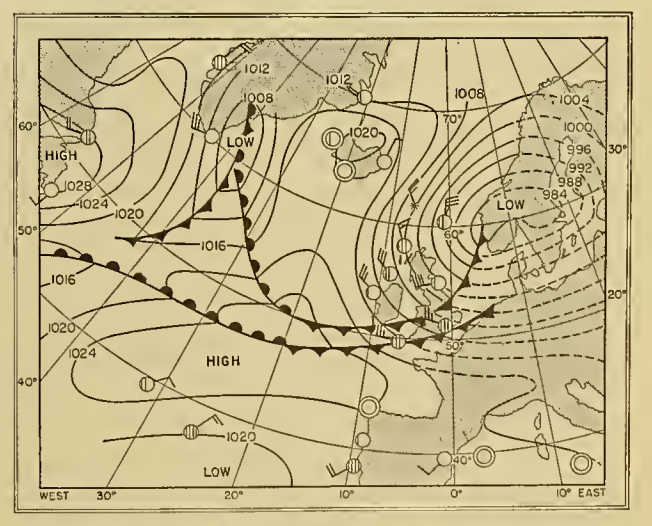

Fig. 5*b*.—Sea-level synoptic chart at about 0600 GMT, May 3, 1944.

Except for the shallow layer at 345 mb all the air above 600 mb has a lower humidity mixing ratio than would correspond to saturation at the tropopause, while the observations at 345, 700, and 800 mb show that at these levels the air is only slightly more humid.

If we assume that all the air was saturated and has moved continuously downward during any recent dynamic movements, during which entropy and humidity mixing ratio have been conserved, we may compute, for each observation, the level from which the air has subsided. This is shown in Fig. 5*a* in which the temperature-pressure levels from which the air has subsided are shown joined to the corresponding observed temperatures by isentropic lines. It will be seen that there is a sharp discontinuity in the nature of the source air mass between 345 and 400 mb, the air above 345 mb presumably being warm air and the air below 345 mb polar air, most of which has subsided strongly. It should be noted that the demonstration of this feature depends entirely upon the water-vapour measurements. The temperature-height curve does not indicate any significant change in the layer between 345 and 400 mb or in any other layer.

The thermal stability of the polar air mass from which the present air mass is derived is to be noted. This stability may be due to the cooling by radiation of the lower parts of the subsided polar air, and radiative adjustments of temperature may be the cause of the smoothness of the temperature-height curve. Alternatively, the air now found at the level of 600 to 800 mb may have originated from relatively farther north, so that the coldest air has been selected for the greatest subsidence. On thermodynamic grounds it is to be expected that the coldest air would subside most strongly. There is little doubt that all the processes of the atmosphere are not adiabatic, as may be seen from the observations in the stratosphere. The apparent source from which the stratospheric air could have been obtained (by adiabatic compression from saturated air) is shown in Fig. 5*a*, but this is a temperature-pressure relation which is not known to occur in the atmosphere.

The Water-Vapour Structure of an Anticyclone. During March 1945 an anticyclone persisted over Europe, its central position varying between the limits of southern England and southern France. Several ascents were made in the northern sector of this anticyclone. All the ascents showed a very sharp temperature inversion, the level of which varied from 900 to 800 mb, though it was most frequently found near 800 mb, higher than in most anticyclones. In the region of the inversion, and immediately above it, there was always a relatively dry layer, but this was usually only about 500 to 1000 m deep, with moister air above. The depth and dryness of this shallow layer varied considerably from day to day. One ascent (March 21, 1945) which showed this dry layer very strongly has already been published [6]. As further examples, two additional ascents (March 18 and March 20, 1945) are shown in Figs. 6 and 7 together with the corresponding sea-level and 500-mb charts. On March 18th the dry layer at the inversion

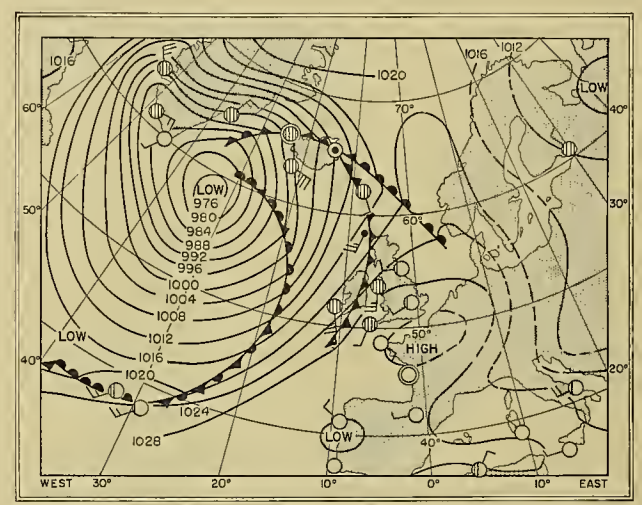

Fig. 6*b*.—Sea-level chart at about 0600 GMT, March 18, 1945.

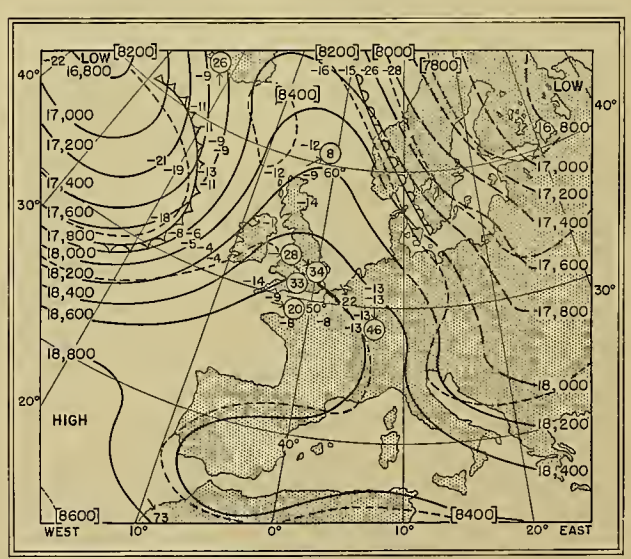

Fig. 6*c*.—Contour chart from 500 mb at 0600 GMT, March 18, 1945. Contour heights are given in feet and temperatures in degrees Fahrenheit. Figures in circles are wind speed in knots. Broken curves show isopleths of thickness of the layer 750–500 mb.

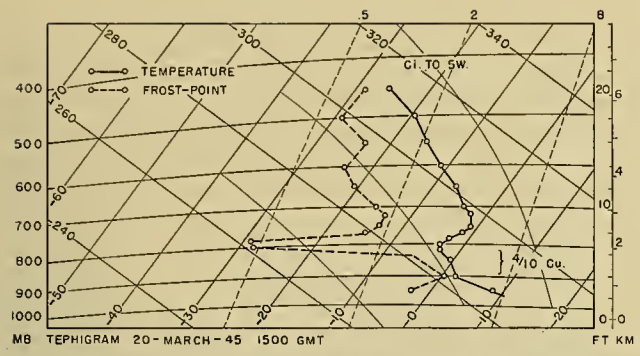

FIG. 7*a*.—Ascent in an anticyclone, March 20, 1945. Ascent made over southern England at approximately 51°N 2°W.

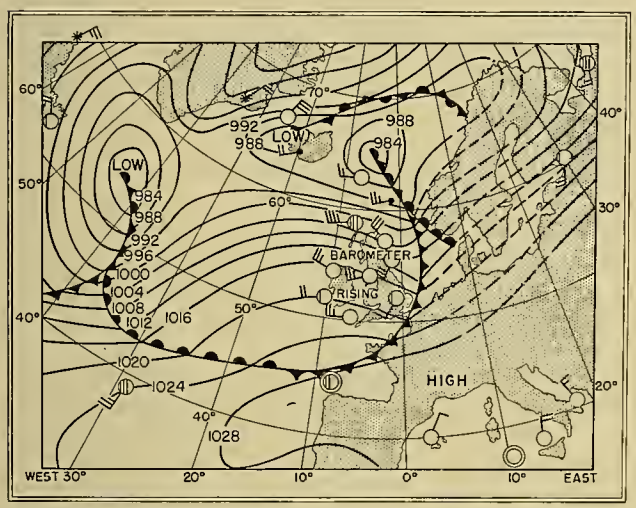

FIG. 7*b*.—Sea-level chart at about 0600 GMT, March 20, 1945.

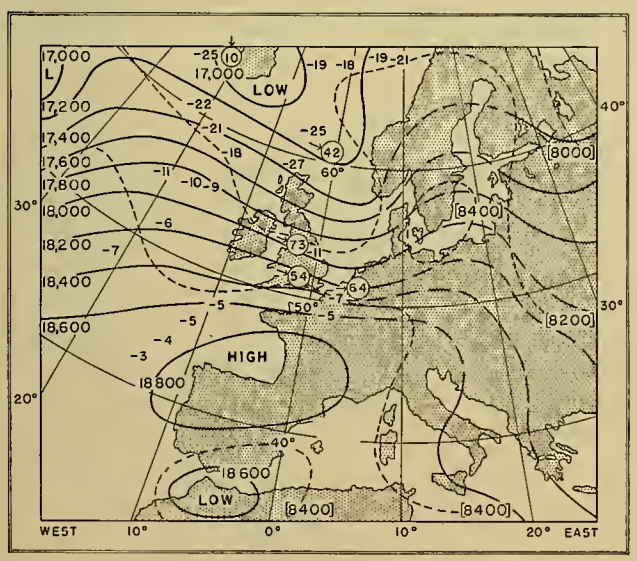

FIG. 7*c*.—Contour chart for 500 mb at about 0600 GMT, March 20, 1945. Contour heights are given in feet and temperature in degrees Fahrenheit. Figures in circles are wind speed in knots. Broken curves show isopleths of thickness of the layer 750–500 mb.

was shallow and weak and the air above was quite dry, particularly at 550 to 600 mb, where the frost-point depression was 32C. On March 20th, the dry layer at the inversion was well marked and it was accentuated by the moistness of the air above. If the surface synoptic charts are compared, the ascent of the 18th is seen to have been made in a weak warm sector with falling barometer, while the ascent of the 20th was made in a ridge. This would seem to contradict the relative dryness of the upper air on the 18th. On the 500-mb charts, however, the position is reversed. The dry air observed on the 18th between 700 and 500 mb is seen to be in an upper-air ridge, while the moister air of the 20th is in an upper-air trough.

Figures 10*a* and 10*b* give another example of an ascent in an anticyclone.

Intrusion of Moist Air Tongues into Dry Air. The ascent of June 7, 1943 (Fig. 8*a* with the surface synoptic chart Fig. 8*b*) was made in a ridge in advance of a weak frontal system which is shown on the charts as having a double structure. The nature of the frost-point

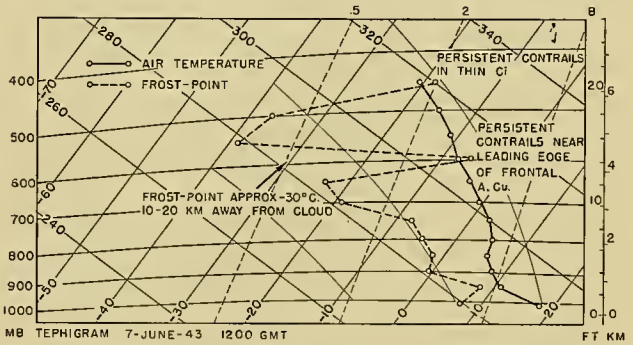

FIG. 8*a*.—Ascent showing moist air tongue intruding into dry air, 1200 GMT, June 7, 1943. Ascent made over southern England at approximately 51°N 2°W.

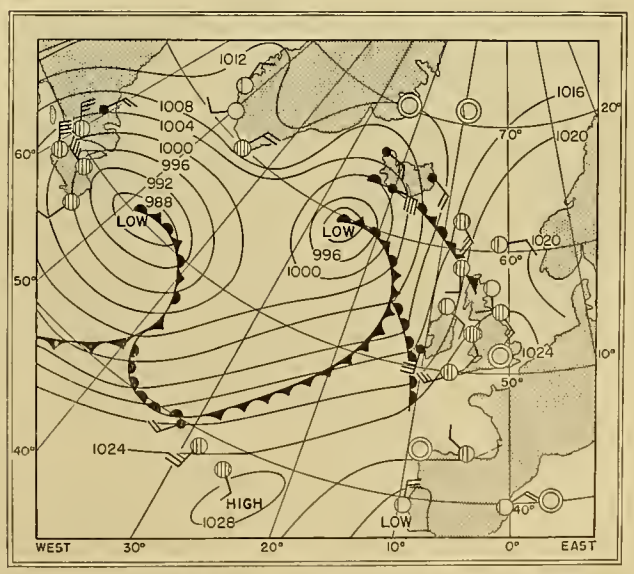

FIG. 8*b*.—Sea-level synoptic chart for approximately 0600 GMT, June 7, 1943.

curve is to be noted. At 600 mb, within one or two kilometres of the leading edge of a sheet of frontal altocumulus, the air was supersaturated with respect to ice, the observed supersaturation being confirmed by the formation of persistent condensation trails by the aircraft. At the same level, but 10 or 20 km from the cloud sheet, the air was dry with a frost-point depression of about 22C and a relative humidity of about 13 per cent, substantially on the smooth curve of the environment. The supersaturation with respect to ice at 450 mb is also to be noted.

Very Low Relative Humidities. Air of relative humidity as low as 1 per cent is occasionally found over southern England in ordinary subsiding polar maritime air, but the lowest relative humidity we have observed, 0.65 per cent, was at 800 mb on January 17, 1946, in air which was an outflow from a strong continental winter anticyclone (Figs. 9*a* and 9*b*). On that day the general structure of the overrunning moist air was shown by all the radiosonde ascents in southern England, though the details vary. The moist air is of Mediterranean origin.

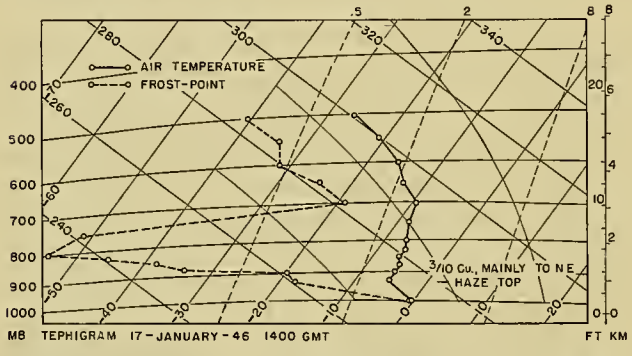

Fig. 9*a*.—Very dry air in a continental winter anticyclone, 1400 GMT, January 17, 1946. Ascent made over southern England at approximately 51°N 2°W.

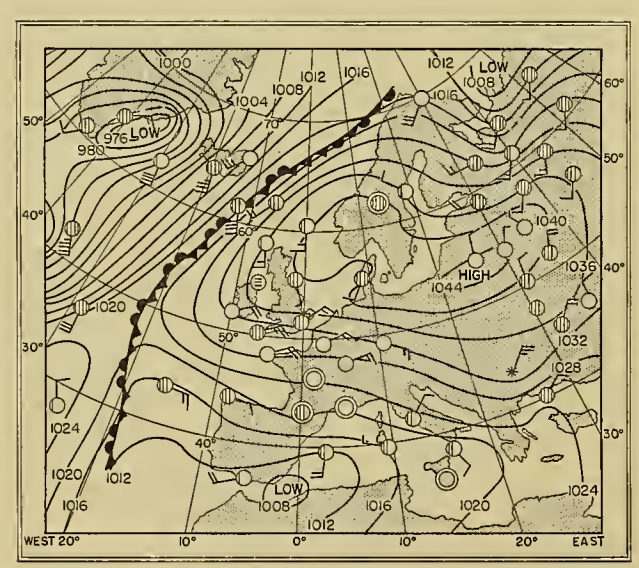

Fig. 9*b*.—Sea-level synoptic chart for approximately 0600 GMT, January 17, 1946.

The dry air could have originated from saturated air by adiabatic compression from a level of 350 mb at 212K. If water vapour had diffused into the layer then its origin would be higher and colder. It is possible that the air had originated from within the stratosphere and that the additional water vapour required, 18 mg m^{-3}, had diffused into it. It would then be necessary for the air to have cooled by radiation to its present potential temperature.

Small-Scale Temperature and Humidity Patterns in Free Air. Frith [7], using a frost-point hygrometer, has made careful investigations of the detailed temperature and humidity structure in the free air both in a horizontal and in a vertical plane. In a horizontal plane he finds evidence for the existence of closed temperature and humidity patterns on a scale of tens of miles and some similarity between the temperature and humidity isopleths; low frost points tend to be associated with high air temperature and vice versa. While the temperature variations are normally only of the order of one degree centigrade, the frost-point variations may be up to 15C.

Similarly, in the vertical plane, when strong strati-

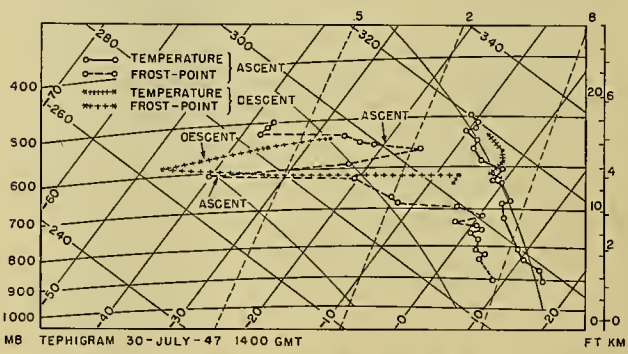

Fig. 10*a*.—Variation of observed conditions with position. Observations during ascent and descent showing changes, 1400 GMT, July 30, 1947. Ascent over southern England at approximately 51°N 1°W. (*By R. Frith.*)

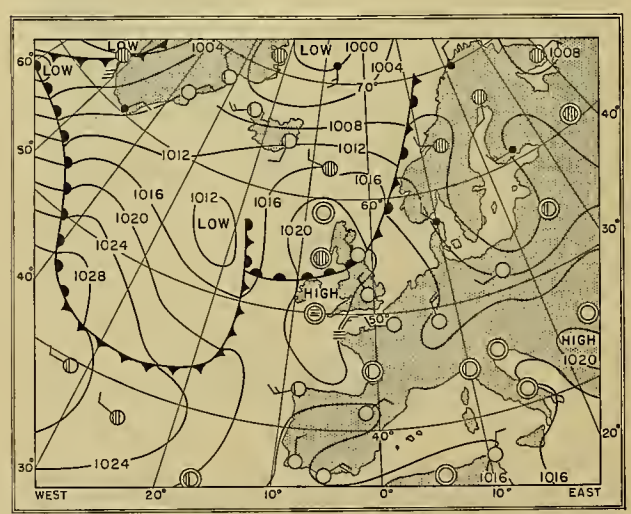

Fig. 10*b*.—Sea-level synoptic chart for approximately 0600 GMT, July 30, 1947.

fication of the water content is observed, the temperature variations from a smooth temperature-height curve are only about $\frac{1}{10}$ or $\frac{1}{20}$ of the variations shown in the frost-point–height curve. As in the horizontal plane, low frost points tend to be associated with relatively high air temperatures.

It is the writers' experience that the atmosphere is extremely variable in this respect; the structure is sometimes relatively simple but sometimes very complex. Figure 10, for July 30, 1947, shows measurements on both ascent and descent through a dry layer. As might be expected, the height and detailed structures change between ascent and descent, there being a difference in both the time and place.

FUTURE WORK

Only data collected by the Meteorological Research Flight and by Barrett and collaborators are at present available, and only a very few ascents with accurate humidity measurements have yet been published.

Experience in England has shown that almost every ascent is of great interest, and features are frequently observed which are difficult to explain. There is an urgent need for more observations in every part of the world in all types of weather and particularly on a synoptic basis, mainly to permit a systematic study of the widespread and fundamental phenomena of subsidence. The structure of anticyclones, both warm anticyclones and also winter continental anticyclones such as the Siberian High, will prove of interest. The higher tropopauses which occur in warm anticyclones have not yet been investigated in England because they are beyond the ceiling of the Mosquito aircraft used. The scope for the useful collection of observational data is believed to be world wide. Meteorologists will also have to learn to use and appreciate the data.

On the instrumental side the eye instrument is very satisfactory as a reliable instrument which will get results, but the observational skill required will inevitably restrict its use. A fully automatic hygrometer for widespread use is urgently needed, but the development of such an instrument is a difficult problem and will not easily be solved. It is also hoped that alternative methods, such as the spectroscopic method, or the method of Simon and Peckover, will be pursued.

We are greatly indebted to the Director of the British Meteorological Office for permission to reproduce unpublished data obtained by the Meteorological Research Flight of the Office. Figures 1 and 2 are reproduced from the *Proceedings of the Royal Society* by permission of the Council. Figure 3 is reproduced by permission of the Physical Society, London. The synoptic charts are reproduced from the appropriate British Daily Weather Reports by permission of the Controller of His Britannic Majesty's Stationery Office and the Director of the Meteorological Office. DIFFUSION IN THE UPPER ATMOSPHERE

By HEINZ LETTAU

Geophysics Research Division of the Air Force Cambridge Research Center

FUNDAMENTALS OF THE THEORY OF DIFFUSION

1. General Remarks. The kinetic theory of gases defines diffusion as the average motion of selected molecules relative to other molecules. The physical units of diffusion are number per square centimeter per second, that is, diffusion velocity times number of selected molecules per cubic centimeter. Diffusion depends on the composition of the gaseous mixture. A classical model considers two sets of molecules of different mass, effective diameter, and velocity distribution. The theory of diffusion results in complicated equations, even in the simple case of binary mixtures in a closed system when the physical state is well defined.

Pure, dry air is more complex than a binary mixture. Water (vapor, liquid, solid) and particulate matter (nuclei, smoke, dust) complicate the composition of the atmosphere. The atmosphere is not a closed system and the physical state beyond the scope of soundings is uncertain in many respects [35]. Sources[1] and sinks[2] of constituents must be considered. Large- and small-scale atmospheric motions produce eddy diffusion.

Diffusion equilibrium results when molecular and eddy diffusion balance the effects of forces acting on the molecules or the effects of sources and sinks so that the composition is a steady function of height or of height and the horizontal coordinates. Time variations of composition result from variations of the physical state—especially of motion and turbulence—and from intensity variations of sources and sinks of certain constituents.

Because of the scarcity of direct observations, the problems of diffusion in the upper atmosphere were developed theoretically and on the basis of conjecture. In this article, the author has tried to point out the inadequacies of the field by thoroughly outlining the assumptions necessary for a mathematical analysis of atmospheric diffusion. In general, applications of the theory must be confined to the lowest 200 km. Future work will be more promising when theoretical research can be supported by more and better observations from the stratosphere and ionosphere.

2. Molecular Diffusion. The study of nonuniform gases by Chapman and Cowling [4] resulted in the following general equation of diffusion velocity in a binary gas mixture:

$$\mathbf{c}_1 - \mathbf{c}_2 = -d_{12}\left\{\frac{\nabla\nu_1}{\nu_1\nu_2} - (\mu_1 - \mu_2)\nabla \ln p + \frac{m_1 m_2}{mkT}(\mathbf{F}_1 - \mathbf{F}_2)\right\} - d_T \frac{\nabla \ln T}{\nu_1 \nu_2}. \quad (1)$$

1. Gas and particle production of the lithosphere and hydrosphere, volcanic activity, photochemical reactions, industrial processes, etc.

2. Outflow of light gases into space, condensation, sedimentation, coagulation, recombination, etc.

The symbols in equation (1) are explained in Table I.

Table I. List of Symbols

The subscript s denotes one constituent of the mixture; for a binary mixture, $s = 1$ and 2. The rectangular coordinates x, y, and z are oriented so that z is positive towards the zenith. The unit vectors $\mathbf{i}$, $\mathbf{j}$, and $\mathbf{k}$ are in the directions x, y, and z.

Constituent gases

$\mathbf{c}_s = c_{sx}\mathbf{i} + c_{sy}\mathbf{j} + c_{sz}\mathbf{k}$ = vector of mean molecular motion
n_s = number of molecules per cm³
m_s = mass of the molecule
p_s = hydrostatic partial pressure
$\mathbf{F}_s$ = external acceleration acting on the molecules
d_T = coefficient of thermal diffusion
d_{ss} = coefficient of self-diffusion

Gaseous mixture

$d_{12} = d_{21}$ = coefficient of mutual diffusion
$n = \Sigma n_s$ = total number of molecules per cm³ (Loschmidt's number) $= 2.705 \times 10^{19}$ at NTP
NTP = normal temperature and pressure
p = hydrostatic pressure; normal pressure = 1013 mb
T = absolute temperature; normal temperature = 273K
$\nu_s = n_s/n$ = number concentration
$m = \sum_s \nu_s m_s$ = mass of a fictitious average molecule
$\rho = nm$ = density of the mixture
$\mu_s = (m_s - m)/m$ = relative weight factor
$k = 1.372 \times 10^{-16}$ ergs per degree = Boltzmann's constant

Fundamental equations are Dalton's law:

$$p = \sum_s p_s , \quad (2)$$

and the equation of state:

$$p_s = n_s kT \quad \text{or} \quad p = nkT. \quad (3)$$

Equation (1) shows that the vector of diffusion velocity $\mathbf{c}_1 - \mathbf{c}_2$ has four constituents,

$$\mathbf{c}_1 - \mathbf{c}_2 = \mathbf{c}_d + \mathbf{c}_p + \mathbf{c}_F + \mathbf{c}_T ,$$

where $\mathbf{c}_d$ is ordinary diffusion velocity,
$\mathbf{c}_p$ is pressure diffusion velocity,
$\mathbf{c}_F$ is forced diffusion velocity,
$\mathbf{c}_T$ is thermal diffusion velocity.

Experiments are usually based on ordinary diffusion due to initial nonuniform composition in a closed system, $\nabla\nu_s \neq 0$, when $\mathbf{c}_p$, $\mathbf{c}_F$, and $\mathbf{c}_T$ are neglected. In the atmosphere, pressure diffusion (an indirect effect of gravity since the direct effect of gravitational acceleration on all molecules is the same) must be considered; $\mathbf{c}_p$ is due to the gradient of $\ln p$ set up by gravity and/or rotation in compressible media. The most important example of forced diffusion is the effect of electric fields on the motion of ionized gases. Thermal diffusion results when different parts of the mixture are maintained at different temperatures; however, the degree of separation produced by $\mathbf{c}_T$ is small; experience has proven that $d_T/d_{12} \approx 0.1$ and decreases when n_2/n_1

decreases. Thus, $\mathbf{c}_T$ can be disregarded in the atmosphere in view of the smallness of $\nabla \ln T$.

Table II shows experimental d_{12}-values when one gas diffuses into pure air. Observations of d_{12} are difficult and are liable to experimental errors; this fact explains the discrepancies between the findings by different authors.

TABLE II. OBSERVED DIFFUSION COEFFICIENTS
(According to Chapman and Cowling [4])

Gaseous Mixture	d_{12} at NTP (cm² sec⁻¹)
H_2—air	0.616
O_2—air	0.178
CO_2—air	0.138

Theoretically, d_{12} does not vary with the proportions of a binary mixture. There exist only approximate expressions for d_{12}, the degree of approximation being determined by the assumptions of the nature of molecular encounters. For atmospheric diffusion, it is sufficient to study the model of rigid, elastic, spherical molecules of effective diameter σ_s. Then, the kinetic theory results in

$$d_{12} = \frac{3}{4n(\sigma_1 + \sigma_2)^2}\sqrt{\frac{2kT(m_1 + m_2)}{\pi m_1 m_2}}\ \text{cm}^2\ \text{sec}^{-1}, \quad (4)$$

where $\pi = 3.14159\ldots$. Equation (4) fails when air is one constituent of the binary mixture under consideration, since air itself is a mixture. It is a favorable circumstance that nitrogen dominates in the atmosphere, and that molecular nitrogen, N_2, abounds approximately up to 200 km above sea level. For the sake of clarity, atmospheric diffusion is defined as the motion of relatively small numbers of different gas molecules in the medium of an N_2-atmosphere. Only then can the laws of mutual diffusion be applied to the atmosphere, that is, the diffusion of different gases can be studied separately.

Consequently, $\nu_s \approx n_s/n_{N_2}$ = concentration by volume, $\mu_s \approx (m_s - m_{N_2})/m_{N_2}$, and $d_{12} = d_{sN_2}$. The quantity ν_s is a small variable number, $0 < \nu_s \ll 1$; μ_s is a constant for each gas, and d_{sN_2} is defined by equation (4). Table III lists the molecular properties of N_2 and other gases of the atmosphere. The relatively small differences between corresponding values of Tables II and III justify the foregoing assumptions at NTP. However, they must become dubious at levels above approximately 200 km.

TABLE III. MOLECULAR PROPERTIES AND DIFFUSION COEFFICIENTS OF ATMOSPHERIC CONSTITUENTS*

Gas	m_s (relative)	μ_s	$\sigma_s \times 10^8$ cm	d_{sN_2} at NTP (cm² sec⁻¹)		$\delta_s = d_{sN_2}/d$
				Equation (4)	Observed	
H_2	2.015	−0.93	2.5	0.67	0.67	3.7
He	4.00	−0.86	2.0	0.59	—	3.3
N	14.0	−0.50	1.4	0.45	—	2.5
O	16.0	−0.43	1.2	0.47	—	2.6

O_3	48.0	0.71	4.0	0.14	—	0.8
Kr	82.9	1.96	3.4	0.15	—	0.8
Xe	130.2	3.61	3.8	0.13	—	0.7

* Mass of the molecules $= m_s \times 1.66 \times 10^{-24}$ g; σ_s and observed d_{sN_2} values were averaged from tables in [4] and [15]. It is assumed that $\sigma_{O_3} \approx \sigma_{CO_2}$. The coefficient of self-diffusion $d_{N_2N_2} = 0.18$ is taken as the atmospheric standard coefficient d in the ratio $\delta_s = d_{sN_2}/d$.

3. Eddy Diffusion. In consequence of the assumptions referred to in Section 2, the diffusion velocity of a gas in the atmosphere equals $\mathbf{c}_s - \mathbf{c}_{N_2}$ when diffusion itself $= n_s(\mathbf{c}_s - \mathbf{c}_{N_2}) = n_s\mathbf{c}_s - n_s\mathbf{c}_{N_2}$. In order to measure diffusion on an absolute scale, the term $n_s\mathbf{c}_{N_2} = \nu_s n_{N_2}\mathbf{c}_{N_2}$ or the mean motion of the medium of diffusion must be investigated. For convenience, we express $\mathbf{c}_{N_2}$ by the instantaneous wind vector $\mathbf{V}_t$ which is a function of space and time.

The motion of the atmosphere is turbulent; irregular, random movements are superposed on the regular or representative flow $\mathbf{V}$ such that

$$\mathbf{V}_t = \mathbf{V} + \dot{\mathbf{V}}. \quad (5)$$

The vector $\mathbf{V}$ is an average with respect to time as denoted by the bar:

$$\mathbf{V} = \overline{\mathbf{V}_t}, \qquad \overline{\dot{\mathbf{V}}} = 0. \quad (6)$$

When $\nabla\nu_s \neq 0$ in an eddying medium, turbulent fluctuations of ν_s are created such that

$$(\nu_s)_t = \nu_s + \dot{\nu}_s\ ; \quad \overline{(\nu_s)_t} = \nu_s\ ; \quad \overline{\dot{\nu}_s} = 0. \quad (7)$$

If turbulent fluctuations of n_{N_2} are neglected,

$$\overline{n_s\mathbf{c}_{N_2}} = n_{N_2}\overline{\nu_s\mathbf{c}_{N_2}} = n_{N_2}(\nu_s\mathbf{V} + \overline{\dot{\nu}_s\dot{\mathbf{V}}}) = n_s\mathbf{V} + \frac{n_s}{\nu_s}\overline{\dot{\nu}_s\dot{\mathbf{V}}}. \quad (8)$$

Let the eddy diffusion-velocity be defined by

$$\mathbf{C}_s = \frac{1}{\nu_s}\overline{\dot{\nu}_s\dot{\mathbf{V}}}. \quad (9)$$

In order to separate the properties of the wind from the properties of the ν_s-distribution, a radius vector $\dot{\mathbf{l}}$ is introduced which is assumed to be independent of the special ν_s, that is,

$$\dot{\nu}_s = -\dot{\mathbf{l}}\cdot\nabla\nu_s\ , \quad (10)$$

Then,

$$\overline{\dot{\nu}_s\dot{\mathbf{V}}} = -\overline{\dot{\mathbf{V}}\cdot\dot{\mathbf{l}}}\nabla\nu_s, \text{ or } \mathbf{C}_s = -\frac{1}{\nu_s}\overline{\dot{\mathbf{V}}\cdot\dot{\mathbf{l}}}\nabla\nu_s, \quad (11)$$

where $\overline{\dot{\mathbf{V}}\cdot\dot{\mathbf{l}}}$ is the coefficient of eddy diffusion. Its components are

$$\overline{(\dot{\mathbf{V}}\cdot\mathbf{i})\,(\dot{\mathbf{l}}\cdot\mathbf{i})} \equiv D_x\ , \quad (12)$$

$$\overline{(\dot{\mathbf{V}}\cdot\mathbf{j})\,(\dot{\mathbf{l}}\cdot\mathbf{j})} \equiv D_y\ , \quad (13)$$

$$\overline{(\dot{\mathbf{V}}\cdot\mathbf{k})\,(\dot{\mathbf{l}}\cdot\mathbf{k})} \equiv D_z \equiv D. \quad (14)$$

The units of D_x, D_y, and D are cm² sec⁻¹ = length times velocity, the same as d_{sN_2} and d.

Let λ and ζ be lengths and velocities such that the product $\lambda\zeta$ equals a given diffusion coefficient. In molec-

ular diffusion, λ_d and ζ_d correspond to the mean free path and the average velocity of molecular motions. In eddy diffusion, λ_D is a length fixing the scale of turbulent displacements (mixing length), and ζ_D is a velocity fixing the speed of turbulent motions.

The differences between molecular and eddy diffusion are more obvious in terms of λ and ζ than in terms of d and D. The quantity ζ_d^2 corresponds to the internal energy or heat of a gas, while the energy for maintaining ζ_D^2 will be taken from external sources, such as the potential energy of the horizontal pressure distribution. The term λ_d is a unique function of the density of the atmosphere when λ_D depends on geometrical conditions like distances from bounding surfaces; the vertical mixing length is also affected by the vertical thermal stratification.

The value of D can equal that of d when $\lambda_d/\lambda_D = \zeta_D/\zeta_d$; however, this ratio is never unity. Differences between the mechanisms of diffusion are emphasized when time terms (λ/ζ) and acceleration terms (ζ^2/λ) are studied. Reasonable conditions—such as $\lambda_{d,D} < z$, $\lambda_D/\zeta_D < 1$ day, and $\zeta_D^2/\lambda_D < g$ when g = gravity—narrow a priori the variability of D-values. The diffusion diagram, Fig. 1, summarizes our present knowledge of

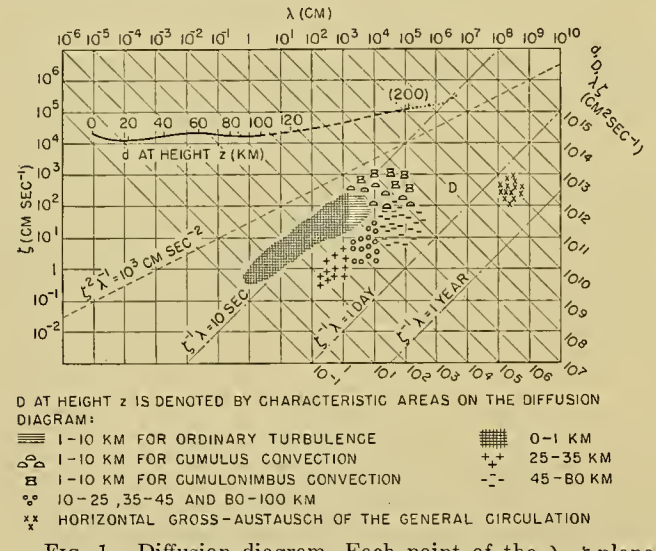

FIG. 1.—Diffusion diagram. Each point of the λ, ζ plane determines a diffusion coefficient (cm² sec⁻¹). In molecular diffusion, $\lambda \approx$ free path and $\zeta \approx$ mean molecular speed; $d = \lambda\zeta$ is fixed by the density and temperature of the atmosphere; consequently, the height variation of d is marked by a curve. In eddy diffusion, $\lambda \approx$ mixing length and $\zeta \approx$ mixing velocity; owing to the variability of these elements, $D = \lambda\zeta$ and its variation with height are denoted by characteristic areas when the possible variability of D is narrowed by the consideration of limiting values of eddy accelerations (ζ^2/λ) and time terms (λ/ζ).

molecular and vertical eddy-diffusion coefficients in the atmosphere. Values of D above 15 km and values of d above 100 km are not very reliable. Inasmuch as temperature and density are known, d_{sN_2} is a unique function of height. However, D will vary with height, weather, season, and latitude. Inasmuch as D is a statistical parameter, it will depend on the averaging process when λ_D/ζ_D is a measure of the minimum time interval required for the definition of representative values of wind and concentration ν_s .

4. The Equation of Atmospheric Diffusion. Let us define an atmospheric gas as "permanent" when there are no sources or sinks, as "neutral" when gravity is the only force acting on the molecules, and "at rest" when the vertical pressure distribution follows from the hydrostatic equation, $\partial p_s/\partial z = -n_s m_s g$. Let molecular nitrogen, as the medium of atmospheric diffusion, be a permanent, neutral gas at rest. Then, in equation (1), $\mathbf{F}_{N_2} = -g\mathbf{k}$ and $\mathbf{c}_{N_2}\cdot\mathbf{k} \equiv \mathbf{k}\cdot\mathbf{V} = 0$. However, $\mathbf{k}\cdot\tilde{\mathbf{V}} \neq 0$.

Other gases may be nonpermanent and ionized. The most important assumption is $\nu_s \ll 1$. Then, the density distribution in the N_2-atmosphere is not affected by the processes of diffusion and turbulence: $\nu_{N_2} \approx 1$, $n_{N_2} \approx n$, $m_{N_2} \approx m$, $\mu_{N_2} \approx 0$. Since diffusion equals diffusion-velocity times the number of diffusing molecules per cubic centimeter, the equation of atmospheric diffusion follows from (1), (8), and (9),

$$n_s\mathbf{c}_s = n_s(\mathbf{c}_d + \mathbf{c}_p + \mathbf{c}_F + \mathbf{C}_s + \mathbf{V}) \equiv \alpha\mathbf{i} + \beta\mathbf{j} + \gamma\mathbf{k}, \tag{15}$$

when $\mathbf{c}_T$ is neglected and

$$\mathbf{c}_d = -d_{sN_2}(\nabla\nu_s)/\nu_s\,, \tag{16}$$

$$\mathbf{c}_p = d_{sN_2}\mu_s\nabla \ln p, \tag{17}$$

$$\mathbf{c}_F = -d_{sN_2}m_s(\mathbf{F}_s - g\mathbf{k})/kT \equiv -d_{sN_2}m_s\mathbf{f}_s/kT, \tag{18}$$

$$\mathbf{C}_s = -\tilde{\mathbf{V}}\cdot\tilde{\mathbf{l}}(\nabla\nu_s)/\nu_s\,. \tag{19}$$

Let us define as an auxiliary parameter

$$Q_s = \frac{d_{sN_2}}{(d_{sN_2} + \tilde{\mathbf{V}}\cdot\tilde{\mathbf{l}})}. \tag{20}$$

With the aid of (15)–(20), the fundamental equation of atmospheric diffusion becomes

$$n_s\mathbf{c}_s = -nd_{sN_2}\left\{\frac{\nabla\nu_s}{Q_s} - \nu_s\left[\mu_s\nabla(\ln p) - \frac{m\mathbf{f}_s}{kT}\right]\right\} + n\nu_s\mathbf{V}. \tag{21}$$

The equation of continuity is

$$\frac{\partial n_s}{\partial t} = -\nabla\cdot(n_s\mathbf{C}_s) \equiv -\left(\frac{\partial\alpha}{\partial x} + \frac{\partial\beta}{\partial y} + \frac{\partial\gamma}{\partial z}\right). \tag{22}$$

Steady states or diffusion equilibriums are defined by $\partial n_s/\partial t = 0$, unsteady states by $\partial n_s/\partial t \neq 0$.

In the upper atmosphere, diffusion acts mainly in the vertical. Under the assumption that $n_s\mathbf{c}_s = \gamma\mathbf{k}$, $\partial\nu_s/\partial x = \partial\nu_s/\partial y = 0$, $\mathbf{f}_s = f_s\mathbf{k}$, $\partial \ln p/\partial z = -mg/kT$, and $\mathbf{k}\cdot\mathbf{V} = 0$, when $\tilde{\mathbf{V}}\cdot\mathbf{k} \neq 0$, equation (21) yields a differential equation for ν_s where height is the independent variable and the coefficients of the equation are fixed by molecu-

lar and eddy diffusion and the forces acting on the s-molecules:

$$\frac{\partial v_s}{\partial z} - \frac{v_s Q_s(\mu_s g m + m_s f_s)}{kT} + \frac{Q_s \gamma}{n d_{sN_2}} = 0, \quad (23)$$

when

$$Q_s = \frac{d_{sN_2}}{d_{sN_2} + D}, \quad (24)$$

and equation (22) is reduced to

$$\frac{\partial n_s}{\partial t} = -\frac{\partial (n_s \mathbf{c}_s \cdot \mathbf{k})}{\partial z} \equiv -\frac{\partial \gamma}{\partial z}. \quad (25)$$

Permanent gases are characterized by $\gamma_0 = 0$ in both steady and unsteady states; unsteady states are caused by time variations of T, Q_s, and/or f_s. Sources and sinks of nonpermanent gases can be *external* when matter enters one and leaves the other boundary of the atmosphere (or of the layer under consideration), and *internal* when production and destruction of matter (as measured by $q^{(+)}$ and $q^{(-)}$) are height functions in the layer under consideration. In steady states of nonpermanent gases with external sources and sinks,

$$\gamma = \gamma_0 = \text{const} \neq 0, \quad (26)$$

where γ_0 measures the strength of the continuous external source which equals the negative strength of the corresponding sink. In steady states of nonpermanent gases with internal sources and sinks, which are independent of x and y,

$$-\frac{\partial \gamma}{\partial z} + q^{(+)} + q^{(-)} = 0, \quad (27)$$

or diffusion balances the effects of internal production and destruction. Unsteady states of nonpermanent gases result, mainly, from time variations of γ_0, $q^{(+)}$, and $q^{(-)}$. Complications arise when the production of matter influences the physical state of the atmosphere (temperature, motion, turbulence), and when the ejection from sources causes an initial movement of matter, as in case of eruptions or explosions. Further details will be discussed in Section 12.

Atmospheric diffusion can also be studied in connection with the motion and distribution of particles (dust, nuclei, droplets, etc.). Let a_i be the diameter and n_i the number of particles per cubic centimeter. The kinetic theory represented by equation (4) fails in defining a coefficient of particle diffusion when a_i is large in comparison with $\sigma_{N_2} \approx 10^{-8}$ cm. There will be a Brownian movement of such particles, which becomes less intense as the size of the particles increases. When a_i is large in comparison with the free path of nitrogen molecules (10^{-5} cm at NTP), the integrated effect of the continuous action of numerous collisions with the molecules of the atmosphere is called the viscosity. If gravity is the only force acting on the particles, the motion reduces to a simple fall in a hypothetical atmosphere without wind and turbulence. For instance, spherical particles with $10^{-5} < a_i < 10^{-2}$ cm attain a rate of descent

$$c_i = -g a_i^2 (\rho_i - \rho)/9\mu, \quad (28)$$

according to Stokes' law, where ρ_i = density of the particle and μ = dynamic viscosity of the atmosphere = 0.00017 g cm^{-1} sec^{-1} at T = 273K.

The equation of particle diffusion in a turbulent atmosphere becomes

$$n_i \mathbf{c}_i = -n_i c_i \mathbf{k} + n_i \mathbf{C}_i + n_i \mathbf{V}, \quad (29)$$

where $\mathbf{C}_i$ is defined by (11) when $v_s = v_i = n_i/n_{N_2} \equiv n_i/n$.

DIFFUSION IN THE VERTICAL—STEADY CONDITIONS

5. The General Solution. One of the possible causes of forced diffusion is electromagnetic fields. The heat transfer in gases—which is very similar to the process of diffusion—is perceptibly affected at NTP by electric fields greater than 10^4 v cm^{-1}, as was shown experimentally by Senftleben and Gladisch [34]; the effect becomes less intense when pressure decreases. The magnitude of electric fields in the upper atmosphere normally is smaller than the value given above when ionospheric layers are electrically neutral. The possible influence of the earth's magnetic field on the diffusion of ions was found to be dubious by Ferraro [10]. Thus, we assume $f_s = 0$ in the following computations, based on equation (23).

The linear differential equation

$$\frac{dy}{dx} + y\phi(x) + \psi(x) = 0 \quad (30)$$

has the solution

$$y = \left[y_0 - \int \psi \exp\left(\int \phi \, dx\right) dx\right] \exp\left(-\int \phi \, dx\right), \quad (31)$$

when y_0 = const.

We define the scale height (height of the homogeneous atmosphere) as

$$H = kT_0/mg_0. \quad (32)$$

When N_2 is the medium of atmospheric diffusion, $m = m_{N_2} = 28.02 \times 1.66 \times 10^{-24}$ g. Normally, the scale height is expressed in terms of m_0, the average molecular weight of pure dry air ($m_0/m_{N_2} = 1.033$). In the following computations, the value of H = 8 km is used.

When $\gamma = \gamma_0$, that is, when internal sources and sinks do not exist between 0 and z, the solution of (23) with the aid of (31) and (32) is

$$v_s = v_{s0} \exp\left(-\frac{\mu_s}{H}\int_0^z \frac{gT_0}{g_0 T} Q_s \, dz\right) \cdot \left[1 - \frac{\gamma_0}{v_{s0}} \int_0^z \frac{Q_s}{n \, d_{sN_2}} \exp\left(\frac{\mu_s}{H}\int_0^z \frac{gT_0}{g_0 T} Q_s \, dz\right) dz\right]. \quad (33)$$

If $T = T_0$ and $g = g_0$ throughout the layer under consideration,[3] then ϕ/ψ = const in equation (30), and

3. Some investigators may prefer to omit the assumption $g = g_0$ by measuring the vertical scale in dynamic meters rather than in geometric meters.

equation (33) becomes

$$\nu_s = \nu_{s0}\left\{\exp\left(-\frac{\mu_s}{H}\int_0^z Q_s\,dz\right) - \frac{H\gamma_0}{\nu_{s0}\mu_s n\, d_{sN_2}} \cdot\left[1-\exp\left(-\frac{\mu_s}{H}\int_0^z Q_s\,dz\right)\right]\right\}. \tag{34}$$

In steady states, the height variation of the number concentration of a gas without internal sources in a nitrogen atmosphere depends on the ground concentration ν_{s0}, the relative weight factor μ_s, the scale height H, the molecular diffusion coefficient d_{sN_2}, the eddy diffusion (in the ratio Q_s), and the intensity of continuous external sources and sinks γ_0. Height variations of temperature and gravity are of secondary importance. The general solutions given above can readily be specialized, as was shown by Lettau [21].

6. The Border Cases of Maximum Mixture and Maximum Separation. A permanent gas constituent is defined by $\gamma_0 = 0$. Then, two extreme cases of equation (33) exist:

(*i*) The state of maximum mixture,

$$Q_s = 0 \quad \text{or} \quad D = \infty; \quad \nu_s = \nu_{s0} = \text{const.} \tag{35}$$

(*ii*) The state of maximum separation or the Dalton atmosphere,

$$Q_s = 1 \quad \text{or} \quad D = 0;$$
$$\nu_s = \nu_{s0}\exp\left(-\frac{\mu_s}{H}\int_0^z \frac{gT_0}{g_0T}\,dz\right), \tag{36}$$

$$\nu_s = \nu_{s0}\exp\left(-\mu_s z/H\right), \quad \text{if} \quad T = T_0 \quad \text{and} \quad g = g_0. \tag{37}$$

Different investigators have described these cases by different terms. For instance, case (*i*) was called "turbulent mixture" by Bartels [2], "state of convection" by Götz [12], and "adiabatic equilibrium" by Mitra [26]; case (*ii*) was called "gravity equilibrium" by Maris [24], "separation" by Penndorf [28], "atmosphere at rest" by Regener [31], and "isothermal equilibrium" by Mitra [26].

Normally, case (*i*) was attributed to the lower atmosphere. Chapman and Milne [5] introduced the hypothetical "datum level" as the height below which (*i*) and above which (*ii*) should be verified. Götz [12] and Haurwitz [17] remarked that eddy mixing can hardly stop completely at a certain level; there should be a gradual change from pronounced to slight mixing in the vertical direction. Lettau [21] pointed out that molecular diffusion acts everywhere when the effects of eddy diffusion vary with elevation, being nowhere infinite; in reality $0 < D < \infty$ or $0 < Q_s < 1$; (*cf.* equation (24)).

Consequently, Q_s is termed the separation factor. In reality, Q_s and $\partial Q_s/\partial z$ will vary with elevation. In the border cases (*i*) and (*ii*) $\partial Q_s/\partial z = 0$; then, the vertical pressure distribution can readily be found. In case (*i*)

$$P = P_0\exp\left(-\frac{1}{H}\int_0^z \frac{gT_0}{g_0T}\,dz\right) \tag{38}$$

or, if $T = T_0$ and $g = g_0$

$$P = P_0\exp\left(-z/H\right). \tag{39}$$

If $\partial\nu_s/\partial z = 0$, the vertical diffusion velocity as defined by equations (15)–(19) becomes

$$c_s = \mathbf{c}_s\cdot\mathbf{k} = \mu_s\, d_{sN_2}\frac{\partial \ln P}{\partial z} \tag{40}$$

or, if $T = T_0$ and $g = g_0$,

$$c_s = -\frac{\mu_s}{H}\frac{n\, d_{sN_2}}{n_0}e^{z/H}, \tag{41}$$

when C_s is undetermined.

Since $nd_{sN_2}/n_0 = (d_{sN_2})_0 = \text{const}$, c_s is inversely proportional to P/P_0. Values are given in Table IV in which the height variation of c_s is expressed by the varying velocity units. These motions must be thought of as compensated by an unlimited degree of vertical turbulence such that $\nu_s = \nu_{s0}$.

TABLE IV. DIFFUSION VELOCITY* IN THE HYPOTHETICAL STATE OF MAXIMUM MIXTURE (H = 8 km, $g = g_0$, $T = T_0$)

z (km)	H_2	He	O	O_2	A	Velocity units
0	25	20	8	−1	−3	cm yr^{-1}
40	99	81	32	−4	−12	cm day^{-1}
80	10	8	3	−0.4	−1.2	cm min^{-1}
120	25	20	8	−1	−3	cm sec^{-1}
200	6	5	2	−0.2	−0.7	km sec^{-1}

* Positive when directed upward

The magnitude of c_s in Table IV shows that, at and above 200 km, the state of maximum mixture will not be realized.

In a Dalton atmosphere, that is, case (*ii*), the pressure distribution is readily expressed by P as defined by (40) and (41):

$$p_s = p_{s0}\,(P/P_0)^{1+\mu_s}, \tag{42}$$

$$p = \sum_s p_s = P\sum_s \nu_{s0}\,(P/P_0)^{\mu_s}. \tag{43}$$

The number concentration of the light constituents ($\mu_s < 0$) must increase, the heavy constituents ($\mu_s > 0$) must decrease with elevation; inasmuch as $m = m_{N_2}$,

$$\nu_s = \frac{\nu_{s0}(P/P_0)^{\mu_s}}{\sum_s \nu_{s0}(P/P_0)^{\mu_s}}. \tag{44}$$

Hann [16] first verified this concept in 1903. Since then, computations of the composition of the upper atmosphere have been carried out repeatedly. Obviously, (44) is deficient with regard to eddy diffusion and the case where γ_0 or $\partial\gamma/\partial z$ differs from zero.

7. Partial Separation. If $\gamma_0 = 0$, $0 < D < \infty$,

equations (33) and (34) yield the equations of "partial separation" for permanent constituents:

$$\nu_s = \nu_{s0} \exp\left(-\frac{\mu_s}{H}\int_0^z \frac{gT_0}{g_0 T} Q_s\, dz\right) \tag{45}$$

or, if $T = T_0$ and $g = g_0$,

$$\nu_s = \nu_{s0} \exp\left(-\frac{\mu_s}{H}\int_0^z Q_s\, dz\right). \tag{46}$$

For convenience, a general separation factor Q, which is independent of the special gas, is defined as

$$Q = \frac{d}{d + D}, \tag{47}$$

in which $d = 0.18(p_0/p)(T/T_0)^{\frac{3}{2}}$ is the standard coefficient of the N_2-atmosphere (see Table III). We may also write (*cf.* equation (24))

$$Q = \frac{Q_s}{\delta_s + Q_s(1 - \delta_s)}, \quad \text{and} \quad Q_s = \frac{Q\delta_s}{1 - Q(1 - \delta_s)}. \tag{48}$$

The factor Q depends on pressure, temperature, and turbulence as functions of height. With reference to [38], $0.78 < T/T_0 < 1.25$ for $0 \leqq z \leqq 100$ km; the average T/T_0 is rather close to unity. If $T/T_0 = 1$, the logarithm of d increases proportionally to z. Crude values of D were estimated from the intensity of the atmospheric circulation and vertical thermal stratification for $0 \leqq z \leqq 100$ km (see Fig. 2). Equation (46) was applied for molecular oxygen, argon, and helium. The theoretical ν_s-variation, as shown in Fig. 2, reflects the Q-variation with height.

Inasmuch as $Q \neq 0$, the tendency towards separation begins at sea level. However, when $Q \leqq 10^{-4}$ and $(z_2 - z_1) \leqq 10$ km, all permanent constituent gases show that $|\nu_{s1} - \nu_{s2}|/\nu_{s1} \leqq 0.01$ per cent. Therefore, the concentration of permanent gases is practically constant throughout the entire troposphere where $Q \approx 10^{-5}$, as follows from Fig. 1.

Regener [30] showed that ν_{O_2} decreases slightly in the stratosphere from 15 to 29 km. Lettau [21] and Dütsch [8] used this fact for computing $A \equiv \rho D$ between 15 and 30 km. Because of the term $\delta_s\mu_s/[1 - Q(1 - \delta_s)]$, the percentage separation of helium should be approximately 20 times that of molecular oxygen. However, helium is not a permanent constituent. The observed helium distribution will be explained in Section 8. When no helium source and sink would exist, the height variation of ν_{He} should follow the dotted line in Fig. 2.

The coefficient d increases monotonically with height; increasing temperature can only slightly modify this trend. Regions above 100 km are subject to turbulence caused by diurnal heating and cooling and by tidal effects. However, in contrast to d, the value of D is limited. An estimated maximum D-value is approximately 10^8 cm^2 sec^{-1} since ζ_D and λ_D are unlikely to exceed 10^3–10^4 cm sec^{-1} and 10^5–10^4 cm, respectively (see Fig. 1). Thus

$$\lim_{z\to\infty} Q = 1. \tag{49}$$

When $D \leqq 10^8$ cm^2 sec^{-1} and (39) is used for computing d,

$$1 > Q > 0.5 \quad \text{if} \quad z \geqq 160 \text{ km}. \tag{50}$$

$$1 > Q > 0.99 \quad \text{if} \quad z \geqq 200 \text{ km} \tag{51}$$

If $Q \approx 0.99$, there should result, practically, a Dalton atmosphere. From this point of view, the datum levels

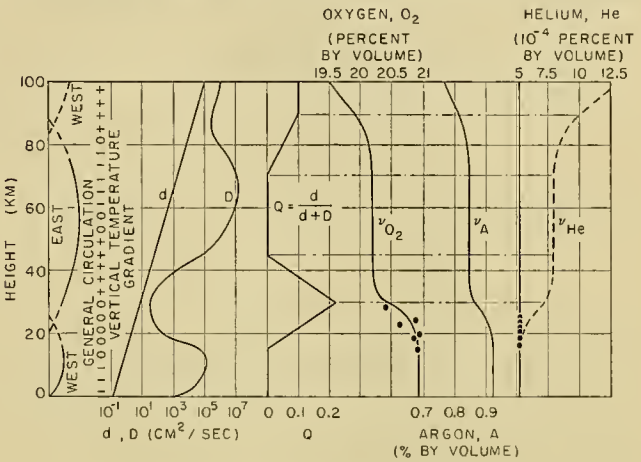

FIG. 2.—The influence of the separation factor Q on the height variation of concentration of heavy and light permanent gases. Regener's and Paneth's observations of ν_{O_2} and ν_{He} (highest levels of analyses are 29 and 25 km, respectively) are marked by dots. Helium is not a permanent gas and therefore ν_{He} = const when condition (52) is satisfied. The absolute values and the height variations of the eddy diffusion coefficient D will be valid for temperate latitudes since they were estimated from assumptions with regard to the representative zonal circulation in temperate latitudes and the sign of $\partial T/\partial z$ (−, 0, and + denote lapse, isothermal, and inversional stratification, respectively) such that strong zonal motion and/or lapse conditions cause large D-values when weak zonal motion and/or inversional stratification cause small D-values. Other facts giving support to the existence of layers of $\partial D/\partial z < 0$ above approximately 15 and 70 km are discussed in Sections 9 and 14.

of 12–50, 100, and 150 km as assumed by Chapman and Milne [5], Mitra [26], and Maris [24], respectively, appear to be too low, except possibly for the last one. Internal sources and sinks due to photochemical processes—which also affect nitrogen above 200 km—impair the computation of diffusion effects in the ionosphere, even though D might be neglected in comparison with d.

8. Effects of Sources and Sinks. If $\gamma = \gamma_0 \neq 0$ and $0 \leqq Q \leqq 1$, equation (34) describes steady height variations of nonpermanent gases with external sources and sinks. A basic flow enters one boundary of the layer under consideration and leaves the other. A highly interesting special case exists when

$$\gamma_0 = \gamma_{\text{crit}} \equiv -\nu_{s0}\mu_s n d_{sN_2}/H \equiv -n_{s0}\mu_s d_{sN_2}/H \equiv -n_{s0}(c_p)_0\,. \tag{52}$$

Then (34) reduces to

$$\nu_s = \nu_{s0} = \text{const.} \tag{53}$$

The concentration is constant when γ_0/n_{s0} equals the negative velocity of pressure diffusion at sea level (see equations (17) and (41)). Petersen [29] discussed this

result for a Dalton atmosphere; Lettau [21], for the general case $0 \leqq Q \leqq 1$.

Paneth and Glueckauf [27] showed that ν_{He} between 15 and 25 km is slightly larger than at the ground. In contrast to the oxygen deficit measured by Regener, the helium surplus is not a systematic height function. It is relatively small, so that on the scales of Fig. 2, ν_{He}-averages for layers of 2.5 km are practically constant. The ground concentration is $(\nu_{He})_0 = 5.2 \times 10^{-6}$. The assumption that (52) is satisfied yields

$$(\gamma_0/n)_{He} = -(\nu_{He})_0 \mu_{He}\, d_{HeN_2}/H = 3.3 \times 10^{-12}\ \text{cm}^3 He\ \text{cm}^{-2}\ \text{sec}^{-1}, \tag{54}$$

or, integrated over the entire earth's surface (5.1×10^{18} cm^2),

$$\overline{(\gamma_0/n)_{He}} = 17\ \text{m}^3\ He\ \text{sec}^{-1}. \tag{55}$$

By multiplying (54) with Loschmidt's number (Table I), the units of γ_0 are number of molecules per square centimeter per second. Helium is discharged from rocks which contain uranium or thorium. Gutenberg [14] discussed the total lithospheric helium production and estimated its order of magnitude as 10 m^3 sec^{-1}, which is sufficiently close to (55) in order to justify the assumption that $\gamma_0 \approx \gamma_{crit}$. Consequently, helium cannot increase with height, even in the Dalton atmosphere above 200 km. This would correspond to the absence of helium lines in the spectra of the aurora and of the night sky. Similar conditions will exist for hydrogen. The departure into space at the same steady rate with which these lightest gases leave the ground appears consistent with Jeans' theory of escape.

When $\gamma_0 \neq \gamma_{crit}$, equations (33) and (34) must be studied. Lettau [21] considered a small $\partial \nu_{He}/\partial z$ between 15 and 25 km and corrected the result (55) slightly. When γ_0 differs considerably from γ_{crit}, the concentration will vary, even in layers where Q is very small. Examples of such nonpermanent gases are carbon dioxide (produced at the surface over land), ozone (produced in the lower stratosphere), and atomic oxygen (produced in the upper stratosphere), when the regions of production are left outside the layer under consideration. The concentration decreases with increasing distance from the region of production. The intensity of continuous sources can be computed when $\partial \nu_s/\partial z$ is steady and Q is known. As an example, the CO_2-observations of Glueckauf [11] in Great Britain, $\nu_{s0} = 3.4 \times 10^{-4}$ and $\nu_s \approx 2.5 \times 10^{-4}$ at $z \approx 7$ km, yield

$$(\gamma_0/n)_{CO_2} \approx -(\nu_s - \nu_{s0})D/z \approx 5 \times 10^{-5}\ \text{cm}^3\ CO_2\ \text{cm}^{-2}\ \text{sec}^{-1}, \tag{56}$$

for $D = 5 \times 10^4$ cm^2 sec^{-1} and $d_{CO_2N_2} \ll D$. In all probability, this rate of CO_2-diffusion holds for industrialized areas only. For central Europe, Lettau [21] derived 10^{-6} cm^3 CO_2 cm^{-2} sec^{-1} from Wigand's observations. A compensating negative flux of carbon dioxide will exist in the troposphere over the oceans.

In a similar manner, the average downward-directed diffusion of ozone through the troposphere was found to be approximately 10^{-9} cm^3 O_3 cm^{-2} sec^{-1} $= 4 \times 10^9$ molecules cm^{-2} sec^{-1}; Dütsch [8] estimated $(\gamma_0)_{O_3}$ as 7.1×10^{10}, 2.6×10^9 and 0.4×10^9 molecules cm^{-2} sec^{-1} at latitudes 0°, 45°, and 80°N, respectively.

The problem of diffusion equilibrium becomes more complex when $\partial\gamma/\partial z \neq 0$ at certain regions of the layer under consideration (*cf.* equation (27)). Then the main difficulties arise from the mathematical analysis of the rate of production $q^{(+)}$ and extinction $q^{(-)}$ as functions of height. These processes will depend on the physical state of the atmosphere and on solar radiation.

With regard to equations (23) and (27), the classical model of such investigations will be the distribution of ozone. The processes of production and extinction are fairly well known and localized in the lower stratosphere and at ground level. The requirements that N_2 can be considered the medium of diffusion and that ν_s is small are satisfied. Dütsch [8] studied the subject comprehensively and found the effects of molecular diffusion small in comparison with those of eddy diffusion. However, the vertical ozone distribution is not in equilibrium, that is, the main problem is the explanation of time variations at different heights and latitudes due to meridional and seasonal differences of $q^{(+)}$ and $q^{(-)}$, eddy diffusion, and general circulation. Consequently, Dütsch's results will be dealt with in a discussion of three-dimensional diffusion.

Layers above the stratosphere are characterized by the production and destruction of ions due to radiation and recombination. According to the theory of ionization, $q^{(+)}$ is a complicated function of height and the sun's zenith distance when $q^{(-)}$ is proportional to the square of the number density of ions. It must be mentioned that the assumptions made in Section 4 do not hold, especially when N_2 is also ionized; the number density of ions can become of the same order as that of the molecules. Therefore, equation (1) rather than equation (15) must be considered in connection with $q^{(+)}$ and $q^{(-)}$, and the diffusion coefficient of ionized matter must be properly defined. Ferraro [10] found that the effect of molecular diffusion is negligible in the E- and F_1-layers, and small and possibly negligible also in the F_2-layer. Similarly, Bagge [1] showed that molecular diffusion may influence the number density of ions above 200 km. The effect of eddy diffusion was not considered; when reference is made to Section 7, it follows that eddy diffusion should be considered in the E-layer and for the distribution of atomic oxygen around 100 km.

Since the diffusion problems of dissociated and ionized gases are highly complex and decisively determined by forced oscillations due to solar radiation, they will not be studied in this article.

9. Diffusion of Particulate Matter. Let ν_i be the number concentration of particles and let us consider horizontal uniform ν_i-distributions. Then diffusion is in the vertical and in (29)

$$n_i \mathfrak{c}_i = \Gamma \mathfrak{k}. \tag{57}$$

In steady states without sources or sinks, $\Gamma = 0$; thus, $\mathbf{c}_i \cdot \mathbf{k} = 0$; when $\mathbf{k} \cdot \mathbf{V} = 0$,

$$0 = -c_i - D \frac{1}{\nu_i} \frac{\partial \nu_i}{\partial z}, \tag{58}$$

$$\nu_i = \nu_{i0} \exp\left(-\int_0^z \frac{c_i}{D}\, dz\right). \tag{59}$$

By definition, $\nu_i = n_i/n_{N_2} = n_i/n$, when

$$n = n_0 e^{-z/H}, \tag{60}$$

if $T = T_0$ and $g = g_0$. The number of particles per cubic centimeter therefore is

$$n_i = n_{i0} \exp\left(-\frac{1}{H}\int_0^z \frac{D_c + D}{D}\, dz\right), \tag{61}$$

where

$$D_c \equiv c_i H. \tag{62}$$

Equation (58) shows that the vertical concentration gradient is everywhere negative. The term $\ln \nu_i$ decreases in the ratio of D_c/D per 8 km. In layers of high turbulence, ν_i will be practically constant when n_i decreases proportionally to the density of the atmosphere. When $\partial D/\partial z < 0$, ν_i must decrease rapidly with height. Such effects might be the cause of "dust horizons." With regard to Fig. 2, one would expect "dust horizons" at approximately 15 and 70 km, provided dust particles exist in the stratosphere. The optical phenomena due to scattering of solar radiation prove the presence of dust in the stratosphere. With reference to Gutenberg [14], the duration of civil and astronomical twilight leads to the assumption of dust boundaries at approximately 15 and 60–80 km.

Difficulties arise with regard to the rate of descent of atmospheric dust particles. Stokes' law, equation (28), is true for small spheres when Reynolds' number—defined as $Re = a_i c_i \rho/\mu$—is smaller than a fixed value. In air at NTP, $\mu/\rho = 0.2$ cm^2 sec^{-1}; therefore a_i must be smaller than 10^{-2} cm. More accurate is the formula of Oseen, which is valid also for $a_i > 10^{-2}$ cm. Both of these aerodynamic formulas fail for nonspherical particles and for values of a_i of the order of the free path of air molecules (10^{-4} cm at $z = 20$ km and 10^{-2} cm at $z = 60$ km). Humphreys [18] considered Cunningham's corrections of Stokes' law as applied to the stratospheric conditions.

As an example, we assume $c_i = 0.063$ cm sec$^{-1} \approx 50$ m day$^{-1} \approx 20$ km yr^{-1} corresponding to $a_i = 10^{-4}$ cm when, in equation (28), $\rho_i = 2$. Such a_i- and ρ_i-values correspond to volcanic dust particles which can exist in varying amounts in the stratosphere (see §14). Equation (62) then yields $D_c = 5 \times 10^4$ cm^2 sec^{-1}, which equals normal D-values in the troposphere when, in the stratosphere, D is alternately larger and smaller than 5×10^4. The study of optical phenomena appears to be useful for the discussion of turbulence in the stratosphere.

DIFFUSION IN THE VERTICAL—UNSTEADY CONDITIONS

10. The General Equation. In unsteady states, $\nabla \cdot (n_s \mathbf{c}_s) \neq 0$ in equation (15). For nonpermanent gases the equation of continuity yields

$$\frac{\partial n_s}{\partial t} = -\nabla \cdot (n_s \mathbf{c}_s) + q_s^{(+)} + q_s^{(-)}. \tag{63}$$

For the solution of (15) with regard to (63), we assume the gas to be permanent ($q_s^{(+)} = 0$, $q_s^{(-)} = 0$), and

(*a*) the N_2-atmosphere to be steady and at rest when $\nu_s \ll 1$,

$$\frac{\partial n}{\partial t} = \frac{\partial n_{N_2}}{\partial t} = 0, \qquad \frac{\partial n_s}{\partial t} = n \frac{\partial \nu_s}{\partial t}, \qquad \mathbf{k} \cdot \mathbf{V} = 0, \tag{64}$$

(*b*) $T = T_0$, and $g = g_0$,

$$\frac{\partial \ln p}{\partial z} = -\frac{1}{H}, \qquad n = n_0 e^{-z/H}, \tag{65}$$

(*c*) diffusion to be vertical,

$$n_s \mathbf{c}_s = \gamma \mathbf{k}, \qquad \nabla \cdot (n_s \mathbf{c}_s) = \frac{\partial \gamma}{\partial z}, \tag{66}$$

(*d*) gravity to be the only external acceleration,

$$\mathbf{f}_s = 0. \tag{67}$$

When equations (64)–(67) are considered, the differentiation of (23) with respect to z yields

$$\frac{\partial \nu_s}{\partial t} = \frac{d_{sN_2}}{Q_s}\left[\frac{\partial^2 \nu_s}{\partial z^2} + \frac{\partial \nu_s}{\partial z}\left(\frac{\mu_s Q_s}{H} - \frac{\partial \ln Q_s}{\partial z}\right)\right], \tag{68}$$

or

$$\frac{\partial \nu_s}{\partial t} = (d_{sN_2} + D)\left\{\frac{\partial^2 \nu_s}{\partial z^2} - \frac{\partial \nu_s}{\partial z}\left[\frac{\partial \ln d_{sN_2}}{\partial z} - \frac{\partial \ln (d_{sN_2} + D)}{\partial z}\right]\right\} + d_{sN_2}\frac{\mu_s}{H}\frac{\partial \nu_s}{\partial z}. \tag{69}$$

Let Q_s be constant throughout the layer under consideration, $Q_s = \bar{Q}$. Then D is proportional to d_{sN_2}, or D varies with height in the same way as does $1/\rho$. Consequently, the product ρD (usually called the austausch coefficient A) is independent of elevation. We introduce a new variable Z,

$$Z \equiv e^{-z/2H}, \tag{70}$$

such that

$$d_{sN_2} = (d_{sN_2})_0 e^{z/H} \equiv (d_{sN_2})_0 Z^{-2}. \tag{71}$$

For steady cases, equation (46) yields

$$\nu_s = \nu_{s0} Z^{2\mu_s \bar{Q}}. \tag{72}$$

With the aid of equations (68)–(71),

$$a^2 \frac{\partial \nu_s}{\partial t} = \frac{\partial^2 \nu_s}{\partial Z^2} + \frac{1 - b}{Z}\frac{\partial \nu_s}{\partial Z}, \tag{73}$$

where

$$a^2 \equiv 4H^2\bar{Q}/(d_{sN_2})_0 = \text{const}, \tag{74}$$

$$b = 2\mu_s\bar{Q} = \text{const}. \tag{75}$$

Equations (68), (69), and (73) prove that the form $\partial\nu_s/\partial t = K^*\partial^2\nu_s/\partial z^2$—usually called Fick's equation of vertical diffusion when K^* defines the "diffusion power" of the medium—is an inadequate expression of atmospheric diffusion. The differential equation (73) is solved by Bessel functions, and the solution expresses the concentration as a function of z and $(t - t_0)$ when allowance is made for the appropriate boundary conditions of the problem. For example, let $\bar{Q} = \bar{Q}_i$ at $t < t_0$, and $\bar{Q} = \bar{Q}_{ii}$ at $t \geqq t_0$; then, according to (72),

$$\nu_s = (\nu_{s0})_i Z^{2\mu_s\bar{Q}_i} \qquad \text{at } t < t_0, \tag{76}$$

when

$$\lim_{(t-t_0)\to\infty} \nu_s = (\nu_{s0})_{ii} Z^{2\mu_s\bar{Q}_{ii}}, \tag{77}$$

such that the total amount of s-molecules in vertical columns remains constant.

11. The Time Required for Establishing Equilibrium. The "transition period" is the time needed to transform state (76) into (77). The special transformation, where $\bar{Q}_i = 0$ (maximum mixture) and $\bar{Q}_{ii} = 1$ (Dalton atmosphere), was studied by Epstein [9] in terms of Bessel functions, and by Maris [24] and Mitra and Raksit [26] with the aid of numerical and graphical integrations. Lettau [21] derived (68) and (73) in the forms given above, which allow us to discuss more general cases where

$$0 \leqq \bar{Q}_i < \bar{Q}_{ii} \leqq 1. \tag{78}$$

Since the gas is permanent, the total amount of s-molecules in vertical columns of infinite height must be constant,

$$\Psi_s = \int_0^\infty n_s\, dz = \text{const}. \tag{79}$$

We define the number integral of s-molecules as

$$\psi_s = \int_0^z n_s\, dz, \qquad \lim_{z\to\infty} \psi_s = \Psi_s. \tag{80}$$

Since $n_s = \nu_s n$, it follows from (65) and (72) that

$$n_s = n_{s0} \exp[-(1 + \mu_s\bar{Q})z/H], \tag{81}$$

and

$$\psi_s = \frac{(n_{s0} - n_s)H}{1 + \mu_s\bar{Q}}, \qquad \Psi_s = \frac{n_{s0}H}{1 + \mu_s\bar{Q}} = \text{const}. \tag{82}$$

Equation (82) relates n_{s0} to $\bar{Q}$. Therefore, a general value of the ground concentration is defined:

$$n_{s00} = \Psi_s/H = \nu_{s00} n_0\,. \tag{83}$$

Then,

$$n_{s0} = n_{s00}(1 + \mu_s\bar{Q});$$

$$n_s = \frac{n_{s00}}{1 + \mu_s\bar{Q}} \exp[-(1 + \mu_s\bar{Q})z/H], \tag{84}$$

$$(\nu_s)_i = \frac{\nu_{s00}}{1 + \mu_s\bar{Q}_i} \exp(-\mu_s\bar{Q}_i z/H), \tag{85}$$

$$(\psi_s)_i = Hn_{s00}\{1 - \exp[-(1 + \mu_s\bar{Q}_i)z/H]\}. \tag{86}$$

When diffusion (initially characterized by $\bar{Q}_i$) is $\bar{Q}_{ii}$ at $t \geqq t_0$, it follows from (86) that the difference of the number integrals is a height function:

$$(\psi_s)_i - (\psi_s)_{ii} \equiv \Delta\psi_s = Hn_{s00}e^{-z/H}[\exp(-\mu_s\bar{Q}_i z/H) - \exp(-\mu_s\bar{Q}_{ii}z/H)]. \tag{87}$$

The term $\Delta\psi_s$ is zero at $z = 0$ and at $z = \infty$; consequently, $\Delta\psi_s$ must have an extreme value at a finite level, $z = z^*$. The level z^* is defined by $\partial\Delta\psi_s/\partial z = 0$. The differentiation of (87) with respect to z yields

$$z^* = \frac{H}{\mu_s(\bar{Q}_{ii} - \bar{Q}_i)} \ln\frac{1 + \mu_s\bar{Q}_{ii}}{1 + \mu_s\bar{Q}_i}, \tag{88}$$

and

$$\lim_{(\bar{Q}_{ii}-\bar{Q}_i)\to 1} z^* = \lim_{\left(\frac{\bar{Q}_{ii}\to 1}{\bar{Q}_i\to 0}\right)} z^* = \frac{H}{\mu_s}\ln(1 + \mu_s), \tag{89}$$

$$\lim_{(\bar{Q}_{ii}-\bar{Q}_i)\to 0} z^* = H. \tag{90}$$

By definition, $n_s = \partial\psi_s/\partial z$; therefore, z^* is the level where $(n_s)_i = (n_s)_{ii}$ or $(\nu_s)_i = (\nu_s)_{ii}$; that is, where the initial ν_s-curve intersects the final ν_s-curve (compare equations (76) and (77) and, as an illustration, Fig. 3).

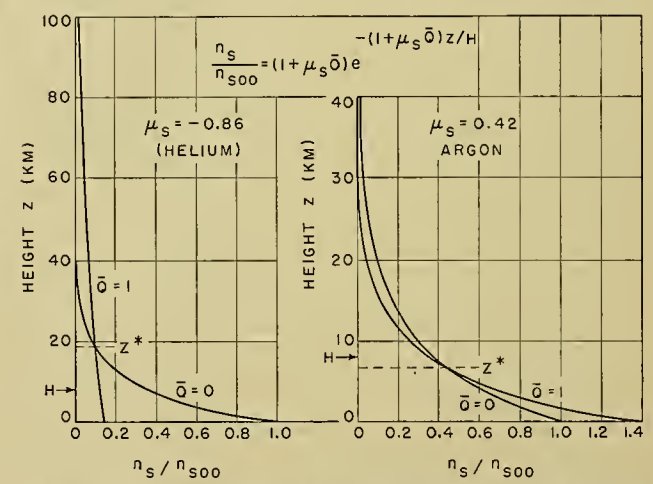

FIG. 3.—The height variation of density (relative to the ground density) of a light and a heavy gas for the border cases of maximum mixture ($\bar{Q} = 0$), and of maximum separation or Dalton atmosphere ($\bar{Q} = 1$). It is assumed that the gases have no sources and sinks.

Our result, equation (90), corresponds to the fact that $z = H$ represents the isopycnic level which was discovered by Wagner and explained by Linke (see Humphreys [18] and Doporto and Morgan [7]).

The transition period has no finite value since $(\nu_s)_{ii}$ will be approached asymptotically even if $\bar{Q}_i$ changes suddenly into $\bar{Q}_{ii}$ at $t = t_0$. The transition period can be studied only in relative terms. Epstein and Maris measured the transition period by the time necessary for accomplishing a certain fraction of the whole transformation. Lettau [21] considered the final time interval

$$\Delta t_s = \frac{\Delta\psi_s}{(n_s)_i(c_s)_{ii}^i}, \tag{91}$$

where $(n_s)_i$ refers to the initial state when $(c_s)^i_{ii}$ is the vertical diffusion velocity as fixed by the final diffusion conditions $(\bar{Q}_{ii})$ and the initial concentration-distribution $(\nu_s)_i$. The changes of both ν_s and c_s with the progress of the transition are not considered; therefore, Δt_s in equation (91) represents a minimum value of the transition period.

Expressions more accurate than equation (91) could be obtained; however, the gain in accuracy does not justify the added complexity of computation in view of the crude assumptions that Q is independent of height and changes its value suddenly and simultaneously throughout the entire atmosphere.

With the aid of (87) and (91),

$$\Delta t_s = \frac{H}{(c_s)^i_{ii}[1 + \mu_s \bar{Q}_i]} \{\exp[-\mu_s(\bar{Q}_{ii} - \bar{Q}_i)z/H] - 1\}. \quad (92)$$

Let us investigate the three special transformations:

$$\left.\begin{aligned} &(a)\ \text{complete mixture } (\bar{Q}_i = 0) \rightarrow \\ &\qquad \text{Dalton atmosphere } (\bar{Q}_{ii} = 1) \\ &(b)\ \text{Dalton atmosphere } (\bar{Q}_i = 1) \rightarrow \\ &\qquad \text{partial separation } (\bar{Q}_{ii} = \epsilon_1) \\ &(c)\ \text{partial separation } (\bar{Q}_i = \epsilon_1) \rightarrow \\ &\qquad \text{partial separation } (\bar{Q}_{ii} = \epsilon_2), \end{aligned}\right\} \quad (93)$$

when $0 < \epsilon_2 < \epsilon_1 << 1$. The diffusion velocity follows from (15)–(19) and from the special assumptions above,

$$\left.\begin{aligned} &(a) \qquad (c_s)^i_{ii} = -\frac{\mu_s}{H}(d_{sN_2})_0 e^{z/H} \equiv c_a \\ &(b) \qquad (c_s)^i_{ii} \approx c_a/\epsilon_1 \\ &(c) \qquad (c_s)^i_{ii} \approx c_a\, \epsilon_1/\epsilon_2\,. \end{aligned}\right\} \quad (94)$$

As an abbreviation, we define $\Delta\tau_s \equiv H^2/\mu_s\,(d_{sN_2})_0$; then equation (92) yields

$$\left.\begin{aligned} &(a)\ \Delta t_s = \Delta\tau_s\, e^{-z/H}[1 - \exp(-\mu_s z/H)] \\ &(b)\ \Delta t_s \approx \Delta\tau_s \frac{\epsilon_1}{1 + \mu_s} e^{-z/H}[\exp(\mu_s z/H) - 1] \\ &(c)\ \Delta t_s \approx \Delta\tau_s \frac{\epsilon_2(\epsilon_1 - \epsilon_2)}{\epsilon_1} \frac{\mu_s z}{H} e^{-z/H}. \end{aligned}\right\} \quad (95)$$

The transition period is zero at the lower and upper boundary of the atmosphere, thus attaining a maximum value at the level defined above, that is, at $z = z^*$. Figure 4 illustrates the conditions for argon when in (b), $\epsilon_1 = \frac{1}{3} \times 10^{-5}$; that is, $D_0 = 0.54 \times 10^5$ cm^2 sec^{-1} or $\bar{A} = 65$ g cm^{-1} sec^{-1}; and in (c), ϵ_1 remains as before, $\epsilon_2 = 0.30 \times 10^{-5}$; that is, $D_0 = 0.60 \times 10^5$ cm^2 sec^{-1} or $\bar{A} = 72$ g cm^{-1} sec^{-1}.

For argon, $z^* = 6.7$ km in (a) and (b). At this level, the transformation of a complete argon-nitrogen mixture into a Dalton atmosphere takes at least 34,000 years. The reverse transformation of a Dalton atmosphere into a steady state of partial separation characterized by a constant austausch coefficient of 65 g cm^{-1} sec^{-1} takes at least 1.5 months. The changes owing to a 10 per cent variation of austausch of the order given above are accomplished in not less than 5 days.

In case (a) the transition period above 200 km is less than one hour whereas it is measured by years below 100 km. Evidently, very slight turbulence will prevent

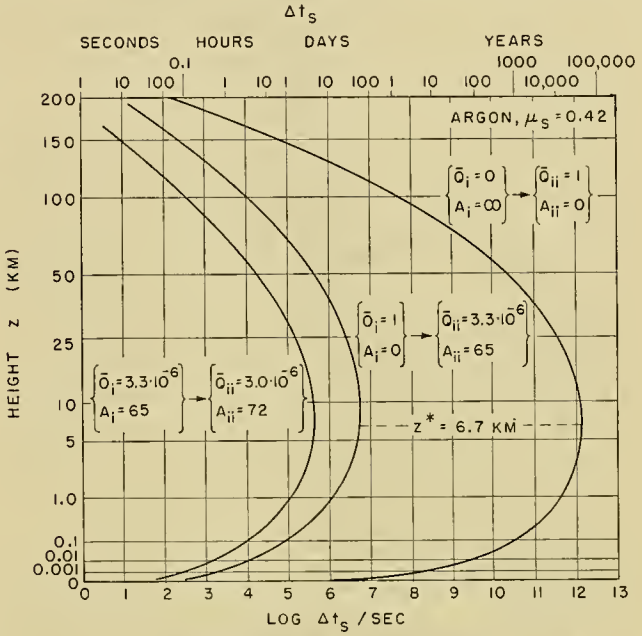

FIG. 4.—The height variation of the minimum values of the transition period Δt_s in three different cases of initial and final diffusion conditions. The computation was carried out for argon; other gases will have different values for Δt_s and for z^*, the height of maximum transition period (see Fig. 3), but the order of Δt_s will not differ from the above. The height scale is proportional to $z^{1/3}$.

the establishment of a Dalton atmosphere below 100 km when the effects of occasionally enlarged turbulence will be extinguished after less than one minute above 200 km. This result supports the findings concerning the height of the datum level (see §7).

When similar computations are based on more accurate assumptions $(\partial Q/\partial z \neq 0)$, the results might be interesting with regard to seasonal and long-time variations of turbulence, or with regard to the intensity of the general circulation and its effect on the composition of the upper atmosphere. Time variations due to variable rates of production of gases should also be investigated with the aid of equations (63) and (73). However, the effect of natural or artificial external sources on the composition of the atmosphere will be very small and measured only within geological epochs.

THREE-DIMENSIONAL DIFFUSION

12. The General Causes of Three-Dimensional Diffusion. As a result of the earth's shape, the use of spherical coordinates (longitude, latitude, height) is natural. Atmospheric diffusion is a three-dimensional problem when the physical state of the atmosphere and/or the strength of sources and sinks depends on height, latitude, and longitude. As indicated by equation (4), the coefficient of molecular diffusion is a func-

tion of density and temperature; the coefficients of eddy diffusion depend on horizontal and vertical gradients of pressure and temperature. These elements will vary at surfaces of constant height in the upper atmosphere while diurnal, interdiurnal, and seasonal variations will be different at different latitudes. However, apart from the troposphere and substratosphere, data are scanty and the effects of meridional variations of d and D on the composition of the upper atmosphere are hypothetical.

In the discussion of diffusion in the vertical, under steady conditions, large-scale external area sources and sinks were considered which covered the entire earth's surface (*e.g.*, helium) or considerable parts thereof (*e.g.*, carbon dioxide). External and internal point or line sources can exist (*e.g.*, meteor trails); production and destruction of matter may be instantaneous, continuous, or periodical as exemplified by volcanic eruptions, lithospheric helium production, or photosynthesis. As demonstrated by the first and second versus the third of these examples, the process can or cannot be independent of the state of the atmosphere. It must be concluded from the above that diffusion in general is not only a three-dimensional, but a time-varying process. Solutions of equations (15), (22), and (63) must be found which satisfy appropriate initial and boundary conditions.

13. The Horizontal Coefficients of Eddy Diffusion and the Effect of the Representative Wind Field on Diffusion Processes. In contrast to molecular diffusion, the coefficients of eddy diffusion at a fixed point may be different in horizontal and vertical directions; with regard to equations (12)–(14), $D_{x,y} \neq D$. Another important factor is that the eddy-diffusion coefficients depend on the averaging process.

Defant [6] considered the traveling cyclones and anticyclones of middle latitudes as individual turbulent elements in an intensive meridional mixing process where $\zeta_D^{(D)} \approx 10^3$ cm sec^{-1} and $\lambda_D^{(D)} > 10^8$ cm are horizontal values; thus, $D_{x,y}^{(D)} = \zeta_D^{(D)} \lambda_D^{(D)} \approx 10^{11}$ cm^2 sec^{-1} (*cf.* Fig. 1). The magnitude of the virtual time-terms, $\lambda_D^{(D)}/\zeta_D^{(D)} > 10^5$ sec, manifests the differences of $D_{x,y}^{(D)}$ in comparison with $D_{x,y}$ due to normal turbulence, since $\lambda_D/\zeta_D = 10$ to 10^2 sec. Representative with regard to $D_{x,y}^{(D)}$ are monthly means; with regard to D, hourly means. The coefficient $D_{x,y}^{(D)}$ effectively equalizes the meridional differences of physical properties and composition; however, very little is known about $D_{x,y}^{(D)}$ in the upper atmosphere.

Even in normal turbulence, D_x or D_y may differ from D, denoting nonisotropic turbulence caused by thermal stratification [22]. In the surface layer, the isotropy coefficient deviates only slightly from unity and it can be expected that throughout the entire atmosphere D_x and D_y have the same order of magnitude as D.

Another important consequence results when the medium of atmospheric turbulence is not "at rest" (*cf.* §4). In reality, $\mathbf{k}\cdot\mathbf{V}$ equals zero for the atmosphere as a whole. The term $\mathbf{k}\cdot\mathbf{V}$ and the components of $\nabla\cdot\mathbf{V}$ and $\mathbf{V}$ are functions of height, latitude, and longitude, since hemispheric circulation cells are superimposed on the general zonal motions. The most general equation of three-dimensional diffusion is equation (63) or

$$\frac{\partial n_s}{\partial t} = -\nabla\cdot[n_s(\mathbf{c}_d + \mathbf{c}_p + \mathbf{c}_F + \mathbf{C}_s + \mathbf{V})] + q_s^{(+)} + q_s^{(-)}, \tag{96}$$

which can be expressed by the individual time variation

$$\frac{dn_s}{dt} = \frac{\partial n_s}{\partial t} + \mathbf{V}\cdot\nabla n_s = -\nabla\cdot[n_s(\mathbf{c}_d + \mathbf{c}_p + \mathbf{c}_F + \mathbf{C}_s)] - n_s\nabla\cdot\mathbf{V} + q_s^{(+)} + q_s^{(-)}, \tag{97}$$

where $q_s^{(+)}$ and $q_s^{(-)}$ and the velocity terms as defined earlier (see §§2–4) are functions of space and time. Lettau [23] found that the term $\nabla\cdot(n_s\mathbf{C}_s)$ depends on the wind shear and that the effects of local wind derivatives increase with time and with the geometrical dimensions of the air mass under consideration. This explains why Fick's simple equation of diffusion

$$\frac{dn_s}{dt} = \nabla\cdot(K\nabla n_s) \tag{98}$$

or

$$\frac{dn_s}{dt} = K^*\nabla\cdot\nabla n_s \tag{99}$$

results in a "diffusion power" K or K^* which must depend on arbitrary physical parameters, such as time of the diffusion process and the geometrical dimensions of the distances under consideration. Richardson [32] and Stommel [36] maintain the point of view that the diffusion coefficient is a function of distance.

Observations of moisture variations along isentropic surfaces in large-scale tropospheric currents to the north or to the south led Rossby [33] and Grimminger [13] to the concept of lateral diffusion processes where the effective coefficients $D_{x,y}^{(R)} \approx 10^9$ cm^2 sec^{-1} are such that $D_{x,y}^{(D)} \approx 10^2\, D_{x,y}^{(R)} \approx 10^4\, D_{x,y}$. Lettau [23] considered, as a criterion of real coefficients of eddy diffusion, that $D = \zeta_D\lambda_D$ when ζ_D and λ_D can be statistically related with observable properties of irregular motions and depend on physical parameters dealing with the energy and the heat transfer of the flow. The term $D_{x,y}^{(R)}$ does not satisfy the requirements of a real diffusion coefficient. Consequently, Lettau [23] termed it an "apparent" coefficient which may be caused by steady deformation fields superimposed on the mean current. This explanation appears to be supported by the findings of Miller [25] that a strong positive correlation exists between the vertical wind velocity and the mean speed of the south-to-north components of the air flow, and the finding of Grimminger [13] that there is a definite indication that the coefficients of lateral mixing increase downstream.

14. Examples of Three-Dimensional Diffusion. All terms of equation (96) were accounted for in Dütsch's study of ozone; the only simplification of (96) was that $\mathbf{c}_F = 0$. Dütsch [8] systematically investigated the ν_{O_3}-equilibrium in vertical columns. Direct radiation and also direct plus diffuse radiation explained only

the basic facts of the vertical distribution of ozone, when incorrect meridional distributions of the total ozone (vertical number integral, as defined by equation (79)) were obtained. Molecular diffusion proved to be negligible; the addition of vertical eddy diffusion improved the results with regard to the meridional distribution. However, the annual variation was still incorrect. Finally, the addition of vertical and horizontal advection due to the average general circulation in the lower stratosphere yielded fairly satisfactory theoretical values. Tables V and VI condense the findings of Dütsch

Table V. Meridional Variations of Total Ozone* (in cm)
(*After Dütsch* [8])

Basis of computation	Latitude North					
	Midsummer			Midwinter		
	25°	45°	70°	25°	45°	60°
Direct radiation	0.52	0.33	0.28	0.31	0.17	0.07
Direct + diffuse radiation	0.39	0.27	0.20	0.26	0.17	0.14
Direct + diffuse radiation + vertical eddy diffusion	0.19	0.20	0.21	0.19	0.20	0.22
Observation	0.20	0.24	0.26	0.19	0.23	0.26

* Under the assumption of equilibrium in vertical columns.

and may be regarded as proving the influence of terms like $n_s \mathbf{C}_s \cdot \mathbf{k}$ and the horizontal components of $\nabla \cdot \mathbf{V}$ in equation (96).

Other studies based on all the terms of equations (96) and (97) do not exist. The main reason is the lack of appropriate observations of gas concentration, including moisture, in the upper atmosphere. Particulate matter and its diffusion appear to be more easily observable.

As an example of dust transportation, a paper by Brandtner [3] may be mentioned. On March 29, 1947, dust from North Africa (latitude 32–35°N, longitude 0–3°E), which was brought into the upper troposphere by the passage of two cold fronts, was transported with south-southwesterly winds and arrived approximately 15 hours later at latitude 50° in western and central Europe. Brandtner's study of the upper-air weather maps proved that the rising of the dust was due to horizontal convergence, the settling to divergence of the wind.

Another example is the eruption of Krakatoa on August 26–27, 1883. The extremely violent catastrophe and the attendant optical phenomena commanded general attention in all parts of the world. Reports like those of Kiessling [19] and Symons [37] offer excellent bases for future studies of atmospheric diffusion.

Great masses of fine volcanic dust were ejected to levels of more than 30 km. Floating with the currents in the stratosphere, the haze caused extraordinary twilight glows and Bishop's ring around the sun. From this, the diameter of the average particle was deduced to be 0.1×10^{-4}—$0.4 \times 10^{-}$

Table VI. Annual Variations of Total Ozone at 60°N (in cm)
(*After Dütsch* [8])

Basis of computation	Month											
	I	II	III	IV	V	VI	VII	VIII	IX	X	XI	XII
Direct + diffuse radiation + vertical eddy diffusion (under the assumption of equilibrium in vertical columns)	0.22	0.22	0.22	0.22	0.22	0.22	0.21	0.21	0.22	0.22	0.22	0.22
Direct + diffuse radiation + vertical eddy diffusion + average horizontal and vertical circulation in the lower stratosphere	0.23	0.25	0.27	0.25	0.22	0.19	0.18	0.17	0.17	0.17	0.18	0.20
Observation	0.27	0.30	0.31	0.30	0.29	0.26	0.24	0.23	0.23	0.23	0.23	0.25

Systematic differences between the last two lines of Table VI can be disregarded; they may be caused by unreliable values of physical constants in the term $q^{(+)}$.

Annual averages of the vertical ozone distribution show a slow increase of O_3-concentration in the troposphere and lower stratosphere when a rapid increase occurs a few kilometers above the tropopause. This appears to be due to rapidly decreasing D-values in these layers. Thus, another proof for the shape of the D-curve about 15 km above sea level, as shown in Fig. 2, is obtained [21]. In this connection, the observed correlation between total amount of ozone and pressure at sea level appears to be explained by vertical oscillations of the tropopause and layers of $\partial D/\partial z < 0$ when the layers of $q^{(+)}$ remain unchanged.

cm. The mean height of the glow stratum decreased 15 km fairly continuously during 5 months which is approximately 0.1 cm/sec [*c.f.* §9]. The glow stratum travelled several times around the globe completing one circuit in approximately 13 days. On the first circuit the band of twilight glows was centered at the latitude of Krakatoa, 6°S., and the mean extension north and south was 15°. During the second circuit the limits were not so determinate. Up to Oct. 5th the rate of lateral expansion was maintained, but after this epoch a distinct retardation in the latitudinal spread of the main body of haze occurred. In November, a sudden rush took place, which by the end of this month, caused the phenomenon to be seen on the major parts of North America and Europe up to latitude 60°. While the material was crossing 30°N it was simply spreading north and south, and afterwards turned around to move from SW to NE [19].

The Krakatoa eruption and the subsequent phenomena show that three-dimensional diffusion problems in the upper atmosphere cannot be solved without considering the average horizontal and vertical motions and the pertinent steady or unsteady deformation fields of representative motion.

PROSPECTS FOR FUTURE WORK

The present-day inadequacies of the field require experimental as well as theoretical investigations.

More plentiful and improved observations of the composition and the geophysical conditions of the upper atmosphere with the aid of high-altitude balloons and rockets will stimulate considerably the interest in diffusion problems. To be certain of the representativeness of the data, it is imperative that upper-level soundings should be distributed more uniformly than before with regard to season and geographic latitude.

The deficiencies of our knowledge are fairly well illustrated by Fig. 2. The purpose of this graph was to demonstrate how an assumed $D(z)$-function affects the height variation of gas concentration in the stratosphere. Only when $D(z)$ can be verified more soundly than by arbitrary assumptions can the composition of the stratosphere be computed.

The most promising method of direct attack requires chemical analyses of the air at levels above 15 km, especially from the layers of presumably small turbulence at 20–30 and 80–100 km approximately. Because of certain facts discussed in Section 4, permanent gases like argon are preferable in such an analysis; nonpermanent gases like helium, ozone, water vapor, etc., must be compared to permanent gases in order to ascertain the location and characteristics of sources and sinks.

Difficulties encountered in the mathematical analysis of time-varying one- or three-dimensional diffusion must, of necessity, confine the discussion to simplified models of the processes. More thorough and critical considerations than before appear necessary in order to avoid misleading results owing to oversimplification of the models used.

THE IONOSPHERE

By S. L. SEATON

Geophysical Institute, University of Alaska

Introduction

The ionosphere is that portion of the earth's atmosphere containing a sufficient free-electron population to noticeably affect propagation of electromagnetic waves in the radio-frequency spectrum. It might be described also as that region of our atmosphere in which the refractive index has a value perceptibly less than unity.

The free-electron concentration is brought into being through detachment of electrons from negative ions and by ionization of neutral molecules and atoms. Contemporary thought indicates that the principal electron-liberating agent is ultraviolet light from the sun, but other factors are probably active, for example, bombardment by particles, freeing of electrons through molecular recombination processes, and so on.

There is a tendency towards horizontal stratification of electron distribution. Important concentrations of free electrons exist from about 90 km to over 400 km above sea level. In a broad sense, greatest electron densities are to be found at the subsolar point. Because of the high probability of collision and the estimated maximum energy falling on the atmosphere, it is believed that large free-electron populations cannot exist continuously at altitudes less than about 10 km. Balloon-carried detectors indicate no large concentrations of electrons to 30 km, and radio measurements point to no continuous free-electron populations below about 60 km.

There seems to be no reason to restrict the upper limit of the ionosphere, although above about 600 km the atmospheric density is so low that the free-electron concentration is probably limited. Thus the upper and lower limits of the ionosphere are not well-defined.

Historical

As early as 1880 those studying terrestrial magnetism and its variations postulated an electrically conducting region high in the atmosphere in which electric currents flowed, inducing at the earth's surface a small magnetic field. This postulate seems to have been stimulated by speculation upon the causes of the aurora polaris. However, it was not until 1925 that direct evidence was obtained by Appleton and Barnett in England, and by Breit and Tuve in America, proving the existence of a conducting region in the earth's upper atmosphere. These investigators identified electromagnetic waves returned from a reflecting region above their energy source and determined grossly the height of this reflecting region. At first only one layer was detected but subsequently echoes were found to be returned from other heights, giving rise to the idea of separated strata. More recent investigations point towards a continuous region with maxima and minima.

In using the term *free-electron density*, it must be realized that a free electron is one which has become separated from its original environment as part of a negative ion, a positive ion, or a neutral particle. This free electron is likely to be captured soon by another similar environment, there to remain until set free again. Electrons per se, perhaps arriving from space, are usually neglected in considerations of the ionospheric electron density, since the origin of specific electrons cannot be determined at present. Thus the free-electron concentration is made up of the average number of free electrons per cubic centimeter measured over convenient lengths of time, usually of the order of a fraction of a second or more. The contribution made by electrons other than those supposed to belong naturally to the environment has not been investigated, and indeed the means for such an investigation does not seem to be at hand. The same thing is true in regard to the flux of energy through the region.

Neglecting philosophical utterances, which may have struck home by chance, the mathematician Gauss, followed by the physicists Balfour Stewart and Sir Arthur Schuster, showed from studies of terrestrial magnetic-field variations that there should be a region of high electrical conductivity in the upper atmosphere. Their works were known to only a few, and when Marconi succeeded in sending electromagnetic waves over long distances in 1900 it was not understood how these waves could bend round the earth. Unaware of the earlier suggestions, Professor A. E. Kennelly of Harvard University, and the British engineer, O. Heaviside, independently proposed that an electrically conducting region must exist high in the atmosphere which would bend electromagnetic waves back to earth at a distance. Of these two approaches, that is, inference from terrestrial magnetic variations, and propagation of electromagnetic waves, only the latter has given direct evidence of the ionosphere. The former may have unexpected possibilities. The latter gives information about the former.

Methods for Studying the Ionosphere

In addition to the tools already mentioned, the instrument-carrying rocket and examination of energy arriving at the earth from space promise useful information. Other means of exploring the ionosphere, for example, study of compressional wave propagation, light scattered from modulated searchlight beams, meteorological variations, and cosmic ray changes, are worthy of serious consideration. Further seemingly more remote possibilities exist.

Since 1925 only electromagnetic-wave propagation has given adequate information about the ionosphere. In 1925 there were two laboratories, one near London, England, and one near Washington, D. C., at which direct measurements of the ionosphere were being made. In 1949 the reasonable hope of direct measurement by instrument-carrying rockets presented itself. In 1949 over sixty ionospheric measuring stations scattered throughout the populated regions were in operation. Despite these advances an adequate number of observing stations does not yet exist. There is a serious lack of knowledge over a twelve-degree-wide belt in equatorial regions, and both north and south polar areas are virtually unexplored from an ionospheric standpoint. Regions of especial interest are where geomagnetic and geographical equators cross, where they are farthest apart, and polar regions, particularly in the zones of greatest auroral activity. Intermediate locations are also necessary.

Because the electromagnetic wave has so far been of greatest usefulness in exploring the ionosphere, theoretical developments have occurred allowing the alterations suffered by the wave in its passage through an ionized atmosphere to be interpreted. In 1912 Eccles laid the foundation for determining the effect of charged particles upon the propagation of radio waves. The theory was incomplete and in 1924 Larmor supplied improvements. The Eccles-Larmor theory forms the foundation for understanding electromagnetic-wave propagation in the ionosphere, if the effect of the earth's magnetic field is neglected. The problem becomes much more complicated with inclusion of the effect of collisional friction and of the earth's magnetic field traversing the ionosphere. The magneto-ionic theory developed by Appleton, Nichols and Schelleng, Hartree, Goldstein, and others, together with the theories of Lorentz, Booker, and contemporaries, give the broad foundations for interpretation of information collected experimentally. There are still uncertainties, and without doubt additional elegant theoretical work and experimentation must be done before our knowledge approaches completeness. But notable progress has been made since 1880.

Elementary Concepts

Originally the ionized region of the upper atmosphere was called the Kennelly-Heaviside layer. Later, when stratification was indicated, each investigator named his "layer." The ensuing arguments over names became so troublesome that by mutual consent the whole structure was designated the *ionosphere*, with letters and subscripts to indicate the principal regions within it. There are three principal maxima of free-electron concentration: the E-region at about 100 km, the F_1-region at about 225 km, and the F_2-region at about 350 km. The normal E- and F_1-regions develop maximum electron density with greatest solar altitude and exist only by day. Behavior of the F_2-region is more complicated. With low solar altitude F_1- and F_2-regions merge to form a general F-region which persists throughout the night. In the E-region sporadic ionization occurs with quite large free-electron concentrations. Sporadic E-region phenomena are not understood but the ionization appears to be patchy and does not follow solar altitude control. Figure 1 is drawn to a distorted scale in order to permit visualization of the principal ionospheric regions.

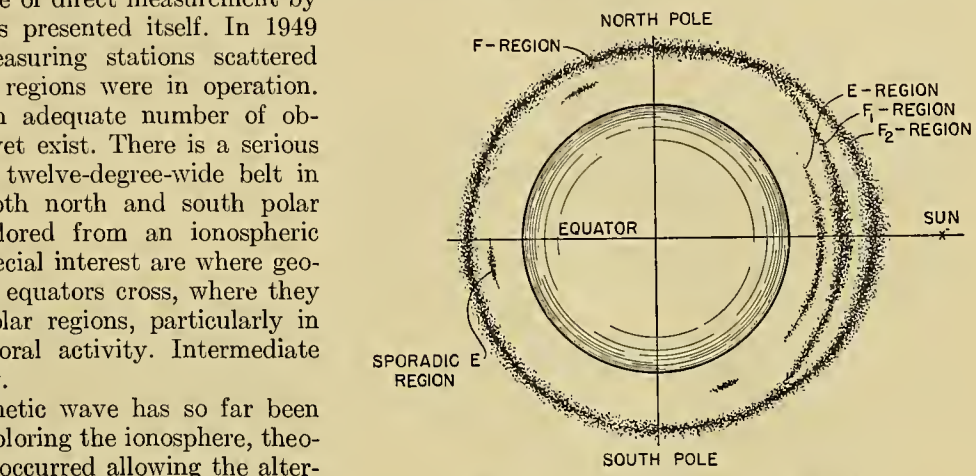

FIG. 1.—Principal ionospheric regions.

In addition to diurnal variations dependent upon solar altitude there is a pronounced change related to solar activity as measured by sunspot numbers. Arguments in favor of some ionization being caused by charged particles bombarding the atmosphere are called up by behavior of the F_2-region. Because the earth's magnetic field extends far into space, charged particles entering the upper atmosphere from space will be deflected by this field. Average maximum F_2-region ionization, studied with respect to the geomagnetic coordinates, shows values in accordance with action of charged particles under the influence of the magnetic field. However, the origin of the particles, their charge, mass, and velocity, are not known. It has not been definitely shown, either, that the observed behavior is surely caused by charged particles. If particles do influence the ionospheric layers, it is not known whether they come from space or whether they are parts of our own atmosphere thrown high up by thermal agitation and returning under gravitational influence.

Typical Data

In exploring the ionosphere by means of the electromagnetic wave at radio frequency, it is usual to emit short wave-trains approximately 10^{-4} sec long of known radio frequency and polarization. The time of departure of each wave packet is noted. One or more wave packets may be expected to return from the ionosphere when the radio frequency emitted lies below a value limited by the number of free electrons and described approximately by

$$N = 1.24\ (10)^4 f^2, \qquad (1)$$

where N is the number of electrons per cubic centimeter and f is the radio frequency in megacycles per second. The returning wave packets are altered during their flight. The elapsed time between transmission and reception, magnitude of returned energy, polarization of the returned wave, splitting of the original wave packet

into two or more returned components, and the angle of arrival give information concerning the medium responsible for return of the wave energy.

In terms of the penetration frequency f_0 and the wave frequency f, the index of refraction for elementary purposes is given by

$$\mu^2 = 1 - \frac{f_0^2}{f^2}. \tag{2}$$

Clearly the index of refraction is a function of frequency and therefore the ionosphere is a dispersive medium. Usually, also, each successive wave packet emitted is of a radio frequency differing incrementally from that preceding. When this process is carried out over a large frequency range, the results can be recorded on a graph as in Fig. 2.

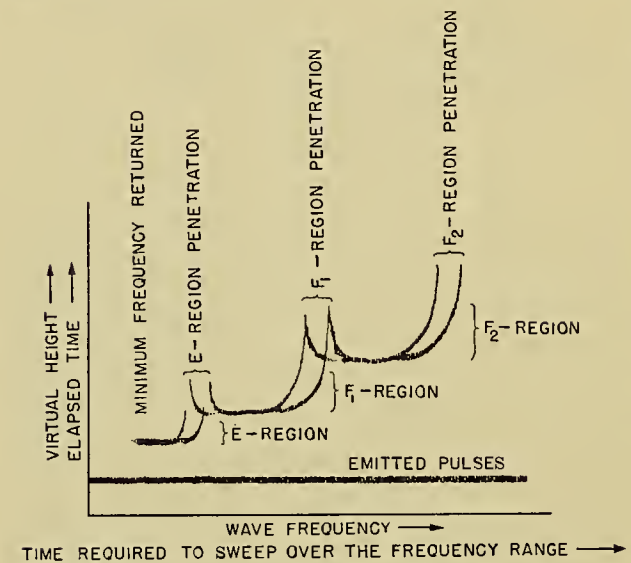

FIG. 2.—Typical data obtained by radio sounding of the ionosphere.

This is the usual form taken by data embracing time of flight versus frequency in temperate latitudes during daylight. Splitting of the original wave packet into two or more components is caused by the effect of the earth's magnetic field. Transmission and reception are at vertical incidence. This technique is the most widely used and is an elegant development of the original Breit-Tuve experiment. Study of the ionosphere at vertical incidence immensely simplifies the general theory for a special case and, although involving some approximations, has given the bulk of useful information about the ionosphere. This procedure fails at low frequencies and is usually replaced by the Appleton-Barnett phase-interference method. Polarization and angle-of-arrival measurements are quite important but have been little used systematically because of inherent interpretative and instrumental difficulties. More attention should be given to them because some uncertainties in the theory cannot be resolved otherwise.

The amount of information to be derived from data represented in Fig. 2 has not been fully realized. For years it was known that the time of flight of a wave packet to and from the ionosphere did not measure the height of the region returning the wave energy. It was not until about 1940, however, that the heights and reasonably sure distributions of ionization were possible. The theoretical investigations of Booker and Seaton, and especially of Rydbeck, now permit distributions to be determined from data in the form of Fig. 2. Briefly, the Booker-Seaton relationship is as follows.

Define a function

$$\varphi(x) = \frac{x}{2} \ln \left| \frac{1+x}{1-x} \right| - 1, \tag{3}$$

and write

$$h' = h_M + \tau \cdot \varphi(f/f_0), \tag{4}$$

where h' is the virtual (or apparent) height at a wave frequency f, and f_0 is the penetration frequency. If heights at two convenient values of f are taken, τ (the semithickness of the parabolic distribution) and h_M (the height of maximum electron density) may readily be determined.

Because of the discontinuities evident in Fig. 2 it was believed at first that the ionosphere was divided into discrete layers. Application of Rydbeck's equations gives a different viewpoint and indicates a general region wherein maxima and minima of ionization occur, but probably no sharp separation into strata.

The difference between penetration frequencies in a region is a measure of the strength of the earth's magnetic field at that height. The reason for this is given in the complicated magneto-ionic theory.

Probable Distribution of Ionization

Consider Fig. 3, in which the heavy curves represent oft-measured quantities, heavy broken lines infrequent

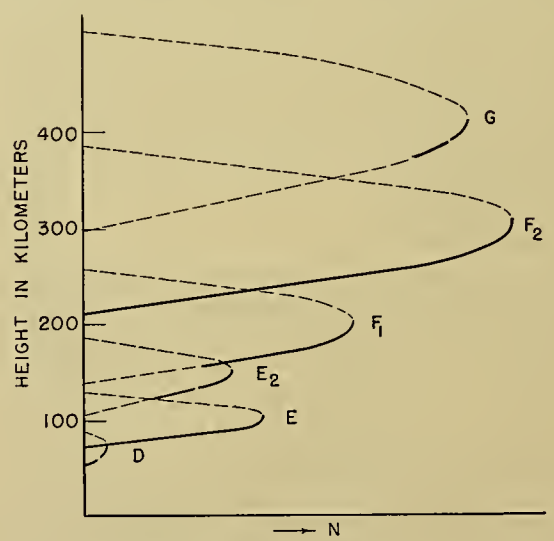

FIG. 3.—Contemporary ideas of free-electron distribution in the ionosphere.

determinations, and dashed lines estimates based upon what seem at present to be reasonable assumptions. Parabolic distributions are shown, but may be replaced

by other distributions as analysis may indicate. Appleton has detected tidal effects in the E-region heights, and Jones has recently found a lunar tide in F-region thickness of some 10 km for a station in high latitudes.

It is to be noted that additional regions are indicated beyond and between those shown in Figs. 1 and 2. The distribution in Fig. 3 represents the most likely ionospheric situation according to contemporary thought. (There is a considerable variation in heights from this typical situation.) The penetration frequencies of Fig. 2 occur whenever the ionization gradient along the direction of wave travel becomes zero in Fig. 3.

The D-Region

Starting at the bottom in Fig. 3, the D-region is not well-defined. There is some evidence that very low radio frequencies are reflected at oblique incidence from heights in the vicinity of 60 km. It is also known that medium-to-high frequencies are absorbed at times in a region below 100 km. The latter information gives no evidence of the height of the absorbing area except that it must be where the mean free path of the electron is small. Wulf and Deming believe that formation of the D-region is the result of photo-ionization of ozone by ultraviolet light. Maximum electron concentration is probably of the order of 2×10^5 electrons per cc. Recombination of electrons with positive ions near the 60-km height is very rapid so that within a few seconds after the ionizing agent ceases to operate any existing free-electron population will disappear. It is in some zone below 100 km that the direct relationship between solar chromospheric eruptions and absorption of radio-wave energy appears. At such times some evidence is available pointing to enhancement of low-frequency oblique-incidence radio-wave propagation by virtue of reflections from a height of about 60 km. Height variations and details of the distribution are unknown. Electron density varies diurnally, seasonally, and with solar activity.

The Normal E-Region

Above the D-region there is to be found a zone in which changes in electron density follow solar altitude quite closely. In the E-region maximum free-electron concentration occurs shortly after local noon; reaching values of the order of 3×10^5 electrons per cc. For the normal E-region, ionization disappears within a few minutes after ultraviolet light from the sun is cut off by the earth. Heights display some variation with geographic location and vary diurnally, seasonally, and with the sunspot cycle. Lowest E-region heights are near 90 km, with maxima near 130 km. Electron distribution within the E-region is not known accurately but probably follows either a Chapman distribution or a parabolic law. The lower boundary is usually well-defined. The half-thickness is of the order of 5 to 20 km. It is in this region that the transition from predominantly molecular oxygen to predominantly atomic oxygen occurs. It is thought that electrons are freed in the E-region by photo-ionization of oxygen molecules.

Sporadic E-Region

In addition to the normal E-region, there occurs an E-region ionization sporadic in occurrence and density. Some of this sporadic ionization is brought about by meteors encountering the earth's atmosphere. However, at present it is believed that meteors are not the only source, but that some other mechanism is present. There is a semblance of system in occurrences of sporadic E-region ionization such that the phenomenon appears most frequently in the arctic regions at night, particularly near zones of maximum auroral activity.

Maximum electron concentrations reach values for the sporadic E-region of over 3×10^6 electrons per cc. Heights appear to be about the same as those of the normal E-region. Duration of sporadic E-region ionization may be from a few seconds to several hours. There is some indication that the sporadic E-region may be of patchy form and at times may move or propagate rapidly. The recombination coefficient between electrons and positive ions is of the order of 1×10^{-8} cc sec^{-1} for the E-region generally.

The E_2-Region

Until recent times it was thought that E- and F_1-regions were virtually separate entities with essentially no intermediate free-electron density. However, enough experimental evidence is now available to indicate the probability of an E_2 distribution centering near 150 km in height. This distribution is not always seen because the maximum concentration is normally less than that of the E-region. Little is known of the E_2-region, but it may be existent by virtue of photo-ionization of atomic oxygen. It appears to occur most frequently in the daytime.

The F_1-Region

The F_1-region exists in identifiable form in the daytime with large solar altitudes. In general behavior the F_1-region resembles the E-region. Maximum densities occur a little after local noon and attain values of the order of 4×10^5 electrons per cc. With low solar altitudes F_1- and F_2-regions merge to form the general F-region which persists throughout the night at all latitudes where measurements have been made. Maximum electron density varies diurnally, seasonally, and with sunspot activity. There is at present no conclusive evidence that ionization is caused by other than ultraviolet light. Wulf and Deming favor one of the nitrogen-molecule absorptions as responsible for formation of the F_1-region. Mohler has pointed out that, because the recombination coefficient between electrons and positive ions is a function of pressure, the height at which maximum production of ionization takes place is probably below the height at which maximum concentration occurs. Heights of the F_1-region vary over wider limits than do those of the E-region. The range in height is roughly from 160 to 280 km. There is a diurnal variation with lowest heights around midday. This region rises slightly to merge with the F_2-region near sunrise and sunset. Seasonal and longer-period variations in height occur and there is a variation with latitude.

The half-thickness of the F_1-region ranges roughly between about 10 and 30 km, depending largely upon time of day, season, and solar activity. Very occasionally during disturbance a well-formed F_1-region appears at night. This latter phenomenon is not understood. The recombination coefficient between electrons and positive ions is of the order of 1×10^{-9} cc sec^{-1} for the F_1-region.

The F_2-Region

The F_2-region of the ionosphere has been extensively studied because its variations present peculiarities not immediately evident in the lower regions. When the F_2-region is mentioned it is customary to think of the general F-region at night and the F_2-region in the daytime as being of the same character. During intervals when the F_2- and F_1-regions are not separately identifiable the region unresolved is thought of as the general F-region and as having F_2-region characteristics predominantly.

An outstanding oddity of the F_2-region (or the general F-region) is that maximum electron density occurs everywhere in the Northern Hemisphere in midwinter when the solar altitude at noon is much lower than in midsummer. From this behavior it is evident that F_2-region maximum electron concentration does not follow solar altitude changes in the same manner as do the E- and F_1-regions. Berkner and Wells, and later Seaton and Berkner, demonstrated the existence of a nonseasonal component in the F_2-region electron concentration which is world-wide in appearance and may be caused by the annual change in distance between earth and sun. Maximum free-electron density in the F_2-region is quite sensitive to solar activity, varying some 300 per cent during the sunspot cycle, but this nonseasonal variation persists throughout.

Frequently, depending upon location, season, and solar activity, the maximum concentration of electrons does not occur near noon. While there is always an afternoon maximum, the time of its occurrence varies from about an hour to several hours after midday and there frequently is a pre-noon maximum. The effect of such variations is often to create a minimum at noon. This noon decrease in F_2-region electron population was originally thought to be caused by heating and consequent expansion of the region. Later it was suggested that such a proposal was untenable when Northern and Southern Hemisphere data were examined over the same time interval. In more recent years a different approach to the description of the ionosphere has arisen in which electron concentration is replaced by total electron content in the region. This concept is particularly important for the F_2-region. When F_2-region behavior is examined by this newer measure, much if not all of the peculiar bimodal behavior is removed, leaving a single maximum occurring after noon. It has been demonstrated that the F_2-region may grow thinner over an interval of time, leaving the electron concentration unchanged but reducing the total electron content. In other words, maximum concentration is not necessarily a correct indication of the behavior of this region, and the use of concentration alone may lead to false concepts especially when rates of electron production, recombination processes, and other factors are sought.

Early unexplained asymmetry of the F_2-region has to some extent been clarified through consideration of data in terms of geomagnetic coordinates. It is in this layer that strongest evidence exists pointing towards ionizing agents other than ultraviolet light from the sun. All characteristics of the F_2-region display wide variations when compared with those of the lower layers.

One of the important methods for study of the ionosphere is examination of electron-concentration variations during eclipse of the sun. The E- and F_1-regions show behaviors in good agreement with theory, but eclipse effects in the F_2-region have been difficult to detect. One reason for difficulty in isolating such effects in the F_2-region is of course the small recombination coefficient between electrons and positive ions, which is of the order of 1×10^{-10} to 1×10^{-11} cc sec^{-1} at these great heights. Another reason for difficulty is the immense variability which is always evident in the electron density of the F_2-region. Some investigators have pointed out that if an important part of the F_2-region ionization is caused by corpuscular bombardment, eclipse of the ultraviolet light would not coincide with eclipse of the particle stream. Corpuscular eclipse has been sought without success. There is some evidence, although not wholly satisfactory, of ultraviolet light eclipse in the F_2-region. The semithickness of this region ranges between about 30 and 100 km.

Free-electron densities in the F_2-region range between about 2×10^4 electrons per cc for winter night and 3×10^6 electrons per cc for daytime during maximum solar activity. The free-electron population in the F_2-region is probably the result of photo-ionization by ultraviolet light of the nitrogen molecules. Ionization of atomic nitrogen and atomic oxygen may also contribute during the middle of the day.

The G-Region

The highest ionospheric region for which any evidence exists is the G-region (see Fig. 3). This region may be present in reality. Occasionally data of the type shown in Fig. 2 develop an additional retardation beyond the F_2-region penetration frequency. In some records where additional reflections appear, the character of the data suggests Rayleigh scattering from patches of ionization of the order of a wave length or less in diameter. On other occasions, however, the data are so suggestive of another higher region that credence must be given this possibility. There is certainly no a priori reason why such a G-region should not be present. It may always be present but, because of rarity of the atmosphere in the vicinity of 400 km, may only develop free-electron concentrations greater than those in the F_2-region during unusual conditions. So little is known of the G-region that it can only be said of the free-electron concentration there that it is almost always less than that of the F_2-region. Height of maximum concentration is probably of the order of 400 to 500 km.

Relations between the Ionosphere and Surface Meteorology

When it is remembered that postulates concerning the existence of the ionosphere originated with mathematicians and magneticians and that proof of the reality of the ionosphere was given by engineers and physicists, it is not astonishing to observe that many years passed before the ionosphericists and the meteorologists found a common interest in the ionosphere from a meteorological point of view. The meteorologist with his nose to the ground and the ionosphericist with his head above the clouds have, since about 1946, permitted themselves to recognize the possibility of mutually profitable cooperative studies of the high atmosphere.

Oliver Wulf investigated F-region variations in connection with upper-air meteorological soundings. The Australians studied ionospheric phenomena together with movement of fronts across the continent of Australia. Appleton searched for and found a small tidal effect in the E-region, and other investigators sought connections between the behavior of upper and lower portions of the earth's atmosphere. One of the greatest hindrances to appreciation of important variations in pressure, temperature, and state of the upper atmosphere has been the concept of an isothermal upper atmosphere in diffusive equilibrium. Serious suspicion was first cast upon this concept by the Norwegian students of the aurora polaris and by Whipple and his colleagues in study of meteor trails. Contemporary thought has all but discarded the idea of such a quiescent upper atmosphere.

Available evidence points towards an ionosphere in which thorough mixing of atmospheric gases is the rule. Proportions of nitrogen, oxygen, hydrogen, and so on, appear to be about the same in the ionosphere as at sea level with the exception that the atomic states may prevail in the ionosphere at higher levels. The amount of water vapor in the ionosphere is thought to be negligible.

From the meteorological standpoint the ionosphere appears to have immense possibilities. It is clear that energy entering the environment of the earth from space first strikes the high atmosphere and at least some of this energy causes large changes in the ionosphere. Ionospheric behavior is quite sensitive to variations in energy in the ultraviolet light portion of the spectrum. The ionosphere probably is influenced to a noticeable extent also by corpuscular streams of energy. Jones has recently isolated variations in thickness of the general F-region which correlate inversely with ground barometric pressures. While this work is incomplete, tentatively it appears that variations in ground barometric pressures lag several hours behind changes in F-region thickness in some latitudes.

Ionospheric Temperatures

Many attempts have been made to deduce, by various means, temperatures in the ionosphere. The first speculations favored an isothermal condition with temperatures near 230K. Later when the noon decrease in F_2-region electron concentration was noted in the Northern Hemisphere, temperatures of the order of 2000K were proposed for this region.

Several approaches have been employed in trying to determine ionospheric temperatures. The Norwegians, remembering that the aurora polaris occurs in the same space as does the ionosphere, have estimated (from spectroscopic measurements) nighttime temperatures of 228K in the vicinity of 100 km and have argued on the basis of similar measurements that this temperature increases as soon as the sun's rays impinge on atmospheric gases at these heights. Penndorf, using scale height of the ionosphere, gives values for the E-region temperature near 350K and for the F_2-region near 700K. Other students give values for the E-region ranging from 100K to 1000K, and for the F-region between 120K and 4000K. Many of the results have been highly speculative and based upon other than conservative estimates.

One of the most promising methods to emerge in recent years is deduction of ionospheric temperatures on the basis of hour-to-hour changes in data of the form of Fig. 2. By means of such data, application of the Booker-Seaton method of reduction to true heights, use of Appleton's arguments, and the invoking of Thomson's relationship between recombination coefficient and absolute temperature, it has been possible to make an objective approach to this problem. The time rate of change of electron density is given by

$$\frac{dN}{dt} = q - \alpha N^2, \tag{5}$$

where q is the rate of production, and α the recombination coefficient between electrons and positive ions. The relationship between the recombination coefficient and the absolute temperature is given by

$$\alpha = \alpha_0 \, (P_0/P)^\gamma \, (T/T_0)^3, \tag{6}$$

where α_0, P_0, and T_0 are reference values of recombination coefficient, pressure, and temperature respectively, and γ probably has a value near $\frac{1}{3}$. Neither of the foregoing expressions is exact, but in this simplified form they serve to illustrate the central line of reasoning. While the results cannot be considered entirely satisfactory, the method has been tested for some twenty geographic locations over a range of conditions. In most instances results are reasonable and self-consistent. One of the unexpected concepts to come from this method has been that of a cellular arrangement of temperature isopleths, indicating the probability of systematic wind systems in the ionosphere. While by no means conclusive, application of this objective method at the same location and time as soundings by rockets gives excellent correspondence at E-region heights.

It is clear from the foregoing discussion that it is no longer acceptable to consider the ionospheric temperature as a simple function of height. Rather it appears to be necessary to examine the data from many stations over the world throughout the seasons and, from the derived information, to construct isopleths descriptive of the arrangement of ionospheric temperatures.

By this method, temperatures for January 1947 taken on a world-wide basis range between 100K and 500K for the E-region; between 50K and 1500K for the F_1-region; and between 100K and 1000K for the F_2-region. The ranges indicated are a function of latitude and of local time; and probably of season, solar activity, and other factors. Thus there seems to be a strong possibility of being able, in the near future, to calculate from the dynamics of the situation the probable wind systems in the ionosphere and to investigate possible connections between the ionosphere and lower-atmosphere meteorology.

Aside from electromagnetic-wave propagation, the study of propagation of sound waves from large explosions throws some light upon E-region temperatures. Preliminary results indicate E-region temperatures of the order of 400K for temperate latitudes.

Probable Formation Mechanisms

Wulf and Deming have given what appears to be the most acceptable discussion of causes of the ionospheric structure. Their work, taken with that of Mohler, constitutes a good basis for further study as knowledge of the ionosphere develops. Only the D-, E-, and F-regions are examined by these authors. Knowledge of the probable existence of the G-region came at a time after these original papers had been presented.

Wulf and Deming have shown that above about 100 km oxygen atoms predominate and that below about 100 km oxygen molecules predominate (other constituents being the same) and have assumed a temperature of 219K up to 100 km, with a temperature of 700K above 100 km, and have consequently decided that the F_2- and F_1-regions are caused by two distinct nitrogen-molecule absorptions and that the E-region is the result of oxygen-molecule absorption. According to these authors, the D-region is the result of a broad absorption by ozone. By inference, using arguments of Wulf and Deming not elaborated upon by them in terms of later experimental evidence, it may be that the E_2-region is formed by oxygen-atom absorption and that the G-region is developed through nitrogen-atom absorption.

It appears in light of later work on ionospheric temperatures that the temperatures assumed by Wulf and Deming may not be correct. However, alteration of the temperature arrangement to what seem to be more appropriate values will only change somewhat the heights where maximum absorptions occur. In fact, the adoption of the more recent temperature postulates will improve the results of Wulf and Deming, giving better agreement between their deductions and the experimental information about the location of the regions.

Need for Additional Studies

While many observations of the ionosphere as deduced from electromagnetic-wave propagation have been made, a great portion of this information is poorly controlled from the standpoint of accuracy. Much of the available information is in the form of short series of measurements over restricted frequency ranges. There is a great need for accurate, long-continued observations over all geographic locations. Only in this way can sufficient data be accumulated to permit satisfactory study of the ionosphere and its relationship to the lower atmosphere. In addition, the various theories need to be re-examined and extended to remove uncertainties now present. The region of ten to twelve degrees above and below the equator at all longitudes is in great need of exploration. Both north and south polar areas are virtually unexplored. In all but polar regions it is entirely feasible for the governments of countries considered civilized to establish permanent observatories for study of the ionosphere. Such programs must lead to results of importance from many viewpoints.

It is quite difficult, on the other hand, to establish stations within about 25 degrees of either pole. It is suggested that with modern high-speed ionospheric recorders it is entirely within the realm of possibility to make systematic ionospheric measurements from long-range aircraft. Such a program, ideally, should be a cooperative one engaged in jointly by all nations, and particularly by those bordering upon the polar areas.

NIGHT-SKY RADIATIONS FROM THE UPPER ATMOSPHERE

By E. O. HULBURT

Naval Research Laboratory, Washington, D. C.

Introduction

In places remote from artificial illumination at night, with no moon, the luminosity of the sky is due to several sources of light, all of which are at a considerable distance. The sources are (1) radiations from the gases of the upper atmosphere, (2) polar aurorae, (3) zodiacal light, (4) comets and possibly scattered sunlight in interplanetary space (if there is something there to scatter the sunlight), and (5) stars and nebulae in interstellar space.

If we omit polar aurorae from consideration, the radiations from the high atmospheric gases are the strongest source of night illumination, being four or five times as intense as all of the other sources combined. In more detail, the intensity of the night-sky light averaged over the sky is divided as follows: For the photographic spectrum [5] region from 3500 to 4500 A about $\frac{1}{6}$ is due to the stars, $\frac{1}{6}$ to the high atmospheric emissions, and possibly $\frac{1}{6}$ to emissions from interplanetary space (the amount attributed to sources in interplanetary space has decreased as the measurements have improved; it is now down to about $\frac{1}{6}$ of the whole and may eventually become a few hundredths or even less); for the visible spectrum [17] seen with the dark-adapted eye, about $\frac{1}{5}$ is due to the stars and $\frac{4}{5}$ due to the high atmosphere; for the entire spectrum from about 3000 to 10440 A, because of its strong infrared nitrogen emissions, the high atmosphere contributes more than $\frac{9}{10}$ of the nocturnal radiation and the stars less than $\frac{1}{10}$. These fractions are average values; for areas in the sky such as the Milky Way where there are many stars the fractions of the sky luminosity due to the stars are greater than the average values, and for areas in the sky where there are few stars the fractions are less.

Spectrum

The night-sky light is feeble, and even with spectrographs of the highest light-gathering power, relatively low dispersion and long exposures are necessary to obtain spectra. We need to refer only to recent work and mention that the best spectra at present available were those obtained by Cabannes and Dufay [8] in 1933–34 in France; by Elvey, Swings, and Linke [12] in 1939 at the McDonald Observatory, University of Texas; by Barbier [4] in 1942–44 at the Observatory of Haute Provence, France; and by Meinel [19] in 1948 at the Lick Observatory, University of California.

The dispersion of the spectrograph of Barbier was 150 and 630 A mm^{-1} at 3200 and 5000 A, and the length of the spectrum from 3200 to 5000 A was about 7 mm; exposures from 100 to 200 hours were used. The McDonald spectrograph had slightly higher dispersion and much greater light-gathering power; the dispersion was 115 and 500 A mm^{-1} at 3200 and 5000 A, the length of the spectrum from 3200 to 5000 A was about 10 mm, and exposures of 9 hours were used. These were prism spectrographs and therefore had low dispersion for the longer wave lengths. To obtain better data for wave lengths longer than 6000 A, Meinel built a spectrograph with an f/1 camera and a 7500 line per inch transmission grating with a dispersion of 250 A mm^{-1} in the first order; exposures of 30 hours were used. Night-sky spectra are shown in Fig. 1, in which *A* is a spectrum photographed by Barbier [18], *B* by Elvey, Swings, and Linke [12], and *C* by Meinel [19]. In Fig. 1*C* the narrow

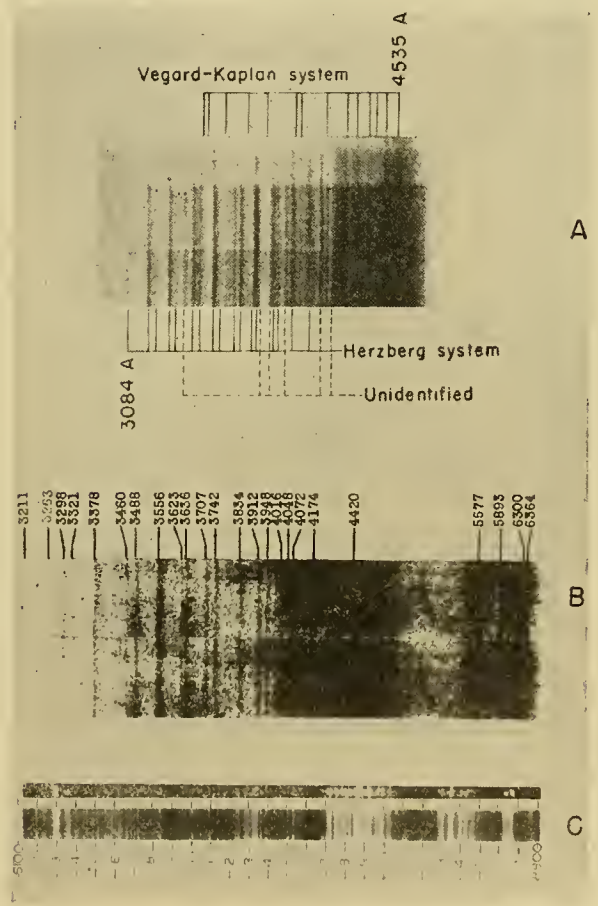

FIG. 1.—Spectra of the night sky, *A* by Barbier [18] (*reproduced by permission of The University of Chicago Press*); *B* by Elvey, Swings, and Linke [12]; and *C* by Meinel [19].

upper strip was the original spectrum from which the lower strip was obtained by spreading; Meinel remarked that many of the features of the lower strip were spurious and were caused by grains of the photographic plate.

The night-sky spectrum is very complex and is composed of many lines and bands, for the most part in-

completely resolved. In Table I are listed the wave lengths of the night-sky emissions and their identifications which are probably agreed to at present; "h" indicates the Herzberg system of molecular oxygen, and "vk" the Vegard-Kaplan system of molecular nitrogen. Wave lengths 8829 to 6300 A in Table I were from the list of Meinel [19], and wave lengths 5896 to 3029 A from the lists of Déjardin [9]. The sources of the emissions whose identification seemed certain are given in Table I. The only atomic lines are the green line 5577 and the red pair 6364, 6300, which are forbidden transitions of oxygen, and the yellow pair 5896, 5890 of sodium. All the remaining lines and bands are of molecular origin. The line at 10440 A of the first positive system of N_2 is by far the strongest emission thus far observed, being about thirty times as intense as the green line 5577, the next most intense emission. It was discovered in 1940 by Stebbins, Whitford, and Swings [25], by means of a photoelectric cell and filters, and its wave length was determined within ±25 A. It was also discovered independently by Herman, Herman, and Gauzit [15]. A group of lines 6580, 6530, and 6470 A, also due to the first positive system of N_2, were mentioned by Déjardin, but were not listed by Meinel; they cannot be seen in Fig. 1*C*, and have not been included in Table I.[1] About 35 bands, which include the strongest blue-violet bands, were identified with the Vegard-Kaplan system of N_2, and about 33 bands, which include the strongest ultraviolet bands, were identified with the Herzberg system of O_2.

4869	1	N_2,vk	4004					

In addition, in Table I, there are a number of unidentified lines or bands due to unknown systems. A weak continuous background with a trace of Fraunhofer absorptions, which was mentioned in earlier work, was not observed in the better, more recent spectrograms. It was this background which was attributed to sunlight scattered by material in interplanetary space. But since its existence is now uncertain one may be doubtful of inferences based on it. The Shumann-Runge system of O_2 and the Lyman-Birge system of N_2 have been looked for, but no certain identifications have been made; the same is true for *CO* and CO_2, H_2, O_3, NO_2, N_2O_4, N_2O, N_2O_3, NH_2, NH_3, *CH*, *CN*, H_2O, and compounds of *Na*, *Si*, and *S*.

The spectral intensity distribution received at the surface of the earth [6] is given approximately in Table II.

Table II. Intensity of Night-Sky Emissions

Wave length (A)	Emitter	Intensity (erg cm^{-2} sec^{-1})
10440	N_2	190 × 10^{-4}
6300, 6363	*O*	5 × 10^{-4}
5890, 5896	*Na*	0.7 × 10^{-4}
5577	*O*	7 × 10^{-4}
Main band systems	N_2, O_2	10 × 10^{-4}

The only reported spectral energy distribution of the night-sky light is that of Babcock and Johnson [3] derived from measurements of a small photographic spectrum of dispersion 1100 A mm^{-1} at $H\gamma$. Their curve is given in Fig. 2; it rises with increasing wave length throughout the extent of the spectrum from 3800 to 6500 A, with bumps at the various lines and bands A color temperature of 3450K was ascribed to it. Thus the night-sky light may be said to be yellowish in color.

Variations

If we exclude polar aurorae, the variations in the total intensity of night-sky emission are relatively

1. In a private communication Dr. Meinel stated that photometric traces of his spectra showed a faint feature centered at 6562 A.

small, rarely as much as a factor of 2. During the full nighttime hours there appear to be many small irregular and complex intensity fluctuations which vary with the

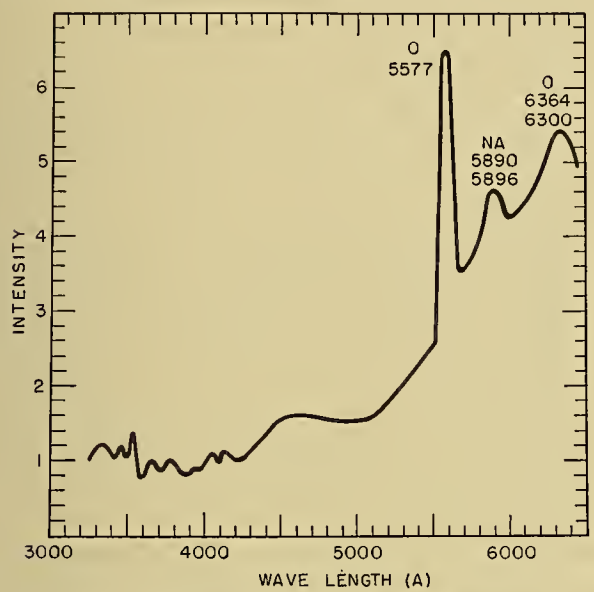

FIG. 2.—Spectral energy distributions of night-sky light. (*After Babcock and Johnson* [3].)

place in the sky and which are different for the various wave lengths. There are strong intensity changes during twilight.

Diurnal Variations. In France, Dufay and Tcheng Mao-lin [10] obtained 588 spectrograms during 189 nights from October 1940 to January 1944. From these spectrograms systematic measurements were made of the intensity variations of the oxygen lines 5577 and 6300 A and of the sodium pair 5893. The oxygen line 5577 A usually showed a weak maximum around midnight (not more than 40 per cent) often obscured by fluctuations; 6300 and 5893 A merely weakened slowly during the night, the enfeeblement for 6300 being greater than that for 5893 A, which amounted only to 10 or 15 per cent. In Russia [23] photocell measurements of radiation in the infrared region 850 to 11000 A indicated that the intensity was at a maximum around midnight, being about twice as great then as at 10 P.M. and 2 A.M.

Twilight Effects. The green line 5577 was observed to exhibit no twilight enhancement. On the other hand, the sodium yellow emission 5893 dropped suddenly in intensity to one per cent of its former value at about ten minutes after sunset [7] with a corresponding recrudescence near dawn. Likewise the red oxygen lines 6300 showed a similar but slower change during twilight [13]. The strong N_2^+ flash at twilight discovered by Slipher is intense in aurorae but absent from the night sky.

Annual Variations. In temperate latitudes 5577 has slight maxima in October and February, and a 27-day variation in intensity, hence a faint correlation with solar phenomena; 6300 and 5893 have maxima near midwinter and minima in summer of amplitude factors of about 2.5 and 5, respectively; they seem indifferent to solar phenomena [2, 10, 12].

Latitude Variations. A survey [17] of the visual brightness of the night sky in various latitudes was carried out with standardized visual photometers which had a field of view about 11° in diameter. Visual measurements of the night-sky luminosity refer mainly to the strong atomic oxygen line 5577. This is because, by multiplying the night-sky spectral energy curve of Fig. 2 by the sensitivity curve of the dark-adapted eye, one finds that 5577 has the main effect (8/10) with only minor influence from the oxygen red lines 6300, 6363, the sodium yellow lines 5896, 5890, and the molecular bands in the blue and green.

Observations were made at stations in Bocaiuva (Brazil), Bikini, Maryland, Whiteface Mountain (New York State), and Greenland, at latitudes −17°, +12°, +39°, +45°, and +63°, respectively. The results are plotted in Fig. 3, in which the ordinates are the night-

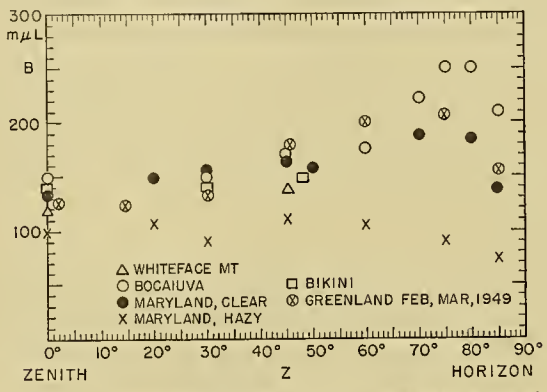

FIG. 3.—Average night-sky brightness at several localities [17].

sky brightness B in millimicrolamberts (mμL; 1 mμL = 10^{-9} lambert = 2.96×10^{-7} candle ft^{-2}) and the abscissas are the zenith angle Z of the place in the sky. Each point of Fig. 3 was the average of values observed in several directions for several nights when no polar aurorae were visible [17].[2] From the data of Fig. 3 it was concluded that there were no changes with latitude in the visual night-sky brightness which could not be attributed to variations in haze.

In connection with the geographical distribution of night-sky intensity, Farnsworth and Elvey [13] concluded that their photographic observations with a glass-prism spectrograph indicated no major differences at Bosque Alegre, Argentina (32°S), Portrerillos, Chile (27°S), and in the southern New England states; their data were too meagre for much generalization. Rayleigh [21] concluded from his visual observations that the average intensities of the blue, green, and red spectral regions at Terling, England (51°N), Capetown, Africa (34°S), and Canberra, Australia (35°S) were of comparable magnitude, but tended to be highest at Terling

2. Data for latitude +63° were observed in February and March, 1949, by personnel at a United States Air Force weather station in Greenland using a Naval Research Laboratory visual low brightness photometer.

and lowest at Capetown. Visual measurements of the sky near Polaris, reported by Fessenkoff [14], indicated that the brightness increased by a factor of 4 from latitudes +44° to +80°, but the result may have been influenced by polar aurorae; it is not in accord with the observations of Fig. 3.

Variation with Zenith Angle. The variation of the visual brightness of the night sky with zenith angle is also shown by the data of Fig. 3, which as has been pointed out refer mainly to the oxygen green line 5577 A. It is seen that the variation of the brightness with zenith angle Z was about the same for latitudes from −17° to +63°, and that the brightness increased from about 130 mμL at the zenith to a maximum of about 230 mμL at about 15° above the horizon for a clear atmosphere; with slight haze the maximum near the horizon became less pronounced, and with more haze it disappeared [17]. The variation was observed at the Pic du Midi Observatory, France, to be somewhat different for red and green wave lengths [1], the sky intensity observed through a red filter being about 2.2 times as bright at $Z = 80°$ as at the zenith, and through a green filter being about 1.7 times as bright at $Z = 80°$ as at the zenith. The difference was probably due to the greater scattering of the lower atmosphere for green wave lengths than for red wave lengths.

Altitude

The altitudes of the regions in which the high atmospheric emissions originate are not known with certainty. The method which has been used has been well described [17] and need not be detailed here. It is based on the observed variation of the night-sky intensity with zenith angle, and when applied to the night-sky observations led to erratic and discrepant values from fifty to several hundred kilometers. The uncertainties were due to nonuniformity of the emissions and to incompletely worked-out corrections for atmospheric attenuations. But even with better correction formulas no improved or more trustworthy values of the altitudes were determined [17]; and in no case was the atmospheric attenuation measured at the same time that the sky intensity was observed. Swings [26] stated the situation thus:

> There are great irregularities in the distribution of the emission over the sky. These irregularities appear consistently when simultaneous exposures in different azimuths at the same zenith distance are compared. No layer of uniform brightness exists, but rather a set of bright clouds, which move around and change brightness. The only remaining hope is that, by taking a sufficiently large number of observations, the erratic fluctuations will average out.

From 1941 to 1944 Dufay and Tcheng Mao-Lin [11] in France made several series of measurements with their spectrograph of the ratios of the intensities of various wave lengths at the zenith to the intensities near the horizon. From averages of the observations with approximate corrections for estimated atmospheric attenuation, they obtained an altitude of 103 km for 5577 A, 80 km for 5892 A, and 181 km for 6300 A. In 1948 Roach and Barbier [22] carried out surveys of the night-sky intensity in California with recording photocell equipment and interference filters for isolating narrow regions of the spectrum. By using average values, with correction for scattered starlight and estimation of atmospheric attenuation, they obtained an altitude of 100 km for 5577 A and about 300 km for 5892 A. Plans are under way to carry out direct photocell measurements from rockets to determine whether the nocturnal radiations arise in regions accessible to the rockets.

The altitude of the yellow sodium line 5892 A in twilight was determined in another way based on the fact that these radiations decreased suddenly in intensity at twilight when the region in which they originated was shielded by atmospheric ozone from the direct ultraviolet rays of the sun. Calculations made by Penndorf [20] from the observations of Vegard and Tønsberg [27] in February and March 1939, at Tromsö and Oslo, indicated definitely that the altitude of the sodium emission at twilight in those places was in the region from 80 to 116 km.

At present one should keep in mind the probability that the various night-sky radiations may arise at different levels, and that the levels may change in the course of the night and may vary with the latitude and season. Further, it seems reasonable to think that the night-sky emissions originate mainly in the atmospheric levels of the aurorae and the ionosphere, that is, from about 80 to 300 km, for it is in this region that strong photochemical effects occur.

Theory

The spectral identifications show that most of the night-sky emissions come from the two most abundant gases of the atmosphere, oxygen and nitrogen; a small portion comes from sodium. No one has questioned the general notion that the nocturnal emissions derive their energy from the sun, but no processes or quantitative details have been agreed upon because information is lacking about radiation transitions and atmospheric composition. In fact, without exception, all theoretical processes, qualitative or quantitative, thus far proposed, have been weighted down with a wealth of criticism [6].

The excitation energy of the line systems 5577 *O* I, 6300 *O* I, 5893 *Na* I are 4.2, 2.0, and 2.1 ev, respectively; and of the band systems Vegard-Kaplan N_2, Herzberg O_2, Schumann-Runge O_2, and Lyman N_2 are 7.0, 4.7, 6.2, and 8.7 ev, respectively. Three theoretical suggestions for the source of the energy in the high atmosphere are that it arises from (1) the association energies of atomic oxygen and nitrogen which are 5.09 and 7.38 ev, respectively; (2) the energies of ionization, which are about 13.5 and 14.5 ev for the first ionization potentials of atomic oxygen and nitrogen, respectively; (3) particles of solar origin or particles swept up from the dust of interplanetary space. It appeared that (1) was sufficient for the line systems but for none of the band systems except that of Herzberg (perhaps the Shumann-Runge and the Lyman band systems need no longer be considered because, as has been said, they are not listed in

the more recent night-sky spectral identifications); (2) seemed energetically satisfactory, but not completely in accord with the Frank-Condon probabilities; (3) is speculative and has not been put in quantitative terms.

The relatively small amount of sodium in the upper atmosphere necessary to account for the 5890, 5896 emissions may come either from the surface of the earth, as the sea, or from interplanetary space. Both views have been suggested and the correct one is not known. There have been no explanations of the remarkable winter enhancement of the sodium emissions observed in temperate latitudes. It would be of interest to observe the emissions in low latitudes. Whether the sodium emissions are merely a minor geophysical phenomenon or have wider astronomical interest is not yet clear.

Zodiacal Light

The zodiacal light is a well-known luminous phenomenon of the night sky which adds appreciably to the brightness of certain regions of the sky near the ecliptic. At present the facts available are not adequate to allow us to say whether the zodiacal light arises in the terrestrial atmosphere or at a greater distance, and therefore space will not be taken here to describe it. There are two theories to explain the zodiacal light. An older theory [24] attributes it to sunlight scattered from a lens-shaped disk of dust particles in the plane of the ecliptic extending well beyond the orbit of the earth; a more recent theory [16] attributes it to sunlight absorbed and re-emitted by a band of atmospheric ions surrounding the earth in the outer fringes of the upper atmosphere. Each theory has points in its favor but further investigations of the zodiacal light with modern spectrographic and photocell techniques and better determinations of its parallax are necessary to reach a correct explanation.

Aurora

We have attempted to exclude the aurora from the foregoing survey of the night-sky light knowing that this cannot be done, and in the end should not be done. It is probable that a complete understanding of the night sky cannot be reached without at the same time having a complete understanding of the aurora. Both, it is believed, derive their primal energy from the sun. The aurora emissions are mainly from the same familiar gases of our atmosphere, oxygen and nitrogen, as are those of the night sky, but with different spectral distributions, with enormously greater intensities and in quite different geometrical patterns. The auroral energy is believed to be received in concentrated form from explosions or outbursts on the sun, in contrast to the relatively gentle and steady solar-energy stream which supports the normal night-sky light. The kinship between the aurora and the night-sky light may be analogous to that between a hurricane and a gentle rain.

Suggested Experiments

At the present time enough is known about the light of the night sky to indicate that it is an important and interesting phenomenon of the upper atmosphere. Some further experiments may be suggested which may increase understanding of the nature and origin of the light. However, the experiments are not easy and require the best of modern equipment. This is true, of course, of most experimental sciences, for in any field the easy experiments are done so quickly by the pioneers that later experimenters almost always find themselves in the stage where further progress is difficult.

Improved spectra of high dispersion of the night-sky light should be obtained. For such a purpose powerful spectrographs and the facilities of a first-class observatory are required. The spectra would provide needed additional information about the types of emitting atoms and molecules, and perhaps might answer the important question whether *any* of the night-sky light is sunlight scattered by material sufficiently distant from the earth to be in sunshine. Spectra should also be taken of the zodiacal light in order to discover whether it is a luminous apparition which originates in the outer reaches of the terrestrial atmosphere or in some more distant place. Spectra of the aurorae should be included.

The distribution of energy in the spectrum of the night-sky light should be redetermined with improved equipment; this has been done only by means of spectrographs of very low dispersion. Detailed measurements of the intensities of the lines and bands of the spectrum should yield information about the excitation phenomena of the radiations and the physical state of the regions of the atmosphere in which they occur.

Surveys should be made over the entire sky in the several wave-length bands in order to determine the nature and behavior of the variations of the luminosity. Sensitive photocells and filters which pass narrow bands of wave lengths could be used for this purpose. Such surveys should be carried out at several stations for a period of time to bring out geographical and temporal variations and to establish relations, if any, with other phenomena, such as season of the year, solar activity, and ionospheric variations. From the variation of the intensity with zenith angle the data might yield better determinations of the altitude of the luminosity. The strong infrared radiations should be included in the survey.

The survey of the night-sky brightness in several wave lengths with carefully standardized and calibrated photometric apparatus should be extended to high latitudes and regions near the magnetic pole in order to determine the geographical distribution of the luminosity. Such observations might throw further light on the differences between the night-sky light and aurorae.

Measurements with photocells should be made from rockets fired at night to heights of 130 km and above in order to discover whether the rocket enters or traverses the regions of the nocturnal luminosity.

AURORAE AND MAGNETIC STORMS

By L. HARANG

Norwegian Defense Research Establishment

Introduction

In this survey of our present knowledge of aurorae, the first two sections which follow will be concerned mainly with the appearance, or morphology, of the auroral forms. The first section contains material obtained for the most part from observations at a single station, while in the second section the material (mainly height determinations) was obtained from two or more stations. The principal instrument used was the auroral camera. The third section gives a survey of spectral investigations, and the fourth section outlines the corpuscular theory of aurorae and magnetic storms. Although this theory must be regarded as only a first approximation to the real conditions, it is of the greatest value in discussing observations and in developing new points of view for further research. Two sections are devoted to a discussion of the connection between aurorae and magnetic storms, and a new field of research—the scattering of radio waves in the VHF-band from aurorae—is briefly mentioned. We can assume that new and important knowledge of the details of the auroral processes will emanate from the fields of research mentioned in these two sections. The final section lists some promising lines for further research.

Appearance of the Aurorae

Forms. The variety of auroral forms and the gradual shift from one form to another have made necessary a general classification, involving international cooperation. The atlas of auroral forms [10] published under the auspices of the International Union of Geodesy and Geophysics (Prague, 1927), is based mainly on the photographs and descriptions presented by Störmer. In this atlas the forms are divided into two main classes: forms without ray-structure and forms with ray-structure. An additional class, flaming aurorae, can be added.

I. Forms without Ray-Structure.

1. Homogeneous Quiet Arc (*HA*). This form may appear near the horizon, usually in the northern sky. It is diffuse along the upper border, sharp along the lower. This is the most stable of all auroral forms, and may maintain its shape for a period of time ranging from several minutes to half an hour. A double arc often appears, or several arcs may simultaneously be seen in the sky.

2. Homogeneous Bands (*HB*). These forms are irregular in shape and often move rapidly. As with *HA*, the upper border is diffuse while the lower is sharp. The homogeneous bands often change into bands with ray-structure.

3. Pulsating Arc (*PA*). This form is seldom visible. The arc or parts of an arc show more or less regular pulsations in luminosity. The period of pulsation ranges from about twenty seconds down to a few seconds. In some cases *PA* may disappear almost completely and then reappear, at approximately the same place, at regular time intervals.

4. Diffuse Luminous Surfaces (*DS*). These appear in the form of a diffuse veil over parts of the sky. They have no distinct limitations. These surfaces often appear *after* intense displays of rays and curtains. The appearance of *DS* is therefore usually restricted to the later hours of the night, after brilliant auroral displays.

5. Pulsating Surfaces (*PS*). These appear in the form of diffuse patches which come and go rythmically at the same place, retaining the same irregular form. They usually appear after a display of flaming aurorae.

6. Feeble Glow (*G*). This form resembles the dawn. It often appears as the upper part of an arc whose lower border is below the horizon.

II. Forms with Ray-Structure.

These consist of short or long rays which can be arranged in various ways.

1. Bands with Ray-Structure (*RB*). These resemble *HB*, but consist of a series of rays close to one another along the band. When a band is near the magnetic zenith it may have the form of a corona.

2. Draperies (*D*). If the rays along a band become longer, the form resembles a curtain or drapery, the lower border of which is often very luminous. With the exception of the homogeneous arc, the drapery is the most common auroral form. When it appears near the magnetic zenith, perspective may give *D* a fanlike form.

3. Rays (*R*). These forms may be isolated, or parallel in bundles. In the latter case they often resemble *D*. The vertical extension may vary considerably, ranging from short rays to the very long, sunlit rays.

4. Corona (*C*). When rays or draperies approach the magnetic zenith they appear to converge, because of the perspective, and a corona is formed. This corona is often incomplete, and only one-half of it may be developed. It can also be formed by bands which converge towards the magnetic zenith.

III. Flaming Aurorae (*F*).

This is a form consisting of strong waves of light which characteristically move rapidly one after the other in the direction of the magnetic zenith. The waves may take the form of detached arcs which move upwards towards the magnetic zenith. Flaming aurorae appear frequently after strong displays of rays and curtains and are often followed by the formation of a corona.

PLATE I.—Typical auroral forms: (a) Homogeneous Arc; (b) Band; (c) Arc with Ray-Structure; (d) Corona; (e) Drapery; (f) Rays. (*After C. Störmer.*)

Variations in Latitude. The most remarkable fact about the geographical distribution of the aurorae is that the greatest frequency, in both arctic and antarctic regions, occurs along a zone lying about 20°–25° from the earth's magnetic axis point. For the arctic region this was stated as early as 1881 by Fritz [4]; White and Geddes [19] have drawn up a similar zone of maximum frequency for the antarctic region (Fig. 1). However, the records are too few for a complete construction of the lines of equal frequencies over the antarctic region, and additional observations from conveniently distributed points would be of great interest.

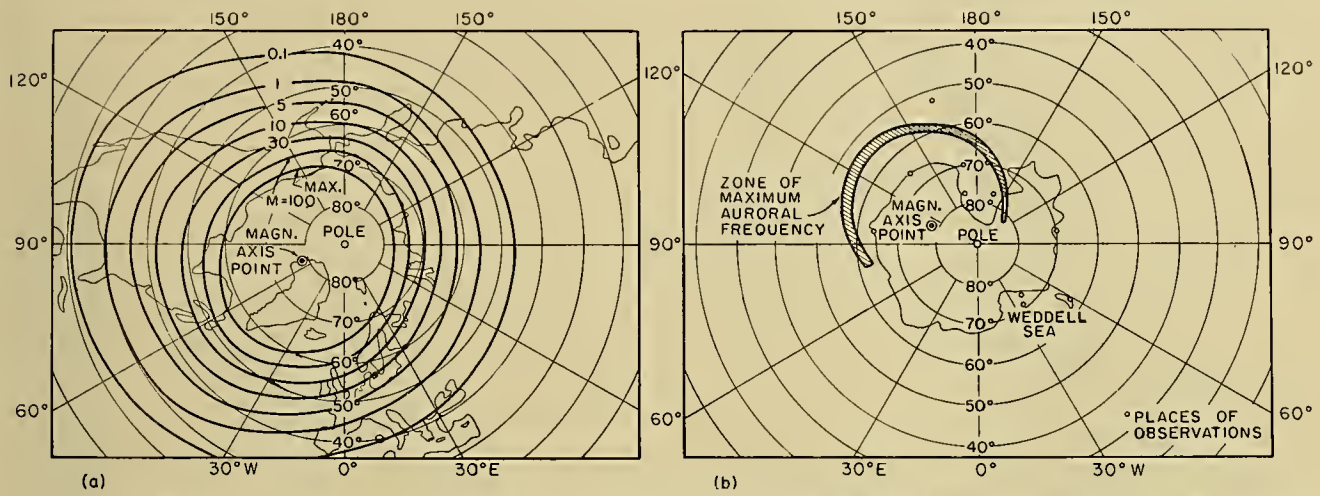

FIG. 1.—The geographical distribution and zone of maximum auroral frequencies in the north and south polar regions. (*After Fritz* [4], *and White and Geddes* [19].)

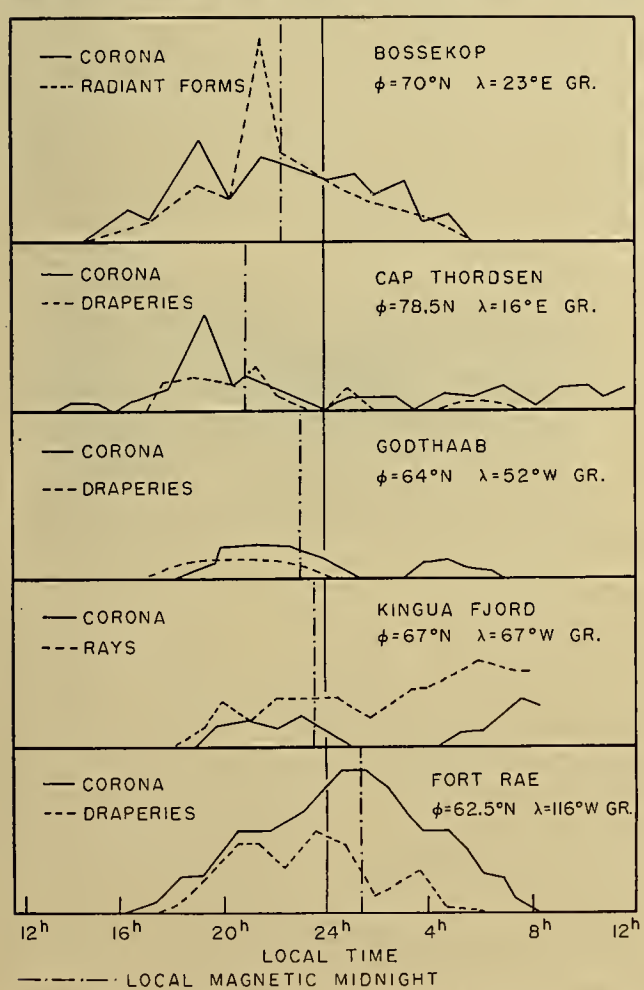

FIG. 2.—Diurnal variation of the aurorae, observed during the Polar Year 1882–83. (*After Vegard* [15].)

Variations in Time. The mean diurnal appearance of the aurorae seems to be correlated with *local magnetic time.* The maxima apparently occur about 1.3 hours before magnetic midnight (Fig. 2). (Magnetic midnight is here defined as the time at which the plane through the point of observation and the magnetic axis passes the sun.)

Position in Space of the Aurorae

The Method of Height Determination. Reliable height determinations can be made only by means of parallactic photography. If objectives of high light-power (about f 1:1.5 and less) and sensitive plates are used, the time of exposure for aurorae of medium intensity is even less than a second. Graphical methods, chiefly developed by Störmer [12],[1] are used for reduction of the plates. The base line should not be less than 20–30 km.

Direction of the Arcs and Position of the Radiation Point. The position and the direction of the arcs are closely connected with the direction of the earth's magnetic field at the place of observation. The position of the radiation points of coronae is similarly dependent on the inclination and declination of the earth's magnetic field at the place of observation.

Height Statistics of Aurorae. The positions in space of the auroral forms are usually characterized by the lower and upper limits of the luminosity. In the photographs of such forms as arcs, bands, and draperies, the lower limit is usually easy to determine, since a sudden decrease in the luminosity is apparent. The determination is more difficult with such forms as rays and pulsating surfaces. It is always difficult to determine the upper

1. Methods for the reduction of a pair of parallactic photographs are described in detail in [5]. (See also [16].)

limit precisely for all forms. In Fig. 3 the *lower* limits of all forms of polar aurorae are shown. The measurements are the result of three series of observations.

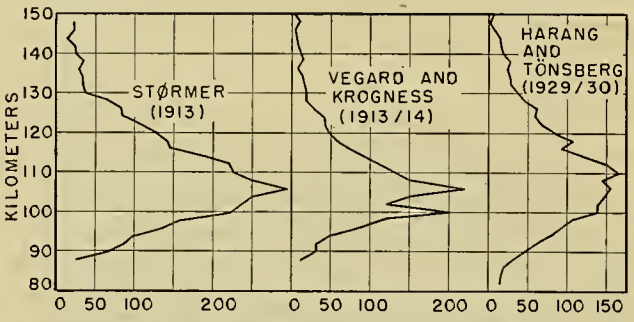

Fig. 3.—Height statistics. Lower limits of polar aurorae, all forms. (The number of points appearing in 2-km height intervals are used as abscissae.)

The lower limits lie between 80 and 140 km, with a pronounced maximum at about 106 km. Störmer has made an extensive study of the lower limits of different forms and has also compared the lower limits of the polar aurorae and aurorae appearing at more southerly latitudes. There appear to be only small systematic changes in the *lower* limits for the various types and latitudes.

There is a wide range of variation in the *vertical* extent of the luminosity. In polar regions the rays extend to heights up to 200–250 km. In lower latitudes the vertical extent may increase to as much as 800–1000 km. Aurorae appear only at these latitudes during very intense magnetic storms, and radio-echo measurements indicate that there is a considerable increase in the reflection heights of the ionosphere during the storm phase. The increases in vertical extent of the aurorae at lower latitudes may therefore be due partly to the special conditions of the ionosphere during strong magnetic storms.

Sunlit Aurorae. Height measurements in arctic regions near the auroral zone have shown that the rays and draperies in the *dark* atmosphere very seldom attain heights over 250–300 km. Störmer has shown, however, that faint rays, often of a grayish color, appear-

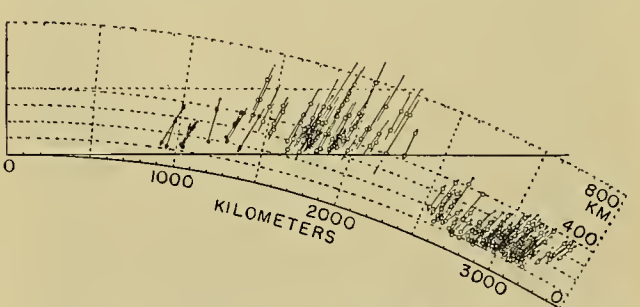

Fig. 4.—Aurorae situated in the border region between the dark and sunlit atmosphere. The horizontal line indicates the shadow line. (*After Störmer* [13].)

ing over southern Scandinavia at a considerable distance from the auroral zone, may attain heights up to 800–1000 km. Aurorae appearing at such great heights are always situated in the sunlit atmosphere and, at these low latitudes, appear only during great magnetic storms. Figure 4 shows how the lower limits concentrate along the shadow line between the dark and the sunlit atmosphere. Spectrographic observations by Störmer have shown that the nitrogen band in sunlit aurorae is strongly enhanced relative to the green auroral line.

Spectrum of the Aurorae

The intensity of the auroral luminosity is low, and if spectrographs are to be used, they must be of considerable light-gathering power. The spectrum consists of a number of lines and bands; more than one hundred are listed in the wave-length tables. They extend from 8100 A (infrared) to 3100 A (ultraviolet) where ozone absorption cuts off the spectrum.

Wave Lengths and Average Intensities of Spectral Lines. By exposing a spectrum over a number of nights, an average spectrum with intensities approximating the values given in Table I is obtained. Here only the *stronger* of the auroral lines, together with their identifications, are listed. The spectrum is dominated by the nitrogen band systems, the negative group ($N\ G$) and the first and second positive groups ($1\ P\ G$ and $2\ P\ G$), which are all well known from the study of gas discharges. The visible color of the aurorae, however, is produced by the atomic oxygen lines 5577 A in the green (Fig. 5) and the doublet 6363, 6300 A in the red. In addition to the stronger lines a considerable number of weak lines and bands have been listed, some of which seem to be atomic lines of O and N. Of special interest is the appearance of the forbidden nitrogen line $N\text{I}$ ($^4S - {}^2P$) at 3466 A.

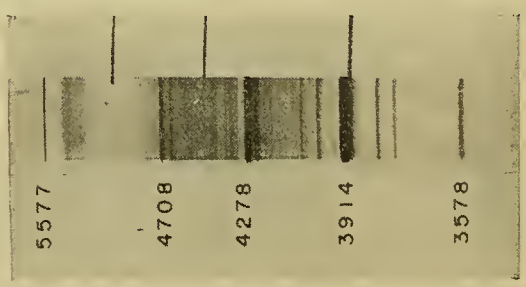

Fig. 5.—Spectrum of aurorae. (*After Vegard* [15].)

Intensity Effects. The study of intensity variations within the auroral spectrum is of great importance, but because of the rapid movements and low intensity it is difficult to carry through. Here one has to use small spectrographs of the highest light-power, permitting short exposures, and the measurements are therefore limited to the stronger lines. The following intensity measurements have been made: (1) intensity variations within a single auroral form from the lower edge to the upper limit; (2) intensity variations from one auroral form to another; and (3) latitudinal variations between polar aurorae and aurorae at lower latitudes.

1. Altitude Effects. In all auroral forms there is a distinct increase in the intensity of violet nitrogen bands relative to the green auroral line as one goes

TABLE I. AURORAL LINES AND BANDS
(*After Vegard* [15])

A	Intensity	Identification	
7906	47	1 *P G*	7–6*
7867		—	—

3942	2	2 *P G*	2–5
3914	47	*N G*	0–0
3805	5	2 *P G*	0–2
3755	4	2 *P G*	1–3
3578	10	2 *P G*	0–1
3537	5	2 *P G*	1–2
3466	—	N_I	$(^4S - {}^2P)$
3371	9	2 *P G*	0–0
3159	6	2 *P G*	1–0
3126	4	2 *P G*	2–1

* Vibrational quanta numbers for the transition.

from the lower edge to the upper limit of the aurorae. There is also a distinct increase in the relative intensity of the red doublet at 6300 A compared to the green line 5577 A. At the same time the red nitrogen bands 1 *P G* at 6500 A are relatively stronger at the lower part of the border than at the upper limit, when compared with the green line.

2. Type Effects. Forms such as diffuse and pulsating surfaces, compared with strong and radiant forms such as draperies, bands, and arcs, show violet nitrogen bands of considerably greater intensity than the green line. In the sunlit aurorae, where the upper limits may attain heights of 800–1000 km, the violet region is also strongly enhanced relative to the green line, and the color may appear to be gray-violet.

The red coloring of aurorae is due either to an enhancement of the red oxygen line 6300 A or to the red nitrogen bands at 6500 A. The former effect occurs especially at lower latitudes; the red coloring at the lower edge of strong aurorae is usually due to the enhancement of the nitrogen bands. When the aurorae appear in uniform red-colored forms, especially at low latitudes, the coloring is due to the oxygen line. However, the red color of the lower edge of strong aurorae is due to the nitrogen bands.

3. Latitudinal Effects. These effects were summarized by Vegard in a comparison between 70°N (Tromsö) and 60°N (Oslo), as follows: (1) The intensity of 6300 A relative to the green line increases towards lower latitudes. This relation is even more pronounced when the green line is compared with the negative bands. (2) The intensity of the green line relative to the negative bands increases towards the lower latitudes.

Appearance of Hydrogen and Sodium Lines. Among the fainter lines in the auroral spectrum are the two Balmer lines, $H\alpha$ (6563 A) and $H\beta$ (4816 A), which may appear with varying intensities. Furthermore, the *Na*-line (5891 A) also appears. This line is strongly enhanced in the sunlit part of the night-sky spectrum.

Determination of Temperature from the Nitrogen Bands. According to the quantum theory, the width of the nitrogen bands depends on the temperature of the gas. By measuring the intensity distribution within the *R*-branch of a band, the apparent temperature of the gas can be calculated. In laboratory experiments these measurements are based on spectra taken with great dispersion. In auroral spectroscopy, the dispersion is limited, and the accuracy is accordingly limited. Quantitative measurements by Vegard based on the photometry of the nitrogen band 4278 A give a temperature of about −45C.

The Corpuscular Theory of the Aurorae

The coincidence between the appearance of magnetic storms, aurorae, and sunspot activity leads naturally to the assumption that the primary cause of both magnetic storms and aurorae must be a corpuscular radiation emitted by the sun. The fact that aurorae appear on the night side of the globe may be explained by the effect of the earth's magnetic field on an electrically charged stream of corpuscles. Different views have been expressed as to the nature of the particles emitted by the sun, and at the present time we have no definite evidence as to whether they are electrons, positive rays, or a mixture of both held together by electrostatic action.

Störmer [14] has treated extensively the case of the movement of an electrically charged particle approaching the earth's magnetic dipole field. The theory can be applied to both negative and positive charges, but it has been especially worked out for the assumption that corpuscles are fast electrons. Chapman [3] and later Alfvén [1] developed a corpuscular theory in which a cloud of negatively and positively charged particles leaves the sun at a comparatively moderate velocity. This ion cloud is polarized in the earth's magnetic field, and electrostatic fields are set up. The detailed analysis of the orbits of the particles is difficult because of the complexity of the problem.

The Model Experiments of Birkeland. A first approach to a corpuscular theory of aurorae and magnetic storms was made through the model experiments of Birkeland. A small uniformly magnetized sphere, the "Terrella," was placed in a vacuum and a stream of electrons was directed against the sphere. At low pressures the paths

of the electron stream can be made visible, and these model experiments gave a striking picture of the possible orbits for an incoming electron stream approaching the earth. These model experiments were later extended by Brüche and Malmfors (see [1]).

The Movement of a Charged Corpuscle in the Earth's Magnetic Field—Störmer's Calculations. The movement of an electron with a certain initial velocity is well known for a number of simple types of magnetic fields, such as movement in a homogeneous field parallel or transverse to the direction of the field. In a radial field which is produced by a single magnetic pole the orbits of the electrons will be like geodetic lines on a cone. It has not been possible to solve completely the more general case represented by the field of a dipole such as that of the earth. The differential equations for the movement of a particle in the dipole field are easily set down, but a general integration of these equations has not been possible. Störmer has discussed the equations in several papers and given many numerical solutions which he has applied to auroral problems. It may be added that the same problem appears in the theory of cosmic rays, where fast electrons from space enter the earth's magnetic field. Störmer's calculations explain several of the effects associated with the appearance of the aurorae. According to theory, the electrically charged particles will impinge on the earth along two zones, symmetrical with respect to the magnetic axis points, which represent the auroral zones. Further families of trajectories of the particles will end on the earth's night side, thus making the appearance of the aurorae on the night side possible.

Different views have been expressed concerning the motion of the electrically charged particles in an auroral form. In the case of a fine auroral ray it may be assumed that the earth's magnetic field can be regarded, to a first approximation, as equivalent to the field of a single pole. The motion should be along a geodetic line. When approaching the earth, the electrically charged particle will reach a certain minimum height, where the motion will be in a circle lying at right angles to the field. The radius ρ of this circle is a measure for the stiffness ($H\rho$) of the rays, given by the formula,

$$H\rho = \frac{mv}{e},$$

where H is the magnetic field intensity, and m and e are, respectively, the mass and the charge of a ray-corpuscle. Measurements of the width of fine auroral rays show that the stiffness ($H\rho$) may attain values of 10^5. This corresponds to stiffness of the order of β-rays or of fast positive rays in gas discharges. The measurements of $H\rho$ therefore do not give any definite information on the nature of the corpuscles producing the aurorae. But if, after entering the earth's atmosphere, the primary rays are spiraling down along the lines of the earth's magnetic field, the velocity must be considerable, and slow electrons or positive ions seem to be excluded. Störmer's mathematical theory treats only the highly idealized case, that is, the movement of a *single* electrically charged particle in the earth's field. In nature we have to consider the movement of a stream or cloud of charged particles, perhaps of both signs and of different masses and charges, leaving the sun and approaching the earth. During the passage, the cloud will induce changes due to electrostatic attraction or repulsion. In addition, upon entering the earth's magnetic field, the positive and negative charges will be displaced relative to each other and polarization effects will occur. Chapman [3] and, later, Alfvén [1] have extensively treated the passage of an ion cloud emitted by the sun and approaching the earth. Chapman has paid especial attention to the terrestrial effects appearing as magnetic storms, while Alfvén has discussed the auroral effects.

The Aurorae and Magnetic Storms

Physically, one must regard the aurorae and the polar magnetic storms as two effects with the same primary cause—an ionizing corpuscular radiation penetrating the atmosphere to a level of 80–100 km. Magnetic storms have been studied thoroughly and different types and phases within a storm have been classified. The appearance of the polar magnetic storm is of the greatest interest for auroral studies. This type of storm appears regularly and is mainly confined to the belt of the auroral zones. Physically it can be explained as the effect of a current sheet flowing along or parallel to the auroral zone at a height of 100–150 km. Birkeland [2] studied this storm type extensively, using synoptic charts. The records from the Polar Year 1932–33 gave a unique opportunity of studying this storm type in more detail than ever before. McNish [9], Vestine [11], Chapman [18], and others have made synoptic and statistical studies of the polar magnetic storm. Most interesting in this connection is the study by Vestine. He showed that the mean position of the current sheet coincided almost exactly with the position of the auroral zone, both lying at a distance of about 23° from the earth's magnetic axis point.

A most remarkable effect is the increase of the angular diameter of the auroral zone which coincides with increasing strength of magnetic storms. During great storms the aurorae are displaced towards the south; at places along the auroral zone the aurorae are then usually seen towards the south. Störmer has explained this widening of the auroral zone as due to the effect of a ring current appearing in the equatorial plane of the earth, but lying far outside the atmosphere.

The Aurorae and the Ionosphere

The normal polar aurorae appear at heights ranging from 80 to 300 km above the surface of the earth. At lower latitudes and during great storms auroral forms may appear at much greater heights. The ionosphere consists mainly of two regions of ionization, the E-layer at 120 km above the earth, and the F_2-layer at about 230 km. The normal ionosphere is produced by the ionizing effect of the sun's ultraviolet spectrum. Owing to the stratification in the air's composition at different levels, ionization maxima are produced when the sun's rays pass through the atmosphere, giving rise to

the normal stratification of the ionosphere—the E-, F_1-, and F_2-layers. In addition to the ultraviolet rays from the sun, corpuscular rays emitted by the sun may also have an ionizing effect when they penetrate the earth's atmosphere. The penetration of these corpuscular rays is made visible by the appearance of aurorae. A marked increase in the ionization of the layers during auroral displays might therefore be expected, and this is what actually happens. The effects of aurorae on the ionosphere are treated below.

The Appearance of the Abnormal E-Layer during Auroral Displays. We must here distinguish between the effects of *faint* and *strong* auroral displays. During a faint auroral display the electrically charged corpuscles will emit light visible as aurorae, and in addition they will produce ionization by impact which will increase the electron density of the layers, especially the E-layer. In polar regions there is a very close connection between the appearance of faint or medium aurorae, small magnetic storms, and a simultaneous increase in the electron density of the E-layer. This increase of the electron density of the layers can be followed by radio-echo observations which measure the critical penetration frequencies of the layers. From the critical penetration frequencies one can easily calculate the *maximum* electron densities of the layers. Figure 6 shows how the maximum electron densities of the F_2- and E-layers change at a polar station during a small magnetic storm accompanied by a faint aurora overhead.

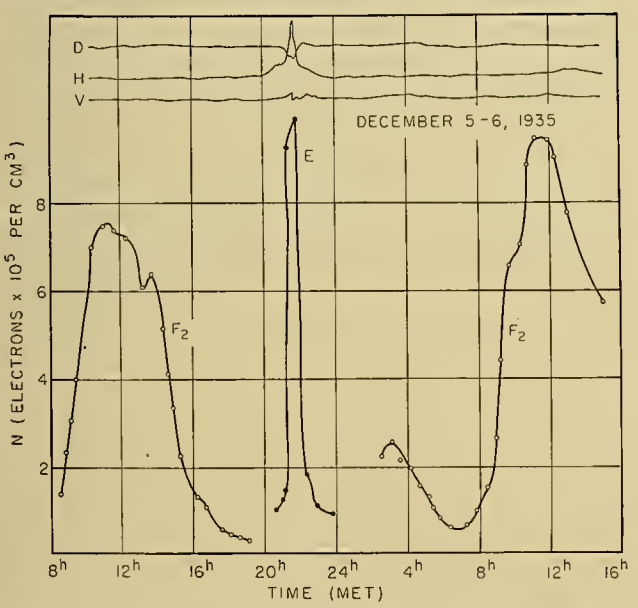

Fig. 6.—Appearance of abnormal E-layer during a small magnetic storm accompanied by faint aurorae (observed in Tromsö). Magnetic declination (*D*), horizontal intensity (*H*), and vertical intensity (*V*) of the magnetic field are shown above. (MET = Middle European Time.)

During stronger magnetic storms and aurorae the conditions are more complex, and the effect of absorption is of the greatest importance. During strong auroral displays, the radio echoes reflected from the ionosphere are usually weak, and there may be a complete cessation of radio echoes during the greatest displays. At the same time there may be a complete breakdown of medium- and short-wave commercial radio transmission. The explanation of these two effects—the increase in electron density in the E-region during small storms and faint aurorae, and the complete cessation of radio echoes during strong magnetic storms—is the following: During small storms the impact of the electrically charged particles increases the ionization of the E-layer down to a height of 100–110 km. This increase in ionization is measured by the increase in critical penetration frequencies of the layer. During strong magnetic storms and aurorae, this increase in ionization is displaced farther down in the atmosphere, to a height of about 80 km. Here the density of the air will be considerably greater than in the E-layer, and this will increase the collision frequency between the free electrons and the surrounding gas molecules. The increase in collision frequency will cause a strong absorption of radio waves in the medium- and short-wave bands. The irregular disturbances in radio communications show very close connections with the appearance of magnetic storms and aurorae, and it is possible, to a certain degree, to forecast the disturbances by carefully observing magnetic storms and aurorae.

The propagation of long and very long radio waves is only slightly influenced by irregular changes in the ionosphere. The long waves are propagated mainly as ground waves over short distances. Over longer distances there will be a fraction—about 10–20 per cent of the field strength at the receiving station—which is propagated as a reflected wave. For such long waves the ionosphere acts almost as a reflecting mirror. An increase in the electron density in the lowest part of the E-layer only increases the reflective power of the layer for these waves, and receiving conditions for very long radio waves are therefore usually more favorable during disturbed periods than during quiet periods.

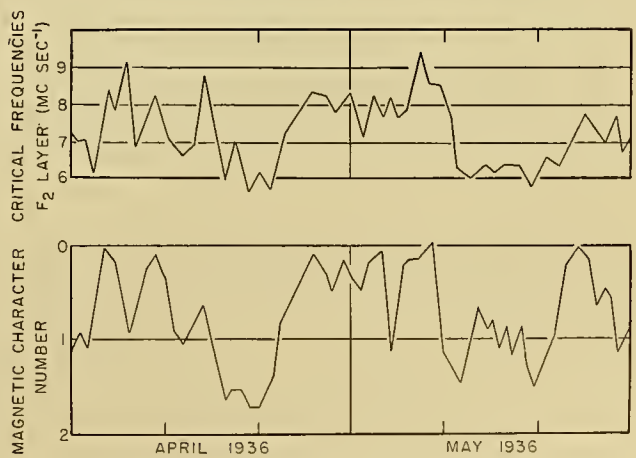

Fig. 7.—Critical frequencies of the F_2-layer and magnetic character numbers (observed in Tromsö). During periods of great magnetic activity the critical frequencies decrease.

The Effects on the F_2-Layer. The effect of magnetic storms and aurorae on the F_2-layer is more complex, since disturbances at this height (about 250 km) are accompanied by changes in the structure of the layer.

There is an inverse correlation between magnetic activity and critical penetration frequency, that is, the maximum electron density of the layer. During disturbed periods the maximum electron density decreases. This effect is commonly explained by assuming a vertical expansion of the ionosphere during disturbed periods. Figure 7 shows the inverse correlation between the critical frequencies of the F_2-layer and the magnetic character numbers, as recorded at a polar station.

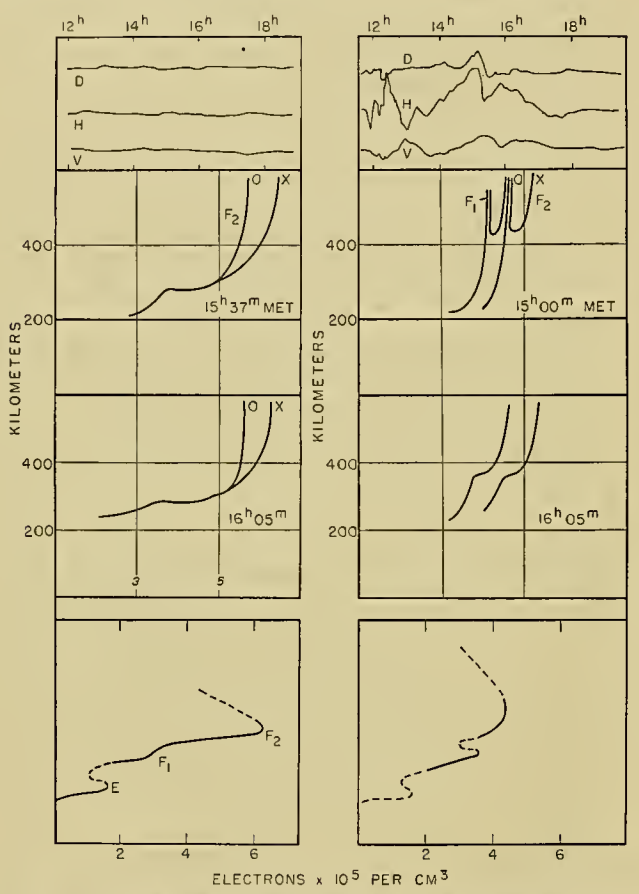

Fig. 8.—Changes in the structure of the ionosphere in the auroral zone from a quiet day to the following disturbed day (from records in Tromsö). The magnetic records are shown above. The echo curves and the structure of the ionosphere are given below.

The changes in the structure of the ionosphere during intense magnetic storms are evident from the echo records. A typical example indicating the conditions of the ionosphere on a quiet day and a following disturbed day at a polar station is given in Fig. 8. The structure of the ionosphere can be deduced from the character of the echo curves (virtual heights of echoes versus frequency). The expansion of the F_2-layer, and the more pronounced stratification between the F_2- and F_1-layers, are evident.

Scattered Reflections from Aurorae in the VHF-Band. It has already been mentioned that strong aurorae and magnetic activity are accompanied by an increase of ionization in the lower edge of the E-layer. This increase in ionization at a level at which the density is comparatively high produces a strong absorption of the radio waves in the usual high-frequency band 1–15 mc sec^{-1}, which is usually in operation for ionospheric radio-echo recording. During strong auroral displays this absorbing region usually screens off the higher part of the ionosphere, and the echo records give no information about the conditions of the ionosphere and auroral region during the phases of strong absorption.

The amount of absorption will, however, decrease with increasing frequency, and it thus becomes possible to use waves in the VHF-band for studying *scattering* effects from the dense ionization in the aurorae. Scatter from aurorae has been obtained by Harang and Stoffregen [6], using 41 mc sec^{-1} waves. Lovell, Clegg, and Ellyett [8] used frequencies of 72 and 46 mc sec^{-1} and obtained scattering effects. The use of VHF-waves for the study of scattering in the ionosphere must be regarded as a new and promising field of research for obtaining information during the phases of strong absorption.

Concluding Remarks

Auroral phenomena are the visual results of an action of a stream of solar particles on the upper layers of the earth's atmosphere. Magnetic storms and changes in the structure of the ionosphere occur simultaneously with the aurorae.

A quantitative theory of the aurorae, magnetic storms, and the irregular changes within the ionosphere would presuppose a knowledge of the nature of the solar particles and a detailed knowledge of the physical condition of the upper atmosphere.

In the preceding sections it has been pointed out that auroral phenomena give no definite indication of the nature of the solar particles producing the aurorae. Furthermore, the physical conditions of the upper atmosphere—density, pressure, temperature, chemical composition, vertical and horizontal displacement of the air masses, and the variations of these quantities during the day and the year—have mainly been deduced in indirect ways. The picture of the physical condition of the upper atmosphere has therefore been put together like a mosaic, with information supplied by the various branches of geophysics. If one of these questions—either the nature of the solar corpuscles or the physical state of the upper atmosphere—could be solved independently, an important step forward would have been taken in the theory of the aurora. Through V-2 rocket experiments, reliable values for densities and pressures up to heights of 90 km have now been obtained [7]. Further measurements will remove many uncertainties concerning the physical properties of the upper atmosphere. A direct experimental investigation of the nature of the solar particles should be possible by means of V-2 rocket flights through aurorae in polar regions.

The position of the auroral zone and the distribution of the auroral frequency with the latitude has hitherto been based on Fritz' chart, published in 1881 [4]. In the last few decades a vast amount of statistical information has been gathered which should pro-

vide possibilities for more reliable determinations of the auroral frequency curves.

A detailed morphological study of auroral phenomena has hitherto been carried on mainly over Scandinavia. It would be of the greatest interest to extend this detailed study of types of aurorae and their position in space to other places along the auroral zone. In this connection it would be of great interest to study the horizontal extension of a single quiet auroral form, such as a homogeneous arc or band, along the auroral zone. From a single station one can determine the extension of such a form up to 600–700 km, but it is still an unsolved question whether or not such a form may have even greater extension, or may even cover a greater part of the auroral zone. The question could perhaps be solved most conveniently by using a series of airplanes flying at fixed distances from each other along the auroral zone.

The spectrum of the aurorae shows an increasing number of lines with each new improvement in the spectrographic equipment used [17]. The most important new features of the spectra are the number of faint atomic lines from *N* and *O* which seem to be present. Further, the hydrogen lines $H\alpha$ and $H\beta$ show great changes in intensity together with a strong broadening of the line width, which indicate Doppler movements of the emitting atoms.

A new and promising field of research on ionization processes within the aurorae is the study of the scattering of radio waves from aurorae in the VHF-region. In this case, the ion clouds within an auroral display would act as scattering centers, and a detailed study would give information about the dimensions of these centers.

METEORS AS PROBES OF THE UPPER ATMOSPHERE

By FRED L. WHIPPLE

Harvard College Observatory

INTRODUCTION AND ASTRONOMICAL BACKGROUND

In this short discussion of the use of meteors in upper-atmospheric research no attempt is made to achieve historical completeness. For an interesting historical account of meteors and the basic theory of the earth's attraction, the reader is referred to Olivier's book on the subject [61]. Watson's *Between the Planets* [85] covers in semipopular style the related subjects of comets, meteors, meteorites, and minor planets. Pioneering work on meteoric and atmospheric theory such as that by Schiaparelli [76] in 1871 is discussed by Kopff [37] in his section on meteors in the *Handbuch der Astrophysik*. Hoffmeister [30] has summarized much of the other material in his book on the subject. A recent account, concentrating mostly on the early work by Lindemann and Dobson, is given by Mitra [59] in his valuable volume *The Upper Atmosphere*.

The reality of stones falling from space was not generally recognized in the scientific world until the first decade of the nineteenth century. Previously, the French Academy had remained particularly obdurate in denying the phenomenon, even though Halley had been convinced of the general idea in 1686 and the concept was very commonly accepted in ancient times.

Once the fact is accepted that meteors arise from an interaction between the atmosphere and bodies falling from space, certain limits on the phenomenon can be set immediately. The lower limit of the velocity near an altitude of 100 km is about 11.1 km sec^{-1}, the velocity of fall from rest at infinity. The earth itself is moving in a nearly circular orbit about the sun with a mean velocity of 29.7 km sec^{-1}, while the velocity of escape from the sun at the earth's distance is about 42.1 km sec^{-1}. Hence, the maximum velocity of encounter is nearly 73 km sec^{-1}, representing the head-on case and allowing for the earth's attraction [61].

The average velocity rises statistically from 6:00 P.M. to 6:00 A.M. as the observer is turned from the following hemisphere of the earth to the leading hemisphere. Meteors of maximum velocity cannot be observed before midnight.

There is still no proof from photographic or radio meteor studies that *any* meteoric bodies originate outside the solar system. The Harvard two-station photographic studies of some sixty brighter meteors give vectorial velocities with a precision of about one per cent. The radio-doppler studies of some 3000 meteors by McKinley [52] provide scalar velocities of somewhat less accuracy, but to a brightness limit well below the capacity of the naked eye. Lovell[1] has observed scalar velocities of more than eighty radio meteors coming from directions including specifically the apex of the earth's motion. None of these studies yield a statistically decisive excess of velocities above the solar-system limit within the visual magnitude range from −4 to possibly +7 or +8.

To clarify terminology, the term *meteor* will be used here to indicate the meteoric phenomenon and the term *meteoroid* to indicate the material body producing a meteor. Meteors sufficiently bright to cast shadows are called *fireballs*, while detonating fireballs are *bolides*. In case a meteoric body is sufficiently large for part of it to reach the earth's surface as a solid, the resultant body is a *meteorite*. These distinctions are necessary because of the rapidly accumulating evidence that the meteoroids producing the common meteors observed visually, photographically, and by radio techniques have a different origin than the meteorites. Hence, there is no justification for assuming that the chemical and physical structures of the meteoroids commonly seen as meteors are exemplified by the meteorites.

A large percentage of meteors are observed in *showers*, repeated with variable intensity at the same dates from year to year. Since the meteoroids in a shower strike the earth in parallel paths relative to the observer, the resultant meteors appear to radiate from a *radiant* on the sky. The various meteoric *streams* or showers are usually named for the constellations in which the radiants are located. Schiaparelli first showed that the Perseid shower, observable for more than half the month of August, is associated with Comet 1862 III. Since then a number of the major meteor showers have been associated with comets [85] and there is every reason to believe that essentially all shower meteors arise from comets.

The remaining meteors not associated with known showers are called *sporadic* meteors. The Harvard photographic meteor studies show that the major percentage of the bright sporadic meteors move in very elongated and randomly oriented cometlike orbits about the sun before striking the earth. The remainder move in orbits of low eccentricity, small major axis, and low inclination to the fundamental plane of the planets. These orbits are similar to those of the few minor planets or asteroids that approach the sun within the earth's distance, but also similar to the orbits of short-period comets. Wylie [95] has shown that several fireballs followed similar orbits. It is not possible to state definitely whether these sporadic meteors are of cometary, of asteroidal, or of other origin.

The recent studies of meteorites by Brown and Patterson [9] and Bauer [6], on the other hand, indicate strongly that meteorites represent debris from a broken planet or planets. The writer doubts seriously that comets can have such an origin. Hence, the commonly

1. Private communication.

observed meteoroids are probably of a different structure than meteorites.

The studies of meteor spectra, largely by Millman [55, 56, 57], indicate predominance of low-excitation *Fe*I lines, with *Fe*II lines [85] possibly showing in one case, probably for a very high-velocity meteor. Present also are lines of the atoms *Na*I, *Ca*I, *Mg*I, *Mn*I, *Cr*I, *Si*I, *Ni*I, *Al*I, *Ca*II, *Mg*II, *Si*II, and possibly *Fe*O. No atmospheric constituents have been observed. The relatively low states of excitation correspond to temperatures of only a few thousand degrees, in spite of the high energies of the impinging atoms; for example, a nitrogen atom at a velocity of 70 km sec^{-1} carries an energy of 410 ev.

The average meteoroid is probably an irregularly shaped stone or stony iron. There is no reason to believe that it is structurally strong or homogeneous in physical or chemical structure. Roughly 3 per cent of the meteors photographed by Harvard split into two or more pieces in the upper atmosphere, while nearly 10 per cent showed *flares* in brightness. Jacchia [35] has shown definitely that flares arise from quick losses of material, probably by crumbling or breakage of the meteoroid. Direct evidence as to the nature of meteoroids may sometime be obtained from micrometeorites [38, 92], those meteoroids that are sufficiently small to be stopped by the atmosphere without vaporizing. Until then we can only postulate the structure of meteoroids and check our postulates indirectly by various observations and deductions. An acceptable theory as to the nature and origin of comets would also be of value in the study of meteors.

ATMOSPHERIC RESEARCH BASED ON VISUAL OBSERVATIONS

Visual Observations of Meteors. As early as 1798 Brandis and Benzenberg set out to determine the heights of meteors by simultaneous observations from two separated stations. In all they observed 402 meteors, of which 22 appeared to be identical. Newton [60], a major contributor to early meteor studies, analyzed 21 of these "pairs" and calculated heights, ranging from 12 to 245 km, with a mean of about 100 km. The mean is in good agreement with modern measures but the range is far too great. Average visual meteors become observable at a height of about 100–110 km with a large scatter, and persist to 90 km or lower, depending upon their brightness. High-speed photographic meteors first show at greater heights, about 120 km, while the chief activity observed by electronic techniques is generally near the E-layer. The slowest and brightest photographic meteors observed at Harvard disappear in the neighborhood of 40 km.

Lindemann and Dobson [41, 43] made the pioneer application of meteoric theory and observation to a study of the density and temperature of the upper atmosphere. They developed the first comprehensive theory of the meteoric process and then utilized the extensive visual observations of meteor heights that had been made by that most assiduous of meteor observers, W. F. Denning, and by his co-workers. Since Mitra [59] has recently reproduced *in extenso* the theoretical developments by Lindemann and Dobson, only a few remarks concerning their work will be made in this article. Briefly, Lindemann and Dobson recognized and stated clearly the fundamental meteoric processes, namely, surface heating by impact with air molecules, stressing the importance of effective mean free path, vaporization of the meteoroid, luminosity produced by encounter of the vaporized material with the air, and the relatively slow deceleration of the nucleus remaining.

Although their thermodynamic, rather than kinetic, approach to the problem of heat transfer through the gas cap led to erroneously high values of the calculated air densities at great altitudes, as pointed out by Sparrow [81] and later workers, nevertheless the basic processes as visualized by Lindemann and Dobson are in other respects fundamental. Progress towards a completely satisfactory theory is still surprisingly slow.

Lindemann and Dobson showed clearly that the previous concept of a constant stratospheric temperature in the upper atmosphere must be replaced by the recognition of higher temperatures at great altitudes. They noted further that from Denning's observations the end heights of meteors were markedly less frequent in the region from 50 to 60 km than immediately above or below. From this fact they concluded that the atmospheric temperature must rise abruptly at a height of about 60 km so that "As the meteor passes into colder air the temperature of the air cap will fall so that the heating will be reduced." This latter argument and consequent conclusion must be revised slightly. It is more accurate to conclude that a region of maximum temperature must be present between 50 and 60 km because the existence of a smaller logarithmic density gradient prolongs the lifetime of a meteoroid reaching this height; the meteoroid has, therefore, a smaller chance of disappearing in the critical range of altitude. The air temperature, per se, is not the dominating factor; it is the consequent reduced density gradient which is important.

Related effects of a variable logarithmic gradient in atmospheric density show markedly in meteor trails photographed at Harvard and account largely for the phenomenon observed by Hoffleit [29] (see also [23]) that the point of maximum brightness moves systematically forward in meteor trails with increasing velocity (for discussion see [87]).

Lindemann and Dobson also pointed out the fact that meteor heights are systematically greater during the summer than during the winter. They could not conclude positively, however, that the height of a point of given density in the atmosphere is greater in summer than in winter. It is possible that there are systematic differences in velocity between the seasons and that the heights of meteors are very dependent upon velocity. These general problems concerning visually observed meteors still constitute a source of considerable discussion or disagreement [44, 51, 72, 73].

The Arizona Expedition for the Study of Meteors was planned by Shapley, Öpik, and Boothroyd [77].

The goal of the expedition was to obtain measures of meteor velocities, heights, radiants, and statistical data visually by the use of the "rocking mirror" technique. In applying this technique the observer determines the angular velocity of a meteor by looking at its reflection in a plane mirror, the mirror being made to oscillate in such a fashion that a normal to its surface describes a conical surface of small apex angle, with the apex near the center of the mirror. Trajectories and heights were measured by simultaneous visual observations from two stations separated by 36 km.

The active direction of the expedition and the analysis of the results were conducted by Öpik. From October 1931 to the end of July 1933, some 22,000 individual meteors were observed, and heights were determined for 3540. Most of the latter were sporadic meteors (about 80 per cent) and only 7 per cent came from the major showers. In analyzing the heights, Öpik [65, 66] made statistical corrections for all effects that he thought might possibly introduce systematic errors into a seasonal phenomenon, if present. He found that an average meteor corrected to standard conditions of brightness, velocity (actually elongation of radiant from apex of earth's motion) etc., appears at a greater altitude in summer than in winter. From this he concluded that the data "suggest an annual fluctuation of the height of the atmosphere, more or less corresponding to the annual temperature curve, of an (total) amplitude of 3.7 $\pm$ 0.7 km," applying at a mean altitude of about 88 km above sea level.

From his theory [67, 69] of the meteoric process he concluded that an atmospheric temperature of +100C at an altitude of 90 km and a mean molecular weight as at sea level would be consistent with the meteor observations by the Arizona Expedition.

Öpik's further conclusions as to a "night effect," in which the height of the "normal" meteor decreases during the course of the night, has not yet been confirmed or disproved. His conclusion [68] as to the appreciable percentage of "hyperbolic" velocities among visual meteors appears not to be consistent with the radio observations of meteors mentioned earlier.

Long-Enduring Meteor Trains and Winds in the Upper Atmosphere. The most comprehensive study of atmospheric winds and turbulence as reflected in the motions of long-enduring meteor trains has been made by Olivier [62, 63], who gives data for nearly 1500 trains. Of great importance also is the work by Fedynsky [20], who reports on 41 night trains observed systematically for the purpose.

Olivier finds from more than fifty cases that the average beginning height of night trains is 104 km, with average end heights of 80 km, while the corresponding data for twilight trains are 77 and 45 km respectively (twenty-six cases) and for daylight trains, 45 and 27 km (nine and fourteen cases). He calculates from the observed motions that the average wind velocity is 203 km hr^{-1} for the fifty best-observed night trains, 182 km hr^{-1} for night trains whose heights have been assumed, and 173 km hr^{-1} for day or twilight trains. A more detailed analysis suggests that the winds increase with altitude, that is, from daylight to night trains. It is clear, from both photographs and drawings, that "layers of the atmosphere, lying quite close together, have winds blowing in different directions and at quite different velocities." In very brief intervals of time after the appearance of trains "the photographs show that the trains have become zigzag in shape. . . . There seem to be inescapable proofs, in certain cases, of vertical components."

As for the directions of the train motions, Olivier finds that for America the greater number drift north with strong east-west components. See Fig. 1. For all

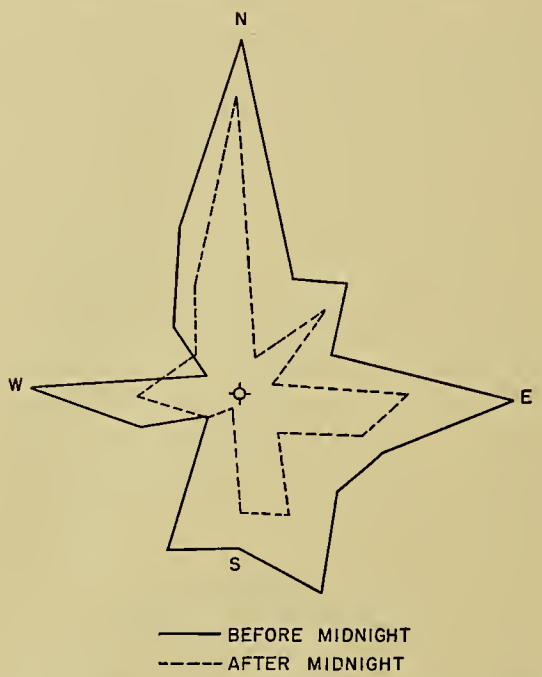

Fig. 1.—Frequency of night wind vectors over America.

Europe an eastern tendency is strong, while other areas of the earth show various preferential drifts. Unfortunately, Olivier has not searched for seasonal effects —a search that almost certainly must lead to important conclusions concerning upper-atmospheric circulation.

The results given by Fedynsky include a number of unusually high velocities, of the order of 1000 km hr^{-1}, and it is difficult to appraise the accuracy of the observations. His average deduced velocity is 391 km hr^{-1}. Additional confirmation would be desirable before accepting completely his separation of the winds into two groups of low and high velocity.

PHOTOGRAPHIC METEOR STUDIES

Methodology. Since photographic meteors have been used as a tool for research on the upper atmosphere almost solely at the Harvard Observatory, the discussion of this section will be confined largely to a short résumé of that work.

Systematic photography of meteors by the use of two cameras equipped with rotating shutters was begun by Elkin [16, 17] at the Yale Observatory in 1893 and continued until 1909. The astronomical results of this

work were analyzed by Olivier [64]. Unfortunately, the base line used (approx. 3.5 km) was inadequate for precision results, and in addition the original photographs have been destroyed. Lindemann and Dobson [42] used this method to a limited extent. Whitney [94] experimented successfully with electronically synchronized shutters for paired meteor cameras, but obtained few observational results. Fedynsky and Stanjukovitsch [21] measured the deceleration of a meteor photographically.

In the Harvard two-station photography of meteors the base line has been 37.9 km, between the Cambridge and Oak Ridge stations in Massachusetts [88, 90]. The two Ross Xpress lenses of aperture 1.5 inches, focal ratio F/4, were occulted 20 times per second by single-bladed shutters powered with synchronous motors from commercial power lines. Meteor trails show 5 to 80 breaks spaced uniformly in time. Exposure times were normally 1^h or 2^h, the cameras being driven on polar axes to follow the stars. The camera settings were so chosen as to produce an overlap in areas at meteor altitudes.

Analysis of the photographic meteor trails is simplified because the trails are amazingly straight [3, 22, 78, 89], that is, great circles; a change in direction of 20′ along a trail is rare indeed, occurring probably in less than one per cent of the (1700) trails in the Harvard plate collection, except in a few cases, very near the end. Hence the measurement and reduction of two-station trails are straightforward though tedious. The general method has been described by the writer [88] although the detailed formulas have not been published. In the most common case the data consist of the trajectory referred to sea level, the velocity V and deceleration $-V'$ at a known altitude, and the light curve. Longer and brighter trails often provide deceleration measures at several points, although the deceleration is barely measurable in most cases. The precision of the trajectory is extremely high (within a few meters) when the instant of the meteor is observed; the velocity is determinate to better than one per cent on the average; the deceleration may be well or poorly determined, while the uncertainty in the brightness ranges perhaps from 20 to 40 per cent.

Because the available wide-angle lenses can photograph only very bright meteors (-1 to -2 visual magnitude or brighter) the rate of photography is slow, one meteor in perhaps 50 to 100 hours of total exposure [86]. Hence, in ten years of continuous photography during clear moonless nights, only about sixty meteors were doubly photographed in the Harvard program. However, a program sponsored by the U. S. Naval Ordnance Department is under way to photograph fainter and more frequent meteors [91].

The Theory of Photographic Meteors. Theories of the meteoric process have been presented by Lindemann and Dobson [41], Hoffmeister [31, 32], Sparrow [81], Maris [50], Öpik [67, 69], Hoppe [33], Levin [39, 40], and others. Of these investigators Öpik has delved most deeply into the detailed physical processes involved, particularly that of the production of light. The writer [88, 90] has used physical data and concepts based largely on Öpik's work but has combined them in a mathematical framework modeled on that of J. Hoppe. The present account will present a very abbreviated version of this composite theory, influenced by the simplifications introduced by Jacchia [34] for the case where the meteor trail is completely observed. A criticism of the basic assumptions follows the formal presentation of the theory.

In its passage through air of density ρ at a velocity V, a meteoroid of mass m and effective cross section $Am^{2/3}$ will, in time dt, encounter an air mass

$$dm_a = Am^{2/3} \rho V dt. \tag{1}$$

We may assume from the kinetic viewpoint, at the high velocities involved, that in large measure the atmospheric molecules in the direct path of the meteoroid are trapped by the meteoroid or the gases escaping from its surface, momentarily carried along, and then swept backward at a relatively low velocity with respect to the meteoroid. It can be shown that for the photographic meteors the effective mean free paths of the air molecules (reduced, as shown by Lindemann and Dobson [41], by the ratio of the temperature velocity to the meteoric velocity) are generally smaller than the dimension of the meteoroid, except at extremely high velocities or faint magnitudes. Hence, in most cases there is a concentration of air (and meteoric gas) in front of the meteoroid in excess of that which might be expected from the relatively slow escape velocity of the molecules. Some sort of shock wave must form, but the significance of the shock-wave concept has not yet been useful in the theory.

The acceleration of the meteoroid may be written in the form:

$$V' = \frac{dV}{dt} = -\gamma \frac{V}{m} \frac{dm_a}{dt} = -\gamma A m^{-1/3} \rho V^2, \tag{2}$$

where γ is one-half the usual drag coefficient. Equation (2) expresses the conservation of momentum if $\gamma = 1$ and if the trapped air molecules are assumed to escape with negligible relative velocity.

The rate of mass lost by the meteoroid is undoubtedly a complex function of ρ, V, m, A and the physical and chemical structure of the body. Öpik [67] has shown that a meteoroid of pure iron would probably lose a considerable fraction of its mass as liquid because of its high thermal conductivity. On the other hand, the writer questions (as did Öpik) that a large fraction of the photographic or visual meteors arise from iron meteoroids. More likely the mass is a heterogeneous or conglomerate solid of low physical strength. Hence its thermal conductivity is probably low. In this case the mass loss would be directly proportional to the heat transferred to the surface and inversely proportional to the latent heat of vaporization ζ at approximately room temperature.

We may expect that the heat available for vaporizing the meteoroid will be roughly proportional to the energy released by the trapped air mass, dm_a. If the efficiency

of the heat transfer to the surface is given by λ, then the rate of mass loss will be:

$$\frac{dm}{dt} = -\frac{V^2}{2}\frac{\lambda}{\zeta}\frac{dm_a}{dt} = -\frac{\lambda}{2}Am^{2/3}\rho V^3 . \qquad (3)$$

The problem still remains to determine the mass m of the meteoroid. Equation (2) will lead to such a solution when velocity, deceleration, density shape-factor (A) and air density are known. But to determine the air density from meteor observations, we must evaluate m independently. This can be done by equation (3) if we assume that the luminosity of the meteor is proportional to the kinetic energy of the mass lost and if we can evaluate the proportionality factor. The greatest success in this evaluation has been attained by Öpik. For photographic meteors of velocity greater than about 20 km sec^{-1}; Öpik's calculations [69] are reasonably well approximated by the relation:

$$I = \tau_0 V\left(\frac{1}{2}V^2\frac{dm}{dt}\right), \qquad (4)$$

where I is the intensity of the visual radiation and $\tau_0 V$ is the luminous efficiency, τ_0 being a constant.

The rate of mass loss, from equation (4), becomes:

$$\frac{dm}{dt} = \frac{2I}{\tau_0 V^3}. \qquad (5)$$

The mass at any instant t_0 is then obtained from the integral:

$$m = \frac{2}{\tau_0}\int_{t_0}^{\infty}(I/V^3)\,dt. \qquad (6)$$

From a completely observed meteor trail in which the velocity V_0 and deceleration $-V_0'$ are well determined at time t_0 the air density ρ_0 can be determined by equations (6) and (2) in the form:

$$\rho_0 = -\frac{2^{1/3}V_0'}{\gamma A\tau_0^{1/3}V^2}\left[\int_{t_0}^{\infty}(I/V^3)\,dt\right]^{1/3}. \qquad (7)$$

This form of the solution for ρ has been used by Jacchia [34], [in equation (10), his $K = 2^{1/3}/(\gamma A\tau_0^{1/3})$] in recent Harvard results in the Naval Bureau of Ordnance program, as contrasted to the writer's direct use [90] of equations (3) with (5) and (2) for the less numerous earlier meteor observations. In practice the numerical constants γ, A and τ_0 of equation (7) may be evaluated separately from theoretical considerations, or as a single constant by comparison with atmospheric densities at the 50- to 60-km level where the densities are fairly well known. The agreement of the two methods is surprisingly good when Öpik's luminosity factor is used, γ is taken as near unity, and a reasonable value of A is chosen.

Jacchia [35] confirms Öpik's calculation of a decrease in τ_0 for velocities below about 20 km sec^{-1} by studies of bright slow meteors in the 40- to 50-km zone. At greater altitudes an attempt [34] to minimize the relative residuals in log ρ for the various meteors by varying the exponent of velocity in equation (7) indicates that a little improvement in the results can be obtained if the exponent of V in the denominator is reduced by 0.5 to 0.8.

We must conclude generally from Jacchia's work that the largest systematic error (excepting a constant multiplying factor) in atmospheric densities as calculated from meteoric decelerations from equation (7) rests in the assumed constancy of γ with respect to both velocity and density. At extremely great heights (> 100 km) where we deal with fast, small meteoroids the value of the drag coefficient may possibly in some cases exceed 2 (*i.e.*, $\gamma > 1$). Where mean free paths are relatively large the re-emitted air material will increase the drag, as shown by Tsien [82] and Heineman [24]. Furthermore, the vaporized meteoric material will cause an even greater increase by a similar process. As the height decreases, meteors of similar luminosity represent larger masses moving at lower velocities in air of greater density. Hence one should expect the drag coefficient to decrease. Consequently, the calculated values of air density from equation (7) may be somewhat overestimated at great heights if correctly evaluated at lesser heights. This drag problem is under investigation.

Less precise measures of atmospheric density can be determined from the luminosities early in the trails, while atmospheric pressure can be determined at the end points. Jacchia [36] finds, as did the writer [90], that the results obtained by these other methods are consistent with the more accurate results from the deceleration data when analyzed by the simple theory. Also, the light curves are accurately predicted except for flares. From the theoretical viewpoint it is interesting to note that the other methods involve λ/ζ, and that the ratio $\lambda/(\gamma\zeta)$ can be found by intercomparison of results. Jacchia [35] shows that this ratio requires no correction in the velocity exponent, suggesting that λ, the heat transfer coefficient, and γ, the drag coefficient, are truly constants or else show a similar velocity dependence. This conclusion is not surprising, at least from a qualitative point of view, but complete theoretical determinations of λ and γ are essential to an entirely satisfactory theory of the meteoric process.

Atmospheric Density Distribution and Seasonal Variations. As shown in the preceding section, the major uncertainty in the determination of atmospheric densities by photographic meteor observations rests in a constant multiplying factor. The density curve for meteors is, therefore, anchored to that obtained by other means in the 50- to 60-km zone. It is found that the gradient follows closely the gradient of the Tentative Standard Atmosphere of the National Advisory Committee for Aeronautics [84]. This result is not surprising in view of the fact that the N.A.C.A. atmosphere at great heights was based, to a considerable extent, upon results obtained by meteor photography.

The atmospheric densities found from the decelerations of thirty-five well-observed photographic meteors were compared by Whipple, Jacchia, and Kopal [93] with the densities of the N.A.C.A. atmosphere. The residuals show a strong correlation with season. In

Fig. 2 these residuals $\Delta \log_{10} \rho$ are plotted against the mean average ground temperature at Boston (lat. 42.5°N) at the date of each meteor. Three velocity

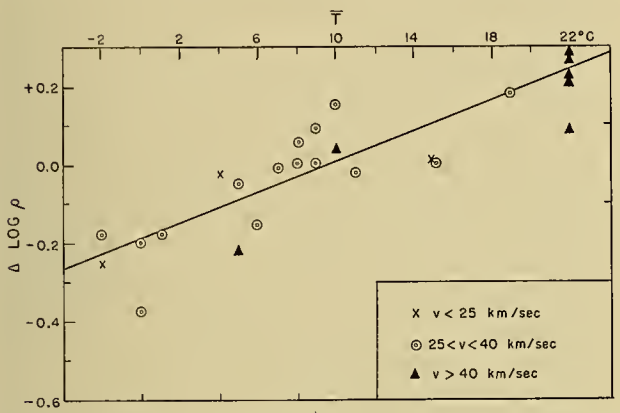

Fig. 2.—Seasonal density variations from photographic meteors.

groups among the meteors exhibit the same correlation. A least-square solution shows that $\log_{10} \rho$ increases 0.019 ± 0.0013 (P.E.) per degree centigrade of ground temperature. This result applies at a mean height of 78 km. The total seasonal range would be 0.46 in $\log_{10} \rho$, corresponding to a height variation of 8.6 km.

The seasonal correlation is less marked when the solar declination is used in place of the ground temperature. The correlation is not improved by comparison with the actual ground temperature at the date rather than the general average; hence, the correlation is truly a seasonal one which does not measure local variations. No effects associated with synoptic weather fronts, deviant temperatures in the lower stratosphere, sunspot numbers, lunar-hour angle or solar-hour angle are conspicuous. From further meteor investigations, including also atmospheric data from the beginning and end points of photographic meteors, Jacchia [36] finds evidence that the seasonal effect decreases with increasing height, becoming small and uncertain around the 100-km level.

Combining the photographic meteor data from decelerations and beginning-point data, Jacchia [36] has derived the upper-atmospheric density distribution given in Table I. Heights are given in kilometers above sea level and density in grams per cubic centimeter. The deviations of $\log_{10} \rho$ from the N.A.C.A. Tentative Atmosphere are given in the third column; the N.A.C.A. values have been adjusted slightly to avoid discontinuities in the temperature gradient, which are awkward physically. The values of atmospheric temperature in Table I are calculated with a constant molecular weight but include the decrease of gravity with height. The temperatures may be varied greatly within the range of solution, particularly the minimum values near 83 km and the values above 100 km.

The observational basis of Table I is shown in Fig. 3. The deceleration data are considerably more reliable than the beginning-point data. The results given in Fig. 3 and Table I have been derived purely from meteoric data without reference to other methods except for the zero point in $\log_{10} \rho$. The simple theory has been used, the power of the velocity having been varied to produce the best interval agreement among the meteoric data.

Table I. Adopted Density Profile

H (km)	$\log \rho$	$\Delta \log \rho$ (Derived − N.A.C.A.)	T (deg K)
70	−6.801	0.000	281
72	−6.883	0.001	266
74	−6.971	0.001	252

108	−9.019	−0.132	256
110	−9.131	−0.141	256

The determination of atmospheric densities and seasonal effects from the photographic observations of meteors can be improved by at least four methods of approach:

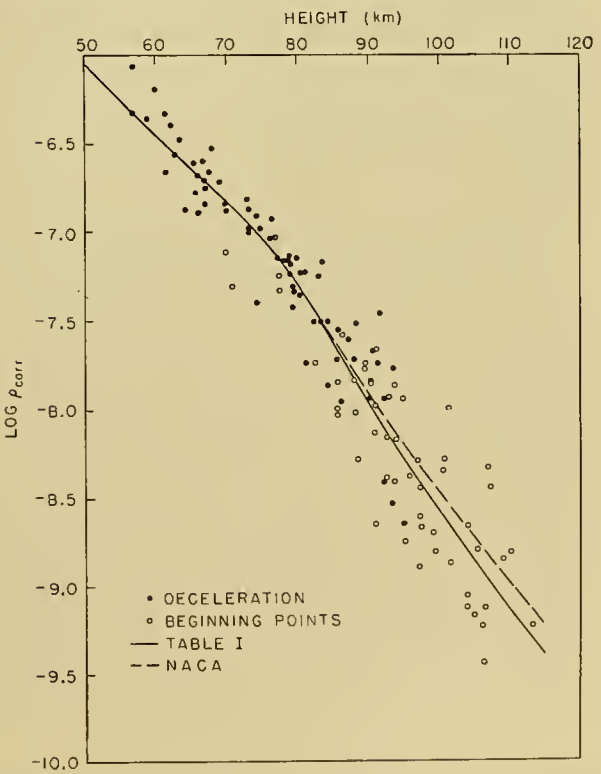

Fig. 3.—Atmospheric densities from photographic meteors.

1. More numerous and accurate observations of me-

teors, by photographic techniques and by combining photographic and radio techniques.

2. Improved theoretical evaluations of the drag coefficient γ, the heat-transfer coefficient λ, and the luminous efficiency factor τ_0.
3. Experimental determinations of γ, λ, and τ_0 by wind-tunnel, ballistic-range, or rocket procedures.
4. Studies of the physical and chemical nature of meteoroids through the study of micrometeorites.

The U. S. Naval Bureau of Ordnance has made possible the continued analysis of Harvard meteor data at the Center of Analysis at the Massachusetts Institute of Technology, carried out by Dr. L. Jacchia under the general direction of Dr. Z. Kopal and with advice from the writer. Meanwhile the Bureau of Ordnance, via the Harvard Meteor Ballistic Project, has made possible the establishment of meteor-observing stations in New Mexico under the direction of the writer [91]. This program includes the procurement of Super-Schmidt Meteor Cameras being made by the Perkin-Elmer Corporation from optical designs by Dr. J. G. Baker and with critical glass produced by the U. S. Bureau of Standards. These cameras, of focal length 8 inches, aperture 12 inches (optically F/0.66), and field of diameter 52°, should satisfy requirement (1) above, particularly if radio equipment can be operated simultaneously nearby. Requirement (4), the study of micrometeorites, will also be undertaken by the Harvard-Bureau of Ordnance program.

The cooperation of the Naval Ordnance Laboratory at White Oak, Maryland, has been obtained toward the fulfillment of requirement (3), particularly the determination of the heat-transfer and drag coefficients for a model meteoroid made from a substance of low melting point, such as CO_2, in a high-velocity wind-tunnel.

It is hoped that the interest of other scientists and research groups may be roused with respect to the various problems mentioned in requirements (2), (3), and (4). The writer is of the opinion that the potentialities of the photographic-meteor approach to upper-atmospheric research have by no means been exploited fully and that rich returns lie ahead. Besides the increased precision possible in density determinations to an altitude of 120 km or more, there are the correlations with latitude and season, as well as conceivable synoptic air-mass and other correlations. A start is just being made on the determination of winds in the region from 50–100 km by photographic meteors. Close cooperations with radio techniques (next section) should produce extremely important results concerning dissociation, ionization, recombination, absorption of quanta, composition, turbulence, and other processes in and near the E-layer of the ionosphere.

RADIO METEORS

The progress in radar techniques for observing the ion columns produced by meteors has been so active since Skellett's suggestion [79, 80] in 1932 that this review can touch on only a few points of major interest. The reader, for detailed enlightenment, must refer to survey articles, such as those by Hey [26], Lovell [45], and Herlofson [25], or to the original papers. Even the present short account will show, however, that the future possibilities of these electronic techniques are truly enormous for the study of the upper atmosphere to a height of at least 130 km via meteoric phenomena.

The basic principle in the radio observation of meteors involves the "reflection" of high-frequency radio waves from the ion column produced by a meteoroid. Pierce [70] suggested that the column should produce maximum "reflection" for normal incidence of the radio beam. The ion columns tend to be more intense in the neighborhood of the E-layer; hence the geometrical relations limit the radar observation of a given meteor. It is found that there is by no means a one-to-one coincidence between the visual and radio meteors unless the geometrical conditions are well satisfied.

Two basic electronic techniques are used for observing meteors by radio. The first involves the transmission of radio pulses a number of times per second, the range (distance) being measured by the time lag of the reflected pulse packets—the standard radar technique. The second depends upon continuous-wave transmission, the Doppler principle providing a modulation at the receiver by the beating between the ground wave and the reflected wave.

The pulse-packet technique, first used for ionospheric research by Breit and Tuve [8], has been the chief tool for radio meteor work until recently. The research previous to 1945 was mostly exploratory, finally establishing the reality and general character of transient echoes from meteor ion columns. The chief workers in this period were Skellett [79, 80], Schafer and Goodall [74, 75], Appleton, Naismith, and Ingram [1], Piddington [2], Pierce [70], Eckersley [14], and Farmer [15]. In 1945 Hey and Stewart [28] began their observations with modified radar equipment operating at a wave length of 4–5 m and established the existence of extensive daytime meteor activity. They recorded range versus time to measure the velocity of the 1946 Giacobinids by the fast-moving echo preceding the main, more persistant, echo.

Lovell [45] and his colleagues at Manchester have since made more extensive meteor observations with similar basic equipment, operating for the most part near a wave length of 4 m but also near 6 and 8 m. As a part of this research project Clegg [11, 12] developed a novel and effective method for measuring the radiants of meteor showers by a single radar. A narrow beam antenna is used to record the frequency and ranges of meteors at various orientations of the radiant (time) and the antenna. The spacial direction of the radiant can then be deduced on the assumption, proven by Lovell, Banwell, and Clegg [47], that an ion column gives the strongest echo when the radar beam is directed perpendicularly to it. By this technique, Clegg, Hughes, and Lovell [13] observed a number of daylight radiants from May to August 1947 and, with Aspinall [4], confirmed their reoccurrence in 1948.

In close coordination with Clegg's work, Ellyett and Davies [19] developed an ingenious method for measur-

ing the velocities of meteor streams. The strengths of individual pulses are recorded on a rapid time base triggered by early echoes from the meteoric ion trail. At nearly perpendicular incidence the echoes from the lengthening ion column vary in strength according to the Fresnel pattern presented from instant to instant. The time rate of the variations measures the angular velocity, which, combined with range data, gives the meteoric velocity. The method was proven on the Geminid shower of 1947 and has been used by Ellyett [18] to demonstrate the heliocentric character of a number of the daylight radiants. The radar technique is being used for radio meteors by Bateman, McNish, and Pineo [5] at the U. S. Bureau of Standards.

The study of meteors by the continuous-wave, Doppler, or "whistling meteor" method was initiated by Chamanlal and Venkatamaran [10] in 1941. Hey, Parson, and Stewart [27] showed that the rapid changes in pitch must arise from changing range rather than deceleration of the meteoroid. A number of investigators listened to the whistles during the Giacobinid shower in 1946. Manning and Villard, heading a group at Stanford University, developed, with Peterson [49], the technique of recording "whistle" oscillations in 1948, a technique that was proven by excellent velocities derived for the 1948 Perseid shower. An important meteorological development by Manning and Villard [48] is that of determining wind velocities and directions in the upper atmosphere by the "body doppler" motion of the meteor ion columns. In eighteen observations from May to September 1949 wind velocities have varied from 47 to 210 km hr^{-1} (mean = 105) with a predominant direction towards SSE, but with a number of motions oppositely directed. This method of observing high-altitude winds shows exceptional promise.

The electronic group of the Canadian Research Council, under the direction of McKinley and cooperating with Millman of the Dominion Observatory, have done some excellent work on meteors, combining radar techniques [53, 54] with visual and photographic techniques (Millman, McKinley, and Burland [58]) and have made most remarkable progress in measuring meteoric velocities by the Doppler method. McKinley [52] has reported on some 3000 meteor velocities measured by this method; the data show no indication of extra-solar-system bodies. The group have succeeded in measuring the deceleration of a meteor by radio techniques alone,[2] a significant step forward in meteoric and upper-atmospheric research. Since the Canadian-group plan to combine radio techniques with visual and photographic meteor observations, using Super-Schmidt cameras when available, their further activities should be scrutinized frequently by those interested in the upper atmosphere.

Theoretical progress in the radio meteor field is still somewhat behind the technological progress; several of the basic processes have not been clearly demonstrated. It is probable that the radio meteor echo arises from the coherent scattering by electrons in a long column of diameter *small* compared to the wave length, as suggested by Blackett and Lovell [7] and investigated more fully by Lovell [45] and Lovell and Clegg [46]. At shorter wave lengths this theory appears to be in better agreement with the observations than Pierce's theory involving a column diameter finite compared to the wave length. Added confidence in the former theory is provided by Herlofson [25], who has semiquantitatively determined the fraction of the meteoroid energy devoted to electron production as about 10^{-4}.

The marked increase in the number of meteors observed at wave length 8 m as compared to 4 m is partially explained. The lower limit of wave length useful for observing meteors, at roughly 3 m, is set by the high electron densities required and by the infrequency of meteors with sufficient energy. The facts of an upper useful limit in wave length, around 100 m, and the time delay (several seconds) in the formation of the observed echoes indicate, however, that an ion column of finite width is required at longer wave lengths. The upper limit is also dependent upon the effects of other atmospheric ionization and the lack of resolving power.

Evidence that the electron diffusion in the ion trail is influenced by the earth's magnetic field has been presented by Lovell [45], following a suggestion by Herlofson. The detailed processes of dissociation, ionization, detachment, diffusion, turbulence, recombination, and attachment of electrons in meteor ion columns, however, require much more theoretical elaboration, since only a modest advance has been made beyond Öpik's meteor theory. Even so, the present theory [45] shows clearly that an important fraction of sporadic-E ionization must arise from some source other than meteors as we now understand them and that the ionization normally produced by meteors is trivial compared to the normal daytime E-layer ionization. During the 1946 Giacobinid Shower, however, meteors produced an appreciable E-layer; Pierce [71] calculated an energy flow of 3 watts km^{-2} over a 4-hour period.

Also, there still is needed a detailed theoretical mechanism for the formation of the ion cap of short duration that follows the motion of the meteoroid. It is difficult to choose among the hypotheses of electron production (1) ultraviolet radiation from the meteoroid, (2) encounters arising from excessive mean free paths of the high-velocity atoms from the meteoroid, or (3) encounters arising from crumbling or spraying effects from finite particles of the meteoroid.

Nevertheless, these present uncertainties only serve to stress the enormous technological progress that has been made in the field of radio meteors. The future possibilities of upper-atmospheric research by radio meteors appear brilliant.

SOUND PROPAGATION IN THE ATMOSPHERE

By B. GUTENBERG

California Institute of Technology

THEORY OF SOUND WAVES IN GASES

Velocity of Sound. The velocity C with which a change in volume is propagated in a material with Lame's constants λ and μ and with the density ρ is given by

$$C^2 = (\lambda + 2\mu)/\rho. \tag{1}$$

In gases, the rigidity μ is practically zero, and the constant λ is equal to the bulk modulus k. Therefore equation (1) reduces to

$$C^2 = k/\rho \qquad \text{where} \qquad k = -(dp/dv)v, \tag{2}$$

and p = pressure, v = volume. Newton assumed that the propagation of sound is an isothermal process, but disagreement between observations and calculations under this assumption led Laplace to suppose that it is an adiabatic process. Except for instances where the change in pressure is large as compared with the pressure itself, results calculated under this assumption agree with the observations.

If v = volume and p = pressure, $K = c_p/c_v$, where c_p = specific heat at constant pressure, c_v = specific heat at constant volume, the condition for an adiabatic process is

$$pv^K = \text{const} \qquad \text{or} \qquad dp/dv = -Kp/v. \tag{3}$$

Introducing this in equation (2), we obtain

$$k = Kp \qquad \text{and} \qquad C^2 = Kp/\rho. \tag{4}$$

It has been assumed in equation (3) that K does not depend on the pressure. In general, this approximation is sufficient; for a better approximation, see Hardy and others [15]. If T is the absolute temperature and R the gas constant of the specific gas,

$$R = p_0\alpha/\rho_0 = p/\rho T, \tag{5}$$

where $\alpha = 1/273.18$ and ρ_0 = density of the gas at 0C and a pressure of 1 atmosphere; if C_0 is the corresponding sound velocity, equation (4) can be written

$$C^2 = KRT = C_0^2\alpha T \quad \text{where} \quad C_0^2 = KR/\alpha. \tag{6}$$

For dry air $K = 1.403$, $R = 2.87 \times 10^6$ cm^2 sec^{-2} deg^{-1} which gives $C_0 = 331.6$ m sec^{-1}. From a critical discussion of observations, Hardy and others [15] found 331.46 ± 0.05 m sec^{-1}. With this value equation (6) becomes

$$C = 20.06\sqrt{T}\ (\text{m sec}^{-1}). \tag{7}$$

Experiments did not disclose any appreciable difference in the sound velocity for frequencies between 10^3 and over 10^6 cycles. However, at very low and very high temperatures the observed velocity is smaller than the value calculated from equation (7). At -100C the difference is about 2 m sec^{-1}, at $+1000$C about 10 m sec^{-1}. Quigley [25] suggested the following empirical equation from observations at low temperatures:

$$C^2 = 387.62T + 180430T^{-1} - 20364000T^{-2} + 806 + 0.03007T^2, \tag{8}$$

which gives $C = 330.6$ m sec^{-1} for $T = 273.1$K.

In humid air the sound velocity is higher than in dry air by an amount H given approximately [8] by

$$H = 0.14Ch/p, \tag{9}$$

where h = partial pressure (or tension) of the water vapor. For warm, humid air near the ground H may be as high as 5 m sec^{-1}.

Sound Rays in Quiet Air. The ray equation for sound waves in still air follows from Snell's law and equation (7):

$$\frac{\sin i_1}{\sin i_2} = \frac{C_1}{C_2} = \left[\frac{T_1}{T_2}\right]^{1/2}, \tag{10}$$

in which i = angle of incidence (between the ray and a vertical line) at the points 1 and 2, where the wave velocities are C_1 and C_2; C and T are supposed to be a function of height z only.

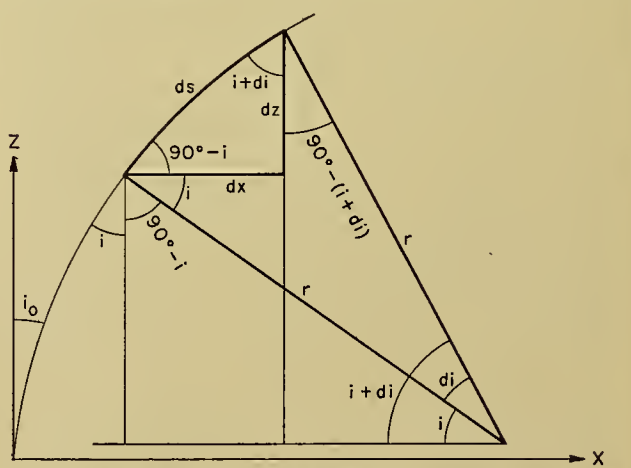

FIG. 1.—Path of sound waves, angles of incidence i, and radius of curvature r.

The radius of curvature r of the ray can be found from Fig. 1 and equation (10):

$$r = ds/di = dz/(\cos i)\, di = dz/d(\sin i),$$

$$\frac{1}{r} = \frac{d(\sin i)}{dz} = \frac{\sin i}{C}\frac{dC}{dz} = \frac{dT}{dz}\frac{\sin i}{2T}. \tag{11}$$

In a layer with a constant value of

$$\gamma = -dT/dz, \tag{12}$$

$$r = \frac{-2T}{\gamma \sin i}. \tag{13}$$

Since the lapse rate γ is usually several degrees per kilometer, the radius of curvature of sound rays is in most instances of the order of 100 km. In the troposphere, positive values of γ (*i.e.*, negative values of dT/dz) prevail, and the sound rays are turning upward; in layers of inversions and in the lower stratosphere γ is negative, and the sound rays are turning towards the earth's surface in still air.

The ray equation in Cartesian coordinates follows from Fig. 1 and equation (10):

$$x = \int (\tan i)\, dz = \int \left[\left(\frac{C_0}{C \sin i_0} \right)^2 - 1 \right]^{-\frac{1}{2}} dz = \int \left[\frac{T_0}{T \sin^2 i_0} - 1 \right]^{-\frac{1}{2}} dz. \tag{14}$$

Even in the simple case of a constant lapse rate the solution becomes rather complicated:

$$x = (AY - Y^2)^{\frac{1}{2}} + \tfrac{1}{2} A \sin^{-1}[(2AY/A) - 1], \tag{15}$$

where

$$A = \frac{-T_0}{\gamma \sin^2 i_0}, \qquad Y = z - T_0/\gamma.$$

For this reason, the radius of curvature is frequently used to find approximately the form of the ray, or $\tan i$ is calculated from equation (10) and graphically integrated to find the horizontal distance x corresponding to a certain part of the ray (using the first part of equation (14)). The corresponding travel time t follows from

$$dt = \frac{ds}{c} = \frac{dz}{C \cos i} \quad \text{or} \quad t = \int \frac{dz}{C \cos i}. \tag{16}$$

The angle of incidence i at a given level, especially at the ground, can be found from Fig. 2,

$$\sin i = dw/dx = C\,(di/dx) = C/V, \tag{17}$$

where V is the "apparent velocity" of the sound observed in the horizontal direction (along x) and given

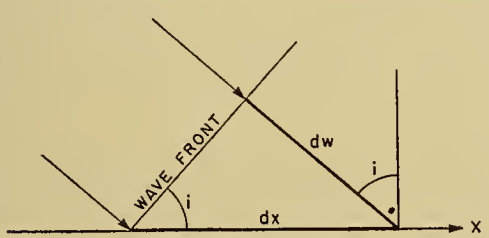

FIG. 2.—Sound waves arriving at the surface of the earth and angle of incidence i.

by the "travel-time curve" (time of arrival of a given impulse plotted against the distance x).

The apparent velocity V is equal to the true velocity C^* at the highest point of the ray (if $i_2 = 90°$ and $C_2 = C^*$, in equation (10), we find $\sin i = C/C^*$; equation (17) then gives $V = C^*$). The corresponding height $z = H$ can be found from

$$H = \frac{1}{\pi} \int q\, dx \quad \text{where} \quad \cosh q = \frac{V_\Delta}{V_x} = \frac{\sin i_\Delta}{\sin i_x}. \tag{18}$$

This equation is based on a solution by Herglotz [17] which, in simplified form, can be found in any book on theoretical seismology. The quantities V_Δ and i_Δ are the apparent velocity and angle of incidence respectively at a given level for the ray which arrives at the distance $x = \Delta$ and has its highest point at $z = H$; V_x and i_x are the corresponding values for all points between $x = 0$ and $x = \Delta$. Equation (18) can be used only if the travel-time curve is continuous in this interval. In this case it permits the calculation of H as a function of the distance x, while the velocities at the height H (and from them T) are given by the value of V at the corresponding distances x. Since in most practical cases the temperature T and the velocity C decrease with height in the troposphere, the method can not be applied there. In this case a reference height (the tropopause or a higher surface) must be selected above which the temperature increases with height, and the horizontal component for the path and the corresponding travel time t for the parts of the ray below the reference height must be calculated from equations (14) and (16) and deducted from the total distance and travel time. Then equation (18) can be applied to the part of the ray which is above the reference height.

Sound Rays in Moving Air. Equations for the paths of sound waves, in the case where the wind direction forms an angle with the horizontal component of the sound path, are too complicated to be useful [6] (even if it is assumed that the wind has no vertical component and that its direction does not change with height) since the sound path is no longer a plane curve. Usually the wind component in the plane of the sound wave is considered and the component perpendicular to it is neglected.

If W = wind component in the direction of the sound wave, and C = sound velocity given by equation (7), then the ray equation is

$$(C/\sin i) + W = \text{const}, \qquad \sin i = C/(C_0/\sin i_0) + W_0 - W. \tag{19}$$

Neglecting squares and higher terms in W/C, the radius of curvature r of the ray is now given [8] by

$$r = \frac{C + 3W \sin i}{\frac{10}{\sqrt{T}} \left(\sin i - \frac{W}{C} \cos 2i \right) \frac{dT}{dz} + \left(1 + \frac{W}{C} \sin^3 i \right) \frac{dW}{dz}}, \tag{20}$$

where C and W are measured in meters per second and i is given by equation (19). If $-dT/dz = \gamma$ = lapse rate, and the change of wind velocity with height,

$dW/dz = a$, the condition for a curvature of the ray towards the ground is given by

$$a\,[1 + (W/C)\sin^3 i] > 10\gamma T^{-\frac{1}{2}}\,[\sin i - (W/C)\cos^2 i]. \quad (21)$$

Equation (21) shows that for our problem the lapse rate γ and the change a of wind velocity with elevation are more important than the ratio of the wind velocity to the sound velocity (W/C).

For very flat rays (i near 90°) equation (21) leads to

$$a > 10\gamma T^{-\frac{1}{2}}, \quad (22)$$

from which it follows that under average conditions in the lower troposphere (γ about 6C km^{-1}, T = 290K) the wind must increase with elevation by more than about 3½ m sec^{-1} km^{-1} in the direction of the sound propagation to bring the sound rays, which leave the source nearly horizontally, back to the surface. In the opposite direction the sound rays are curved upward more strongly than in still air (r is smaller).

The following are a few critical values of a for straight rays under the same assumptions for γ and T and supposing that W/C is 0.1:

i	80°	45°	5.7°	0°
$a = dW/dz$ (m sec^{-1} km^{-1})	3.1	2.5	0	−0.4

If a exceeds these critical values, the ray curves downward in the wind direction; if a is smaller, the rays turn upward. It is noteworthy that in general the wave front is no longer perpendicular to the rays if sound is propagated in air in which the wind velocity changes with elevation.

If the paths of the rays are close to a part of a circle, use of trigonometry shows that the maximum height H^* which is reached by a ray at the distance Δ is given approximately by

$$H^* = r\{1 - [1 - (\Delta/2r)^2]^{\frac{1}{2}}\} \approx \Delta^2/8r. \quad (23)$$

If, for example, a = 5 m sec^{-1} km^{-1}, γ = 6C km^{-1}, T = 300K, W_0 = 5 m sec^{-1} (which gives C = 348 m sec^{-1}, r = 235 km), the following values result:

Δ	1 km	10 km	100 km
i	89.9°	88.8°	77.6°
H^*	½ m	54 m	5½ km

The values in the last column would normally be useless, since the assumption of circular rays is not fulfilled between the ground and an elevation of 5½ km. On the other hand, the results show that conditions favorable to good audibility of sound waves to distances of many kilometers at the ground need not extend to great heights.

The preceding equations can also be used to answer the question, How close must a sound source at an elevation h be in order that the sound can be heard at the ground? If, for example, the lapse rate is γ and the wind is negligible, the maximum horizontal distance Δ^* at which direct rays arrive at the ground is given approximately (assuming circular rays) by

$$\Delta^* = a\,(Th/\gamma)^{\frac{1}{2}},$$

which for γ = 6C km^{-1} and T = 289K gives $\Delta^* = 14h^{\frac{1}{2}}$.

All preceding results are based on the assumption that the change in pressure during the process is small compared with the pressure itself. For larger changes in pressure, the sound velocity is greater than given by the preceding equations. Since the theory is very complicated and has rarely been needed in problems of sound propagation in the atmosphere, it is not considered here.

Another assumption is that the wave length is small as compared with the height A of the homogeneous atmosphere, since otherwise dispersion results as an effect of gravity. Assuming that the gravitational constant g does not change with altitude (which does not hold for the higher parts of the stratosphere), Schrödinger [26] found that the velocity v of sound waves moving vertically upward is given approximately by

$$v/C = 1 + (1/32\pi^2)\,(L/A)^2 = 1 + 0.003166\,(L/A)^2, \quad (24)$$

where L = wave length, C = sound velocity in quiet air and for waves moving horizontally; C is given by equation (7). For waves with periods of less than 1 sec, the last term in equation (24) is smaller than 10^{-6}, and the effect of the dispersion (long waves travel faster) is negligible. In addition, in most practical cases the sound waves travel much closer to the horizontal than the vertical direction, which decreases the effect of dispersion. The group velocity for waves travelling upward is given by an equation similar to (24) except that the last term is negative.

For long waves, equation (24) cannot be used. In addition to the effect of decrease in gravity with elevation, free vibrations of the atmosphere affect the wave propagation. The theory for various models representing the atmosphere has been developed by Pekeris [23]. In addition to the body waves discussed above, waves corresponding to free oscillations may be excited within certain ranges of frequencies, depending on the assumed model.

Energy of Sound Waves in the Atmosphere. The energy and amplitudes of sound waves in the atmosphere with periods not exceeding a few seconds depend on two major effects: (1) absorption, and (2) changes due to the increase (or occasionally decrease) in the distance between rays (which controls the energy flux).

The absorption of the energy is usually introduced by a factor e^{-kD}, where k is the coefficient of absorption, supposed to be constant over the distance D along the ray. If k changes along the ray, kD has to be replaced by $\int k\,dD$.

The propagation of sound is a molecular process. The velocity C of sound and the molecular velocity c are connected by the equation (see, for example, Schrödinger [26]):

$$(C/c)^2 = K/3; \quad (25)$$

for air $K = c_p/c_v$ = 1.403, and

$$C = 0.6840c.$$

As long as the molecules are relatively close together, absorption of sound remains small. It increases rapidly

if the wave length L approaches the mean free path l of the molecules. Schrödinger [26] writes

$$k = Fl/L^2, \tag{26}$$

where

$$F = 12\pi^2\sqrt{3}[(K-1)AK^{-3/2} + 4BK^{-1/2}].$$

$K = c_p/c_v$; A and B are constants depending on the heat conduction q of the gas, its coefficient of internal friction u, the molecular velocity c, and the mean free path l of the molecules:

$$q = Ac, \qquad u/c = Bcl. \tag{27}$$

Schrödinger calculated from laboratory experiments $F = 30.1$; Kölzer [18] later used $F = 33.0$. Consequently, loss of energy E from absorption between two points close enough to each other so that the absorption can be assumed to be constant is given by

$$\ln(E_2/E_1) = -0.4343\,Fl\,D/L^2 = -0.0013\,e^{h/8}/L^2. \tag{28}$$

The factor $e^{h/8}$ is based on the assumption of constant temperature throughout the atmosphere, but the resulting mean free paths are within the limits given by the N.A.C.A. tables for the stratosphere (see Table I).

TABLE I. MEAN FREE PATH ($l \times 10^{-5}$ cm) OF MOLECULES AT DIFFERENT LEVELS

	Height above sea level (h km)						
	0	20	40	60	80	100	120
(a)	1.0	12	150	1,800	22,000	270,000	3,300,000
(b)	0.6	15	580	14,000	200,000	6,160,000	66,000,000
(c)	0.7	10	259	2,600	20,000	260,000	1,700,000
(d)	0.8	8	120	830	4,400	36,000	140,000

(a) $l = 10^{-5}\,e^{h/8}$.
(b) N.A.C.A. [21] tentative minimum temperatures.
(c) N.A.C.A. tentative standard temperatures.
(d) N.A.C.A. tentative maximum temperatures (for $h = 100$ and 120 km during the day).

If it is assumed that the distance D is 1 km, that the free path of the molecules decreases exponentially with altitude h (in km) from 10^{-5} cm at sea level, that the height of the homogeneous atmosphere is 8.0 km, and that the wave length L is measured in meters,

$$\ln L = 0.27h - 1.443 - \tfrac{1}{2}\ln[-\ln(E_2/E_1)]. \tag{29}$$

Equation (29) enables the calculation of L as a function of h for a given absorption. Results are plotted in Fig. 3, which can be used to find the height h above which waves of a given length L lose their energy by absorption too quickly to be observed. Figure 14 shows that sound waves travel relatively long distances near the top level of their path. If it is assumed that a loss of 10 per cent of the energy per kilometer over a distance of 100 km (which results in a reduction of the energy to less than 10^{-4} and of the amplitude to less than 0.01) corresponds to the normal limit for the observation of such waves, it follows from Fig. 3 that, even in the lower stratosphere, tones with frequencies above that of a soprano cannot travel very far without being absorbed almost completely. For waves with a frequency near that of the middle a (435 cps, wave length at 0C about ¾ m) the critical level is about 25 km; for the lowest audible tones (16 cps, L near 20 m) the critical level is below 80 km; and for waves with periods of 0.3 sec it is about 100 km.

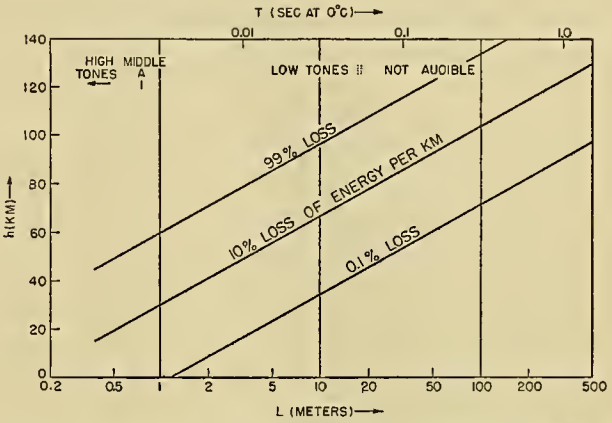

FIG. 3.—Fractions of sound energy which are lost by absorption when the sound waves travel a distance of 1 km (assuming a temperature of 0C throughout the atmosphere) based on the research of Schrödinger [26]; h = height in km, L = wave length in meters, T = period in seconds.

The preceding equations give only the order of magnitude of the absorption. Fog, smoke, water droplets, etc., affect the absorption, and the equations do not hold for waves with very short wave lengths (less than one meter), for which the absorption increases faster than given by the equations, nor for waves with lengths over a few hundred meters, for which the wave length is an appreciable fraction of the height of the homogeneous atmosphere.

The amplitudes of recorded sound waves through the troposphere and the lower part of the stratosphere depend less on absorption than on the change in energy flux due to the change in size of the wave front. To find these effects [8] we suppose that there is no wind,

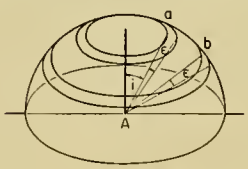

FIG. 4.

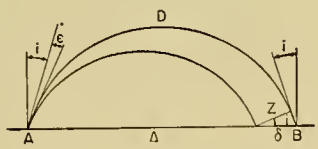

FIG. 5.

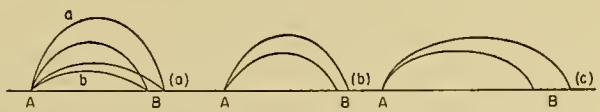

FIG. 6.

and that sound waves produced at A in Fig. 4 start with the same energy in all directions. The energy flux E_0 through a zone z between two cones formed by rays with angles of incidence i and $i + \epsilon$ respectively is given (see Figs. 4 and 5) by

$$E_0 = A[\cos i - \cos(i + \epsilon)] = -B\delta\,\frac{d\cos i}{d\Delta}, \tag{30}$$

where A and B depend on the energy at the source. Neglecting the absorption along the path D (Fig. 5) the energy arrives on a zone of area Z perpendicular to the rays,

$$Z = \pi[\Delta^2 - (\Delta - \delta)^2] \cos i = 2\pi\delta\Delta \cos i. \quad (31)$$

The energy flux E at the distance Δ is then given by

$$E = \frac{E_0 z}{Z} = \frac{C\delta\left(\frac{d \cos i}{d\Delta}\right)}{\delta\Delta \cos i} = \frac{C(\tan i)\frac{di}{d\Delta}}{\Delta}. \quad (32)$$

C is a constant depending on the energy at the source. The factor $\tan i$ is partly a consequence of the fact that near the source less energy passes through the zone a (Fig. 4) than through the larger zone b (see also Fig. 6a). The greatest changes are produced by $di/d\Delta$. If i changes slowly with distance (Fig. 6c), the energy flux near B is relatively small.

To simplify the picture, we assume that rays are parts of circles (r = radius). Then $\cos i = \Delta/2r$, and equation (32) becomes in this special case [8]

$$E^* = (C/\Delta^2)\,[1 - (\Delta/r)\,(dr/d\Delta)], \quad (33)$$

which shows the expected decrease in energy with the square of the distance. It is evident that in general the energy at a given point is especially large if the (mean) radius of curvature r decreases rapidly with distance Δ (or with the maximum height reached by the ray). According to equation (20), this requires that either the wind or the temperature or both increase rapidly with increasing height in the region of the highest point reached by the sound wave. Focal points (caustics) will result if $di/d\Delta$ becomes infinite; this would correspond to Fig. 6b, if two rays with small differences in i arrive at the same point B. On the other hand, the energy decreases considerably with distance if the highest parts of the rays enter a region where the radius of curvature increases rapidly, until the limit for straight rays is reached (equation (21)) and no energy arrives at the ground. For rays through the stratosphere, the absorption must be considered, and

$$E = Ce^{\int k d\nu}\,\frac{(\tan i)}{\Delta}\,\frac{di}{d\Delta}. \quad (34)$$

INSTRUMENTS FOR THE RECORDING OF SOUND WAVES

Most instruments used in recording sound waves through the atmosphere react to the change in pressure produced by the sound. In addition, records of distant explosions are sometimes obtained through seismographs; in such instances the vibrations of the atmosphere are transmitted by buildings or otherwise to the ground near the instrument. For sound-recording instruments, membranes or pistons which form a part of an airtight container of a given volume of air are frequently used; their movements are magnified either by levers which operate a recording pen, by the mirror of an optical recording system, or through electromagnetic systems which record by means of galvanometers. Even rather simple devices, such as a wire attached to the center of a windowpane and wound under tension around a thin needle carrying a mirror, have been used successfully for the recording of sound waves from distant explosions. The magnification of these types of instruments for long-period movements equals their magnification for a constant continuous pressure; it decreases in the case of high damping to about 25 per cent for waves with half the free period of the vibrating system and exponentially toward zero for waves with still higher frequencies. If the damping ratio is less than 23:1, resonance increases the magnification near the free period of the instrument [9] and produces a maximum there of about twice the static magnification for a damping ratio of about 2½:1.

Many types of microbarographs with galvanometric recording have been developed in recent years. In Benioff's microbarograph [13] a permanent-magnet moving-conductor type loud-speaker mounted in one of the sides of a sealed container is used as the responding element. Output currents are recorded on standard seismograph galvanometric recorders. With a 1.2 sec galvanometer the maximum sensitivity is approximately 1 mm deflection for 0.001 mb. In the microbarograph of Baird and Banwell [2] a diaphragm of "dulalium," 0.005 mm thick, separates the body of the microphone into two compartments, one of which is closed to short-period pressure changes. Parallel to the diaphragm at a distance of about 0.015 mm is a brass disk which together with the diaphragm acts as a condenser whose capacity changes are magnified by electronic means and recorded by a galvanometer. The maximum sensitivity is about 1-mm deflection for less than 0.0001 mb. In the instruments designed and built at the Naval Ordnance Laboratory, Washington, D. C. [1] to record the subsonic waves from the Helgoland explosion in 1947, the flexing of a diaphragm in a microphone alters one of two matched inductive circuits; the unbalance produces a signal voltage. This signal, the low-frequency modulation of an audiofrequency carrier, is amplified and used to drive a modified Esterline-Angus graphic recorder for which a response curve has been given by Cox [4]. The maximum sensitivity is about 0.8-mm deflection for 0.001 mb. Other microbarographs, such as Macelwane's, have their maximum response for longer waves.

Unfortunately, all these instruments respond not only to pressure waves, but also to pressure changes caused by air currents. If three instruments, forming a triangle with sides of somewhat less than one half the wave length of the sound waves, are used, the time differences between the instruments indicate whether the disturbance has travelled with the velocity of sound or with the much smaller velocity of air currents [3]. Simultaneously, the time differences between the passing of a given point of the same wave at two pairs of stations makes it possible to calculate the direction from which the waves arrive and their angle of incidence [19]; the sound velocity must be calculated from the temperature.

OBSERVATIONS AND THEIR INTERPRETATION

Natural Sound. Microbarographs of sufficient sensitivity record a background which consists of the effect of air currents and of natural pressure waves which are sometimes especially clear on calm winter days. There are several types of natural sound waves. At Pasadena, California, the most frequent are sinusoidal waves with variable amplitudes and periods of about ½ to 5 sec [3, 13] (Fig. 7), corresponding to wave lengths of about

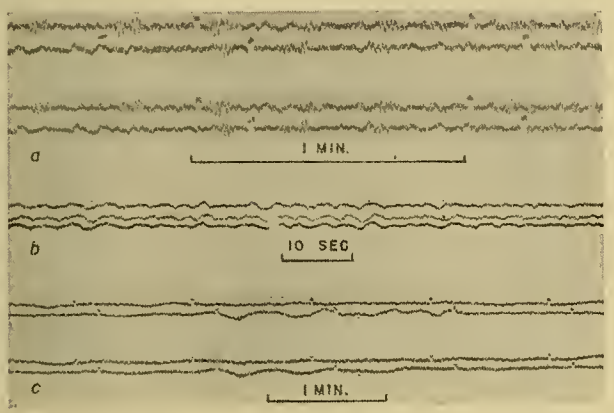

FIG. 7.—Pressure waves recorded by Benioff microbarographs at Pasadena. (*a*) January 6, 1939; these coincided with the largest surf waves in several years near Scripps Institute of Oceanography at La Jolla; no meteorological element had unusually great values within several hundred miles; the two records correspond to two instruments about 30 m apart. (*b*) Pressure waves recorded on December 27, 1940, with three microbarographs forming a triangle with sides of 290, 320, and 264 m, respectively; these waves are frequent during the winter and arrive usually from the SW. (*c*) Pressure waves with longer periods, recorded on January 8, 1939, by two instruments 120 m apart. (*After Benioff and Gutenberg* [3].)

100 m to 1500 m. In general, they are largest in winter. During the three winter months of 1940/41, three microbarographs were operating (Fig. 7*b*) which permitted the calculation of the direction from which the waves arrived; all came from southwest to west (azimuths between west and 40° south of west). In all instances of large amplitudes a low-pressure area was situated off the coast of southern California; as soon as the low-pressure area passed the coast, the amplitudes decreased rather rapidly. The waves arrived almost horizontally, but this is to be expected (even if the source is rather high in the atmosphere) due to the curvature of the rays. No connection with microseisms could be found. Similar air-pressure oscillations have been recorded in Christchurch, New Zealand [2]. Their periods were between 4 and 10 sec, and they showed similarity to microseisms, but a time lag of pressure oscillations, up to 200 sec, was suspected. Baird and Banwell believed that the two types of waves are independent phenomena but possibly have the same cause. Polli (1949) found similar results in Trieste. Observations of these pressure waves at other locations are very desirable.

Occasionally, short groups of pressure oscillations were recorded at Pasadena with periods of about ½ to 1 sec and occurring at intervals of about 20 sec (Fig. 7*a*). Their direction (from SW), their regular coincidence with high ocean waves at the coast, and the lack of other unusual phenomena make it likely that they are "sound" from surf. The causes of longer pressure waves which were recorded occasionally (Fig. 7*c*) could not be found due to the scarcity of the observations.

Sound Waves through the Troposphere. When unusually strong sound waves from distant explosions were first heard, attempts were made to explain the observed zones of audibility and of silence by combinations of temperature, lapse rates, and change of wind with elevation [20]. This possibility was disproved by the occasional occurrence of instances in which the abnormal zone formed a full ring around the source of sound, separated from the normal zone of sound by a zone of silence. However, there are instances, not infrequent, of strong sound in relatively small areas, which are due to meteorological conditions in the troposphere. It follows from equations (20) to (22) that either a temperature inversion, or a certain increase of wind with elevation (depending on the lapse rate), or both jointly, may produce zones of strong sound. It is of interest to note that in the attempted explanations mentioned above an increase of wind with elevation by 4 or 5 m sec^{-1} km^{-1} was usually assumed together with the typical temperature lapse rate, after considering a variety of conditions; such requirements follow now from equation (22). Figure 11*a* shows records with clear dispersion. Schulze [27] explained this dispersion as a consequence of the fact that the velocity changes with elevation, and because the energy of longer waves is propagated in a thicker layer than that of shorter waves.

Strong audibility of certain sounds (*e.g.*, of trains) is occasionally used by laymen for short-range weather forecasting. This possibility is based on the fact that the repeated occurrence of a certain unusually strong sound from the same source will frequently be a consequence of similar meteorological conditions at a given place.

Sound Waves Through the Stratosphere and Abnormal Audibility Zones. In 1903 an accidental explosion of dynamite in Westphalia resulted in sound waves which were heard far away, beyond a zone of silence. The observations were investigated by von dem Borne who believed that an increase in the percentage of light gases with elevation in the atmosphere causes an increase in sound velocity. (For historical data and bibliographies see [28, 10].) The details of these abnormal zones were studied in instances of artificial explosions, especially in Germany [16], of gun fire, and of accidental explosions, using ear observations (Fig. 8) as well as instrumental records. There are instances where the abnormal zone forms a complete ring around the source, and others in which only parts of a ring with audible sound were developed. Frequently, parts of a second or third ring of abnormal audibility were found (Figs. 8 and 9).

In Europe and in Japan, the radius of the ring as well as the distance of the largest sound intensity shows a yearly period (Fig. 10) with a minimum distance of about 100 km late in winter or early in spring,

and a maximum (about 200 km) late in summer [28; 29, pp. 184–187]. In central Europe, the ring is much better developed to the east of the source during winter,

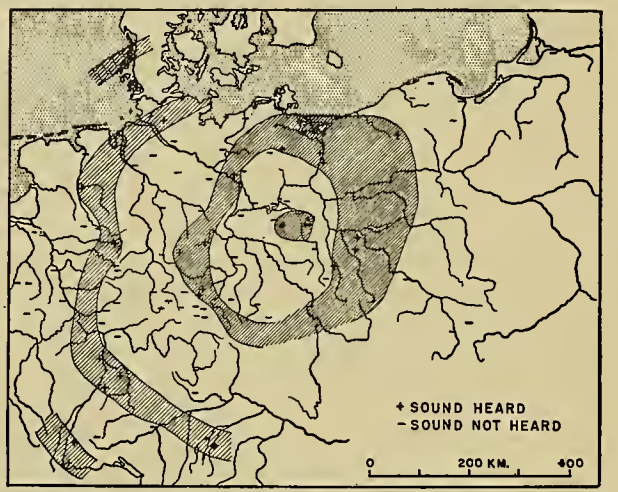

FIG. 8.—Observations of sound waves through the stratosphere after explosion of 5000 kg of ammunition, December 18, 1925. (*After Hergesell and Duckert* [16].)

to the west during summer. This is due to the fact that the rays have rather large angles of incidence (normally between 75° and 90°) so that at the source sin i is usually larger than 0.98. If the temperature at the point of observation is more than about 10C higher than at the source (continent in summer, ocean in winter), it becomes increasingly probable that this difference makes the return of the ray to the ground impossible; the rays turn upward again at a level with a temperature given by equation (10). Similar effects can be produced by prevailing winds (equation (19)).

Records show relatively small differences in travel time of rays to the abnormal zone between day and night [19], although details of the records change gradually (Fig. 11*b*). Wide variations in the amount of explosive do not result in different travel times. This proves that the return of the rays to the ground is not affected by an increase in the ratio of the pressure change to the pressure itself and that, even at the highest levels reached by the rays, equation (7) holds. This conclusion has been confirmed by the agreement between the temperatures calculated from equation (7) and those found from records made with V-2 experiments (Fig. 12). Finally, records taken at equidistant points in opposite directions from the source did not give appreciably different travel times. Therefore, the conclusion can be drawn that relatively high temperatures in the stratosphere account for the sound in the outer zones, as suggested by Whipple [30].

FIG. 9.—Sound intensities observed after an explosion near Vergiate, Italy. (*After Oddone.*)

Annual changes in the travel-time curves (Fig. 12), and the annual period of the radius of the zone of abnormal audibility, are caused by (1) annual changes

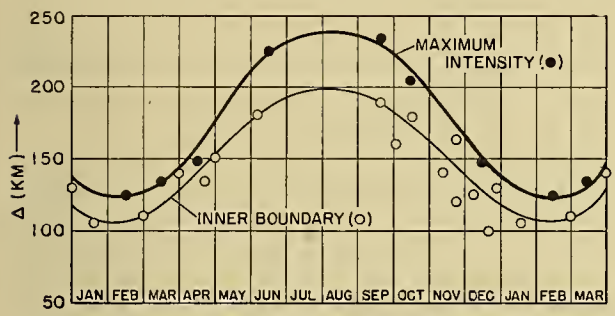

FIG. 10.—Yearly period of the distance from the source at which the first ring of audibility begins (circles and thin curve) and of the distance of the maximum number of reported observations (dots and thick curve) based on data collected by Wegener [28, 29].

in the speed and direction of the wind, or (2) an increase in temperature above the value near the ground at elevations varying, in central Europe, between about 30 km in late winter and 40 km in late summer. Either (1)

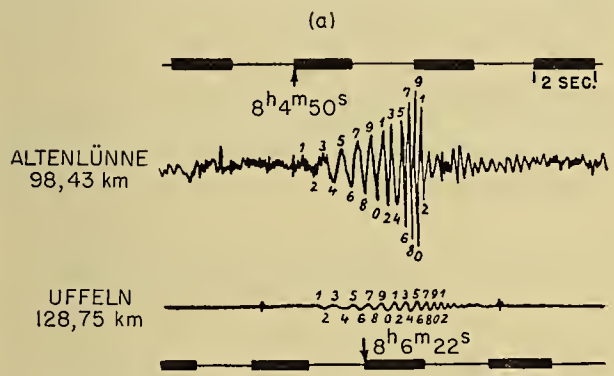

FIG. 11*a*.—Direct sound waves, recorded by Kühl's undograph, showing dispersion. (*After Schulze* [27].)

or (2) or both operating jointly may produce this effect. Since the travel times for the rays arriving in the second abnormal zone were always close to twice the travel time at half the distance in the first zone (Fig. 12) it was concluded that the second ring is produced by rays reflected at the surface of the earth [11, 29]. Similarly, the following zone (travel-time curve *c* in Fig. 12) is probably due to twice-reflected waves. Still later phases may be due to waves which left the ground under too small an angle of incidence to be turned back in the warm layer near 55 km, passed upward into the colder layer above, and finally were turned back (Fig. 14) in the layers at an elevation about 100 km [5], where the temperature increases beyond that near 55 km.

Calculations of the temperature in the part of the stratosphere in which the sound waves are turned down to produce the first abnormal zone can be made as follows [10, 11]. First, equation (7) is used to calculate the sound velocity in the troposphere, and possibly in the lower part of the stratosphere. Equation (17) gives the angles of incidence corresponding to the travel-time curve (*b* in Fig. 12); usually they change little with distance. Equation (14) gives the horizontal distance

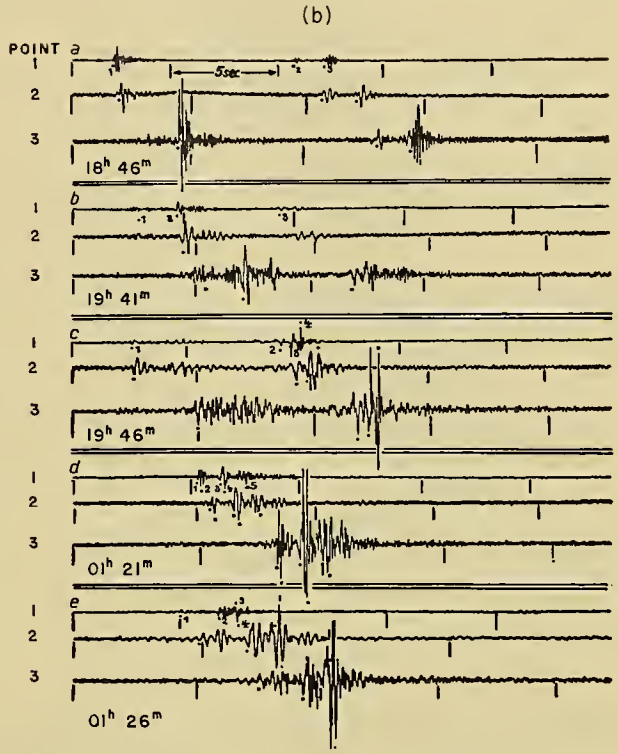

FIG. 11*b*.—Records of sound waves at a distance of about 200 km from the source at three points (distances from each other about 450, 910, and 845 m, respectively) at different times between July 21, 1927, 6:46 P.M. and July 22, 1:26 A.M.; source near Jüterbog, recorded near Wurzbach, Thüringen, in Germany. (*After Meisser* [19].)

corresponding to the ray section between the ground and the level for which the sound velocity has been calculated, and equation (16) the corresponding travel time. Twice these distances and times are subtracted

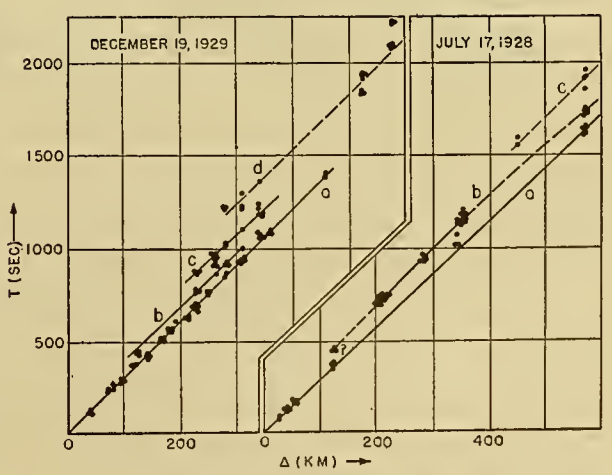

FIG. 12.—Travel-time curves from explosions near Jüterbog, Germany, in summer (July 17, 1928) and in winter (December 19, 1929). Curves *a*, *b*, *c*, and *d* apply to the first, second, third, and fourth zones of abnormal audibility, respectively. (*After Gutenberg* [10].)

from selected observed values of the travel-time curve considering the calculated angles of incidence at the ground. This results in a travel-time curve for rays

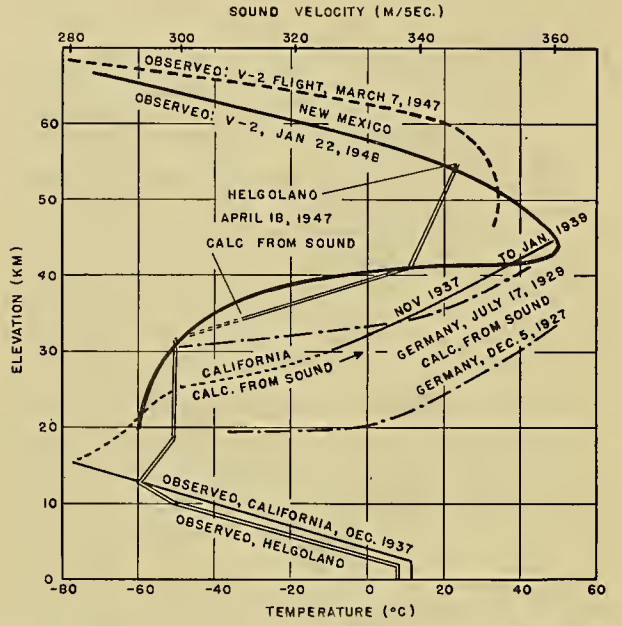

FIG. 13.—Temperature and sound velocity in the atmosphere from various sources.

at the level where the temperature observations end. Equation (18) then permits the calculation of the highest point H^* above the level of reference reached by a given ray; the wave velocity at this point is equal to the apparent velocity at the distance where the ray arrives. In this way the velocity (and consequently the temperature) for a number of points in the stratosphere can be found as far as the temperature increases with height. If necessary and possible, corrections for the wind should be made. The upper limit of height for which results can be found is given either by the increasing absorption or by a decrease in wave velocity with height (usually as a consequence of a decrease in temperature); both may be involved. Figure 13 gives a few results. The temperatures, calculated from the sound observations, agree with the observations from V-2 data [22] within the limits of error.

The yearly period of the radius of the abnormal zone (Fig. 10) and of the travel times (Fig. 12) is affected by the yearly period of the wind, but it is caused mainly by the annual period of the temperature (and thus by the similar period of the ozone content) at elevations between about 25 and 60 km. Annual changes in the direction of the wind near and above the tropopause shift the whole zone in the direction of the prevailing wind, but cannot explain the annual expansion and contraction of the zones which has been observed.

Observations of the amplitudes of sound waves through the stratosphere are very scarce. The maximum near the inner boundary of the abnormal zone results from the concentration of energy connected with the cusp of the travel-time curve at the minimum distance (Fig. 14) reached by the rays [11], where the very large values of $di/d\Delta$ produce a focal point according to equation (32). The intensity of the sound waves there may be so large that windowpanes are broken [14]. The records of the Helgoland explosion [4] showed good agreement between the observed sound-intensity and the energy calculated from equation (32). However, Cox [4] has pointed out that the decrease in short waves relative to the long waves with increasing distance (to be expected from the increase in absorption, see Fig. 3) is not confirmed by these records. The differences in recorded periods are relatively small and may be a consequence of local effects.

In very large explosions, another group of waves is recorded. The best example is furnished by barograph records following the explosion of Krakatao in 1883; the pressure waves circled the earth several times, with

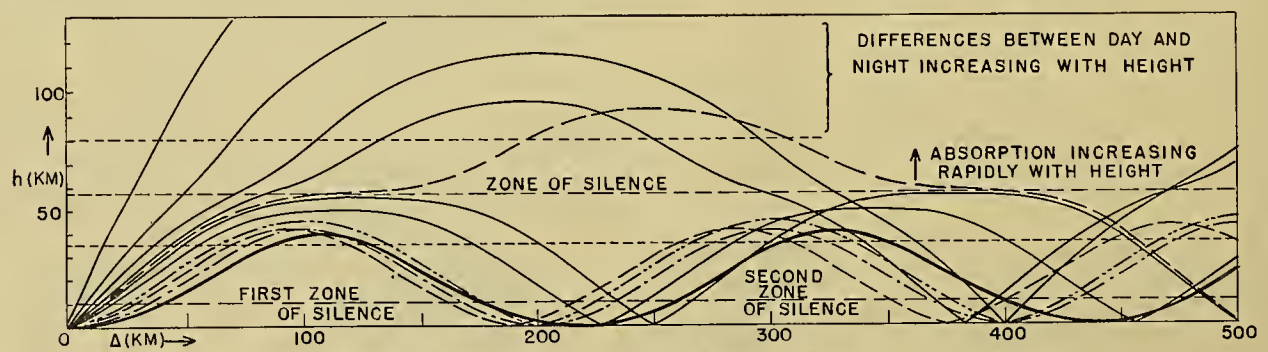

FIG. 14.—Typical paths of sound waves in the atmosphere. (*Extended from Gutenberg* [11].)

a mean velocity [24] of 314.1 m sec^{-1} (measured along the surface of the earth); the mean value from recorded sound waves travelling three times around the earth eastward was about 320 m sec^{-1}, westward about 304 m sec^{-1}. The velocity of 314 m sec^{-1} corresponds to a temperature of −28C. Similar waves with a velocity of 301 m sec^{-1} (not corrected for wind effect) were recorded at Tucson, Arizona, in southern California, and in Nevada [12] after the explosion of the atomic bomb in New Mexico in 1945. This group of waves followed, after many minutes, the waves discussed previously, and carried the largest amplitudes. At Pasadena, it was strong enough to record on the strain seismograph as a single wave having a period of about 12 sec; apparently, the arriving pressure wave com-

pressed the hill on which the Seismological Laboratory is located. The waves are probably of the type discussed theoretically by Pekeris [23].

If the source of the sound is not at the surface of the earth, sound paths can easily be constructed by using equations (10) to (17). For a source in the tropopause, the rays follow patterns similar to those constructed by Ewing [7] for the "tropopause" in the ocean.

PROBLEMS FOR FURTHER RESEARCH

Results concerning the following problems would aid most in the interpretation and use of recorded sound waves passing through the atmosphere:

1. Determination of the velocity and absorption of sound waves in rarified air at pressures down to 0.01 mb.

2. Effect of wind at various levels up to 100 km on sound propagation. (Some authors probably overestimate such effects, others underestimate them.)

3. Effects of the wind component perpendicular to the direction of the sound propagation.

4. Determination of additional travel-time curves for sound waves refracted in the stratosphere (*a*) in various latitudes, (*b*) their annual period, (*c*) their diurnal period (no clear period has been found), (*d*) correlation of results under (*a*) to (*c*) with periodicities of ozone content in the "ozonosphere."

5. Change in frequencies prevailing in sound waves with distance from the source; effects of selective absorption.

6. Indications of dispersion of sound waves under various conditions. (Present experiments do not indicate dispersion.)

7. Theory of free pressure waves in the atmosphere; extension of the theory of Pekeris [23] to other models, considering the most recent data on temperature in the stratosphere and in the ionosphere.

8. Properties of sound waves refracted at levels near 100 km [4] and of free pressure waves [12, p. 329].

9. Natural pressure waves in the atmosphere in various latitudes, on islands, near coasts, and far inland (including use of tripartite stations with base lengths of about ¼ of the wave length of the waves to be studied, see Fig. 7); causes of such waves [13] and their possible use in weather forecasting.

SOLAR ENERGY VARIATIONS AS A POSSIBLE CAUSE OF ANOMALOUS WEATHER CHANGES

By RICHARD A. CRAIG

Harvard College Observatory

and H. C. WILLETT

Massachusetts Institute of Technology

INTRODUCTION

This article is concerned only with the possible relationships existing between anomalous changes of weather and the variations, in one form or another, of the output of solar energy. There can be no question that the sequence of weather change which is represented by the normal diurnal and seasonal sequences of weather over the globe is to be explained entirely by the corresponding diurnal and seasonal variation of the sun's distance and position in the sky, whether or not the quantitative explanation of this normal variation is entirely satisfactory. There is no suggestion of any normal diurnal or seasonal variation of the output of solar energy which would account for any part of the normal variation of global weather. This is entirely a question of the regularly variable distribution of the solar energy.

As soon as a comparison is made between the irregular, anomalous fluctuations of world weather patterns and the irregular variability of the output of solar energy, the evidence of definite relationship between the highly complex variations of these two patterns of change becomes at many points contradictory, indecisive, and highly controversial. In our present state of ignorance as to (1) the specific nature and amount of the solar energy changes, (2) the specific effects which this irregular solar activity produces in the higher atmosphere, and (3) the mechanism of interaction between the higher and the lower atmosphere, it is quite impossible conclusively to prove or disprove the effective influence of irregular solar energy variations on the anomalous fluctuations of the global weather patterns. The evidence for this influence must inevitably depend to a large extent on inference and on the elimination of possible alternative explanations of observed effects. Such evidence is of necessity somewhat subjective in character, and liable to some stretch or strain in its interpretation. In the following discussion an effort will be made to maintain objectivity in the presentation and judgment of the evidence, but the interpretation is intended to be sympathetic to the view that irregular solar activity is the primary factor in the control of anomalous weather fluctuations.

To facilitate the presentation of irregular solar activity as the predominant factor in controlling the anomalous fluctuations of weather and climate, the following discussion is divided into three sections, as follows:

1. The nature, periodic character, and observed effects in the higher atmosphere of irregularly variable solar activity, which presumably is causally related to anomalous weather fluctuations.
2. The periodic character and geographical pattern of anomalous weather fluctuations, which are presumably related to variable solar activity.
3. The applicability of variable solar activity as the primary explanation of anomalous weather fluctuations.

THE NATURE AND PERIODIC CHARACTER OF VARIABLE SOLAR ACTIVITY

Systematic studies of the sun have revealed several characteristic features that vary semicyclically. It is the purpose of this section to discuss briefly these features, their variations, and the observed effects of the variations on terrestrial phenomena. The only book devoted exclusively to a technical discussion of the sun is that of Abetti [1]. A more recent semipopular book is that of Menzel [15]. Various astronomical texts, for example [2] and [19], give brief discussions of the sun.

The sun's visible surface, or *photosphere*, presents a mottled appearance on telescopic inspection. Many small brilliant *granules* can be detected against a darker background. *Sunspots* and *faculae* are much larger and more stable features of the solar surface. The sunspots are relatively dark areas, roughly circular in form. They usually occur in groups, dominated by two large spots. The individual spots vary in diameter from a few hundred miles to tens of thousands of miles. Faculae, on the other hand, are relatively bright areas, usually occurring in the vicinity of sunspot groups.

The spectroheliograph photographs the sun in the selective radiation of one element, and hence enables us to study the sun at levels above the photosphere. In both calcium and hydrogen light, large bright (relatively hot) or dark (relatively cool) patches are observed, especially in the vicinity of the sunspots. These are called *flocculi*. When the hydrogen flocculi are carried by the sun's rotation to the solar limb, they appear as bright *prominences*, or projections of gas from the sun. At times very intense outbursts, called *flares*, occur. These flares are accompanied by hydrogen emissions detectable at the wave length of the $H\alpha$ line in the visible part of the solar spectrum. Another solar phenomenon, recently noted by Roberts, is the occurrence of *spicules*. These are relatively small and relatively short-lived extensions of gas from the chromosphere, and are most noticeable at high solar latitudes.

Even farther out from the photosphere is a very

tenuous envelope of gas called the *corona*. Recent evidence shows that the corona is extremely hot, having a temperature of about 1,000,000K compared with the photospheric temperature of about 6000K. The cause of this high temperature is still a mystery.

All of the solar phenomena described above vary with time in intensity or character. The variations of all the features seem to be in phase. Only the sunspots have been observed for a long enough period of time to include a large number of cycles of variation. Accordingly, sunspot variation is discussed here as an indicator of solar variation.

The *relative sunspot number* is an index of the number of spots and groups of spots visible on the solar surface. Reasonably reliable records of sunspot numbers extend back to 1749, although the earlier years of this record are much less reliable than the later ones. These records show that the sunspot number has alternately increased and decreased with a period that has averaged about eleven years. The length of this period, however, has varied from seven to seventeen years and the sunspot number has also varied from maximum to maximum.

The beginning of a solar cycle is characterized by the appearance of a few spots near 30°N and S heliographic latitudes. As the cycle progresses, the number of spots increases and the latitudes of most frequent occurrence move toward the solar equator. The largest number of spots occurs when the spot zones are near 16°N or S. After sunspot maximum, the spot zones proceed equatorward and at sunspot minimum there are only a few spots near the equator and a few spots in higher latitudes marking the beginning of a new cycle.

Sunspots possess intense magnetic fields. The polarities of these fields vary characteristically, with a period twice that of the ordinary sunspot cycle. The two large spots in a group, which are called the *leader* and *follower* spots, have opposite polarities. The leader spots in the Northern and Southern Hemispheres also have opposite polarities. Moreover, spots in the same relative position in their groups and in the same hemisphere have opposite polarities from one sunspot cycle to the next.

Along with sunspot variations, other solar phenomena show characteristic changes. Faculae, flocculi, flares, and prominences are more numerous and intense at sunspot maximum, although they are by no means absent at sunspot minimum. The corona is approximately circular at the time of sunspot maximum, but is flattened at the poles near sunspot minimum. The intensity of the coronal emission lines is also greater at sunspot maximum than at minimum, according to recent observations.

The energy output of the sun is difficult to measure at the earth's surface, because of absorption and scattering of sunlight by the earth's atmosphere. Nevertheless, the Smithsonian Institution has for the past forty years undertaken the routine measurement of the *solar constant*. This is the amount of solar energy incident at the outer edge of the earth's atmosphere per unit area and time reduced to mean solar distance. These measurements, of course, do not include solar energy to the violet of about 2900 A, which is completely absorbed in the earth's upper atmosphere. This energy is estimated and included in the solar constant.

The value of the solar constant is near 1.94 cal cm^{-2} min^{-1}. C. G. Abbot, who has supervised most of the measurements, claims that the solar constant varies from time to time by a few per cent of the mean value. This claim has been disputed by many other scientists, who feel that the uncertainties involved in the measurements are at least as great as the suspected range of variation. In any case, Abbot's work gives an upper limit to the amount of solar variability during the past forty years in the part of the spectrum available for routine measurement. The measuring program of the Smithsonian Institution is described fully in the *Annals* of the Smithsonian Institution and in numerous papers of the *Smithsonian Miscellaneous Collections*.

Abbot has claimed that the variations in the solar constant primarily reflect large variations in the violet and ultraviolet part of the spectrum. This claim seems to be verified by some measurements of Pettit [16]. Pettit measured the ratio of solar radiation at 3200 A to that at 5000 A. Over a period of years from 1924 to 1931, this measured ratio varied by about 40 per cent of its mean value, presumably reflecting variability in the ultraviolet. Unfortunately, observing conditions were not ideal and atmospheric factors were suspected to be the cause of at least part of this variation. On the other hand, none of the specific tests applied by Pettit showed instrumental or atmospheric effects of this magnitude. To some extent, at least, the ratio varied in a manner similar to that of the sunspot number.

Farther into the ultraviolet, below about 2900 A, solar energy is absorbed in the upper atmosphere and cannot be observed at the earth's surface. In the ultraviolet, however, there is abundant indirect evidence of solar variability because of effects on the upper atmosphere. The frequency of occurrence of magnetic storms and of aurorae, as well as the ionization of the upper atmosphere, clearly varies over the solar cycle. The correlation between upper-atmospheric phenomena and sunspot number becomes progressively poorer as the parameters involved are averaged over shorter and shorter periods of time. Thus, there is little or no correlation between daily sunspot numbers and daily values of the various indices of upper-atmospheric conditions. This would make it appear that all spots do not affect the earth directly but rather are correlated with the occurrence of the solar phenomena that do affect the atmosphere. Effects in the upper atmosphere indicate clearly solar variations only in the short wave lengths of hydrogen and helium emission ($\lambda < 1216$ A) and variations in particle emission of the sun. For the wavelength interval 1216–3200 A, there is apparently no evidence to indicate whether the sun's energy is or is not variable.

The present state of knowledge of solar variability, then, reveals little or no variability in the infrared and visible spectrum, perhaps some moderate variability in the violet and near ultraviolet, and almost certainly rather large variability in the far ultraviolet. The solar

variability that exists is related to the sunspot number, at least in a general way. The record of sunspot number in the past 200 years, therefore, gives some idea of the character of solar fluctuations. A study of the record shows great irregularity. Although the average time from maximum to maximum has been eleven years, the interval between maxima has been exactly eleven years only three times in eighteen cycles and has varied from seven to seventeen years. The annual mean sunspot number at maximum has varied from 46 (1816) to 152 (1947). The maxima appear to have run in cycles of four large values and three small values. This longer-period variation can also be expressed in terms of an 80-year cycle, that is, in successive forty-year periods the average number of sunspots has been alternately large and small.

There is some evidence that during the historical past solar activity has varied considerably more than during the past 200 years. Fragmentary observations and records indicate that during parts of the 13th and 14th centuries (a period of considerable climatic stress in Europe and Asia) solar activity as evidenced by very large and numerous sunspots was probably greater than it has been since, although observations were so few and primitive that no real comparison can be made. On the other hand, between 1672 and 1704 (the 17th and 18th centuries were notably lacking in climatic stress) not a single sunspot was observed on the solar northern hemisphere, so that in 1705 when the observation of such a spot was announced it was considered a surprising fact of extreme scientific interest.

THE PERIODIC CHARACTER AND GEOGRAPHICAL PATTERN OF THE ANOMALOUS WEATHER FLUCTUATIONS

The flow pattern of the general circulation of the earth's atmosphere, by which the world weather pattern is determined, is in a perpetual state of anomalous fluctuation comparable in amplitude to and much more rapid than the normal slow seasonal fluctuation. The periodic character of these anomalous fluctuations of the general circulation has been the subject of extensive statistical analysis. Components of periods ranging from a few days to millenia or geological epochs in length can be detected, but it has not been possible to demonstrate any regular periodicity of real statistical significance in these fluctuations. To all practical purposes, there are no established periods of anomalous fluctuation of the general circulation.

The fluctuations occur in an almost continuous spectrum of periods from the very short to the very long. For purposes of discussion it is convenient to group the anomalous fluctuations of the general circulation (*i.e.*, of the world weather pattern) by length of period of the fluctuation concerned, in five general classes. A discussion of each of these classes follows.

Geological Fluctuations. These refer to the major glacial and interglacial periods during geological time. According to the best geological evidence [7], major glacial epochs, at least during the last billion years, have occurred approximately at quarter-billion-year intervals, but no over-all climatic trend towards more mild or more severe conditions is indicated. Each of these glacial epochs (with the exception of the Pleistocene, which is not yet terminated) continued for many, perhaps as much as 50 million years, being separated by approximately 200 million years of relatively mild interglacial climate. The geological evidence indicates that each major glacial epoch was by no means continuous, but consisted of an extended sequence of periods of maximum glaciation (ice-sheet development) separated by periods of ice-free interglacial conditions. These glacial-interglacial sequences apparently run in cycles of from one hundred thousand to five hundred thousand years duration.

The present Pleistocene Epoch, which apparently has not lasted more than one or two million years, has experienced four such glacial maxima, separated by three interglacial periods, of which the middle and longest one lasted for at least two hundred thousand years [7]. Since the Pleistocene sequence of glacial and interglacial climates is known in much greater completeness and detail than that of the earlier glacial epochs, and since it occurred under essentially the present condition of topography (land and water distribution) which determines our climatic patterns today, only this epoch is referred to in the following discussion of glacial and interglacial climates. It is assumed that any deviation of the earlier glacial-interglacial patterns from those of the Pleistocene period are to be explained by the extensively different terrestrial topography of the earlier periods.

The climatic conditions of a period of maximum glaciation may be characterized essentially as follows:

1. Ice sheets covering up to 30 per cent of the continental area of the Northern Hemisphere, with principal ice sheet centers between latitudes 60° and 65° over northeastern America and over Scandinavia, extending southward over favorably located continental areas to the 40th parallel of latitude.

2. Greatly expanded anticyclonic polar-cap circulations, with a corresponding equatorward displacement of the climatic belts and zonal wind systems, notably of the prevailing storm tracks of middle latitudes.

3. Increased poleward temperature gradient in middle latitudes, with a correspondingly marked intensification of the general circulation, notably of storminess in middle latitudes and of the effective operation of the evaporation-precipitation cycle.

4. Predominance of excessively cool and wet conditions in the middle and lower middle latitudes of maximum storminess; of excessive rainfall in the intertropical convergence zones, and probably of hot dry conditions in a narrow intense subtropical high pressure belt on either side of the equator.

In contrast the climatic conditions of a typical interglacial period may be characterized essentially as follows:

1. Complete disappearance of permanent ice from the face of the globe on land and sea, with only tempo-

rary freezing of shallow portions of the polar seas during the winter season.

2. Complete disappearance of the anticyclonic polar-cap circulations with a corresponding poleward displacement of the climatic belts and zonal wind systems, notably with the contraction of the circumpolar storm tracks of either hemisphere into permanent cyclonic centers over the poles.

3. Great warming of the polar regions, with a correspondingly weakened poleward temperature gradient, decreased circulation, and absence of storminess in middle latitudes.

4. Expansion of the subtropical high-pressure belts with relatively storm-free, dry, and mild conditions prevailing through most of the middle latitudes. Precipitation restricted to the local convective rather than cyclonic type, with a marked weakening of the intertropical convergence, hence with relatively dry conditions in the tropics as well as in the middle latitudes.

This contrast between the typical glacial and interglacial climate is summarized here in its essential detail because it is quite characteristic of, though somewhat more extreme in degree than, the shorter-period climatic, secular, and anomalous fluctuations of the general circulation.

Climatic Fluctuations. These include the considerable fluctuations of climate during postglacial time. The last glacial maximum of the Pleistocene Epoch terminated officially some 8000 years ago, at approximately 6500 B.C. Geological evidence indicates that at that date the recession of both the Scandinavian and the North American ice sheets, and the corresponding amelioration of climate, had reached the point at which conditions stand today. However, during these 8000 years there have occurred very substantial fluctuations of climate [4, 7, 12, 27], running in irregular cycles of from three to five thousand years. In amplitude these fluctuations probably have amounted to at least half of a glacial-interglacial cycle, and according to all evidence they have followed almost identically the glacial-interglacial pattern of climatic change. The evidence is quite clear that during the preceding twenty thousand years of the recession of the last ice sheet, and also during the preceding glacial maxima of the Pleistocene Epoch, a similar considerable secondary fluctuation of climate was superposed on the primary glacial-interglacial cycle, to such a degree that each glacial stage was marked by temporary peaks and recessions.

During postglacial time, in the period of the Climatic Optimum, which lasted from approximately 4000 to 2000 B. C., the world climate very closely approximated the interglacial type. Warm, dry, storm-free conditions prevailed in middle latitudes so that hardwood forests flourished in Scandinavia, in the British Isles, and in much of North America in regions where the climate is far too severe (cold and stormy) for such growth today. The polar regions were warm and stormy, the polar seas free of permanent ice, and the Greenland and antarctic icecaps probably several hundred feet lower than today. Lake levels in Asia, in northern and central Africa, and in the western United States reached their lowest levels of postglacial time, many of them drying up entirely, while most glaciers in middle latitudes completely disappeared. Most of these glaciers today represent new formations, not remnants preserved from the last glacial maximum. If this condition had persisted for fifty thousand instead of only two thousand years, it probably would have constituted a true interglacial period.

At the start of the sub-Atlantic period, which was well established from about 1000 B.C. to A.D. 300, world climate took a strong turn towards the glacial type. Storminess and cold in Europe became extreme, the extensive forests of the preceding Climatic Optimum were replaced by peatbogs, while glaciers in all parts of the world advanced well beyond preceding limits. The Caspian Sea, the nonoutlet lakes of the western United States, and the lakes of northern and equatorial Africa reached their highest postglacial levels, while relatively cool, moist conditions in the lower middle latitudes permitted the development of extensive civilizations in the Mediterranean and on the steppes of central and western Asia in regions which subsequently became too arid for agricultural pursuits. During the period, severe arctic conditions were re-established in the polar regions.

From approximately A.D. 400–1000 the world climate returned to a minor and abbreviated edition of the Climatic Optimum, mild extremes being reached in the higher latitudes during the eighth and tenth centuries. This period marked the peak of the Viking explorations and colonization in Iceland and Greenland. In their small boats the Vikings regularly traversed seas which today would be impassable for them by reason of ice and storms, and their colonies throve by agricultural pursuits in areas of Greenland which are now covered by glaciers. Dryness in the Mediterranean and central Asia led to mass migrations and to the crumbling of many civilizations. The degree of dryness was attested to by tree-ring records and by the lowest lake levels in Asia, Africa, and the western United States since the Climatic Optimum. Relative dryness in tropical regions which at present have heavy rainfall was evidenced by the development of the Mayan civilization of Central America and the great city of Angkor in French Cambodia. The sites of both of these civilizations were reclaimed by the jungle during subsequent centuries of wet climate.

The eleventh and twelfth centuries saw a return of the glacial type of climate, which during the 13th and 14th centuries reached a peak of great storminess and climatic stress in Europe and other regions in higher middle latitudes. This period repeated all of the characteristics of the sub-Atlantic period to a moderate degree. Since the 14th century there has been some amelioration of conditions, particularly during the first half of the 17th and last half of the 18th centuries. This was followed by increased severity of climate during the early nineteenth century, and a turn for the better from 1880 to the present. Although the climatic fluctuations of the past 500 years have been relatively slight, the

prevailing type of climate has been that of postglacial severity rather than mildness. The important fact about the postglacial period is that in the relatively short time of 8000 years the world climate has swung through two cycles of change which in amplitude are a substantial part of the much longer typical glacial-interglacial cycle of the Pleistocene Epoch.

Secular Fluctuations. These refer to cycles of change or trends of weather and climate which are completed within a single century. Examples are the so-called *Brückner Cycle*, the single or double (Hale) sunspot cycle, and the world-wide trend since 1880 towards higher temperatures which has progressed poleward and reached a crest in the higher latitudes during the past two decades. Many investigations of these secular fluctuations of the world weather pattern have been undertaken. Here it need only be mentioned that these fluctuations are small in amplitude compared with both the climatic and the geological fluctuations, but they do show notably similar characteristics as to latitudinal displacement of the zonal wind systems and prevailing storm tracks, and as to the corresponding severity of cyclonic storm activity in middle latitudes. This latitudinal shift of storm tracks and belt of maximum cyclonic precipitation is shown quite clearly by the last, and statistically best-established, of Brückner's rainfall cycles (1855–1885), by a number of Tannehill's secular trend graphs of pressure, temperature, and rainfall [24], by the trend since 1880 towards warmer and drier conditions in progressively higher latitudes, and by many of the double sunspot-cycle phase-change patterns of pressure, temperature, and rainfall [27, 28]. The basic similarity of the geographical patterns of secular changes and trends of weather anomalies to the patterns of climatic and geological changes is considered to be highly significant for any physical interpretation of these fluctuations.

Anomalous Fluctuations. This class is made up of the anomalous irregularly cyclical fluctuations of the general circulation from week to week, from month to month, or from season to season within the year. In recent years considerable synoptic and statistical analysis has been directed toward the determination of the essential character and the most significant parameters for the diagnosis and prognosis of these fluctuating patterns of the general circulation. As a result of these studies there was developed the concept of the high- as opposed to the low-index pattern of the general circulation as an expression of the essential character of the opposite extremes between which the pattern typically fluctuates. These fluctuations usually run in cycles of from three to seven or eight weeks. During some periods the opposite type patterns reach more extreme development than during others, and during some seasons or years or even longer periods (secular, climatic, and geological) one type or the other is largely predominant. The most noteworthy feature of these two contrasting type patterns is that they are world-wide in character, so that they appear to express the operation of a mechanism of basic significance in all of the longer-period fluctuations of the general circulation [17, 23].

Originally the single parameter by which the high- and low-index patterns of the general circulation were defined was that of the strength of the sea-level zonal westerly winds between latitudes 35° and 55°, but much statistical and synoptic analysis [18, 28] has indicated that there are other parameters which are probably of more significance.

In the light of these statistical studies the change from a high- to a low-index pattern (the reverse of a change from low to high index) is best expressed by the significant parameters of the state of the general circulation, other than by a weakening of the sea-level zonal westerlies, in the following terms:

1. An intensification and expansion of the polar anticyclonic circulations, with a corresponding equatorward displacement of the zonal wind systems and the related climatic zones, notably of the zonal westerlies and the prevailing storm tracks.

2. An intensification of the cellular (as opposed to the zonal) pressure and wind pattern. At sea level this trend is indicated by a splitting of the major cyclonic and anticyclonic centers of action, with a north-south rather than east-west orientation of the major axes. At upper levels the trend is indicated by an increased amplitude and shortened wave length of the trough-ridge pattern, with a tendency toward the formation of closed anticyclonic centers in the higher latitudes and closed cyclonic centers in the lower. The result is an increase of the latitudinal exchange of air masses, and of storminess and extreme air mass contrasts in lower middle latitudes.

3. Initially an increased poleward temperature gradient in the lower troposphere in middle latitudes, hence, with the increased austausch, a marked increase of poleward transport of heat and energy.

It is immediately apparent, from the above summary of the high-low index contrast, how strikingly this contrast of the general circulation pattern resembles the interglacial-glacial, and less extreme climatic and secular, contrasting world weather patterns.

Daily Fluctuations. These are essentially the day-to-day progression of pressure centers, with related air mass and frontal phenomena, as observed on the daily weather maps. Essentially the daily fluctuations of the weather pattern are local rather than global in character, for only relatively small-scale circulation phenomena can run through a cycle of change in a day or two. However, it must be recognized that the sum total of these small-scale fluctuations integrated over a period of days or weeks constitute the world-wide patterns of weather change discussed above as the anomalous changes. When the anomalous changes are progressing rapidly, the trend of this progression, and the contribution to it of the daily local changes, becomes quite evident. In particular, the progressive effects of any sudden impulses (solar) to the anomalous fluctuations of the world weather pattern must be traced in daily pattern changes. Such effects are noted below in the reference to Duell and Duell's study [6] of the effects

of sudden solar outbursts on the large-scale pressure changes.

HYPOTHESES OTHER THAN SOLAR VARIABILITY AS PRIMARY FACTORS CONTROLLING THE ENTIRE SPECTRUM OF ANOMALOUS WEATHER CHANGES

The irregular weather changes described above have many characteristics that seem to indicate solar variability as a primary causative factor. These arguments cannot be considered as definite proof of the existence of an atmospheric reaction to solar variability. At least, however, they point out the importance of further studies of the question.

Perhaps the most striking feature of these changes is the fact that the entire spectrum of weather variations reveals a similar oscillation between two definite types of weather pattern. The severe, stormy weather of the glacial epochs, glacial stages, glacial substages, peat-bog period, and stormy centuries could be satisfactorily explained in terms of the predominance over varying periods of time of the low-index patterns that are apparent in our weather today. Thus, all these weather patterns indicate an expansion of the circumpolar vortex, with extension into middle latitudes of polar conditions, a retreat southward of the zone of westerlies and the storm tracks, a contraction and equatorward movement of the subtropical high-pressure systems, and probably a contraction and intensification of the intertropical convergence zone. On the other hand, the relatively mild and dry weather which has predominated at various times in the earth's history is similar in nature to our mild seasons characterized by high-index patterns.

This similarity of pattern is strongly indicative of similarity of the disturbing impulses for all fluctuations. The necessity of some *universal* disturbing impulse which varies irregularly in long as well as short cycles is indicated by the fact that the amplitude of the fluctuations increases with the period. No random combination of localized centers of disturbance of the cellular patterns of the circulation could be expected to produce such globally consistent and integrated patterns of change.

Unfortunately, the physical basis for present-day changes between high-index and low-index weather patterns is not understood. Rossby [17] has shown that relatively high pressure near the poles (anticyclonic polar vortex) is dynamically unstable and that cold anticyclonic domes tend to move southward with a resulting increase in the meridional austausch.

Starr [23] considers the latitudinal transport of *momentum* and *heat* and arrives at the conclusion that relatively high pressure in higher latitudes is a necessary condition for, but does not require, poleward transport of heat and kinetic energy. Thus Rossby's interpretation is essentially dynamic and Starr's is thermodynamic. Correlation studies based on Starr's hypothesis have yielded coefficients considerably higher than those based on any other hypothesis of the mechanics of the general circulation.

Irregular weather changes also seem to be world-wide in extent. Certainly the glacial epochs and probably the glacial stages have been essentially simultaneous throughout the Northern Hemisphere. This also applies to the climatic fluctuations. For the secular and week-to-week changes, we cannot be so certain, but even there evidence indicates the same tendency. The difficulties of calibrating the geological time-scale in the Southern Hemisphere with that in the Northern Hemisphere are great; however, the evidence now available indicates the coincidence of the gross weather variations in the two hemispheres.

If the two premises are accepted that irregular weather variations of all periods have a common cause and tend to be world-wide in extent, it is natural to look to solar variability as the controlling factor. All that we know about solar variability indicates a striking similarity between the patterns of solar changes and of weather changes. The sun is capable of short-term changes in emission of ultraviolet light and charged particles. It also shows a secular change in these emissions that is only roughly periodic. The meagre evidence available from sunspot observations indicates also changes extending over centuries that might correspond to climatic weather changes. Quite probably the sun has varied even more in the geological past than in the immediate past where records are available.

In spite of these considerations, many previous investigators have suggested other causes for various types of weather changes. Each of these suggestions has encountered serious objections. None, except solar variability, is capable of explaining *all* irregular weather variations. Nevertheless it is of interest to consider the various weather changes in turn and to discuss the alternative suggestions that have been offered.

Geological Weather Changes. The cause of the ice ages has been and still is a subject of lively debate. Of the many theories that have been propounded, three have seemed particularly attractive and have received the most attention. These are (1) the *theory of distribution of insolational heating*, (2) the *theory of mountain or continent building*, and (3) the *theory of solar variability*.

1. The theory of distribution of insolational heating holds that variations in the earth's orbital elements (eccentricity, inclination of the earth's axis, and precession) affect the distribution of solar radiation over the earth and thus cause cycles of weather. The cyclic variation of these elements is such as to predict the pattern of Pleistocene glaciation (four glacial stages and three interglacial stages), and at one time was used to establish a Pleistocene chronology. The arguments against this theory are:

a. These same cyclic changes carried back beyond the Pleistocene Epoch predict similar patterns of glaciation, whereas pre-Pleistocene time was relatively free of glaciation for some 250 million years.

b. These solar effects require that changes in the Northern and Southern Hemisphere be out of phase, contrary to present opinion and available evidence.

c. This solar variation does not affect the total

amount of radiation received in either hemisphere in a year, and scarcely affects the total annual insolation at a given latitude.

d. The effects are extremely small according to recent calculations by Simpson [22].

2. The theory of mountain or continent building is based on the idea that glaciation is caused by periods of continental uplift and mountain building. Continentality presumably leads to cold winters, and mountains focus the precipitation orographically and give cool summers. Even today, evidence is abundant that these factors are favorable for glaciation. However, it seems likely that these factors, while they probably determine the patterns of glaciation and perhaps are necessary conditions for glaciation, are not in themselves sufficient. Simpson [22] has very neatly pointed out that the Southern Hemisphere, with only about one-half as much land as the Northern Hemisphere, actually averages 2C colder in its annual mean, a maximum effect of 3C being reached at latitude 60° where the Northern Hemisphere is 60 per cent land, the Southern 0 per cent. Moreover, geological evidence indicates that periods of continental uplift have occurred in some cases without subsequent glaciation, and that in other cases the associated glaciation has followed only after millions of years. Furthermore, the glacial and interglacial stages and substages of the Pleistocene ice age have no associated geological changes.

Climatic Weather Changes. Climatic changes, with their smaller amplitudes, have received less attention than geological changes. Of the theories discussed above for the geological changes, only the theory of solar variability could carry over to explain climatic changes. For example, C. E. P. Brooks, a proponent of the theory of continental uplift as a cause of geological variations, has turned to solar variability as a cause of climatic changes [4]. As was pointed out above, climatic oscillations have been similar in character and intermediate in degree to geological variations, on the one hand, and to secular or week-to-week changes on the other. The inability of a given theory to explain all the changes is therefore a weakness in that theory.

Secular Weather Changes. No cause of the secular weather changes, other than possible solar effects, has been seriously offered. Some of the statistical studies attempting to relate secular weather changes to the sunspot cycle are reviewed below (see pp. 386–387).

Week-to-Week Weather Changes. In recent years week-to-week changes in the general circulation have been studied extensively by many meteorologists. In particular the Weather Bureau–M.I.T. Extended Forecasting Project under Willett's direction has conducted an exhaustive statistical study of the week-to-week pressure changes. Using a linear-correlational technique, Willett [26] has compared the zonal index with parameters that describe other segments of the general circulation, such as the zonal easterlies, the subtropical easterlies, and the intensity of meridional interchange. These studies yield a number of consistent and statistically significant contemporaneous correlations between the various parts of the general circulation. However, they fail to yield any consistently significant lag correlations.

The implication of this result is that the causes of large-scale weather changes are not to be found in the pre-existing state of the general circulation. Possible explanations are that:

1. The changes are purely chance fluctuations.
2. The crudeness of the statistical techniques has masked some real relationships.
3. The control mechanism is in the earth's atmosphere, but is outside the region thus far studied—the Northern Hemisphere between the surface and 3 km.
4. The control mechanism is outside the earth's atmosphere, presumably in solar variability.

The first explanation, that of chance fluctuations, is not only unlikely in view of the world-wide and persistent character of the fluctuations, but also represents an extremely undesirable conclusion which could not be accepted until all other possibilities were definitely ruled out. With regard to (2), the statistical methods, while undoubtedly crude, have served to show up certain contemporaneous relationships and could hardly fail at least to indicate the existence of significant lag relationships. Explanation (3) cannot be investigated further at the present time because of lack of data. The external control mechanism, here, as in the cases of other types of irregular fluctuations, remains as a distinct possibility, in that adequate causes of any other nature have not been established.

THE SOLAR HYPOTHESIS AS THE PRIMARY FACTOR CONTROLLING THE ENTIRE SPECTRUM OF ANOMALOUS WEATHER CHANGES

The discussion of the preceding pages indicates in certain respects the general over-all aptness of the solar explanation for the entire range of irregular weather fluctuations, and certain objections to possible alternative explanations of the individual categories of climatic change. It remains only to present any available evidence favoring the solar explanation of the specific categories of the fluctuation of world weather or climate.

Geological (Glacial-Interglacial) Fluctuations. As indicated above, the work of Simpson and others renders relatively untenable both continentality (terrestrial topography) and the long-period geometrical variation of the distribution of insolation as the primary cause of the fluctuations of climate during geological time. Of the current widely accepted hypotheses by which to account for the glacial-interglacial climatic cycles, only the variable output of solar energy remains.

There are two schools of thought as to the probable solar energy change required to produce an ice age, that of most geologists, as formulated by Flint [7], which calls for a substantial decrease of the solar constant, and that of Simpson [20, 21, 22], which requires a substantial increase of the solar constant. Neither hypothesis visualizes any important selective variation of the energy distribution in the solar spectrum.

It is inevitable that a sufficient decrease of the solar constant would lead to a corresponding lowering of the

mean temperature of the earth's surface by 11C, the approximate difference of mean temperature which most geologists accept as differentiating between a glacial and an interglacial climate. However, this temperature differential is computed on the assumption that total precipitation remains unchanged during the temperature cycle, a totally unjustified assumption.

Simpson [20, 21] pointed out that a general lowering of the earth's mean temperature by a decrease of the solar constant would inevitably decrease both the moisture content of the air and, by reducing the latitudinal temperature contrast, the intensity of the general circulation. These two effects would cause a drastic worldwide reduction of precipitation, which precludes the possibility of an ice age, rather than favoring it. No adequate answer to this objection has been offered by the proponents of a reduction of the solar constant as the primary cause of an ice age.

Simpson's conception of glaciation by increased solar heating rests on the assumption that the effect of this heating is reflected primarily by an intensification of atmospheric circulation, cloudiness, and precipitation. The mean temperature of the entire earth's surface is not decreased, but heating in certain regions (subtropical high-pressure belts) and cooling in others (zones of convergence, storm tracks) is a necessary part of the intensification of the general circulation. Glaciation occurs in regions of increased storminess and localized cooling. Simpson recognizes that if the increased solar heating proceeds far enough, the temperature of the entire atmosphere must rise enough to reverse the trend towards glaciation abruptly, with a quick reaction to a warm, very wet (pluvial) interglacial period. He considers that the Pleistocene Epoch consisted of two solar maxima, each of which corresponded to a double glacial maximum interrupted in the middle by a short pluvial interglacial. The long second interglacial presumably represented a dry period of reduced solar constant.

The principal objection to Simpson's hypothesis of glaciation lies in the paradox of warmer sun and cooler earth, at least locally. Most geologists find it very difficult to accept the possibility of an ice age without a substantial lowering of the earth's mean temperature such as that caused by a decreased solar constant. However, there are several considerations that definitely favor Simpson's hypothesis over the opposite point of view, in particular the following:

1. The increased intensity of the general circulation, with the great increase of precipitation not only in glaciated areas, but also in the lower middle latitudes and in the tropics, which is noted to characterize a glacial (in contrast to an interglacial) climate, certainly fits Simpson's conception of the effect of an increased (as opposed to a decreased) solar constant.

2. The statistical verification of Starr's concept [23] of the low-index pattern (relatively high pressure in the polar latitudes) as a necessary condition for increased poleward heat transport definitely conforms to the low-index character of the glacial as opposed to the interglacial weather pattern. By Starr's hypothesis the glacial low-index pattern manifests the necessity of an increased poleward transport of heat, hence presumably also the occurrence of increased solar heating.

3. Two advantages for Simpson's Ice Age theory, including a partial removal of the primary objection to it, ensue from the assumption that the necessary variation of the solar constant occurs primarily in the ultraviolet, increasing with an increase of the other solar phenomena discussed above (see pp. 379–381). These advantages are:

a. Contrary to the lack of any observational evidence of significant variation in the visible spectrum, there is much direct and indirect evidence of highly erratic fluctuation in the ultraviolet roughly paralleling the sunspot cycle. This erratic sunspot fluctuation apparently runs in irregular cycles which increase in amplitude with the time range and which to some extent parallel the correspondingly irregular weather cycles (see below).

b. The increase of solar ultraviolet does not entail the same increased heating of the earth's surface and entire atmosphere as must a significant increase in the entire visible spectrum. The total absorption of the *increased* ultraviolet in the higher atmosphere may alter and intensify the pattern of the general circulation without sufficient heating of the troposphere to interfere with glaciation as Simpson conceives its occurrence.

Climatic (Postglacial) Fluctuations. There has been little effort made to explain the very considerable postglacial fluctuations of climate. Of the currently accepted explanations of the glacial-interglacial fluctuations, only irregular solar variability can conceivably be applied to the similar postglacial fluctuations of relatively short period. Furthermore, there are a few scattered observations since the twelfth century which indicate that solar disturbances (sunspots) have been exceptionally active during periods of exceptional climatic stress (13th and 14th centuries), and exceptionally inactive during the period of minimum climatic stress (later 16th and earlier 17th centuries). However, in general, solar observations previous to 1750 were entirely inadequate to make possible any satisfactory correlation with climatic conditions. On the other hand, the marked similarity of the postglacial to the geological climatic fluctuations suggests the operation of the same factor of climatic control (probably variation of solar ultraviolet radiation), and there is no alternative explanation which has been suggested.

Secular (Intra-Century) Fluctuations. Only the secular fluctuations of the climatic changes are short enough in period so that extensive comparison with observations of variable solar activity is possible. Many studies of the secular variations and trends of climate have been undertaken, but only solar activity survives as a plausible primary factor of control, and that control is far from proved. Certainly it can be said that the secular fluctuations of the general circulation unmistakably show the influence of the sunspot cycle, but it is equally certain that there exists no demonstrable strict correspondence between solar variability (sunspots) and

the secular weather cycles. The connection between sunspots and weather is so complex and indirect that it remains completely unexplained physically, but unfortunately sunspots are the only index of irregular solar activity for which the record of reliable observation is sufficiently long to be useful for extended correlation. Among the many studies of this kind which have been made, the following might be mentioned briefly as among the more significant:

1. Köppen [13], Walker [25], and others have demonstrated beyond question the reality of an eleven-year sunspot cycle of temperature in many regions, primarily in the tropics, such that lower temperature occurs with the sunspot maximum.

2. Helland-Hansen [11], and others, have indicated that at least across the North Atlantic Ocean prevailing storm tracks tend to be displaced equatorward during periods of high sunspots. Some of Tannehill's graphs [24] indicate a similar latitudinal displacement of storm tracks on the west coast of the United States.

3. Hanzlík [8, 9] finds quite impressive changes of the world-wide distribution of pressure, particularly during the winter season, from the three years centered at sunspot minimum to the three years at the *following* sunspot maximum. The most striking feature of Hanzlík's pattern studies is that, in high latitudes, the pressure changes in effect give a decreasing zonal index as a *major* sunspot maximum commences, and an increasing zonal index as a *minor* sunspot maximum commences. This double sunspot cycle of pressure rise in the higher latitudes is confirmed by Clayton [5], and by Wexler (unpublished manuscript) from the Weather Bureau Northern Hemisphere historical maps. Both of these investigations indicate, on alternating successive minor and major sunspot maxima, anomalous zonal pressure rises which reach their peaks at about 50°N and north of 60°N, respectively. Willett [28] has confirmed Hanzlík's alternating high- and low-index patterns of pressure anomaly on successive sunspot maxima, and has found further that the anomaly patterns of temperature and precipitation manifest corresponding characteristics. In fact the contrasting anomaly trends of pressure, temperature, and rainfall going into successive sunspot maxima correspond in a small degree over both North America and northern Europe to the contrast between the Pleistocene glacial and the interglacial pattern of climate. The occurrence of the high- versus low-index pattern contrast in connection with the double sunspot cycle is particularly suggestive of a primary solar role in this basic change of the general circulation pattern.

4. Baur [3] has produced some impressive statistical evidence, from temperature records of 160 years in the northeastern United States and of 180 years in north-central Europe, that the occurrence of severe winters in both localities shows a marked preference for certain phases of the sunspot cycle, notably just preceding and shortly following the sunspot maximum. According to Baur the years of sunspot minimum and maximum are times of the least probable occurrence of a severe winter in these localities. Other miscellaneous relationships of this type have been found by a number of investigators for specific localities, but they contribute little to any improved understanding of the physical control of the secular weather fluctuations. However, it certainly can be stated that the solar factor is the one which is usually implicated in most of the secular fluctuations of climate.

Anomalous (Weekly, Monthly, or Seasonal) Fluctuations of the World Weather Pattern. The week-to-week and month-to-month anomalous fluctuations of the general circulation pattern manifest quite clearly essentially the same type of high- versus low-index contrast that is evidenced by the secular, postglacial, and glacial-interglacial fluctuations. In fact, it is primarily from these relatively short-period fluctuations that the index types were recognized, and their essential characteristics identified. The recognition of essentially identical characteristics in the longer-period anomalous fluctuations of the general circulation followed. Consequently the question naturally arises as to the extent to which variable solar activity, for which there is so much evidence as the controlling factor in the longer period fluctuations, also exerts primary control on the anomalous fluctuations. This question is particularly pertinent because the major single or double sunspot cycle is very long in comparison to the weekly, monthly, and seasonal anomalous fluctuations. There are a number of observational and deduced facts which have a direct bearing on the probability of such solar control, notably as follows:

1. Besides the longer periods of variable solar activity as evidenced by the so-called eleven-year sunspot cycle and multiples thereof, the sun is almost continuously undergoing a great variety of short-period sudden disturbances and almost eruptive outbursts, as evidenced by faculae, flocculi, flares, prominences, etc., and by a two or three fold or larger variation of sunspot numbers from week to week and month to month (see pp. 379–381). Hence there occur outbursts of solar activity of variable frequency and intensity corresponding to the large-scale variable weather activity. Maris [14], Haurwitz [10], and others have indicated that the sudden emission of short-wave radiation which apparently accompanies this eruptive activity of the sun is capable of producing considerable heating of the higher atmosphere in only a few hours, and thus leads indirectly to substantial poleward displacement of atmosphere in the higher levels, that is, to a rise of sea-level pressure poleward from the latitudinal zone of maximum heating. This reasoning suggests one possibility of a mechanism by which sudden solar outbursts can change the index character (zonal pressure distribution) of the general circulation.

2. As mentioned earlier, Willett's results [26, 27, 28] may be interpreted as an indication of the existence of some primary external control of the anomalous fluctuations of the general circulation, for example, variable solar activity. To test this hypothesis statistically, Willett [28] correlated daily and five-day mean values of a number of indices of solar activity with corresponding indices of the general circulation, but no significant

correlation was found. This negative result constitutes statistical (but by no means conclusive) evidence against an important role of variable solar activity in the anomalous fluctuations of the general circulation. Our qualitative and quantitative knowledge of the physical characteristics of the variable solar emissions, of their direct effects in the higher atmosphere, and of their possible indirect effects in the lower atmosphere, is utterly inadequate either for the certain designation of suitable indices of solar activity, or for any estimate of the probable manifestation of their complex and indirect effects on the circulation of the earth's troposphere. One rather surprising bit of evidence for a direct solar influence on the zonal distribution of pressure on both hemispheres is furnished by highly consistent, but not significantly high, negative correlation between monthly mean zonal pressure anomalies in the lower latitudes, and the contemporary monthly mean solar pyrheliometric values as determined by all recording stations in Europe and North America [28]. In the polar latitudes of the Northern Hemisphere there is a seasonal reversal of the sign of this correlation from summer to winter, a reversal which cannot be checked on the Southern Hemisphere for lack of pressure data.

3. Without comparison the highest correlations which have been found between basic parameters of the general circulation pattern are those based on Starr's concept [23] of the thermodynamics of the general circulation. By this concept the index character of the circulation pattern limits the effective poleward transport of heat. The fact that these correlations pertain to the anomalous fluctuations of the general circulation, with specific implications for the tropical-polar heat balance, is cited as further possible evidence for the direct role of variable solar energy in the anomalous fluctuations.

4. One final item in evidence of direct solar influence on the general circulation pattern must be mentioned as of particular interest in that it indicates a clear day-to-day progression of the disturbing effect. Duell and Duell [6] show that during the winter months (November–February) of years of low sunspot activity (relative sunspot number less than 40), following geomagnetically disturbed days (presumably days of strong particle emission by the sun), pressure falls on the average by about 2 mb at European stations within two to three days, while at stations in the Greenland-Iceland area the pressure rises by an equal or larger amount. Hence by the second day following the disturbance, the pressure gradient from Greenland to northwestern Europe is increased by 5 mb on the average, representing definitely a trend towards a low-index or glacial weather pattern. On the other hand, Duell and Duell found that during the same period of time the pressure variation in northwest Europe after quiet geomagnetic days is in the opposite direction, that is, toward *higher* pressure a few days after the quiet conditions. Craig has carried out similar investigations for many other geographical points in the Northern Hemisphere. He has found that the pressure variations after disturbed geomagnetic days are, to a highly significant degree, negatively correlated with the variations at the same location and during the same period of time after quiet days. However, the patterns of change after disturbed days are not always the same and seem to depend markedly on initial conditions in the atmosphere.[1]

A less extensive investigation of the pressure changes following days of strong solar flares (presumably representing strong outbursts of solar ultraviolet radiation) gives indications of a reverse trend of the pressure pattern, towards a higher index condition. This trend is noted irrespective of season and sunspot number.

Duell and Duell's results need extension and further verification. Taken at their face value, their results appear to be highly significant, in the first place as a clear indication of direct solar influence on the day-to-day weather changes of the basic index type, and in the second place as a possible physical clue to the opposite effects of major and of minor sunspot-maxima on the world weather patterns as first determined by Hanzlík.

SUGGESTIONS FOR FUTURE RESEARCH

As long as there remains a reasonable possibility that irregular weather changes may be linked with solar variations, the subject deserves expanded and careful study. The possibility of long-range weather forecasting as a result of such studies holds the promise of great returns for the efforts involved. The suggestions for future research that follow are based on the conviction that such a reasonable possibility exists.

First of all, an attempt should be made to investigate, independently of the Smithsonian Institution, the variations of the solar constant. It seems rather incongruous to discuss the effects of solar variability, when variations in solar energy over the entire spectral range above 3000 A are not definitely established. Despite the fine efforts of the Smithsonian investigators, probably the present controversy can best be resolved by an independent study. In particular, there should be additional direct determinations of solar variability in the ultraviolet, from the earth's surface in the case of the 3000–3500 A spectral region and from rockets or balloons at shorter wave lengths.

Secondly, the theoretical and physical meteorologist must give attention to the question of how impulses received in the upper atmosphere can affect the troposphere. Duell and Duell's results have no explanation at present. If they stand up under future investigation, they become an important clue to the whole problem of solar-weather relationships.

Thirdly, if the effects of ultraviolet solar variability on the weather become established, there is room for much synoptic and statistical study of interrelationships between the troposphere and the stratosphere. The question is of great interest, in any case, as a strictly meteorological problem.

Finally, and most obviously, the statistical study of day-to-day, week-to-week, and secular weather varia-

tions as related to solar variability should continue. Certainly, this type of approach is the least economical in that much time has been and will be wasted in correlations of parameters that are actually not related. From such work, however, may come occasional important clues to the understanding and explanation of solar effects. In any case, it is the most direct method of investigation and, in the absence of basic physical understanding of the sun and of our atmosphere, may turn out to yield the most important information.

SUMMARY

The discussion and description of known irregular weather changes leads to some important conclusions:

1. Changes ranging in time scale from weeks to epochs apparently involve oscillations between two extreme types of weather pattern that are observed today.

2. The changes tend to be world-wide in extent.

3. The amplitude of the changes does not decrease as the time scale increases.

4. The variability of the world weather pattern seems to be similar in its quasi-periodic character and variable period to the known variability of the sun.

The specific investigations of solar-weather relationships outlined herein are only a small fraction of those that have been accomplished. Perhaps others equally significant are in existence, but the ones cited are illustrative of techniques and results. Walker's studies [25] show that no significant results can be expected from a simple correlation of annual means of sunspot numbers and weather elements. The work of Hanzlík shows further that atmospheric changes may vary significantly from season to season and even from one sunspot maximum to the next. Tannehill has furnished some striking examples of weather changes that parallel the sunspot curve. Duell and Duell have given the first suggestion of relationships between day-to-day weather changes and specific solar anomalies. Their work also suggests the possibility that more than one solar phenomenon (particle emission versus ultraviolet emission) may affect the atmosphere.

These considerations suggest that glacial epochs, stages, and substages, periods of climatic stress such as the sub-Atlantic period, and stormy centuries, probably result from the predominance over various periods of time of low-index conditions such as are apparent in the weather at the present time. Further, these conditions may result from comparatively great solar activity, particularly with relation to particle emission that affects the upper atmosphere. These tentative suggestions are the best that can be made on the basis of present knowledge, but, unfortunately, they are vague and uncertain. They merely suggest the direction of future research.

The writers feel that the present state of the problem justifies much additional research of observational, theoretical, synoptic, and statistical nature. At present, there is no definite agreement as to the extent of solar ultraviolet variability or even as to the existence of variability in the visible part of the spectrum. These questions should be cleared up as soon as possible, by observation in the latter case and by observation if possible, or by astrophysical reasoning, in the former case. The meteorologists themselves have many problems to investigate of a theoretical, synoptic, and statistical nature.

Intensified research should at least settle the questions of the extent of solar variability and whether it significantly affects the weather. Even definite information that no such relationships exist would be extremely valuable in planning the direction and emphasis of future meteorological research.

THE ATMOSPHERES OF THE OTHER PLANETS

By S. L. HESS

Lowell Observatory and Florida State University

and H. A. PANOFSKY

New York University

Introduction

The study of planetary atmospheres is a relatively new field of meteorology. Its main impetus comes from the likelihood that the behavior of the several planetary envelopes, with their varying masses, rotations, constituents, and other physical parameters, may yield important evidence bearing on the general laws which govern our own atmosphere. Much of the information sought through a study of the other planets cannot be obtained by investigation of the terrestrial atmosphere simply because its various parameters of interest are fixed and the effects of their variation cannot be determined.

Beyond the possibility of gaining information that may add to our understanding of Earth's atmosphere lies the hitherto somewhat neglected fact that the behavior of planetary atmospheres, per se, is a proper field of study for meteorologists. One really needs no further justification than the knowledge that there exist several atmospheres, besides Earth's, whose behavior may be observed and interpreted.

In Table I various meteorological parameters are listed for all the planets known to possess atmospheres. They are divisible into two distinct groups. The first three planets listed are relatively small and have atmospheric constituents of moderately high molecular weight. The last four are much larger and have predominantly light-weight constituents. This difference in composition is a natural consequence of the greater masses and far lower temperatures of the outer planets, since these two factors enable them to retain the light gases which the smaller, warmer planets have lost to space.

The most interesting planets in this list are Mars and Jupiter. This is because both planets present, at times, sufficiently large discs to enable us to examine and photograph the atmospheric phenomena which are present. Venus, too, has a large enough disc for this purpose but it is characteristic of her that little visible atmospheric or surface detail exists. Thus our knowledge of Venus' atmosphere is rather small. Saturn, Uranus, and Neptune have successively smaller discs and, in addition, probably have progressively less detail.

Venus

The planet Venus is the closest in size and mass to Earth; she is also our nearest planetary neighbor. Despite this we know relatively little about her atmosphere and surface. Little detail can be discerned in visible light, which leads one to believe that we may be seeing not the actual solid surface but a continuous cloud sheet. This is consistent with the planet's high albedo (0.59). The lack of surface markings prevents a direct determination of the rotation period. Spectroscopic investigations of the rotation indicate that the day on Venus is probably more than three of our weeks [9, p. 317]. It may even be that Venus always presents the same face to the sun, in which case her day would be equal to her year (225 terrestrial days). In any event, we may be certain that the rotation is so slow that atmospheric motions are not subject to significant Coriolis deflections.

There is no question that Venus possesses an atmosphere. This is demonstrated by various physical phenomena [9, p. 318] and by the positive, spectroscopic identification of carbon dioxide as one of its constituents. The amount of CO_2 is estimated to be some 500 times that contained above a unit area on Earth [3, p. 351]. No appreciable amounts of oxygen or water vapor are present. Consequently the basic cloud layer cannot be aqueous; it may be dust. When Venus is photographed in ultraviolet light, large dark and light bands may appear. The nature of these markings is unknown, except that they are undoubtedly manifestations of some sort of cloud because they vary in shape and size from day to day.

Despite our lack of observational knowledge of the circulation of Venus' atmosphere we may be confident, in view of the long period of rotation, that the major feature of the circulation is a rapid exchange of air between the warm, sunlit hemisphere and the cool, dark hemisphere. This would be a direct circulation, and the direction of motion ought to be close to the direction of the pressure-gradient force. This circulation apparently succeeds in transferring considerable quantities of heat to the dark side of Venus because infrared radiation can be detected from the night side. Also important in keeping the dark side warm is the large greenhouse effect supplied by such an enormous quantity of CO_2.

On occasion the far infrared radiation (10 μ) emitted by the warm CO_2 fails to appear [4]. This is certainly not due to a failure of the gas to emit such radiation, but must be due to a transient layer of high cloud which prevents the energy from escaping. The nature of this high cloud layer (as distinct from the lower cloud surface) is unknown, but it may well be condensed carbon dioxide itself. Even on such a warm planet as Venus the saturation vapor pressure of CO_2 can be reached in the

vicinity of only 20 km above the surface if an adiabatic lapse rate is established. This suggests that these clouds and their movements could be detected if one could examine the planet's image in the far infrared. The relationship between these clouds and the ultraviolet markings should also be investigated.

Table I. Values of Meteorological Parameters for Certain Planets

Planet	Mean distance from sun (⊕ = 1)	Length of year (⊕ = 1)	Coriolis parameter at pole ($sec^{-1} \times 10^4$)	Mean radius (⊕ = 1)	Inclination of equator to orbit	Albedo	Surface gravity (⊕ = 1)
Venus	0.72	0.6152	<0.07	0.97	?	0.59	0.86
Earth	1.00	1.0000	1.46	1.00	23° 27′	0.39	1.00
Mars	1.52	1.8808	1.42	0.53	25° 12′	0.15	0.37
Jupiter	5.20	11.862	3.5	11.0	3° 07′	0.44	2.64
Saturn	9.54	29.457	3.3	9.0	26° 45′	0.42	1.17
Uranus	19.19	84.013	3.3	4.0	98°	0.45	0.91
Neptune	30.07	164.783	2.2	3.9	29°	0.52	1.12

Planet	Most important probable atmospheric constituents in order of abundance	Probable value of adiabatic lapse rate (°C km^{-1})	Approximate pressure at "visible" surface (mb)	Approximate temperature at "visible" surface in sunlight (°C)
Venus	N_2?, CO_2	10.0*	>160	50–100
Earth	N_2, O_2, H_2O, A, CO_2	9.8	1000	10
Mars	N_2?, A?, CO_2, H_2O	3.7†	50–100	0
Jupiter	H_2, He, CH_4, NH_3	4.4‡	>50‡	−120
Saturn	H_2, He, CH_4, NH_3	2.0‡	>50‡	−150
Uranus	H_2, He, CH_4	1.5‡	>170‡	
Neptune	H_2, He, CH_4	1.9‡	>350‡	

* For a pure CO_2 atmosphere; in a predominantly N_2 atmosphere the value is 8.0.

† For a predominantly N_2 atmosphere.

‡ Assuming a mixture of six molecules of H_2 to one molecule of CH_4. In such a mixture the amount of He affects neither the adiabatic lapse rate nor the molecular weight.

Mars

The planet Mars is the one which, in meteorological matters, most closely resembles Earth. The Martian day is almost the same length as ours, and the inclination of the polar axis to the plane of rotation about the sun is approximately the same (thus his seasons are much like ours), but the year is almost two of Earth's. Mars is distinguished from Venus and the major planets by the fact that his solid surface is usually clearly visible. Indeed, so little does the atmosphere interfere (except in blue light where a high haze layer is evident) that we suffer from a relative lack of data on such factors as cloud motions, upon which to base a discussion of Martian meteorology.

That Mars possesses an atmosphere has been known for many years, mainly because the polar caps, which wax and wane with the seasons, must have a vapor phase. Various optical scattering phenomena support this conclusion. Recently the first definitely identified constituent of the Martian atmosphere, carbon dioxide, was found by Kuiper [3, p. 335]. The planet has about twice as much CO_2 per unit area as Earth. Water vapor has not been definitely identified, but this is because the amount present is usually too small for spectroscopic detection [1]. The presence of clouds and polar caps points to the presence of water, and the similarity of the reflection spectrum of the caps to that of snow makes the conclusion inescapable. Little can be said about other constituents, except that considerable quantities of nitrogen are to be expected because of this element's universal abundance, its resistance to chemical combination with the planet's crust, and the sufficiency of Martian gravity to prevent its escape.

Radiometric measurements permit estimation of the surface temperature over areas as small as 200 miles in radius. This allows delineation of the general temperature field [2]. The analysis of an extensive sequence of measurements made during 1926 is presented in Fig. 1. The salient features are a belt of high temperature at about lat. 20° in the summer hemisphere, markedly lower temperatures and larger gradients in the winter hemisphere, and an anomalously warm region near lat. 30°S, long. 350°. The first two features are in qualitative agreement with the situation on Earth, while the last feature, which is probably real, is associated with an anomaly in the circulation.

The vertical shear of the zonal winds computed from these data and the thermal wind equation are given in Table II. The rates of increase of west wind with elevation are somewhat smaller than corresponding values on Earth. Since the wind velocity next to the ground must be quite small due to friction, the magnitude of the wind U at some elevation z must be roughly $\frac{\partial U}{\partial z} z$. On

this basis the data of Table II indicate somewhat lower wind velocities than on Earth. This is consistent with the results of observation of the motion of clouds on Mars, which also indicate relatively low wind-speeds.

TABLE II. MEAN VALUES OF THE VERTICAL WIND-SHEAR ON MARS COMPUTED FROM THE DATA OF FIG. 1

Latitude	$\partial U/\partial z$ (m sec^{-1} km^{-1})
15°N–50°N	4.0
15°S–47°S	0.8
47°S–78°S	1.6

The last value in Table II, however, is appreciably larger than the corresponding value on Earth. Nevertheless, this does not mean higher wind-speeds than on Earth, because this value is from the most poleward zone considered in the summer hemisphere, and the temperature at the southernmost boundary (lat. 78°S) is probably influenced by the proximity of Mars' polar icecap. This depresses the temperature at the surface and makes the gradient seem quite high. If one could measure the temperature at, let us say, one kilometer above the surface, the effect of the polar ice would be diminished and the north-south temperature gradient reduced. This is to say that more stable lapse rates predominate near the icecap than elsewhere, a common situation on Earth.

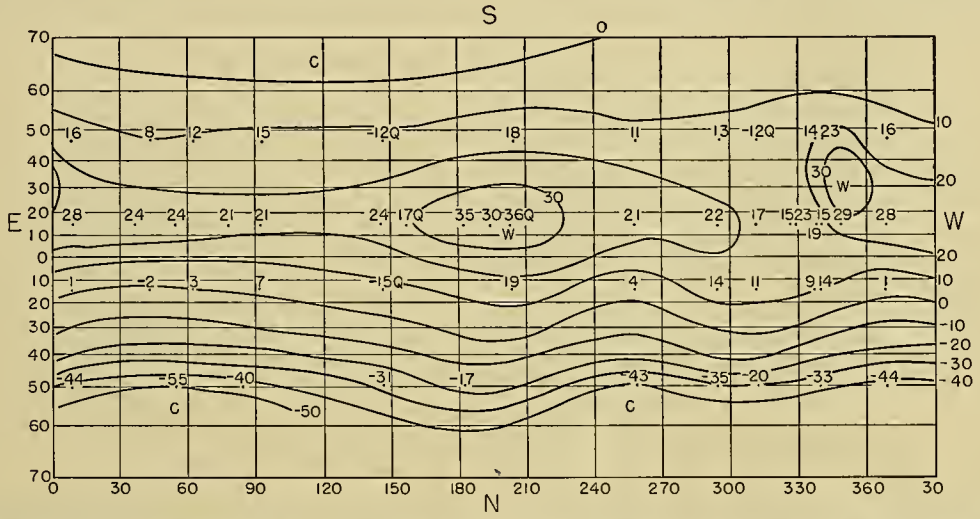

FIG. 1.—The distribution of temperature (°C) on Mars in Northern Hemisphere winter. This is the normal telescopic view with south at the top. To obtain the usual meteorological view, merely invert the page. The observations marked "*Q*" are questionable either because they are interpolated values or because of the presence of clouds. A fifth row of data at 78°S was available for the analysis but does not appear on this projection. Taken from [2].

Figure 2 is a streamline map for Mars drawn in a fashion as consistent as possible with the temperature distribution of Fig. 1, eighteen wind directions deduced from the observed drift of clouds, and general meteorological principles. While these did not suffice to define the flow pattern uniquely, the amount of imagination required was quite small.

The most striking aspect of Fig. 2 is its marked resemblance to terrestrial weather maps. *Mars has an atmospheric circulation very similar to Earth's.* This is by no means due solely to a tendency on the analyst's part to force the pattern into a familiar shape. An examination of the winds will show that the broader aspects of this map could not be altered very much by another independent analysis. The existence of a more or less broad belt of westerlies in both hemispheres is clearly indicated, and there are observations to support the drawing of a pair of subtropical high-pressure belts which are broken up into individual cells. The pairs of winds which form the basis of the two cyclonic storms indicated in the Southern Hemisphere are synchronous in one case, and in the other case were observed on successive nights. Thus there is no way of avoiding an analysis which involves sharp cyclonic shears, that is, fronts, without ignoring the data.

The cyclonic circulation at lat. 35°S, long. 345° is indicated by an easterly cloud drift in a latitude where one would expect to find west winds. But this is the same region in which the temperature distribution indicated an abnormally warm spot. It is probable that we have here an example of a "heat low." This is all the more remarkable because the two pieces of evidence are a cloud-drift direction observed in 1894 and a temperature field determined in 1926. This persistence points to a local peculiarity of the surface which is conducive to high summer temperatures and the formation of a heat low. Examination of a map of the normal surface markings of Mars reveals no visible feature that can explain this phenomenon, but there is a large dark area which forms seasonally in this region. It is present in Southern Hemisphere summer (when these measurements were made) and disappears in winter. It would be valuable to obtain radiometric measures of this area at other Martian seasons to see if the high temperatures vanish with the dark coloration.

Despite these similarities the circulation on Mars differs in important respects from that on Earth. Factors contributing to such differentiation are: (1) the absence of oceans and sharp mountain ranges, (2) the lesser water-vapor content, and (3) the longer year on

Mars. The greater uniformity of the Martian surface should lead to more pronounced regularities in weather; thus one may be justified in combining observations from different years and in accepting a very short climatological record with more confidence than would be possible for Earth. The severe Martian aridity, as manifested by the scarcity of clouds, should also contribute to this greater uniformity of weather from year to year and day to day, since insolation and outgoing radiation are not subject to the erratic and complex interference experienced on Earth.

The fact that the Martian year is almost twice ours means that the temperature contrast between the summer and winter hemispheres ought to be larger on Mars. Here on Earth one can deal with the circulation qualitatively by assuming it to be driven by the temperature difference between equator and poles. While this would not be completely invalid on Mars it would seem that the temperature contrast between the hemispheres should also be an important factor. That is,

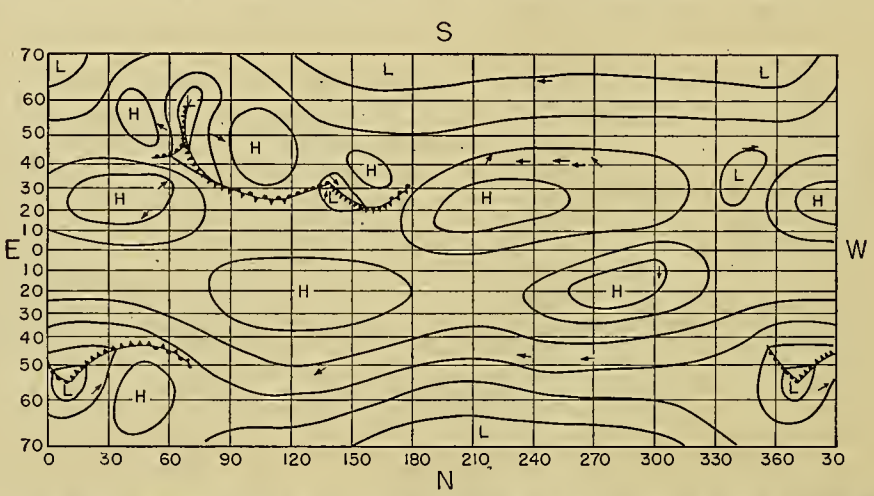

Fig. 2.—A schematic streamline map for Mars in Northern Hemisphere winter. This is the normal telescopic view with south at the top. To obtain the usual meteorological view, merely invert the page. The arrows represent observed cloud-drift directions. Taken from [2].

the long Martian seasons would seem to promote an exchange of air between hemispheres as a major feature of the circulation. One can check this conclusion by computing the magnitude of the interhemispheric exchange from the known rate of transfer of water vapor from the dissipating icecap to the forming one [2]. This calculation indicates the necessity for a wind of the order of 10–15 m sec^{-1} blowing from the warm to the cold hemisphere all around the equator, at low levels. This constitutes an appreciable interhemispheric flow.

The Characteristics of the Atmospheres of the Major Planets

The four major planets are, in order of distance from the sun, Jupiter, Saturn, Uranus, and Neptune. Jupiter's linear dimensions are 11 times larger than those of the Earth; Neptune's, 3.9 times larger. The other two planets are intermediate. All four planets are massive enough to retain hydrogen and, because of the cosmic preponderance of hydrogen, it is very likely the most important constituent of the major planets. Similarly, helium almost certainly is abundant [3, p. 316]. Unfortunately, neither hydrogen nor helium show strong spectral lines in the accessible regions of the spectrum at the temperatures of the visible surfaces of these planets (below 155K) and therefore estimates of the amounts of these molecules in the atmospheres of the outer planets must be extremely crude. Hydrogen and helium differ greatly from most other gases in some of their physical constants such as specific heat and, of course, molecular weight, so that, for example, the adiabatic lapse rate and the relation between pressure, temperature, and density are not well known.

Methane and ammonia are the only constituents of the major planets which have been identified spectroscopically. In the atmospheres of all four planets, methane is more abundant than ammonia; but the relative abundance of the two gases is not constant. The absorption of light by methane becomes more pronounced in the spectra of the more distant planets, whereas the ammonia absorption almost disappears. The surfaces of all these planets are sufficiently cold so that ammonia can exist in its frozen state. The vapor pressure of the gas in equilibrium with this frozen ammonia becomes smaller for the more distant planets, so that hardly any gaseous ammonia can exist in the atmosphere of Neptune. Ammonia is practically "frozen out" on this planet.

The spectrograph not only indicates the presence of ammonia, but also permits an estimate of the total amount of ammonia in the line of sight between us and the visible "surface." If we then assume that the atmosphere is thoroughly mixed, and if we know the approximate mean molecular weight of the other gases, we can calculate the partial pressure of ammonia at the "surface," the level of the visible markings. Since the vapor is presumably saturated or nearly saturated with respect to frozen ammonia, measurements of the strength of absorption by ammonia can be used to determine the planet's temperature. Such considerations lead to a temperature of 150K for Jupiter, about 45 degrees warmer than the temperature expected if

Jupiter were heated by the sun only and his atmosphere were transparent to radiation of all wave lengths. Therefore two possibilities suggest themselves: either Jupiter is heated from the inside as well as from the outside, or Jupiter has an appreciable greenhouse effect which is relatively much more pronounced than the Earth's.

The other giant planets also are considerably warmer than would be expected from their distances from the sun. This can be seen from the tremendous absorption by methane. If Uranus and Neptune were black bodies heated by solar radiation only with no greenhouse effect, their temperatures would be 70K and 50K respectively, low enough to "freeze out" methane. Since methane is not frozen out the actual surface temperatures must be considerably higher [8, p. 89].

In summary, the outer atmosphere of all the major planets consists mostly of hydrogen and helium, with methane being the next most common gas, at least on Jupiter and Saturn. In the atmospheres of Uranus and Neptune, inert gases, such as neon, which have lower boiling points, may be more abundant than methane.

The relative brightness of Jupiter's limb as compared to the central portion, the rate of disappearance of a satellite behind the planet's disc, and other optical phenomena indicate that comparatively little atmosphere can exist above the "visible" surface of Jupiter, at least near the equator. The pressures at the surfaces of the major planets can be estimated from the amount of methane observed spectroscopically and an added amount of hydrogen [7].

The largest portion of the atmospheres of Jupiter and Saturn must lie below the visible surface. The variable speed of the "surface" features on these planets shows that the surface is not part of any solid core. The exact thickness of the gaseous portion of the atmospheres is difficult to estimate because both the lapse rate and the exact composition are unknown. It is possible to show from the oblateness, the moment of inertia, and the mean density of these planets that the density of their outer 10 per cent must be considerably less than 0.50 g cm^{-3} [10]. Even gaseous hydrogen will reach densities greater than that at depths of the order of 1000 km [8]. For this reason, the gaseous portion of the atmospheres is estimated to extend down to a depth of several hundred kilometers. Apparently, then, the visible features in the atmospheres of Jupiter and Saturn are high-level phenomena; in contrast to conditions on Mars, little is known from observations concerning the solid core of these planets.

The appearance of Jupiter and Saturn in the telescope is characterized by a system of belts (dark or reddish color) and zones (light color), parallel to the latitude circles. Belts have also occasionally been seen on Uranus. Neptune is too far from us for any such detail to be recognized. Jupiter and Saturn differ from each other in that Jupiter's belts are more pronounced near the equator, whereas Saturn's are distributed more uniformly. Jupiter shows a "zone" centered at the equator (equatorial zone), generally bordered by the two equatorial belts. These are followed by the "tropical" zones and further by a series of "temperate" belts and zones. North of 45°N and south of 45°S, one finds generally greyish regions, which, due to the foreshortening, have been called the "polar" regions. The aspect of these zones and belts, in color and width, may change considerably from year to year. At irregular intervals a belt disappears altogether, apparently covered by a white haze. Other zones and belts change their latitudinal boundaries and get narrower or wider as time progresses.

Superimposed on these general markings is a wealth of detailed structure. White and dark spots may form almost anywhere, lasting normally from a week to several months; rifts appear in the belts, or wavelike patterns form along the boundaries between belts and zones. These patterns may have the peaked appearance of unstable waves yet persist for months. Only the *Great Red Spot*, an oval 22,000 miles long zonally and 7000 miles wide meridionally, seems to show a high degree of permanence, having been observed in the south tropical zone of Jupiter with substantially the same shape for at least seventy years, possibly for several centuries. But even the aspect of the Red Spot changes from year to year; for a few years it may be very red, then turn grey or white and be almost invisible. Its shape, also, undergoes changes; one or the other extremity may develop a peak, or the whole spot may become a little smaller or larger. There is no indication, however, that the Red Spot shows any systematic increase in its dimensions, which would be observed if it were composed of volcanic dust, a hypothesis accepted by many. Another marking, the *South Tropical Disturbance*, which has persisted since 1901, spread almost all around the planet and disappeared entirely in 1949. This marking was apparently destroyed by diffusion.

Spots on Saturn are relatively rare occurrences. Several times, large white spots have been observed for a number of weeks. No details of this type have been seen directly on the discs of Uranus or Neptune; however, Uranus occasionally shows small changes in brightness of the same period as the period of rotation. These changes are of rather an ephemeral nature and soon disappear, making it likely that they are due to fairly short-lived spots.

The inclination of Jupiter's orbit to its equator is only three degrees, so that seasonal effects, if any, should be small. Jupiter's "year" is 12 Earth-years, and color changes in the belts with that period have been reported [11]. However, this result seems to be based on a good deal of uncertain interpretation.

Saturn's seasonal effects should be considerable because of the 27-degree inclination between its orbit and equator; however, as seen from Saturn, an observer on Earth is always in nearly the same direction as the sun; hence only the summer hemisphere of Saturn can be studied in detail. The same is true to an even larger extent for Uranus, the equator of which is almost at right angles to its orbit.

Circulation of the Atmospheres of the Major Planets

All four major planets rotate about their axes rapidly, with periods between 9 and 15 hours. The super-

ficial axial symmetry and the oblateness are related to this fact. The periods can be measured by two independent methods:

1. Extremely accurate average periods have been obtained from definite markings,[1] these averages extending over weeks or months. The probable error of some such determinations is only a fraction of a second. This corresponds to errors of speed of rotation of a few tenths of a meter per second. Related to this method is the use of the periodic light variation of the more distant planets.

2. When the spectroscope slit is set parallel to a latitude circle of a planet, the planet's rotation causes the spectral lines to be inclined to the vertical. The tangent of the angle of inclination is proportional to the speed of rotation. This method gives the instantaneous speed of the layers of the atmosphere which reflect the light. The probable error of this type of measurement is of the order of 100 m sec^{-1}, a quantity which is small from an astronomical point of view, but large in comparison with normal meteorological experience.

For Jupiter, the spectral speed of rotation agrees with the speeds of the spots. In view of the large error of spectral velocities, this does not exclude the possibility that the spots may move with speeds differing from those of the general current by 50 m sec^{-1} or more.

On Saturn, the period of rotation determined by spots near the equator is about 10 hr 14 min. A very careful spectral investigation resulted in a period of 10 hr 2 min [5]. These values differ from each other by three times more than the probable error of the spectroscopic value. If real, the discrepancy probably means that the general currents on Saturn move faster than the markings. This interpretation is tenable if, for example, the markings were of the nature of storms (which usually do not move with the wind speeds).

Even though the nature of the "spots" is not known—they appear to be large cloud systems—the spot periods are usually interpreted to approximate the period of the "air" in the neighborhood of the spots. The heavy crosses in Fig. 3 show the normal distribution of the periods of spots and markings on Jupiter as function of Jovicentric latitude. The same figure, with the sign reversed, would also show the relative velocity distribution. In the bright equatorial zone the periods are short, corresponding to fast westerly winds. A transition from short to long periods takes place in the dark equatorial belts. Spots of nearly the same relatively long period occur in the tropical zones, temperate belts, temperate zones, and even the so-called polar regions near latitude 45°.

The short periods in the equatorial zone might lead to the interpretation that the equatorial spots are situated at a higher level than the markings in the other zones and belts. However, spots on Jupiter occasionally move around each other but never cover each other up as might be expected if they were at different levels.

1. Jupiter data are collected in various Memoirs of the British Astronomical Association, Jupiter Section. For Saturn, see [10] for example.

It is interesting to make an attempt to estimate the period of the core of Jupiter from the given distribution of the spot periods with latitude. One might assume, for example, that the net torque of the currents about the planet should vanish. In that case, the period of the planet would be near 9 hr 52 min, with westerlies near the equator and easterlies between latitudes 20° and 60° in both hemispheres. Such speculation, however, is misleading. After all, we are looking at a high level in Jupiter's atmosphere. If we observed only high levels of Earth's atmosphere, we would find westerlies at almost all latitudes. If, as is likely, the meridional temperature gradient on Jupiter is in the same direction as that on Earth, the high-level winds on Jupiter should also nearly all be westerlies. In that case the period of the core may be longer than that of any of the spots, that is, about 10 hours.
